Considering the magnitude of the settlements obtained in these calculations, as well as the fact that the consolidation of the muddy soils under the action of that load is still far from complete in a significant area of the stage at the time of the event, a method to reduce stage settlement, without causing environmental impacts was investigated. This approach entails constructing a pre-load embankment prior to the construction of the stage and leaving it *in situ* for 6 months to one year to allow the foundation ground to be consolidated. Table 4 shows the results of the model that simulates this solution. Figure 5 shows the distribution of settlements along a longitudinal profile of the stage and along three cross sections that include points 1, 2, and 3.

Table 5. Stage settlement after one year of pre-load.

Point	δ_i (m)	δ_{3m} (m)	δ_{6m} (m)
1	0.029	0.031	0.032
2	0.030	0.032	0.033
3	0.042	0.047	0.051

di – initial settlement; d_{3m} – settlement 3 months after construction; d_{6m} – settlement 6 months after construction.

According to the study's results, the highest foundation settlement caused by the pre-load embankment occurs in the west area, where the soft soil thickness is lower, and the sanitary landfill thickness is higher. This occurs because the time required to consolidate landfill materials is substantially shorter than the time required to consolidate muddy soils.

Six months after the construction of the pre-load embankment, the rate of settlement of the alluvial

formation is already very low, which explains the reduced increase in settlements (in the range of 1 to 8 %) after an additional six months of pre-load. The removal of the pre-load embankment causes an expansion, which is followed by ground settlement with the construction of the stage. Since the stage load is lower than the load of the embankment in its central and western areas, the accumulated settlement of the foundation is smaller than that recorded before the removal of the pre-load embankment. Due to the process of consolidation of the foundation ground, the longer the stage's lifespan, the greater the settlements it will suffer.

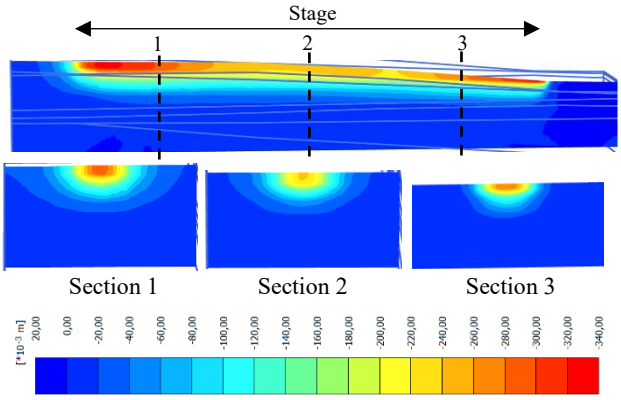

Figure 5. Foundation settlements, 6 months after stage construction (one year of pre-load).

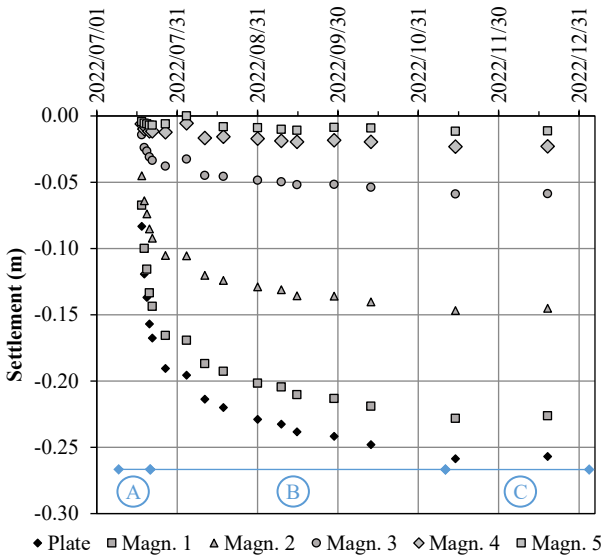
Figure 5 also shows that the settlements of the sanitary landfill are small from a distance of the order of 25 m from the centre of the stage and that this distance decreases to the east.

4 CONSTRUCTION OF THE PRE-LOAD EMBANKMENT

Construction of the pre-load embankment began on July 7, 2022, following the installation of two multi-point magnetic extensometers on the foundation, near point 2 of Figure 4, 12 topographic marks, distributed by the stage area, and 4 topographic marks in its surrounding region.

It should be noted that the final location and layout of the stage were changed during construction, with the western half being eliminated and the stage being enlarged to 40 m in the north-south direction.

Figure 6 exhibits the evolution of the settlements measured in one of the extensometer installed at the site during pre-load embankment construction and thereafter, until its complete removal on January 4, 2023. Figure 7 presents the accumulated settlement of the same extensometer at different depths after 4 months of pre-load.



A – Construction of the pre-load embankment.
B – Consolidation period.
C – Removal of the pre-load embankment.
Figure 6. Settlement of the extensometer magnets over time.

The following conclusions can be drawn from Figures 6 and 7:

- The settling rate fell significantly six days after the completion of the pre-load embankment, on 27 July. 75% of the total settlement took place during these first 20 days, which included the pre-load embankment construction.
- By mid-August the rate at which settlements occurred was gradually decreasing. At the time of removal of the pre-load embankment, settlement occurred at an approximately constant average rate of 3 mm/week.
- The total settlement recorded by the two extensometers was of the same order of magnitude as the adjacent topographic marks. At the end of 3.5 months, the greatest value of settlement was 0.26 m.
- Figure 7 demonstrates that the total settlement of the pre-load embankment was caused by the sanitary landfill settling up to 13.5 m depth. The clayey mud layer had just a minor effect, most likely because its compressibility was lower than predicted.
- The extensometer settlement was 18 % higher than calculated at the nearest point (0.22 m) at the end of six months, but less than the maximum calculated value (0.30 m). An explanation could be related with the higher consolidation rate of the sanitary landfill.
- The removal of the pre-load embankment was anticipated since a lighter structure than the modelled one (with half the load) was adopted for the stage during the works.

- As shown in Figure 6, a minor expansion occurred when the pre-load embankment was removed.

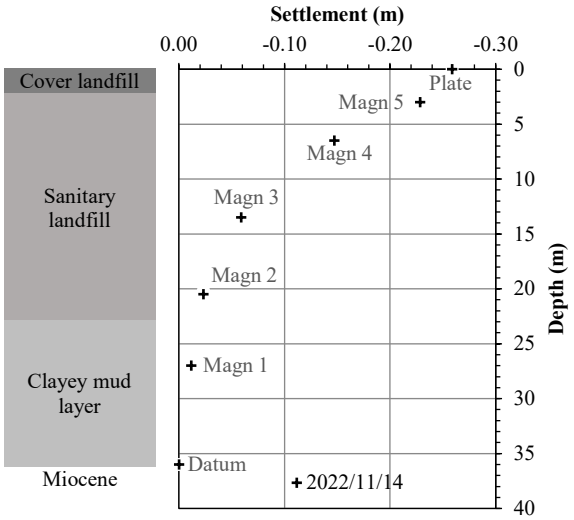


Figure 7. Accumulated settlement at different depths after 4 months of pre-load.

5 CONCLUSIONS

Given the history of instability at the Beirolas sanitary landfill and the geological-geotechnical characteristics of its foundation, numerical analyses were performed to verify the global static stability of the slopes and estimate the settlements caused by the construction of the JMJ stage.

Using a finite element model, it was also determined that stage settlements could reach an amount that would jeopardise its serviceability. Taking this into consideration, as well as the fact that the consolidation of the muddy soils under the action of that load could still be far from complete at the time of the event, a strategy to limit settlements without producing adverse environmental effects was investigated. This method entailed constructing a pre-load embankment prior to the construction of the stage, which would stay in place long enough for the consolidation of the sanitary landfill and the soft soils in the foundation to occur.

Data collected from the extensometers and topographic markers placed on the foundation and the pre-load landfill built at the forthcoming stage's location confirmed the results reached during the design phase. The use of a lighter structure for the stage, together with a small settlement rate observed by the monitoring system, allowed the pre-load embankment to be removed ahead of schedule. The stage was built without any sign of differential settlement.

ABSTRACT: The development of the second generation of EN1997 has reached its final stage. The formal vote will take place in autumn 2024. Numerical methods are now largely considered for the design of geotechnical structures both for SLS and ULS verifications in terms of mechanical and hydraulic issues. This paper presents how numerical methods are now implemented in EN 1997 and three main topics are dealt with:
- (i) SLS verifications with the importance of the choice of constitutive models in line with the geotechnical design model. Representative values of the ground properties shall account for all these situations based on the derived values presented in the ground model,
-(ii) ULS verifications with the input and ant the output factoring approaches: several examples are discussed in order how to choose and implement these two approaches. The verification of structural elements including nonlinearities is highlighted. Other approaches where geotechnical resistances may be calculated by numerical models by forcing geotechnical structures to fail by particular mechanisms are also presented.
-(iii) hydraulic verifications where numerical modelling can help the designer to check the hydraulic gradient and the variation of pore water pressures as proposed now by EN 1997 regarding hydraulic issues.

RÉSUMÉ: Le développement de la deuxième génération d'EN1997 a atteint sa phase finale. Le vote formel aura lieu à l'automne 2024. Les méthodes numériques sont désormais largement envisagées pour la conception des ouvrages géotechniques tant pour les vérifications des ELS que des ELU en termes de problématiques mécaniques et hydrauliques. Cet article présente comment les méthodes numériques sont maintenant mises en œuvre dans l'EN 1997 et trois sujets principaux sont traités:
- (i) Vérifications des ELS avec l'importance du choix des modèles de comportement en lien avec le modèle de dimensionnement géotechnique. Les valeurs représentatives des propriétés du sol doivent tenir compte de toutes ces situations sur la base des valeurs dérivées présentées dans le modèle de terrain,
-(ii) Vérifications des ELU avec les approches de factorisation d'entrée et de sortie: plusieurs exemples sont discutés afin de choisir et de mettre en œuvre ces deux approches. La vérification des éléments structuraux, y compris les non-linéarités, est mise en évidence. D'autres approches où les résistances géotechniques peuvent être calculées par des modèles numériques en forçant des mécanismes de rupture particuliers sont également présentées.
-(iii) des vérifications hydrauliques où la modélisation numérique peut aider le concepteur à vérifier le gradient hydraulique et la variation des pressions interstitielles comme proposé maintenant par le nouvel Eurocode 7 concernant les questions hydrauliques.

Keywords: Eurocode; numerical methods; partial factor; constitutive law.

1 USE OF NUMERICAL METHODS IN EN 1997-1

At the end of 1990's, when the first generation of Eurocode 7 was drafting, the use of numerical methods was at its beginning mainly due to the low computational power available. Meshes including very few elements and only 2D analysis were possible in practice. This first draft provided very limited information for geotechnical design assisted by numerical methods.

During the last 20 years, the use of numerical modelling has increased significantly with the reduction of computation time and the commercial development of many software packages (see Figure 1). In order to provide appropriate responses to this

new context, in comparison to this previous draft of EN 1997-1, the new draft deals with the use of numerical methods for the design of geotechnical structures by providing useful and applicable recommendations for the verifications of SLS (serviceability limit states) and ULS (ultimate limit states). This paper aims to address specifically three main issues: the SLS verifications, the ULS verifications and the hydraulic verifications.

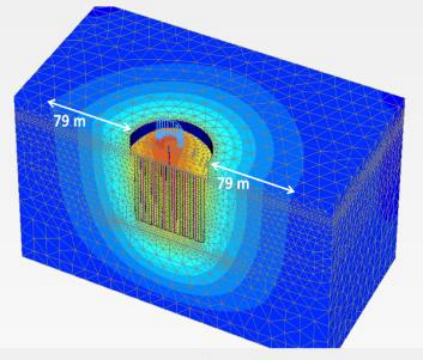

Figure 1. Example of a 3D typical mesh for a piled-raft foundation.

2 SLS VERIFICATIONS

SLS verifications are a fundamental part of the geotechnical design as they allow justification of a structure regarding its functioning under normal use, the comfort of people and the appearance of the construction works. These issues require a relevant choice of constitutive models in line with the geotechnical design model considering for each verification case the amplitude and the frequency of the loading as well as the strain or the stress range and the failure mechanism taking into account stress paths. Representative values of the ground properties shall account for all these situations based on the derived values presented in the ground model. prEN 1997-2 provides some recommendations regarding both strain and strength parameters: the complexity of the models shall be consistent with the available data and the verifications to be carried out. Ground parameters are also presented for coupled calculations (consolidation, thermos-mechanical analysis, etc.). Based on these different issues, the main issue is the selection of the ground parameters (Figure 2) from the derived values presented in the Ground Investigation Report (GIR) to generate the representative values that form the basis of the Geotechnical Design Model (GDM). Back-analysis can also be used in this way.

3 ULS VERIFICATIONS

3.1 Principles

In the second generation of the Eurocodes partial factors on actions γ_F and action effects γ_E are grouped in four Verification Cases (VC1 to VC4) in prEN 1990 (CEN 2022) for all types of structures and are partly listed in Table 1. (The tables in this paper contain considerable simplifications and omissions, refer to the tables in prEN 1990, prEN 1997-1 and prEN 1997-3 for all de-tails, Smith and Walter, 2023).

For geotechnical structures, partial factors on material strength parameters γ_M and resistances γ_R are supplied in prEN 1997-1 if they are valid for all types of geotech-nical structures, and in prEN 1997-3 if they are specific for certain types of geotechnical construction. Partial factors on material strength parameters are listed and grouped in sets M1 and M2 in prEN 1997-1 and are partly listed in Table 2.

Whether partial factors on material strength parameters (Material Factor Approach, MFA) or partial factors on resistances (Resistance Factor Approach, RFA) are used, the choice of the Verification Case and of set M1 or M2 and suggested values for partial factors on resistances are specified in prEN 1997-3 for the different types of geotechnical structure. National standards bodies may modify these specifications, including the val-ues of the partial safety factors.

A specific procedure is given in prEN 1997-1 for numerical methods. Two approaches are described and the more unfavourable of the two governs the design, currently without a distinction between different types of geotechnical construction:

- Input factoring using VC3 and M2,
- Output factoring using VC4 and M1.

These approaches are given to facilitate the straightforward use, and to take full advantage of the power of numerical methods. However, it is also clear that design check outcomes may differ if using factors for numerical methods compared to using factors for specific design calculation methods as listed in prEN 1997-3. prEN 1997-3 allows to perform ULS verifications by focusing on specific failure mechnisms: Geotechnical resistances may be calculated by numerical models by forcing geotechnical structures to fail by particular mechanisms.

Table 1. Table of values for verification cases for persistent design situations (where k_F is a consequence factor).

Type	Resulting effect	VC1	VC3	VC4
Permanent action (G_k)	unfavourable (all)	1.35 k_F	1.0	G_k is not factored
	unfav. (water)	1.2 k_F	1.0	
	favourable	1.0	1.0	
Variable action (Q_k)	unfavourable (all)	1.5 k_F	1.3	1.1
	unfav. (water)	1.35 k_F	1.15	1.0
Effects of action (E)	unfavourable	γ_E is not applied		1.35 k_F
	favourable			1.0

Table 2. Table of values for material sets for soil and fill (where K_M is a consequence factor).

Ground property	M1	M2
Shear strength in effective stress analysis (τ_F)	1.0	1.25 K_M
Coefficient of peak friction (tan ϕ'_p)	1.0	1.25 K_M
Peak effective cohesion (c'_p)	1.0	1.25 K_M
Coefficient of friction at critical state (tan ϕ'_{cs})	1.0	1.1 K_M
Shear strength in total stress analysis (c_u)	1.0	1.4 K_M

3.2 Input factoring

This approach is now mainly based on the use of shear strength reduction procedures that are fully available in many softwares. prEN 1997-1 recommends:

- (i) to reach the value γ_M 1.25 to check the geotechnical verifications,
- (ii) to check the structural forces that are obtained from this calculation with strength reduction to γ_M without or with the use of elastoplastic structural elements.

For each phase, the calculation is performed with representative values of the loads and the ground properties. Each phase can be used for SLS verifications (ignoring the results with strength reduction). The calculations can be organised according to Figure 2.

Instead of using a strength reduction procedure, the shear strength parameters can also be reduced ab initio or after previous steps with representative values of the strength parameters. One has to keep in mind that these variants can result in different displacements and different forces on the structural elements.

3.3 Output factoring

For each phase, the calculation is performed with representative values of the loads and the ground properties. Using VC4, the representative values of the action effects are multiplied by 1.35 in order to obtain the design values. When it is possible, the mobilized resistance that can be calculated and then evaluated and compared to the ultimate resistance determined by a separate calculation. In the case of a retaining wall for which a subgrade reaction approach is used, Figure 3 presents the typical results.

3.4 Coupling input and output factoring approaches

Input and output factoring approaches can be combined in the same calculation as proposed by Figure 5.

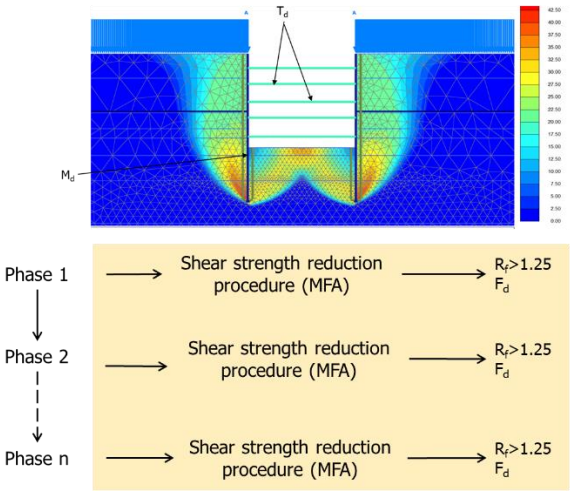

Figure 2. input factoring with shear strength reduction procedure.

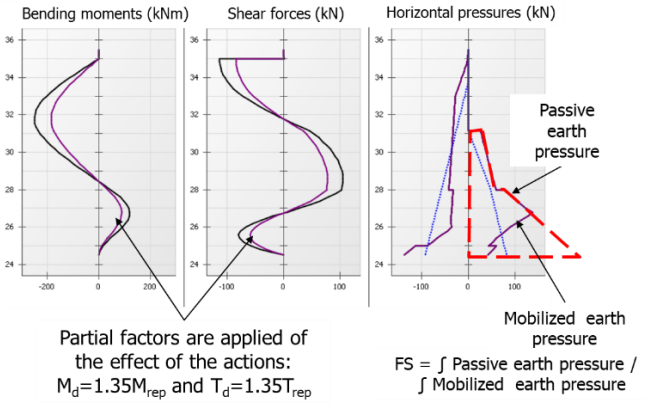

Figure 3. Output factoring with subgrade reaction methods.

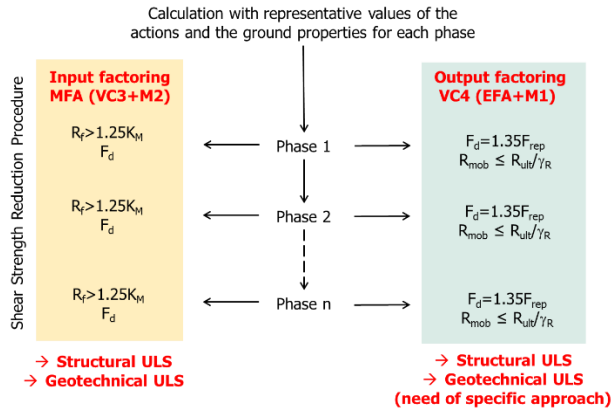

Figure 4. Coupling of input and output factoring.

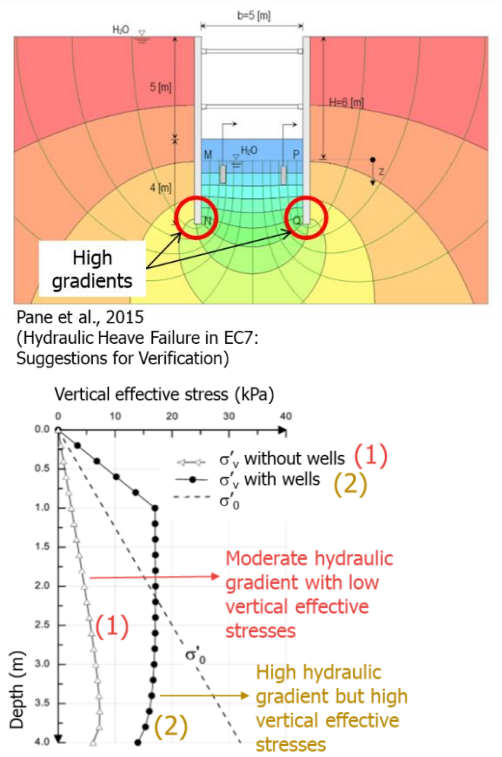

Pane et al., 2015
(Hydraulic Heave Failure in EC7: Suggestions for Verification)

Figure 5. Hydraulic verifications.

3.5 Identifying particular mechanisms

Identifying particular failure mechanisms is sometimes very useful for the design of foundations. Two options can be performed:

- Option 1: calculate the ultimate resistance R_{ult} by means of a numerical method and check that:
$$1.35G + 1.5Q \leq R_{ult}/\gamma_R$$
- Option 2: Increase the load to show that it induces low settlement:
$$\alpha.V < R_{ult} \text{ (with low settlements)}$$

and α can be written as: $\alpha = (1.35 \text{ to } 1.5).\gamma_R$ then:

$(1.35 \text{ to } 1.5).\gamma_R.V \leq R_{ult} \leftrightarrow 1.35G + 1.5Q \leq R_{ult}/\gamma_R$

4 HYDRAULIC VERIFICATIONS

Numerical methods are also very useful to perform hydraulic verifications required by prEN 1997-1. Two failure mechanisms are presented: the first one is related with the hydraulic gradient and corresponds to a local verification while the second one deals with the equilibrium between the vertical stresses and the groundwater pore pressures and corresponds to a global verification. An example taken from a paper published by Pane et al. (2015) illustrates these two verifications. These calculations do not require any partial factors as input, which simplifies the analysis (the worst case hydraulic conditions are adopted).

5 CONCLUSIONS

The new subclause on numerical methods in prEN 1997-1 paves the way for using numerical methods as a standard tool for verifying ULS and SLS in geotechnical design for both mechanical and hydraulic mechanisms. A variety of geotechnical constructions can be tackled using this tool as has been demonstrated at the hand of three construction types. The list of requirements in prEN 1997 is sufficiently open, both for following more traditional paths of verification and for making full use of nonlinear constitutive laws for ground and supporting elements. Engineering judgement is still required, especially in case of strong soil-structure-interaction, where the stiffnesses of ground and structure may be affected as a side effect of strength reduction.

ACKNOWLEDGEMENTS

The authors have been involved at various stages in the development of the second generation of Eurocode 7, serving on a range of evolution and working groups or project teams. They are grateful to their colleagues for all the fruitful discussions. However, the content of the paper reflects the opinion of the authors and does not reflect the official opinion of SC7.

Tensile strength of rocks: Comparison of different testing methods

Résistance à la traction des roches: Comparaison de différentes méthodes d'essai

J. Castro*, J. Justo, M.H. Olson, M. Miranda
Universidad de Cantabria, Santander, Spain

**castrogj@unican.es*

ABSTRACT: While direct tensile testing is widely acknowledged as the most accurate method of determining tensile strength, indirect methods are frequently employed, due to the problems and the precision required to obtain viable results with the direct method. Accurate values of tensile strength are very important, especially for design purposes. Thus, values obtained from the direct tensile test are beneficial and they should be compared to other experimental values measured with different methods. This study compares experimental results of standard methods of indirect tensile testing, such as the Brazilian (splitting tensile) test and three and four point bending flexural tests with the ones obtained from direct tensile testing performed following the ASTM standard. For the comparison, a highly isotropic and uniform rock, namely a Moleanos limestone, is used. Results show that bending tests produce higher values than those obtained using the Brazilian test, and in turn, the latter produces also slightly higher values than direct tensile testing.

RÉSUMÉ: L'essai de traction directe est généralement considéré comme la méthode la plus précise pour déterminer la résistance à la traction ; cependant, les méthodes indirectes sont souvent utilisées en raison de la difficulté et de la précision requises pour obtenir des résultats viables avec la méthode directe. Il est important d'obtenir des valeurs de résistance à la traction précises, en particulier pour la conception, c'est pourquoi les valeurs obtenues à partir de l'essai de traction directe sont utiles, pour pouvoir les utiliser et les comparer à d'autres valeurs expérimentales et à d'autres méthodes. Cette étude compare les résultats expérimentaux des méthodes standard d'essais de traction indirects, tels que l'essai brésilien (traction par fendage) et les essais de flexion à trois et quatre points, avec ceux obtenus à partir d'essais de traction directs réalisés conformément à la norme ASTM. Pour la comparaison, une roche hautement isotrope et uniforme, à savoir un calcaire du Moleanos, est utilisée. Les résultats montrent que les essais de flexion produisent des valeurs plus élevées que celles obtenues à l'aide de l'essai brésilien et, ces dernières produisent également des valeurs plus élevées que celles obtenues avec de l'essai de traction directe.

Keywords: Tensile strength, Brazilian test, direct tensile test, three-point bending test.

1 INTRODUCTION

Measuring the tensile strength of rocks is critical due to their sensitivity to tensile loading, which is a common cause of failure. However, accurately measuring this strength is challenging due to the low tensile strength of rocks and various factors that affect the stress state during testing. The direct tensile (DT) test (Figure 1) is the common method for many construction materials, such as steel, but it may not always be feasible or accurate enough for rocks.

The difficulties associated with conducting direct uniaxial tensile tests on rocks have resulted in the development of different variations of the test, such as using dog-bone specimens or indirect methods (Table 1). These indirect methods involve experimental configurations that create inhomogeneous stresses in the specimen. However, when interpreting the results from these indirect methods, the multi-axial stress state and the influence of other components of the stress tensor are usually not considered. Additionally, linear elastic behavior is typically assumed.

Modified tension test	Luong (1990)

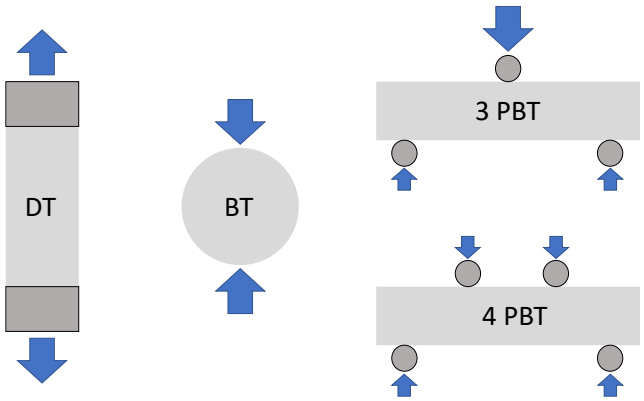

Figure 1. Summary of performed tests to measure Moleanos limestone tensile strength.

Among the indirect tensile tests, the bending of prismatic bars with circular or rectangular cross sections is widely used in mechanical and civil engineering to assess the tensile strength of various materials, such as ceramic materials, rocks, mortars... Three (3PT) and four (4PBT) points bending tests (Fig. 1) are adopted as a standard (e.g., ASTM C99: 2018, ASTM C880: 2018).

In rocks, the so-called Brazilian (splitting tensile) test (BT) (ASTM D3967: 2008) is commonly used due to the cylindrical shape of specimens. This test is preferred as it is relatively easy to prepare specimens, the testing method is straightforward, and the results obtained from the test exhibit low variability (Coviello et al., 2005). Detailed discussions on the Brazilian test have been presented by various authors (e.g., Colback, 1966), emphasizing its relevance in rock testing.

In recent years, with the development of high resistance glues that make easier using glued end caps, the direct tensile test is being revisited (e.g., Jensen, 2016; Zhang et. al., 2021; Pérez-Rey et al., 2023). In this way, the direct tensile test has recently been developed and implemented at the Geotechnical Engineering Laboratory of the University of Cantabria (Spain), following the ASTM standards with glued end caps (Castro et al., 2023).

Using the variety of tensile testing methods available (Figure 1), the different results obtained in a sample material, namely Moleanos limestone, are here compared and analysed, complementing existing comparisons between different testing methods to obtain the tensile strength (e.g., Coviello et al. 2005, Perras & Diederichs 2014).

2 LITERATURE REVIEW

Several authors have compared different methods to measure the tensile strength of rocks in the laboratory. For example, Coviello et al. (2005) compared tensile strength values measured with different tests, namely direct tensile test, Brazilian test, ring test, three and four-point bending tests and the Luong test (LT). They tested an artificial building stone (Gasbeton) and a natural calcarenite of the Gravina di Puglia geological formation. DT tests were perfomed using glued end steel caps and spherical joints in both ends. Good aligment was ensured and inclinometers were mounted on the lateral surface of the specimens. This is likely the reason to the fact that measured tensile strength using DT tests was higher than usual. Bending tests provided higher tensile strengths than those measured using the BT, and LT provided the lowest values.

On the other hand, Wang et al. (2020) performed tests on a granite from China and obtained that BT provided the higher tensile strength values in comparison to other methods, such as hydraulic fracturing hollow-cylinder, LT and DT tests.

Tensile strength obtained using bending tests relies on the linear elastic behaviour of the rock until failure. Thus, tensile strength is usually overestimated when using bending tests, unless a large thickness specimen is used (e.g., Biolzi et al., 2001).

For the DT test, some authors (e.g., Biolzi et al., 2001; Rabat et al., 2023) introduce a notch at the mid-section, but that could concentrate stresses and give overconservative tensile strength values.

As a brief summary, Table 2 compares the DT/BT ratio measured by different authors. More complete information and comparisons may be found for example in Perras and Diederichs (2014) or Rabat et al. (2023).

3 LABORATORY TESTING

3.1 Moleanos limestone

Moleanos limestone may be classified as an intrasparitic-pelsparitic limestone or grainstone. The most abundant components are pellets and intraclats, comprising 51% and 43% of the grains, respectively, with an additional 6 % of bioclasts. This limestone has been previously analyzed by the authors (e.g., Justo et

al. 2017, 2021) and it is predominantly isotropic and relatively homogeneous from a microstructural point of view, which simplifies the analysis.

3.2 Indirect tensile tests

6 BT tests were performed (Table 2) on disc-shaped specimens with a diameter of 64 mm and a thickness of 32 mm (Figure 2). The tests were performed under displacement control at 2.5 mm/min following ASTM standards (ASTM D3967: 2008).

For the bending tests, parallelepiped 180x30x30 mm specimens were used. A repetitiveness of 3 was used for both 3 and 4 PBT (Table 3). It is worth noting that both specimen size and repetitiveness are low and larger specimens and more tests should be used for an improved accuracy. The support span at the base was 150 mm and the upper loading span for the 4PBT was 50 mm.

All the tested specimens failed as expected (i.e., along a vertical central plane).

Table 3. Summary of performed laboratory tests.

Type	***Number***	***Result, σ_t (MPa)***
BT	6	7.8, 7.7, 7.1, 7.0, 6.8, 4.8
3PBT	3	10.8, 9.5, 9.2
4PBT	3	11.0, 10.1, 9.1
DT	15	7.9, 7.7, 7.6, 7.5, 7.3, 7.3, 6.4, 6.3, 6.3, 5.5, 5.3, 5.2, 5.2, 5.1, 4.4

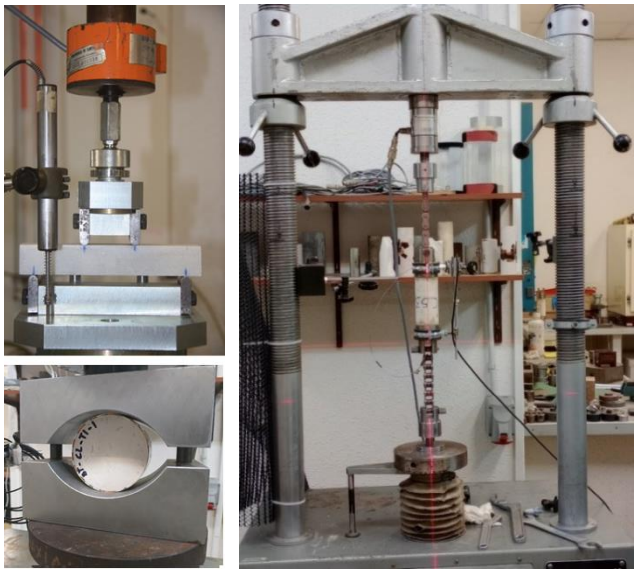

Figure 2. Test set-up of the different tests.

3.3 Direct tensile tests

DT tests were implemented at the Geotechnical Engineering Laboratory of the Univerisity of Cantabria mainly following the ASTM D2936: 2020. Samples of 50 mm diameter with a length diameter ratio of 2.5 were employed. They were glued to the metallic caps of 300 mm thickness and same diameter. Efforts were made to achieve a good alignment and failure of DT samples was reached in any area of the central part and was approximately horizontal. Detailed description of the DT tests may be found in Castro et al. (2023).

4 COMPARISON OF RESULTS

The interpreted tensile strength, σ_t, measured in each test is presented in Table 3 and plotted in Figure 3. The dispersity of the results for the DT is slightly higher than that of the BT (standard deviation of 1.15 vs 1.08 MPa).

The tensile strength predicted by the DT is the lowest. This is attributed to the fact that any misalignment introduces bending moments that reduce the theoretically calculated value. Nevertheless, the difference between the DT and the BT is not large (mean value of 6.3 vs. 6.9 MPa, respectively). Trying to discard the low values affected by possible misalignments, a truncated mean value (mean value of the 2/3 higher values) is shown in Figure 3. The truncated mean is slightly more similar, 7.0 vs 7.4 MPa for DT and BT, respectively.

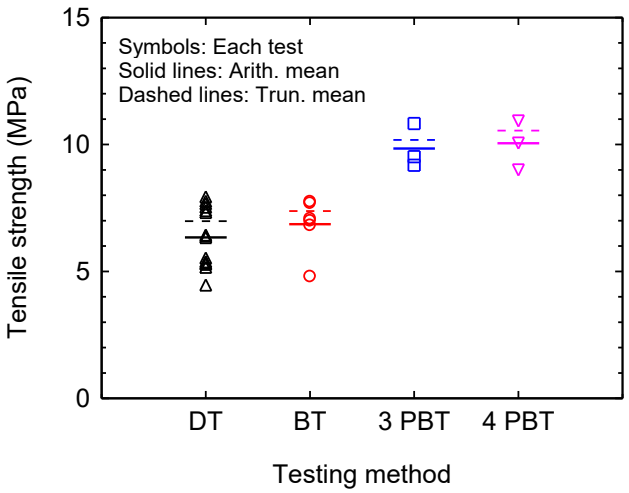

Figure 3. Tensile strength of Moleanos limestone obtained using different testing methods.

Bending tests give a much higher tensile strength, 10.2 and 10.5 MPa for the 3PBT and 4PBT, respectively. This is attributed to the stress gradient effect (e.g., Coviello et al. 2005), which is more notable in these samples of low thickness (30 mm of thickness). The 4 PBT has a zone of constant bending moment in the central part, while the 3 PBT reaches the maximum bending only in the central cross section. On the other hand, the application of the load in the 3 PBT may introduce some damage.

5 CONCLUSIONS

Measuring the tensile strength of rocks is crucial due to their susceptibility to tensile loading, a common cause of failure. Direct tensile testing, although the most accurate method, can be challenging and require precise conditions. Factors such as sample preparation, gripping, misalignments and stress concentrations tend to reduce the measured value. Therefore, indirect methods are often employed and several authors have presented comparisons between different methods.

The comparison presented here shows that DT results had slightly higher dispersity than BT, but the DT mean value was only a bit lower than that measured using BT (6.3 vs 6.9 MPa, a ratio of 0.91). On the other hand, bending tests yielded much higher tensile strength values (over 9 MPa in all the cases), highlighting the impact of the stress gradient effect, especially in low-thickness samples and when using linear elasticity until failure for the interpretation. In summary, while direct and indirect methods provide insights into rock tensile strength, careful consideration of specimen characteristics and testing conditions are essential for reliable results.

ABSTRACT: Landslides have emerged as a critical disaster type due to the increasing frequency of extreme rainfall events attributed to climate change. In recent years, research on landslide analysis and slope stability has grown. The most common research methods in landslide studies fall into two categories: numerical modeling and machine learning models. Both approaches hold potential for contributing to landslide disaster management, although research combining these methods remains limited. Therefore, the primary objective of this study is to harness the strengths of both approaches, which involves the establishment of landslide susceptibility maps and the subsequent development of probability-based numerical model, providing valuable insights for disaster prevention on high-risk areas. The results from this preliminary phase indicate that the categorization boundaries in the machine learning-based landslide susceptibility maps are primarily influenced by the proportion of historical landslide areas. However, given that this factor does not represent the main characteristics of the target objects, it should be excluded in future research. The forthcoming stages will emphasize the examination of slope and dip slope area proportions while incorporating additional landslide-related geomorphic and hydrological factors and enhancing data resolution to improve predictive model accuracy. In the context of probability-based numerical model, the research highlights the sensitivity of cohesion and the internal friction angle to the probability of slope system failure. Real-world slope and soil parameter experiments are planned for the next phase to establish a more realistic probability-based numerical model.

RÉSUMÉ: Les glissements de terrain ont émergé comme un type de catastrophe critique en raison de l'augmentation de la fréquence des événements pluvieux extrêmes attribués au changement climatique. Ces dernières années, la recherche sur l'analyse des glissements de terrain et la stabilité des pentes a augmenté. Les méthodes de recherche les plus courantes dans les études sur les glissements de terrain se répartissent en deux catégories : la modélisation numérique et les modèles d'apprentissage automatique. Les deux approches ont le potentiel de contribuer à la gestion des catastrophes liées aux glissements de terrain, bien que la recherche combinant ces méthodes reste limitée. Par conséquent, l'objectif principal de cette étude est de tirer parti des forces des deux approches, ce qui implique l'établissement de cartes de susceptibilité aux glissements de terrain et le développement ultérieur de modèle numérique basés sur la probabilité, fournissant des informations précieuses pour la prévention des catastrophes dans les zones à haut risque. Les résultats de cette phase préliminaire indiquent que les limites de catégorisation dans les cartes de susceptibilité aux glissements de terrain basées sur l'apprentissage automatique sont principalement influencées par la proportion de zones de glissements de terrain historiques. Cependant, étant donné que ce facteur ne représente pas les principales caractéristiques des objets cibles, il devrait être exclu des recherches futures. Les prochaines étapes mettront l'accent sur l'examen des proportions de pentes et de zones de pentes inclinées tout en incorporant des facteurs géomorphologiques et hydrologiques supplémentaires liés aux glissements de terrain et en améliorant la résolution des données pour améliorer la précision du modèle prédictif. Dans le contexte des modèle numérique basés sur la probabilité, la recherche met en évidence la sensibilité de la cohésion et de l'angle de frottement interne à la probabilité de défaillance du système de pente. Des expériences sur le terrain réel des paramètres de pente et de sol sont prévues pour la prochaine phase afin d'établir un modèle numérique basé sur la probabilité plus réaliste.

Keywords: Landslide management; susceptibility maps; reliability analysis; sensitivity analysis

1 INTRODUCTION

Landslides pose a significant threat to human life and property, making them one of the most critical disaster types. Moreover, with the increasing frequency of extreme rainfall events due to climate change, landslides triggered by heavy precipitation demand more attention and management (Crozier, 2010). Over

the years, there has been a multitude of research in slope stability analysis and landslide disaster mitigation. The most common research methods fall into two categories: (1) numerical modeling and (2) machine learning models. In this study, the term "numerical models" refers to methods based on a deterministic approach. These methods rely on complex mathematical computations that require computer calculations. Examples include Limit Equilibrium Methods (LEMs), Finite Element Method (FEM), and the Material Point Method (MPM). Numerical models can simulate the movement of slopes and study the mechanisms of failure, but typically limited to relatively small areas. On the other hand, machine learning models use geospatial and hydrological data to generate risk assessment maps on a broader scale, employing a data-driven approach. This method offers the advantage of identifying areas with potential high risk (Merghadi et al., 2020).

Both machine learning and numerical models have their merits and can significantly contribute to landslide disaster management. However, there is limited research that combines both methods for analysis. Hence, the ultimate aim of this study is to leverage the strengths of both approaches. Initially, a machine learning model will be used to establish landslide susceptibility maps. Subsequently, probability-based numerical model using a probability of failure approach will be constructed for areas with a potential high risk, offering valuable insights for disaster prevention.

The research consists of three phases. The first phase involves creating preliminary machine learning and probability-based numerical model for simpler cases. Factors affecting landslide susceptibility will be analysed, and adjustments made based on their impact. The future direction for model complexity will also be discussed.

In the second phase, the most suitable combination of factors identified in the first phase will be incorporated into more complex model designs, considering additional real-world conditions in the study area. The representative model will be employed to identify hazard zones and conduct probability-based numerical model analysis. Finally, the third phase involves model validation and optimization and an attempt to generalize this hybrid model for landslide disaster applications in other regions.

This draft paper primarily focuses on the outcomes of the first phase and presents specific plans for future research work based on these results.

2 METHODS

2.1 Study area

The Jhuoshuei River is Taiwan's longest river, approximately 187 km in length, and it flows through the central region of Taiwan, spanning four counties and cities. Its upper and middle reaches are characterized by fractured bedrock and heavy rainfall in mountainous areas, resulting in high sediment content in the river. The lower reaches are densely populated and heavily involved in agricultural activities. Taking into account slope vulnerability and the considerations for resident safety, this area was chosen for the first phase of the study.

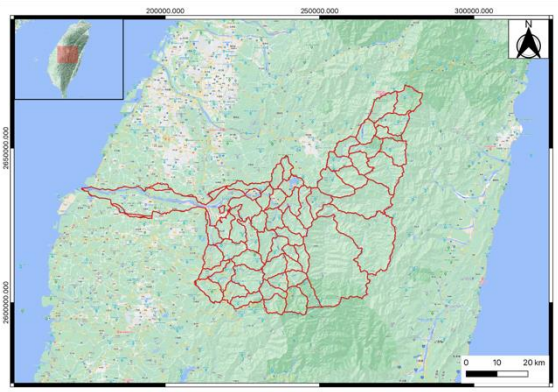

Figure 1. Study watersheds and their slope units.

2.2 Establishment of Machine Learning Models

The study area was divided into 53 sub-watersheds using watershed analysis methods (Figure 1). Three major extreme rainfall typhoons in recent years, namely, Typhoons Saola, Soulik, and Meranti, were selected as the main events for landslide analysis. Geospatial and hydrological factors were chosen as parameters for building the machine learning models and included slope, dip slope area proportion, historical landslide area proportion, and rainfall from individual typhoon events.

Using the landslide records corresponding to the selected typhoon events as known landslide outcomes, Support Vector Machine (SVM) was employed to create landslide prediction machine learning models. The dataset was divided into a training set (3/4 of the data) and a testing set (the remaining 1/4). Two types of classification boundaries, linear and non-linear (RBF), were utilized to compare the classification performance of the two SVM models.

2.3 Identification of key factors in machine learning models

As a classification model, visual representation of SVM classification boundaries can be created by pairwise combinations of factors. This allows for a comparison of the determinative impact of different factors on landslide classification outcomes. For instance, if the classification boundary appears to be vertical, it signifies that the classification results are entirely dependent on the horizontal-axis factor. Conversely, if the boundary is horizontal, it implies that the classification results are solely dependent on the vertical-axis factor.

By comparing the pairwise combinations, it is possible to rank and assess the significance of each factor in determining landslide prediction outcomes within this model. ranking is instrumental in determining the level of emphasis to be placed on each factor.

2.4 Establishment of probability-based numerical model

This research focuses on landslides with large displacement, and traditional slope stability analysis methods like the Limit Equilibrium Method (LEM) and Finite Element Method (FEM) have limitations in simulating large displacements and cannot describe the motion processes adequately (Kaur and Sharma, 2016; Soga et al., 2016). In contrast, the Material Point Method (MPM) can provide better simulations of the motion processes and offer in-depth insights into the physical mechanisms of slope failure (Wyser et al., 2020).

In this study, Anura3D software was chosen for the MPM analysis of slope stability. To simplify the problem in the initial stages of the research, a basic geometric scenario was selected for analysis (Anura3D MPM Research Community, 2022a). The geometric is illustrated in Figure 2.

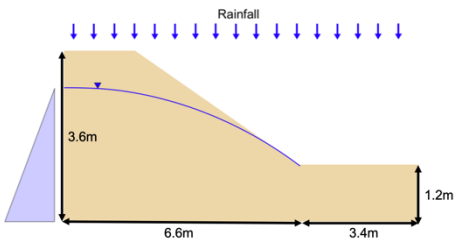

Figure 2. Geometric of selected problem (Anura3D MPM Research Community, 2022a).

To quantitatively assess the slope's safety level, this study introduces reliability analysis. This involves using AK-PSO-HHs (Thedy and Liao, 2023) to calculate failure probabilities under various conditions based on the MPM results. Note that the accuracy of this method has been validated, for details, please refer to Thedy and Liao, 2023.

In reliability analysis, it is essential to provide a clear definition of „failure“. As the shear stress-based safety factor cannot fully represent the occurrence of large landslides, this study chooses to define failure in terms of „displacement“, which is a more direct indicator of landslide occurrence. In practical management, displacement or displacement rates are often used to establish warning thresholds.

2.5 Identification of key factors in probability-based numerical model

This study analyses seven factors, encompassing cohesion (C), internal friction angle (ϕ), wet density (ρ), Young's modulus (E), along with hydrological parameters, including infiltration rate (I_R), groundwater level (H), and the correlation coefficient between cohesion and internal friction angle (r). These parameters are selected within reasonable ranges, their respective probability distribution types and statistical parameters are detailed in Table 1.

A sensitivity analysis of the system's failure probability concerning various factors is conducted following established methodologies (Malkawi et al., 2000). By adjusting the coefficients of variation (COV) for these seven factors within their reasonable ranges, the impact of each factor's variability on the system's failure probability is explored. This comparative analysis identifies the sensitivity of each parameter, and parameters demonstrating sensitivity within the system are considered as key factors of interest.

Table 1. Parameter information.

Parameter	Probability distribution	Mean	Range
C (kPa)	Lognormal	2.5	1.1~5.3
ϕ (°)	Lognormal	27	19.2~41.2
E (kPa)	Lognormal	30000	8450~11540
ρ (kg/m^3)	Lognormal	2650	2175~3250
I_R (m/s)	Uniform	0.0002	0.0001~ 0.0004
H (m)	Beta	2.2	1.5~2.5
r (-)	–	0	-0.9~0.9

3 RESULTS

3.1 SVM model performance

Performance assessment of the models includes confusion matrices for both linear and non-linear

classification boundaries (Table 2, Table 3). Three primary validation indices, True Positive Rate (TPR), True Negative Rate (TNR), and Accuracy, are utilized to gauge model effectiveness. The findings consistently favour the linear model over the non-linear one across all metrics. Subsequently, emphasis will be placed on the superior linear model in the ensuing discussion.

Table 2. Linear SVM Model performance.

	Actual landslides	Actual no landslides
Predicted Landslides	11	6
Predicted no landslides	2	21
TPR	84.6%	
TNR	77.8%	
Accuracy	80%	

Table 3. Nonlinear SVM Model performance.

	Actual landslides	Actual no landslides
Predicted Landslides	9	8
Predicted no landslides	8	15
TPR	52.9%	
TNR	65.2%	
Accuracy	60%	

3.2 Factor analysis in the SVM model

To establish a landslide prediction model, the factors used are combined pairwise. A linear classification boundary model is employed to visualize the relationships between the classification boundary and various factors, aiming to compare the significance of each factor in predicting „landslide occurrence“, as shown in Figure 3.

In the combination of dip slope area proportion and slope, the model categorizes all data points as „no landslide“ (Figure 3a), resulting in an overall accuracy of only 57.5%. Conversely, when combining historical landslide area proportion with dip slope area proportion (Figure 3b), the overall accuracy reaches 75%.

However, the classification boundary is solely dependent on historical landslide area proportion, as one factor. A similar situation is observed in the combination of historical landslide area proportion with slope (Figure 3c).

Finally, by combining rainfall of each event and historical landslide area proportion, the overall predictive accuracy reaches 77.5% (Figure 3d), approaching the predictive accuracy of the model with four integrated factors (80%). Nevertheless, the classification boundary remains primarily influenced by historical landslide rates, with only slight adjustments based on rainfall.

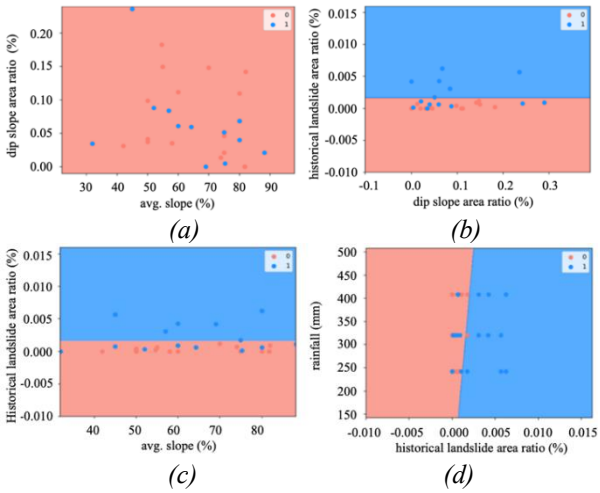

Figure 3. Pairwise comparison SVM classification boundaries. (a) Combination of dip slope area proportion and slope. (b) Historical landslide area proportion and dip slope area proportion. (c) Historical landslide area proportion and slope. (d) Rainfall of each event and historical landslide area proportion.

3.3 Factor sensitivity in the probabilistic numerical model

In this section, the approach outlined by Malkawi et al. (2000) is employed to create sensitivity assessment plots of the variation in failure probability concerning each parameter.

The results of this simulation exhibit a linear relationship in all cases, except for the negative correlation between friction angle and cohesion. The sensitivity of each parameter can be assessed by examining the slope of the regression line. In this research case, the most influential factors in terms of their impact on the system's failure probability are COV($\emptyset$) with a slope of 0.3077 and COV(C) with a slope of 0.2492. Following these are the positive correlation (r_+) between cohesion and friction angle with a slope of 0.028, COV(H) with a slope of 0.0175, and COV(I_R) with the smallest slope of 0.0023. COV(ρ) and COV(E) exhibit minimal sensitivity in this context.

4 DISCUSSION

4.1 Factors of interest in the SVM model

The impact of slope and dip slope area proportion on classification boundaries, as observed in pairwise evaluations, seems to be minimal (Figure 3).

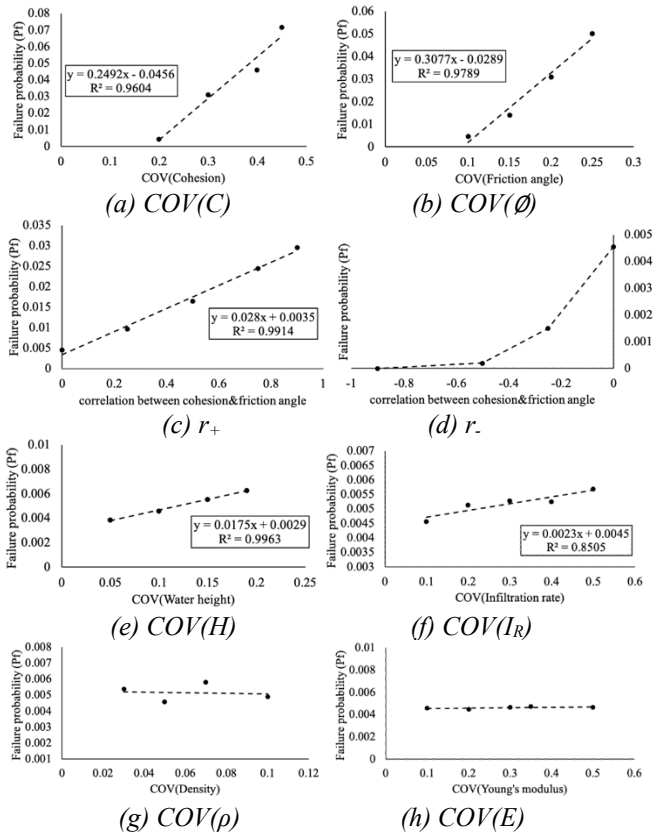

Figure 4. Sensitivity analysis of each parameter.

However, it is essential not to draw conclusions regarding the insignificance of these two geomorphic factors. The historical landslide area proportion, which takes precedence, represents the proportion of landslide-prone areas within sub-watersheds. Disasters tend to recur in regions where critical conditions exist, making the „historical landslide area proportion“ an integrative measure that accounts for all contributing landslide factors. Thus, incorporating it along with natural background conditions, such as slope and dip slope area proportion, as predictive factors in the model, can dilute the effects of individual natural conditions and potentially lead to misleading conclusions about their importance.

In the final phase of this study, the primary objective is to identify high-potential landslide areas that have been previously overlooked. These areas typically lack significant historical landslide records. While the historical landslide area proportion predominantly influences the classification in this research phase, considering its impact on other factors, along with its misalignment with the target characteristics, suggests its exclusion from the list of factors of interest in subsequent research phases. Moreover, the predictive performance highlights the need to incorporate additional landslide-related geomorphic and hydrological factors, such as rock type, rock fragmentation, and groundwater levels, as factors of interest. This comprehensive approach will provide a more complete understanding of the influence of various spatial factors on landslide occurrence.

4.2 SVM model refinement directions

Based on the current phase's results, recommendations for enhancing the machine learning model in the next phase are: (1) Continue investigating rainfall of each event, and focusing on diluted factors like slope and dip slope area proportion while diversifying relevant factors for improved predictions; (2) Increasing the spatial resolution of factors to better represent sub-watershed characteristics; (3) Considering a smaller study area, focusing on a few key sub-watersheds due to enhanced data resolution.

4.3 Factors of interest in the probability-based numerical model

Based on the results of parameter sensitivity analysis (Figure 4), cohesion (C), the internal friction angle ($\emptyset$), and their correlation were identified as the most sensitive factors influencing system failure probability. Therefore, they have been included as attention factors.

While groundwater level (H) and infiltration rate (I_R) showed some sensitivity in the model, their impact on slope stability, particularly the influence of „water“ in the context, is not as significant as expected.

Hence, their exact implications require further investigation, and they will be retained as attention factors for subsequent stages of research.

On the other hand, soil moisture density (ρ) and Young's modulus (E), which were found to be insensitive in this stage, may be excluded from the attention factors in sensitivity analysis during the subsequent phases.

4.4 Further discussion on the groundwater level in the numerical model

This study examines the sensitivity of groundwater levels in slope safety evaluation, essentially altering the soil submerged range. The changes in groundwater level arises from alterations in excess pore water pressure, leading to a reduction in effective stress and, consequently, triggering slope instability. The material properties adopted in this study are single point two-phase. Specifically, pore water and the acceleration of soil is set as unknowns to solve the governing equations. Ultimately, this calculation yields the physical behavior of saturated soil (Anura3D MPM Research Community, 2022b). The effectiveness of analyzing the impact of groundwater level changes on landslides using the MPM has been validated through the study by Troncone et al., 2020.

Our founding here is that the sensitivity of groundwater level is relatively smaller than soil strength parameters. However, this doesn't imply its insignificance to landslides. Since the Mohr-Coulomb criterion directly relies on soil strength parameters, it is reasonable for these two parameters to exhibit the highest sensitivity. Besides these two parameters, groundwater level is the most significant factor affecting slope stability, where soil infiltration naturally also becomes an important factor influencing slope stability. Thus, in a situation where a slope undergoes rainfall infiltration without soil strength parameter changes, groundwater level demonstrates the highest sensitivity to slope stability.

4.5 Probability-based numerical model refinement directions

The initial phase of this research focused on simplifying the analysis of case study, primarily applicable to artificial slopes with a height of 3.6 meters or less. Caution is needed when extending this model to slopes exceeding this range. Hence, future phases should focus on making the numerical model's geometry more complex, resembling real-world scenarios or directly conducting motion analyses for specific slope conditions. Regarding parameter values, using actual soil experiment data from the analysis area is essential to realistically reflect the impact and sensitivity of various considerations on slope failure mechanisms.

5 CONCLUSIONS AND FUTURE WORKS

This study is the initial phase of the three-tiered objectives, concentrating on simpler scenarios to establish initial machine learning and probabilistic-numerical model. Based on these findings, the second phase should consider the following adjustments:

1. Enrich the factors in the landslide prediction machine learning model. In addition to the factors explored in this phase, such as rainfall of each event, slope and dip slope area proportion, incorporate more landslide-related geophysical and hydrological factors to enhance predictive performance.
2. Narrow down the research scope of the landslide prediction machine learning model for improved spatial data resolution.
3. Refine the probability-based numerical model by real-world slope geometry and soil parameters. In sensitivity analyses, emphasize discussions about the variation in soil strength parameters (C, ϕ) and the sensitivity of hydrological factors (H, I_R) within the system.

ABSTRACT: We present large-scale ground investigations along 170 km of the Lucas do Rio Verde railway, a new, 730-km-long railway being planned in Mato Grosso, Brazil through airborne geoscanning. We combe airborne geophysical data with limited intrusive ground data to generate 3D ground models, with the help of machine learning algorithms. These rapidly acquired data and generated models allowed us to quickly characterize geological heterogeneity in the area, predict the depth to the soil-rock interface, and identify key groupings of soil types. While some results were limited by poor geophysical contrast between sand and sandstone in some portions of the survey area, they allowed to focus the next phase of ground investigation on critical areas. We show that we reduce the uncertainty in estimating rock excavation costs by 30% compared to a conventional, borehole-only workflow. This case study is the first successful example of airborne geoscanning in an infrastructure project in a tropical climate.

RÉSUMÉ: Nous présentons des études de terrain à grande échelle le long de 170 km de la voie ferrée Lucas do Rio Verde, une nouvelle voie ferrée de 730 km de long en cours de planification dans le Mato Grosso, au Brésil en utilisant la géoscanographie aérienne. Nous combinons des données géophysiques aéroportées avec des données terrestres intrusives limitées pour générer des modèles 3D terrestres, à l'aide d'algorithmes d'apprentissage automatique. Ces données rapidement acquises et ces modèles générés nous ont permis de caractériser rapidement l'hétérogénéité géologique de la région, de prédire la profondeur de l'interface sol-roche et d'identifier des groupements principaux de types de sol. Bien que certains résultats aient été limités par le faible contraste géophysique entre le sable et le grès dans certaines parties de la zone d'étude, ils ont permis de concentrer la phase suivante d'investigations sur les zones critiques. Nous montrons que nous réduisons l'incertitude liée à l'estimation des coûts d'excavation de roches de 30 % par rapport à un flux de travail conventionnel, uniquement constitué de forages. Cette étude de cas est le premier exemple réussi de géoscanographie aérienne dans un projet d'infrastructure dans un climat tropical.

Keywords: Railway; geological risks; site investigation; geophysics; machine learning.

1 INTRODUCTION

Site investigations using traditional intrusive techniques have limitations in mitigating geological risk in large infrastructure projects. They are relatively slow, costly, and only provide information at a single point. Airborne electromagnetics (AEM) is a geophysical method with complementary strengths: low unit cost, rapid acquisition, continuous data coverage. In a workflow we call *airborne geoscanning*, we combine both AEM and traditional geotechnical soundings using machine learning to generate geological models that take advantage of the strength of both data types. This new case study presents airborne geoscanning results from the Lucas do Rio Verde Project, a 730-km-long railway being planned in Mato Grosso state, Brazil. Our aims were to (1) understand large-scale geological trends; (2) map different soil and rock types, and (3) optimize future drilling campaigns. This text focuses on the first 130 km of the railway of the planned railway.

2 METHODS

2.1 Airborne electromagnetics

Airborne electromagnetic (AEM) systems allows one to map differences in the electrical resistivity of the subsurface, and have been widely used in mineral

exploration, hydrogeology, and, more recently, infrastructure applications (Auken et al., 2017). In 2021, EMerald Geomodelling and Rumo Logística used the RESOLVE EM system by Xcalibur Multiphysics to survey 170 km of railway, collecting 5 parallel flightlines in a 200-m-wide corridor centred on railway alignments.

Pre-processing of these data was consisted of four main tasks: (1) removing data adversely affected by nearby man-made, metallic structures; (2) removing measurements taken outside of acceptable flight parameters (roll, pitch, altitude); (3) averaging of consecutive sounding points to improve signal to noise ratio; and (4) removing measurements with low signal amplitude, usually due to highly resistive geology. We then used inversion modelling to transform this dataset into a model of electrical resistivity, which formed the basis for subsequent geological interpretation. All these steps were executed using a combination of in-house software and AarhusGeoSoftware's Aarhus Workbench.

2.2 Geotechnical data

At the time of the survey, 104 standard penetration tests (SPs), 68 auger borings (STs) and 14 combined SPs and rock core drillings (SMs) were available as ground trust training data. Data was logged at intervals of 1 m in most cases, meaning the vertical precision of these data is assumed to be 1 m. Materials were classified using two different schemes. First, we used the Brazilian Geological Association's (ABGE) criteria for classifying sandstones by friability (Pastore et al. 2015), separating unconsolidated sediments (Category 1) from partly weathered rock (Cat. 2) and intact rock (Cat. 3). (Too few instances of Category 2 material were encountered to determine a meaningful correlation with electrical resistivity, so Categories 2 and 3 were merged for our interpretation.) Second, five broad categories of material were parsed from the textual descriptions of material recording during field observations: clay, silt, sand, rock, and laterite. Where multiple materials were mentioned, only the primary constituent (e.g., the "silt" in a "clayey silt") was used.

2.3 Data Integration and modelling

We use three techniques to analyse the field data. First, we use a hierarchical clustering algorithm on the electrical resistivity model to group locations with similar results in the uppermost 30 m of the subsurface. Second, we use an artificial neural network

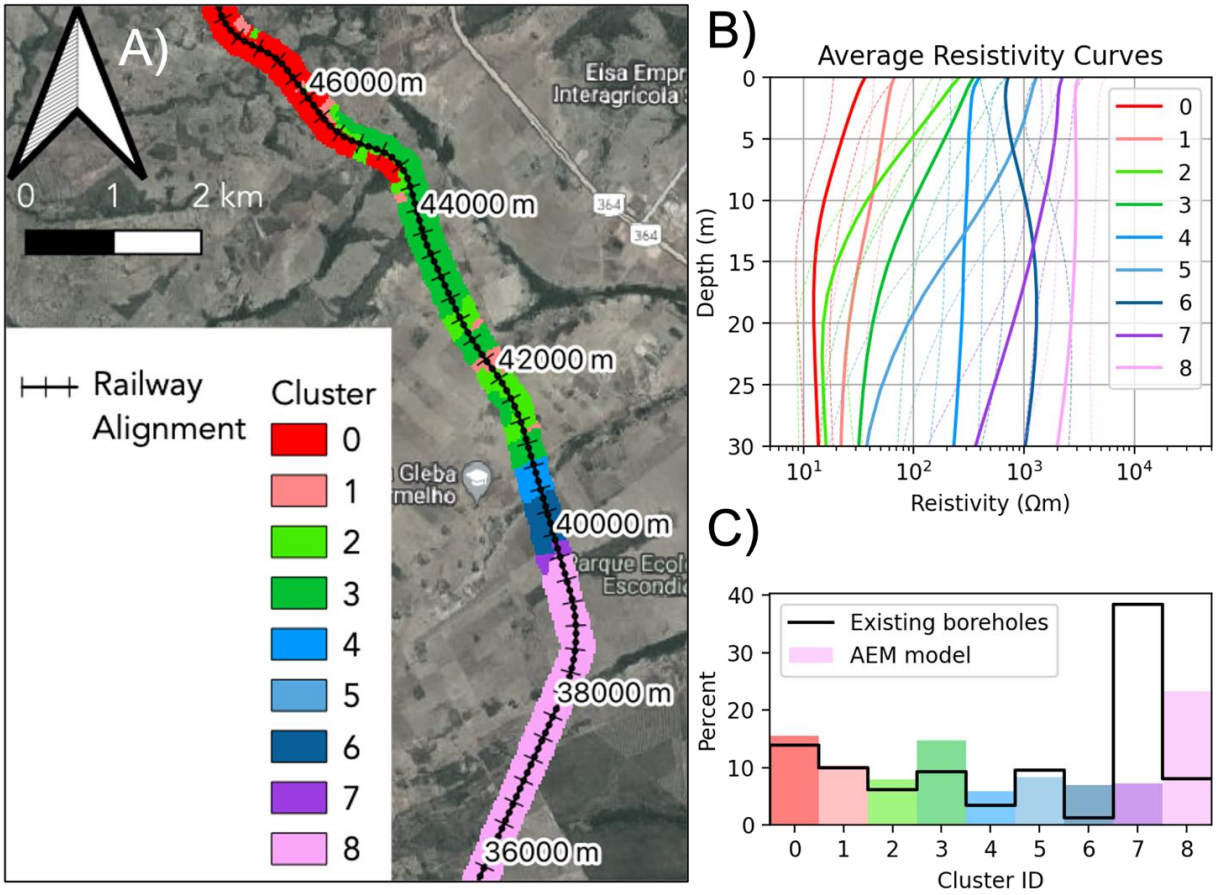

Figure 1. Outputs of the cluster analysis: A) Map view of a portion of the survey; B) Average resistivity curves of each cluster; C) Proportion of clusters within the resistivity model and the existing geotechnical soundings. Adapted from Christensen et al. 2023.

(ANN) approach based on Lysdahl et al. (2022) to predict the depth to the interface between Category 1 and Category 2/3 material. Lastly, we use a supervised machine-learning algorithm based on Christensen et al. (2021) to generate a volumetric model of material types. Whereas clustering only uses the resistivity model, the latter two techniques combine electrical resistivity and geotechnical data.

3 RESULTS

The resultant geophysical clusters (Figure 1), interface model (Figure 2A) and material classification model (Figure 2B) provided information on not only the expected ground conditions, but also where there was variability, and where there was uncertainty or a lack of data. For instance, we compared the relative proportion clusters among AEM and geotechnical sounding location and note that medium-resistivity (Clusters 2, 4, and 6) and the highest-resistivity cluster (8) are undersampled by existing drillings. In the interface model, median depth of 6.0 m, the 75th percentile was 8.7 m, and a few isolated cases of depths exceeding 20 m in some tall hills. Uncertainties had a median value of 3.4 m. Lastly, the material classification model showed that there are long stretches with a very high probability of sandy materials and multiple shorter stretches that are clearly fine-grained. High uncertainties occur at the transitions between these major, uniform zones and in isolated instances of local heterogeneity.

To assist with planning of subsequent ground investigations, we used these models to divide the survey area into high-, medium-, and low-priority zones (Figure 3). High-priority zones highlight areas with one of or multiple of the following: elevated uncertainty in the interpreted geological models, undersampled clusters, elevated heterogeneity, poor correlation between geophysics and geological targets, intersections between geological targets and the planned railway alignment or unexplained/unsampled features in the geophysical models. In all, 50% of the railway alignment is assigned as high priority, 38% as medium, and 12 % as low priority.

4 DISCUSSION

Airborne geoscanning has led to reductions in time and direct cost in this phase of this project. We estimate that 33% fewer geotechnical soundings were needed to adequately characterize these railway alignments, a similar magnitude to past projects in Norway (Christensen et al. 2020). This is achieved reduction comes from targeting regions with higher geological uncertainty and avoiding redundant holes where resistivity models can be explained by existing data.

Quantifying risk is challenging, but one way we attempt to do so is to compare estimated excavation costs from the ANN-based interface model to a boreholes-only one. Standard practice in Brazil is to perform a linear interpolation (i.e., triangulation) of depth. Uncertainty estimation is not common, so we use variogram modelling and ordinary kriging to estimate uncertainties. While the median estimated excavation costs from either model do not vary by more than 3 %, the confidence range for the borehole-only method (R$74-231 million) is 30% wider than that of the ANN-based on (R$86-210 million) due the fact that uncertainties in the ANN-based interface model are lower. This shows that airborne geoscanning reduced the worst-case scenario by R$21 million. Though difficult to quantify, we expect other indirect, long-term benefits such as reduced exposure risk for field personnel, reduced risk of work stoppage and litigation from unforseen ground conditions, and avoidance of overcommitment to suboptimal design thanks to a more rapid investigation.

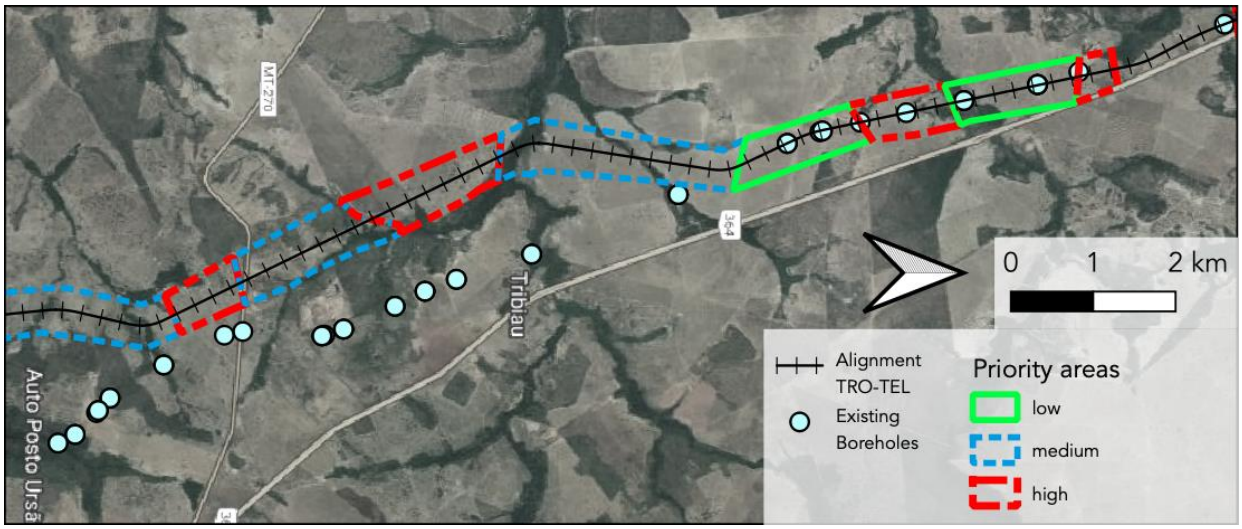

Figure 3. Example of mapped priority zones along a 14-km segment. Adapted from Christensen et al. (2023).

This technology is not without limitations. For one, there are some sections where there is limited electrical resistivity contrast, notably between some sands and sandstones. Boreholes are still necessary to identify the soil-rock interface within these zones. In addition, past case studies have shown that the main benefit from airborne geoscanning comes from optimizing linear infrastructure alignment, an impact that far exceed beyond direct savings of a reduced number of drillings (Christensen et al. 2020). Nonetheless, this case study adds to the growing body of literature on airborne geoscanning and its versatility as a ground investigation tool for large infrastructure projects.

5 CONCLUSIONS

This case study demonstrated that airborne geoscanning is a valuable tool for performing more efficient, large-scale site investigations in infrastructure projects. Though resultant ground models had some uncertainties and were not available early enough in the project‘s lifetime to be used for route optimizations, there were significant benefits in short-term cost and time savings and long-term benefits by reducing risk. This study exapnds on the literature on airborne geoscanning by being the first example from Brazil and the first example in an infrastructure project in a tropical climate.

ABSTRACT: Execution control during and after driving precast concrete piles is a critical issue for work validation and acceptance. This is especially important due to the high compressive stresses usually expected to be resisted by precast piles, taking advantage of the high-resistant concrete used on its manufacture and given the effects of driving and lateral displacement of the soil on increasing geotechnical bearing capacity. Among others, refusal measure is one of the main aspects of the execution control of every driven piles, and the refusal criterion is defined using pile driving formulas, usually conservative. Dynamic load tests play a key role in the execution control process, testing a sample of piles, driven with the refusal criterion, to a maximum axial load defined with a given Safety Factor. The results of the Dynamic Load Tests are then used to check and set the refusal driving criterion or calibrate it if needed. In this paper is presented a description of the execution control process used by KELLER in major piling works for logistic warehouses, and a preliminary study comparing the allowable loads deducted from Dynamic Load Tests results and the allowable loads estimated through refusal measurement.

RÉSUMÉ: Le contrôle de l'exécution pendant et après le battage des pieux en béton préfabriqués est une question critique pour la validation et l'acceptation des travaux. Ceci est particulièrement important en raison des fortes tensions de compression auxquelles les pieux préfabriqués s'attendent généralement à résister, en tirant parti du béton à haute résistance utilisé pour sa fabrication et compte tenu des effets du battement et du déplacement latéral du sol sur l'augmentation de la capacité portante géotechnique. Entre autres, la mesure de refus est l'un des principaux aspects du contrôle d'exécution de chaque pieu battu, et le critère de refus est défini à l'aide de formules du battage des piex, généralement conservatrices. Les essais de charge dynamique jouent un rôle clé dans le processus de contrôle de l'exécution, en testant un échantillon de pieux, battus avec le critère de refus, à une charge axiale maximale définie avec un facteur de sécurité donné. Les résultats des tests de charge dynamique sont ensuite utilisés pour vérifier le critère de refus du battage ou pour le calibrer si nécessaire. Dans cet article, nous présentons une description du processus de contrôle d'exécution utilisé par KELLER dans les grands travaux de battage pour les entrepôts logistiques, et une étude préliminaire comparant les charges admissibles déduites des résultats des essais de charge dynamique et les charges admissibles estimées par mesure de refus.

Keywords: Driven piles; execution control; pile driving formulas; dynamic load tests.

1 INTRODUCTION

Driven precast concrete piles have been a foundation technique widely used in logistic warehouse projects in the Iberian Peninsula.

Execution control during and after driving precast piles is a critical issue for work validation and acceptance. This is especially important due to the high compressive stresses usually expected to be resisted by precast piles, taking advantage of the high-resistant concrete used on its manufacture and given the effects of driving and lateral displacement of the soil on increasing geotechnical bearing capacity.

A description of the execution control process, used by KELLER for driven piles works, is presented in this paper, including driving and loading data from some major logistic warehouse projects performed in Portugal.

2 EXECUTION CONTROL PROCESS

2.1 Refusal driving criterion

Quoting Lawton et al. (1986): "dynamic pile-driving formulas have been available for more than 160 years to predict the static bearing capacity of piles. In the early 1960s the editors of Engineering News-Record had 450 dynamic pile formulas on file. All these formulas are based on the assumption that the ultimate capacity of the pile under static loading is directly related to the driving resistance of the pile in its last stages of embedment.

The stress-strain relationship in a pile during driving is extremely complicated, making on exact theoretical treatment impractical. A small percentage of the available pile-driving formulas are empirical in their entirety; however, most formulas are based on Newton's law of impact and conservation of energy principles and are modified to account for energy losses during impact and during the propagation of stresses."

There are around 20 (more or less) dynamic pile driving formulas commonly used world wide, and the Dutch formula is one of them.

In Portugal and Spain, KELLER uses the Dutch formula to set the refusal criterion, which is a pile driving formula widely used in the Iberian peninsula because of its easy application and easy refusal measurement on site.

The Dutch formula correlates the penetration of the pile, at the end of the driving process, with an estimated allowable axial compression load on the pile ($N_{allowable}$), in order to achieve the following:

$$N_{allowable} \geq N_{SLS} \qquad (1)$$

where N_{SLS} is the maximum axial compression load for Serviceability Limit State.

$N_{allowable}$ is estimated with the Dutch formula as follows:

$$N_{allowable} = \frac{M^2 \times H}{(FS \times e \times (M+P))} \qquad (2)$$

where M is the weight of the mass of the driving hammer, H is drop height of the hammer, FS is the safety factor (6.0 for pile lengths ≥ 12m and 7.0 to 10.0 for pile lengths < 12m), e is the pile penetration per blow, and P is the pile weight.

The refusal driving criterion is finally set as the maximum penetration for the last 10 blows of the driving process ($e \times 10$) for each kind of pile, equalizing $N_{allowable}$ to the respective maximum N_{SLS}.

This is an empirical way to ensure the $N_{allowable}$ needed for every driven pile, and it comes with some uncertainty. Nevertheless, it's known as a conservative approach because of the high safety factors used (6 to 10) and the expected increase of piles bearing capacity in the following days after the driving end and set-up, especially due to the soil rearrangement along the shaft in clayey soils.

2.2 Dynamic load tests

In addition to the refusal driving criterion, dynamic load tests are performed on at least 5% of the piles, 24 or 48 hours (minimum) after the driving end. These are non-destructive tests, consisting in re-driving the piles with the same equipment, and previously installing 2 accelerometers and 2 extensometers at the pile's head. An example is shown in Figure 1.

Figure 1. Instrumentation and load application during a dynamic load test.

The instruments are connected to a PDR unit (data acquisition recorder) which sends the stress wave signals to the monitoring field computer, where curves for force and velocity x impedance are registered for further processing. Later, a FEM software is used for signal-matching, and after that a static calculation of the model is performed, obtaining the total axial compression load applied in the pile test and estimating the shaft load and the base load separately.

Maximum compression stresses, tension and displacements are also obtained.

As part of the execution control process, with these dynamic load tests on a sample of piles the following objectives can be achieved:

- Confirm the $N_{allowable}$ of each kind of pile, applying a maximum test load in order to check the following:

$$Max.Test\ Load \geq N_{SLS} \times FS_{EC7} \qquad (3)$$

where FS_{EC7} is the combination of the partial safety factors and model factor, as defined in the Eurocode 7 (usually around 2.0m for SLS).

- Confirm and calibrate (if needed) the refusal driving criterion.
- Verify the structural integrity of the tested piles.
- Verify hammer efficiency.

3 REFUSAL MEASUREMENT VS. DYNAMIC LOAD TEST

As a preliminary study, data from dynamic load tests (DLT) has been collected from 4 sites of logistic warehouses piling projects in Portugal, and the $N_{allowable_DLT}$, has been considered equal to the maximum test load divided by a FS of 2.0.

At the same time, the respective $N_{allowable_REFUSAL}$ for each tested pile has been estimated using the Dutch formula with a FS between 6.0 and 10.0 depending on the driven length of the piles.

The time after the pile installation has been registered for each pile tested.

The sites have been chosen in order to have 2 sites of clayey soils and 2 sites of sandy soils.

The tested precast concrete piles have square sections, from 270, 300 and 350mm, with concrete class ≥ C50/60.

The pile lengths vary between 12.0 and 15.3m for site 1; 24.9 and 25.9m for site 2; 10.4 and 16.4m for site 3; and between 5.7 and 6.0 for site 4.

The graphics summarizing the results are presented in the Figures 2 to 5, showing in the horizontal axis the penetration of the piles for the last 10 blows at the end of the installation process, and in the vertical axis the ratio ($N_{allowable_DLT}$ / $N_{allowable_REFUSAL}$).

If this ratio is near 1.0, it means that there is a good correlation between the axial allowable compression load of the pile, deducted from the dynamic load test and from the refusal measurement. It would indicate that the applied execution control process is safe and nearly optimal.

If the ratio is much lower than 1.0, it means that the applied execution control process is safe but conservative. This usually occurs when the penetration of the pile during refusal control is very small (with very high $N_{allowable_REFUSAL}$), but the maximum test load of the DLT is only the needed to verify the serviciability load ($N_{SLS} \times FS_{EC7}$).

If the ratio is higher than 1.0, it means that the there will be a doubt during the refusal measurement, related to a low $N_{allowable_REFUSAL}$ value, but if the maximum test load of the DLT is enough to verify the serviciability load ($N_{SLS} \times FS_{EC7}$), then the doubt will be cleared, preserving the safety of the applied execution control process. If this kind of situation happens consistently in a site, then calibration of the refusal driving criterion would be advisable.

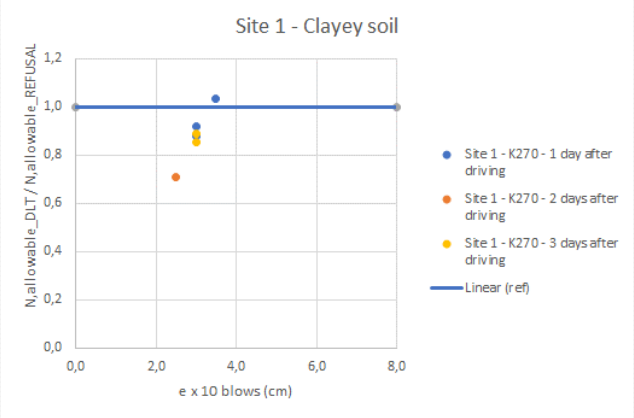

Figure 2. Site 1_Clayey soil - $N_{allowable}$ comparison DLT / REFUSAL.

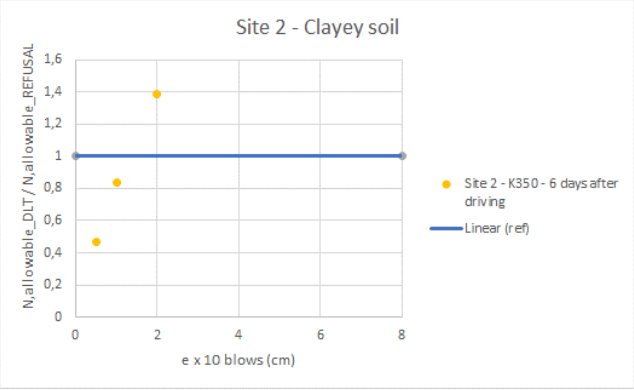

Figure 3. Site 2_Clayey soil - $N_{allowable}$ comparison DLT / REFUSAL.

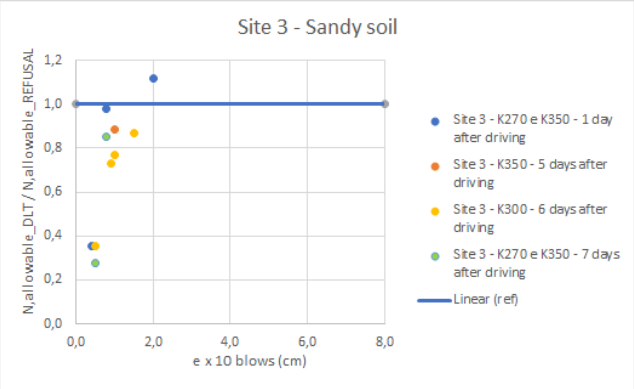

Figure 4. Site 3_Sandy soil - $N_{allowable}$ comparison DLT / REFUSAL.

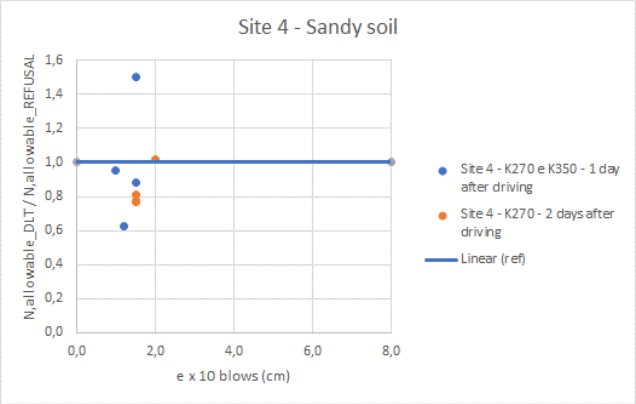

Figure 5. Site 4_Sandy soil - $N_{allowable}$ comparison DLT / REFUSAL.

Analyzing the results presented in the figures above, it is possible to observe that the ratio ($N_{allowable_DLT}$ / $N_{allowable_REFUSAL}$) is usually between 0.8 and 1.0, but sometimes hits low values (minimum of 0.3) and also values higher than 1.0 (maximum os 1.5).

Influence of the soil type and/or time after pile installation hasn‘t been clearly noticed in this results.

4 CONCLUSIONS

The execution control process proposed and applied by KELLER for pile driving works, combining the refusal driving criterion from the Dutch formula, in all piles, with dynamic load tests in a sample of them, has been proved to be safe and robust. Nevertheless, it’s important to ensure that the process isn’t too conservative, optimizing it if possible.

The preliminary study presented in this paper aims this objective, and within the limits of the analised data it seems that, in general, the execution control process has been nearly optimal, and when it isn‘t it has been proved safe.

Seeking the optimization of the process, it will be necessary to extend the analysed sites and data as much as possible, in order to identify the situations where calibration of the refusal criterion could be advisable and to clarify the theoretical influence of the soil type and/or time lag after pile installation.

ACKNOWLEDGEMENTS

The authors are grateful to KELLER Cimentaciones for the motivation and support provided for the preliminary study presented in this article.

Review of SPT-undrained shear strength correlation for UK soil deposits

Examen de la corrélation entre la résistance au cisaillement SPT et non drainée pour les dépôts de sol britanniques

ABSTRACT: The Standard Penetration Test (SPT) is a ubiquitous test undertaken during ground investigations in the UK (and worldwide). In UK geotechnical practice the Stroud relationship is often used to estimate undrained shear strength using the plasticity index and the SPT blow count. Increasingly geotechnical engineering is adapting to the presence of open-data which can be used to re-evaluate and update design rules. This paper makes use of data from various literature sources and data obtained from archived AGS files, which store digital ground investigation information in an industry standard format. AGS files were obtained from the British Geological Survey's (BGS) National Geoscience Data Centre (NGDC) to compare test results with the original Stroud relationship. This work quantifies the potential parameter variation that may be encountered when estimating undrained shear strength using the SPT across six geological deposits. This allows for improved risk mitigation during the design process and, while the existing relationship remains in line with the new results, this highlights the possibility of material specific correlations.

RÉSUMÉ: L'essai au pénétromètre dynamique (SPT) est un essai omniprésent lors des études du sol au Royaume-Uni (et dans le monde entier). Dans la pratique géotechnique britannique, la relation de Stroud est souvent utilisée pour estimer la résistance au cisaillement non drainé en utilisant l'indice de plasticité et le nombre de coups du SPT. L'ingénierie géotechnique s'adapte de plus en plus à la présence de données ouvertes qui peuvent être utilisées pour réévaluer et actualiser les règles de conception. Cet article s'appuie sur des données provenant de diverses sources de littérature et sur des données obtenues à partir de fichiers AGS archivés, qui stockent des informations numériques sur l'étude du sol dans un format standard industriel. Les fichiers AGS ont été obtenus auprès de l'Institut d'études Géologiques Britannique (BGS) du Centre National de Données Géoscientifiques (NGDC) afin de comparer les résultats des tests avec la relation originale de Stroud. Ce travail quantifie la variation potentielle des paramètres qui peut être retrouvée lors de l'estimation de la résistance au cisaillement non drainé à l'aide du SPT dans six gisements géologiques. Cela permet d'améliorer l'atténuation des risques au cours du processus de conception et, bien que la relation existante reste conforme aux nouveaux résultats, cela met en évidence la possibilité de corrélations spécifiques aux matériaux.

Keywords: Standard penetration test; undrained shear strength; soil variability; correlations.

1 INTRODUCTION

Many geotechnical design parameters are difficult to obtain directly during routine design work due to the need for complex and/or time-consuming field or laboratory tests. Therefore, practitioners often use published correlations to estimate more complex parameters (e.g. undrained shear strength, s_u; shear modulus, G) from those parameters which are more readily available. The Standard Penetration Test (SPT) is commonly used in this context (e.g. Terzaghi *et al.* 1996, Reid and Taylor, 2010) and a number of authors have attempted to obtain correlations which relate plasticity index (I_P) and SPT blow count (N) to the s_u parameter for fine-grained soils.

1.1 Skempton (1954)

Skempton (1954) presented the following empirical correlation for s_u measured with field vane ($s_{u,FV}$) normalised by the effective overburden pressure (σ'_{v0}):

$$s_{u,FV}/\sigma'_{v0} = 0.11 + 0.0037(I_P, \%) \quad (1)$$

In Skempton (1957) further data were added, and Mayne (2013) gave the following regression coefficients proving similar to the original regression result (R^2 = 0.946, n = 19):

$$s_{u,FV}/\sigma'_{v0} = 0.1006 + 0.0038(I_P, \%) \quad (2)$$

As detailed in Wood (1990, pp. 302-305) data from Bjerrum (1973) were used by Mesri (1975) to question the dependence of s_u/σ'_{v0} on I_P. Mayne (2013) showed regressions fitted to data from Ladd and DeGroot (2003) showing weaker correlations linking s_u/σ'_{v0} to I_P (%) for other shear modes (e.g. direct simple shear, DSS; triaxial compression, TC; and triaxial extension, TE). The significance of I_P on s_u parameters for fine-grained soils will be discussed in this paper.

1.2 Stroud (1974)

Past studies (e.g. Sowers 1954 and de Mello 1971) had linked soil strength parameters to SPT-*N*. Stroud (1974) then proposed the following estimation for the s_u of insensitive clays and soft rocks, mostly from unconsolidated undrained triaxial compression tests (therefore expressed here as $s_{u,UU}$):

$$s_{u,UU} = f_1 N \quad (3)$$

where f_1 is an empirical factor that Stroud (1974, p. 369) noted 'is a constant essentially independent of depth and of discontinuity spacing, although it may vary in some way from site to site according to the characteristics of the material being tested'. The parameter f_1 ranges from 3.1 to 7.6 for the soils studied by Stroud (1974) and Stroud and Butler (1975), who showed that f_1 varies with I_P for the studied clays. However, the lack of a statistically derived trend was noted by Reid and Taylor (2010).

Further studies using the SPT to estimate s_u include Hara *et al.* (1974), Terzaghi *et al.* (1996), Sivrikay and Toğrol (2006) and Tan and Ramli (2023). The SPT has also been used to estimate various other geotechnical design parameters, e.g. soil stiffness (e.g. Hara *et al.* 1974, Rocha *et al.* 2023) and stress ratios that result in liquefaction (e.g. Seed *et al.* 1985). Seed *et al.* (1985) recommended using a standardized energy ratio to 'correct' raw SPT-*N* values: a value of 60% was advised. This corrected SPT parameter (N_{60}) was also supported by Skempton (1986) who also recommended a correction for overburden pressure denoted as $(N_1)_{60}$. Stroud (1989) then recast the plot from Stroud and Butler (1975) with $f_1 = s_u/N_{60}$.

Following Stroud (1974), Stroud and Butler (1975) and Stroud (1989), f_1 is essentially a 'site' parameter which is derived site-by-site by assuming the s_u with depth trend has the same gradient as the SPT-*N* versus depth data. This means that f_1 is averaged and that individual locations on a site may deviate from the site value. Also, the I_P value may not be available at each SPT-*N*:s_u test pair and hence the f_1 value is related to a representative I_P value in the original work of Stroud (1974) and Stroud and Butler (1975).

White *et al.* (2019) recently presented a revised method for the calculation of f_1; essentially f_1 values are calculated for specific pairs of s_u and SPT-*N* values which can then be arithmetically averaged across a geological unit. However, White *et al.* (2019) retained the method of averaging these f_1 values for each site. The analysis of nine sites presented in White *et al.* (2019) suggested an increase in average representative f_1 values for London Clay from 4.4 to 5.7, the cause of which was attributed to changes in the SPT test since the original Stroud (1974) paper.

1.3 Open data sources

The challenges of data sharing in the geotechnical community have been reviewed in Gilder *et al.* (2021). Considerable open data is available from the British Geological Survey's (BGS) National Geoscience Data Centre (NGDC), which has been used in various UK research projects (e.g. Thorpe and Terrington 2023).

The BGS NGDC provides archived files in AGS format (described in AGS 2017) detailing the results of ground investigations across the UK. So far, 54 projects have been found with SPT-*N*, s_u and I_P data (project references are not reported here for brevity).

1.4 Study Aims

Following the observations in Reid and Taylor (2010) regarding the lack of detailed statistical analysis in the UK studies reviewed in Section 1.2, the authors have used open AGS data from the BGS NGDC to investigate if:

- this data can be used to calculate f_1 values for UK soils to verify the proposed range provided by past studies and provide statistical measures;
- the increased f_1 for modern SPTs in White *et al.* (2019) can be extended to other deposits;
- the data statistically supports the link between f_1 and I_P over geological deposits (rather than project sites); and
- alternative parameters, such as depth, show a more statistically significant correlation with f_1.

This paper presents the preliminary results of this study, focussed on the first two points listed above.

2 DATA PROCESSING

Python software was used to combine AGS data files from multiple projects. Following White *et al.* (2019), each triaxial test result was paired with the nearest SPT test from the same borehole to form an SPT-N:s_u pair. These were then used to calculate f_1 values, and the nearest I_P value was assigned to this result. Additionally, the SPT was required to be in the same geological unit and undertaken within 1.5m of the triaxial test and the I_P value had to be obtained from a sample within 3m. Note that these preliminary results do not include investigation into the sensitivity of the proximity between SPT-N, s_u and I_P values; suitable SPT corrections could not be applied; and no outliers were excluded.

A significant proportion of the data was sourced from linear infrastructure projects such as the A14 Cambridge to Huntington project and the Thames Tideway Tunnel. In these cases, it was not intuitive to average values over a whole project or split them into sites. This highlights the problems with performing a statistical analysis based on data grouped by sites with different amounts of information. Instead, this data has been grouped only by geological deposit. Excluding non-glacial superficials, six deposits were found to have enough data to analyse using this approach.

3 RESULTS

Table 1 shows the summary statistics for the f_1 and I_P values obtained in each of the six geological deposits. The mean values are plotted in Figure 1 and compared to the tabulated UK data from Stroud (1974), Stroud and Butler (1975) and White *et al.* (2019). Note that the Mercia Mudstone data were not based on triaxial tests and were therefore excluded, and the geological deposits were renamed according to BGS (2023).

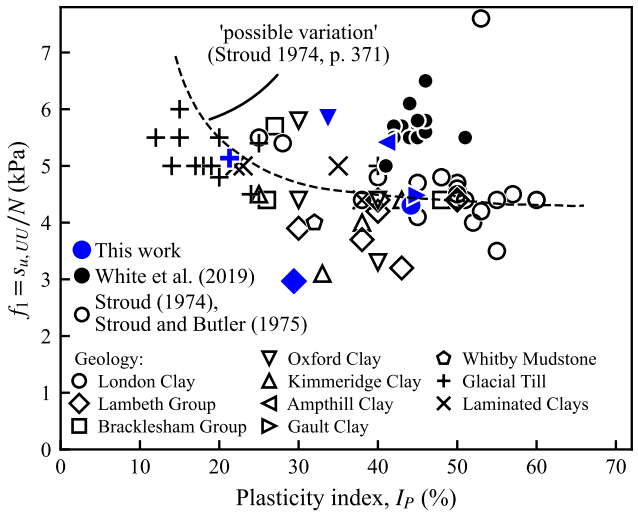

Figure 1. f_1 vs. I_P values compared to tabulated UK data.

Table 1. f_1 and I_P summary statistics by geological deposit. n=number of points, μ=mean value, P_{25}= 25th percentile, and P_{75}=75th percentile, COV=Coefficient of Variation.

Geology	n	param.	P_{25}	μ	P_{75}	COV (%)
London Clay	283	f_1 (kPa)	3.0	4.3	5.4	46
		I_P (%)	40	44	49	16
Lambeth Group	89	f_1 (kPa)	1.3	3.0	3.7	100
		I_P (%)	22	29	36	35
Oxford Clay	94	f_1 (kPa)	2.9	5.8	6.7	83
		I_P (%)	29	34	37	18
Ampthill Clay	36	f_1 (kPa)	3.8	5.4	6.4	47
		I_P (%)	38	41	45	13
Gault Clay	31	f_1 (kPa)	2.6	4.5	5.0	62
		I_P (%)	43	45	48	8
Glacial Till	72	f_1 (kPa)	3.3	5.1	6.6	57
		I_P (%)	16	21	25	31

The following observations are made from these preliminary results: (a) the mean f_1 values show a similar range to the original dataset by Stroud (1974) and Stroud and Butler (1975); (b) the coefficient of variation for f_1 is relatively high in each deposit; (c) the mean f_1 = 4.3kPa for London Clay is notably lower than in White *et al.* (2019); and (d) no strong evidence of the correlation between f_1 and I_P was found.

4 SUMMARY AND CONCLUSIONS

This paper presented the preliminary results of a study investigating f_1 values for UK soil deposits. In total, 54 projects were analysed to obtain 605 suitable datapoints in six geological deposits. A similar variation of f_1 values to that indicated in the Stroud (1974) and Stroud and Butler (1975) results was found. Summary statistics were provided quantifying the variation by deposit. The f_1 values for London Clay were generally closer to those from Stroud (1974) than the newer results from White *et al.* (2019), suggesting that the proposed higher values should be supported with site-specific data before use. The methodology presented here can be refined further to investigate the suitability of correlating f_1 with I_P and other parameters. However, due to the inherent variability of SPT and UU triaxial tests, significant scatter is expected and engineers should exercise caution when relying on correlations between these parameters.

This study shows how open data can be used to re-examine the variability of geotechnical design parameters and highlights the importance of increased data sharing (Gilder *et al*. 2021). This correlation is in common use in UK geotechnical practice and improved confidence could represent considerable cost savings and sustainability gains.

ACKNOWLEDGEMENTS

The authors thank Garry Baker and Martin Nayembil for their help obtaining data from the BGS NGDC and Dr Ahmad EL Hajjar for his assistance with the translation of the abstract into French. *Data availability:* the project references are available from the first author upon request.

ABSTRACT: Data science technologies are universally known, but only some people understand the foundations and how to implement them operationally on real projects. "Data science" is the common ground between business knowledge (in our case geotechnical engineering), computer science, and advanced mathematics. The example of geotechnics is a typical case, as soil data is a significant part of construction projects. So why is it not common to use those algorithms in geotechnical engineering in 2023? This article describes the current state of the art in which geotechnical engineers, designers, and contractors manage the transfer of geotechnical data in Poland, France, and the Anglo-Saxon world. The authors of this article believe that the solution for implementing data science in geotechnical engineering is first to address the issue of data transfer. This involves providing a specially designed software that will allow companies, at first, to build their own geotechnical database. It is only at this point that one can begin to think about going further, by processing the data and using geostatistical and artificial intelligence techniques.

RÉSUMÉ: Les technologies de la science des données sont universellement connues, mais seules certaines personnes en comprennent comment les mettre en œuvre de manière opérationnelle sur des projets réels. La « science des données » est le terrain commun entre les connaissances commerciales (dans notre cas l'ingénierie géotechnique), l'informatique et les mathématiques avancées. L'exemple de la géotechnique est un cas typique, car les données sur les sols constituent une part importante des projets de construction. Alors pourquoi n'est-il pas courant d'utiliser ces algorithmes en géotechnique en 2023 ? Cet article décrit l'état actuel de l'art dans lequel les géotechniciens gèrent le transfert de données géotechniques en Pologne, en France et dans le monde anglo-saxon. Les auteurs de cet article estiment que la solution pour mettre en œuvre la science des données en ingénierie géotechnique consiste d'abord à aborder la question du transfert de données. Il s'agit de fournir un logiciel spécialement conçu qui permettra aux entreprises, dans un premier temps, de constituer leur propre base de données géotechniques. C'est seulement à ce stade que l'on peut commencer à réfléchir à aller plus loin, en traitant les données et en utilisant les techniques géostatistiques et d'intelligence artificielle.

Keywords: Geotechnical engineering; cloud database; artificial intelligence; machine learning.

1 INTRODUCTION

The current era is witnessing an unprecedented surge in data science applications across diverse industries. However, despite its wide-ranging capabilities, the integration of data science within specialized fields like civil engineering and going even more into details, geotechnical engineering, remains limited.

It is important to distinguish AI (artificial Intelligence) from ML (Machine Learning). AI is a broader field that relates to intelligent systems. ML on the other hand is much more specific where the focus is on developing algorithms that learn from data and improve their performance over time. The key is the data quality. If the data quality one has in hand is poor, the ML algorithm will be unsatisfactory and therefore it will not be widely used by professionals.

In geotechnical engineering, building a database becomes the problem, as all documentation for small to medium projects are transferred between the parties in the PDF format. For large projects, such as infrastructure (roads, tunnels etc.) we are witnessing a change - engineers realized that it is impossible to manage the related risks with thousands of pages of data (graphs and tables) in PDF. Consequently, before tackling AI/ML related applications, the whole industry needs to "play the game" of structuring geotechnical data and transferring the data in digital, organized formats (PDF isn't considered as a digital format). This article will show a couple of approaches,

with their advantages and disadvantages, to solve this data structuring and transfer problem.

2 POSSIBILE AI/ML APPLICATIONS IN GEOTECHICAL ENGINEERING

This paragraph is a non-exhaustive list of possible AI/ML applications in geotechnical engineering:

1. Image recognition can be used for example to recognize the size distribution of grains in a sieve analysis test. After taking a picture of the strewed soil grains, the AI algorithm, will be able to scale all grain sizes, draw conclusions and get a grain size distribution curve.
2. Image recognition can be used for soil description applications where the soil descriptions would be made automatically (hopefully verified by engineers/geologists).
3. Image recognition can be used during cone penetration test (with a camera use) to be able to interpret the results on more than just the qc and fs parameters.
4. A classic application of ML would be the interpretation of the Menard pressuremeter test (PMT). This case is very specific as a large database of PMT's would be needed. A geotechnical management system called SoilCloud (used mostly in France) has the largest PMT dataset verified by humans (over 400,000 PMT's with datasets at each of the interpretation steps made by a human). Such a database would suffice to have conclusions on PMT interpretations and perhaps replace the human factor which would greatly decrease the risk related to PMT data interpretation (it is greatly dependent on the person doing the interpretation).

This list is not exhaustive and many other AI or ML applications in geotechnical engineering are possible and will be available to engineers in the future.

3 STATE OF THE ART ON NATIONAL GEOTECHNICAL DATA INFORMATION SYSTEMS

Without going too much into detail, there are very interesting national initiatives in many countries to gather geological and geotechnical data.

As an example, for France, the BRGM (the French Geological Survey) works on gathering geological and geotechnical data since it was founded in 1959. Among their large range of initiatives, one of them called la Banque du Sous-Sol (BSS) covers now the whole French territory with over 2 million exploratory holes and its data in PDF format. The quality of the data remains questionable by professionals. According to the code minier (French mining code), all geotechnical data have to be transferred to the BRGM so it can be imported to the BSS (on real projects it doesn't happen very often and soil investigation companies are not eager to transfer the data).

For Poland, the Panstwowy Instytut Geologiczny (Polish geological survey) is working on similar initiatives but are focuing much more on geological data and not geotechnical data – there is a clear separation and no foundation design parameters are stored in the database.

For the UK, the BGS (British geological survey) has smiliar initiatives with a very large comunity of geologists and engineers woring around these projects.

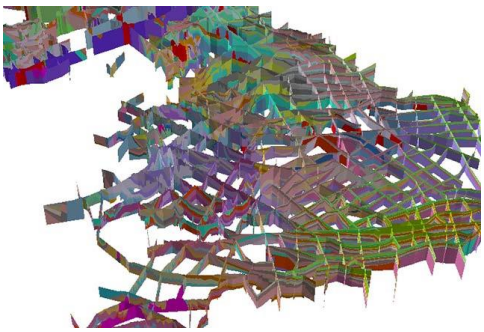

Figure 1. BGS geotechnical cross-sections (source: bgs.as.uk).

Figure 1 shows geotechnical cross-sections based on thousands of borehole data used for foundation design projects.

A last example worth mentioning is the one for the Netherlands: Basisregistratie Ondergrond (BRO), i.e. the underground database, was created for a system of 26 geotechnical input data types. According to general knowledge, as a public initiative, this system compiling such an extensive scope of geotechnical research is the most advanced system in the world. The system was opened in 2020 (Source: Basisregistratie Ondergrond).

4 STATE OF THE ART ON DATA TRANSFER IN GEOTECHNICAL ENGINEERING

This paragraph describes the current state of art of geotechnical datasets being transferred between civil engineers during the life of a project across three European countries: France, Poland and the UK. The advantages and disadvantages of each transfer method are presented for each of the three countries with the names of the leading software companies that provide geotechnical data management software. For all three countries, more than 50% of all geotechnical data (all borehole, in-situ and

laboratory tests performed in each country) is/was being imported on these software packages.

4.1 Transfer of geotechnical data in France

In France, there is no obligation to transfer data in any digital format. The NF P 94-500 standard: Geotechnical engineering projects specifies the sequence of geotechnical projects/missions. This standard only requires the transmission of an inseparable engineering report but without specifying its format. Thus, the transmission of geotechnical data in France was done using reports in paper and/or PDF format. This was until about 2019, the SoilCloud company proposed a very innovative way to share the geotechnical data for a project. The users can export the data in many digital formats or share dynamic links. The exports have been used over 45 thousand times since on over 35 thousand projects (over 350 thousand boreholes with their in-situ and laboratory tests information).

It is important to note that depending on the country, geotechnical investigations are based on different geotechnical tests which has an impact on data transfer. In France, most of the structural designs (shallow and deep foundations or deep excavations) are based on the PMT where the final interpreted results (pressure and module) are discreet values every (most often) 1.5m. Before the technology proposed by SoilCloud, during the design stage of a project, the design engineer was retyping the PMT data from PDF to a tabular type format (Excel for example).

4.2 Transfer of geotechnical data in Poland

Geotechnical reports in Poland are managed by the Ministerial Decree 463 of April 25, 2012. This decree refers to Parts 1 and 2 of the Eurocode 7. The Polish Geological Institute has published a guide to use of project owners and contractors, Wytyczne badań podłoża budownlanego na potrzeby budownictwa drogowego, indicating the content of soil investigation campaigns. This guide also discusses data transfer and storage issues. However, in practice, the use of this guide is considered complex and ultimately, the recommendations regarding the transfer of digital data are not followed.

In Poland, the tests carried out on infrastructure projects are mainly CPT (Cone Penetration Test) and laboratory tests. For CPTs, their interpretation is almost impossible without prior transfer of the data in digital format. Thus, CPT data are sometimes appended, in csv (comma separated values) digital format, to geotechnical engineering reports. This data transfer only applies to CPT, the other data being transmitted directly in non-digital format in the engineering PDF report.

The transmission of CPT data in digital format is therefore not motivated by a desire to manage the geotechnical project, but by practical common sense. This practical common sense brings, despite everything, the advantage of having data in digital format but has the disadvantage of neglecting the digital transfer of other geotechnical data of the project, in particular laboratory tests or the coordinates of the survey points.

At the beginning of the century, a company called Geostar proposed a database solution to manage the data for geotechnical projects (only borehole data). Today, this software seams to encrypt the database, on purpose which means that the users of this software cannot open their own database in any other software.

4.3 Transfer of geotechnical data in the UK and the .ags format file

In the UK, the content of geotechnical engineering reports is defined in BS5930, the code of practice for site investigations. Chapter 62 of this standard specifies "The data generated from the ground investigation should be put into a format which allows data communication between all parties and data manipulation at various stages throughout the life of the works". In NOTE 2, of the same chapter 62, the .ags format is mentioned. Thus, although recommended, no transfer of data in digital format is imposed.

However, the experience of the authors of this publication on large infrastructure projects in Great Britain shows that geotechnical data is commonly transferred using .ags format files. This format, written and worked on since the end of the 1990s by the Association of Geotechnical & Geo-environmental Specialists, was designed to respond to the problem of standardized transmission of geotechnical data with the aim of reducing geotechnical risk. An .ags format file is a text file containing only ASCII (American Standard Code for Information Interchange) characters. The .ags file contains all the digital data of the project structured around headers defined in the standard. In particular, the .ags file contains the location information of the surveys (latitude, longitude, altitude), the dates of completion, the lithological descriptions, the raw results of the tests carried out, the references of the samples taken, etc.
The use of .ags files allows immediate transfer of geotechnical data between the different stakeholders in a project, which is a real advantage. However, each time the project is updated, in the case of an additional campaign for example, the transmission of a new .ags

file is necessary. This therefore requires discipline from all project stakeholders so that each geotechnical engineer has access to new data, which represents the main drawback of using .ags files.

In the UK, a software called Holebase was used since the beginning of the century and was structured around the .ags format. This means, that it has all the advantages of the .ags format but also its disadvantages. Being a very well documented and complete text format is its largest advantage. At the same time, being a text file and not a database format file (for example .xml) is its disadvantage as error in the file are very probable (data repetitions in the files and no direct links in the file, just text).

Additionally, the use of the .ags files is often limited to the duration of the project. Thus, once the project is completed, these files are "forgotten" because current software does not allow centralized storage and visualization. Over the years, this represents a loss of value for all stakeholders in geotechnical projects.

5 ADVANTAGES OF A CENTRALIZED AND COLLABORATIVE GEOTECHNICAL DATA MANAGEMENT SYSTEM

As discussed above, the use of interoperable files, such as the .ags format files, provide better control of geotechnical data, but, however, has the drawback of requiring discipline from each of the parties involved in transferring these files. Therefore, a centralized solution on a project and enterprise scale is more relevant. Today, IT technologies provide tools for centralized exchange of data. The Internet/web is a modern way to exchange, store and visualize geotechnical data, as well as providing specially designed applications. The web technology allows collaborative work. Thus, as soon as a stakeholder adds or modifies data from a project, all the other stakeholders have immediate access to it. The discipline effort mentioned previously is therefore reduced to nothing.

6 CONCLUSIONS

The following conclusions come to mind to answer the question asked in the title:

1. AI/ML algorithms require organized and verified datasets to give expected results. In geotechnical engineering, such datasets can be created once the engineers use digital data formats when working on civil engineering projects. Such formats are for example .ags format files or database format files.

2. A verified technology for transferring of geotechnical data is the web technology with centralized and collaborative data management systems.

3. Although none of the countries discussed previously legally require digital geotechnical data transfer, an exchange of geotechnical data in digital format improves the quality of engineering and reduces geotechnical risk. National initiatives led by the national survey institutes are important to educate and spread the knowledge about the importance of digital files.

An additional reflexion on this topic would be: The technologies for AI/ML algorithms already exist but using such technologies mean a deep change in the way the geotechnical engineers presently work. Might the geotechnical engineers' habits and resistance to change be the main obstacle to generalisation of AI/ML?

ABSTRACT: As a result of the several events involving dams around the world, the construction of upstream dams was banned, new regulations have been established, and revisions to waste disposal norms have been made. New technologies were developed for the tailings treatment, allowing alternatives for their disposal, such as the construction of different stacking methodologies. Several measures are taken in order to assure the structures safety, such as carrying out geotechnical tests throughout the construction and technological control, which ensure that the project technical specifications are complied. Some tests must be carried out in the laboratory and require a long execution time, reducing the information number of materials physical and geomechanical parameters. In this way, important geotechnical parameters for the complete understanding of the behaviour of the tailings are restricted to a few points of the structures, and with deterministic results. Despite to work with a distribution of samples that represent the structure in a significant way, as they may be subjected to different levels of stresses, humidity, granulometry, among other conditions, using values from specific locations to assure the safety of the whole construction can lead to erroneous estimates in unsampled locations. In this article, data from piles of different locations in MG/Brazil extracted of Geolabor, an ecosystem of applications for managing geotechnical data, were used to estimate different geotechnical parameters from the technological control at non-tested points. Multiple spatial and non-spatial regressions were implemented, and the results obtained were satisfactory, showing the importance of the methodology developed and implemented with Geolabor.

RÉSUMÉ: En raison des nombreux événements impliquant des barrages dans le monde entier, la construction de barrages en amont a été interdite, de nouvelles réglementations ont été établies et des révisions des normes de traitement des déchets ont été effectuées. De nouvelles technologies ont été développées pour le traitement des résidus miniers, permettant des alternatives à leur élimination, telles que la construction de différentes méthodologies d'empilement. Plusieurs mesures sont prises pour assurer la sécurité des structures, telles que la réalisation de tests géotechniques tout au long de la construction et le contrôle technologique, qui garantissent que les spécifications techniques du projet sont respectées. Certains tests doivent être effectués en laboratoire et nécessitent un temps d'exécution long, réduisant le nombre d'informations sur les paramètres physiques et géomécaniques des matériaux. De cette manière, d'importants paramètres géotechniques pour la compréhension complète du comportement des résidus miniers sont restreints à quelques points des structures, et avec des résultats déterministes. Malgré le travail avec une distribution d'échantillons représentant la structure de manière significative, étant donné qu'ils peuvent être soumis à différents niveaux de contraintes, d'humidité, de granulométrie, entre autres conditions, l'utilisation de valeurs provenant de points spécifiques pour garantir la sécurité de toute la construction peut conduire à des estimations erronées dans les emplacements non échantillonnés. Dans cet article, des données extraites de Geolabor, un écosystème d'applications pour la gestion des données géotechniques, provenant de tas de différentes localités de MG/Brésil, ont été utilisées pour estimer différents paramètres géotechniques à partir du contrôle technologique aux points non testés. Des régressions spatiales et non spatiales multiples ont été mises en œuvre, et les résultats obtenus étaient satisfaisants, montrant l'importance de la méthodologie développée et mise en œuvre avec Geolabor.

1 INTRODUCTION

In soil study, there are uncertainties in the calculations of the physical and geomechanical materials properties, possibly associated with the limited number of samples in the structure, the tests carried out and the geological field conditions (Flores, 2008). Statistical studies in mining geotechnics have as main objective to considere these uncertainties, searching for results that are more coherent with reality. The practical applications of the statistical analyzes in mining geotechnics have been growing and gaining prominence in recent years, but they still constitute a study with a restricted approach (Ferreira, 2022).

Literature authors, such as Azevedo (2019), Badaró (2022) and Ferreira (2022), discuss different ways of applying statistics in mining geotechnics, these being, respectively: The study of outliers for identification discrepant readings in piezometers when monitoring dams; The use of statistical analyzes to compare the performance of different methods of obtaining moisture for the technological control of filtered waste disposal structures; And the comparison of deterministic and probabilistic analyzes to determine the safety factor in the study of dam stability. In this article, a case study will be carried out with real data from iron ore tailings piles, applying statistical techniques to predict geotechnical variables from technological control.

As emphasized by Phoon (2020), one of the greatest difficulties in carrying out statistical analyzes in geotechnics is the small amount of data available. This problem is not caused by the lack of soil studies in geotechnical constructions, but by the lack of a database that can be used for future analyses, enabling relationships between different parameters, types of materials and interpretations of data in relation to the regions under study.

Despite being recognized for years in the literature, the importance of working with a data management system has been gaining prominence in recent years, and there are currently many mining companies that carry out geotechnical processes on physical paper, writing results for digitizing information (de Lacerda and Chammas, 2023). In order to meet this need, Geolabor was developed, an intelligent geotechnical data management system, aimed at the mining field. Acting in all engineering processes, from planning, operation, data processing and approval of results, Geolabor builds a structured database, automatically updated with its use for field investigations, laboratory and technological control.

By using Geolabor data, it is possible to compile data from different structures to carry out a complete statistical analysis. In this article, data from two iron ore tailings piles from different locations in Minas Gerais/Brazil will be used to estimate geotechnical parameters of technological control, via Bayesian geostatistical models. Totaling more than two thousand samples collected, the main objective of this article is to predict the missing values of geotechnical variables obtained in tests carried out in the technological control of the structures under study.

Spatial and non-spatial analyzes will be carried out in order to understand the importance of taking into account spatial effects for this type of material. In that way, this work validates the possibility of using data from different piles together, resulting in analyzes with a greater quantity of observed data and enabling, for example, the future estimation of the material's physical and geomechanical parameters obtained from triaxial tests in the laboratory and carried out less frequently than those resulting from other tests from technological control.

2 MISSING DATA

The three main types of missing data are Missing Completely At Random (MCAR), Missing At Random (MAR) and Missing Not At Random (MNAR), where: MCAR applies when there is no need to treat missing data, since the data observed in the sample are representative of the population; MAR applies to cases where the missing data is not random, however, there is information in the other variables in the sample that can be used to complete the data; and MNAR, which will deal with samples where the reason for the existence of missing data is related to the variable of interest, resulting in the possibility of biased analyzes (Little and Rubin, 2019).

In this paper, the missing data will be characterized as MAR, since the geotechnical variables can be explained by the other variables observed from the same material. The analyzes will be carried out in R, by using the averages of the nearest neighbors; the MissForest packages (Stekhoven and Bühlmann, 2012), a non-parametric method that allows interactive effects and no linear, working with data of mixed types; and MICE package (Van Bureen and Karin, 2011), a method that works with imputation under the multivariate normal and log-linear distribution, specifying a multivariate distribution for the missing data and imputing the values from MCMC (Markov Chains Monte Carlo).

3 ANALYSIS

In this article, predictions were made of the following geotechnical parameters, obtained from HILF tests:

Ground Moisture (w_{med} – %); Maximum Dry Density (γ_{dmax} – g/cm³); Optimum Moisture (w_{opt} – %); Degree of Compaction (Dc – %); Moisture Degree (Dw – %). As the work is being carried out with real information, the missing data is, in fact, unknown. Thus, in order to enable compare the predicted values with the real ones, ramdom points were removed, for subsequent verification of results. Table 1 presents the number of points analyzed, along with the percentage of missing data for each variable studied in each pile.

Table 1. Missing data percentage of each covariate.

Pile	Pile 1	Pile 2	Pile 1 and Pile 2
Total Samples	1823	655	2478
Removed Samples	182	57	239
Missing w_{med} (%)	9.98	20.15	12.67
Missing γ_{dmax} (%)	10.09	9.47	9.93
Missing w_{opt} (%)	10.04	9.47	9.89
Missing Dc (%)	10.20	21.83	13.66
Missing Dw (%)	10.04	20.15	13.59

The histograms of each geotechnical variable observed in Pile 1 and Pile 2 together are shown in Figure 2.

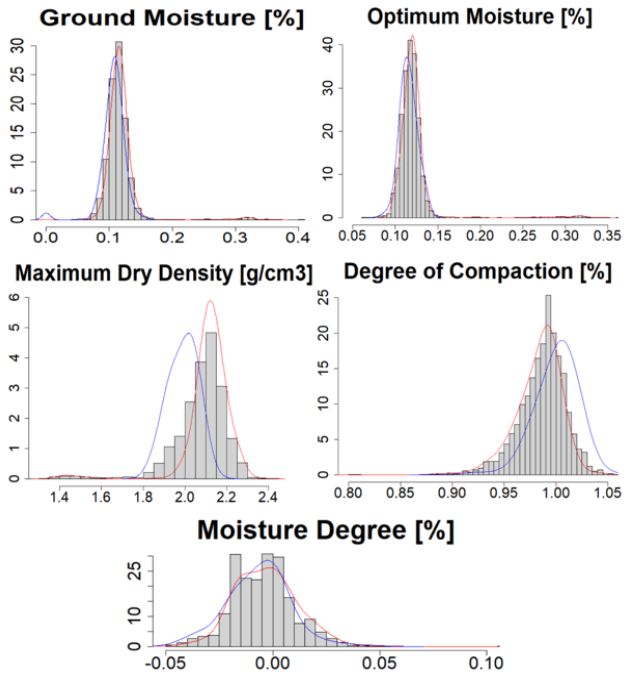

Figure 1. Histograms of each geotechnical variable observed in Pile 1 and Pile 2 together, along with the density curves of Pile 1, in red, and Pile 2, in blue.

Figure 2 presents the two-by-two relationships between the geotechnical variables observed in Pile 1, in red, and in Pile 2, in blue.

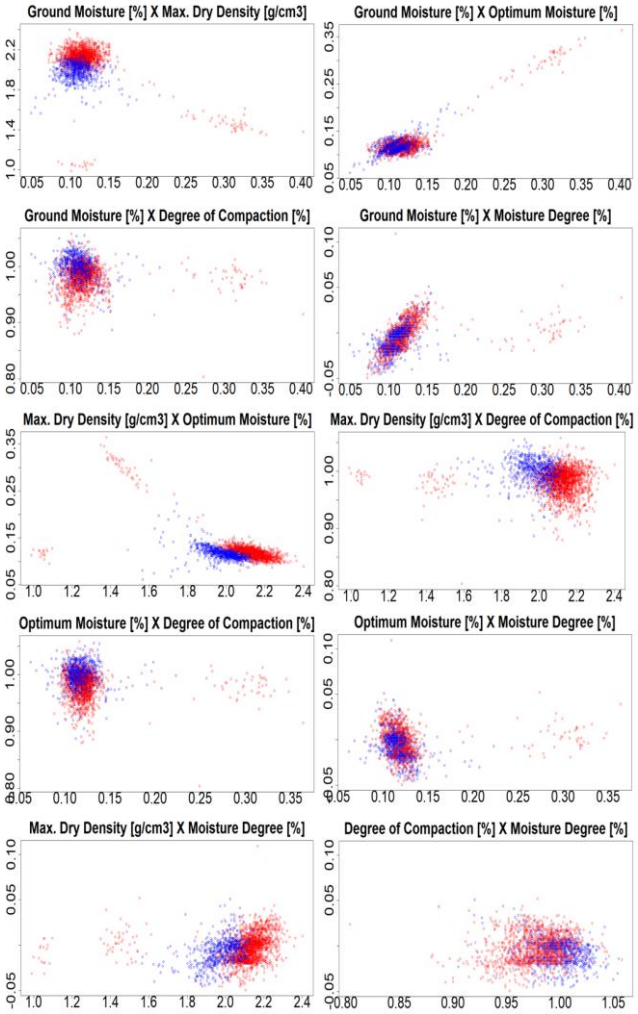

Figure 2. Two-by-two relations between the variables in analyse (red are referred to Pile 1 and blue to Pile 2).

It can be observed, from the histograms presented in Figure 2 and the graphics presented in the Figure 3, that the geotechnical variables present a similar behavior, with a slightly greater discrepancy in values for the Maximum Dry Density. This similarity is due to the same type of material being studied, despite coming from different mineral activities, and arranged in different structures.

Table 2 contains the percentage errors of the predictions made from the missing data imputation. The percentages of points where the error obtained was less than 5% and 10% are also presented. The results are obtained by comparing the value predicted by the above methodologies with the real values that were initially artificially removed for verification. An1 is refer to Close Neighbouhood; An2 to MissForest R Package; and An3 to MICE R Package. All results in Table 1 are given as percentages (%).

Table 2. Errors from analysis, with the best results in bold.

Error	w_{med}	γ_{dmax}	w_{opt}	Dc	Dw
Pile 1: Error <= 5%	31.87	89.56	58.79	94.51	4.4
	89.01	**92.86**	**89.01**	**96.7**	26.92

	2.37	**2.87**	**2.05**	**1.74**	**35.7**
	4.22	4.3	3.92	2.53	45.41

4 CONCLUSIONS AND NEXT STEPS

Based on the results presented in Table 2, the methodology that presented the best results in most analyzes was the MissForest R package. It is possible to state that the implemented methodologie is mostly satisfactory, achieving predictions with percentage errors lower than 4% for all geotechnical variables analyzed, but to the Moisture Degree. The error quality analysis corroborates this statement, by presenting at least 73% of results with a percentage error of less than 5% and at least 91% than 10%. The domain of the moisture deviation variable is very close to zero, which may be affecting the predictions or the calculation of errors. This in-depth analysis will be carried out later.

So far, no multivariate imputation methodology that takes spatial effects into account has been implemented, nor has the existence and influence of potential outliers been analyzed. Analyzing the results presented, it is possible to verify that the reduction in error quality is not significant when data from the same material and different locations are combined in the analyses. Thus, the development of the work so far suggests that it is feasible and makes practical sense to combine information from different stacks to make predictions of values that would not be possible in a single structure due to insufficient data. Following the development, the same analyses presented in this article will be performed with the geotechnical variables obtained in the CPN, GPS, MES, and CIUsat tests, considering outliers and spatial effects.

ACKNOWLEDGEMENTS

The authors are thankful for the support of the Institute of Mathematics and Statistics at UFRJ and the team at Simplelab Tecnologia, for the Geolabor data.

ABSTRACT: Innovations in geotechnics in the mining field have been constant, aiming to evolve construction techniques and the management of the generated information throughout the work. In order to provide a practical, fast and efficient methodology for data management of stacks and dams, it was developed the first interactive 3D model focused at the technological control of these structures. Geotechnical constructions are dynamic and complex, in addition, they are large constructions, new layers are compacted every day and several tests are carried out, which must be in accordance with the norms and technical specifications of the project. In this way, the importance of the possibility of critical analysis in real time is evident, making it able to avoid future problems. By integrating the project implemented with the Cesium geospatial model platform into the Geolabor, geotechnical data management system, a complete three-dimensional view is generated, which associates geometry with information. The 3D model is updated in real time, automatically and without the need for any programming or modeling skills from the user. The geometry of the as-built model is associated with the information that is registered in Geolabor throughout the construction, allowing the visualization in scales of colors of the evolution of the work, of the samples, tests and their respective geotechnical parameters and the compliance with the project technical specifications. This article presents a case study carried out in a waste and tailings stacks of the mining company Samarco, presenting the practical advantages of using the 3D model integrated to Geolabor.

RÉSUMÉ: Les innovations géotechniques dans le domaine minier sont des techniques de construction et une gestion des informations générées sur site constantes et en évolution. Dans le but de fournir une méthodologie pratique et efficace pour la gestion des données des pieux et des barrages, le premier modèle 3D interactif axé sur le contrôle technologique de ces structures a été développé. Les constructions géotechniques sont dynamiques et complexes, en plus d'être des constructions à grande échelle et chaque jour de nouvelles couches sont compactées et divers tests sont effectués, qui doivent répondre aux normes et spécifications techniques du projet. De cette manière, l'importance de la possibilité d'une analyse critique en temps réel devient évidente, contribuant ainsi à éviter de futurs problèmes. En intégrant le projet mis en œuvre avec la plateforme de modèles géospatiaux Césio dans le système de gestion des données géotechniques Geolabor, une vue tridimensionnelle complète est générée, combinant la géométrie et l'information. Le modèle 3D est mis à jour en temps réel, automatiquement et sans aucune connaissance en programmation ou modélisation de la part de l'utilisateur. La géométrie du modèle as-built est associée aux informations enregistrées dans Geolabor tout au long de la construction, permettant la visualisation en échelles de couleurs de l'évolution de la structure, des échantillons, des tests et des paramètres géotechniques respectifs et du respect des spécifications techniques du projet. Cet article présente une étude de cas réalisée sur une décharge et une halde à déchets Samarco, présentant les avantages pratiques de l'utilisation du modèle 3D intégré à Geolabor.

Keywords: Three-dimensional model; data management; stacks and dams; mining geotechnics; technological control.

1 INTRODUCTION

Despite essential for the safety, geotechnics did not always follow clear regulations regarding the practice of its exercise (Araújo, E. R., 2016). Over the past few years, the search for innovation in the mining geotechnical field has been growing, seeking to develop new methodologies, norms and good practices that help prevent possible new disasters involving stacks and dams around the world. With technological progress, this process of evolution becomes constant, in order to guarantee the safety and compliance of the constructions.

In this scenario, the importance of carrying out careful technological control and the use of a

centralized and structured data management system has been gaining prominence in the geotechnics practice (de Lacerda, B. M., 2023). Technological control is the process that ensures that technical design specifications are met throughout construction. In order to optimize this process and assist in critical decision-making, the first interactive three-dimensional model aimed at managing geotechnical data for the technological control of stacks and dams was implemented by de Lacerda, B. M. (2022).

The 3D model was implemented using the Cesium platform, a complete tool for developing spatial models of different types. Using Cesium JS, all internal programming of the model was performed, automating the entire creation of the geometry of the geotechnical structure, based solely on the data collected during technological control. Without the need for user knowledge in modeling or programming, this model is an innovation for the geotechnical area.

The main objective of this article is to present the integration of the 3D model developed into a geotechnical data management system, Geolabor, enabling automatic and real-time updating of geometry and associated information, in accordance with the construction of the structure. Geolabor operates in all engineering processes, from planning, execution, and conducting analyses to issuing reports. Geolabor is a software in constant development, which seeks evolution and innovation daily, pioneering the practice of different methodologies that increase the safety of geotechnical constructions, guaranteeing the quality of the works.

After integrating the 3D model into the Geolabor system, both the geometry and the information associated with the structure are now updated in real time, according to the natural use of Geolabor in the technological control. To make use of the 3D model, nothing different from the routine of technological control needs to be done, as the system utilizes the information registered in the data management system to create and update the geometry and information contained in the 3D model. The 3D as-built model allows a practical visualization of the progress of the work, facilitating the control of geometry, samples, compliance with the technical design specification criteria and geotechnical parameters obtained in tests carried out throughout construction.

2 CASE STUDY

In order to put into practice the three-dimensional data management model integrated in Geolabor, a case study was developed with the mining company Samarco. The 3D model was implemented at PDER Alegria Sul (Tailings Storage Facility – TSF Alegria Sul), located at Mine Alegria Sul of Samarco (Mariana, MG/Brazil); a shared disposal stack of waste rock and filtered tailings, where the layers of landfill are built following thickness and compaction controls (Simplelab, T., 2022). The main objectives of this study are to highlight the practical importance of using the 3D model developed in the day-to-day life of a geotechnical construction, using real data.

The Samarco team uses Geolabor to manage technological control at PDER Alegria Sul and used Geolabor's 3D module for a month to carry out analyzes of this case study. Figure 1 presents the three-dimensional visualization of the stack under study.

Figure 1. PDER Sul Three-dimensional as built model.

It is possible to observe in Figure 1 that the model developed has no restrictions on the geometry of the structure, following the normally irregular shapes of tailing stacks. The model is built based on a methodology that takes into account the information that is collected throughout construction, as layers thickness and topographic data. The input of the coordinates (E, N, and Z) of the polygonal of the layers can be done manually or from a .csv file, with no need for any drone flights or point cloud file.

To create the initial model of a project that was already in progress before the start of implementation of the 3D module, only information relating to the last two compacted layers is required. The coordinates of the subsequent layers are inferred by the system, building the complete model with all layers registered in the Geolabor. Throughout the construction, it is not mandatory to register the coordinates of all built layers, as these are inferred by the system and automatically created in the 3D model. However, the more layers have their coordinates registered; the closer to reality the visualization will be, although the inference of coordinates does not affect the use, efficiency and interactivity of the 3D model for technological control.

All geometry is associated with information, constituting a complete model for managing the

geotechnical data of stacks and dams. Being completely interactive, when clicking on a certain layer, its respective information is displayed, such as elevation, start and end dates, status, volume, and acceptance criteria, as shown in Figure 2 below.

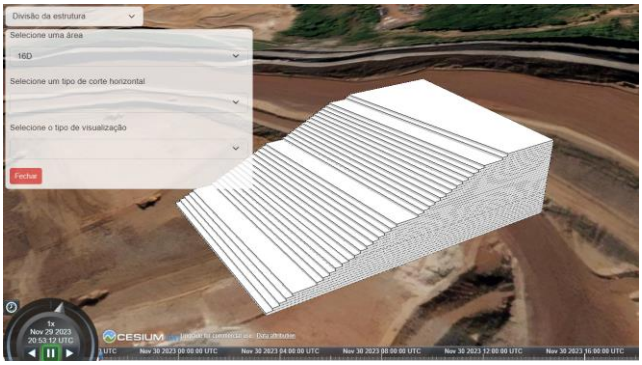
Figure 2. Visualization of information registered in Geolabor for a specific layer, when selected in the 3D model.

In addition to visualize the layers and their information, it is also possible to view all the samples collected throughout the construction and registered in Geolabor, as shown in Figure 3. Without losing interactivity in any of its features, when clicking on a specific sample, they information relating to the selected sample are displayed, also including the tests that were carried out on this sample and the geotechnical parameters obtained in each test.

Figure 3. Representation in the 3D model of samples registered in Geolabor for the PDER Alegria Sul stack.

From Figure 3, it is possible to observe, in a practical and immediate way, that there is at least one sample with its coordinates registered with some error, since there is a point outside the space of the structure. This type of verification is one of the direct advantages of using the 3D module, where it becomes possible to guarantee the conformity of construction records, with complete management of construction technological control data.

Geolabor allows areas and subareas to be specified in the system, so that technological control can be carried out in a personalized way for each project, as makes the most sense for the user. In the 3D model, it is possible to view and filter each of these areas or make horizontal cuts in the structure, by elevation or by layer, enabling a careful view of the division of the structure and the construction progress, as shown in Figure 4 below.

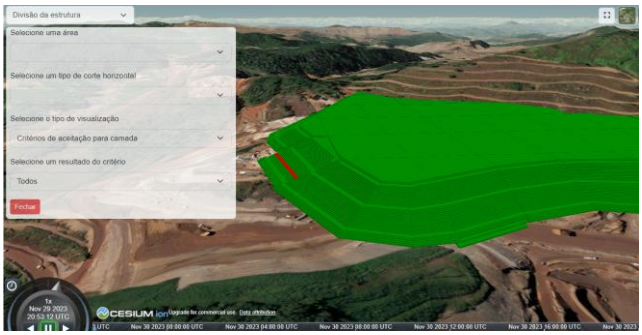


(a)

(b)

Figure 4. (a) Representation of a specific subdivision of the stack; (b) Horizontal cut to visualize a specific layer or elevation.

Once the technical project specifications are registered in the system, upon completing a test, it is calculated whether the geotechnical parameters obtained are within the previously specified limits, and the acceptance of the project criteria is presented in Geolabor. It is then possible to visualize these results in color scales on the 3D model, and filter the areas and layers according to what is registered, as shown in Figure 5.



(a)

(b)

Figure 5. (a) Color scale visualization of compliance with technical specifications; (b) Filtering to visualize layers that did not meet the requirements of the registered technical specifications.

With the 3D model use, it was possible for the Samarco team to verify that there were typing errors in the registration of some layers. As can be seen in Figure 4, the layers in red would have the status of "did not comply", as they did not comply with the acceptance criteria, however, carrying out a critical analysis, registration errors were found. It was also possible, just by using the model, to verify that there were obsolete or duplicate criteria registered in the system. Previously, all this information was compiled in Excel spreadsheets, which are no longer necessary on a day-to-day basis with the full use of Geolabor and its features.

3 CONCLUSIONS

The case study carried out allowed to verify the practical usefulness of the 3D model integrated into Geolabor, presenting satisfactory results. The Samarco team was satisfied with the use of the functionality, and excited for future implementations, which are already in the development phase.

In the next work, the Heatmap will be implemented, allowing the visualization of the results of the geotechnical parameters obtained in the tests carried out, in a color scale and in the form of a three-dimensional graph. The functionalities to be developed later will be defined according to the practical needs of geotechnics, always seeking innovation, practicality and quality in the process of technological control of stacks and dams.

ACKNOWLEDGEMENTS

The authors would like to thank the team at Simplelab Tecnologia, for the work carried out on Geolabor, and the Samarco team, for their availability to carry out the case study and for seeking to use all of Geolabor's functionalities in the best way as possible, contributing to the constant improvement of the system.

A method for the prediction of greenfield 3D settlement troughs around deep excavations

Une méthode de prédiction des tassements en 3D dans des conditions greenfield autour d'excavations profondes

M. De Luca, G. Russo, M.V. Nicotera, I. Esposito*
Università degli studi di Napoli Federico II, Naples, Italy

**ilaria.esposito3@unina.it*

ABSTRACT: The evaluation of ground movements induced by deep excavations is a topic of considerable importance, especially in the context of urbanized environments. Semi-empirical 2D methods, aimed at a first approximation of the problem, have been developed and widely used in literature to evaluate the settlement profile along retaining wall perpendicular direction whilst less attention has been paid to describe the profile along parallel direction. Recently, a 3D semi-empirical closed-form function, obtained by modifying existing 2D solutions, has been proposed to better grasp the three-dimensional effects induced by excavation. The four independent parameters that define the shape of the settlements and the scale parameter constituting the 3D subsidence function were calibrated through least squares regression of data sets from 3D FEM analyses. This calibration, in the context of a first comparison with real cases, has led to satisfactory and encouraging results revealing dependencies of the parameters on the excavation geometry. This paper is dedicated to the application of this three-dimensional subsidence function to additional real cases of open pit excavations to evaluate the applicability and the possible generalization of the method. Correlations between some of the four independent shape parameters and geometry of the pit are simply outlined.

RÉSUMÉ: L'évaluation des mouvements du sol induits par les excavations profondes est d'une grande importance, surtout dans le contexte des environnements urbanisés. Des méthodes semi-empiriques en 2D, visant une première approximation du problème, ont été développées et largement utilisées dans la littérature pour évaluer le profil de tassement le long de la direction perpendiculaire au mur de soutènement, tandis que moins d'attention a été accordée à la description du profil le long de la direction parallèle. Récemment, une fonction semi-empirique en 3D sous forme fermée, obtenue en modifiant les solutions existantes en 2D, a été proposée pour mieux appréhender les effets tridimensionnels induits par l'excavation. Les quatre paramètres indépendants qui définissent la forme des tassements et le paramètre constituant la fonction de subsidence en 3D ont été calibrés par régression des ensembles de données issus des analyses par la méthode des éléments finis en 3D. Cette calibration, dans le cadre d'une première comparaison avec des cas réels, a conduit à des résultats encourageants révélant les dépendances des paramètres vis-à-vis de la géométrie de l'excavation. Cet article est dédié à l'application de cette fonction de subsidence tridimensionnelle à des cas réels d'excavations à ciel ouvert pour évaluer l'applicabilité et la possible généralisation de la méthode. Des corrélations préliminaires entre les quatre paramètres indépendants de forme et plusieurs facteurs additionnels sont simplement esquissées.

1 INTRODUCTION - 3D SETTLEMENT FIELD AROUND A DEEP EXCAVATION

Settlements induced by deep excavations in urban settings can generate structural damage to neighbouring buildings. Two approaches for the prediction of ground movements around excavations are commonly used: the semi-empirical and numerical methods. The latter exploits advanced computational techniques like finite element method (FEM) or discrete element method (DFM) software to accurately model geometries, materials and construction sequences. The semi-empirical approach leverages geometric parameters such as excavation depth, bedrock depth, and plan dimensions to predict settlements troughs. Various empirical methods have been proposed by different researchers, including Ou (2006), Clough and O'Rourke (1992), Bowles (1996), and Roboski and Finno (2006). A novel analytical framework for describing three-dimensional subsidence around deep excavations has recently been introduced by Russo and Nicotera (2022). The function, which combines modified two-dimensional semi-empirical methods, resulting in a two-variable subsidence function, has the following form:

$$\frac{\delta_v(x,y)}{\delta_{v,max}} = f(y) \cdot g(x) \qquad (1)$$

where *g(x)* represents the 2D settlement pattern in the direction parallel to the supporting wall (i.e., x direction) while *f(y)* represents the 2D shape function for transversal settlement pattern (i.e., along y direction). The first member of Eq. 1 is the ratio between the function $\delta_v(x,y)$, which describes the 3D settlement trough, and the maximum measured settlement, $\delta_{v,max}$.

The proposed framework has been validated through meticulous 3D FEM nonlinear analyses conducted on practical urban soil profiles, where the influence of various factors such as the distribution of support props, excavation depth, and the presence of openings, was indagated. As clearly shown by the eq. 1, the two combined functions describe a shape while the exact subsidence profile is scaled on the basis of the maximum vertical settlement $\delta_{v,max}$. On the transversal shape governed by *f*(y) the above-mentioned literature offers many suggestions which Russo and Nicotera (2022) have summarized and validated with reference to the maximum value of *f*(y) and its first derivative at y=0.

On the other hand, the longitudinal shape *g*(x) has been first proposed by Russo and Nicotera (2022) in its actual form and a graphical representation is given in Figure 1:

$$g(x) = \frac{1}{2} erfc\left[2.8 \frac{|x/L| - (1/2 - A/L)}{(1/2 - A/L) - \Delta/L}\right] \qquad (2)$$

with x representing the distance from the center of the excavation, L the excavation length and A the distance of the function inflection point from the corner of the excavation, as already proposed Roboski and Finno (2006). Russo et al. (2019) introduced the new coefficient Δ to simulate different longitudinal settlement profiles: very smooth (i.e., large Δ) to very sharp ones (i.e. small and even negative Δ).

Correlations between A and Δ and geometry of the pit have been explored on the basis of 3D FEM non-linear analysis (Russo and Nicotera, 2022). The proposed two variable function was also experimented for best fitting exercises on case studies in the city of Napoli where a huge development of the existing underground network is going on since a couple of decades and mainly in sandy profiles. Here in the following, case studies in clay are used to further validate and calibrate the proposed semi-empirical method. In both cases the results showed a promising alignment between the proposed analytical framework and the observed settlement patterns, affirming its potential applicability in practical scenarios.

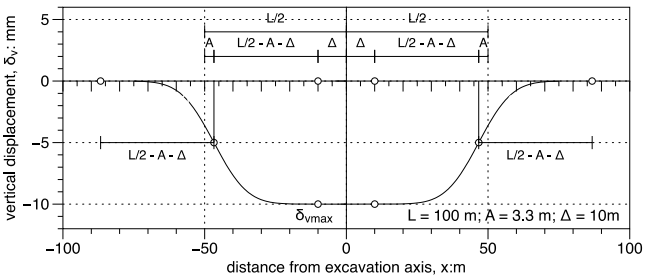

Figure 1. Longitudinal settlement trough – example case Δ =+10 > 0.

2 CASE STUDY

In the present paper the results in terms of ground settlement of six case studies of deep excavations are used and compared with the previously described shape function proposed by Russo and Nicotera (2022), derived for excavations in sand. The cases taken into account are: Chicago Robert H. Lurie Medical Center (CRHLM); Chicago and State Subway expansion (CSSE); Hangzhou Metro Basement (HMB); Taipei National Enterprise Center (TNEC); South Qilianshan Road Station (SQRS); Tokyo excavation (TKY).

Both the excavations in Chicago are about 12 m deep and the involved stratigraphy crosses granular soils overlying clays of stiffness increasing with depth (Roboski and Finno, 2006). The CRHLM excavation is 68x80 m in plan and the retaining system is made by sheet pile walls supported by two or three levels of tie-back prestressed anchors. Along three out four sides of the excavation 200 survey points were installed to monitor ground movements (Finno and Roboski, 2005). In the CSSE, secant pile walls anchored both with struts and tieback anchors were used as a retaining structure for the shaft, whose plan dimensions are 24×47 m. On a building adjacent to the pit instruments aimed to monitor ground movements were installed (Roboski and Finno, 2006). The excavation in clay silt, for the HMB, is 190×20m in plan and 17.5 m deep.

The retaining system is composed by 37 m long diaphragm walls supported by five strut levels. 10 monitoring lines were arranged on both sides of the basement, orthogonally to its axis, allowing surface settlements control during different stages of the excavation (Ying et al., 2022). The 107×45 m in plan excavation for the construction of the TNEC, 19.7 m deep, was conducted through subsequent layers of silty clays and silty sands with increasing shear strength, overlying a gravel formation 46 m below ground level (b.g.l.). Concrete floor slabs (constructed in top -down) sup-

ported the perimeter diaphragm walls and the settlements were monitored along a 36 m stretch of the 107 m excavation side (Roboski and Finno, 2006). The SQRS shaft has 188×26 m dimensions in plan, and a depth varying between 17 and 26 m. A perimeter wall supported by struts and waterproofed by a jet grouting treatment forms the retaining structure for the excavation. Due to the large dimensions of the pit, twelve monitoring sections were provided, orthogonal to the principal axis of the excavation, installing level instruments on the surrounding buildings (Tan et al., 2014). The deepest excavation (28 m) here considered is the one carried out in Tokyo in a two-layers stratigraphy: silt overlying fine sand, separated by a thin layer of peat. There is no information about the support system. Settlements data were collected along the 30 m side of the excavation for two reached depths: 20 and 28 m (Roboski and Finno, 2006).

3 DATA FITTING

The settlement data collected in the literature database and summarized in the paragraph 2 were fitted using the two-variable subsidence function to further calibrate and validate the proposed semi-empirical method. All the mentioned case studies are propped deep excavations in different soil conditions, but all characterized by enough monitoring data in a nearly greenfield condition to support a 2D fitting operation.

In the paper by Russo and Nicotera (2022) both propped and unpropped cases in sand were analysed by using 3D FEM. The obtained fitted surfaces are generally satisfactory, and the quality of the fitting synthetically represented by the value of the coefficient of determination, R^2 is indeed promisingly high as reported in Table I.

Table I. Coefficient of determination, R^2 for all the cases.

Case	Samples	Soil type	Range of R^2
CRHLM	1	Clay	0.80
CSSE	1	Clay	0.84
HMB	2	Clay silt	0.83-0.84
SQRS	2	Clay	0.75-0.91
TNEC	3	Silty Clay-Sand	0.94-0.97
TKY	2	Silty sand	0.95-0.98

Some cases have provided more settlement trough samples to be fitted with reference to different level of intermediate excavation or to different sides of the shaft.

The transversal profile f(y) is fully described by the parameters f_0 (f value at y=0), f'_0 (inclination of the settlement trough at the excavation edge) and f_I (f value at y equal to the extension PIZ of the "primary influence zone" as defined by Ou, 2006), while the longitudinal one is described by A and Δ (Russo and Nicotera, 2022). In the context of this study, we focus on the longitudinal profile parameters and the relationship between these last ones and the dimensionless depth of the excavation. As shown in Russo and Nicotera (2022) the parameters A and Δ show different trends in propped and unpropped excavations. For propped cases, like the ones analysed in this study, A depends linearly on the ratio H/L between depth (H) and length (L) of the excavation parallel to the settlement trough regardless of openings presence in the slabs used as props. As regards the parameter Δ, it depends linearly on the natural logarithm of the ratio H/L.

The following equations represent the relationship between A, Δ and the excavation depth H for propped excavations:

$$\frac{A}{L} = -0{,}1 \cdot \left(\frac{H}{L}\right) - 0{,}02 \quad (3)$$

$$\frac{\Delta}{L} = -\frac{1}{3} \cdot ln\left(\frac{H}{L}\right) - 0{,}59 \quad (4)$$

Figures 2 and 3 show the above described linear relationships between A, Δ and the ratio H/L, together with the FEM results (see legend) used in the best fitting exercise. The linear realationships 3) and 4) are drawn as dotted lines and represent a sort of either a lower or an upper bound of all the data for the parameter A and Δ respectively.

The results referred to the newly added case studies, togheter with the case studies SPS (i.e. San Pasquale Station) and MTD (i.e. Monte di Dio car park) in sand already used and discussed by Russo and Nicotera (2022), are also reported in both Figures. All the available data are included within the shaded areas bounded by two dotted lines: in each figure one of them represents Eq. 3) or 4), the other one was obtained by enveloping all the available data.

Only two values of Δ/L from Tokyo case study are not inclued in the shaded area because they appear as a sort of outliers compared to the overall population of data. Furthermore this case reports settlement profiles measured on a buried pipe whose stiffness is likely to bridge and thus to modify the concave shape of the observed settlement longitutindal profile. Finally the full line reported in the plot represent a tentative new linear correlation whose inclination is kept equal to the numerical derived equations (3) and (4) while the intercept is accodomated to fit only the experimental

data. The experimetally based intercepts are thus 0.06 and -0.79 for A/L and Δ/L respectively.

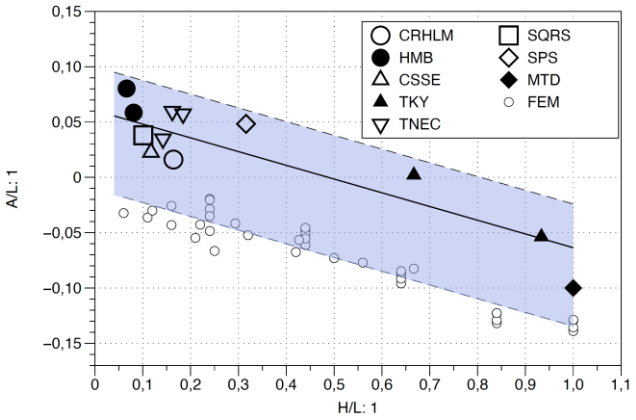

Figure 2. A/L as a function of the dimensionless depth of excavation H/L.

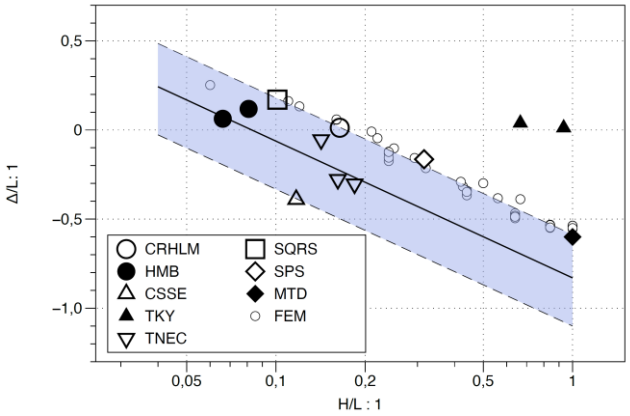

Figure 3. Δ/L as a function of the dimensionless depth of excavation H/L.

4 CONCLUDING REMARKS

The addition of case studies has reinforced some findings of previous studies about the 3D subsidence trough around a deep excavation based on 3D FEM computations of propped and unpropped excavations in sand. For space reason focus has been kept only on the longitudinal trough:

a) The inclination of the relationships of A and Δ with the depth of excavation H is confirmed;
b) As already anticipated by Roboski and Finno (2006) for increasing values of H/L the inflexion point tends to move outside the excavation (i.e. A<0);
c) The new parameter Δ introduced by Russo and Nicotera (2022) has a similar trend with the natural logarithm of the H/L ratio.

Further well documented case studies are needed to improve the reliability of the semi-empirical method.

Monitoring of soil deformations induced by deep mixing using an FME-based data analysis tool

Suivi des déformations du sol induites par un mélange profond à l'aide d'un outil d'analyse de données basé sur FME

ABSTRACT: A vast land reclamation project is under construction in Sweden, within a bay of the Baltic Sea. To enclose the area from the bay, a 600 m long rubble mound of crushed rock founded on deep mixing is constructed. The area has previously been prone to slides with its very soft clay. This paper focuses on the design and execution of the rubble mound in the western land connection, where the rubble mound serves as a temporary working platform. A rigorous control program was developed to ensure a safe work progress. To process all the data and facilitate analysis an FME-based tool was developed providing instant feedback for the designer. This paper describes the design process and the monitoring during execution as well as the measures taken when deformations exceeded alarm values. The paper also presents measured soil displacement and provides practical tips for future deep mixing projects where deformations are of concern.

RÉSUMÉ: Un vaste projet de poldérisation est en cours de construction en Suède, dans une baie de la mer Baltique. Pour entourer la décharge, un remblais de gravier de 600 m long, composé de roches concassées, fondé sur mélange profond. La zone était auparavant sujette aux glissements de terrain en raison de son argile très molle. Cet article se concentre sur la conception et l'exécution du remblais de gravier dans la connexions terrestre ouest, où le remblais sert de plate-forme de travail temporaire. Un programme de contrôle rigoureux a été élaboré pour garantir une progression sécurisée des travaux. Pour traiter toutes les données et faciliter l'analyse, un outil basé sur FME a été développé, fournir un retour instantané au concepteur. Cet article décrit le processus de conception et le suivu pendant l'exécution ainsi que les mesures prises lorsque les déformations dépassent les valeurs d'alarme. Le document présente également le déplacement mesuré du sol et fournit des conseils pratiques pour les futurs projets de mélange en profondeur où les déformations sont préoccupantes.

Keywords: Monitoring; deep mixing; soil displacement; soft clay; FME-programming.

1 INTRODUCTION

In the middle of Sweden, a vast land reclamation project is under construction. The planned area consists of an onshore and an offshore area within Skönviken, a bay of the Baltic Sea. To enclose the area, a 600 m long rubble mound of crushed rock founded on deep mixing is constructed, see Figure 1. The deep mixing consists of both dry soil mixing (DSM) and wet soil mixing. The DSM is conducted as overlapping columns with a coverage rate of approximately 96%.

This paper focuses on the design and execution of the DSM and the rubble mound in the western land connection. At the western connection the shallow water depths meant that the columns had to be installed from land, where the filled area (i.e the rubble mound) will serve as a working platform, as the installation progresses eastward. In order to ensure a safe work progress, a rigorous control program and active design was needed. To process all the data and facilitate analysis an FME-based tool was developed.

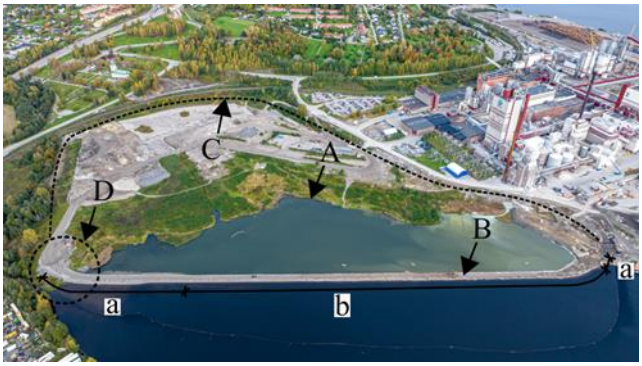

Figure 1. Overview of the project. (A) Existing shoreline, (B) New shoreline consisting of rubble mound on deep mixing, (a) dry soil mixing and (b) wet soil mixing, (C) Onshore boundary, (D) Western land connection. Photo: Håkan Sjödin.

Installation of DSM can cause relatively large ground movements due to the mixing and the addition of binder in the soil (Porbaha et al., 2001, Larsson, 2005 and Dong & Whittle, 2018). This mass displacement disturbs the soil and temporarily reduces its' strength (Shen et al., 2008). The aim of the developed data analysis tool is to collect and present data of mass displacement caused by the column installation. To avoid slope failure, this is important information for the designer. With the tool, it is possible to check the soil mass displacement effect of the column installation at different distances to the column front. Hence, it is possible to decide a likely distance in front of the DSM installation that is disturbed and model a strength reduction of the soil in this area. This provides a good basis for safe progress in the project.

The aim of this paper is to describe the challenges in the design process and the monitoring during execution as well as the measures taken when deformations exceed alarm values. The measured soil displacements are analysed based on distance from the DSM front and are also compared with previous measured displacement providing generalized conclusions regarding soil displacement induced by deep mixing.

2 GEOTECHNICAL CONDITIONS

The soil in the area consists generally of very soft to soft clay on silt and sand upon till on bedrock. The clay has an undrained shear strength varying from 3 to 20 kPa. In some areas, the clay is classified as quick clay. The thickness of the clay stratum varies between 10 to 20 m. During a backfill operation in the early 1980's, a landslide occurred and the area close to the shoreline has since been prohibited from any construction activity.

The shear strength of the clay is an important parameter for the design. The undrained shear strength of the clay has been investigated through CPT, direct shear tests, active undrained triaxial tests and fall cone test. Any disturbance of the clay will reduce its' strength; hence, it is highly important that any disturbance is accounted for.

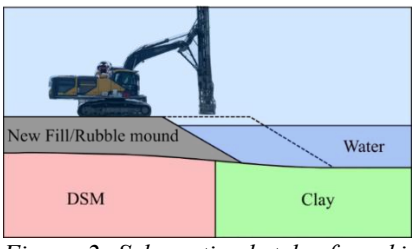

Figure 2. Schematic sketch of working order for western land connection.

3 DESIGN PROCESS

The planned working order was to perform DSM in sections and then fill with 0,5-2,0 m of crushed rock on the stabilized area. After certain curing time of the columns the DSM rig could advance out onto the newly filled area and commence with the subsequent section of further DSM installation. A schematic sketch of the working order is shown in Figure 2.

Initial stability calculations were made to ensure the rig's advancement. As the rig relies on the capacity of the relatively young DSM columns before advancing, a reduced shear strength of 30 kPa was chosen for the stabilized material, whereas the original design shear strength after 28 days is set to 100 kPa. The calculations and the availiable machine park gave that the rig was able to install columns 5 m in front of the reinforced area and needed to wait for 12 hours until it could advance to ensure enough aging of the DSM. 5 m ahead of the rig's working platform a new future platform was filled. As this fill was placed on non-reinforced soil and was not loaded by machines, a lower safety factor was accepted. However, the safety factor under the rig was satisfactory, as can be seen in Figure 3, as a minimum safety factor of 1,5 was required.

Figure 3. Stability calculation for installation of the DSM.

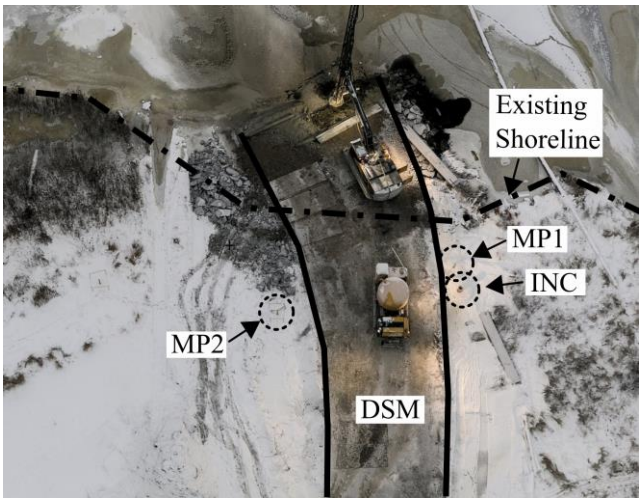

Figure 4. Location of instrumentation in plan.

4 MEASUREMENTS AND CONTROL PROGRAM

To monitor soil displacement during installation of the DSM, a control program was implemented. The control methods included instrumentation in the form of an inclinometer (INC) and two prisms (MP1 and MP2). For location of measurement equipment see Figure 4. In the INC the horizontal displacement with depth was monitored, whereas in MP1 and MP2 both vertical and horizontal displacements were measured at the surface.

To monitor the location of installed columns machine control with GPS was used for exact location of the columns.

Instrumentation was installed prior to DSM installation. From the start of DSM installation, the prisms were measured manually every second day, except weekends, until the end of installation. The inclinometer had automatic logging every 60 minutes. Both the construction management and the designer had access to the inclinometer data at a web-based platform.

The alarm values for horizontal displacement were set to 50 mm based on previous reported deformations stated in Larsson (2005). No alarm values were set for vertical displacements, these were monitored for follow-up and to gain understanding of the soil mass displacement. In the control program the first action point to be taken if the above set alarm value was exceeded was to stop production and perform updated stability calculations based on the assumed shear strength reduction considering the measured displacements.

5 DATA PROCESSING

Follow-up of column installation and inclinometer movements has been carried out using FME Desktop and Excel. FME has been used to manage the raw data from inclinometer measurements, prisms, and information of executed columns. The inclinometer data is read from an Excel sheet and is transformed and reordered to be better adapted to the purpose of the survey. For columns, as-built DSM pdfs are read to extract information such as coordinates and installation time and then fit to appropriate structure. When new data is received, the already established FME runs easily, and no other measures are required regarding formatting or manual input.

The Excel file reports the result in the form of graphs for installed columns and inclinometer results at a given time, which is selected with a slider (upper left corner), see Figure 5. The deflection of the inclinometer is then reported at the time where installed (reported) columns are located. The difference from the previous day is also reported. In our model, the stage is increased in days, but it is also possible to analyse in narrower intervals.

The plan graph is an xy dot graph where the column coordinate list is read, together with other coordinated objects (inclinometer, shoreline). The coordinate list is in a separate sheet designed to check if the column exists at the searched date. Then the coordinate values are reported, otherwise they are not reported. The inclinometer data is in another sheet designed to use one more search function to look for the searched date and return the corresponding deformations.

6 ACTIVE DESIGN

During installation of DSM from the western land connection, vertical and horizontal displacements were closely monitored. After 17 days of DSM installation, the horizontal displacements of the inclinometer passed the set alarm value of 50 mm.

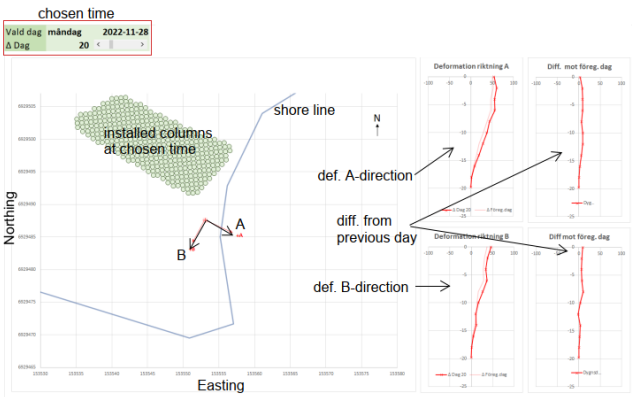

Figure 5. Example of results presented in the Excel file.

According to the actions in the control program, production was stopped, and new stability calculations were performed to ensure that the soil displacement would not endanger the previous assumptions. In the new calculations, the clay 10 m ahead of the DSM front was reduced to 50% of the initial shear strength. This lowered the overall safety factor to 2,186, but it was still satisfactory, see Figure 6.

During the production stop, the soil displacement in the INC remained constant, hence there was a clear correlation between displacement and DSM installation. Due to the poor stability and the risk for loss of strength in the clay, there was a planned break in production every 12 hours. During these breaks, the same correlation between soil displacement and DSM column installation was observed. Hence, it was decided that installation could be recommenced, with the restriction that no increase in recorded displacement during the planned breaks occurred.

7 ANALYSIS AND DISCUSSION

The soil displacement induced by deep mixing within this project was correlated with previous experiences. Both Porbaha et al. (2001) and Larsson (2005) has presented graphs showing horizontal soil displacement against the distance from DSM installation. Larsson (2005) has compiled the results from Uchiyama (1996), Masuda et al. (1996), Hirai et al. (1996) and Kakihari et al. (1996). A comparison with the measured soil displacement at the ground surface in the INC, MP1 and MP2 within this project is shown in Figure 7. As can be seen there is good correlation between the current measurement data and the previously reported in Larsson (2005). That the soil displacement within this project is at the upper boundary can be related to the high coverage rate of approximately 96%.

Analysing the soil displacement at the ground surface, measured displacements in the INC show a direction that is almost always perpendicular to the point of installation, see Figure 8 where the measured displacement in the beginning, when the distance (x) from the DSM front is large in comparison to its' depth (L), is purely in the A-direction. Whereafter the displacement increases more rapidly in the B-direction as x/L decreases. The horizontal soil displacement at the ground surface reached a limit value of 55 mm in the A-direction and 64 mm in the B-direction resulting in a total soil displacement of 84 mm.

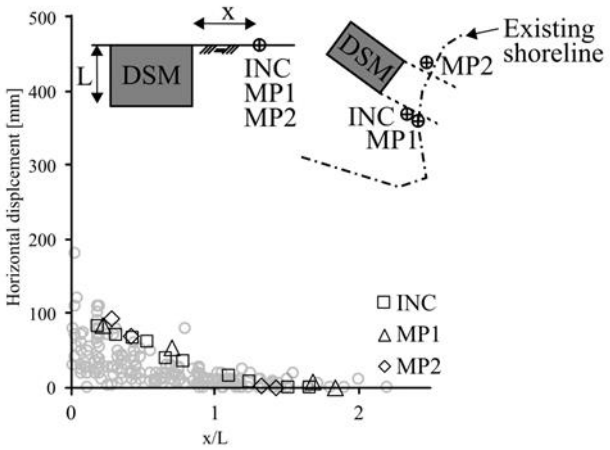

Figure 7. Horizontal displacement of INC, MP1 and MP2 plotted against distance from DSM (x/L), compared to data presented in Larsson (2005) in grey.

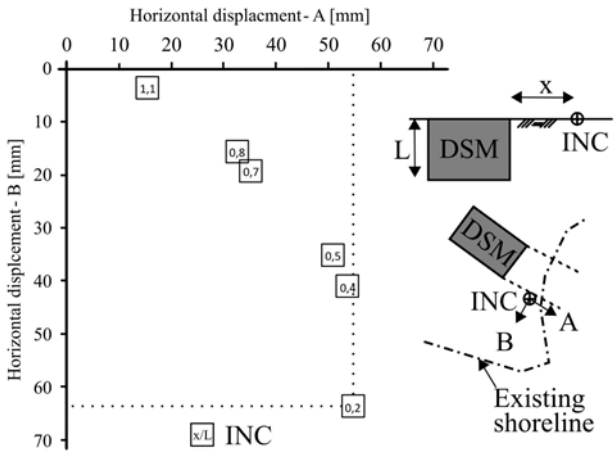

Figure 8. Horizontal displacement of INC in plan view plotted for different distances from DSM (x/L).

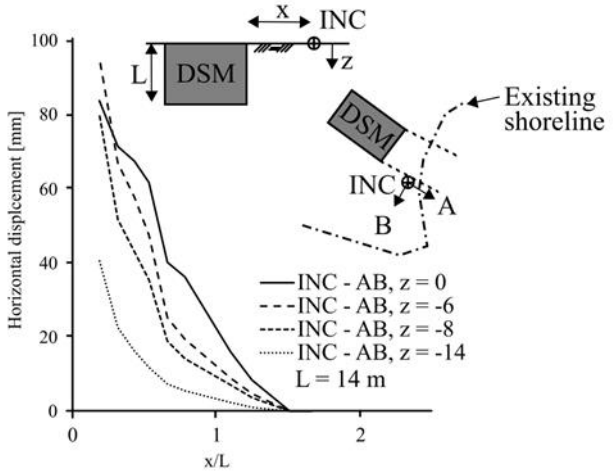

Figure 9. Horizontal displacement of INC for direction AB (resultant) with depth "z" below the ground surface plotted against distance from DSM (x/L).

With the INC as well the development of the soil displacement with depth could be monitored and analysed, see Figure 9. The displacements show over all depth a close to exponential increase as the distance between the installation and the measurement point decreases. Comparing the horizontal soil displacement with depth it can be observed that the maximum soil displacement does not occur at the ground surface at closest distance to the measurement point. The maximum value of 95 mm is measured at a depth of 6 m from the ground surface, which approximately coincides with the slip surface indicated in Figure 3 and Figure 6.

8 CONCLUSIONS

In a land reclamation project in Sweden an FME-based data analysis tool was developed to enable reliable and efficient monitoring of soil displacement due to installation of deep mixing columns. The tool provided the designer with easy access to measurement data that was used in the decision-making process to minimize the risk for slope failures and ensure a safe work progress during installation of DSM.

The main conclusions from the measurement of horizontal displacement were:

- The displacements are mainly perpendicular to the point of installation.
- The increase of displacement shows an exponential increase as the distance between installation and measurement point decreases.
- Maximum soil displacement does not occur at the ground surface closest to the DSM front, but at a depth of 6 m from the ground surface.
- Soil displacement related to DSM installation was instant.
- The horizontal ground displacements in the current project align well with previous observed displacements during DSM installation.

For future projects, with comparable geotechnical conditions, where ground deformations in relation to DSM installation is of importance, the presented graphs of displacement in relation to distance from installation can be used to predict a likely horizontal displacement.

ABSTRACT: Limited knowledge available on the soil-structure interaction of piled rafts under cyclic and dynamic loading together with gaps in national building codes frequently prevents the design of technically and economically optimised foundations for sensitive structures, such as foundations for high-rise buildings or bridges. As the first step in a research project to investigate the bearing behaviour of piled rafts under dynamic loading, existing model tests and in-situ measurements are evaluated to provide a database for the calibration of numerical models. This paper focuses on the numerical back-analysis of the centrifuge model tests on piled rafts by Horikoshi et al. (2003a; 2003b). The 3D finite element model employs the Hardening Soil model with small-strain stiffness (HSsmall) to simulate the material behaviour of the Toyoura sand used in the model tests. In the scope of this work, the calibration process of the material parameters and the results of the back-analysis of the model tests are presented.

RÉSUMÉ: Les connaissances limitées disponibles sur l'interaction sol-structure des radeaux de pieux sous charge cyclique et dynamique, ainsi que les lacunes des codes de construction nationaux, empêchent souvent la conception de fondations techniquement et économiquement optimisées pour les structures sensibles, telles que les fondations des immeubles de grande hauteur ou des ponts. Dans le cadre de la première étape d'un projet de recherche visant à étudier le comportement des radeaux de pieux sous charge dynamique, les essais sur modèle et les mesures in situ existants sont évalués afin de fournir une base de données pour l'étalonnage des modèles numériques. Cet article se concentre sur la rétro-analyse numérique des essais en centrifugeuse effectués sur des radeaux de pieux par Horikoshi et al. (2003a ; 2003b). Le modèle d'éléments finis 3D utilise le sol durcissant avec une rigidité à faible déformation (HSsmall) pour simuler le comportement du matériau du sable de Toyoura utilisé dans les essais sur modèle. Dans le cadre de ce travail, le processus d'étalonnage des paramètres matériels et les résultats de la rétro-analyse des essais sur modèle sont présentés.

Keywords: Piled raft; dynamic loading; centrifuge test; numerical analysis; HSsmall soil model.

1 INTRODUCTION

The piled raft is a well established foundation system especially for tall buildings (e.g. O'Neill et al, 1996, Poulos, 2001, Reul and Randolph, 2003) under predominantly vertical static loading. For this load case a guideline for design, dimensioning and construction already exists (ISSMGE Technical Committee 212, 2013) with piled rafts designed according to this guideline termed Combined Pile-Raft Foundations (CPRF). Also, piled rafts are applied frequently for bridge foundations (e.g. Hecht and Dürrwang, 2001, Comodromos et al., 2016) where lateral loads generally are of more importance. However, in contrast to piled rafts under predominantly vertical loading, comparatively few in-situ measurements on completed structures and large-scale model tests (field

investigations) have been documented for piled rafts under combined vertical and horizontal loading, regardless of whether monotonic, cyclic or dynamic actions are involved. To investigate the bearing behaviour of piled rafts under complex loading conditions small scale model tests as well as centrifuge model tests have been carried out by different researchers (e.g. Horikoshi et al., 2003a; 2003b; Sawada and Takemura, 2014; Unsever et al., 2014; Hamada et al., 2015).

In some recent studies, the behaviour of piled rafts under dynamic loading conditions was studied numerically using model tests as a means of validation (e.g. Eslami et al., 2011; Kumar et al., 2016; Bhaduri and Choudhury, 2019; Akbari et al., 2021). However, frequently the capability to realistically capture main aspects of soil-structure-interaction is limited by the use of linear elastic-perfectly plastic soil models, which generate only elastic strains upon small strain load reversals. Evidently, more advanced constitutive models are vital to model for example hysteretic damping.

The current research projects aims on providing a better understanding of the bearing behaviour of piled rafts under lateral monotonic and dynamic loading by means of numerical simulations with the finite element method (FEM) applying the Hardening Soil model with small-strain stiffness. This paper presents the results of the first phase of the project with the calibration of the material parameters of HSsmall model for dry Toyoura sand by means of the back-analysis of the centrifuge model tests employing of 3D finite element analysis (FEA).

2 CALIBRATION OF THE HSSMALL MODEL

The HSsmall model (Benz, 2007) is an extension of the standard Hardening Soil (HS) model (Schanz et al., 1999) incorporating two additional parameters: the shear modulus at a very small strain G_0^{ref} and the threshold shear strain $\gamma_{0.7}$, the shear strain at which the secant shear modulus G_s^{ref} is degraded to $0.72 \cdot G_0^{ref}$. Thus, the model accounts for the small strain stiffness, which can be related to a degrading secant stiffness with an S-shaped characteristics curve according to the formulation of Santos and Correia (2001) and an accompanying increasing damping ratio with increasing strain amplitudes. As a result, it reproduces hysteretic elastic soil behaviour in loading-reloading cycles leading to hysteretic damping.

Most of the model parameters of the HSsmall model for Toyoura sand were calibrated using the tool Plaxis SoilTest for simulating element tests where the hypoplastic parameters for Toyoura sand provided by Herle and Gudehus (1999) and Ng et al. (2013) were used as a reference.

Due to the limited space available, in the following, the description of the calibration procedure is restricted to the two parameters mainly controlling the material behaviour at small strains, namely G_0^{ref} and $\gamma_{0.7}$. The reference small strain shear stiffness modulus G_0^{ref} was estimated by means of three different approaches which all yielded similar values. In the first approach, an initial tangent slope of a hysteretic loop of a cyclic triaxial test simulation was evaluated. Alternatively, G_0^{ref} was determined by making use of the secant shear stiffness at a very small shear strain, where the secant shear stiffness in turn was determined from the deviatoric stress and shear strain values of standard triaxial test simulation. In the third approach, the initial Young's modulus E_0^{ref} of the standard triaxial test was used to determine the small strain shear stiffness from

$$G_0^{ref} = E_0^{ref} / \left(2 \cdot (1 + \nu_{ur})\right) \qquad (1)$$

where $\nu_{ur} = 0.2$ was employed as suggested by Benz (2007). Additionally, the obtained result was compared with the values extracted from charts by Alpan (1970) and Benz (2007), showing reasonable agreement.

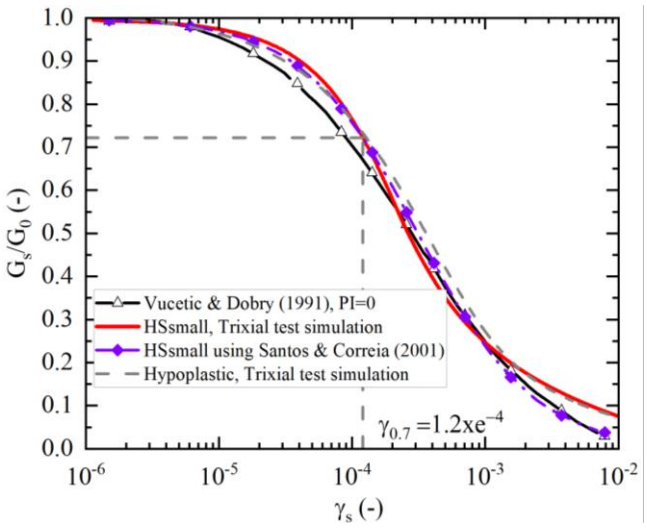

Figure 1. Shear stiffness degradation curves.

The second small strain parameter, the threshold shear strain $\gamma_{0.7}$, was calibrated using an iterative curve fitting procedure with reference to the secant shear modulus degradation and damping ratio curves of the reference hypoplastic model. The degradation curves were generated from deviatoric stress and small strain values of the triaxial simulation results and using the approach by Santos and Correia (2001). The result

was further refined by fitting with the secant shear modulus reduction curves of Vucetic and Dobry (1991) for a zero plasticity index value. As shown in Figure 1, the shear stiffness degradation curves of the current study are in good agreement with the hypoplastic reference model result and the curve presented by Vucetic and Dobry (1991).

The basic parameters defining the HSsmall model and their calibrated values, as determined from the calibration process, are listed in Table 1. It has to be noted that a cohesion was introduced for the reason of increasing numerical stability (in the dynamic FEA). This approach appears to be legitimate since the focus of the research project is on the serviceability rather than the ultimate capacity of foundations.

Table 1. Calibrated HSsmall model parameters.

Parameters		Description	Values
E_{50}^{ref}	MPa	reference secant stiffness at 50% of q_f	42.1
E_{oed}^{ref}	MPa	Tangent oedometric stiffness	30.2
E_{ur}^{ref}	MPa	unloading-reloading stiffness	126.9
ν_{ur}	-	unloading-reloading Poisson's ratio	0.2
m	-	power for stress-level dependency of stiffness	0.65
p^{ref}	kPa	reference stress for stiffness	100.0
G_0^{ref}	MPa	reference shear stiffness at very small strain	149.0
$\gamma_{0.7}$	-	threshold shear strain at which $G_s = 0.722 \cdot G_0$	$1.20 \cdot 10^{-4}$
c	kPa	cohesion	5.8
φ	°	angle of internal friction	35.6
ψ	°	angle of dilatancy	8.7
K_0^{nc}	-	at rest earth pressure coefficient for NC soil	0.47
R_f	-	failure ratio (q_f/q_a)	0.9

3 NUMERICAL MODEL

The numerical simulation of the centrifuge tests by Horikoshi et al. (2003a; 2003b) was carried out with the program PLAXIS 3D in prototype scale applying the appropriate scaling laws (e.g. Muir Wood, 2004). The dimensions of piles and raft as well as the material properties applied in the 3D FEA are summarised in Table 2. The piles were installed "wished-in-place" in the FE model which is considered to capture the installation process in the centrifuge tests reasonably well where the sand was poured around the piles at 1g level.

The soil as well as the piles and the raft were modelled with 10-node tetrahedral volume elements. Between soil and piles, respectively between soil and raft 12-node interface elements, with $R_{int} = 0.59$, are located. The piles and the raft are rigidly connected. The finite element mesh is shown in Figure 2 together with the boundary conditions applied at the lateral and bottom surfaces of the model for both static and dynamic loading conditions, reflecting the situation in the centrifuge model tests. For dynamic loading conditions, energy dissipation is reproduced by introducing free field boundary conditions at the side boundaries in the direction of loading and by using Rayleigh damping in addition to the hysteretic damping considered in the chosen constitutive model.

In FEA, careful selection of the mesh size plays a vital role in ensuring the accuracy of the numerical analysis at an optimum computational time. Accordingly, the size of the model and the discretisation were systematically varied to check and minimise their effect on the analysis. Based on convergence of the results and computing time criteria, a fine-sized mesh with additional refinement in the vicinity of the foundation was generated. For dynamic loading, the mesh size should be smaller than one-eighth of the wavelength associated with the maximum frequency component of the input motion, as suggested by Kuhlemeyer and Lysmer (1973). A typical model comprising 82698 elements and 131867 nodes with an average element size of 0.68 m fulfills this criteria.

Table 2. Model dimensions and additional parameters.

Parameter		Loading types	
		Vertical (Static)	Horizontal (Static/ Dyn*)
Pile (Solid)			
Length	m	8.5	9.0
Diameter	m	0.5	0.5
Unit weight	kN/m^3	9.72	9.72
Young's modulus	GPa	41.7	41.7
Raft			
Thickness	m	1.25	2.00
Width	m	4	4
Unit weight	kN/m^3	27	27
Young's modulus	GPa	71	71
Soil			
Width	m	20	20
Length	m	35	35
Depth	m	23.5	23.0/16.0*
Unit weight	kN/m^3	15.2	15.2
Initial void ratio	-	0.75	0.75
Interface			
Interface str., R_{int}	-	0.59	0.59

* dynamic loading

The loads were applied similar to the procedure followed in the centrifuge test. For the monotonic loading conditions, the loads were employed in two stages. In the first stage, the vertical load was applied

as a raft weight plus an additional vertical pressure. Whereas in the subsequent stage, the monotonic loads were applied by means of prescribed displacement cycles in their respective directions. Similarly, for the dynamic loading case, the vertical load was induced by making use of an increased unit weight of the raft, and the horizontal dynamic load was excited at the bottom of the soil model by applying harmonic loading of 1 m/s^2 amplitude and frequency of 1 Hz for 20 s with an additional 5 s steady- state (zero amplitude) condition before and after the main excitation. For both the static and dynamic lateral loading cases, a total vertical load of 5751 kN was applied, equalling a total mass of 4.69 kg in the model scale. Moreover, Rayleigh damping was introduced by employing damping coefficients $\alpha = 0.52,$ and $\beta = 0.0027,$ at a damping ratio of 5%.

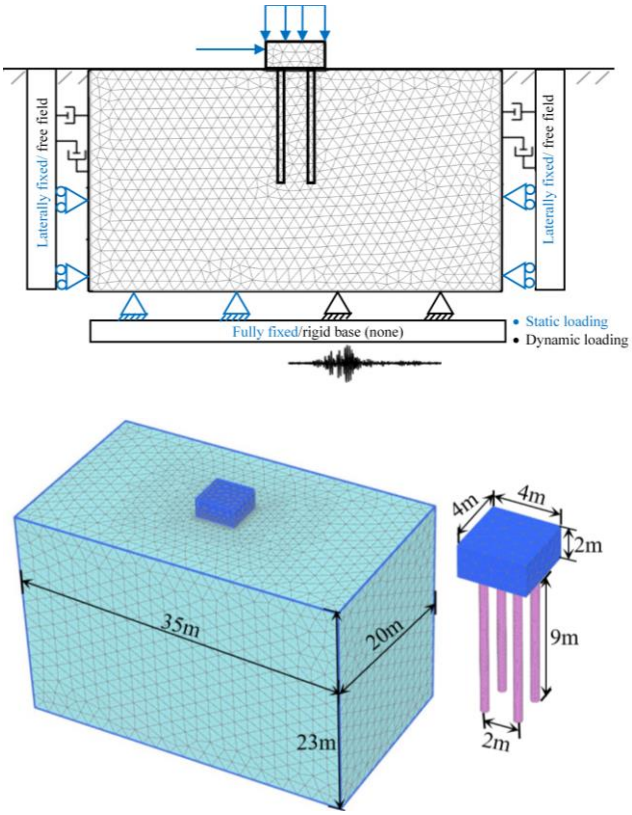

Figure 2. Schematic illustration and FE mesh of the model for static lateral loading case.

4 COMPARISON OF CENTRIFUGE TESTS AND NUMERICAL SIMULATIONS

4.1 Static vertical and horizontal loading

To validate the numerical model and verify the suitability of the selected constitutive model and its model parameters the results of 3D FEA are compared to the respective centrifuge test results on piled rafts. The results for the vertical monotonic load test are presented in Figure 3 and Figure 4 showing a very good agreement between centrifuge model tests and numerical simulation.

The minor difference in the vertical load share is probably related to software limitations in extraction of the structural forces of the piles. The vertical settlement is also compared with numerical analysis result provided by Alnuaim et al. (2017) using a linear elastic-perfectly plastic soil model with a Mohr Coulomb's failure criteria.

The variation of the horizontal displacement and the horizontal stiffness, defined by the ratio of the horizontal load to the horizontal displacement, is compared and presented in Figure 5 and Figure 6, respectively.

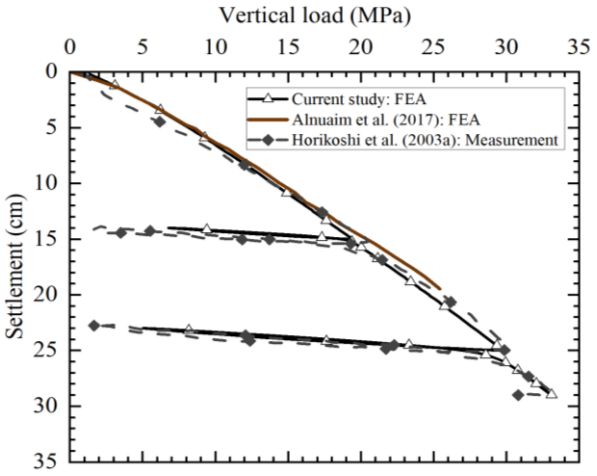

Figure 3. Vertical loading: Variation of settlement with load.

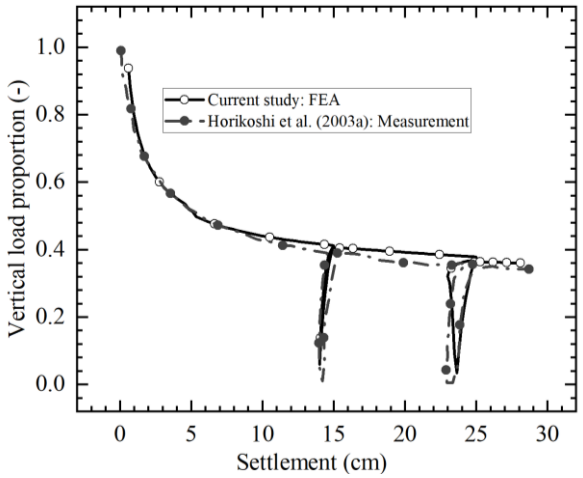

Figure 4. Vertical loading: Variation of pile load share with settlement.

4.2 Dynamic horizontal loading

Back analyses conducted for dynamic loading conditions also revealed a reasonable agreement with the test results. For example, the measured and simulated acceleration and settlement time histories at the top of the raft are compared in Figure 7 and Figure 8,

respectively. The maximum acceleration response at the top of the raft was also compared with the numerical results of Eslami et al. (2011) and Kumar et al. (2016), where a linear elastic-perfectly plastic soil model was used. The comparison indicates that the results achieved with the HSsmall model is in better agreement with the measurements than the two models justifying the application of this more advanced model, particularly for dynamic loading cases.

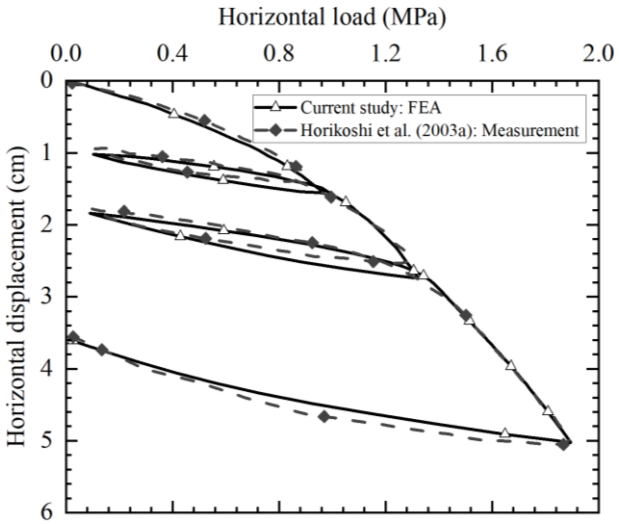

Figure 5. Horizontal loading: Variation of horizontal displacement with load.

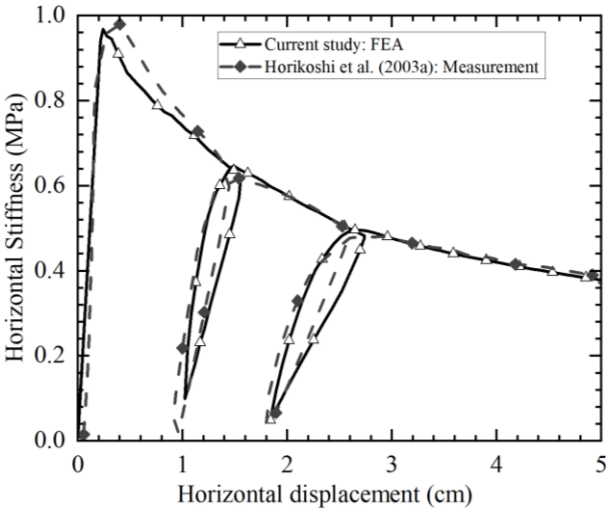

Figure 6. Horizontal loading: Variation of horizontal stiffness with horizontal displacement.

5 CONCLUSIONS

In this work, the calibration of the parameters of the HSsmall model and the validation of 3D numerical model by means of back-analysing centrifuge model tests on piled rafts in sand were presented. Most of the calibrated material parameters were derived by more than one method obtaining similar results. From the validation process, it can be concluded that the 3D numerical model in combination with the HSsmall constitutive model are reasonably well suited for the analysis of piled rafts under static as well as dynamic conditions.

In the next step of the research project the calibrated and verified numerical model will be used for an extensive study investigating piled rafts subjected to different loading conditions.

ABSTRACT: The purpose of Ground Improvement (GI) works is to create usable grounds whose original properties are too weak to meet the design conditions required by the specific construction project. Well-designed ground improvement schemes are being increasingly applied as an alternative to conventional foundation solutions in order to lower construction costs, shorten construction time and reduce CO_2 emissions. The current Eurocode 7 does not cover ground improvement. This will change significantly with the introduction of the second generation of Eurocode 7, which includes a new clause for the design of such geotechnical works. One of the main difficulties of including ground improvement works in the standard was the wide variety of techniques used for this purpose and considering their specific features. Some of them involve soil densification or drainage, while others require installation of various inclusions or treatment of the soil in place using binders. Therefore, it was necessary to establish a comprehensive design methodology that aligns with the philosophy of partial factors in Eurocode 7 and accommodates this versatility. This article presents the adopted concept and highlights the main challenges encountered.

RÉSUMÉ: L'objectif des travaux d'amélioration du sol est de rendre constructibles des terrains dont les propriétés d'origine sont trop faibles pour être utilisés dans les conditions de conception requises par un projet de construction spécifique. Des projets d'amélioration de sol bien conçus sont de plus en plus utilisés comme alternative aux solutions de fondations conventionnelles afin de réduire les coûts de construction, de raccourcir les délais de construction et de réduire les émissions de CO_2. L'Eurocode 7 actuel ne couvre pas l'amélioration du sol. Cette situation changera de manière significative avec l'introduction de la deuxième génération de l'Eurocode 7, qui comprend une nouvelle clause pour la conception de ces travaux géotechniques. L'une des principales difficultés pour inclure les travaux d'amélioration du sol dans la norme était la grande variété des techniques utilisées à cette fin et la prise en compte de leurs spécificités. Certaines d'entre elles impliquent la densification ou le drainage du sol, tandis que d'autres nécessitent l'installation d'inclusions ou le traitement du sol en place à l'aide de liants. Il était donc nécessaire d'établir une méthodologie de dimensionnement globale conforme à la philosophie des facteurs partiels de l'Eurocode 7 qui s'adapte à cette polyvalence. Cet article présente le concept adopté et souligne les principaux défis rencontrés.

Keywords: Second generation Eurocode 7; ground improvement; design methodology.

1 GROUND IMPROVEMENT (GI) CLASSIFICATION AND DEFINITIONS

A wide range of different ground improvement methods are used in practice. An exemplary classification of them was presented by Mitchel (1981), among others. A more recent proposal was also elaborated by TC211 of the ISSMGE (Chu et al., 2009). Both of these and similar classifications take into account executional aspects only and concentrate on the specific techniques used for carrying out the works. However, such a breakdown is not useful regarding the design of ground improvement. A new classification scheme had to be developed taking into account how the ground improvement is applied and also modelled. According to prEN 1997-3, ground improvement shall be classified according to Table 1 considering the diffused or discrete character of the GI and the possibility to measure the unconfined compressive strength (UCS) of the improved ground.

Very important is the definition of rigid inclusions, which represent structural elements with stiffness and strength both significantly higher than the ground in which they are installed. In order to clearly distinguish them from conventional piles, one of the following conditions should be satisfied for Class BII applications, as illustrated in Figure 1:

- structural loads are transferred from the slab and spread foundations or embankment through a Load Transfer Platform (LTP) into the improved ground;
- in absence of a LTP, there is no structural connection between the rigid inclusions and the slab or spread foundation.

2 SELECTION OF THE GROUND IMPROVEMENT TECHNIQUE

The ground improvement technique should be selected considering the following:

- the design situation and load variation;
- thickness and properties of the ground or fill material;
- water pressure in the various strata;
- nature, size and position of the structure to be supported by the ground;
- prevention of damage to adjacent structures or services during execution;
- whether the ground improvement is temporary or permanent;
- in terms of anticipated deformations, the relationship between the ground improvement technique and the construction sequence;
- the effects on the environment including pollution by deleterious substances or changes in groundwater level or properties;
- the durability of the improved ground; and
- any long-term deterioration of the ground.

The actions and ground model shall be assessed according to Parts 1 and 2 of Eurocode 7, respectively: prEN 1997-1 and prEN 1997-2.

3 GROUND INVESTIGATION

The second generation of Eurocode 7 includes a concept of the zone of influence, where construction works or the geotechnical structure can adversely affect the safety, serviceability, robustness, durability or sustainability of the geotechnical structure to be built, other structures, utilities, ground, or groundwater. The depth and horizontal extent of ground investigation shall be sufficient to determine the ground conditions within this zone. The maximum spacing and the minimum number of investigation locations for different types of structures are given in Annex H of EN 1997-2. Unless the National Annex (NA) gives another value, the minimum depth of field investigation below treatment depth is set to 5 m for GI Classes AI and AII, and to the maximum value of 5 m or three times the equivalent diameter of the non-rigid/rigid inclusion for Classes BI and BII. prEN1997-2 specifies that this value should be increased in the case of unfavourable ground conditions and may be reduced in competent ground if sufficient comparable experience exists to allow the determination of its properties throughout the zone of influence.

Table 1. Classification of ground improvement adopted in the second generation of Eurocode 7 (prEN 1997-3).

Class	A-Diffused	B-Discrete
I	**AI – Diffused with no measurable unconfined compressive strength (UCS)** The improved ground has an increased shear strength or stiffness higher than that of the original ground. The improved ground can be modelled as a ground with improved properties. *e.g., deep vibration, dynamic compaction, vertical drains and surcharge, compaction grouting, soil replacement, mass soil mixing.*	**BI – Discrete with non-rigid inclusions** Inclusions, installed in the ground, with higher shear capacity and stiffness compared to the surrounding ground. The unconfined compressive strength of the inclusion is not measurable. *e.g., stone or sand columns, dynamic replacement, geosynthetic encased columns.*
II	**AII – Ground improvement zone with measurable unconfined compressive strength** The improved ground is modified from its original natural state, has a measurable unconfined compressive strength and is significantly stiffer than the surrounding ground. Usually, it comprises a composite of a binder and ground. *e.g., permeation grouting, jet grouting, ground freezing, mass soil mixing with measurable UCS.*	**BII – Discrete with rigid inclusions** Rigid inclusions, installed in the ground, with unconfined compressive strength and significantly higher stiffness than the surrounding ground. The inclusions can be an engineered material such as timber, concrete/grout or steel or a composite of a binder and ground. *e.g., jet grouting and soil mixing columns/panels, concrete or grout columns, steel or timber inclusions.*

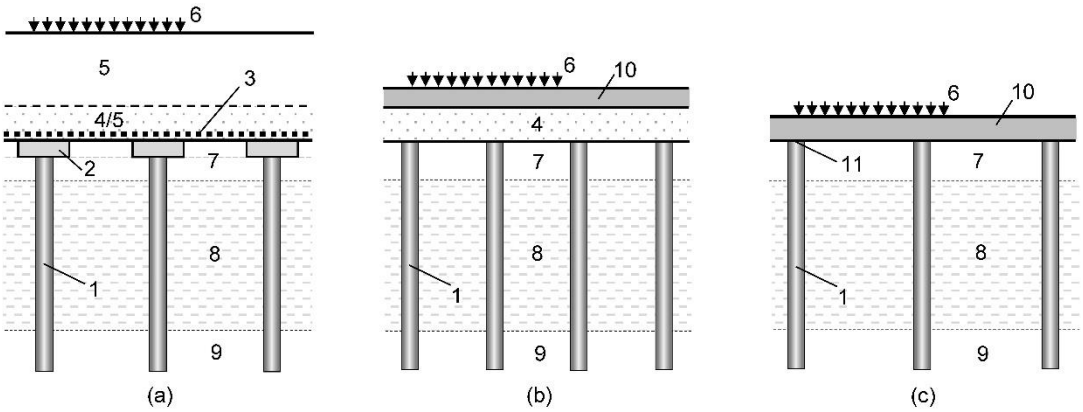

Figure 1. Class BII concepts: a) embankment, b) slab or spread foundation with a LTP, c) slab or spread foundation without a LTP. Key: 1 – rigid inclusions, 2 – optional caps, 3 – optional basal reinforcement, 4 – Load Transfer Platform (LTP), 5 – embankment, 6 – load, 7 – working platform, 8 – weak soil, 9 – load bearing ground, 10 – slab or spread foundation, 11 – no structural connection between 1 and 10 (Figure 1c).

4 GEOMERICAL PROPERTIES AND EXECUTION TOLERANCES

A challenging aspect of the design methodology of the second generation of Eurocode 7 was the consideration of geometrical properties in relation to various GI techniques. According to EN 1990, the design value of a geometrical property (a dimension) is its value including any possible deviation from a predetermined nominal value. Further to what EN 1990 states, acceptable deviations of the geometrical properties shall be considered in GI design.

In geotechnical practice, construction deviations often result from execution tolerances. These are the geometrical imperfections that can occur during the works even with the highest standards of workmanship, corresponding to the best execution practice for a given GI technique. In other words, they are inherent to the construction process selected, and can be maintained by a competent contractor adhering to the state of practice. Moreover, they should not be arbitrarily adjusted to meet specific design requirements, and subsequently enforced on the contractor. Consequently, if consideration of execution tolerances does not allow the design requirements to be met, the extent of works should be increased or a different GI technique or foundation method should be considered.

In accordance with the prEN1997-3, acceptable deviations of the geometrical properties of the GI shall be as specified in the relevant execution standards. In the absence of a relevant execution standard, acceptable deviations of the geometrical properties can be specified in the National Annex. When no national choices are made, the values of these acceptable deviations can be specified by a relevant authority.

For verification of limit states using the partial factor method, the deviation of a geometrical property that is within a specified tolerance is assumed to be catered for by the partial factors γ_F, γ_M, γ_E, and γ_R (cf. EN 1990).

5 GEOTECHNICAL ANALYSES AND DESIGN VERIFICATIONS

Analyses of the interaction between a structure, improved ground and ground should be carried out to verify that the ultimate and serviceability limit states (ULS, SLS) are not exceeded, and should take into account the stiffness ratio of discrete inclusions to the surrounding ground.

For ground improvement the following ULS shall be verified in particular:

- failure of the ground improvement inclusion or zone in compression, tension, bending, buckling or shear;
- failure in the ground due to transverse loading of the improved ground zone;
- uplift or insufficient tensile resistance of the ground improvement zone;
- combined failure in the ground and in the ground improvement inclusion or zone;
- bearing resistance failure below the ground improvement inclusion or zone;
- limit states caused by changes in groundwater conditions or groundwater pressure;
- failure at the edges of the improved ground zone.

Design of Class A ground improvement is similar to the design of structures without the use of any ground improvement technique, and the resulting improved ground or material properties are used in the verification of limit states for the corresponding geotechnical structure. The behaviour of the improved

ground can be conveniently modelled by conventional ground models.

Where Class B ground improvement is used to support or retain a structure, the calculation model shall include:

- the consideration of the interaction effects between the ground, discrete inclusions, and the overlying structure, embankment, or LTP; and
- for Class BII ground improvement a verification of the structural resistance of the individual inclusions.

Interaction effets for Class BII ground improvement are similar to those relevant for a piled raft, whereby a LTP additionally impacts the load distribution between rigid inclusions and supporting ground, leading to the development of negative skin friction in the upper part of the inclusions (Figure 2).

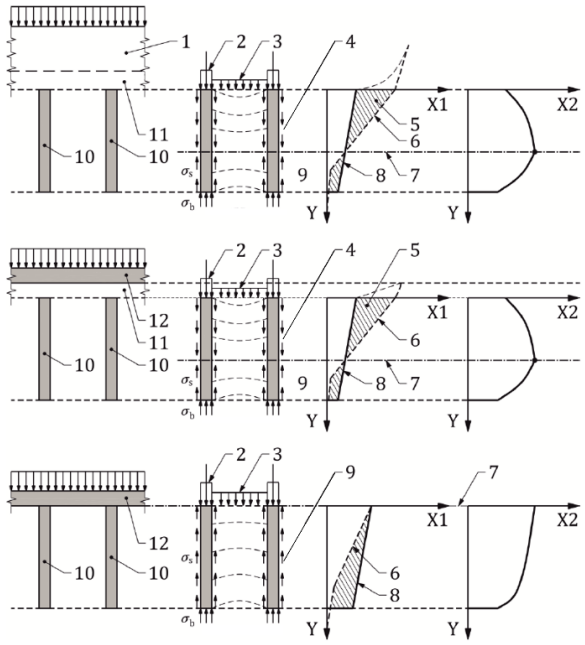

Figure 2. Interaction effects of a ground improvement with rigid inclusions. Key: X1 – settlement, X2 – inclusion axial force, Y – depth, 1 – embankment, 2 – load transmitted to the inclusion, 3 – load transmitted to the ground, 4 – negative skin friction, 5 – differential settlement, 6 – settlement of the ground, 7 – neutral plane, 8 – settlement of the inclusion, 9 – positive skin friction, 10 – inclusion, 11 – load transfer platform, 12 – structure (e.g. slab or spread foundation), σ_s – mobilised shaft friction along inclusion, σ_b – mobilised tip resistance of the inclusion.

5.1 Design resistance of Class B ground improvement

The design resistance of a Class BI ground improvement $R_{sys,d}$ may be determined from the representative value of the total resistance of the ground improvement system with inclusions $R_{sys,rep}$ using a partial factor $\gamma_{R,sys}$ and a model factor $\gamma_{Rd,sys}$, i.e.:

$$R_{sys,d} = \frac{R_{sys,rep}}{\gamma_{R,sys}\,\gamma_{Rd,sys}} \quad (1)$$

For Class BII applications, the design resistance $R_{sys,d}$ may be determined by adding two components:

- the sum of the representative values of the vertical resistance of the i-th rigid inclusion $R_{ri,i}$ with a model factor $\gamma_{Rd,ri}$ and a partial resistance factor for the rigid inclusion system $\gamma_{R,ri}$; and
- the representative value of the vertical resistance of the ground after installation of inclusions R_g with a partial factor γ_{Rg}, i.e.:

$$R_{sys,d} = \frac{\sum_i^n R_{ri,i}}{\gamma_{Rd,ri}\,\gamma_{R,ri}} + \frac{R_g}{\gamma_{Rg}} \quad (2)$$

The representative resistance of a rigid inclusion R_{ri} shall be determined as for piles, depending on the installation technique and taking into account group and further interaction effects, as shown in Figure 2. Consequently, the ultimate geotechnical resistance of a group of rigid inclusions is not the same as the sum of that of the individual inclusions.

The verification of geotechnical limit states for individual inclusions may be omitted provided it is verified that the system is able to redistribute loads without itself exceeding an ultimate or serviceability limit state.

Serviceability limit states of geotechnical structures on improved ground shall be verified according to other relevant clauses of prEN1997-3.

5.2 Unconfined compressive strength (UCS) of Class II ground improvement material

The representative values of the properties of concrete, steel, and timber inclusions shall be determined in accordance with EN 1992-1-1, EN 1993-1-1, and EN 1995-1-1, respectively.

For the treated ground material (e.g. with jet grouting, soil mixing…), provided that at least N samples of the material are tested, the representative value of the unconfined compressive strength $q_{u,imp,rep}$ shall be determined from:

$$q_{u,imp,\mathrm{rep}} = \eta_c \eta_t q_{u,imp,k} \quad (3)$$

where: η_c is a reduction factor accounting for long-term effects, η_t is a factor accounting for the difference in time between testing (typically 28 days) and when the material is exposed to the design stresses and $q_{u,imp,k}$ is the characteristic value of the UCS of the Class II ground improvement material.

$q_{u,imp,k}$ should be determined, according to prEN 1997-1, as the P fractile of the dataset of the relevant

statistical distribution (where recommended values for the parameters N and P are 10 and 10%, respectively, unless the National Annex gives different values). Soils treated with binders typically correlate with the lognormal distribution (Topolnicki and Pandrea, 2012). The P fractile can also be determined from the cumulative frequency curve of the dataset.

If fewer than N samples are tested, $q_{\mathrm{u,imp,rep}}$ shall be determined from:

$$q_{u,imp,\mathrm{rep}} = \eta_c \eta_t q_{u,imp,\mathrm{nom}} \quad (4)$$

where $q_{\mathrm{u,imp,nom}}$, the nominal value of the UCS, should be determined, after execution, as the minimum of the following values:

- the minimum value of all the UCS test results;
- the arithmetic average value of all the UCS test results multiplied by a reduction value k;
- a maximum value $q_{u\,max}$.

Before execution, nominal value can be taken as a cautious estimate of the UCS based on comparable experience, cf. prEN1997-1.

The recommended values of k and $q_{u\,max}$ are 0.7 and 12 MPa, respectively, unless the National Annex gives different values.

For hydraulic binders and cement-based materials, the value of $\eta_c = 0.85$ for geotechnical structures and 1.0 for temporary geotechnical structures (cf. prEN 1997-1) unless the National Annex gives a different value.

The value of η_t should be determined directly from testing for the specific type of Class II ground improvement material, for the specific ground and the specific hydraulic binder or cement-based material. An indicative range of η_t for curing periods $t \leq 28$ days is given in the Annex I to prEN1997-3 (Figure 3).

It is noted that stabilised soils often exhibit significant strength increase with extended curing time over 28 days. This property can also be accounted for in the design by taking $\eta_t > 1$. For example, UCS after 60 days is commonly used in practice. Recommended values for η_t can be found in Topolnicki (2021) with η_t in the range of 1.15 to 1.25.

The design value of the UCS of Class II ground improvement material shall be determined from the representative value as follows:

$$q_{ud} = \frac{q_{u,imp,rep}}{\gamma_M} \quad (5)$$

where $\gamma_M = 1.5$ is a partial material factor for persistent and transient design situations.

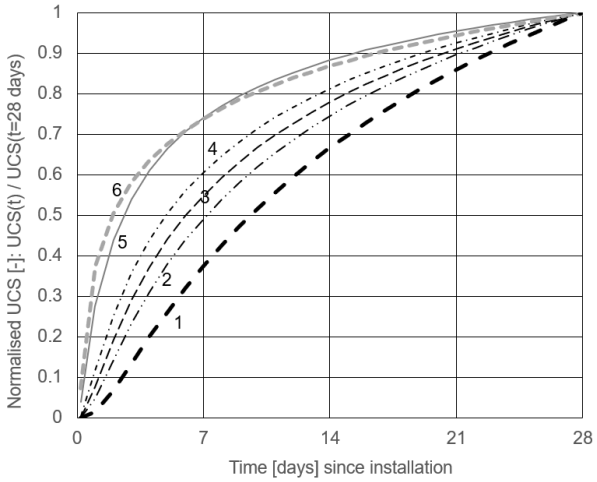

Figure 3. Indicative range for the strength development of Class II ground improvement material over time.
Key: 1− loam-cement (BBRI/SBRCURnet, 2017), 2− sand-cement (BBRI/SBRCURnet, 2017), 3− prEN 1992-1-1 Class CS cement f_{ck} < 35 MPa, 4− prEN 1992-1-1 Class CN cement f_{ck} < 35 MPa, 5− prEN 1992-1-1 Class CR cement f_{ck} < 35 MPa, 6− FHWA Design Manual 2013

5.3 Structural resistance of rigid inclusions

The structural resistance of rigid inclusions shall be verified according to the relevant standard for the material installed. If no such standard exists, for materials of Class II ground improvement, ultimate limit states shall be verified by demonstrating that design effects of actions do not exceed the stress envelope of the material used (Figure 4). When normal stresses and shear stresses are verified separately, the design value of the normal stresses and of the shear stresses shall not exceed $0.7q_{\mathrm{ud}}$ and $0.2q_{\mathrm{ud}}$, respectively.

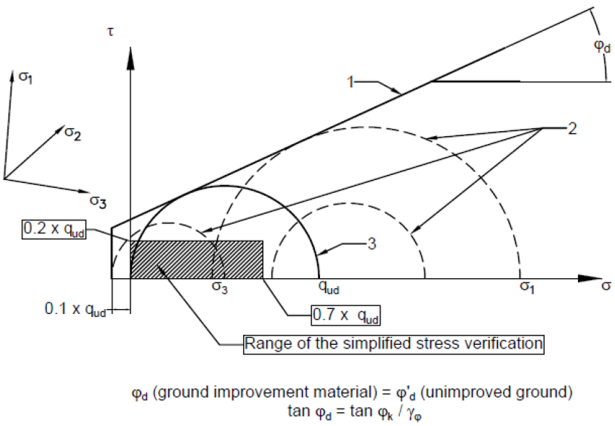

Figure 4. Allowable stresses in ground improved material with UCS.
Key: 1 – envelope for allowed states of stress, 2 – examples for allowed states of stress σ_1, σ_3, 3 – state of stress in uniaxial compression test: σ_3=0, $\sigma_1 = q_{ud}$.

For rigid inclusions subject to compression, buckling shall be verified. When one of the following

conditions is met, verification of buckling of Class BII inclusions may be omitted:

- inclusion diameter $B_{ri} > B_{ref}$;
- thickness of the soft layers, where $c_u < c_{u,ref}$, is smaller than h_{ref}.

The reference values are: B_{ref} = 0.3 m, $c_{u,ref}$ = 15 kPa and h_{ref} = 1.0 m, unless other values are given in National Annex.

5.4 Load transfer platform

The Load Transfer Platform (LTP) and the possible reinforcing elements are designed to transfer the load from the structure or the embankment to the improved ground. ULS verification may be omitted for a LTP where it can be demonstrated that the loads can be redistributed within the confined system, provided that the load transfer platform does not fail at its edges. A confined system can be assumed inside a grid of inclusions in a GI zone (ASIRI, 2012; Bohn, 2016). The tensile resistance of the reinforcements possibly installed in the LTP should be verified according to Clause 9 of prEN 1997-3. In the absence of a LTP, additional verifications may be considered during the design, such as verifications of the stress concentrations at the top of the inclusions and internal forces within the slab or spread foundation.

6 TESTING OF GROUND IMPROVEMENT

The types of testing should be determined according to the GI technique. The minimum frequency and type of control test should be given by the relevant execution standard or, when no relevant execution standard is available, by the relevant authority or, where not specified, as agreed by the relevant parties for a specific project. Typical control tests may include for:

- Class AI: investigations of treated ground as for the original ground in accordance with prEN1997-2, with possible field and laboratory tests and monitoring where relevant (for example, for preloading and vertical drains);
- Class AII: tests on extracted samples of treated ground to verify UCS and other properties;
- Class BI: field testing inside and/or in between inclusions, dummy foundation test on improved ground (individual inclusion and surrounding ground), zone load test on a group of inclusions (group of inclusions and surrounding ground);
- Class BII: load test on isolated rigid inclusions, zone load test on a group of inclusions (group of rigid inclusions and surrounding ground), UCS test of inclusion material.

Material control tests shall be performed to verify that the determined representative values of the improved ground are achieved. The minimum number of control test should be determined based on local experience, ground conditions and the applied ground improvement technique. Sampling should be performed according to relevant execution standard. If undisturbed sampling is impractical, the strength may be determined from documented correlations with other in-situ tests. The stiffness of ground improvement materials should be determined either from laboratory tests on undisturbed samples, documented correlations, or by monitoring of deformations.

The unconfined compressive strength should be determined on undisturbed cylindrical samples with a height to diameter ratio of two. After conducting all UCS tests on suitable samples, the results of the test specimens with unmixed soil inclusions larger than one-sixth of the diameter of the test specimen may be excluded. In addition, no more than 15% of the UCS results of the tested specimens from one specific site may be excluded. In absence of a material standard and unless the National Annex gives different values, the recommended testing frequency is:

- for Class AII ground improvement, 1 test per 125 m³ (minimum of 4 tests) per treated geotechnical unit (volume of ground defined as a single material), conducted on samples representative of the whole treatment depth;
- for Class BII ground improvement, 1 test per 125 m³ (minimum of 4 tests) of rigid inclusion volume, conducted on samples representative of the whole treatment depth.

Estimation of permeability coefficient using machine learning algorithms on the example of AdaBoost and Artificial Neural Network algorithms

Estimation du coefficient de perméabilité à l'aide d'algorithmes d'apprentissage automatique sur l'exemple des algorithmes AdaBoost et Artificial Neural Network

ABSTRACT: The development of the Construction sector in recent decades and the systematic reduction of natural aggregate (NA) resources oblige the search for alternatives and substitutes for these important construction materials. The use of anthropogenic aggregates as replacements for natural aggregates provides an opportunity to reduce the number of landfills and recycle waste materials from construction and demolition (CDW), which can be successfully used in Civil Engineering. It may also involve risks that undoubtedly include estimating geotechnical parameters based on solutions developed to date for natural aggregates. A major factor affecting these estimates is that anthropogenic aggregates could have different properties and chemical compositions. This study analyzed the possibility of estimating the coefficient of permeability for Concrete Aggregate (RCA) using Machine Learning algorithms - AdaBoost and Artificial Neural Networks. The obtained results were compared with each other and with the previously used empirical formulas for estimating the coefficient of permeability in non-cohesive materials. Based on the results received, an attempt was made to interpret the physical characteristics of the aggregate that have a significant impact on the estimation of the model by the Machine Learning algorithm. The analysis carried out will allow the formulation of conclusions for further application of Machine Learning algorithms as a tool to support the prediction of the coefficient of permeability.

RÉSUMÉ: Le développement du secteur de la construction au cours des dernières décennies et la réduction systématique des ressources en granulats naturels obligent à rechercher des alternatives et des substituts à ces importants matériaux de construction. L'utilisation de granulats anthropogéniques pour remplacer les granulats naturels permet de réduire le nombre de décharges et de recycler les déchets de construction et de démolition (CDW), qui peuvent être utilisés avec succès en génie civil. Elle peut également comporter des risques, notamment en ce qui concerne l'estimation des paramètres géotechniques sur la base des solutions développées à ce jour pour les granulats naturels. L'un des principaux facteurs influençant ces estimations est le fait que les agrégats anthropogéniques peuvent avoir des propriétés et des compositions chimiques différentes. Cette étude a analysé la possibilité d'estimer le coefficient de perméabilité pour les granulats de béton (RCA) en utilisant des algorithmes d'apprentissage automatique - AdaBoost et les réseaux neuronaux artificiels. Les résultats obtenus ont été comparés entre eux et avec les formules empiriques précédemment utilisées pour estimer le coefficient de perméabilité des matériaux non cohésifs. Sur la base des résultats obtenus, on a tenté d'interpréter les caractéristiques physiques de l'agrégat qui ont un impact significatif sur l'estimation du modèle par l'algorithme d'apprentissage automatique. L'analyse effectuée permettra de formuler des conclusions pour l'application ultérieure des algorithmes d'apprentissage automatique en tant qu'outil d'aide à la prédiction du coefficient de perméabilité.

Keywords: Permeability coefficient; machine learning; AdaBoost; artificial neural network.

1 INTRODUCTION

Sustainability is the improvement of the quality of life in a healthy environment, positively affecting social, economic and environmental conditions for present and future generations. Growing awareness of environmental degradation caused by human activity is motivating stricter regulations and innovative recycling methods (Kumar Mehta, 2001; McNeil & Kang, 2013). Life cycle analysis of a material begins with its potential reuse, which shapes the sustainable nature of the material. This includes stages such as raw material acquisition, processing, use, preservation and disposal or recycling. Sustainable manufacturing seeks

to reduce waste through a closed-loop economy (Cassiani et al., 2021; Vieira et al., 2016).

An example is the recycling of concrete from demolition, which becomes a valuable concrete aggregate that replaces natural aggregates in many applications, including road construction.

The use of recycled concrete aggregates in construction is a developing technique. According to Buck (Buck, 1973), after World War II, when the demolition of buildings and roads generated large amounts of waste and Europe needed to be rebuilt, the use of these aggregates began to be widely used. The process of obtaining recycled concrete aggregates involves crushing concrete, excluding rebar, bricks and soft materials (wood, glass, polystyrene), and obtaining material with fractions from 0 to 63 mm (Oikonomou, 2005). Physical properties of recycled concrete aggregates include density, moisture content, porosity, water absorption, grain shape, fractional composition and filtration properties. In road construction and dam design, the filtration coefficient is crucial. For cost reduction and waste management, the filtration coefficient can be predicted based on physical properties instead of performing costly field or laboratory tests. Machine Learning is employed to more effectively amalgamate concealed details within datasets. The objective of machine learning involves utilizing algorithms to unveil connections between attributes present in datasets, and these revelations can subsequently enhance the procedure of making informed decisions. The purpose of this publication is to demonstrate the predictive capabilities of AdaBoost and Artificial Neural Network algorithms for estimating the filtration coefficient for recycled concrete aggregates (RCA).

2 MATERIAL

The concrete aggregate used in the study came from the demolition work of a repaired road surface. The grain size curves are presented below in Table 1.

Table 1. A summary of the material's grain size range.

	Minimum	**Maximum**
Particle size (d_5), [mm]	0.15	0.17
Particle size (d_{10}), [mm]	0.28	0.30
Particle size (d_{17}), [mm]	0.60	0.80
Particle size (d_{20}), [mm]	0.98	1.30
Particle size (d_{30}), [mm]	1.90	2.20
Particle size (d_{50}), [mm]	3.30	3.90
Particle size (d_{60}), [mm]	5.50	7.80
Particle size (d_{90}), [mm]	9.80	12.50

Figure 1 presents the results of the coefficient of permeability tests with a compaction energy of 0.59 J/cm^3 and 2.65 J/cm^3.

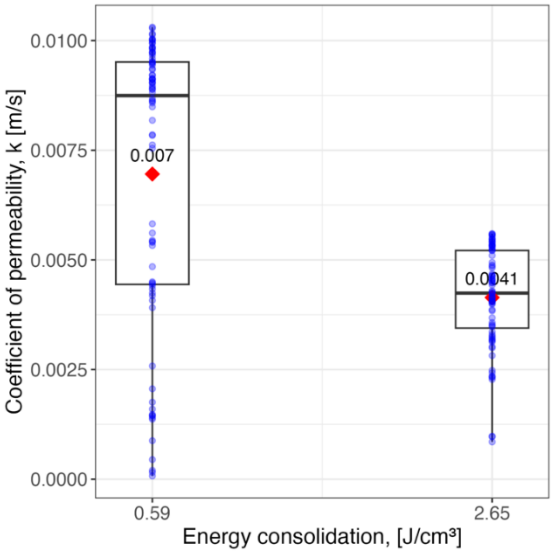

Figure 1. The results of the coefficient of permeability tests.

3 METHOD

A constant head method was applied to test the coefficient of permeability. Artificial Neural Networks and the newer boosting method, AdaBoost, were used for testing and predictive analysis. A brief overview of both Machine Learning algorithms is presented below.

Artificial Neural Networks, often referred to as ANNs or neural networks, represent a widely adopted technique in the realm of machine learning, employed to scrutinize and comprehend data by utilizing an intricate network of decision-making layers. These networks are essentially composed of interconnected decision-making entities, known as nodes, which collaborate through connections akin to the synapses of biological neurons. The arrangement of these nodes takes the form of layers, with the initial layer usually being fed with a comprehensive dataset. This initial layer constitutes raw input data, encompassing a spectrum of information formats such as numerical values, textual data, and even visual or auditory components like image pixels or sound waveforms. In the functioning of an ANN, each input node functions as a transmitter of information, conveying its input to the subsequent layer of nodes via the network's interconnections. This process enables the network to progressively synthesize and process data, capturing intricate relationships among diverse attributes (Lagaros, 2023; Shahin et al., 2021).

The core objective of AdaBoost is the amalgamation of numerous weak learning attributes into a singular potent learning attribute. This technique centers its

attention on these weak learning attributes, often taking the form of decision trees with minimal partitions, akin to what is colloquially known as decision trunks. The primary emphasis lies in enhancing the performance of these less complex learning components and fusing them into a formidable collective force, capable of achieving more robust and accurate outcomes (Lin et al., 2006; Zhou & Yu, 2009).

Cross-validation serves as a fundamental tool within the realm of Machine Learning, aiming to assess a model's capacity for predicting data outcomes. The process involves a parameter known as "k," which signifies the number of partitions in which the dataset is to be segregated. Upon selecting a specific value for "k," it can be directly utilized to characterize the model; for instance, when k equals 10, it transforms into a 10-fold cross-validation (Browne, 2000).

In practical terms, cross-validation entails utilizing a limited dataset to gauge how proficiently the model is likely to perform when making predictions on new, previously unseen data. This practice is particularly advantageous as it mitigates the risk of overestimating the model's predictive prowess, which can occur when using other evaluation techniques (Fushiki, 2011).

This methodology is especially appealing due to its simplicity and comprehensibility. It contributes to the creation of a more dependable model, fostered by the learning and testing phases of its development. The cumulative outcome of k-fold cross-validation is distilled through the computation of the average skill scores exhibited by the model. To gain a comprehensive understanding, it is advisable to incorporate a measure of the fluctuation within these skill scores, which can be conveyed by parameters such as the standard deviation or standard error. The results were verified with the use of error analysis, for individual models were estimated:

- Root Mean Square Error (RMSE):

$$RMSE = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y})^2} \quad (1)$$

- Mean Squared Residuals (MSR):

$$MSR = \frac{\sum_{i=1}^{n}(\hat{y}_i - y_i)^2}{n} \quad (2)$$

- Mean Absolute Error (MAE):

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - y_t^P| \quad (3)$$

- Coefficient of determination (R^2):

$$R^2 = \frac{\sum_{i=1}^{N}(\hat{y}_i - \bar{y})^2}{\sum_{i=1}^{N}(y_i - \bar{y})^2} \quad (4)$$

SHAP analysis was also performed.

4 RESULTS

4.1 Analysis of prediction results

Table 2 presents the prediction results of the permeability coefficient for both algorithms.

The following physical characteristics of the investigated Recycled Concrete Aggregate (RCA) were used to determine models based on AdaBoost and Neural Network algorithms: grain sizes at selected percentage content, including smaller sizes (d_5, d_{10}, d_{17}, d_{20}, d_{30}, d_{50}, d_{60}, d_{90}), grain size curvature index (C_C), and uniformity coefficient (C_U), volumetric density of the skeletal gravel structure, porosity index, and degree of compaction. In addition to material properties, the prediction also included the gradient at which the test was performed. It was decided to include the gradient as an important parameter of the study.

In the case of the training sample, better results of fitting to the observation data were obtained for the AdaBoost algorithm, in its case the R^2 was 0.959, for Neural Network the R^2 was 0.682.

Table 2. Evaluation of training set.

Model	RMSE	MSR	MAE	R^2
AdaBoost	0.001	3.04×10^{-7}	3.62×10^{-4}	0.959
Neural Network	0.002	2.39×10^{-6}	1.26×10^{-3}	0.682

In the test sample (Table 3) the R^2 results obtained for the algorithms were lower for AdaBoost the coefficient of determination was 0.886, and for Neural Network it was 0.640.

Table 2. Evaluation of test set.

Model	RMSE	MSR	MAE	R^2
AdaBoost	0.001	8.07×10^{-7}	6.34×10^{-4}	0.886
Neural Network	0.002	2.53×10^{-6}	1.30×10^{-3}	0.640

The results of the prediction of the filtration coefficient versus the results from the observations are presented in the figures below. For the AdaBoost algorithm for the training sample in Figure 2, for the test sample in Figure 4, the Neural Network algorithm in Figure 3 for the training sample and Figure 5 for the test sample. The R^2 results for both algorithms translate into a distance of the individual results from the reference line, and thus larger values of the residuals. Comparing all the graphs, one can notice a greater concentration of results around the reference line in the case of the AdaBoost algorithm, which harmonizes with the obtained high R^2 results and low error results for this algorithm.

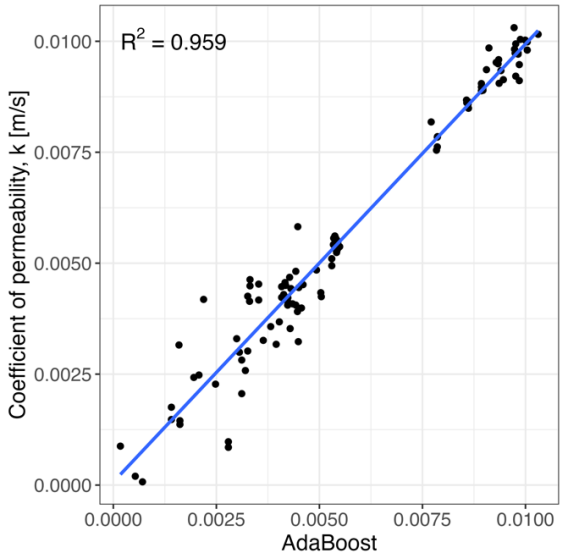

Figure 2. Training set – AdaBoost.

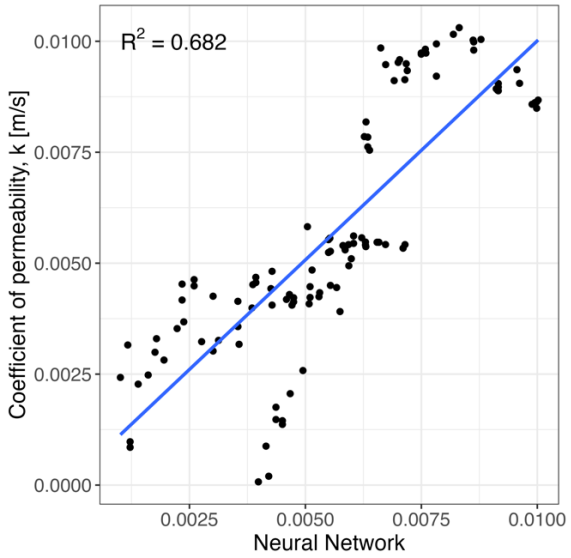

Figure 3. Training set – Neural Network.

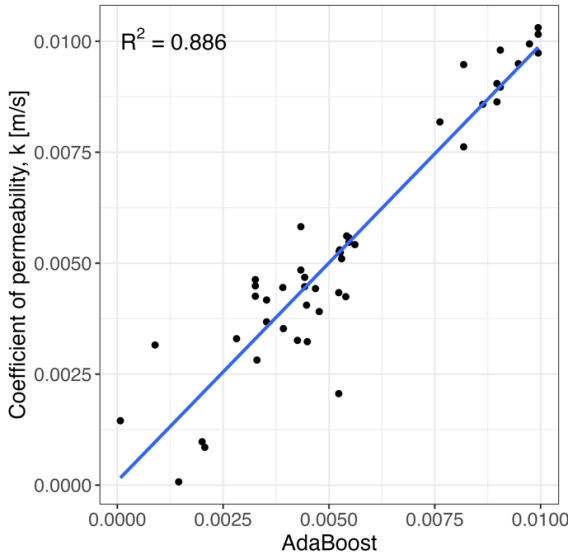

Figure 4. Test set – AdaBoost.

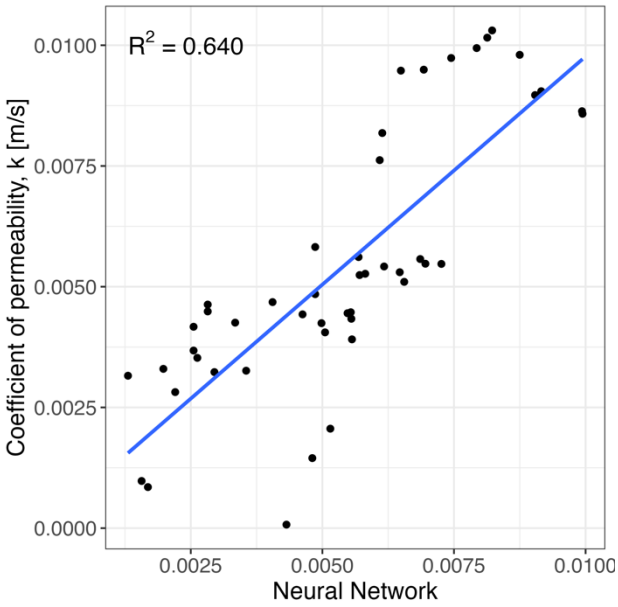

Figure 5. Test set – Neural Network.

Significant discrepancies in the results obtained by the various algorithms should be attributed to their different operating model. Adaboost and Artificial Neural Networks are two distinct approaches to machine learning, each with its characteristics and applications.

Adaboost is an ensemble learning method, specifically a boosting algorithm that combines multiple weak learning algorithms to create a strong learning algorithm. The algorithm sequentially matches these weak learning algorithms to the data, with each successive learning algorithm paying more attention to instances misclassified by previous ones. Artificial Neural Networks are a type of machine learning model inspired by the structure and functioning of the human brain. The process of learning an algorithm is usually done through backpropagation, in which errors are propagated backward through the network, updating the weights to minimize the error. Neural networks require significant amounts of labeled data to train, especially for tasks involving high-dimensionality inputs. Increasing the number of analyzed results may lead to reduced errors.

4.2 Interpretation of results using the SHAP technique

Explanatory methods for predictive models generated by machine learning algorithms offer crucial insights into the inner workings of these algorithms, enabling comprehension of the relationships among dataset features and their impact on model outcomes. Efforts to combine prediction and interpretation models give rise to an unavoidable trade-off between prediction

accuracy and the ease of model interpretation. To address this, the concept of explainable artificial intelligence (XAI) comes into play. In XAI models, such as local interpretable model-agnostic explanations (LIME) and Shapley additive explanations (SHAP), prediction and interpretation models are developed independently. These models enhance interpretability without compromising prediction accuracy.

Interpreting the decisions made by machine learning models like Artificial Neural Networks and Adaboost can be challenging due to their complex structures and opaque decision-making processes. The SHAP technique assigns specific scores to input features in the dataset based on their relevance in predicting the target value. Additionally, it is commonly applied for feature selection and dimensionality reduction, enhancing machine learning model performance by removing less pertinent features.

Applied to ANNs, the SHAP value method helps reveal which input features have the greatest impact on the network's predictions. By studying SHAP values for different features across multiple instances, patterns can be identified and insights can be gained into how the network processes information.

SHAP values can be applied to Adaboost by considering the contribution of each weak learner to the ensemble prediction for a particular instance. This involves evaluating how a change in input features affects the predictions made by each weak learner and aggregating these effects to calculate SHAP values for the ensemble's predictions. Unlike ANNs, Adaboost models are more interpretable because they consist of a collection of simpler models. Therefore, interpreting the contribution of individual weak learner models using SHAP values can provide simpler insights into model behavior.

Figures 6 and 7 in this paper employ SHAP to elucidate the role of features in prediction models, with SHAP calculating the impact of each feature on the predictions made by the learned model.

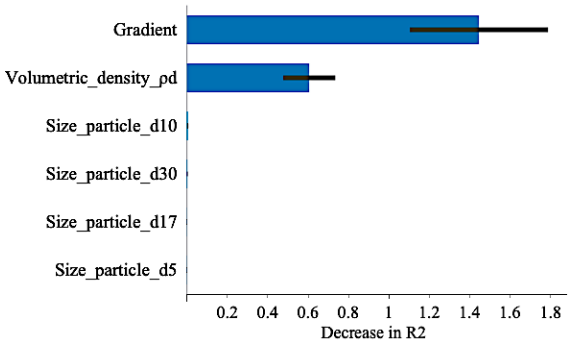

Figure 6. Feature Importance – AdaBoost.

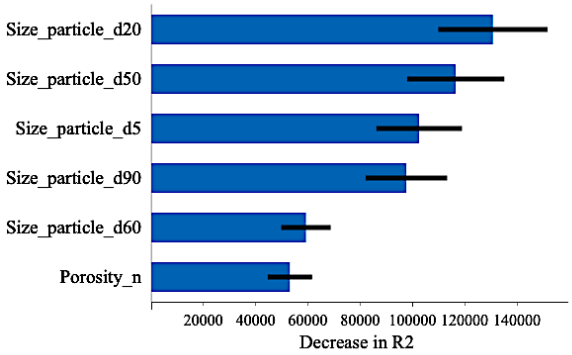

Figure 7. Feature Importance – Neural Network.

The RCA features that turned out to be particularly relevant to the model determined using the AdaBoost algorithm were gradient and volumetric density, in the second place the model took into account particle size in the case of the Neural Network where particle size d_{20}, d_{50} and d_5.

5 CONCLUSIONS

This study explores sustainable practices in recycling concrete aggregates, particularly in predicting the filtration coefficient for recycled concrete. Using machine learning techniques, AdaBoost and Neural Network algorithms were employed and compared. AdaBoost outperformed in the training sample (R^2 = 0.959), and testing sample (R^2=886). The SHAP technique enhanced interpretability, highlighting key features like gradient and volumetric density for AdaBoost and particle size (d_{20}, d_{50}, and d_5) for Neural Network. Overall, the study emphasizes the potential of machine learning in sustainable material practices.

Probabilistic stability assessment of deforested steep slopes using 3D finite element method

Étude probabiliste de la stabilité de pentes raides défrichées en utilisant la méthode des éléments finis 3D

A. Ebener*, K. Lesny
University of Siegen, Siegen, Germany
**andra.ebener@uni-siegen.de*

ABSTRACT: Not all effects of climate change can be described directly; changing boundary conditions bring a multitude of indirect consequences. As an example, the droughts of recent years have caused large-scale forest dieback, also in Germany, and thus led to extensive areas of calamity in the Siegerland, a region in Germany's central low mountain range. The slopes, some of which are very steep here, are no longer covered with trees, so that the root system, the natural reinforcement of the soil, begins to rot. In particular, increasing extreme events such as persistent precipitation and heavy rainfall in combination with the lack of trees raise the question of the stability of the now bare slopes. Due to the variability of soil properties and the uncertainties related to the hydrological boundary conditions as well as to vegetation rooting, a reliability-based approach is deemed to be an appropriate tool to assess the stability of deforested slopes. This paper presents the reliability assessment procedure for slopes with vegetation and discusses the challenges when practically applied to a 3D Finite Element model as compared to an analytical Limit Equilibrium model of the slope.

RÉSUMÉ: Tous les effets du changement climatique ne peuvent pas être décrits directement; les changements des conditions limites entraînent une multitude de conséquences indirectes. À titre d'exemple, les sécheresses des dernières années ont également entraîné un dépérissement des forêts à grande échelle en Allemagne et, par conséquent, de vastes zones de calamité dans le Siegerland, une région du massif montagneux central de l'Allemagne. Les pentes, dont certaines sont très raides ici, ne sont plus couvertes d'arbres, de sorte que le système racinaire, le renforcement naturel du sol, commence à pourrir. En particulier, l'augmentation des événements extrêmes tels que les précipitations persistantes et les fortes pluies combinées au manque d'arbres soulève la question de la stabilité des pentes désormais dénudées. En raison de la variabilité des propriétés du sol et des incertitudes liées aux conditions limites hydrologiques ainsi qu'à l'enracinement de la végétation, une approche basée sur la fiabilité est considérée comme un outil approprié pour évaluer la stabilité des pentes déboisées. Cet article présente la méthode d'évaluation de la fiabilité des pentes avec végétation et examine les défis liés à l'utilisation d'un modèle 3D par éléments finis par rapport à un modèle analytique d'équilibre limite de la pente.

Keywords: Slope stability; probabilistic analysis; failure probability; vegetation; Monte Carlo Simulation.

1 INTRODUCTION

Initial stability investigations of calamity areas on steep slopes in the Siegerland, a German low mountain region, which were caused by the drought of past years, made clear that purely deterministic considerations may not be sufficient to represent the uncertainties of the factors influencing slope stability. Probabilistic approaches instead are suitable to take into account the variability of relevant input parameters and uncertainties in their determination.

The future generation of Eurocode 7 (FprEN 1997-1:2024) will explicitly allow the verification of limit states by reliability-based methods other than the conventional semi-probabilistic approach with partial factors. It further includes explicit recommendations for limit state verification using numerical methods.

This article, therefore, illustrates how to practically represent random variables in a stability assessment of a natural slope considering the effect of tree roots in a Finite Element (FE) analysis. The challenges associated to the reliability-based stability assessment using FE modelling are discussed in comparison to the application of an analytical Limit Equilibrium (LE) model. For this purpose, the geometry and the selection of soil parameters for the slope model have been deliberately kept simple.

2 CONSIDERATION OF VEGETATION IN THE STABILITY ANALYSIS

Especially in naturally formed slopes and hillsides, vegetation generally, but not exclusively, has a positive impact on slope stability (e.g. Schwarz et al., 2013; Rickli et al., 2002), which is expressed in two ways: mechanical effects and hydrological effects, whereby the hydrological effects are not addressed here. Among the mechanical effects is the reinforcement of the soil by the roots, increasing the shear strength of the soil. Roots can also anchor themselves in deeper layers, thus supporting the uphill soil mass against sliding. However, weight of vegetation and its associated downhill forces increase the load on the slope but also the resistance forces.

The enhancement of soil shear strength is a result of the high tensile strength of the roots and the density of the plant root system. However, due to the natural and somewhat random orientation of roots, the influence on the friction angle is assumed to be minor (Gray et al., 1982). Instead, the increase in shear strength through the root system is typically be represented by an increase in soil cohesion, known as root cohesion (c_r). The root cohesion can thus be integrated into the Mohr-Coulomb failure criterion to describe the soil's shear strength as follows:

$$\tau = c' + c_r + \sigma' \cdot tan\,(\varphi') \qquad (1)$$

where τ (kPa) represents the shear strength of the soil, c' (kPa) is the effective cohesion, c_r (kPa) is the root cohesion, σ' (kPa) is the normal stress, and φ' (°) is the effective friction angle (e.g., Chok et al. 2015).

The positive influence of tree roots will be considered accordingly in the following stability analysis, considering the fact that the calamity areas are primarily in coniferous forests on steep slopes. The influence of grasses and shrubs will be neglected, even though it is commonly acknowledged that they may also contribute to slope stability (e.g., Ali & Osman, 2008).

3 3D-FE SLOPE STABILITY MODEL CONSIDERING VEGETATION

In the assessment of slope stability using the Finite Element Method, the linear-elastic ideal-plastic Mohr-Coulomb model is often deemed sufficient to describe material behavior (EANG, 2014). The so-called φ-c reduction is used in this approach. In this process, the shear parameters tan(φ) and c in the FE model are gradually reduced until the limit equilibrium is reached. This is indicated by termination of the FE analysis because the system can no longer achieve equilibrium.

According to FprEN 1997-1:2024, the φ-c reduction starts with representative values of the shear parameters. The safety of the analysed slope is defined as the ratio of available shear strength to the shear strength, below which slope stability is no longer guaranteed, expressed as the safety factor (SF):

$$SF = \frac{c}{c_f} = \frac{tan(\varphi)}{tan\,(\varphi_f)} \qquad (2)$$

where the shear parameters c_f and tan(φ_f) describe the shear strength at the limit state (f: failure).

To illustrate the practical approach of a reliability assessment based on numerical analysis of the ultimate limit state of the slope within this paper, the geometry of the 3D FE-model has deliberately kept simple. The investigated slope is 5 m high and has an inclination of 30°. To consider the effect of vegetation in the stability analysis, a distinct soil layer is defined as a rooted zone, where the cohesion is increased by the root cohesion c_r (see Figure 1). The thickness h_r (m) of the rooted soil depends on the typical rooting depth of the existing vegetation and is subject to both spatial and temporal variations. However, the influence of the variation of h_r is not part of the investigations in this paper. Hence a constant value of h_r = 1 m is assumed. In addition, no groundwater was taken into account at this point. The mesh was created with 10-noded elements and a medium element distribution. In general, a finer mesh may lead to a more accurate solution, but a finer mesh also increases the calculation time. Therefore, a medium mesh with low computation time was used for the purpose of this generic study.

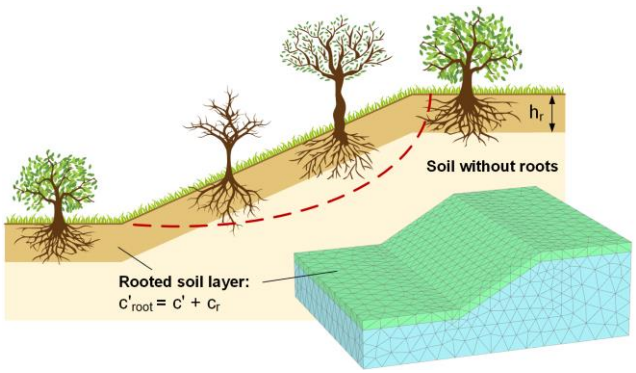

Figure 1. Consideration of vegetation in the FE model by a simplified rooted soil zone.

4 DESCRIPTION OF SCATTERED VARIABLES AND THEIR EFFECTS

Both the material properties of the soil and vegetation exhibit a high degree of variability, leading to

significant uncertainties in their determination. To account for these uncertainties in geotechnical analysis and design, probabilistic approaches are utilized. In the future generation of Eurocode 7 (FprEN 1997-1:2024), these methods are explicitly recognized as an alternative to the traditional design approach involving partial safety factors, aiming to verify a sufficient safety of a geotechnical structure.

Probabilistic approaches rely on the use of probability distributions to model uncertainties in soil properties, geometry, load assumptions, and calculation models. In contrast to semi-probabilistic methods, which rely on a single estimate of parameters, probabilistic approaches allow for the direct consideration of uncertainties and their impacts on the reliability of a system. One fundamental investigation is the probabilistic sensitivity analysis, which can be used to analyse the effect of parameter variability and detect the parameters with the greatest influence on the failure mechanism under study. Based on this, the relevant variables can be modeld as random variables in further reliability studies. Ebener & Lesny (2023) illustrate the performance of a probabilistic sensitivity analysis for the example addressed in this paper.

In the slope model presented here, the parameters c', c'_{root}, and φ' were modeled as random variables represented by probability distribution functions. For the implementation, appropriate distribution functions had to be chosen. Figure 2 displays the selected distribution functions of the soil and vegetation parameters, which are a normal distribution for the friction angle φ' and a log-nomal distribution for the cohesion c' and the root cohesion c'_{root}. Both the associated parameters mean and variance as given in Figure 2, as well as all other deterministic soil parameters were adopted from the literature (e.g., Uzielli et al., 2006; Keller, 2017) and are typical for soils at natural hillsides in the region of the Siegerland.

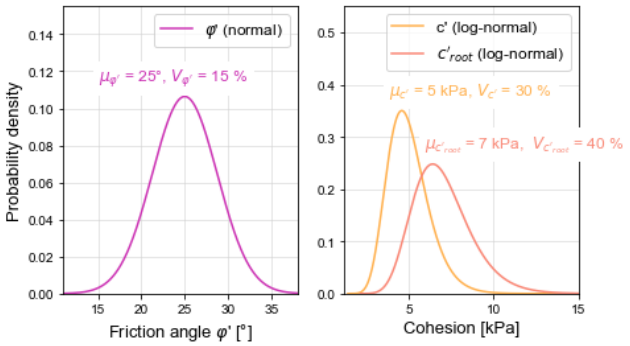

Figure 2. Distribution functions of the random variables assumed in the model.

Accordingly, the deterministic parameter were set to soil unit weight $\gamma = 20$ kN/m³ and Young's modulus $E = 10^4$ kN/m². The poisson's ratio ν was assumed to be 0,35 and the dilation angle ψ to 0° (also EANG, 2014).

5 CALCULATING THE PROBABILITY OF FAILURE

5.1 General application

To assess the probability of failure (P_f) or the reliability index (β), the structural performance is characterized by a limit state function g(X). This function is defined so that g(X) = 0 delineates a limit state separating undesirable ($g < 0$) from desirable ($g \geq 0$) conditions (TC250/SC7/TG-C3 2023). For the slope in the FE model, the limit state function is defined as:

$$g = SF - 1, \tag{3}$$

from which the following can be deduced for the assessment of slope stability in a similar manner:

$$SF \begin{cases} < 1, & unstable\ slope \\ \geq 1, & stable\ slope \end{cases} \tag{4}$$

If the slope stability is now considered as a function of random variables, the slope stability can be assessed for each possible parameter combination (sample). The results of the computational runs, resulting in a safety factor SF for each sample which can then be used in the limit state equation, can be presented as a density function with the corresponding probabilities of occurrence or frequencies. The area under the function less than 0 corresponds to the probability of failure P_f of the slope, which is displayed as failure region in Figure 3.

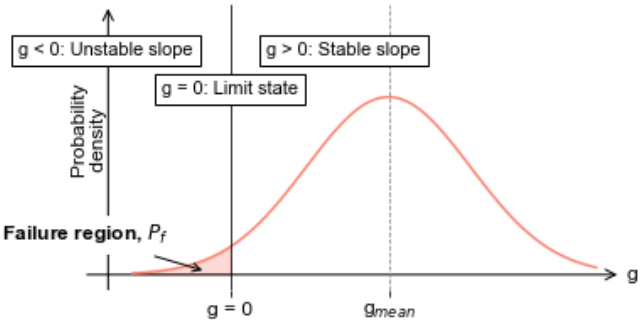

Figure 3. Distribution function of the limit state function, calculated with the resulting safety factor SF for each sample; shaded area represents the failure region corresponding to the probability of failure P_f.

5.2 Target reliability

The selection of a target reliability is crucial in geotechnical design as it forms the basis for ensuring the safety and reliability of geotechnical structures. It allows engineers to assess the probability of failure and its potential impacts on the environment, society, and the economy, ensuring the long-term stability and sustainability of such projects. In accordance with ISO 2394:2015, the selection of target failure probabilities should take into consideration various factors such as the severity and type of failure, economic consequences, societal disruptions, environmental impacts, sustainable use of natural resources, and the associated costs and efforts required to mitigate the risk of failure. EN 1990 Annex C outlines specific reliability index values (β values) for a reference period of 50 years. It is worth noting that different target reliability levels for various reference periods can be established through the National Annexes. A report from JRC (2023) sheds light on the origins of these target values, originally designed for use in buildings and bridges. However, the reliability calibration study within the same report suggests that these target values may also be applicable to geotechnical structures, as exemplified in the case of spread foundations and piled foundations (TC250/SC7/TG-C3, 2023).

5.3 Basic analysis – crude Monte Carlo simulation

In order to approximate the density function of, in this case, SF, sampling methods are widely used. Monte Carlo simulation (MCS) in its simplest form (crude Monte Carlo) is a sampling method, which collects a defined number of random samples from the probability distributions of the random variables involved in a process or system under study. For the calculation of the probability of failure with the MCS, a total of n_{total} samples are generated based on the underlying distribution functions (sampling). The evaluation involves determining which randomly generated parameter combinations result in failure (n_f) when evaluating the corresponding limit state function (in this case Equation 3). The estimator of the probability of failure P_f is the ratio of the number of realizations resulting in failure (n_f) and the total number of realizations or samples (n_{total}):

$$P_f \approx \frac{n_f}{n_{total}} \tag{5}$$

The accuracy of the estimate depends on the number of (failed) realizations, which can be expressed in terms of the coefficient of variation of the estimated probability of failure:

$$V_{Pf} = \sqrt{\frac{1-P_f}{n_{total} \cdot P_f}} \tag{6}$$

A coefficient of variation (V_{Pf}) ranging from 5 to 10% is deemed adequately precise for assessing structural reliability. Consequently, V_{Pf} can serve as a convergence or termination criterion for the Monte Carlo simulation and serves as the foundation for determining the uncertainty bounds of the estimated values. Equation 7 suggests that the required sample size n_{req} can be determined using a prior estimate of the probability of failure (TC250/SC7/TG-C3, 2023):

$$n_{req} \approx \frac{1}{V_{pf}^2 \cdot P_f} \tag{7}$$

5.4 Implementation and problems

To obtain reliable statements regarding the failure probability of a slope or any other geotechnical structure, a high number of MCS is required to represent the overall population of possible parameter combinations as realistically as possible. For example, according to Table C.3 (prEN 1990:2022) for a structure assigned to Consequence Class 2 the target reliability index is $\beta = 3.8$ which corresponds to a failure probability of $P_f = 1 \cdot 10^{-4}$. With Equation 7 this means that one million (10^6) samples would be required to obtain a sufficiently reliable result with a coefficient of variation of 10%. The presented simple model in Plaxis 3D has a computation time of about 3 minutes with a medium mesh coarseness, resulting in a total computation time of 3,000,000 minutes ≈ 2,083 days on the available computer for a required number of simulations with randomly generated parameter combinations of one million. This, of course, is unrealistic for practical applications.

For comparison and to illustrate the need for large sample sizes, MCS for the model slope was performed using a limit equilibrium method of slices with Plaxis 3D LE. The method chosen here was the General Equilibrium Method (GLE) according to Fredlund & Krahn (1977). For a sample size of one million using this model the total computation time was about 2,000 minutes.

Figure 4 shows the results of the MCS for sample sizes n = 100; 1,000; 10,000; 100,000 and $1 \cdot 10^6$. The safety factors, along with their associated relative frequencies for the MCS with various sample sizes n, illustrate the necessity of large sample sizes. With small sample size, a failure probability of 0.00% was calculated, meaning that no combination resulted in a

safety factor less than 1.0 in the randomly generated samples. Only sample sizes starting from $n \sim 3{,}000$ or larger contained parameter combinations that can lead to failure (which is shown in the blue ellipse in Figure 4). Thus, a smaller sample size implies a 100% safety, albeit solely due to the random absence of parameter combinations resulting in failure. While the probability of failure for the MCS in this example is no longer 0 from $n \sim 3{,}000$, it varies between the sample sizes up to about $n \sim 250{,}000$ and slowly converges to an approximately constant value of $P_f \approx 0.03\%$ ($= 3 \cdot 10^{-4}$) with increasing sample size. The limits mentioned here are an outcome of a unique implementation of the MCS with the specified sample sizes n. However, these limits may differ when the MCS is repeated with the same sample sizes, especially in the case of small numbers of samples which only represent a limited number of randomly selected parameter combinations. On the other hand, the results converge if the sample sizes are large enough, as a significantly broader range of possible parameter combinations is represented, thus approximating the overall population. In the case of large sample sizes, it can thus be assumed that even less probable and potentially destabilizing parameter combinations will be considered in the safety assessment.

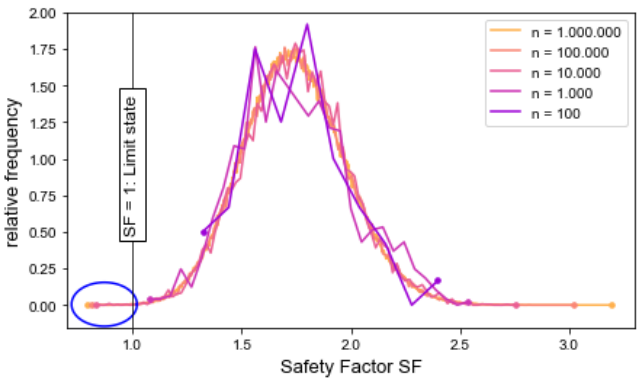

Figure 4. Results of MCS, distribution of the safety factor SF for different sample sizes n; lowest and highest values of each distribution are market with dots.

6 FURTHER STEPS FOR RELIABILITY ANALYSIS OF NATURAL SLOPES

In order to evaluate the reliability of natural slopes using FE, the Monte-Carlo Simulation is not practicable and other methods are needed, for example, surrogate modeling, where the system response to the random variables can be predicted without modelling the real process itself. Surrogate models can provide results within seconds and can be used for MCS (e.g., Furtney et al., 2022). Furthermore, other sampling methods can be used, such as importance sampling, a variance reduction technique that use additional prior information about the failure region for sampling only close to the failure/safe boundary (e.g. TC250/SC7/TG-C3, 2023).

Another relevant aspect of modeling and reliability assessment of natural slopes, which has not been addressed here, is the representation of external influences such as precipitation in particular which can have a significant impact on stability and thus on reliability. In addition, natural and vegetated slopes in particular are subject to high spatial variability in terms of topography and soil stratification as well as soil properties and vegetation. The spatial variability can be taken into account e.g. using various geostatistical methods (e.g., Chilès & Delfiner, 2012). Further, by including vegetation in the slope model, it is possible to study the effects of cleared forests, i.e., the influence of root systems that are no longer present on the reliability of a slope.

In addition, studies have shown that the probability of failure is sensitive to the correlation between shear parameters which as well should be considered in the probabilistic analysis (e.g., Wang & Akeju, 2016).

ABSTRACT: This paper presents several results obtained from the monitoring process of multiple deep excavations performed in Bucharest area. These projects comprised several retaining structures for deep excavations in Bucharest with 2 basement levels or more (more than 6 m in depth), using top – down method or supported by struts or ground anchors. The retaining walls for the deep excavation were monitored during the works for wall deformations (inclinometers), ground settlements, neighbouring building settlements, groundwater level variation etc. The database was started by the authors several years ago for Bucharest specific lithology and geotechnical characteristics, and through this paper supplementary data available is considered. Thus, the previously evaluated indices and ratios, such as the ratios between the excavation depth and length and thickness of the retaining wall, or the ratio between vertical displacement of the ground outside the excavation and horizontal displacement at the top of the retaining wall are reanalysed and updated values are provided. These data and the comparisons made between the projects are very useful to designers for future similar works.

RÉSUMÉ: Ce papier présente plusieurs résultats obtenus à partir du processus de surveillance de multiples fouilles profondes effectuées dans la région de Bucarest. Ces projets comprenaient plusieurs structures de soutènement pour des excavations profondes à Bucarest avec 2 niveaux de sous-sol ou plus (plus de 6 m de profondeur), en utilisant la méthode top-down ou soutenues par des butons ou des ancrages. Les parois de soutènement pour les excavations profondes ont été surveillés pendant les travaux pour détecter les déformations des parois (inclinomètres), les tassements du sol, les tassements de bâtiments voisins, la variation du niveau de la nappe phréatique, etc. La base de données a été créée par les auteurs plusieurs années auparavant pour la lithologie et les caractéristiques géotechniques spécifiques de Bucarest et, dans le présent document, des données supplémentaires disponibles sont prises en compte. Ainsi, les indices et ratios précédemment évalués, tels que les rapports entre la profondeur d'excavation et la longueur et l'épaisseur des parois de soutènement, ou le rapport entre le déplacement vertical du sol à l'extérieur de l'excavation et le déplacement horizontal en tête de la paroi sont réanalysés et des valeurs actualisées sont fournies. Ces données et les comparaisons faites entre les projets sont très utiles aux concepteurs pour de futurs travaux similaires.

Keywords: Monitoring; deep excavations; database creation.

1 INTRODUCTION

Deep excavations in urban areas are works that can affect neighbouring buildings and involve relatively high risks related to their structural integrity. In these conditions, monitoring of the retaining walls of deep excavations, as well as of the neighbouring constructions, is not only indicated, but even mandatory, in order to identify an alert or damage situation, and also to compare the previously calculated efforts and deformations with the real situation (Ciocaniu et al., 2023, Popa, 2010).

In recent years, the calculation models of the retaining walls for deep excavations have evolved a lot. However, the complexity of the characteristic interaction parameters, related especially to the terrain, but also to the configuration of the site in terms of existing constructions nearby, lead to a high degree of uncertainty in the results obtained through

calculations, especially in terms of displacements and the deformations of the supporting work and its surroundings.

The only way to verify the results and validate the calculation models used is monitoring throughout the execution works and sometimes during the service life.

The data obtained through monitoring, however, become really useful by synthesizing the measurements in a database that allows a quick evaluation, even in the preliminary design phase, of the behavior of a retaining wall according to different characteristics: its length in relation to the depth of excavation, lateral displacements related to the free height of the wall, neighboring settlements related to the support system of the wall, etc.

For this reason, the creation of such a database (Marcu et al, 2015) was started many years ago. This database currently has reached over 30 retaining walls for deep excavations over 3 m in urban areas, which were monitored.

The paper presents some aspects of this database and makes some remarks regarding its use.

2 FEATURES OF THE DATABASE

As it was presented in the previous paper (Marcu et al, 2015) the database includes the following features:

- general project information;
- geometric data: excavation depth, retaining wall thickness and length, cantilever height, free height etc.
- main design results: maximum efforts in the retaining wall, horizontal displacements of the retaining wall at characteristic points, vertical displacements;
- measurements from the monitoring process: values of the horizontal and vertical displacements of the retaining wall and of the neighboring constructions, efforts in props or anchors;
- processing area: the evaluation of some behavior indices, such as the ratio between the depth of the excavation and the length or thickness of the wall, the ratio between calculated and measured values, the ratio between vertical and horizontal displacements etc.

In Table 1 are shortly presented the general data of the analyzed works and the geometrical characteristics of the retaining structures.

Table 1. Information of the analysed works and geometric data.

No.	D-wall solution	Support System	H [m]	L [m]	t [cm]
1-6	SW	TD	13-16.4	21-30	60/80
7-9	SW	IS	6-9.4	16.8-20	60
10-17	TP	IS	5.8-11.5	10-20.1	60
18	SP	HS	9.3	17	90
19	SW+SP	3 lvs p-s HS	13.2	19.5	60/90
20	SW	3 lvs A	16	24	80
21	SW	A	12	18	60
22-26	SW	clv	4.8-6	15-19	60
27-33	TP	clv	3-6.6	7.5-13.7	60

SW- Slurry Walls; SP - Secant Piles; TP – tangent piles; TD – Top-Down; HS – Horizontal Struts; IS – Inclined struts; A – Anchorages; p-s – pre-stressed; clv – cantilevel; H - excavation depth; L- DW length (depth); t – DW thickness

Some supplementary remarks should be made to the information given in Table 1:

- the buildings have 2-5 basements;
- when the retaining wall consists of slurry walls or secant piles, it indicates that the hydrostatic level is high (5-9m) and the length of the wall might have been dimensioned for watertightness condition;
- in the cases the top-down technology was chosen or three levels of pre-stressed steel struts were used, the displacements needed to be limited to protect the neighbouring buildings.

3 PROCESSING AND ANALYSIS OF DATABASE VALUES

By using the values measured in the monitoring process and/or by relating them to the values obtained through calculations, a series of indicative indices can be obtained regarding the behaviour of a retaining wall of a deep excavation, depending on the technological solution (diaphragm wall, secant piles, etc.), by the support system (cantilever wall or supported with props or anchors, the top-down system) and by the geometric characteristics of the work.

It should be noted that these observations are indicative, but extremely useful, especially in the initial design phase. It should also be remembered that monitoring on the ground is subject to a certain degree of uncertainty, on the one hand related to the precision of the instruments, on the other hand to the correctness of the monitoring process (for example, the identification of a correct stage of execution of the excavation at the time of the measurements or the limitation of the inclinometric tube at the level of the tip of the wall considered fixed, etc.).

3.1 The ratio between the maximum depth of the excavation and the total length of the retaining wall

Most of the cases indicated values between 0.3 and 0.7 for the ratio between the maximum excavation depth and the total length of the retaining wall.

If the analysis is made by types of wall supports, in the case of cantilever walls this interval is 0.3-0.5, in the case of walls supported on a single level, the interval is 0.33-0.6, and in the case of walls supported on 2 or more levels, the interval is 0.4-0.7.

Of course, these intervals, depending on the lithological characteristics of the site (the presence of weak or hard layers) and the presence of underground water (which requires dewatering works), can be exceeded, in one sense or the other.

But the values of this index can be successfully used for a preliminary assessment of the total required length of a retaining wall, including the number of temporary supports.

3.2 The ratio between the maximum depth of the excavation and the thickness of the retaining wall

The values of the ratio between the maximum depth of the excavation and the thickness of the supporting wall (reinforced concrete walls, panels or drilled piles) are in the range of 7...25. The average value is 16, while the most frequent value is between 10 and 12 for the analysed works.

It must be stated, however, that the thickness of the retaining walls, especially for diaphragm walls, is directly related to the execution technology, which is normally modulated to a value of 20 cm, starting from a minimum of 60 cm. Even in the case of walls made of drilled piles, there is no greater availability in terms of diameters, although in their case atypical diameters can occasionally be found.

The index values serve to choose the thickness that corresponds both from an economic point of view (ratio between the amount of reinforcement and concrete), but also to ensure a good behavior of the wall in terms of movements.

3.3 The evolution of the maximum values of the bending moments in the retaining wall

The bending moment determined from calculations is analysed against the total excavation depth for cantilever and against the maximum free span between two supports (or between support and excavation depth), as shown in Figure 1.

For the analysis of this evolution, the bending moment was normalized by referring to the linear deformation modulus of the wall and to the maximum free span, and the excavation depth was related to the maximum length of the retaining wall (Figure 1).

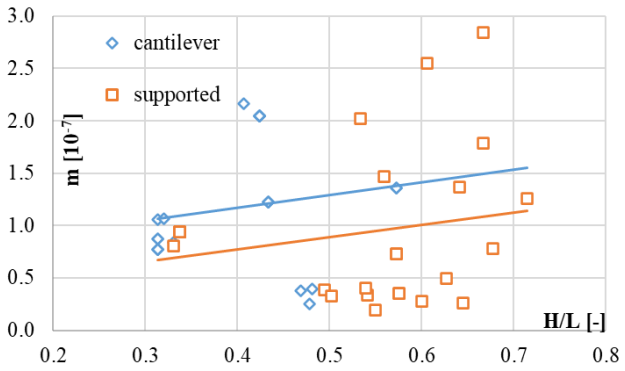

Figure 1. The variation of the bending moment with the maximum depth.

A trend of increase in the bending moment with the excavation depth is observed, as expected, but it should be noted that there is a significant spread of the data due to different ground conditions, but also for the ratio of the excavation depth and the wall length, the last being dictated by the condition of embeddment for groundwater control and not for stability.

3.4 The ratio between the maximum measured values of the horizontal displacements of the retaining wall and the depth of the excavation

For the evaluation of this index, the normalization of the values was used again in the following way: the horizontal displacements were normalized by the excavation depth, and the excavation depth by the length of the wall (Figure 2).

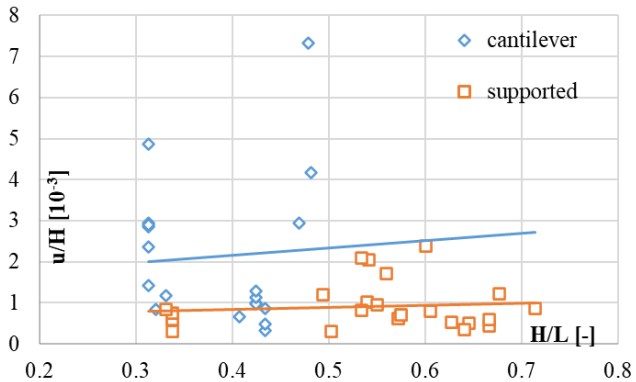

Figure 2. The variation of the wall maximum horizontal displacement with the excavation depth.

The same data spread can be observed and for this case also more because there were different displecements measured for cases where the design conditions were appreciated as similar (Ene et al.,

2019). Still, the same trend of increase in the wall displacment with the excavation depth is observed, as expected.

3.5 The relation between the settlements of the neighbouring constructions and the maximum measured values of the horizontal displacement of the wall

Again, taking into account the variables involved in this dependence, the normalization of the values was resorted to. Thus, the settlement was normalized by the distance to the excavation and the horizontal displacement of the wall was normalized by the excavation depth (Figure 3).

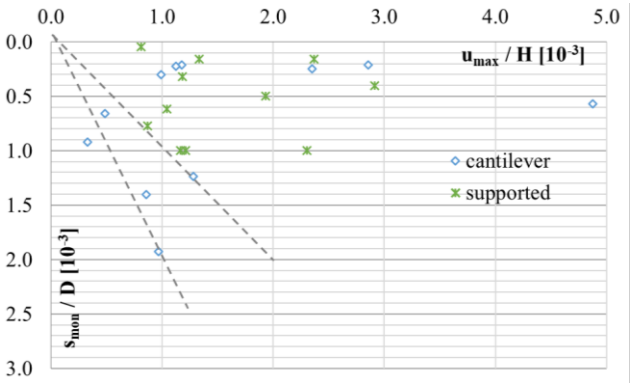

Figure 3. The variation of the settlement of the neighbouring constructions with the maximum displacement of the retaining wall.

It is observed that there is a great spread of the data, justified by the diversity of the neighbouring buildings in terms of loading, height, foundation level, but also because the values of the measured values are small and thus leading to a sensitive ratio. However, it can be concluded that for all the cases the ratio between the normalized settlement and horizontal displacement of the wall is below 1 for supported systems and below 2 for catilever structures.

3.6 The ratio between the measured and calculated values of the horizontal displacements of the retaining wall

For most cases, the values of this ratio fall within the range of 0.3 to 1. The sub-unit value of the ratio indicates a correct and comprehensive calculation in terms of horizontal displacements, corresponding to a typical SLS evaluation.

It should be noted that only the calculation values from the design were filled in the database and not values from back-analysis calculations that seek to obtain the most probable displacement values.

Also, there were cases when the ratio was higher than 1, meaning that the measured values were greater than those estimated for SLS, but that was mostly due to the fact that for very small values, this ratio is very sensitive.

4 CONCLUSIONS

Creating a database with calculated and measured values regarding the behaviour of deep excavation retaining walls is extremely useful in design work or even execution of these structures. Based on these records, different trends of evolution of movements related to the geometric characteristics of the retaining walls and their supported systems can be created and analysed.

Considering the influence that the retaining walls of deep excavations have on the built neighborhoods, such analyzes lead to the choice of technical solutions that meet both the necessary safety criteria and the economic ones, which ultimately means a more efficient design.

Last but not least, it represents a way of validating calculation models or a possible warning in case of behaviors that may pose a risk to the built neighborhoods.

ABSTRACT: This paper explains the concepts behind the different terms involved in the determination of ground properties within the framework of the Second Generation Eurocode 7. The process begins with the derived values that are collected in the ground investigation activities: desk study, site inspection, design investigation and monitoring. It continues to the determination of the "representative value" that is the value that affects the occurrence of the limit state. This value is either used directly in Resistance Factor Approach (RFA) verifications or factored by the partial material factor to obtain the "design value" that will be used in Material Factor Approach (MFA) verifications of the different ultimate limit states of the geotechnical structures. The future Eurocode 7 establishes two possible ways to determine such a "representative value" of a ground property: selecting the value from a limited number of test results, based on engineering judgment and comparable experience in similar cases, being in this case termed a "nominal value"; or evaluating the value by statistical methods, being in this case termed a "characteristic value". Additionally, the paper gives a brief outline of a statistical method to determine the characteristic value of a ground property that accounts for spatial variability.

RÉSUMÉ: Ce document explique les concepts qui sous-tendent les différents termes impliqués dans la détermination des propriétés du sol dans le cadre de la deuxième génération de l'Eurocode 7. Le processus commence par les valeurs dérivées qui sont collectées dans les activités d'investigation du sol : étude documentaire, inspection du site, investigation de la conception et surveillance. Il se poursuit par la détermination de la "valeur représentative", c'est-à-dire la valeur qui affecte l'occurrence de l'état limite. Cette valeur est soit utilisée directement dans les vérifications RFA, soit pondérée par le facteur matériel pour obtenir la "valeur de conception" qui sera utilisée dans les vérifications MFA des différents états limites ultimes des structures géotechniques. Le futur Eurocode 7 établit deux manières possibles de déterminer cette "valeur représentative" d'une propriété du sol : la sélection de la valeur par le jugement de l'ingénieur et l'expérience comparable dans des cas similaires, étant dans ce cas appelée "valeur nominale" ; ou l'évaluation de la valeur par des méthodes statistiques, étant dans ce cas appelée "valeur caractéristique". En outre, le document donne un bref aperçu de la méthode statistique pour déterminer la valeur caractéristique d'un terrain.

Keywords: Representative value; Nominal value; Characteristic value, Eurocode 7, Spatial variability

1 INTRODUCTION

The determination of material property values to be used in geotechnical designs is covered in Part 1/Section 4.3.2 of the 2nd generation Eurocode 7 (FprEN 1997-1:2023). Some of its paragraphs will be used in this paper to explain some of the concepts behind them.

The committee responsible for Eurocode 7 (TC250/SC7) decided in 2020 to establish four "Task Groups" (TGC1 to TGC4) to draft the following four guideline documents to help designers in the understanding, implementation, and use of EC7 in geotechnical designs, with scopes and objectives that are very related to this paper. The tittles of those guidelines are: "Determination of representative values from derived values for verification of limit states with EN1997", "Assembling the Ground Model and the derived values"; "Reliability-based methods for geotechnical design and assessment" and "Implementation of Design during Execution and Service Life". These guidelines will be published by

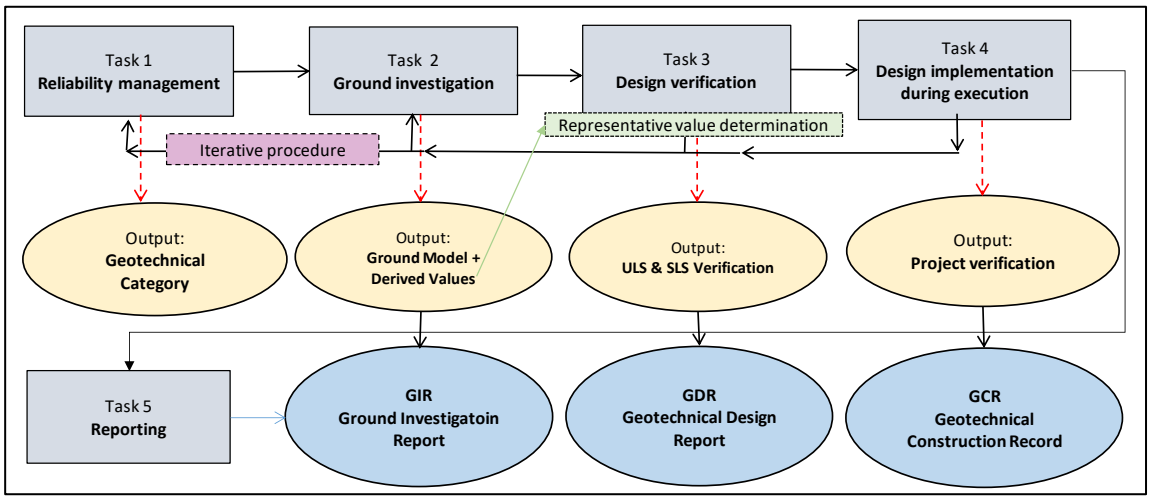

Figure 1. Tasks in the design of a geotechnical structure.

the JRC (Joint Research Centre of the European Commission) probably in 2024.

2 REPRESENTATIVE VALUE DETERMINATION IN THE DESIGN OF GEOTECHNICAL STRUCTURES

According to EN1997, the process of designing a geotechnical structure involves five major tasks, as shown in Figure 1:

1 Reliability management: a series of classifications aimed to place the geotechnical structure into a single Geotechnical Category that can be changed at each stage of design. The Geotechnical Category combines the uncertainty and complexity of the ground and ground-structure interaction with the consequence of failure of the structure.
2 Ground investigation: whose main output is the Ground Model that "comprises the geological, hydrogeological, and geotechnical conditions at the site" and it also includes the derived values.
3 Design verification: covering all the procedures to verify that no limit states are exceeded in any design situations that the structure may encounter during its service life.
4 Design implementation: ensuring that the structure is constructed while meeting the design assumptions and other detailed plans developed during the design phase.
5 Reporting: the work performed during the design and execution of the geotechnical structure must be documented by carrying out the following reports: Ground Investigation Report, Geotechnical Design Report, and Geotechnical Construction Record.

In this design process, the determination of representative values of ground properties is performed at the beginning of the "Design verification" task, when the designer analyses the derived values presented in the Ground Investigation Report, as shown in Figure 1.

3 CHAIN OF CONCEPTS RELATED TO GROUND PROPERTY VALUES: FROM DERIVED TO DESIGN VALUES

3.1 Introduction

Parallel to these different tasks, there is a set of interrelated concepts relative to the following values of the ground properties that appear in the design process: "Measured values", "Derived values, "Nominal value", "Characteristic value", "Representative values" and "Design value".

This section explains the links between such values and concepts that are adopted throughout the design process depending on the design stage. Figure 2 shows the path that a ground property value must travel from when it is obtained during the ground investigation stage to when it is used in a calculation model at the design stage to verify a limit state, either an ultimate limit state (ULS) or serviceability limit state (SLS).

3.2 Ground Investigation and Measured values

The purpose of a ground investigation is to determine the ground properties for design. Part 2 of the new Eurocode 7 gives the requirements for ground investigation, which involve the following types of investigation: a) Desk study; b) Site inspection; c) Performance of field and laboratory tests; and d) Geotechnical monitoring. The upper part of Figure 2 shows the different types of values that can be obtained during these types of investigation, which are: historical values, assessed values, measured values

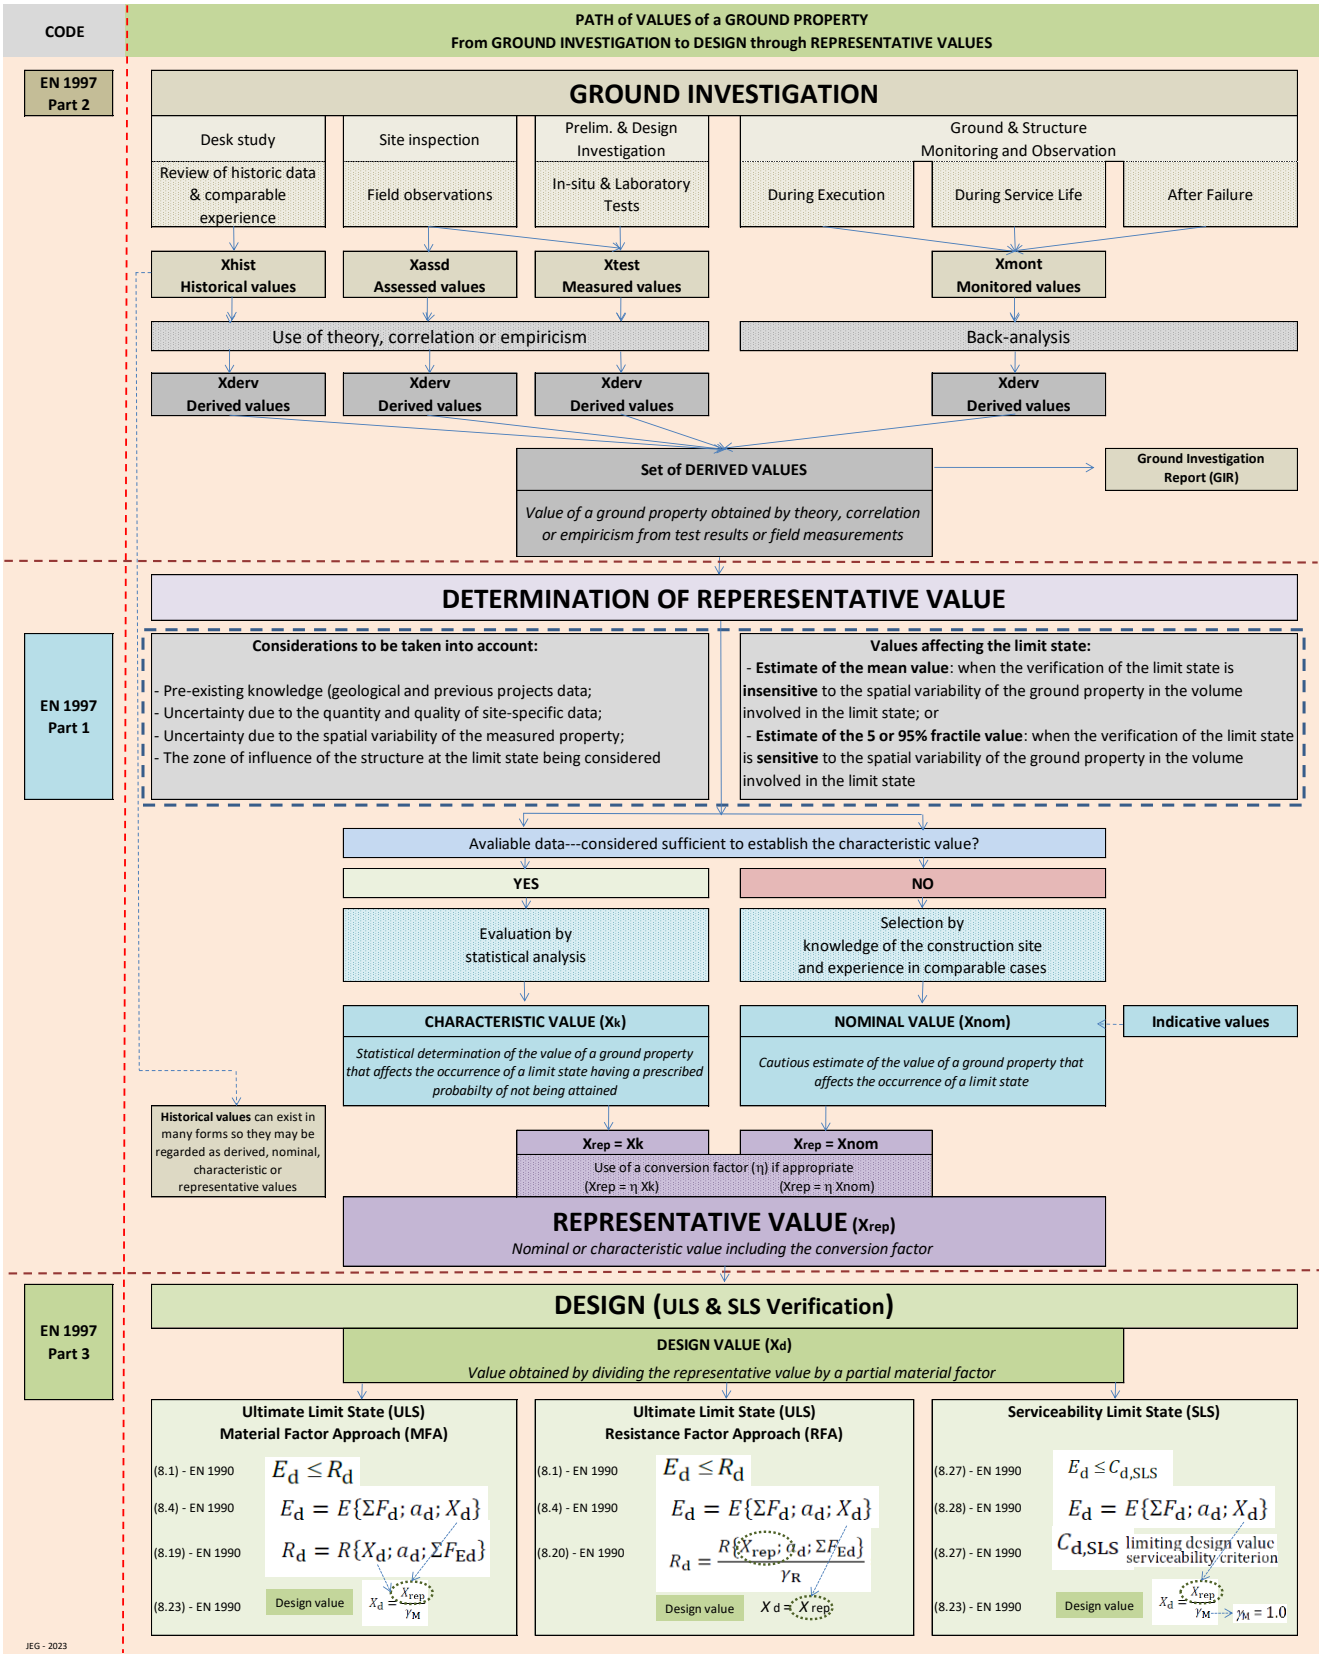

Figure 2. Path of values: From Ground Investigation to Design Stage.

and monitored values. The only value referred to explicitly in the new Eurocode 7 is the measured value, which is defined in FprEN 1997-2/3.1.2.2 as "*the value of a ground property recorded during a test*", while the others appear for the sake of explanation.

3.3 Derived values

The derived value of a ground property is defined in FprEN 1997-1/3.1.3.2, as the "*value of a ground property obtained by theory, correlation or empiricism from test results or field measurements*" and, as shown in Figure 2, may be obtained from historical values, assessed values, measured values and monitored values. Derived values are used to establish the Ground Model that, according to FprEN 1997-2:4.1(5) *"shall reference the derived values of ground properties for encountered geotechnical units*". FprEN 1997-1:3.1.6.5 states that a geotechnical unit is *"the volume of ground that is defined as a single material".*

3.4 Representative value

The representative value of a ground property (X_{rep}) is defined in FprEN 1997-1/3.1.3.5 as a "*nominal or characteristic value…*" while 4.3.2.1 states "*Representative values of ground properties to be used in ultimate and serviceability limit state verifications shall be determined from derived values presented in the Ground Investigation Report*". Consequently, "*the representative value refers to a particular ground property of a single geotechnical unit.".*

According to FprEN 1997-1:4.3.2.1(6) when available data are considered sufficient to establish the characteristic value (X_k), the representative value of a ground property (X_{rep}), should be determined from Formula 1(a). However, according to 4.3.2.1(7), when the available data are insufficient to establish the characteristic value of a ground property, the representative value should be determined from Formula 1(b), where X_{nom} is the nominal value of the ground property:

$$a)\ X_{rep} = X_k\ ; \qquad (1)$$
$$b)\ X_{rep} = X_{nom}$$

The designer needs to decide whether to determine the representative value as a characteristic or a nominal value, based on their understanding of the sufficiency of the available data, i.e. a) its quantity and quality, b) its spatial distribution, c) the extent of the zone of influence, and d) the need to avail of and take into account pre-existing knowledge in the form of comparable experience. These four considerations that need to be considered when determining the representative value are extensively explained in the TGC1 document (JRC, 2024).

While the use of statistics is not extensive in current geotechnical design practice in Europe, it is anticipated that, in the future, as ground investigation methods develop and more data become available, there will be a tendency for an increased use of statistics and of characteristic values. Nationally determined practices may also have an influence on whether the representative value is determined as a characteristic or a nominal value.

On other hand, according to 4.3.2.1(3), "*The representative value of a ground property shall be determined for each limit state, according to its sensitivity to spatial variability of the ground property in the volume of ground involved*". In 4.3.2.1(4) it is stated that "*If the limit state is insensitive to spatial variability of the ground, the representative value of the ground property shall be determined as an average value*", while in 4.3.2.1(5) it is stated that "*If the limit state is sensitive to spatial variability of the ground, the representative value of the ground property shall be determined as an inferior or superior value*".

The significance of the sensitivity of the limit state to the spatial variability of the ground leads to the three "Types of estimates" of the representative value shown in Figure 3. Selecting the appropriate representative value corresponding to Type A, B or C is a function of the designer's understanding of the extent of limit state that mobilises the ground property and the magnitude of the ground spatial variability, represented by the extent of the failure mechanism or zone of influence, L compared to the magnitude of the scale of fluctuation of the ground property (θ), as explained in subsection 3.6 of this paper. Note Type C is introduced in the TGC1 document and is not in FprEN 1997-1.

3.5 Nominal value

The nominal value of a ground property (X_{nom}) is defined in EN 1990-1/3.1.2.29 as the "*value fixed on a non-statistical basis; for instance, on acquired experience or on physical conditions*". FprEN 1997-1/ 4.3.2.3(1) elaborates this by stating that "*the nominal value of a ground property (X_{nom}) shall be selected as a cautious estimate of the (average, inferior or superior) value affecting the occurrence of the limit state (based on the knowledge of the construction site and comparable experience)*".

The nominal value is selected by the designer based on derived values, knowledge of the construction site, consideration of the design situation and limit state, and comparable experience. It is a cautious estimate of the property value chosen to represent the behaviour of the volume of ground involved in the limit state being considered.

The selection of the nominal values also follows the three types of estimates, shown in Figure 3: Type A, a cautious estimate of an average value; Type B, a more cautious estimate of an inferior or superior value and Type C, an estimate of an intermediate value between the Type A and B values.

TYPE	CONCEPT	SCALE FLUCTUATION v REFERENCE LENGTH(1)	REPRESENTATIVE VALUE
A	[In EN1997-1 // 4.3.2.1 – Paragraph (4)] (4) If the limit state is "very" **INSENSITIVE** to ground spatial variability, the Representative Value shall be determined as an **AVERAGE** value	L >> θ	Value: Nominal (Cautious) => Estimate of an AVERAGE VALUE Or Characteristic (Statistical) => Estimate of an MEAN VALUE
B	[In EN1997-1 // 4.3.2.1 – Paragraph (5)] (5) If the limit state is "extremely" **SENSITIVE** to ground spatial variability, the Representative Value shall be determined as an **INFERIOR** (or superior) value	L ≤ θ	Value: Nominal (Cautious) => Estimate of an INFERIOR / SUPERIOR Or Characteristic (Statistical) => 5% / 95% FRACTILE
C	[In TG-C1 Document // Chapter 4] If the limit state has an **INTERMEDIATE** sensitivity to ground spatial variability such that: • Type A is considered **not to be adequately cautious** and • Type B is seen **to be overly cautious**, the Representative Value shall be determined as an **INTERMEDIATE** value between the average and inferior (or superior) value	L > θ	Value: Nominal (Cautious) => Estimate of an INTERMEDIATE VALUE between Average and Inferior / Superior value Or Characteristic (Statistical) => Mean Value and 5% / 95% Fractile
Note (1): Reference length (L) = dimension of the failure surface for the limit state upon consideration			

Figure 3. Types of estimates of the representative values.

3.6 Characteristic value

The definition of the characteristic value of a ground property given in FprEN 1997-1/3.1.3.4 is the "*statistical determination of the value of a ground property that affects the occurrence of a limit state having a prescribed probability of not being attained*".

According to FprEN 1997-1/4.3.2.2(4), the characteristic value should be determined statistically from Formula 2, when a normal distribution is assumed and taking account of the number (n) of derived values:

$$X_k = X_{mean}[1 \mp k_n V_X] \qquad (2)$$

where X_{mean} is the mean value of the ground property X from a number n of derived values, V_X is the coefficient of variation of the ground property; $\mp$ denotes that $k_n V_X$ should be subtracted or added depending on whether a lower or upper value of X_k is required; k_n is a coefficient that depends on the number of derived values used to calculate X_{mean}, the level of knowledge regarding V_X, and the type of characteristic value being determined.

Formulae for k_n for different V_X cases and types of estimates (A, B or C) are given in Figure 4 (inspired by FprEN1997- 1/Table A.3), while Table A.2 gives indicative values of V_X for various ground properties.

Three different cases are identified regarding the knowledge of V_X. According to FprEN 1997-1/Annex A.4 Case 1 - V_X known - *"should be used when the coefficient of variation of the ground property is known from prior knowledge"*; Case 2 - V_X unknown – *"should be applied when the coefficient of variation of the ground property being determined is unknown ab initio*" and Case 3 - V_X assumed – "*should be applied when indicative values are used for ground properties, or for test parameters*".

In addition, FprEN 1997-1/Annex A provides formulae to determine the characteristic value for lognormally distributed data.

Cases with different knowledge concerning V_X	Types of estimates of the characteristic value		
	Type A: Estimate of the mean value ($\Gamma^2 = 0$)	Type B: Estimate of the inferior (5%) or superior (95%) fractile value ($\Gamma^2 = 1$)	Type C: Estimate of the intermediate value when $\Gamma^2 = \theta/L$
Case 1: V_X known and Case 3: V_X assumed	$N_{95}\sqrt{\frac{1}{n}}$ (A1)	$N_{95}\sqrt{1+\frac{1}{n}}$ (B1)	$N_{95}\sqrt{\Gamma^2+\frac{1}{n}}$ (C1)
Case 2: V_X unknown	$t_{95-1}\sqrt{\frac{1}{n}}$ (A2)	$t_{95,n-1}\sqrt{1+\frac{1}{n}}$ (B2)	$t_{95,n-1}\sqrt{\Gamma^2+\frac{1}{n}}$ (C2)

Figure 4. Formulae for k_n for different combinations of types of estimates and V_x cases

To account for the sensitivity of the limit state to the variability of the ground regarding the extent of the volume of ground involved in the limit state, in the TGC1 document (JRC,2024) a more general form of the formulae for k_n that those given in FprEN1997-1/Annex A is proposed for Type C. This Type C formulae includes the sensitivity index (Γ^2), defined by Formula 3, that can only take values between 0 and 1:

$$\Gamma^2 = \theta/L \qquad (3)$$

where θ is the scale of fluctuation, i.e., magnitude of the ground property variability, and L is the extent of the volume of ground involved in the limit state.

Indicative values of the horizontal and vertical scales of fluctuation (θ_h and θ_v) can be found in the literature (e.g. Cami et al, 2020). These indicative values, relative to sedimentary materials not involved in tectonic movements, show that the θ_h values are

much greater than the θ_v values. In addition, examination of these numbers shows that, for normal design situations, θ_v values range mainly from 1 to 1,5 m while θ_h values range from 15 to 50 m.

3.7 Design value

According to FprEN 1997-1/4.4.1.3(3), for inferior values of X_{rep}, the design values of a ground property (X_d), should be calculated from Formula 4:

$$X_d = X_{rep}/\gamma_M \quad (4)$$

where γ_M is the material partial factor, whose values for persistent, transient, and accidental design situations are given in FprEN 1997-1/Table 4.8. This design value of a ground property is used in Material Factor Approach (MFA) design verifications.

When using the MFA, EN 1990-1/8.3.5.2(1) states that the design value of the resistance (R_d) for design verifications should be determined using Formula 5:

$$R_d = R\{X_d; a_d; \sum F_{Ed}\} \quad (5)$$

where a_d denotes the design values of geometrical properties and ΣF_{Ed} is the design value of actions.

Note that in Resistance Factor Approach (RFA) design verifications, X_{rep} is used, as shown in Formula 6, where γ_R is the resistance partial factor:

$$R_d = R\{X_{rep};\ a_d;\ \sum F_{Ed}\}/\gamma_R \quad (6)$$

4 FURTHER CONSIDERATIONS

It is worth highlighting that the TGC1 document (JRC ,2024) also presents guidance on the use of statistic to select the characteristic value of ground properties in four very common situations in design:

- Situations in which there are few derived values. Six different criteria are presented to assess the least number of derived values required for the use of statistics.
- Situations in which properties are depth-dependent. The background and statistical formulae to account for depth-dependency are presented.
- Situations in which the properties are mutual dependent parameters so they cannot be determined independently of each other (for instance, Mohr-Coulomb parameters: cohesion and friction angle).
- Situations in which derived values come from different sources. Three methods, that can be easily applied in practice, are presented to determine representative values from multiple data sources.

Additionally, TGC1 document (JRC, 2024) contains five design cases that cover various aspects: different geotechnical structures and limit states, different number of derived values, different distribution functions, and depth- dependent and independent ground properties.

5 CONCLUSIONS

This paper addresses the determination of representative values of ground properties according to the new Eurocode 7. Overall, it can be stated that this topic has considerably improved in comparison to the current version of the code, since now there is a clear conceptual distinction between the nominal value, where designers select the value according to their knowledge and experience, and the characteristic value, where designers determine the value with the aid of statistics. Also, the factors to be considered when selecting the representative value: the quantity and quality of the geotechnical data; its spatial distribution; the extent of the zone of influence; and the need to avail of and take into account pre-existing knowledge in the form of comparable experience, have been elaborated. Additionally, the procedure to determine the characteristic value taking account of the quality and quantity of the data and the spatial variability, described in FprEN 1997- 1/Annex A, will help to extend the use of characteristic values in design verification.

ABSTRACT: Stabilizing piles can be designed to increase the safety factor of a landslide (acting as a stabilization countermeasure) or to reduce slope displacements (acting as a protection countermeasure). Equally spaced piles are usually installed, in one or more rows transversal to ground movements, adopting a linear arrangement. Since piles must be designed to ensure adequate safety factors for both slope stability and pile structural integrity, the paper focuses on a different plane layout, namely a staggered array, that can be an alternative design choice. A 2D and 3D numerical study has been developed, with the aim to compare the overall behaviour of a two-layer slope reinforced with one row of piles arranged with linear or staggered layouts: soil arching effect, ground movements and resisting forces are analysed and discussed in the paper.

RÉSUMÉ: Les pieux de stabilisation peuvent être conçus pour augmenter le facteur de sécurité d'un glissement de terrain ou pour réduire les déplacements de la pente. Les pieux sont généralement installés en une ou plusieurs rangées ou de manière orthogonale par rapport aux mouvements du sol, en adoptant une disposition linéaire. Étant donné que les pieux doivent être conçus de manière à garantir des critères de sécurité adéquats à la fois pour la stabilité des pentes et pour l'intégrité structurelle des pieux, l'article se concentre sur une disposition plane différente, à savoir la disposition en quinconce, qui peut constituer un choix de conception alternatif. Une étude numérique en 2D et 3D a été développée dans le but de comparer le comportement global d'une pente à deux couches renforcées par une rangée de pieux disposés linéairement ou en quinconce : la voûte du sol, les mouvements du sol et les forces de résistance ont été analysés.

Keywords: Stabilizing piles; soil arching; piles arrangements.

1 INTRODUCTION

The use of rows of vertical piles is a well-developed engineering practice to improve slope stability providing a resisting force to unstable soil masses.

Equally spaced piles are generally used in shallow and slow landslides and are installed transversally to soil movement adopting different arrangements (Figure 1). The well-known "soil arching", allows adjacent piles to act as a linear continuous retaining structure able to transfer part of soil pressure from the unstable layer to the lower stable one. The stabilizing rows of piles must be designed keeping piles spacing (s) as large as possible for cost effectiveness, but not so large to make them unable to generate sufficient soil arching.

In order to guarantee the development of soil arching effect, Durrani *et al.* (2006) suggest adopting a pile spacing ratio (s/D, where D is the pile diameter) less than a critical value $(s/D)_{cr} = k_p^2/(k_p\text{-}k_a)$, where k_p and k_a are the Rankine earth pressure coefficients. For gentle slopes in fine to medium grained soils, the critical spacing ratio is in the range $2.5 < (s/D)_{cr} < 4.0$.

The effects of some relevant parameters (i.e., pile spacing, pile stiffness and embedded length, row position, mechanical soils properties, slope inclination, pile top restrain, soil displacements) on the efficiency of equally spaced piles have been investigated by many authors over the years (Lirer, 2012; Chen and Martin, 2002; Liang and Zeng, 2002; Kourkoulis *et al*., 2011; Muraro *et al*., 2014; Pirone and Urciuoli, 2018, Fantera *et al*. 2022).

Regarding piles arrangement, some authors (Kourkoulis *et al*. 2011, Pham *et al*. 2019; Shangguan *et al*. 2023) highlighted that the staggered (or quincunx) array can be an effective design choice because it reduces the "shadow effect" created by the rear piles to the front ones in a double row layout (Figure 1), also developing a "multiple" soil arch (one between piles

of the rear row and the other one between the front pile and the adjacent rear pile, Figure 1).

Analysing the ultimate lateral resistance of stabilizing piles arranged in linear or quincunx layouts, Pham *et al*. (2019) verified that for cohesive soils the effect of piles arrangement becomes negligible for pile spacing ratio $s/D \geq 3$ (Figure 2b).

Since the ULS condition is generally attained for soil displacements larger than 0.3÷0.4 times the pile diameter, this paper focuses on the stages far away from the ultimate condition, analysing through 2D and 3D numerical models the performance of elastic piles installed with linear and quincunx layouts in a shallow translational landslide in fine-grained soils.

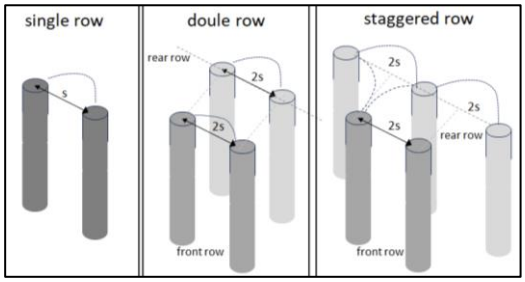

Figure 1. Pile arrangements.

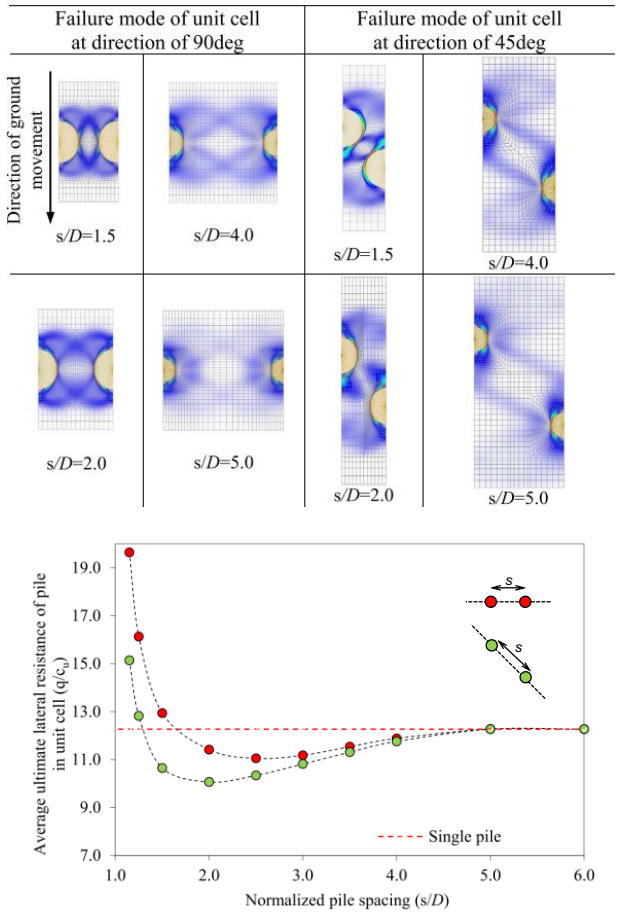

Figure 2. Average ultimate lateral resistance of an infinite row of piles arranged in a linear and staggered layout (Pham et al. 2019) within a cohesive slope.

2 FD NUMERICAL MODELLING

The numerical study (Finite Difference code FLAC) refers to a two-layer slope reinforced with an infinite line of piles shown in Figure 3 (thickness of sliding layer H = 6m). Specifically, a row of piles (length L) is located in the middle of the model (y = ±12D from the vertical boundaries) and two planes of symmetry are introduced through the pile midplanes. An increasing uniform displacement ($u_{y,inp}$) was applied in the analyses at the uphill boundary to simulate soil sliding over the shear band. Soils behaviour (unstable, shear band and stable layer) has been described using an elastic–perfectly plastic soil model obeying the Mohr–Coulomb failure criterion.

A wide three-dimensional parametric study has been developed (Fantera *et al*., 2022) in order to investigate piles efficiency considering the achievement of both force-based and displacement-based requirements within the slope: the influence of the main parameters affecting the complex soil–pile interaction mechanism (pile spacing s, pile embedded length L_2, soil mechanical properties, slope inclination, pile shaft constrains) has been considered (Figure 4). For the simple scheme of infinite slope in fine grained soils, the numerical study permitted to evaluate the non-dimensional resisting contribution given by piles arranged in a linear layout as a function of the spacing ratio s/D and the displacement ratio $u_{y,dw}/u_{y,inp}$, the latter representing the desired reduction of downhill slope movement.

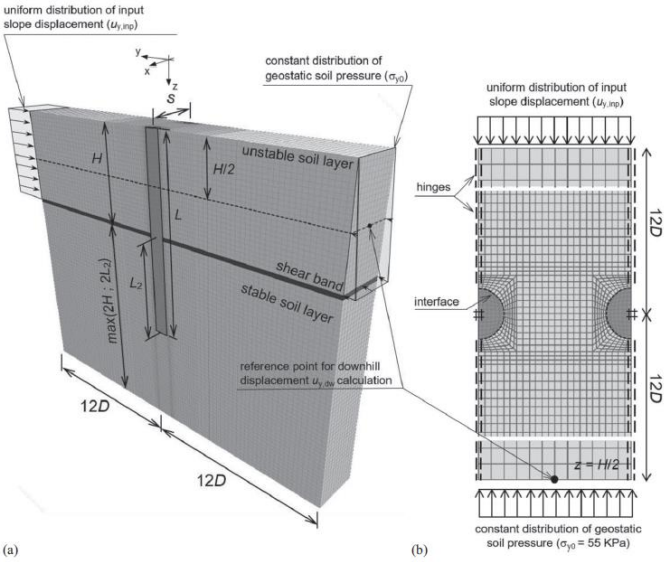

Figure 3. Grids and boundary conditions used in the numerical study (Fantera et al. 2022) of piles arranged in a linear array: a) 3D and b) 2D models (z=H/2=3m).

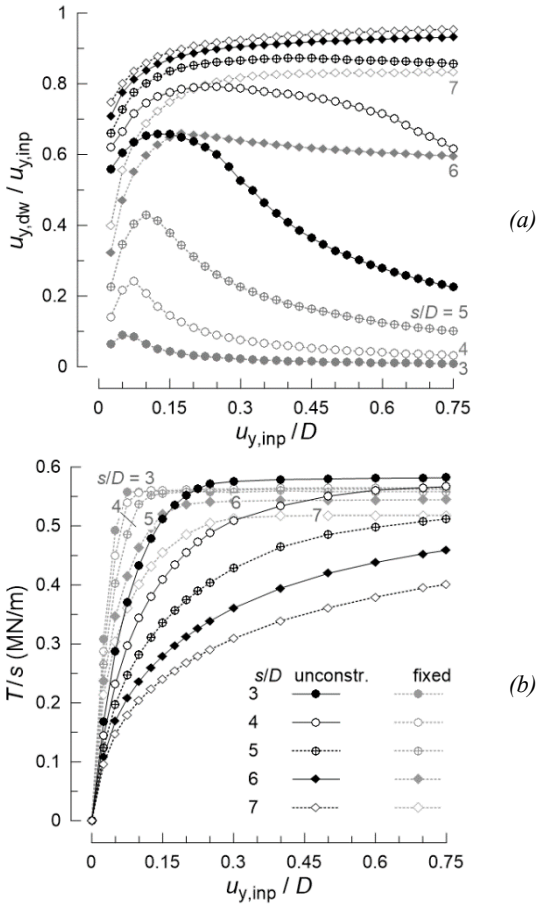

Figure 4. Normalised downhill displacements (a) and resisting contribution (T/s) provided by a line of fixed and unconstrained piles (L_2/H=1, E_p = 30GPa) versus input displacements $u_{y,inp}/D$ (Fantera et al. 2022). Soil properties in Tab.1.

2.1 Soil arching development (2D and 3D models)

Soil arching around the piles has been studied by means of plane strain (2D) and three-dimensional numerical analyses, assuming fixed piles installed in a linear or staggered arrangements, with a spacing ratio $s_x = 3D$ (Figure 5). The adopted soil properties are reported in Table 1.

Soil-pile interaction mechanism has been analysed by examining:

- evolution of principal stresses direction and normal stresses σ_n acting on the piles shaft (2D model, Figure 6);
- evolution of normalised horizontal stress increments ($\Delta\sigma'_{yy}/\sigma'_{yy,0}$) computed uphill of the piled line within the sliding soil mass ($0 < z < 6$m) (3D model, Figures 7-8).

The results from plane strain analyses (Figure 6) show that in both arrangements, the normal stresses acting on the piles (σ_n) move away from the initial (k_0) stress distribution as the imposed slope displacements $u_{y,inp}/D$ increase, as a result of arching-induced stress transfer.

Furthermore, it can be observed that in a staggered layout, the 2D normal stresses acting on the rear and front piles are different (Figure 6b): according to the previous research studies (Pham *et al*., 2019), the front piles are much less loaded than the rear ones, for which the normal stresses are very similar (up to $u_{y,inp} = 3D$) to the ones observed for the linear array (Figure 6a).

The contours of the normalised horizontal stress increments ($\Delta\sigma'_{yy}/\sigma'_{yy,0}$) computed in the 3D model at the same depth (z = 3m) have been plotted in Figure 7 for a given value of the soil movements (i.e., $u_{y,inp} = 0.1$D): the stress contours clearly show the arching effect developing between the rear and the front piles (Shangguan *et al*. 2023; Pham *et al*., 2019).

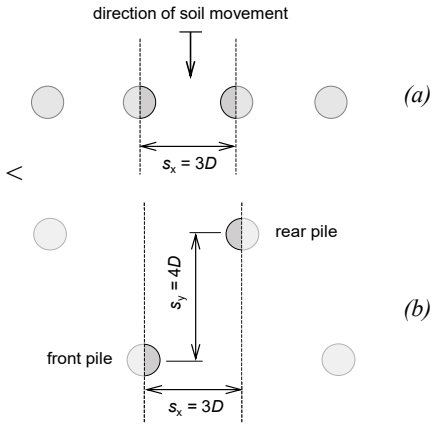

Figure 5. Pile arrangements adopted in the numerical study: (a) linear and (b) staggered layout.

Table 1. Soil properties (Figure 3).

Soil	Unstable	Shear band	stable
γ (kN/m³)	18.5	18.5	18.5
E′(MPa)	30	3000	60
ν	0.2	0.2	0.2
c′ (kPa)	2	0	20
φ′ (°)	28	0.1	28
ψ (°)	0	0	0

The evolution of the resulting horizontal 3D stress increments (integral extended to the thickness of the sliding layer H) with the imposed slope movements (Figure 8), confirms the outcomes of the plane strain models: slope movements mainly act on the piles belonging to the first row, inducing larger loads on the rear fixed piles. Considering that the ratio between the shear force over the pile spacing (T/s) is the resisting contribution provided by the line of piles, it is worth noting that the earth pressure acting on the pile belonging to the liner array is very close to the average value

of the actions acting on the two piles of the quincunx array. This means that the same overall contribution on the slope stability for the two schemes is expected.

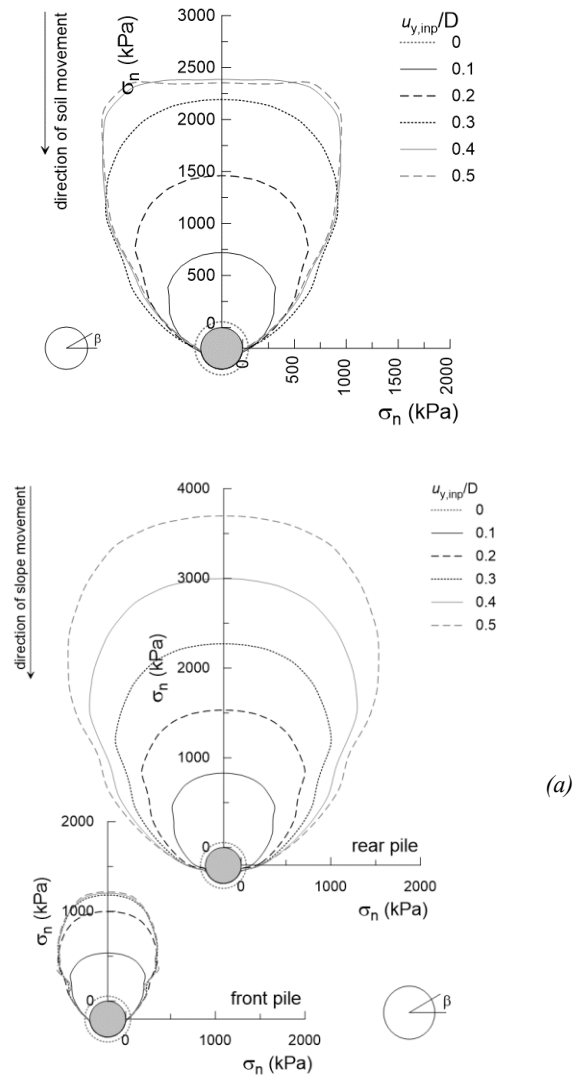

Figure 6. Contours of normal stress computed in 2D models (z=H/2=3m) in linear (a) and staggered (b) arrangements for different normalised input displacement $u_{y,imp}/D$.

2.2 Soil displacements and resisting force (3D models)

The most convenient plane layout should be defined considering the achievement of both force-based and displacement-based requirements, that is, the shear resisting force provided by the piles at the depth of the sliding surface (T) and the reduction of downhill slope displacements ($u_{y,dw}/u_{y,inp}$). For such a reason, a three-dimensional model has been adopted considering unconstrained elastic piles (E_p = 30GPa) in both arrangements and comparing the numerical results in terms of:

- percentage of horizontal displacements transferred from the uphill to the downhill sides of the model, where the downhill displacement ($u_{y,dw}$) was computed in the middle plane between the piles ($x = s/2$, y=+12D, Figure 3), at a depth z = 3 m from the ground surface (Figure 9);
- evolution of the shear force T provided by the piles at the depth of the sliding surface (Figure 10).

For 3D models the profiles of bending moment $M(z)$ and shear forces $T(z)$ have been computed using the profiles of pile displacement u(z):

$$M(z) = E_p I \frac{d^2u(z)}{dz^2} \quad (1a)$$

$$T(z) = E_p I \frac{d^3u(z)}{dz^3} \quad (2a)$$

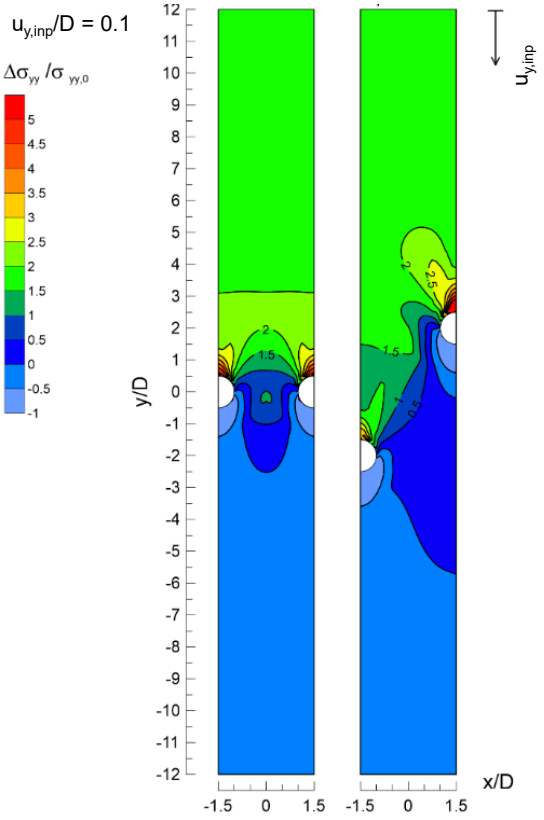

Figure 7. Contours of horizontal stress increments ($\Delta\sigma'_{yy}/\sigma'_{yy,0}$) computed at z= 3m in 3D models in linear and staggered arrangements for $u_{y,inp}/D$=0.1 (fixed piles).

It can be noted (Figure 9) that the two arrangements have the same containment effect, with a reduction of slope displacement of at least 20% to 35%, for $u_{y,inp}/D \approx 0.15$. Since the two schemes have the same effect on the overall displacements of the slope, they are expected to develop the same resisting contribution T/s along the sliding surface. In fact, it can be noted (Figure 10) that the overall piles response is the same: the computed shear force (T) sharply increases in both arrangements with $u_{y,inp}/D$, attaining the maximum

value when soil arching fully develops ($u_{y,inp}/D \approx 0.2$): further soil movements do not affect stress redistribution, and the load acting on the piles remains constant (Figure 10).

The performance of each pile within the group has been also analysed in more detail by plotting the evolution with $u_{y,inp}/D$ of the pile internal forces (bending moments M and shear forces T) normalized to the ones measured in the linear layout (Figure 11). The results show that some differences exist for the two schemes up to $u_{y,inp}/D < 0.25$, with the rear pile slightly more loaded than the front one. For larger soil movements, the difference in shear force T becomes negligible and both the front and rear piles in the quincunx array behave as the ones in the linear array ($T_{quincunx}/T_{linear} \approx 1$). The evolution of the normalized bending moment also stops beyond this threshold, with both the front and the rear piles exhibiting bending moments M lower than the ones computed for a infinite line of piles ($M_{quincunx}/M_{linear} < 1$).

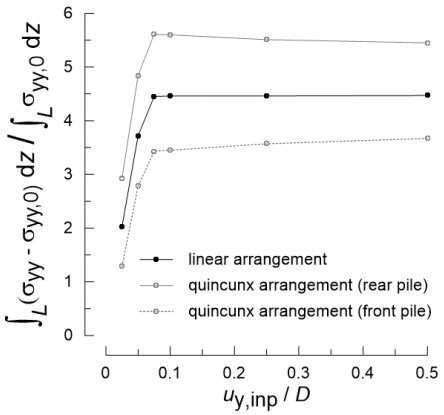

Figure 8. Evolution with $u_{y,inp}/D$ of the integral of the normalised 3D horizontal stress increments ($\Delta\sigma'_{yy}/\sigma'_{yy,0}$) computed uphill of the pile line y=+0.5D (fixed piles).

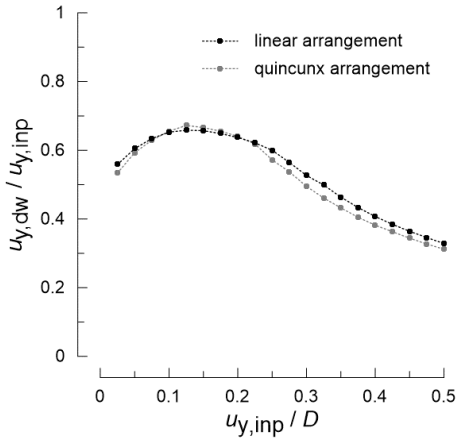

Figure 9. 3D numerical results (unconstrained piles): normalized downhill soil displacements $u_{y,dw}/u_{y,inp}$ versus input slope movements for linear and quincunx arrangements.

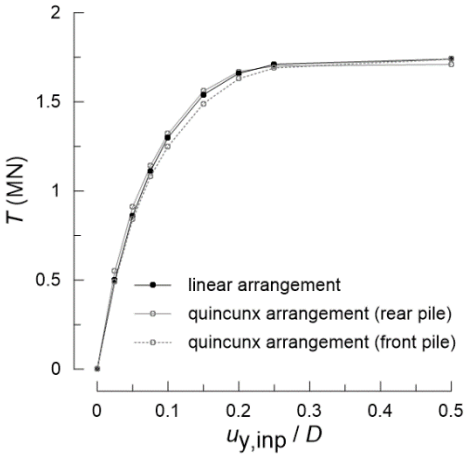

Figure 10. 3D numerical results (unconstrained piles): shear forces T versus input slope movements for linear and quincunx arrangements.

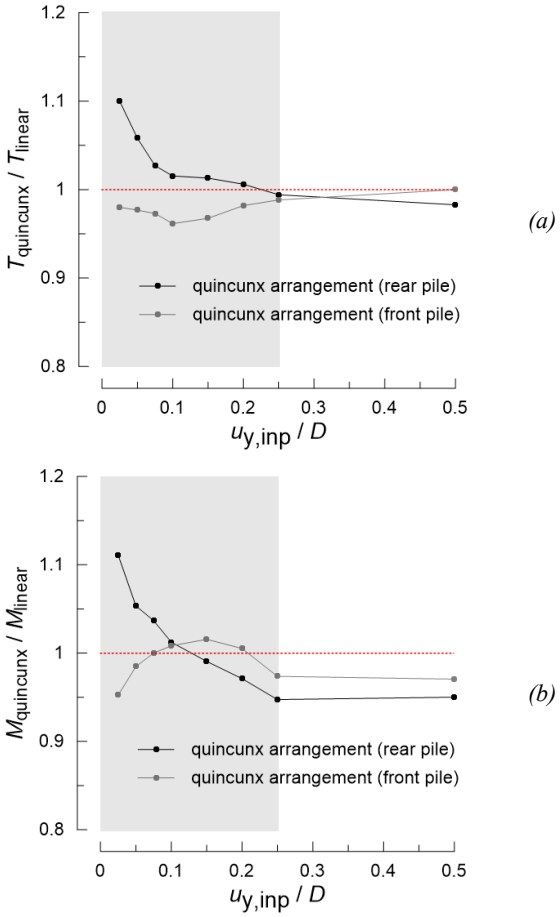

Figure 11. 3D numerical results (unconstrained piles): shear forces T(a) and bending moments M (b) acting in the piles at the depth of the sliding surface in the quincunx array, normalised to the ones measured in the linear array.

3 CONCLUDING REMARKS

Numerical results obtained for unconstrained piles show that, for the adopted pile spacing ($s_x = 3D$) and pile embedded length ($L_2/H = 1$), the linear and quincunx arrangements have the same effectiveness in terms of reduction of soil movements of a shallow translational landslide in fine-grained soils. It is evident that this outcome is strictly related to the chosen pile spacing in the direction of the ground movement (s_y in Figure 4b), between the rear and the front rows: the 2D and 3D numerical results highlighted that for $s_y = 4D$ the "multiple" arching effect makes the two schemes equally effective. On the other side, comparing the performance (shear force T and bending moment M) of each pile within the group, some differences have been observed between the rear and front piles of the quincunx layout. This result seems to indicate that the choice of a different piles arrangement is more related to pile response than slope stability, perhaps allowing a less conservative design of the front piles of the row.

Both aspects (piles effectiveness and performance) will have to be analysed in more detail through a broader 3D parametric study, considering different values of the ratio s_y/s_x in order to identify the threshold that guarantees the formation of the beneficial "multiple" soil arching effect and, at the same time, reduces the internal forces within the front piles.

Safety assessment of a gravity dam using a hydromechanical model: fracture propagation at the dam/foundation interface

Evaluation de la sécurité d'un barrage-poids à l'aide d'un modèle hydromécanique: propagation des fractures à l'interface barrage/fondation

**lbraga@lnec.pt*

ABSTRACT: Most gravity dam failures occur due to sliding along the dam/foundation interface, rock mass discontinuities, or rock mass layers of lower strength. The possibility of sliding of a dam is usually evaluated based on simplified limit equilibrium techniques. In this study an explicit time-stepping small displacement algorithm, Parmac2D-Fflow, is used to assess the safety of gravity dams. This algorithm is based on a discrete representation of discontinuities, simulates the hydro-mechanical interaction, and considers softening constitutive laws that are closer to the actual behaviour of the dam/foundation interface. Seepage flow along the dam/foundation interface is only allowed to occur after contact failure, making it possible to model a coupled propagation failure along the dam/foundation interface due to a hypothetical dam overtopping scenario. For two gravity dams with different heights, the numerical results predicted with a coupled/fracture propagation model are compared with those obtained with a coupled/fully fractured model and with an uncoupled analysis. The results presented highlight the relevance of taking into account a coupled hydro-mechanical for dam safety and show that with coupled-fracture propagation model slightly higher safety factors are predicted.

RÉSUMÉ: La plupart des ruptures de barrages-poids sont dues à un glissement le long de l'interface barrage/fondation, des discontinuités de la masse rocheuse ou des couches de masse rocheuse de moindre résistance. La possibilité de glissement d'un barrage est généralement évaluée sur la base de techniques simplifiées d'équilibre limite. Dans cette étude, un algorithme explicite de petits déplacements à pas de temps, Parmac2D-Fflow, est utilisé pour évaluer la sécurité des barrages-poids. Cet algorithme est basé sur une représentation discrète des discontinuités, simule l'interaction hydromécanique et considère des lois constitutives d'adoucissement qui sont plus proches du comportement réel de l'interface barrage/fondation. Le flux d'infiltration le long de l'interface barrage/fondation n'est autorisé qu'après la rupture de contact, ce qui permet de modéliser une rupture par propagation couplée le long de l'interface barrage/fondation en raison d'un scénario hypothétique de débordement du barrage. Pour deux barrages-poids de hauteurs différentes, les résultats numériques prédits avec un modèle de propagation couplé/fracture sont comparés à ceux obtenus avec un modèle couplé/entièrement fracturé et avec une analyse non couplée. Les résultats présentés mettent en évidence la pertinence de la prise en compte d'un modèle hydro-mécanique couplé pour la sécurité des barrages et montrent qu'avec un modèle couplé de propagation des fractures, des facteurs de sécurité légèrement plus élevés sont prédits.

Keywords: Gravity dam; hydromechanical coupled model; fracture propagation; safety assessment.

1 INTRODUCTION

The hydro-mechanical behaviour of concrete dam foundations must be considered, and the behaviour of the discontinuities must be represented by realistic constitutive models. Studies have been carried out to characterise the properties and failure mechanisms of the concrete/rock interface and its effect on the stability of dams (Dong et al., 2016; Krounis et al. 2015; Tian et al., 2015). The safety of concrete dams is often quantified by a factor, which can be obtained by reducing the resistant characteristics of the discontinuities involved in the failure mechanism or by increasing the hydrostatic pressure on the upstream face of the dam (Azevedo et al., 2021; Farinha et al., 2017; Enzell et al., 2023).

This study uses a hydromechanical model to assess the stability of gravity dams, which consider the opening/closing movements of discontinuities and the water pressures in the dam foundation discontinuities and in the dam/foundation interface, considering a contact model with weakening of cohesion and tensile strength of the concrete/concrete and concrete/rock interfaces. Stability analyses are carried out on two gravity dams of different heights. Using the gradual load amplification method, the sliding safety factors are determined considering a softening model for the

joint elements that simulates the discontinuities (concrete / concrete and concrete / rock) (Azevedo et al., 2010, 2015). Two hypotheses for the foundation rock mass behaviour are considered: linear elastic or brittle failure. A critical analysis of the results is presented in relation to the sliding safety assessment.

2 HYDROMECHANICAL MODEL AND SOFTENING MODEL

This study was carried out with Parmac2D-Fflow (Azevedo et al., 2021; Farinha et al., 2017), which allows fully coupled hydromechanical analysis. The mechanical domain is divided into blocks, which are internally divided into a mesh of plane triangular elements, in order to simulate their deformability. The interaction between these deformable blocks, which simulate both the dam and the foundation, is done using joint finite elements in small displacements. The hydraulic model is superimposed on the mechanical model and thus for each joint element there is a corresponding seepage channel.

An interface contact model with softening was adopted for the behaviour of both concrete/concrete and concrete/rock discontinuities, based on a joint model with bilinear softening in the normal and shear directions. This model has been applied to particle models (Azevedo et al. 2010, 2015). From the moment the maximum strength values (tensile and cohesion) are reached, the maximum strength tensile force and/or the maximum cohesion are reduced based on the damage value, which varies between 0 (no damage) and 1 (contact considered cracked, only working in pure friction). The strength parameters of this contact model are: the ultimate tensile stress (σ_t), the maximum cohesion (C), the friction coefficient (μ_c), and the tensile (G_I) and shear (G_{II}) fracture energies.

3 STABILITY ANALYSIS OF GRAVITY DAMS

3.1 Model description

3.1.1 Geometry and boundary conditions

Four models were considered in this study, representing two large gravity dams of different heights (15 m and 30 m) with their foundations on rock masses with two fracture geometries. Figure 1 shows the schematically geometry of the models, with all the dimensions represented as a function of the height of the dam (H) and the thickness of the construction at the top (a).

The construction joints in the dam body were simulated by a family of discontinuities with a spacing of 3.0 metres (Figure 2 and Figure 3). The foundation rock masses were represented with two families of discontinuities. One model, called "reg", was considered, with a family of continuous horizontal discontinuities with a spacing of 5.0 metres and a family formed by vertical discontinuities with an average spacing of 5.0 metres and a standard deviation of 1.0 metre. Another model was considered, called "dip", with families of continuous orthogonal discontinuities that make angles of 15º and 105º with the horizontal. In the latter case, the orientation and the fact that the families of discontinuities are continuous and flat favours the formation of failure mechanisms, with the formation of wedges that can slide under the dam.

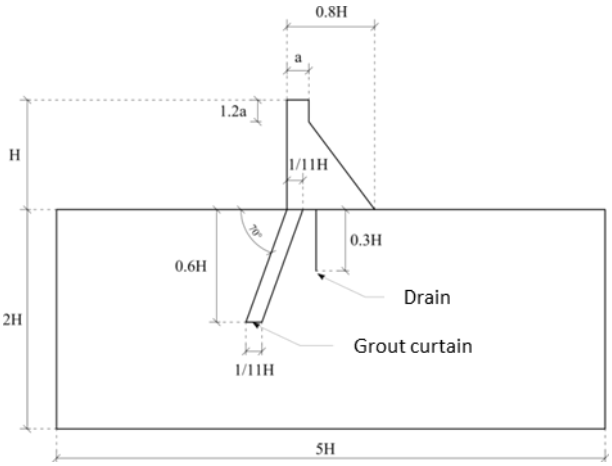

Figure 1. Model geometry.

Table 1 shows the number of mechanical and hydraulic elements used in the four models. It should be noted that the average size of the edges of the triangular elements is 0.6 metres.

Table 1. Model characteristics (number of different elements)

Model	**a***	**b***	**c***	**d***	**e***
15-reg	6531	9629	1420	1322	1379

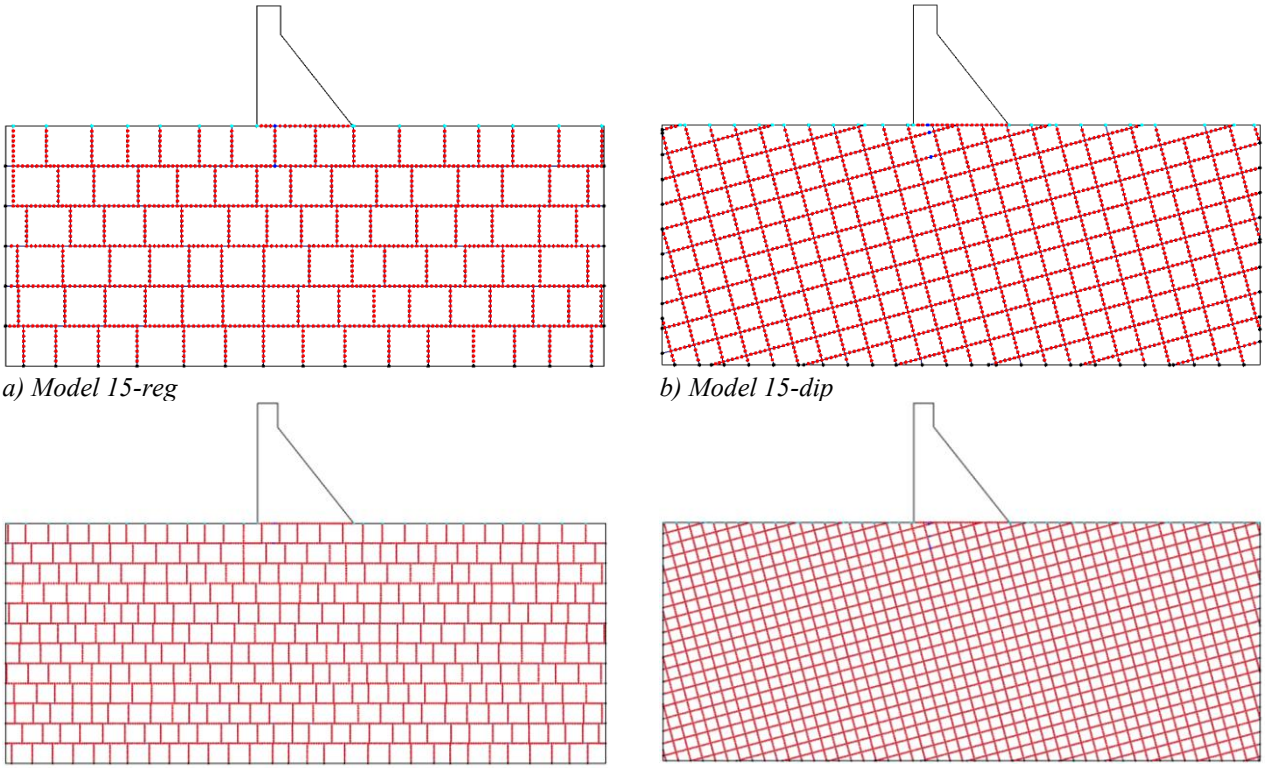
Figure 2. Discontinuum models of the dam/foundation system. a) and b) 15 m high gravity dam; c) and d) 30 m high gravity dam. Each block is discretized using triangular plane finite elements.



a) Model 15-reg *b) Model 15-dip*

c) Model 30-reg *d) Model 30-dip*

Figure 3. Hydraulic models. Hydraulic head assumed on the rock mass surface upstream and downstream from the dam (light blue dots); hydraulic head assumed at the drainage system (dark blue dots); hydraulic channels (red dots); impervious lateral and bottom model boundaries (black dots).

Concerning mechanical boundary conditions, the base of the model was fixed and horizontal displacements on the lateral boundaries were prevented. As hydraulic boundary conditions, zero permeability was assumed at the base and lateral boundaries of the model and the drainage system was simulated by assigning a water pressure along the drain axis equal to 1/3 of the hydraulic head upstream from the dam.

3.1.2 Material properties

The dam concrete and the blocks of the foundation rock mass are assumed to have linear elastic behaviour, with the properties shown in Table 2. At the joints in the concrete zone, the normal stiffness (k_n) is equal to 60.6 GPa/m and the shear stiffness (ks) is equal to 24.2 GPa/m. At the dam/foundation interface and at the rock mass discontinuities, k_n = 120.8 GPa/m and k_s = 51,5 GPa/m. In the rock mass discontinuities, when non-linear behaviour is considered, zero cohesion and traction and a friction angle of 45º are assumed.

Table 2. Material mechanical properties (after Dong et al., 2016).

Material	E [GPa]	ν [-]	ρ [kg/m^3]
Dam concrete	30.3	0.24	2400
Rock mass	64.4	0.20	2700

Regarding the hydraulic apertures of the seepage channels, $a_0 = 1.668\times10^{-4}$ m, $a_{res} = 1/3 \times a_0$ and $a_{max} = 5 \times a_0$ were assumed. It was assumed that the permeability of the dam/foundation interface was half that of the discontinuities in the foundation. The grout curtain permeability is 2.5 times lower than that of the rock mass. The dam construction joints are impervious.

Table 3 shows the softening interface contact model parameters.

Table 3. Softening model parameters for the two different discontinuities: concrete/rock and concrete/concrete.

σ_t	G_I [Nm/m^2]	C [kg/m^3]	G_{II} [Nm/m^2]	tan φ
2.9	250	8.0	2500	1

3.2 Stability analysis

The models developed were used to assess the sliding safety of the dam/foundation system, assuming that sliding can occur not only at the dam/foundation interface but also at the rock mass discontinuities. The analysis was carried out in two phases: first, a hydro-mechanical calculation was carried out, taking into account the weight of the dam, assuming that the water table was at ground level and that the ratio between horizontal and vertical effective stresses in situ was equal to 0.5; then the hydrostatic pressure was applied at the upstream face of the dam and at the base of the reservoir, assuming all the discontinuities had linear elastic behaviour. In this second phase, a mechanical analysis was carried out first, followed by a hydromechanical analysis. In cases where non-linear behaviour of the discontinuities was assumed, this was only considered after equilibrium had been reached. In all calculations, the reservoir was assumed to be at the dam crest level. Figure 4 shows the hydraulic head contours, where the effect of the drainage system can be clearly identified.

For each gravity dam the results obtained with a coupled/fracture propagation model are compared with those obtained with a coupled/fully fractured model and with an uncoupled analysis, where the pressures remained constant and equal to those obtained in the initial equilibrium situation (no hydraulic calculation was carried out in this model). In the coupled analyses, the hydraulic head upstream from the dam was gradually increased given the water height above the dam crest. In the fracture propagation model, seepage along the dam/foundation interface was just allowed after damage initiation at each joint element.

Table 4 shows the safety factors obtained for the four different models carrying out numerical analysis assuming three different hypotheses: uncoupled (UCP), coupled (CP) and coupled with fracture propagation due to water pressure (CP-FP) and two different foundation behaviors: elastic (E) and brittle model (F). Figure 5 shows the horizontal crest displacement during the process of amplification of water pressure for the dam with 30 m height. As shown, with a fractured foundation a higher crest displacement is obtained when compared with an elastic foundation.

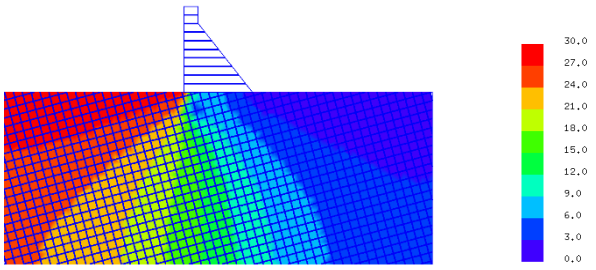


Figure 4. Hydraulic head contours (model 30-dip).

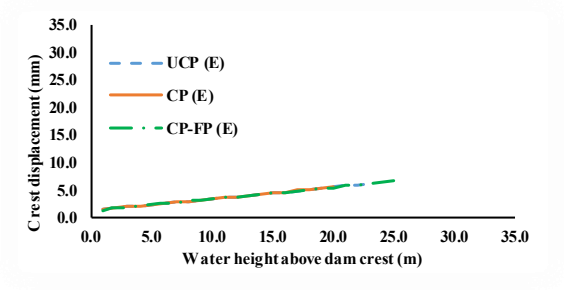
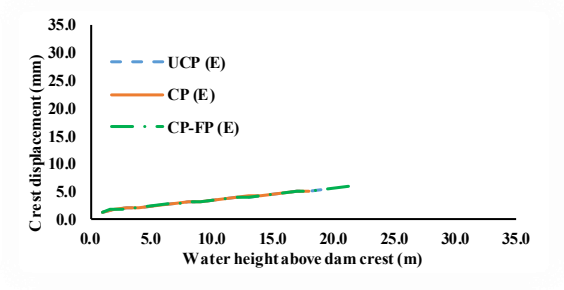
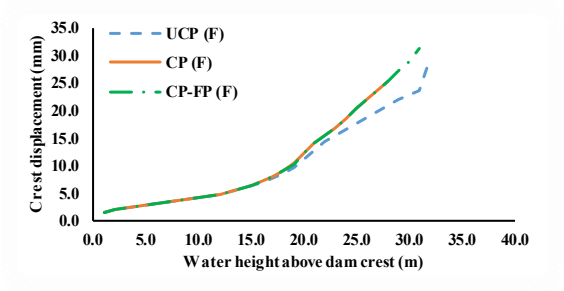


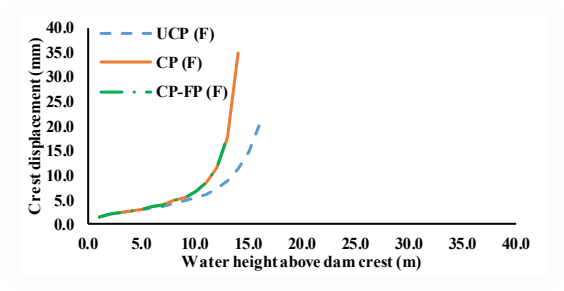
a) Model 30-reg (E)



b) Model 30-dip (E)



c) Model 30-reg (F)



d) Model 30-dip (F)

Figure 5. Horizontal crest displacement during the process of amplification of water pressure.

In the elastic foundation model (E) the simplified uncoupled model (UCP) always predicts a higher safety factor than that obtained with a coupled model (CP), that considers a permeable dam/foundation interface from the beginning of the load amplification process. With a coupled model taken into account fracture propagation (CP-FP) at the dam/foundation interface, the predicted safety factors are, as expected, higher than those predicted with a coupled model, and are also higher than those predicted with a simplified uncoupled model (UCP).

In the fractured foundation model (F) the simplified uncoupled model (UCP) always predicts a higher safety factor. The coupled model with fracture propagation (CP-FP) at the dam/foundation interface leads, when compared with the coupled model (CP) that considers a permeable dam/foundation interface from the beginning of the load amplification process, with the exception of model 30-dip, to a higher safety factor.

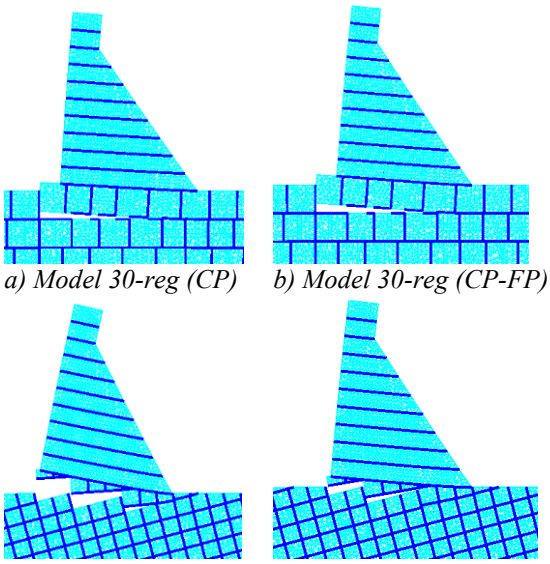
As expected, for a fractured foundation (F), the geometry with discontinuity families with an orientation that favours the formation of failure mechanisms (15-dip and 30-dip), the predicted safety factors are, for all calculation hypothesis, always lower than those predicted with a regular foundation.

Overall the results here presented indicate that with an uncoupled model (UCP) the safety factor predicted may be higher than that obtained with a coupled fracture propagation model (CP-FP). The results presented also show that the coupled model (CP) that considers the dam/foundation interface permeable from the start of the safety factor calculation leads to a value in the range or lower than the value predicted with the coupled fracture propagation model (CP-FP).

Table 4. Safety factors: Elastic foundation (E) and fractured foundation (F).

Model	***15-reg***	***15-dip***	***30-reg***	***30-dip***
UCP (E)	4.60	4.73	2.53	2.27
CP (E)	4.33	4.33	2.33	2.20
CP-FP (E)	4.87	4.87	2.67	2.47
UCP (F)	5.80	3.00	3.13	2.07
CP (F)	5.13	2.47	2.87	1.93
CP-FP (F)	5.67	2.47	3.07	1.87

Figure 6 presents the predicted failure modes for a fractured foundation, for the 30 m high dam using both the coupled model (CP) and the coupled model taking into account fracture propagation (CP-FP). As shown, by taking into account fracture propagation due to the water pressure at the dam/foundation interface, the failure modes are slightly different and occur for a smaller deformation even if for the maximum amplification factor the dam/foundation is fully damaged allowing water to flow along the dam/foundation discontinuity. Figure also shows that the sliding of the dam is accompanied by rotation with an axis at the downstream foot and that failure involves opening of discontinuities in the foundation mass near the upstream toe of the dam.



a) Model 30-reg (CP) *b) Model 30-reg (CP-FP)*

c) Model 30-dip (CP) *d) Model 30-dip (CP-FP)*

Figure 6. Failure modes for the 30 m high dam with fractured foundation for the maximum load amplification factors (block deformation magnified 200 times for the reg model and 50 times for the dip model).

4 CONCLUSIONS

The results of safety analyses of existing dams for situations of overtopping, due to floods greater than foreseen in the design phase and/or due to climate changes, and for seismic actions, will enable the definition of alert levels to be used in the prediction models, in order to anticipate failure scenarios and the production of a database of failure analyses.

The safety assessment of gravity dams should be carried out using a coupled hydromechanical model, with proper material properties and behaviour following a load amplification approach. When compared with the simplistic strength reduction approach, typically applied in foundation design and proposed in current dam safety design guidelines, more realistic safety factors and failure modes can be obtained.

Within a coupled analysis the consideration of an initial impervious dam/foundation interface may be a more realistic scenario. The results presented show that slightly higher safety factors are predicted taking into account fracture propagation during the load amplification process.

Further work is underway in order to assess the coupled model with fracture propagation performance for a large set of material properties (concrete, rock mass and corresponding interfaces), material behaviour, including nonlinear behaviour at both the dam and foundation areas, dam geometries and the consideration of a downstream rock wedge that contributes to the stability of the dam.

ACKNOWLEDGEMENTS

The study presented here is part of the research project StepDam: A step forward for the ability to anticipate and prevent failures of concrete dam foundations, supported by LNEC.

ABSTRACT: The General Directorate of Roads of the Spanish Ministry of Transports requested the Geotechnical Laboratory of CEDEX technical assistance for the study of some pathologies detected in A-33 highway in La Font de la Figuera, province of Valencia (Spain). In 2022, after six years in service, anomalous settlements, up to 10 cm, and some longitudinal cracks on the pavement on both carriageways were detected at several zones around station 85+000 of the highway, all of them located in embankment cross sections. Initially, several possible causes of the pathologies were considered: malfunction of the underground drainage of the pavement structure; presence of an abandoned railway tunnel under the embankment; and the existence of collapsible soils at the embankment foundation. An inspection visit to the area was carried out and a site investigation campaign comprising dynamic penetration tests, execution of boreholes with core recovery and installation of micrometric pipe and piezometers, and hydrogeological tests with tracers has been proposed to determine the cause of the detected pathologies. Meanwhile, measurements of ground surface movements obtained by interferometric processing of 46 high resolution radar images, taken by the Paz satellite, have been used to help analyse the cause of anomalous settlements, pointing out that the most likely cause is the existence of collapsible soils at the embankment foundation, what shall be confirmed by the results of the site investigation campaign. The paper presents the results of the study carried out so far.

RÉSUMÉ : La Direction Générale des Routes du Ministère des Transports espagnol a demandé au Laboratoire Géotechnique de l'Assistance technique CEDEX pour l'étude de certaines pathologies détectées dans l'autoroute A-33 à La Font de la Figuera, province de Valence (Espagne). En 2022, après six ans de service, des tassements anormaux, jusqu'à 10 cm, et des fissures longitudinales sur la chaussée des deux chaussées ont été détectés dans plusieurs zones autour du point kilométrique 85+000 de l'autoroute, toutes situées dans des sections transversales de remblai. Initialement, plusieurs causes possibles des pathologies ont été envisagées : dysfonctionnement du drainage souterrain de la structure de la chaussée ; présence d'un tunnel ferroviaire abandonné sous le remblai; et l'existence de sols affaissables au niveau de la fondation du remblai. Une visite d'inspection a été effectuée dans la zone et une campagne d'étude du site comprenant des tests de pénétration dynamique, l'exécution de forages avec récupération du cœur et installation de tuyaux micrométriques et de piézomètres, ainsi que des tests hydrogéologiques avec traceurs a été proposée pour déterminer la cause des pathologies détectées. Entre-temps, les mesures des mouvements de la surface du sol obtenues par traitement interférométrique de 46 images radar à haute résolution prises par le satellite Paz ont été utilisées pour aider à analyser la cause des tassements anormaux, soulignant que la cause la plus probable est l'existence de sols affaissables sur la fondation du remblai, ce qui sera confirmé par les résultats de la campagne d'étude du site. Le document présente les résultats de l'étude réalisée jusqu'à présent.

Keywords: Subsidence; highway; interferometry; collapsible soils.

1 DESCRIPTION OF THE PROBLEMS

The General Directorate of Roads of the Spanish Ministry of Transports requested the Geotechnical Laboratory of CEDEX technical assistance for the study of some pathologies detected around station 85+000 of A-33 highway in La Font de la Figuera, province of Valencia (Spain). During the first half of 2022, and after six years in service, the A-33 conservation team detected five zones with anomalous settlement and some longitudinal cracks on the pavement on both carriageways of the highway (Figure 1, 2 and 3). The settlement zones are a few hundreds of meters apart one from another and are all located in embankment cross sections. The maximum settlement is about 10 cm.

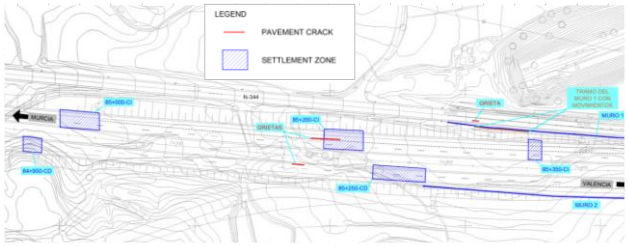

Figure 1. Distribution of zones with cracks and anomalous settlements around station 85+000.

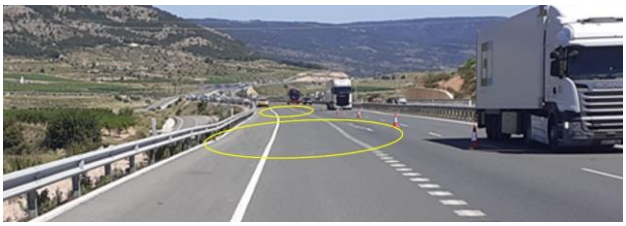

Figure 2. Settlement zone at stations 85+200 and 85+350, (left carriageway, June 2022. View towards Valencia.

Figure 3. Settlement zone at station 85+350, left carriageway, June 2022. View towards Murcia.

In the case of zone 85 + 200-left carriageway, in addition to the settlement, a longitudinal crack of around ten meters appeared. It had an opening of 1-2 cm with no unevenness between lips, see Figure 4.

Figure 4. Longitudinal crack in area 85+200-left carriageway, April 2022.

2 POSSIBLE CAUSES OF THE DAMAGES

Several causes for these pathologies were initially considered:

- Malfunction of the underground drainage of the pavement structure.
- The presence of an abandoned railway tunnel under the section of the highway with the pathologies.
- The existence of collapsible soils in the embankment foundation.

Though the first of the aforementioned possible causes is one of the most frequent when an early bad performance of the pavement is detected, in this case, however, has been discarded: both the superficial and underground drainage systems seem to be well designed, built, and maintained and, up to the moment, there were not anomalies reported or observed regarding this issue. The remaining two are discussed next.

The abandoned railway tunnel is about 1500 m long and was built in the late nineteenth century (1885). The areas with pathologies are relatively close to the tunnel north portal (see Figures 5, 6 and 7).

In a section of the tunnel, about 80 m long and located about 40 m from the north portal (see Figure 7) there are significant water infiltrations, contrarily to the rest of the tunnel. It seems that the section of tunnel with leaks is acting as a general drain of the area and, therefore, causing a hydraulic gradient and a depression of the water table (see Figure 8). The corresponding flow lines towards the tunnel are carrying material to its interior.

As it can be seen inside the tunnel, this transportation process includes two mechanisms: salt dissolution and precipitation and soil drag. This process must have been occurring, with greater or lesser intensity, since the tunnel construction, and could be causing subsidences at the ground surface level.

If the amount of material transported towards the tunnel is large enough there would be a risk of sinkhole formation at the highway carriageways. This could, therefore, cause fatal traffic accidents. During an inspection visit in August 2022, that is, in the driest time of the year and after a long period without rain, the water flow observed at the north portal was of around 0.5-1.0 l/s. It is believed that it could be significantly higher in the rainiest periods. The infiltrations seem to drag a significant amount of material with their flow, consisting of brown clayey-silty soils with a very soft consistency, due to their high humidity. There is also a very intense precipitation of salts (carbonates). This is not observed in the "dry" tunnel areas located further south.

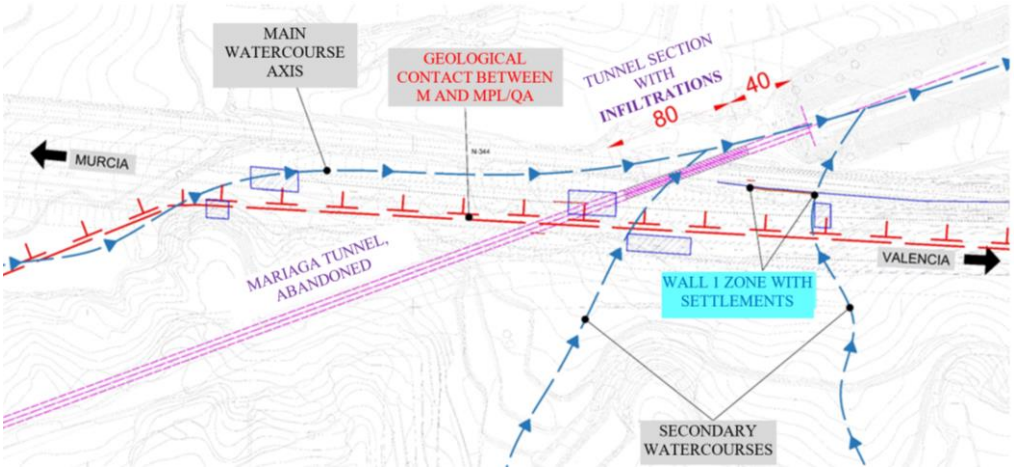

Figure 7. Plan scheme showing location of the geological contact between formations MPL/M and of streambeds.

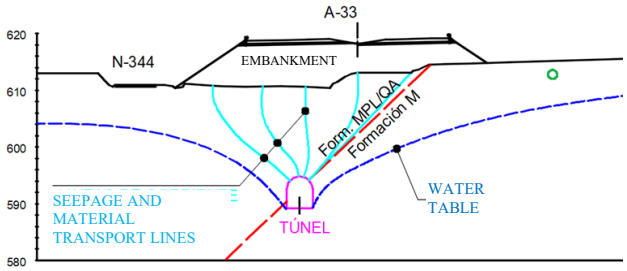

Figure 8. Schematic cross section of seepage towards tunnel (note: this section comes from assumptions).

To help analyze the cause of anomalous settlements, a site investigation campaign comprising dynamic penetration tests, execution of boreholes with core recovery and installation of sliding deformeters and piezometers, and hydrogeological tests with tracers was proposed. Meanwhile, measurements of ground surface movements obtained by interferometric processing of high-resolution SAR images from PAZ satellite have been used. This technology (Mora et al., 2001; Mora et al., 2002) has proved to be very useful to identify the most probable cause of the settlement and will be briefly discussed below.

3 SATTELLITE DATA AND INTERPRETATION OF RESULTS

The lnSAR analysis was carried out using 46 SAR images acquired by PAZ satellite in High Resolution SpotLight mode (1m x 1m resolution), covering the period between 02/02/2021 and 19/09/2022. The analysis provided high quality results and was of the utmost importance for the determination of the cause of the damage.

SAR sensors are sensitive to motion in the LOS direction (Line of Sight direction). Therefore, the displacements measured in the LOS represent a projection of the actual movement. In this context, the lnSAR measurement points are represented by colorations ranging from red to blue (Figure 9) to be interpreted as follows:

- Green-yellow-red: moving away from the radar sensor (subsidence if the motion is assumed to be mainly vertical). Negative values are used to represent this type of movement.
- Blue: stability (meaning no movement)

Sectors without measurement points correspond to areas where the quality of the measurements is not sufficient to ensure the reliability of the results (due to the presence of vegetation or changes on the ground surface).

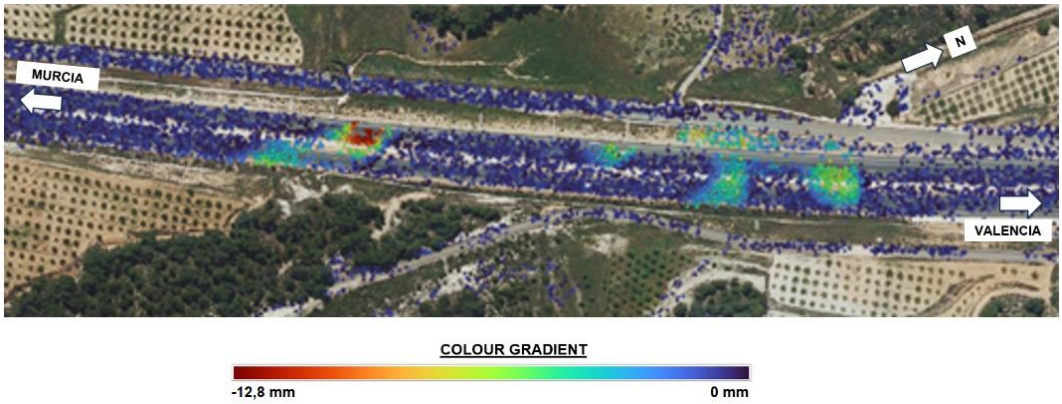

Figure 9. Ground movements obtained by interferometric processing of high-resolution radar images taken by the PAZ satellite around station 85+000. General view.

The precision of the movements obtained by this InSAR procedure is millimetric (2-3 mm, as it is a fraction of a half of the band X radar wavelength, which in this case is 31/2 = 16 mm).

With the aid of the satellite, anomalous settlements in the area around station 85+000 have been compared with those measured in another nearby zone, also with pathologies, at station 86+800 (Figures 10 and 11).

Figure 10. Location of zones with pathologies at station 85+000 and at station 86+800.

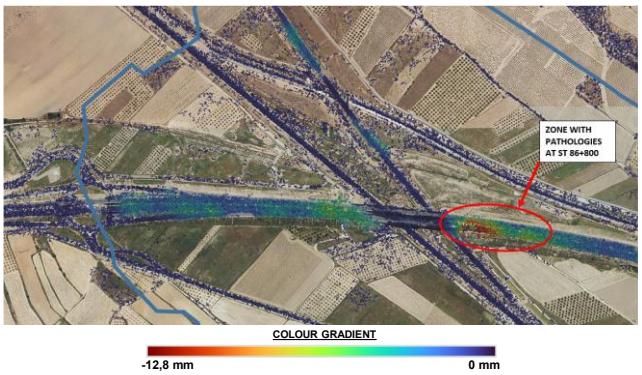

Figure 11. General plan view of the InSAR settlements within the Hoya Manuel basin around station 86+800.

The 86+800 zone is located inside the Hoya Manuel endorheic basin, where rainwater may accumulate creating a temporary lake. This has caused deposition of alluvial soils during its geological history. As known, the finest grained soils are deposited towards the center of this kind of topographical depressions and the coarse soils near the borders. Within this basin, settlements are observed in embankment sections of the A-33 highway and the railway lines, all of them built in the last 6-7 years, but not in cut or at grade sections. The evolution in time of settlements measured in both areas (85+000 and 86+800) is very similar, showing a sharp increase after periods of heavy rain (Figure 12 and 13). Because of that it is thought that the cause of the settlements could be the same.

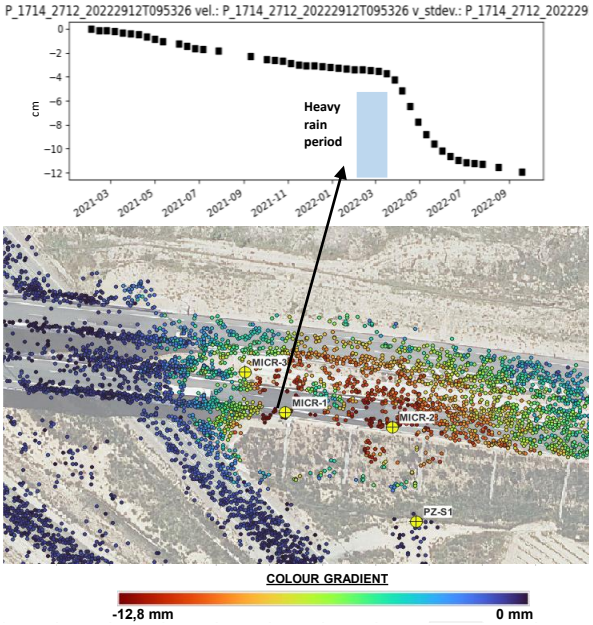

Figure 12. General plan location (below) and displacement time series (top) obtained by InSAR of one representative point at the 86+800 zone (note: see a more detailed rainfall time evolution in Figure 16).

Figure 14 shows the results of vertical displacement measurements obtained from sliding deformeters and the corresponding geotechnical profile at a borehole installed around station 86+800. In Figure 15 it is shown a schematic cross section representing the ground model interpreted according to the boreholes and other relevant information. As can be seen in Figure 14, settlements occur at a depth between 16 and 23 m (from the embankment top and 0-9 m from the general terrain surface), corresponding to a lake deposits layer (Formation QL) consisting of collapsible clayey soils. Under the QL soils there are dense to very dense granular soils (Glacis Formation) that do not settle.

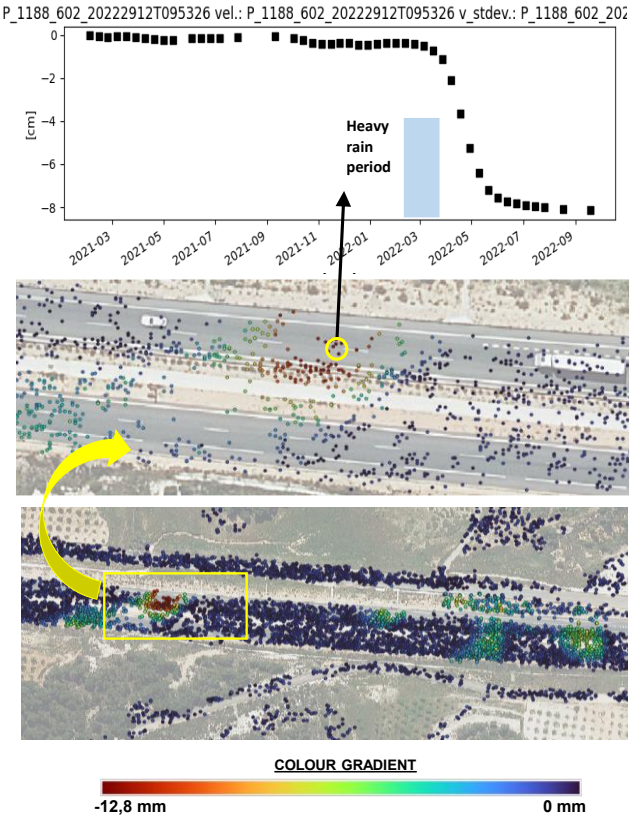

Figure 13. General plan location (below), detailed plan location (middle) and displacement time series (top) obtained by InSAR of one representative point at the 85+000 zone (note: see a more detailed rainfall time evolution in Figure 16).

The existence of the QL deposits, the seasonal humidity variations in them (because they are in general at the ground surface and therefore are directly affected by the rainfall), and the loads imposed by the embankment own weight seems to be the cause of the pathologies in the 86+800 station zone.

Because of that it is thought that in the 85+000 zone the presence of collapsible soils, similar in nature to the ones found at the center of the Hoya Manuel endorheic basin (86+800), and the existence of

recently build embankments could also be the cause of the problems. At the 85+000 the collapsible soils would only appear near the three streambeds that are crossed by the highway in this area (see Figure 7). Also, to be noted is the absence of settlements outside areas loaded with recent embankments.

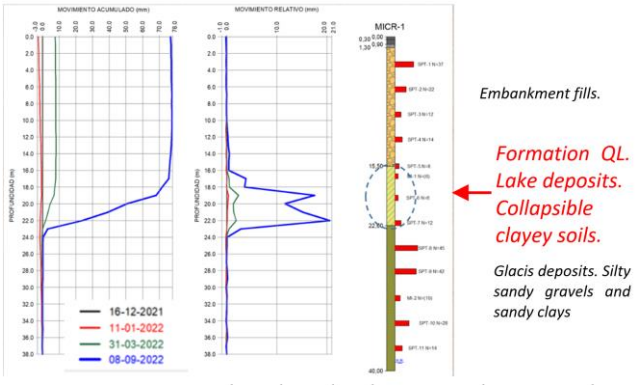

Figure 14. Accumulated and relative settlements obtained from the sliding micrometer MICR-1 located in zone 86+800, and corresponding borehole.

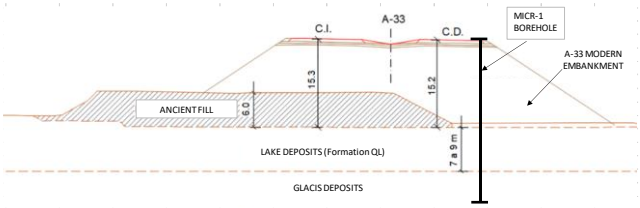

Figure 15. Schematic ground model cross section at the position of the sliding micrometer MICR-1 in zone 86+800.

In the Figure 16 a comparison of the ground settlements time-series at the location of the sliding deformeter MICR-1, using InSAR and sliding deformeter measurements is shown. The vertical movement it also compared with rainfall regime (quarterly precipitations measured at the Fuente la Higuera meteorological station from AEMET). Similar comparisons have been made using other sliding deformeters installed nearby with similar results. As it can be seen the movements obtained by the two methods match reasonably well both in magnitude and in temporal evolution.

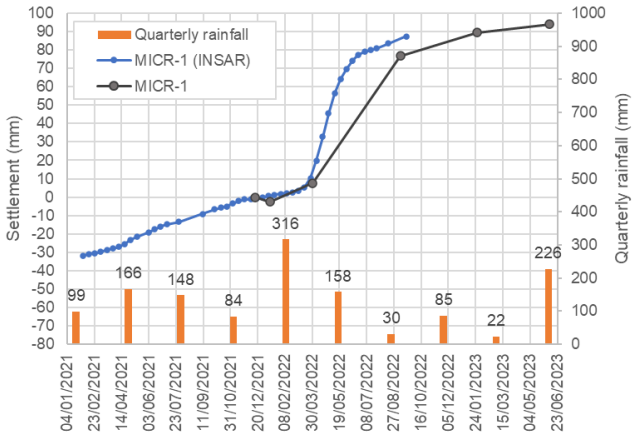

Figure 16. Comparison of the ground settlements time-series at the location of the sliding deformeter "MICR-1" using InSAR (blue) and sliding deformeter measurements (black) and evolution of rainfall regime. (Note: In the figure the InSAR settlements have been forced to be zero at the date when the sliding deformeters measures start. Negative values of settlements of the InSAR time-series indicate only values measured before that date).

4 CONCLUSIONS

The causes of anomalous settlement in a highway section have been analysed with the help of interferometric high resolution radar images. It seems that the most probable cause of these settlements is the existence of collapsible soils at the highway embankment foundation. Another cause, related to the material transportation towards the interior of an abandoned railway tunnel crossing below the highway platform, by salts dissolution or soil dragging, was also considered but does not seem to be the main cause, as there is not subsidence, or at least, it has not been observed, outside the areas occupied by the highway embankments. A site investigation campaign will help to confirm this conclusion.

ABSTRACT: The General Directorate of Roads of the Spanish Ministry of Transports asked the Geotechnical Laboratory of CEDEX for technical assistance for the study of a pathology detected at a section, between stations 12+625 and 12+860, of the Burgos ring highway (BU-30). Just after the inauguration of this highway section in 2016, some longitudinal cracks appeared on the right carriageway. Here, the highway runs on embankment which is contained on its right side by earth reinforced wall that in some sections is founded on a stone wall. The cracks reached a vertical gap of about 5-10 cm and were coincident with the vertical plane where the reinforcement strips of the existing reinforced earth wall ended. To prevent accidents these cracks were fixed several times by sealing, milling, and replacing the pavement, but reappeared shortly after. The evolution of movements has been controlled by topographic procedures and by auscultation devices (inclinometers and sliding deformeters). A terrestrial laser scanner (TSL) has also been used to analyse the wall movements, showing a substantial tilting of the wall face, exceeding 0.5 m at wall crest. From the monitoring results it was inferred that the reinforced earth wall has been tilting at a constant rate of up to 60 mm/year, without tendency to stabilize over time. In this paper the highway pathologies, and the methods to characterize them, are described. The analyses of the probable causes and the recommended remedial actions are also presented.

RÉSUMÉ : La Direction Générale des Routes du Ministère espagnol des Transports a demandé au Laboratoire géotechnique du CEDEX une assistance technique pour l'étude d'une pathologie détectée sur la section entre les stations 12+625 et 12+860 de l´autoroute périphérique de Burgos (BU-30). Juste après l'inauguration de ce tronçon autoroutier en 2016, des fissures longitudinales sont apparues sur la chaussée droite. Ici, l'autoroute passe sur un remblai qui est contenu sur son côté droit par un mur mixte de terre armée au-dessus d'un mur d'enrochement. Les fissures ont atteint une ouverture verticale d'environ 5 à 10 cm et coïncidaient avec le plan vertical où se terminaient les bandes de renforcement du mur de terre armé existant. Pour éviter les accidents, ces fissures ont été réparées plusieurs fois par scellement, fraisage et remplacement de la chaussée, mais sont réapparues peu de temps après. L'évolution des mouvements a été contrôlée par des procédures topographiques et par des dispositifs d'auscultation (inclinomètres et déformètres de forage). Un modèle de scanner laser terrestre (TSL) a également été utilisé pour analyser les mouvements des murs, montrant une inclinaison importante de la face du mur, supérieure à 0,5 m à la crête du mur. Les résultats de la surveillance ont permis de déduire que le mur de terre armé s'inclinait à un rythme constant allant jusqu'à 60 mm/an, sans tendance à se stabiliser avec le temps. Dans cet l'article, les pathologies routières et les méthodes pour les caractériser sont décrites. Les analyses des causes probables et les mesures correctives recommandées sont également présentées.

Keywords: Reinforced wall; tilting; highway; terrestrial laser scanner.

1 DESCRIPTION OF PATHOLOGY

Just after the inauguration of this section of the BU-30 highway in 2016 (Burgos, Spain), some longitudinal cracks appeared between the stations 12+625 and 12+860 (construction stations 3+675 to 3+910) on the right carriageway (river side), Figures 1 and 2. Here, the highway runs on embankment which is contained on its right side by a reinforced earth wall that in some sections is founded on a stone wall. The cracks

reappeared soon after the various repair works carried out (consisting of milling and replacement of mixtures bituminous). At some point the cracks have reached a step of about 10 cm of height and separations between lips of up to 6 cm, which has forced to close to traffic the right lane of the right carriageway on several occasions. The location of the cracks was coincident with the vertical plane where the reinforcement strips of the existing reinforced earth wall ended.

Figure 1. Longitudinal cracks on the right carriageway.

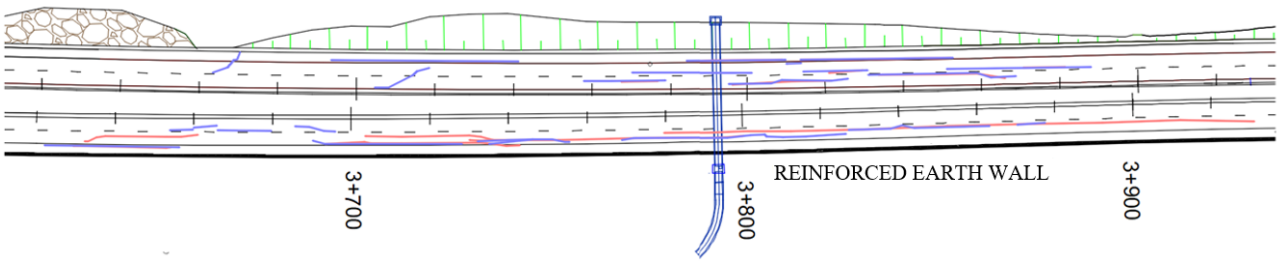

Figure 2. Plan view of the main cracks. In red, October 2019. In blue, September 2020.

The geological-geotechnical cross section of the natural ground, as in the original design project, is shown in Figure 3. The fills and walls that support the platform of the highway in the area of study sit in the lower part of a natural slope, about 90 m high and with an average inclination of 20-25º, which consists of tertiary formations, arranged according to sub horizontal strata, with alternating predominance of clayey or sandy materials.

In the affected area, the reinforced earth wall has variable heights (H) between 6.0 and 13.9 m and reinforcement strip lengths (L) that vary between 0.5· H (in the section with the highest height) and 0.67· H (therefore, between 4 and 7 m). The wall face is made up of reinforced concrete cross-shaped plates of 1.5 m side whose thickness is 14 cm (Figure 4).

The highest movements of the platform and wall occur near the station 3+800, where the embankment/wall height of the highway section is the biggest, on both roads, and also where the drainage cross culvert DCC-3 + 790 is located, see Figure 5.

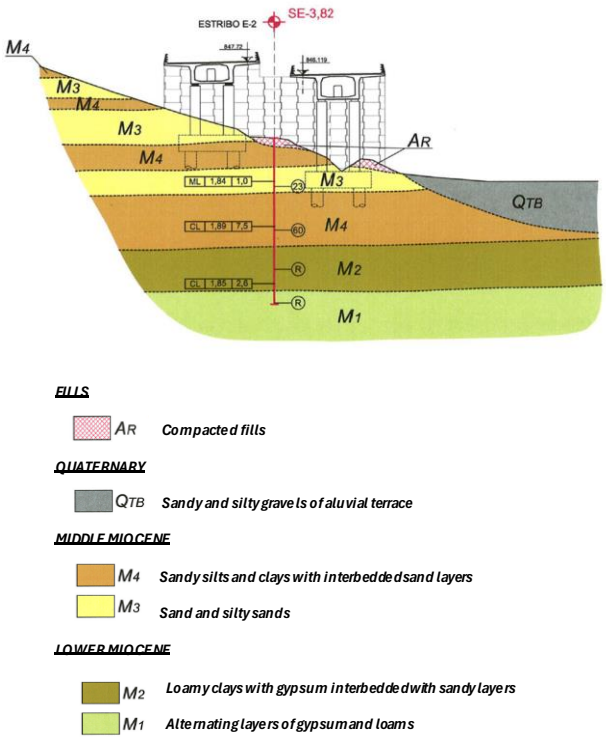

Figure 3. Geological-geotechnical cross section from the original design.

Figure 4. Lateral view of the walls and outlet of drainage cross culvert, DCC-3+790.

The DCC-3+790 consists of a concrete tube, 1.80 m in diameter, which connects both sides of the highway and seems to sit directly on the tertiary substrate. There is also a secondary tube, made of polyethylene and 0.80 m in diameter, which connects the median with the left side of DCC (mountain side inlet) through the core of the embankment fill and under the left carriageway.

Several visual inspections were carried out inside the 1.80 m tube. These inspections showed the DCC is in a general good condition, without failures or loss of alignment due to eventual settlements. This indicated that the foundation of the fill was behaving well. An important issue to note is that in rainy periods it has been observed how jets of pressurized water enter the tube through some of the joints between the tube sections, see Figure 6. This is an indication that there is an accumulation of water, and a saturation of the materials, at the base of fills, which is being evacuated in an uncontrolled manner by the aforementioned "jets".

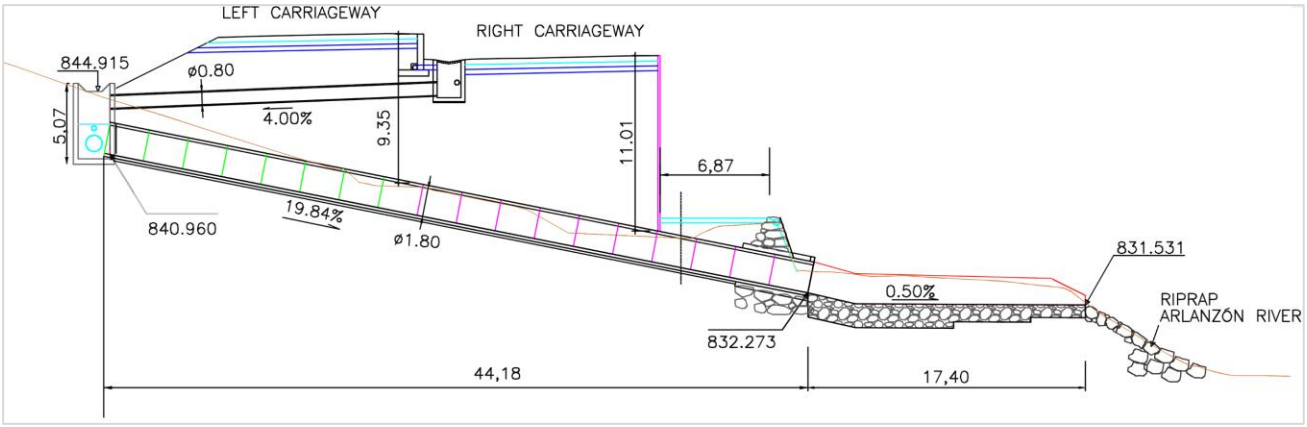

Figure 5. Cross section of the DCC-3+790.

Figure 6. Inside view of DCC-3+790 (October 2020); and view of water entering into the pipe under pressure through one of the joints during a rainy season.

With regard to the face of the reinforced earth wall, there were no significant plate breaks or anomalous joint openings, meaning that there are no significant differential settlements (or angular distortions) longitudinally along the wall. However, transversely considerable tilting of the wall can be seen with the naked eye.

Another aspect to highlight is that neither in the longitudinal vertical profile of the road nor in the barriers or road markings there are losses of alignment, or anomalous undulations, of importance. This is another indication that the pathologies experienced by the road do not produce significant differential movements in the longitudinal direction.

The evolution of movements in the area has been controlled by topographic procedures and by auscultation elements (4 inclinometers/sliding deformeters installed in boreholes drilled in the median). A terrestrial laser scanner model (TSL) has also been used to analyze the wall movements (Figures 8 to 10), showing a substantial tilting of the wall face, exceeding 0.5 m at wall crest. The TLS model showed that the wall tilting varies from 30 to 50 cm, which is equivalent to a loss of verticality of approximately 2.5% to 4%.

It has been found that the reinforced earth wall was tilting with speeds of up to 60 mm/year (wall crest

horizontal displacement) without show a tendency to stabilize over time. Settlements are also recorded, although of lesser magnitude, so it is interpreted that the movement of the wall is fundamentally horizontal.

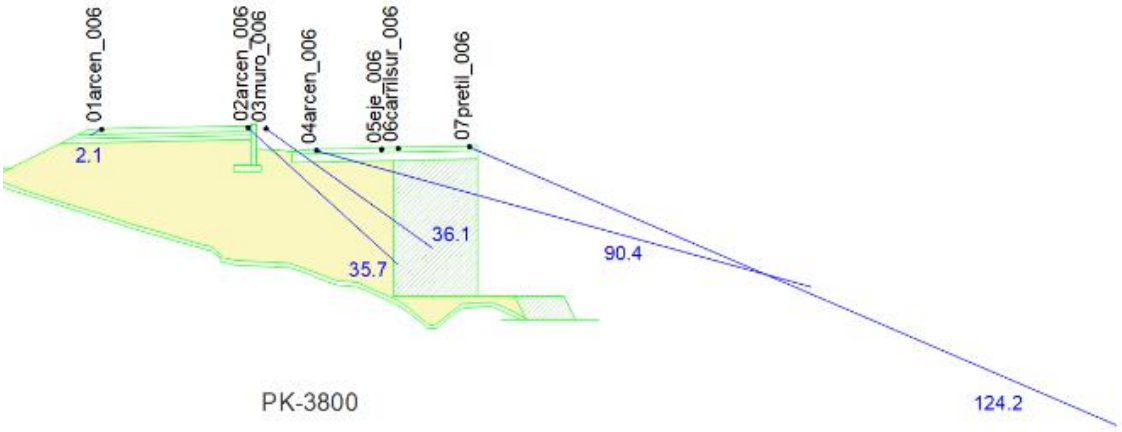

Figure 7. Transversal displacements vectors (in mm), obtained by classical topography and with a total station, between January 2019 and July 2021.

Figure 8. View of the TLS 3D model.

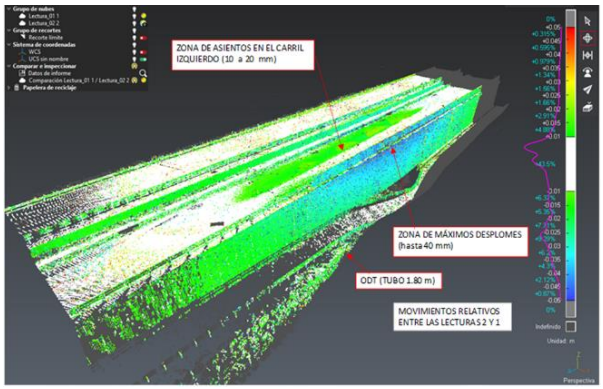

Figure 9. Relative displacements obtained by comparing TLS point clouds from model 1 (taken on October 2020) and model 2 (taken on March 2021).

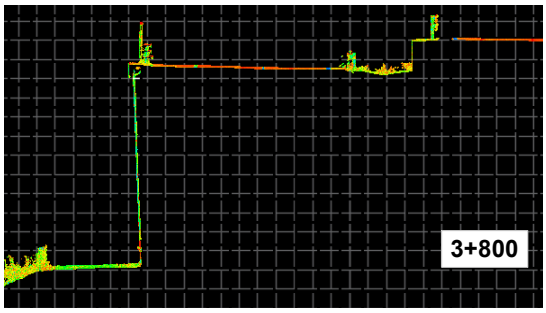

Figure 10. Cross section at station 3+800 obtained from the TLS model (grid on the images is 1 m long).

The movements and movement speeds obtained by the three procedures (TLS, topography and auscultation) have been reasonably consistent.

2 CAUSES OF THE PATHOLOGIES

It is considered that the causes of the pathologies can be the following:

- The existence of earth pressures at the back of the reinforced earth wall greater than expected due to: strength parameters (friction angle) of the retained fill lower than those considered in the design; existence of water pressures on the back of the reinforced earth fill not taken into account in the calculations; and saturation of the lower portion of retained and reinforced fill, or their foundation, by groundwater flows coming from the most pervious layers of the natural slope (sandy soils) or by leakages from the superficial drainage system.
- Inadequate construction details to avoid pavement cracking when a reinforced earth fill partially occupies the road platform (no extension of reinforcement strips in the upper zone of the reinforced earth fill until complete the whole width of the platform).

3 CORRECTIVE MEASURES

The wall has been tilting at a constant speed, that is, without showing a tendency to stabilization. The accumulated horizontal displacement observed at the wall crest ranges from 30 to 50 cm. As the wall had been tilting, at the mentioned rate, at least for around

5 years, it is considered that most of the accumulated displacement took place after construction.

Considering these circumstances, it was recommended to carry out some type of remedial actions. The measures should focus directly on the causes of the problem, that is, on reducing the pressure on the back of the reinforced earth wall and on avoiding saturation of the foundation of the retained and reinforced fill.

Therefore, it was proposed to act in two ways: improvement of strength of the retained fill and improvement of the general underground drainage. A required condition was that any remedial action should be undertaken always allowing the traffic to pass through at least one of the carriageways of the highway.

To improve the underground drainage, a longitudinal alignment of drainage wells located upstream the retained fill and the wall was proposed, see Figure 11. The wells are interconnected at their bottom, by horizontal drills with the adequate slope (2-5%), to allow the drained water to flow towards the central well. From the central well a longer and greater diameter drill hole carries all water drained by the well system to the river.

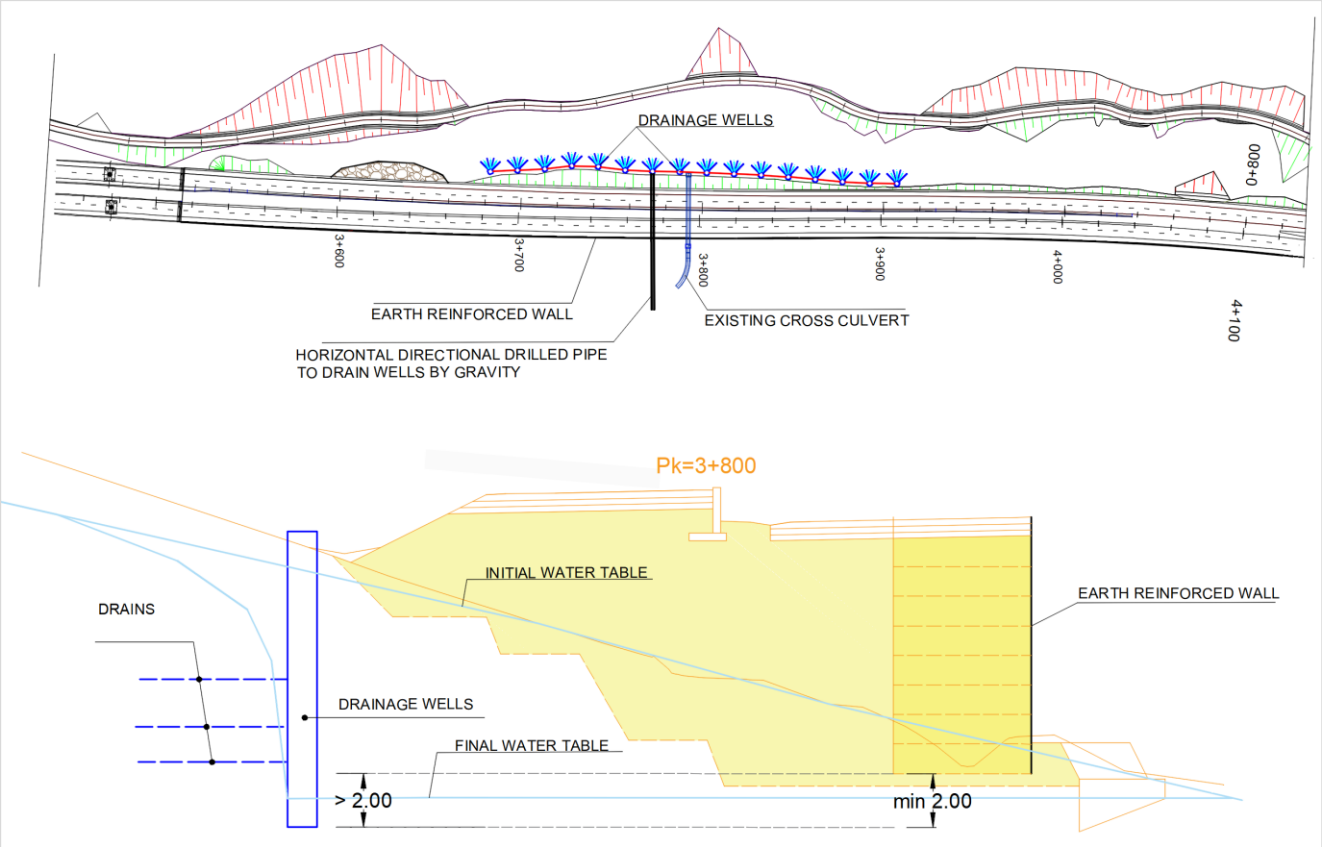

Figure 11. Schematic plan and cross section of the proposed draining wells (the water table position is an assumption).

To improve the retained backfill strength, the construction of transversal mortar (or deep mixed soil) diaphragm walls, 0.6 m thick and 7 m long, placed each 5 m in the longitudinal direction, were recommended. Each diaphragm wall module will act as a buttress of improved soil to reduce earth pressures on the wall, see Figure 12.

Finally, a reinforcement of the pavement structure was also proposed, as shown in Figure 13.

The construction works to implement these corrective measures ended in september 2022. Until now, january 2024, the inclinometer monitoring control of the wall indicates that the tilting movements have ceased. On the other hand, there are no new cracks reported on the pavement surface.

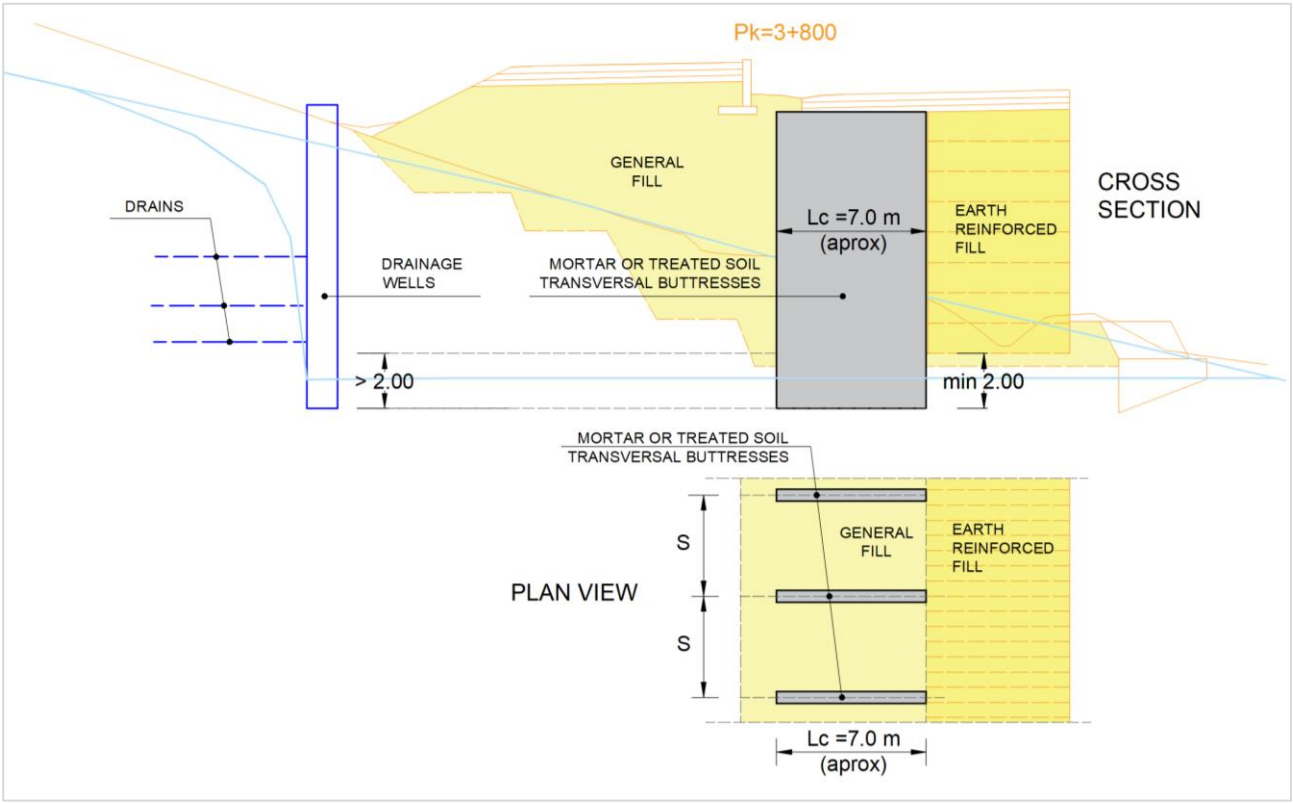

Figure 12. Schematic cross section and plan of proposed backfill improvement.

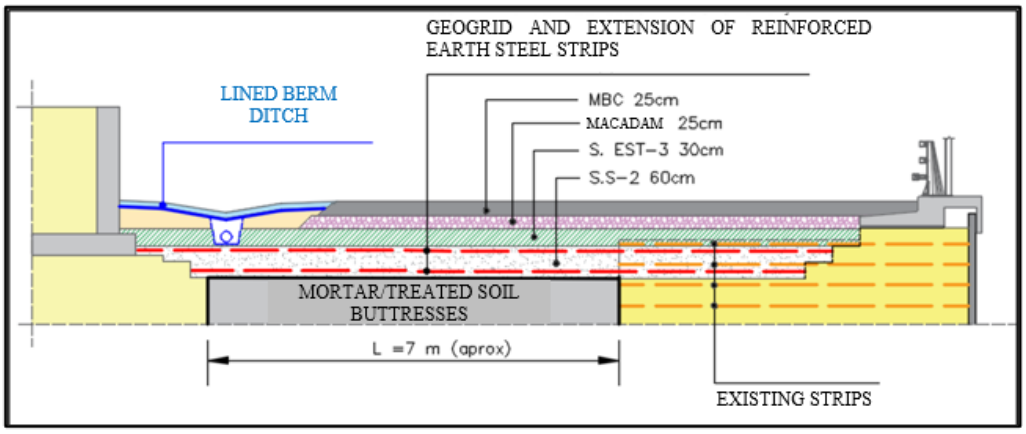

Figure 13. Cross section of proposed pavement structure.

4 CONCLUSIONS

A case of on-going tilting of a reinforced earth wall in a Spanish highway embankment has been presented. In order to analyse the problem, besides traditional monitoring system, a terrestrial laser scanner model (TSL) has also been used. It resulted very useful to analyse and quantify the wall movements. The causes of the pathology have been identified, and remedial measures have been proposed to correct the problem.

Comparison between biocementation and a traditional cover solution to avoid ravines in slopes caused by water flow

Comparaison entre biocementation et une solution de couverture traditionnelle pour éviter les ravins dans les pentes causées par l'eau

R. Fernández Rodríguez*, R. Cardoso
CERIS/IST/University of Lisbon, Lisbon, Portugal

**roman.fernandez@tecnico.ulisboa.pt*

ABSTRACT: The occurrence of intense rainfalls with high erosion potential in roads is expected under a climate change scenario. Malfunction or defective discharge systems may cause downslope soil erosion through scour and runoff, and therefore it is important to increase slope resilience by adopting adequate protection solutions. This paper presents an experimental study where the effectiveness of biocementation through enzymatically induced carbonate precipitation (EICP) was investigated as an alternative to a traditional solution consisting in adopting a riprap cover. Two identical small-scale slopes were built with dry uniform grading size sand in the laboratory. The first slope was treated with enzyme and the second with a calcareous rip rap cover. Both were subjected to a water thread of 0.13 l/min simulating a culvert outflow. For the enzyme-treated slope no scour or runoff erosion have occurred under this concentrated water jet, while resistance to runoff erosion was observed but scour erosion has occurred for the slope where the traditional solution was adopted. Both tests ended when the first signs of instability appeared after saturation. The two methods have prevented runoff erosion of the slopes, but only EICP prevented scour erosion, proofing the efficiency of this treatment against ravine formation. The paper ends discussing the main practical aspects of both solutions, presenting advantages and limitations.

RÉSUMÉ: Dans le cadre du scénario de changement climatique, on s'attend à des précipitations intenses avec un fort potentiel d'érosion sur les routes. Un mauvais fonctionnement ou des systèmes d'évacuation défectueux peuvent entraîner une érosion du sol en aval par affouillement et ruissellement, et il est donc important d'accroître la résistance des pentes en adoptant des solutions de protection adéquates. Cet article présente une étude expérimentale dans laquelle l'efficacité de la biocimentation par précipitation de carbonate induite par voie enzymatique (EICP) a été étudiée en tant qu'alternative à une solution traditionnelle consistant à adopter une couverture en enrochement. Deux pentes identiques à petite échelle ont été construites en laboratoire avec du sable sec de granulométrie uniforme. La première pente a été traitée avec une enzyme et la seconde avec une couverture d'enrochement calcaire. Toutes deux ont été soumises à un débit d'eau de 0,13 l/min simulant l'écoulement d'un ponceau. Pour le talus traité à l'enzyme, aucun affouillement ou érosion par ruissellement ne s'est produit sous ce jet d'eau concentré, tandis qu'une résistance à l'érosion par ruissellement a été observée, mais une érosion par affouillement s'est produite pour le talus où la solution traditionnelle a été adoptée. Les deux essais ont pris fin lorsque les premiers signes d'instabilité sont apparus après la saturation. Les deux méthodes ont empêché l'érosion par ruissellement des pentes, mais seul l'EICP a empêché l'érosion par affouillement, ce qui prouve l'efficacité de ce traitement contre la formation de ravins. L'article se termine par une discussion sur les principaux aspects pratiques des deux solutions, en présentant leurs avantages et leurs limites.

Keywords: Slope; biocemention; riprap; ravine.

1 INTRODUCTION

Road construction often results in the creation of bare slopes. To prevent their erosion, drainage systems are designed to collect runoff water and discharge it downhill through culverts, as shown in Figure 1. However, these concentrated outflows can result in scour and ravine formation (Bochet and García-Fayos, 2004; LaMarche and Lettenmaier, 1998), leading to significant soil losses and high maintenance costs, especially in non-cohesive soils (Chehlafi et al., 2019).

A common countermeasure adopted to avoid this problem, is to cover the slope with rock or gravel blocks. This simple solution is known as riprap and acts as an energy dissipation structure (Price, 2021). The material used in riprap construction should preferably be angular and resistant to weathering, their size being determined by the velocity of water flow (Lagase e al., 2006).

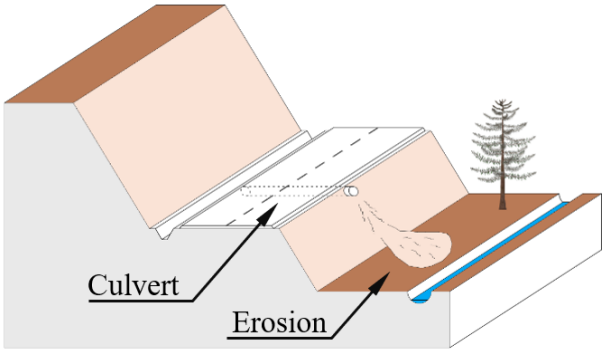

Figure 1. Slope erosion due to culvert discharge (adapted from Fu et al., 2010).

Enzyme Induced Carbonate Precipitation (EICP) is an environmentally friendly technique that can be an effective alternative to riprap, with the advantage of eliminating the visual impact of covering the slope with rocks. This technique is also known under the generic name of biocementation and is based on the use of enzyme urease that is introduced into the soil pores, together with urea ($CO(NH_2)_2$) and a calcium source (ions Ca^{2+}), to promote the precipitation of calcium carbonate ($CaCO_3$). The hydrolysis of urea (Equation 1) is 10^{14} times faster in the presence of the enzyme:

$$CO(NH_2)_2 + 2H_2O \rightarrow 2NH_4^- + CO_3^{2-} \quad (1)$$

The precipitated calcium carbonate (Equation 2) acts as a natural cement binding the soil particles together and thus increasing their strength and stiffness, while reducing permeability due to pore clogging:

$$C_a^{2+} + CO_3^{2-} \rightarrow C_aCO_3 \quad (2)$$

This paper compares these two techniques (biocementation vs. riprap). For this purpose, two small slopes were built in the laboratory. One was treated with enzymes to promote the precipitation of calcium carbonate and the other was covered with gravel to simulate a riprap. Then, both were subjected to a constant flow of water for the same period, simulating the discharge of a culvert.

2 MATERIALS AND METHODS

A commercial fine river sand with mean diameter (D_{50}) 0.3 mm, and coefficient of uniformity (C_u) of 2 was used to build the slopes. It classifies as poorly graded sand (SP) according to the Unified Soil Classification System. Its mineral composition is mainly quartz and feldspar.

For building the slopes, the sand was pre-dried in an oven and then placed carefully in a transparent methacrylate box to have a final porosity of 44%, which corresponds to the void ratio (e) 0.8. The slopes formed, with the horizontal dimension twice the vertical dimension (inclination 30º), were 15 cm high, with 30 cm long and 30 cm wide.

For the enzyme-treated slope, the treatment was carried out in two phases. In the first, 100 ml of distilled water and powdered urease enzyme solution (from the plant *Canavalia ensiformis*) was sprayed on the surface of the slope. In the second phase, 30 minutes later, 200 ml of a 0.5 M equimolar solution of urea and calcium chloride (source of calcium) and 1:10 diluted growth medium were applied. This treatment was repeated for five days. The water content was 10% before the start of the erosion test.

For the second slope, a limestone gravel with a mean diameter (D_{50}) of 4 mm and a coefficient of uniformity (C_u) of 2.2 was used to form a riprap. The soil cover was 100% in the central area of the slope, forming a layer 10 cm wide and 7 mm thick. The size of the riprap particles was compatible with laboratory scale and was tested to ensure that the water jet to be applied would not transport them, such as in real scale solutions.

During the construction of the second slope, a layer of red sand was placed under the riprap, to increase the colour contrast between the sand and the gravel, thus facilitating the observation of possible erosive phenomena.

3 EROSION TEST

3.1 Experimental setup

A water tank was used to ensure a constant water head, being the desired flow rate regulated with a tap. The flow rate of 0.13 l/min was established based on preliminary tests, which showed that this streamflow has energy enough to cause an erosion channel in less than 15 minutes when applied to an untreated slope.

The outlet pipe has a diameter of 5 mm and was positioned at a height of 1 cm above the highest part of the slope in its middle part. The duration of the test was 15 minutes for both slopes.

3.2 Results

The amount of biocement precipitated in the surface area of the enzyme-treated slope was 1.7 %. This percentage was sufficient to prevent scour erosion. Furthermore, runoff erosion was practically negligible, as can be observed in Figure 2. It is worth

to note that the permeability of the treated slope surface remained high, as water continued to infiltrate.

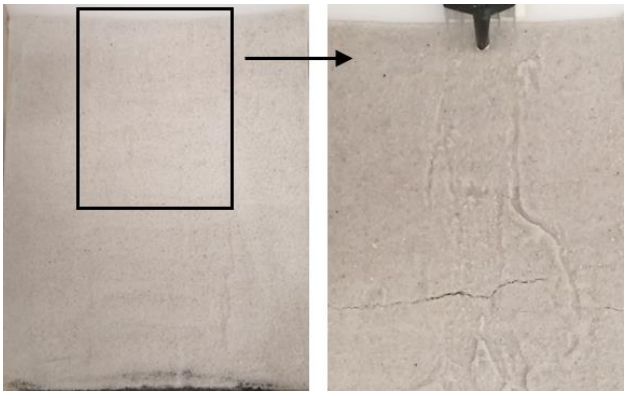

Figure 2. Enzyme-treated slope before (left) and after the test (right). Top view.

For the slope protected by a riprap, the weight of the limestone particles prevented them from being moved by the water jet, thus contributing to dissipate its energy. At the same time, this highly pervious layer acts as a drain, favouring water infiltration and reducing runoff (Li et al., 2022). However, as the test progressed, the particles under the impact zone of the water jet began to move slightly, which favoured the penetration of the water and the undermining of the soil below. This scour is evidenced during the test by the appearance of eroded sand (pink in colour) around some gravel blocks (see Figure 3).

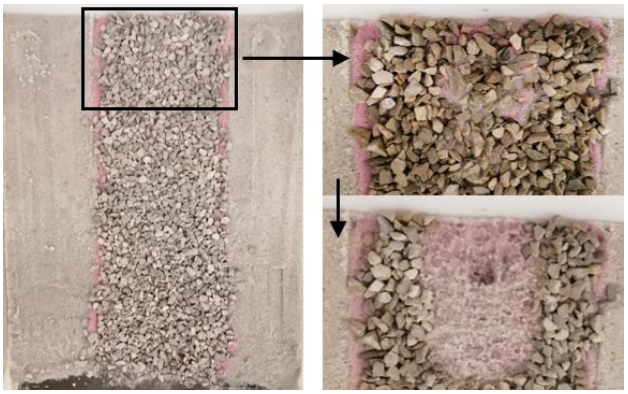

Figure 3. Riprap slope before (left) and after the test (right). Top view. Scour erosion can be seen in the area where the water discharge occurred.

Once the test was completed, the gravel blocks were removed one by one, taking care not to disturb the slope surface. Once this cover was removed, no signs of runoff erosion were visible. However, a small pit or scour of approximately 1 cm in depth can be observed in the water discharge area (see Figure 3). This is the evidence that riprap can be an effective measure to prevent runoff erosion, but it does not eliminate scour erosion.

Regardless of the effectiveness of both techniques in protecting the slope from erosion by runoff and scour, slope instability phenomena occurred in both cases. These were due to the fact that during the test, the soil becomes progressively saturated with water.

Saturation of the slopes resulted in increased water pressure and, as a consequence, reduced shear strength. In addition, once the slope was completely saturated, water started to flow through the bottom interface, between the permeable (sand) and impermeable (methacrylate) material, which also favoured the failure (Li and Mo, 2019).

Although this explanation is satisfactory for both tests, the failure developed was different in each case. In the EICP slope, tension cracks formed because the superficial layer of the slope was cemented. Once broken, this rigid layer moved with the underlying saturated sand in a manner similar to the ground movements known as soil spreading.

In the slope protected with riprap, there was a failure at the foot of the slope due to liquefaction, without the development of cracks such as those in the EICP slope.

Figure 4 shows the frontal view of both slopes at the end of the tests, where the cracks developed are visible.

Figure 4. Failure in the EICP treated (left) and riprap covered (right) slopes. Front view.

4 DISCUSSION

Many are the solutions adopted to protect slopes against erosion caused by concentrated water flow. Figure 5 presents some examples, namely the protection using projected cement, a riprap cover and the used of geotextiles with seeds to promote vegetation growth and root fixation. All these solutions can be used in sandy geological formations.

Not only the mechanical behaviour of such covers to resist to erosion mut be considered, but also their hydraulic characteristics, being both usually linked. Indeed, the adoption of a stiff solution such as when using cement requires drain installation to allow internal drainage because it is impervious. Failure in such case may be caused by the accumulation of water pressure below the protection cover. The use of rip rap

masks also introduces some stiffness, ensuring both drainage and infiltration. Failure in this case may be caused by slope surface instability caused by weight or by heavy water flow during extreme rain events.

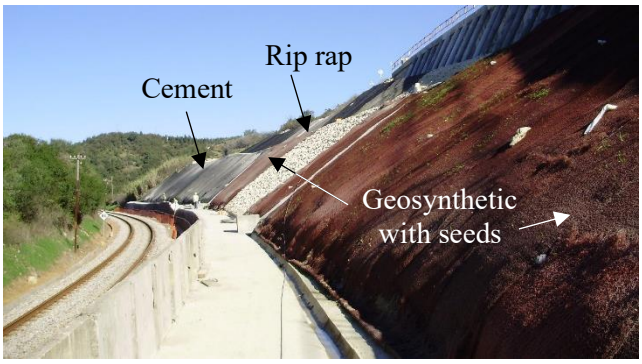

Figure 5. Several solutions adopted for slope protection (from back to front: cement projection, vegetal cover seeded in geosynthetics, gravel mask and vegetal cover seeded in geosynthetics).

It is well known the favourable contribution of vegetation for shallow slope stabilization, ensuring water infiltration. Howevwer, the vegetal cover is not continuous in the entire surface, or the roots may not be deep enough to resist to heavy water flow during extreme rain events. The entire protection of the slope area is ensured when a geosynthetic cover is installed, being this a pervious solution with very low stiffness. The drawbacks of such solution are mainly the time necessary for vegetation to grow, anchor durability and need for some maintenance.

Biocementation is a solution that joins the characteristics of all. In terms of particle cementation and consequent creation of a stiff cover, it is similar to a cement cover but with much lower stiffness than cement. The soil permeability remains high, therefore infiltration (and drainage) still can occur, as for rip rip and vegetation covers. Although further vegetation growth is limited to some species, this treatment solution offers the advantage of ensuring an homogeneous protection of the entire slope area.

5 CONCLUSIONS

The study performed at laboratory scale has shown that biocementation can be a good solution to protect slopes against erosion, introducing some stiffness but keeping the permeability of the soil. These characteristics are desirable for slope protection solutions as discussed. The adoption of a riprap cover did not performed as well because there was some scour erosion below this pervious cover. Biocementation is a promising solution, which must be applied in real cases to evaluate better its performance.

Risk analysis of decommissioning design of tailings dams

Analyse des risques liés au projet du déclassement des barrages de stériles

ABSTRACT: The mining industry usually resorts to dams as tailings storage facilities, and these structures represent a significant risk to the environment and surrounding communities if inadequate solutions are implemented. Several failures of such structures have happened before resulting in disastrous consequences, which has made society aware of the need for proper governance of tailings dams based on risk assessment and safety evaluations. After the most recent tailings dam failures, the concern associated with upstream tailings dams intensified, leading, in some cases, to the need for decommissioning design of these structures in order to prevent further failures. Within the process of improving tailings management systems, risk analysis methodologies have become an important tool. This paper resorts to a set of upstream tailings dam decommissioning designs to identify key aspects related to risk management of such structures before, during and after decommissioning. The application of the Failure Modes Effects and Criticality Analysis (FMECA) allowed to identify the main risks associated with the decommissioning of the dams and to define preventive and mitigation actions as well as controls to be implemented in order to minimize the risk, consistent with the principles of Global Industry Standard on Tailings Management.

RÉSUMÉ: L'industrie minière a généralement recours à des barrages comme installations de stockage de stériles, et ces structures représentent un risque important pour l'environnement et les communautés environnantes si solutions inadéquates sont utilisez. La défaillance de telles structures s'est déjà produite et a entraîné des conséquences désastreuses, ce qui a fait prendre conscience à la société de la nécessité d'une bonne gouvernance des barrages de stériles basée sur l'évaluation des risques et de la sécurité. Après les ruptures les plus récentes des barrages de stériles, les préoccupations associées aux barrages réalisent dan méthode en amont se sont intensifiées, ce qui a conduit à la nécessité, dans certain cas, au démantèlent de ces structures afin de prévenir de futures ruptures. Dans le cadre du processus d'amélioration des systèmes de gestion des résidus, les méthodologies d'analyse des risques sont devenues un outil important. Cet article recourt à un ensemble de projets de démantèlement de barrages de stériles réalisent dan méthode en amont pour identifier les aspects clés liés à la gestion des risques de ces structures avant, pendant et après le démantèlement. L'application de l'Analyse des Modes de Défaillance, de leurs Effets et de leur Criticité (AMDEC) a permis d'identifier les principaux risques associés au démantèlement des barrages et de définir les actions et contrôles de prévention et d'atténuation à mettre en œuvre afin de minimiser le risque, conformément aux principes de la Norme industrielle mondiale sur la gestion des résidus.

Keywords: Risk analysis; decommissioning of tailings dams; tailings dam design.

1 INTRODUCTION

The mining industry has been seizing from technology evolution which made it economically feasible to mine lower-grade ores and significantly increase the excavated volumes (Piciullo et al., 2022; Bowker and Chambers, 2016), leading to significant increase on tailings production over the past 100 years. In 2010, the production of tailings by the mining industry was estimated to be 14 billion tonnes (Jones and Boger, 2012). Being the by-product of the mining activity, tailings are a mixture of granular material with significant content of metals, chemical reagents and process water from extractive industrial processes, considered to be waste after the extraction of valuable minerals, metals, mineral fuels or coal (Kossof et al., 2014). Tailings represent a hazardous material. Its composition is complex and can display dangerous characteristics (corrosive, volatile, acidic and other characteristics related to the mined material), and it has to be safely managed, for its release can pose a threat to the surrounding environment and communities. Tailings management have been done using several approaches which include riverine disposal, submarine disposal, wetland retention, backfilling, dry stacking, and storage in dams (Lottermoser, 2007). Currently, tailings are commonly stored in dams. Typically, these

dams are not built to meet full capacity, instead they follow the production and are raised as storage volume demand increases, commonly heightened upstream, centreline, or downstream. Of these three methods, the upstream raising is the cheapest (Soares et al., 2000) and represents 37% of the total existing facilities, being the most common construction raising method. Although its construction has been greatly decreasing due to its safety issues, active upstream tailings dams report higher incidence of stability problems (Franks et al., 2021).

Tailings dams are among the largest engineered structures and its management is primarily focused on risk reduction strategies, to avoid potential hazard exposure. Historically, there has been some tailings dam failures which resulted in disastrous consequences, e.g. Mount Polley (Canada, 2014), Samarco (Brazil, 2015), Brumadinho (Brazil, 2019), Luming (China, 2021) and Catoca (Angola, 2021). These ocurrences led to a renewed attention to tailings management practices and tailings dam maintenance by government and mining companies (Franks et al., 2021).

This paper highlights the importance of adoption of risk reduction strategies for managing upstream tailings dams. Based on several upstream tailings dam risk analysis regarding its decommissioning design and deconstruction processes, the intention is to identify key aspects of the risk management in decommisioning design.

2 DECOMISSIONING OF TAILINGS DAMS

At the end of available storage volume, tailings dams are either raised further or decommissioned. The decommissioning of tailings dams typically involves the rearrangement of the geometry of the structure to significantly decrease long-term stability risks and hazardous events, e.g. by creating a gentler slope, and ensuring the proper management of the water inflow, alongside with landscape remediation.

Due to the high frequency and consequences of dam failures and upstream tailings dam stability concerns, upstream raised dams have been banned in Chile (1970), Peru (2014) and Brazil (2019) (Franks et al., 2021). Moreover, after the most recent tailings dam failures, the concern associated with upstream tailings dams intensified, leading to specific attention regarding safety, monitoring and decommissioning of these structures. Furthermore, in some countries it is mandatory to decommission all the active upstream tailings dams, in order to prevent future failures. Nonetheless, the decommission of such structures is complex and requires the understanding of the risks acting on the structure before, during and after the decommission process. Additionally, it is important to involve all the stakeholders in this process, understand possible failure modes and make recommendations to prevent them.

3 KEY ASPECTS OF DECOMMISSIONING TAILINGS DAMS

Tailings dams are complex and risky, as they involve numerous risk factors that can provoke catastrophic consequences. The identification of risks and their characteristics is an important part of the system safety management (Zheng et al., 2022). By priorly identifying the failure modes and their causes, safety management of tailings dams can focus on prevention and/or mitigation of its consequences. Consequently, within the process of improving tailings management systems, including decommissioning tailings dam design, risk analysis methodologies have become an important tool (Schaffer, 2021). To identify the key aspects of decommissioning of tailings dams, the present paper resorts to a set of risk analyses previously made to several upstream tailings dams in decommissioning design phase. The analysed dams consist of internal dikes (heights between 10 and 20 m) of a big tailings dam. They were built over tailings and then heightened by the upstream method. The decommissioning design phase considered the need of deconstructing all the internal dikes and leave the main dam intact. The risk analyses were developed by using FMECA methodology (Failure mode, effects, and criticality analysis). This methodology has been widely used for risk analysis of geotechnical structures including embankment dams (Santos et al., 2008).

Decommissioning of tailings dams involves an existing structure with specific characteristics, a defined monitoring system, and a maintenance processes. The decommission is normally related with an existing failure risk, most of the times, associated with some important uncertainties regarding the tailings, the as-built structure (namely method of construction), and the possible consequences in case of failure. Naturally, the risk analyses carried out allowed the conclusion that the failure risk reduces substantially after decommissioning. However, it was verified that during the process itself, the risk could increase if the decommissioning design is not sufficiently robust and could even increase the probability of failure with respect to the situation prior to decommissioning. It was also verified that the decommissioning design must detail construction sequence for each phase, as well as to improve the

monitoring system for most critical phases that could constitute triggers for specific failure modes. By going through the risk analyses during the decommissioning design phase, it was possible to properly adapt the design to decrease the risk associate with failure.

The decommissioning design must take into account several aspects when defining the long-lasting residual structure and also the decommissioning processes to minimise/prevent failure modes and mitigate its consequences. These key aspects are presented further in the next sections.

3.1 Tailings characteristics and its vulnerability to stability problems

Being the byproduct of the mining activity, tailings have an inherent level of uncertainty regarding its properties, for example, in terms of grain size (within a certain range specific to the processing method), saturation level and chemical composition (within a certain spectrum related to the nature of the tailings and industrial process involved). These uncertainties and the heterogeneities of the material make it hard to predict its behaviour. This aspect gains relevance when tailings are used as foundation for heightening of tailings dams. Since there are uncertainties regarding its behaviour, it is risky for the integrity of the structure to be dependent on the mechanical properties of tailings and its response to loading/unloading.

Some recent upstream tailings dam failures were related to liquefaction of the tailings serving as foundation for the dam raised structure. Moreover, the state and saturation conditions of tailings, which normally are difficult to evaluate, add to the uncertainty regarding its mechanical behaviour. This implies that these uncertainties must be taken into consideration when raising a tailings dam but also when decommissioning these structures.

It is important to control and register the deposition process and the properties of the tailings during active deposition phase and create a robust archive of all the information of the structure, to create a basic knowledge and as-built information to diminish these uncertainties.

3.2 Water management

Typically, when contained in dams, tailings are disposed with high water content. Normally, taking into consideration the characteristics and chemical composition of the tailings, the water released during deposition and the contact water cannot be freely discharged in the surrounding environment. So, throughout the lifetime of the dam, there must be a water management system to control the tailings saturation, the inflow of water into the facility and its containment or its diversion to treatment plants to be discharged into the environment (if possible).

During decommissioning, the structure generally evolves from a containment barrier to a stable slope, losing its capacity to contain water. This transition must be very well designed in order to reduce the risk associated with overtopping, erosion and release of untreated/contact water.

This implies that decommissioning design must consider a solution for the management of water inflow at all stages of the decommissioning processes. Special attention must be given to the specific stage where the water inflow is no longer contained but, instead, directed downstream.

Since decommissioned dams have no longer the objective of containing tailings and water inflow, its design must consider a way to divert and/or safely conduct the inflow towards downstream. In this way, decommissioning design must incorporate long-lasting water management systems to diminish infiltration and containment of the water, including drainage structures, both internal and external, with sufficient flow capacity.

3.3 Deconstruction processes

Decommissioning of tailings dams may involve several processes with significant earthworks. When dealing with tailings, an additional concern must be taken into consideration related to the excavation rhythm and type of equipment used. Heavy and invasive vibrations can trigger liquefaction of the tailings (Liew et al., 2020) and endanger the integrity of the structure.

The construction processes should minimise the vibrations to prevent liquefaction. Since there are some limitations in simulate the behaviour of tailings to construction induced vibrations, experimentation and in situ testing may be a good approach to define specific safety criteria and assess the effect of vibration. Besides, it is important to also consider the installation of monitoring equipment to measure the tailings response to vibrations, for example, with geophones. Additionally, measuring the excess of porewater pressure (with vibrating wire piezometers, for example) and its correlation to vibrations can be important to obtain information regarding the behaviour of the tailings in response to the earthworks, especially tailings on the foundation of upstream tailings dams.

3.4 Permanent closure and monitoring

Since the decommissioning objective is to prepare the structure for a long-lasting residual state where its

conditions are maintained throughout the rest of its life, guaranteeing its structural integrity, chemical stability, and resistance to external actions (such as erosion agents, earthquakes, among others) is crucial.

The decommissioning design must take into consideration the objective of turning the structure into a long-lasting safety condition with no need of significant maintenance. In order to have confidence on the general stability of the solution throughout its lifetime, a long-lasting smart monitoring system is needed to measure the evolution of the structure characteristics (e.g., the degree of saturation, ground movement, superficial erosion, among others).

4 CONCLUSIONS

Tailings dams may present high risk of failure during the decommissioning process, if not properly designed and implemented. The risk management of these processes is complex and, based on several risk analysis of decommissioning designs of tailings dams, four main aspects were identified:

- Tailings heterogeneity and behaviour uncertainties can pose additional concerns on safety when decommissioning tailings dams and designing the long-lasting structure;
- By decommissioning tailings dams, one of the concerns is to guarantee an effective water management system. This refers to the effective water diversion to ensure that it does not accumulate in the decommissioned structure and not deteriorate its stability;
- During decommissioning, the earthworks that are involved must take into consideration the triggering of tailings liquefaction. Thus, construction rhythm and type of equipment to be used must be compatible with tailings response to load/unloading;
- The long-lasting residual structure must be considered stable and inert, and so requiring effective and resilient smart monitoring system with low maintenance needs.

Having considered these key aspects, risk and safety management on decommissioning design of tailings dams can provide crucial guidance to successful projects. Additionally, risk analyses during the design phase can significantly contribute to adapt the design and include preventive measures that can decrease failure risk.

Comparison of floating and end-bearing pile wall barriers for tunnelling in layered soil

Comparaison des barrières de parois de pieux flottants et porteurs pour le creusement de tunnels dans un sol stratifié

A. Franza*
Aarhus University, Aarhus, Denmark
**anfr@cae.au.dk*

ABSTRACT: The construction of an embedded pile wall between the excavation and the foundation, before tunnelling, is a possible mitigation measure against excessive movements. This paper presents a three-dimensional interaction model, using the two-stage approach, the layered half-space theory, and the beam theory for the barrier, to study the efficiency of pile walls in layered grounds. In particular, a two-layer undrained ground model is considered which is key to capturing the fundamental differences between barriers of floating and end-bearing piles (as long as the approximation of linear soil behaviour applies). Results illustrate that, when possible, end-bearing barriers (with tips embedded in stiffer bottom layers) should be preferred to floating pile walls with their tips embedded below the tunnel invert depth to maximise the reduction of surface and subsurface settlements; contrarily, the effects of the barrier on lateral ground movements are minor for both floating and end-bearing barriers.

RÉSUMÉ: La construction d'un mur de pieux encastrés entre l'excavation et la fondation, avant le creusement du tunnel, est une mesure possible d'atténuation contre les mouvements excessifs. Cet article présente un modèle d'interaction tridimensionnel utilisant l'approche en deux étapes, la théorie du demi-espace en couches et la théorie des poutres pour la barrière, afin d'étudier l'efficacité des murs de pieux dans des terrains stratifiés. En particulier, un modèle de sol à deux couches non drainé est considéré, ce qui est essentiel pour saisir les différences fondamentales entre les barrières de pieux flottants et celles à appui (tant que l'approximation du comportement linéaire du sol s'applique). Les résultats montrent que, lorsque c'est possible, les barrières à appui (avec leurs pointes encastrées dans des couches inférieures plus rigides) devraient être préférées aux murs de pieux flottants dont les pointes sont encastrées sous la profondeur du tunnel pour maximiser la réduction des tassements en surface et sous la surface. En revanche, les effets de la barrière sur les mouvements latéraux du sol sont minimes pour les barrières flottantes et à appui.

Keywords: Tunnelling; ground movements; mitigation; barrier; pile wall.

1 INTRODUCTION

The excavation of tunnels can detrimentally affect near foundations of buildings, monuments, and infrastructure. Embedded barriers, either pile or diaphragm walls, are a passive, low-cost, low-impact mitigation measure of tunnelling-induced movements.

The use of embedded barriers has been successfully tested in important tunnelling projects in the urban environment (Di Mariano et al. 2007; Losacco et al. 2019). While the underlying mechanisms governing their behaviour have been thoroughly investigated for uniform soil (Bilotta and Russo 2001; Ledesma and Alonso 2017; Song et al. 2023), Franza et al. (2021a) indicated substantial differences in the barrier performance in layered ground (Di Mariano et al. 2007; Rampello et al. 2019). Despite recent analytical studies considering the relative soil stiffness between shaft and tip of piles (Cao et al. 2022), yet there is no design guideline to distinguish between floating and end-bearing pile barriers. For instance, the barrier's efficiency in reducing settlements is currently only related to the embedment of the barrier beneath the tunnel invert level (e.g. Ledesma and Alonso 2017).

This paper studies the shielding mechanism of tip-bearing and floating walls in a two-layered clay deposit using both a three-dimensional linear-elastic two-stage continuum-based interaction model. A parametric study quantifies the barrier's mitigation effects in terms of vertical and horizontal displacement reduction. Finally, the conclusions discuss the implications of linear elasticity in the design context.

2 STUDIED SCENARIOS

Figure 2 summarises the considered tunnelling and barrier scenarios in undrained soil. The study investigates a tunnel with a radius R =5 m and axis depth H = 15 m being excavated into three possible ground cases: namely, *case U* for uniform soft clay; *case S* for a stratigraphy consisting of a soft clay up to 25 m above a stiff clay layer (interface depth H_i = 25 m, giving H_i/H = 1.7); *case D* in which the stiff clay is deeper than Case S and located at the depth of 35 m (interface depth H_i = 35 m, giving H_i/H = 2.3). For all cases, the bedrock is 90 m below the surface. The soft clay has a Young's modulus E_s = 7.5 MPa whereas E_s = 300 MPa for the stiff clay, giving a stiffness ratio of 40 between the strata of the layered cases. For both clayed grounds, undrained conditions are considered (Poisson's ratio ν_s = 0.5).

Barriers of 11 bored reinforced concrete piles are analysed with Young's modulus E_p = 30 GPa, diameter d_p = 1 m, spacing in the tunnel longitudinal direction of S_p = 2 m (S_p/d_p = 2), an offset from the tunnel centreline of X_w =7.5 m (X_w/H = 0.5), and all having a tip level below the tunnel depth H. These tip locations are considered ($L_p > H$) because piles adjacent to and extending below the tunnel lead to efficient protective actions. To investigate the impact of layered grounds on the barrier performance, three possible embedment depths are considered, L_p = 22 m, 30 m, 40 m ($L_p/H \approx$ 1.3, 2.0, 2.7) to cover a variety of floating and end-bearing piles. In particular, floating piles are entirely located in a uniform soil stratum (case U or cases S and D with $L_p < H_i$) while end-bearing piles have their tip embedded in the stiffer bottom layer (cases S and D with $L_p > H_i$).

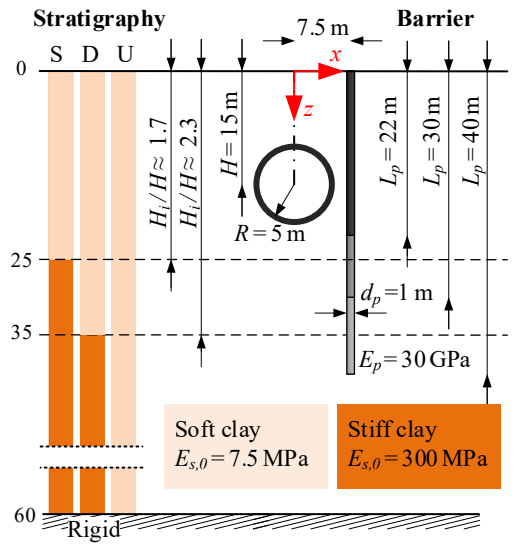

Figure 1. Scenarios of the parametric study.

3 INTERACTION MODEL

The COMPILE model is adopted for the linear elastic continuum-based two-stage analysis of tunnel-soil-barrier interaction (Franza et al. 2021a; 2021b). It allows the analysis of the soil-pile foundation interaction induced by ground movements in either homogeneous or layered ground.

As displayed in Figure 2, this interaction model accounts for the three-dimensional geometry of a pile row aligned along the tunnel longitudinal direction. This model assumes elastic Euler-Bernoulli beams for piles, thus considering pile axial vertical, horizontal, and rotational degrees of freedom. The homogeneous or layered isotropic half-space (referred to as a *continuum*) is adopted for the ground, characterised by Young's modulus $E_{s,i}$ and Poisson's ratio $\nu_{s,i}$ of each stratum. This is done by computing the flexibility functions of the soil (i.e. describing the soil displacements to loads in the three directions (x, y, z) along the pile axes) from integration at the pile boundary, without accounting for the presence of the tunnel. In the elastic solution, perfect compatibility is assumed between the pile axes and the half-space. As detailed by Franza et al. (2023), these functions are used to describe pile-soil interaction, pile-soil-pile interaction, as well as the shielding effect of the barrier on tunnelling-induced movements (the latter to propagate the local variation in displacements induced by the barrier across the half-space).

In this model the excavation is modelled using greenfield ground movements; considering steady-state conditions, the analytical displacement field of Loganathan and Polous (1998) for tunnelling in clay is adopted, as the tunnel invert is distant from the bedrock or stiff clay.

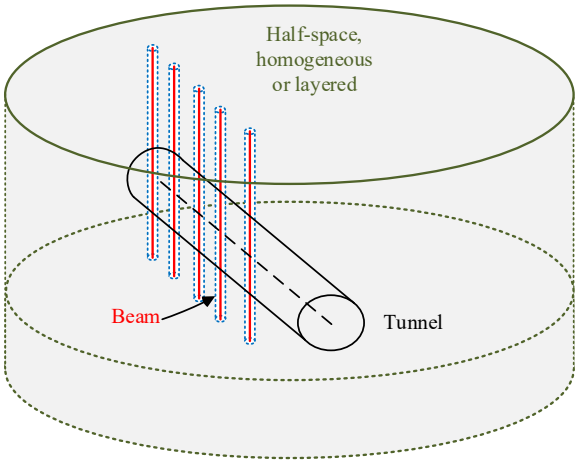

Figure 2. Elements of the three-dimensional interaction model.

4 RESULTS

Figures 3–5 show the results of the parametric study consisting of nine analyses (three barriers with $L_p/H = [1.3; 2.0; 2.7]$ and at an offset $x_w/H = 0.5$, three ground condition). Greenfield movements (GF) are compared with soil–structure interaction elastic results (SSI EL). As the interaction model is three-dimensional, results are at the transverse plane $x - z$ located at the centre of the barrier (in the tunnel longitudinal direction), which is of greatest interest. In particular, sub-plots (a) and (b) show horizontal and vertical displacements at two horizons (surface and subsurface at mid-depth to the tunnel axis), respectively; sub-plots (c) and (d) display, respectively, the horizontal and vertical displacements along the vertical at an offset of 1 pile diameter behind the barrier (for a normalised offset from the tunnel centreline $x/H = (x_w + d_p)/H = 0.57$). In the latter plots, a dashed line is used to indicate the interface depth H_l between soft and stiff clays. Also, displacement results are normalised by $u_{norm} = \Delta V/(\pi H) = V_{l,t}R^2/H$, where ΔV is the ground loss while $V_{l,t}$ the tunnel volume loss (as discussed by Franza et al. (2021a) to focus on the variation in the shape of the displacement field).

Results at surface and subsurface horizons indicate that the floating barriers have a limited capability to reduce settlements (both for the uniform soil case U, as well as for the layered cases S and D), whereas nearly null settlements are obtained behind the wall for barriers embedding in the stiff bottom later. Interestingly, the reduction in settlements extends to both sides of the barrier (consistently with previous analytical elasticity-based works). Contrarily, for all types of barriers, shielding of tunnelling-induced horizontal movements is minimal. Finally, for both pile types, note that settlements are reduced across the entire surface and subsurface horizons (i.e. both behind and on the front sides), as the pile-induced reduction in the greenfield settlement propagates according to the half-space flexibility functions.

The vertical *local wall efficiency* η_w is considered, defined as the complementary to unity of the relative reduction in the ground settlement behind the barrier (at $x/H = 0.57$). For floating barriers with tip at invert level ($L_p/H = 1.3$) the local efficiency is limited to 50–70% across all cases, whereas the embedment of end-bearing piles in the stiff clay layer determines the greatest efficiency (nearly 100%). Therefore, engineers should consider in design if the embedment of the pile tips into stiff deep layers (when present) could improve the barrier performance, as a function of the ratio between the depths of the tunnel invert and stiff layer.

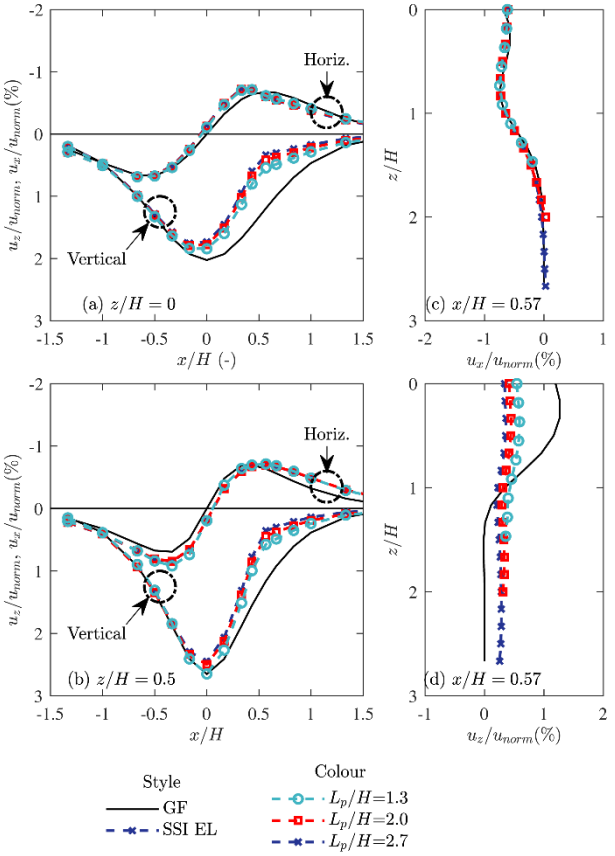

Figure 3. Effects of the barrier embedded in the uniform soil (case U) on surface and subsurface ground displacements.

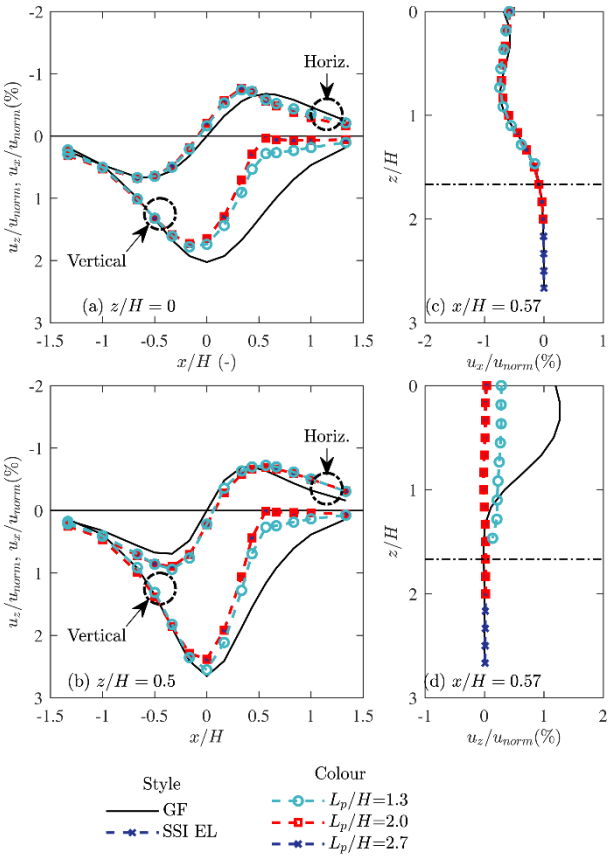

Figure 4. Effects of the barrier embedded in the layered soil (case S) on surface and subsurface ground displacements.

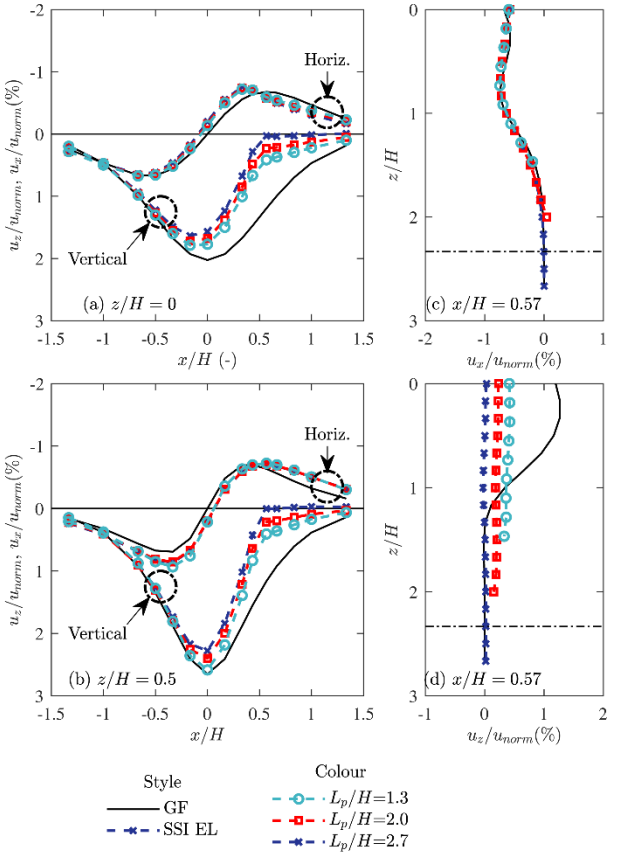

Figure 5. Effects of the barrier embedded in the layered soil (Case D) on surface and subsurface ground displacements.

5 CONCLUSIONS AND DISCUSSION

This paper presented an elasticity-based study of floating and end-bearing pile wall barriers next to a new tunnel in undrained layered soil. The following conclusions are drawn.

End-bearing barriers nearly prevented tunnelling-induced settlements behind the barrier (with local efficiency > 95%). On the other hand, when there is a significant distance between the stiff layer and the barrier tip, floating barriers extending up to or below the tunnel invert could only approximately halve the tunnelling-induced settlements.

For both pile types, as the soil behaviour is linear elastic, ground settlements were reduced both behind and on the front sides. However, literature results indicated that this mechanism may not apply when soil yielding plays an important role. Ongoing research is addressing this aspect.

Both end-bearing and floating barriers had a small shielding action on horizontal movements, despite the high bending stiffness of the considered piles. Therefore, the embedment in a stiff deep layer may not be beneficial if the aim is to limit horizontal ground movements.

A holistic risk sensitivity analytical approach for assessing flood protection infrastructure

Une méthode globale d'analyse des risques pour évaluer les infrastructures de protection contre les inondations

H.K. Fung, V. Nyambayo*
AtkinsRéalis, Epsom, United Kingdom

**vincent.nyambayo@atkinsrealis.com*

ABSTRACT: Many UK regions are flood-prone, with thousands of kilometres of flood defences having been installed to protect communities and infrastructure. Failure of flood defences usually results in huge socio-economic costs and occasionally human life. Since asset owners have limited resources to maintain infrastructure health, they often prioritise renewal and maintenance to assets that are nearing their 'end of life' based on risk analysis. This paper presents a methodology that was used to holistically evaluate the residual life of an existing 400m anchored sheet pile flood defence wall along a major river in UK. The approach included sensitivity analyses to understand risks more broadly and enabled further investigations or planned works to be informed, with awareness of how activities would impact on budget and programme constraints. Studies by previous consultants had concluded that the wall no longer had residual life. Sensitive factors which affect the anchor and sheet pile stability were identified, with the most sensitive factors being combined into models which represent the current and potential future conditions of the wall. A decision tree was then created, combining the critical sensitivity scenarios with the decision options which led to proportionate responses. The resultant benefits enabled the client to optimise resource deployment across their flood defence portfolio.

RÉSUMÉ: De nombreuses régions du Royaume-Uni étant sujettes aux inondations, des milliers de kilomètres de dispositifs de protection contre les inondations ont été installés pour protéger les communautés et les infrastructures. L'échec des défenses contre les inondations entraîne généralement d'énormes coûts socio-économiques et parfois des pertes humaines. Les propriétaires d'actifs disposant de ressources limitées pour maintenir les infrastructures, ils donnent priorité au renouvellement et à l'entretien des actifs proches de leur « fin de vie », selon les analyses de risques. Cet article présente une méthodologie utilisée pour évaluer de manière globale la durée de vie résiduelle d'un mur de protection contre les inondations en palplanches ancrées de 400 m, le long d'une rivière principale au Royaume-Uni. Des analyses de sensibilité ont permis de comprendre les risques de manière plus générale, et de permettre des enquêtes plus approfondies ou des travaux organisés, en tenant compte de l'impact des activités sur les contraintes budgétaires et de planification. Des études précédentes avaient conclu que le mur n'avait plus de durée de vie résiduelle. Les facteurs sensibles qui affectent la stabilité des ancrages et des palplanches ont été identifiés, les plus sensibles étant combinés dans des modèles représentant les conditions actuelles et futures potentielles du mur. Un arbre de décision a ensuite été créé, combinant les scénarios de sensibilité critique avec les options de décision qui ont conduit à des réponses proportionnées. Les avantages issus de cette étude ont permis au client d'optimiser le déploiement des ressources dans son portefeuille de défense contre les inondations.

Keywords: Sensitivity analysis; flood defence; decision tree; WALLAP.

1 INTRODUCTION

This paper demonstrated the application of a novel holistic risk sensitivity analytical approach for assessing the health of infrastructure asset, with an example of a flood protection sheet pile located in the UK. This differs from the traditional deterministic approach that only considers the central most likely case.

The flood defence is in South West England, UK. Following a long history of flooding recorded in the 1980s, a steel sheet pile wall with a reinforced concrete upstand and anchor was constructed in 1992 to protect properties along the riverbank. The wall is 400m long with a maximum retained height of 2.3m. A typical cross section is shown in Figure 1.

Previous studies and condition inspections had been carried out to investigate the residual life of the flood defence wall. Inspections identified possible leakages and extensive corrosion on the exposed riverward steel, which raised a concern regarding stability of the sheet pile wall.

The client requested the undertaking of additional studies prior to any further inspection, maintenance or

anchor lift off tests suggested in previous report recommendations by other consultants. The scope included a sensitivity analysis of factors affecting the stability of the wall, in order to understand the likely stability and risks associated with various possible scenarios. A decision tree was produced to inform the risk assessment to ensure that proportionate measures would be identified taking into consideration the safety, cost, and other key factors.

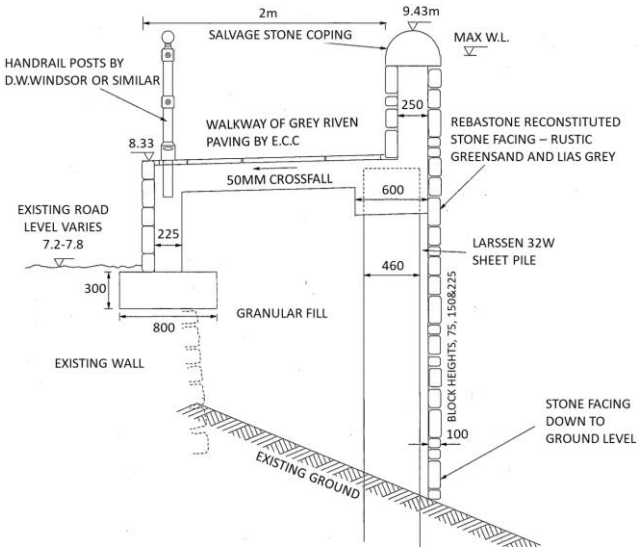

Figure 1a. As-built drawing showing typical cross section.

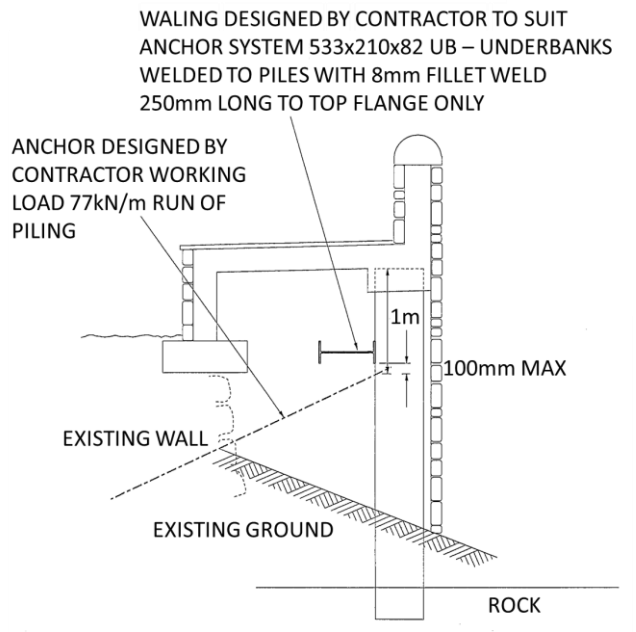

Figure 1b. As-built drawing showing anchorage details.

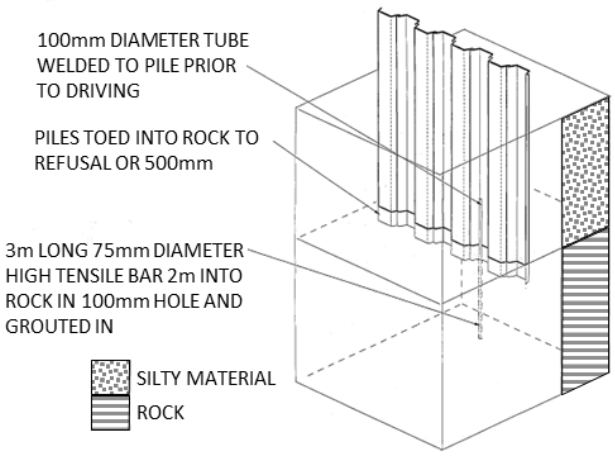

Figure 2. As-built drawing showing the sheet pile details.

2 METHODOLOGY

The following ground model was adopted in the sensitivity analyses:

Table 1. Ground model adopted in WALLAP.

Stratum	Top of Strata (m AOD)
Made Ground	+7.23
Alluvium	+4.93
Conglomerate	-0.07

2.1 Sensitivity Analyses

This study utilizes uses the limit state equilibrium method, as implemented in WALLAP version 6.06. A series of sensitivity analyses were carried out to understand and assess the consequences of different scenarios, based on the available as-built drawings. The presumed construction sequence was modelled in WALLAP (Borin, 2010) as follows:

i) insert Larssen 32W pile sheet piles;
ii) add Made Ground granular fill up to the elevation of the anchors;
iii) insert anchor force, setting the head plates into the sheet piles and adding pre-stress;
iv) complete the filling of the Made Ground to just under the pavement elevation.

Steel properties were adopted from relevant guidance (ArcelorMittal, 2008), with the loading regime being conceptualised as shown in Figure 3.

2.2 Selected sensitivity case types

A central case (Scenario A below) was based on historic design drawings.

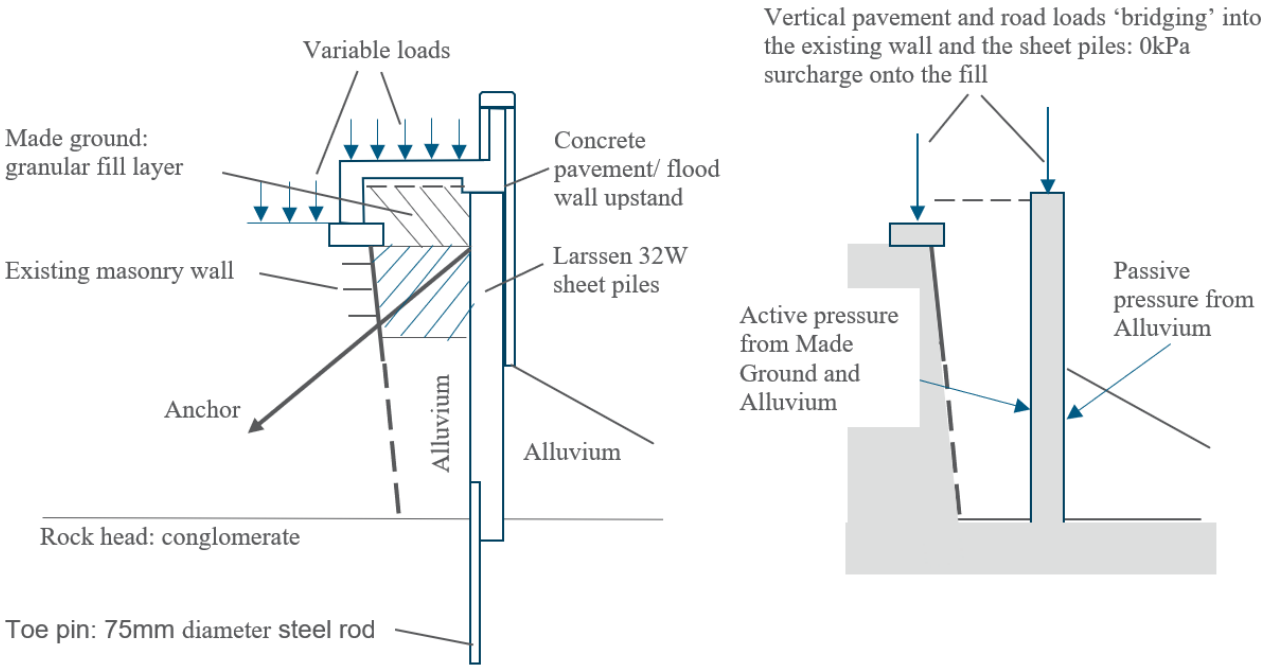

Figure 3. Conceptualised cross section.

In addition, the following cases were also modelled, varying the sensitivity parameters as specified:

- A Base model, as shown in as-built drawings
- B Riverward Alluvium berm at +3.26m AOD and steepened 1 in 1.5 to assess the limiting condition
- C Riverward Alluvium reduced to +1.83m AOD with an assumed gradient of 1 in 3.6
- D Riverward Alluvium reduced to +1.83m AOD with a gradient of 1 in 3.5 to test for the limit of stability (critical factor of safety (FoS) case)
- E Base model except alluvium friction angle adjusted +/- 2 degrees
- F Same as Case C but with extensive corrosion of the sheet piles
- G Base model except raised groundwater on landward side, and reduction in level of Alluvium in Riverside, berm gradient was set in 1 in 3
- H Base model except varying toe fixity and embedment
- I Base model except the riverward Alluvium is reduced to +2.20m AOD and no rod.
- J Base model except assuming pile refusal at top of rock head causing the rod to be lifted
- K Loss of anchor and riverward Alluvium

3 RESULTS

The results, calculated in accordance with Eurocode guidance (British Standards Institution, 2013) and the accompanying National Annex (British Standards Institution, 2009), demonstrated that several mechanisms exist by which the modelled wall section might become unstable, as shown in the table below:

Table 2. WALLAP result ranges for each case type.

Case Type	Factor of Safety	Bending moment (kNm/m)	Shear Force (kN/m)	Anchor Force (kN)	Maximum deflection (mm)
A	2.172	56	27	196	8
B	1.086	156	107	386	16
C	1.012	170	121	406	17
D	0.996	No results – wall stability failure			
E	2.075 to 2.273	55 to 57	23	196	8
F	1.023	172	68	407	19
G	1.012	241	107	646	27
H	1.330 to 2.484	17 to 63	4 to 6	129 to 203	8 to 25
I	1.066	160	64	392	23
J	1.045	81	39	265	16
K	1.021	83	24	No anchor	51

3.1 Overview of Results

Various scenarios have differing levels of probability and different outcomes for wall stability, including structural failure or excessive deflection. The relative probabilities of each scenario are determined qualitatively, based on literature and engineering judgment (Burland, 1987). The implications from the sensitivity cases modelled are listed below:

Low likelihood scenarios

- Case G - extreme retention of elevated groundwater on the landward side combined with riverward Alluvium at +2.75m AOD can exceed the designated strength of the anchor, leading to only marginal stability in the model. This level of lag is considered very low probability, given the granular fill used behind the upper part of the wall;
- Case H - toe fixity and embedment changes are only important to stability when combined with a loss of Alluvium on the riverward side. Loss of toe fixity can be identified as a large deflection along the bank elevation;
- Case K - failure of a single anchor makes the model unstable if combined with riverward Alluvium below +4.40m AOD. The riverbank elevation is already observed as +3.26m AOD, and if an anchor had failed, a larger deflection of the wall at the failure location would be apparent. This is because the waling transfers the load sideways to neighbouring anchors. Since there is no current observation of excessive deflection of the wall, the failure of an anchor remains a low probability.

Moderate likelihood scenario

- Case E - Variable frictional strength of the Alluvium is a moderate probability but does not have a significant impact on the model;

Higher likelihood scenarios

- Case B, C, D, or I - Loss of riverward Alluvium reduces the model stability FoS < 1. Both the elevation of the top of the Alluvium and its slope gradient control the stability.
- Case F - modelling indicates the corrosion of exposed piles impacts wall stability significantly, as corrosion will affect the long term thin section buckling resistance;

In terms of how this affects the future management of the flood defence, the results demonstrate both short and longer term high risks. The short term risk is the loss of an additional 1.43m of Alluvium from the riverward side which will lead to instability. If riverward erosion was controlled but some portion of the sheet piles were permitted to remain exposed, concentrated corrosion of the outpan combined with less rapid corrosion of the flange will eventually lead to a long term thin section buckling failure (Breakell et al., 2015).

4 DECISION TREE

4.1 Background

With any historical structural asset, there is a general risk around obtaining sufficient certainty regarding its current condition and stability. Part of the process of constructing a decision tree involves understanding the current condition of structural elements and making reasonable predictions about their future condition. These aspects were addressed in various ways in the earlier studies of the structure but needed further considerations as follows:

- What manner of corrosion is occurring on the exposed sheet pile faces, what corrosion rate should be projected forward, and on which parts of the pile should this rate be applied?
- Is there a stability risk to the highest retained height along the wall and its supports due to riverbank erosion and sheet pile corrosion?
- Is there a reasonable justification to carry out standard investigations on the anchors (anchor lift of tests) and will testing these anchors make a difference to the overall assessment?
- Is there an optimal cost/benefit option?
- The following summarise the information relating to each of the problems listed above and provide the basis of the decision tree. The decision tree is presented in Figure 4.

4.2 Maintenance aspects

It is understood that periodically during high water events, there is ponding of water accumulating to the western part of the flood defence and to the southern end of the underbanks defence. All stakeholders agreed that the most likely cause of the ponding water is that one or more of the flap valves cannot close properly. The cause of the underbanks ponding is not sufficiently investigated. Part of the decision tree will include remediation of the flap valves that are not working properly and investigation of the underbanks area of concern.

4.3 Decision tree process

The decision tree is constructed as a set of options for the client to consider as ‘do nothing’, ‘do minimum’ and ‘do refurbish / replace / improve’. Information from the sensitivity analysis crosses into the decisions and indicates what risk is attached to the selected

decision. Where text is highlighted red, the risk is considered high that the option could lead to instability of the wall. The amber text indicates that wall stability failure is averted but there are other maintenance tasks which, if not carried out, will lead to deterioration of the asset. The green text indicates decisions which mitigate the stability risk and control deterioration of the wall.

To summarise, the 'Do refurbish' emerges as the optimal technical solution. Whether it is taken forward as the preferred option will be dependent on the economic/carbon benefit delivered in comparison to the Do Minimum / Do Nothing baseline options. The extent of refurbishment would be subject to the cost-benefit / carbon analysis carried out as part of the Outline Business Case.

The analysis indicates a 'Do nothing' option has a limited time frame dependent on the rate of erosion in front of the wall. The overall rate of erosion is currently unknown. It is recommended that the Alluvium level in front of the wall be monitored as part of the ongoing monitoring that has recently started for the wall.

5 SUMMARY

A risk sensitivity analysis methodology to holistically evaluate the residual life of an existing anchored sheet pile flood defence wall in UK has been presented. The approach allows asset owners with finite resources to understand the risks and consequences affecting their asset more broadly, thereby enabling better informed investigations and planned management works to be undertaken. Sensitivity and parametric studies must consider risk, reliability, and public expectations, to better inform the decision process.

ABSTRACT: The Ground Model is defined in the second generation of Eurocode as a *'site-specific outline of the disposition and character of the ground and groundwater based on results from ground investigations and other available data'*. The Ground Model is a compilation of data including maps, plans, sections, and reports that capture objective information regarding the soil, rock types and groundwater conditions across the zone of influence (ZOI). The Ground Model should cover the site and the surrounding area to provide the geotechnical and geological context, potential sources of materials for construction, and the surrounding conditions that may influence the groundworks. Since the Ground Model is an illustration (including the distribution of the geotechnical units within the zone of influence) based on interpolation between factual data and derived values, the model itself can be considered the most likely representation based on the available data during that phase of a project. Uncertainties inherent to such Ground Models may be quantified and reduced during subsequent project phases when more data becomes available.

RÉSUMÉ: Le modèle géotechnique est défini dans la deuxième génération de l'Eurocode comme un "*aperçu spécifique au site de l'arrangement et de la nature des terrains et des eaux souterraines sur la base des résultats des reconnaissances de sol et d'autres données disponibles*". Le modèle géotechnique est une compilation de données comprenant des cartes, des plans, des coupes et des rapports qui contiennent des informations objectives concernant les types de sol et de roche et les conditions des eaux souterraines dans la zone d'influence. Le modèle géotechnique doit couvrir le site et la zone environnante afin de fournir le contexte géotechnique et géologique, les sources potentielles de matériaux de construction et les conditions environnantes susceptibles d'influencer les travaux de terrassement. Étant donné que le modèle géotechnique est une illustration (y compris la distribution des unités géotechniques dans la ZOI) basée sur des valeurs dérivées et une interpolation entre les données factuelles et les valeurs dérivées des essais, le modèle lui-même peut être considéré comme la représentation la plus probable basée sur les données disponibles au cours de la phase en cours d'un projet. Les incertitudes inhérentes à ces modèles géotechniques peuvent être quantifiées et réduites au cours des phases ultérieures du projet, lorsque davantage de données sont mises à disposition.

Keywords: Ground model; Eurocode 7; EN 1997.

1 INTRODUCTION

One of the new requirements in the second generation of Eurocode 7 is the need to prepare a Ground Model. Since the concept of a Ground Model may not be familiar to many practising geotechnical engineers, the Guideline – Assembling the Ground Model and derived values (JRC, 2024) has been prepared to explain the concept of the Ground Model and forms the basis for this paper.

The Ground Model for a project is defined in the Eurocode as a *'site-specific outline of the disposition and character of the ground and groundwater based on results from ground investigations and other available data*'.

There are two distinct models in the current revision of Eurocode 7. The Ground Model (in FprEN

1997-2:2024) includes geology and presentation and evaluation of test results. The Geotechnical Design Model (in FprEN 1997-1:2024) covers the design of the structure, and so includes the selection of the geotechnical design parameters.

A Ground Model is a representation of the geological, hydrogeological and geotechnical conditions, for which we can sensibly read the 'engineering ground conditions', which includes the presentation and evaluation of the test results into derived values. However, the inclusion and selection of design parameters develop this into the next step, which is a 'Geotechnical Design Model'.

The Ground Model is a compilation of data including maps, plans, sections, and reports that capture objective information regarding the soil, rock types and groundwater conditions across the zone of influence (ZOI). The Ground Model should cover the site and the surrounding area to provide the geotechnical and geological context, potential sources of materials for construction, and the surrounding conditions that may influence the earthworks and engineering structure".

It is intended that the Ground Model will make use of the distribution of the geotechnical units within the ZOI, together with an interpolation of factual data, and where appropriate derived values, to produce the most likely indication of the ground and groundwater conditions for this phase of a project.

Uncertainties inherent in the compilation of Ground Models must be quantified. A review of the results, limitations, uncertainties, discrepancies and gaps in data should be recorded as part of the Ground Model development process. It is intended that uncertainties will be reduced during subsequent phases of a project when more data becomes available.

The Ground Model includes, but is not limited to, the following components within the ZOI:

- rockhead and structural geology;
- the geometry of the layers;
- superficial geology and geomorphology;
- seismicity;
- hydrogeological conditions; and
- geotechnical and geochemical conditions.

Within the above list of components, seismicity brings unique and complex issues to the design of structures.

Development of the Ground Model should be commenced as early as possible, but in any case as part of the desk study, using existing geological maps, previous investigations, reports, satellite imagery, photogrammetric and/or LiDAR data, site reconnaissance, and consideration of the site's geological history and geomorphology. The Ground Model captures the general composition and assembly of the soil and rock types and forms the basis of the field and laboratory investigation planning. The Ground Model must be verified with additional geotechnical, geological and hydrogeological data during the life of the project.

The Ground Model should be developed alongside the compilation of the Ground Investigation Report (GIR). The horizontal blue dotted line in Figure 1 shows the delineation between the Ground Model and the Geotechnical Design Model (GDM). All of the data and information relating to the ground and groundwater conditions for the Ground Model area should be captured and presented within the GIR.

2 THE PURPOSE AND PROCESS OF THE GROUND MODEL

The Ground Model is a verbal, graphical and schematic tool and process that is used to advance knowledge of the ground and groundwater characteristics of the ZOI of the structure (or structures), and to help identify the corresponding risks.

The assembling and use of the Ground Model should be a fundamental activity for any geotechnical project. The Ground Model is an essential tool for engineering quality control and provides a transparent way of identifying project-specific, critical ground and groundwater risks and properties.

Any Ground Model must consider the ZOI since they are intrinsically linked. The initial ZOI should be defined at the same time as the Ground Model is first considered.

The following aspects should be reported regarding the selected ZOI:

- the location and type of geotechnical structure(s) that is the origin of the ZOI;
- potential construction methods considered; and
- considerations that have influenced the selection of the ZOI.

Figure 1 shows the transition from the Ground Model to the Geotechnical Design Model. Although not shown in this figure, it is implicit that the Ground Model is developed alongside the Ground Investigation Report (GIR) and indeed much of the data accumulated in the GIR, will help develop the Ground Model.

3 THE EXTENT OF THE GROUND MODEL

It is critical to the success of any project, that the extent of the Ground Model is appropriate to the project and

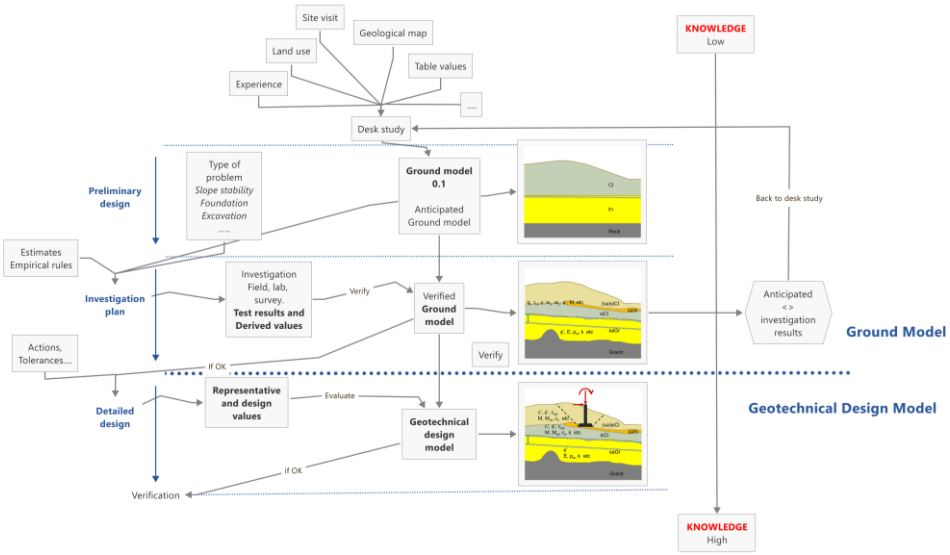

Figure 1. Relationship of Ground Model to Geotechnical Design Model. Source: Guideline - Assembling the Ground model and the derived values.

the ground and groundwater conditions. Whilst the complexity of the Ground Model will vary depending on the phase and nature of the project being considered, in every case, the Ground Model should match the ZOI that has been identified as relevant to the project as a whole.

Initially, as noted in FprEN 1997-1:2024, 4.1.2.1 (4), the extent of the ZOI and by extension, the extent of the Ground Model, shall be estimated before the ground investigation is planned.

4 STAGES

It is advisable to update the Ground Model at each key stage described in the EN 1997 and reproduced in flow chart form in Figure 2. The stages of development of the Ground Model should correspond to the Geotechnical Category and in particular, the Geotechnical Complexity Class into which the ground is classified as the level of detail increases.

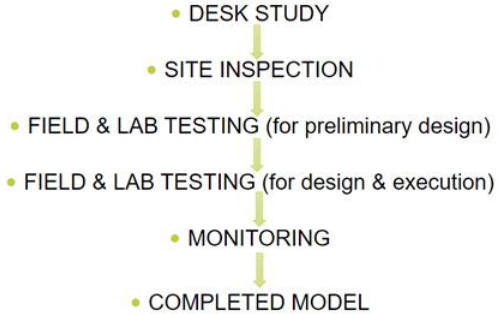

Figure 1. Key Stages for the development and updating of the Ground Model.

It is possible to identify several critical stages where the Ground Model should be assessed and updated as necessary. Whilst the development of the Ground Model is an ongoing activity that will last for the life of the project, the stages shown in Figure 2 are clear milestones at which additional data should be gathered and the model reassessed.

A preliminary version of the Ground Model must be prepared at the desk study/site inspection stage. This will consist of topographical, geomorphological, geomechanical and stratigraphical information obtained from available maps or previous survey campaigns. The preliminary model will allow for optimising and planning site and/or laboratory geotechnical investigations and concentrate them where needed, ensuring a level of detail and a spatial extent of investigations appropriate to the ZOI of the structure. Subsequently, it will be improved iteratively as data are collected.

5 ASSEMBLING THE GROUND MODEL

The identification of the lithology that can be matched between the ground investigation locations (GIL) according to the identification of the ground layers and the mechanical parameters depends on the distance between the GILs and the difference in level between the layers compared. A good correspondence suggests a stratigraphic link between the layers.

Various techniques may be used to form a decision tree (chart, tables, etc.), or the 'Random Forest' technique, depending on the regional practice, projects, expertise, national rules, etc.

Once the description, classification or mechanical characterisation is achieved at a particular 1D location (i.e. borehole), the graphical representation needs to fill the gap by interpolation techniques:

- IDW: Inverse Distance Weighting;
- minimum curvature method;
- irregular triangulation with smoothing;
- rectangular interpolation;
- local polynomial; or
- Kriging.

In practice, these Individual 1D stratigraphies may be jointly interpreted with diverse geophysical surveys to derive a single model of the investigated subsurface region. This approach is, however, largely qualitative and hence the outcome depends heavily on the background, experience and preconceptions of the interpreter.

Interpolation is also a need for:

- Determination of the zones of higher risk
- Determination of areas where more ground investigation is needed
- Volume calculation of excavation

However, in most practice, interpolation shall not be used for determining the layering used in the geotechnical design calculation. In the Ground Model, a clear distinction should be made between the locations where the ground layering was measured and the areas between measurements.

Figure 3 shows the different stages in developing a 3D model.

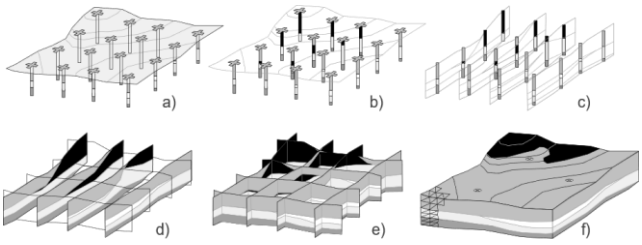

Figure 3. Schematic example of the process to develop the 3D model.

6 GROUND MODEL UNCERTAINTIES

The Ground Model should include the derived values of the relevant ground properties for all the geotechnical units encountered in the ZOI. Several sources of uncertainty appear during the process of assembling the Ground Model and the derived values. Therefore, throughout the process, care must be taken to minimise these uncertainties.

The sources of uncertainties in assembling the detailed Ground Model in the ZOI are related to:

- The accuracy of the information in already available ground investigation including desk-study and site-inspection.
- The accuracy of available geological descriptions, hydrological and geological information, and geological 3D models.
- The accuracy of existing 3D models used as a basis in new 3D models.
- The position and depth measurement of the new ground investigations.
- The interpretation of the results from new ground investigations:
  - CPT, FVT, SPT, PMT, etc;
  - Borehole data: determination of geological formations with intrinsic dependency on the experience of the interpreter (geologist); and
  - Water pressure measurements, piezometer readings, etc.
- The unknown shape of the boundary between measurements (2 points): straight lines, curved lines.
- The presence of manmade hard inclusions (historical foundations, cables, sewerage pipes, etc.)

Other hidden uncertainties may exist such as the one that originates from a too-large adaptation of the investigation program to the shape of the ZOI. The spatial heterogeneity of the investigations may then be a problem, especially in the case of linear infrastructures, which leads to longitudinal over-information.

The definition and treatment of uncertainties encountered during ground investigation testing to obtain derived values are detailed in the test standards.

ACKNOWLEDGEMENTS

The guideline, which is the basis of this paper, has been prepared by Task Group C2 within CEN/TC 250/SC 7/WG 1 as a result of European cooperation. Member countries in Task Group C2 have been Belgium, Estonia, Finland, France, Germany, Italy, Latvia, Luxembourg, Netherlands, Norway, Poland, Portugal, Romania, Slovakia, Spain, Sweden, Switzerland, and the United Kingdom.

The authors would like to thank the members of TG C2 for their cooperation and the parallel task groups C1, C3 and C4. All valuable contributions have made it possible to compile and agree on the guideline.

Influence of lateral stress on soil-structure interface tests in a hollow cylinder apparatus

Influence de la contrainte latérale sur les expérience d'interface sol-structure dans un appareil à cylindre creux

ABSTRACT: The contact shear behaviour between the soil and a structure has a significant impact on the load transfer of geotechnical structures. In the past, several different approaches to test and quantify this soil-structure interface behaviour have been conducted using e.g. modified ring-shear, direct-shear or simple-shear devices. In most experimental studies, the lateral deformation is restricted to zero (stiff frames of direct shear and simple shear devices) and the lateral stress is unknown. To gain insights on the influence of an anisotropic stress state on the interface, contact shear tests on ring-shaped samples with various lateral stresses are presented in this work. Therefore, a modified hollow cylinder apparatus with a contact plate and short sample geometries was used. The first results indicate, that neither the anisotropy of the stress state can be neglected, nor the interface behaviour follows straight the soil shearing behaviour for the test setup used here.

RÉSUMÉ: Le comportement de cisaillement de contact entre le sol et une structure a un impact significatif sur le transfert de charge des structures géotechniques. Dans le passé, plusieurs approches différentes pour tester et quantifier le comportement de l'interface sol-structure ont été menées en utilisant, par exemple, des dispositifs de cisaillement annulaire modifié, de cisaillement direct ou de cisaillement simple. Dans la plupart des études expérimentales, la déformation latérale est limitée à zéro (cadres rigides des dispositifs de cisaillement direct et de cisaillement simple) et la contrainte latérale est inconnue. Pour mieux comprendre l'influence d'un état de contrainte anisotrope sur l'interface, des essais de cisaillement par contact sur des échantillons en forme d'anneau avec différentes contraintes latérales sont présentés dans ce travail. Pour ce faire, un appareil à cylindre creux modifié avec une plaque de contact et des géométries d'échantillons courtes a été utilisé. Les premiers résultats indiquent que l'anisotropie de l'état de contrainte ne peut pas être négligée et que le comportement de l'interface ne suit pas directement le comportement de cisaillement du sol pour la configuration d'essai utilisée ici.

Keywords: Interface tests; contact shear behaviour; anisotropic stress state.

1 INTRODUCTION

In many geotechnical projects, interfaces occur, as they include rigid structures such as piles, walls and foundations. The contact shear behaviour between the soil and the structure has a significant impact on the load transfer of geotechnical structures. For instance, the surface roughness of the structural element has a considerable influence on the behaviour of the entire system. This inspired several authors to experimental investigations and modelling approaches for interface shearing behaviour (e.g. Wernick 1978; Uesugi and Kishida 1986; Stutz and Martinez 2021). Some interface models depend only on the normal stress on the interface (e.g. Ghionna and Mortara 2002) while others use existing soil models for derivation and therefore take the whole stress tensor into account. The last-mentioned attempts for contact modelling are based on different assumptions concerning the stress state at the interface: while Arnold and Herle (2006) suppose all normal stresses to be equal ($\sigma_{11} = \sigma_{22} = \sigma_{33}$) for simplicity, Stutz et al. (2017) make another assumption. They assume the in-plane deformation to be negligible and allow the in-plane stress to take other values than the stress normal to the interface ($\sigma_{11} \neq \sigma_{22} = \sigma_{33}$). The approach of Staubach et al. (2022) couples neither the in-plane stresses nor the in-plane deformations directly with each other but with the neighbour soil (in FEM) so all normal stresses can be different ($\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$). Most previous experimental studies on interfaces have been conducted using modified ring-shear, direct-shear or simple-shear devices. In these cases, the frames restrict the lateral deformation to zero and the lateral stress is unknown. Therefore, important information to characterize interface shear behaviour under different stress conditions is raw (Dumitrescu et al. 2009).

One step towards understanding the influence of the 3D stress state was taken by Dumitrescu et al. (2009). They developed an interface shearing device with one adjustable normal stress on a plane orthogonal to the interface. A cylinder with a contact surface is rotated in a hollow cylinder sample, while the normal stress on the interface is applied through a membrane (radial stress) and the normal stress on one of the planes orthogonal to the interface is applied by a piston (axial stress). The experimental results indicate that the anisotropy of the initial stress state should be considered in the description of contact shear behaviour.

In this work, another device for interface tests with different normal stresses was developed. Therefore, a modified hollow cylinder triaxial device with a contact plate and short samples is used. This allows to control four independent stress or strain components and to take more complex stress states into account. First experiments with Karlsruhe fine sand are presented and compared to simple existing boundary surfaces for soils (section 3.2, Figure 6 and Figure 7).

2 TEST DEVICE AND METHODS

2.1 Test device

In the modified hollow cylinder apparatus (see Figure 1), a hollow cylinder shaped soil sample is tested in a pressure cell. The sample is separated from the cell fluid by membranes on the outer and inner curved surface areas. A plate with glued sand on the bottom of the sample ensures a fully rough contact with a full force transfer. In this modified device, the top plate is a changeable contact plate, so different roughness properties can be tested (see Figure 2). By rotating the bottom plate, torsion can be applied to the sample and shear deformation is induced at the interface.

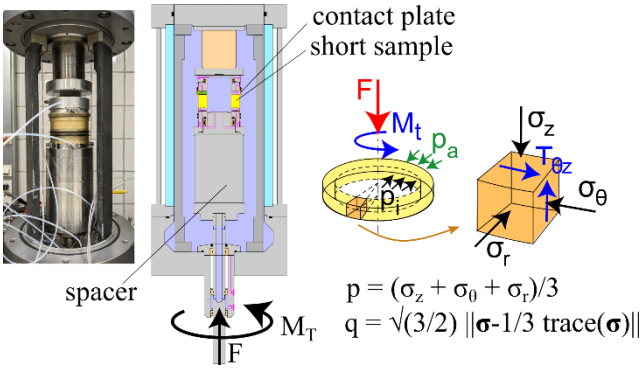

Figure 1. Modified hollow cylinder apparatus to control three independent normal stresses in interface shearing tests (one on shear plane, two on orthogonal planes).

The normal stress at the interface is controlled by an axial load. Additionally, the pressure on the outer cell (p_a) and in the inner cell inside the hollow sample (p_i) can be controlled independently. Thereby, an anisotropic initial stress state can be generated and with different pressures on the outer and the inner membranes, three different normal stresses can be applied (one on the shear plane and two on the planes orthogonal to the shear plane).

Figure 2. Different rough contact plates: with glued sand (left), coarse sandblasted (center), fine sand blasted (right).

2.2 Sample preparation and soil properties

The experiments were conducted on medium dense samples of Karlsruhe fine sand (Figure 3). For preparation, the membranes are placed in a mould and the sand was pluviated between the membranes (Figure 3). The sample has an outer and inner diameter of 100 mm and 60 mm with a height of 20 mm.

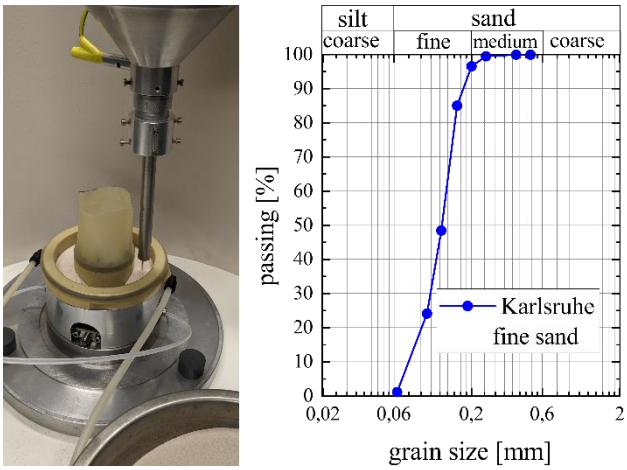

Figure 3. Sample preparation with air pluviation (left) and grain size distribution of Karlsruhe fine sand (right).

2.3 Influence of membrane stiffness

The membranes are fixed at the bottom and top caps hence they are deformed in the same way as the sample and contribute to the measured forces. Especially for the short sample height of 20 mm and a tangential shear deformation up to 30 mm, the influence of the membrane stiffness cannot be neglegted: The measured moment during torsion tests results not only from the mobilised friction on the sample but also from membrane forces. In the literature, dummy tests with water-filled membranes are used to develop correction formulas for the membrane forces in hollow cylinder

tests (e.g. Koseki, Yoshida and Sato 2005). In these tests, unrealistic membrane deformations occur when it comes to large rotation angles. For an enhanced correction, in the present work, tests on soil samples with different membranes were used to capture the actual membrane (or sample) deformation and a mathematical correction was developed. Example test data with the membrane correction is shown in Figure 4.

3 RESULTS

3.1 Loading path

All tests were driven with a constant vertical stress σ_z of 100 kPa (normal stress on the shear plane), except the tests in Figure 5. The normal stresses on the planes orthogonal to the shear plane (radial stress σ_r and tangential stress σ_θ, see Figure 1) were 50 kPa, 100 kPa or 150 kPa and identical in the presented tests. After reaching the test specific initial stress state, the drained contact shearing phase was started by rotating the bottom end plate.

For the medium dense samples ($I_D \approx 0.6$), the corrected shear stress (see Figure 4) increases until an asymptotic state is reached. In the test series a rough contact plate with glued grains and less rough contact plates of fine and coarse sandblasted steel were used.

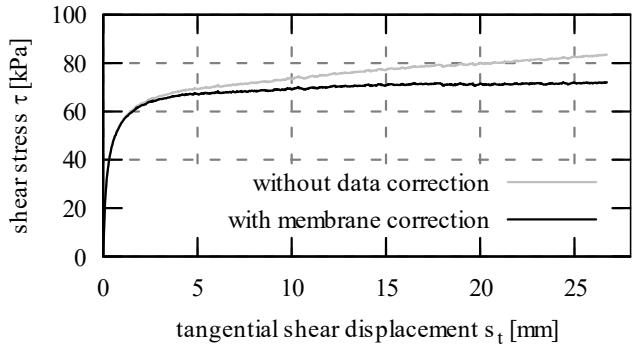

Figure 4. Drained contact shearing phase (torsion) after isotropic initial state (p = 100 kPa) with medium dense Karlsruhe fine sand and a rough contact plate.

3.2 Shear strength

The tests with isotropic initial stress states (Figure 5) show a proportional relation between the shear strength and the mean stress as well as between the shear strength and the normal stress on the shear plane and therefore act in the framework of common yield criteria, e.g. the Mohr-Coulomb criterion.

This behaviour changes for the test series including anisotropic initial states: Figure 6 and Figure 7 show the deviatoric stress in the sample (colored) and the shear stress on the shear plane (grey) during tests with a contact plate with glued grains and one of fine sandblasted steel. Note, that the largest reached deviatoric stress q appears not necessary at the same test as the largest shear stress on the shear plane $\tau_{\theta z}$. The maximum deviatoric stresses do not match with the critical deviatoric stress q_{crit} calculated with the Mohr-Coulomb criterion and the corresponding Lode angle (value at asymptotic state is marked with x). A hypothesis for the explanation is the occurrence of a forced horizontal failure plane. The geometry and

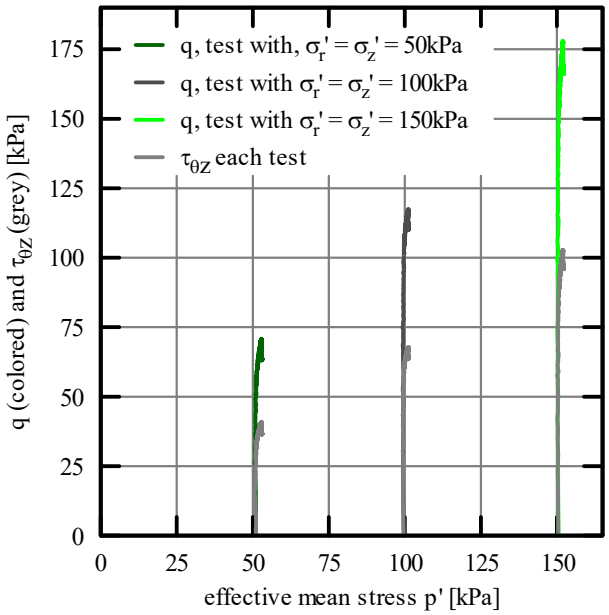

Figure 5. Interface tests with isotropic initial state: $\sigma_z = \sigma_r = \sigma_\theta = p$, rough contact plate of coarse sandblasted steel.

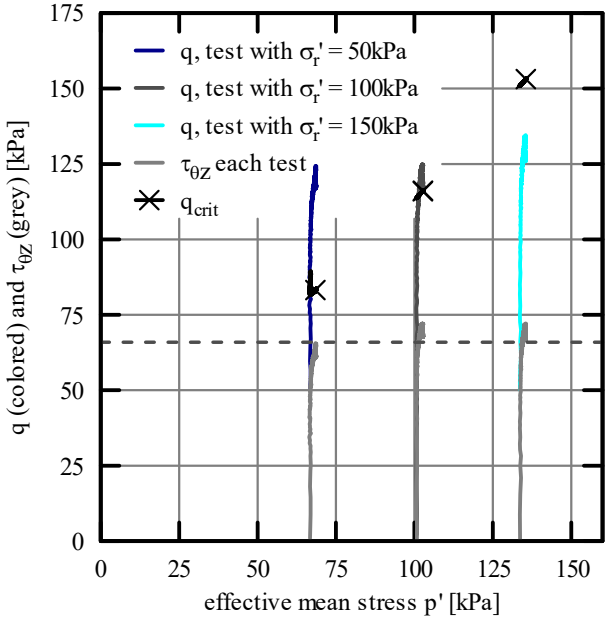

Figure 6. Interface tests with anisotropic confinement and rough contact plate with glued grains.

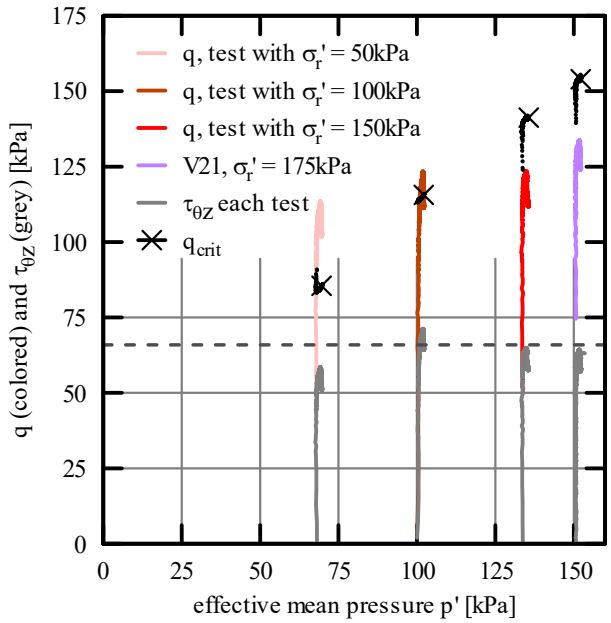

Figure 7. Interface tests with anisotropic confinement and less rough contact plate of fine sandblasted steel.

end plates might constrain the decisive failure plane to be horizontal. Following this assumption and looking at the vector on the shear plane, only the stress components σ_z and $\tau_{\theta z}$ are contributing. As the normal stress is equal in all tests in Figure 6 and Figure 7, the maximum shear stress $\tau_{\theta z}$ should be a constant value (dashed line: calculated with Mohr-Coulomb on horizontal failure plane).

The experimental data diverge from this line and hence indicate, that the anisotropic confining stress influences the shear strength. The different values of lateral stress change the state of the soil above the contact plate and render the shear strength of the interface. These results confirm the findings of Dumitrescu et al. (2009), who reported an influence of the normal stresses on the plane orthogonal to the shear plane (anisotropic confinement).

4 CONCLUSIONS

The presented experiments contribute to the understanding of soil-structure interface behaviour.

- A hollow cylinder apparatus was modified that three independent normal stresses can be controlled during interface shear tests.
- Due to boundary and interface conditions, the maximum deviatoric stress did not match with failure criteria in pure soil shearing. This might result from a predefined failure plane.
- The maximum shear stress on the horizontal (failure) plane is potentially influenced by anisotropic confinement states, as the normal stresses on the planes orthogonal to the shear plane render the state of the soil on the contact and so the shear strength of the interface.
- Further investigations should be conducted on the influence of sample geometry to separate possible effects during monotonic and cyclic shearing.

Numerical investigation of the interaction between existing tunnels and driven pile installation

Enquête numérique sur l'interaction entre les tunnels existants et l'installation de pieux battus

ABSTRACT: The advancement of urbanisation in large cities yields an increased use of piles to support high-rise buildings and critical infrastructure. Compared to bored piles, the impact on existing buried assets and infrastructure including tunnels is often more pronounced for driven pile construction. However, the evolution of the deformation of segmental lined tunnels, which affects the operation and safety of tunnel, during pile installation, has not received significant attention. This study investigated tunnel deformation during pile installation using finite element analysis adopting the Arbitrary Lagrangian Eulerian (ALE) method, which was validated against published data. Three cases with a circular pile of 0.6 m in diameter and 20 m in length near a concrete-continuous-lined tunnel with a diameter of 6 m and a burial depth of 12 m in sandy ground were studied. In these cases, the tunnel cross-section changes from circular to vertical oval with the horizontal contraction being around 0.02% - 0.03% *D* with *D* being the tunnel's outer diameter. The results showed that the deformation varies approximately linearly with respect to the distance between the tunnel and the pile. Additionally, the centre of the tunnel moves away horizontally while it settles first and then uplifts vertically at a certain pile insertion depth. The section begins to heave at a smaller pile insertion depth when the clearance between pile and tunnel is larger. The results showed that the simulation method can accurately capture the behaviour of the tunnel during the pile installation. The results provide more insight with respect to pile design when the pile installation occurs in the vicinity of a tunnel.

RÉSUMÉ: L'avancement de l'urbanisation dans les grandes villes entraîne une utilisation accrue de pieux pour soutenir les immeubles de grande hauteur et les infrastructures critiques. Comparé aux pieux forés, l'impact sur les actifs enterrés existants et les infrastructures, y compris les tunnels, est souvent plus prononcé lors de la construction de pieux battus. Cependant, l'évolution de la déformation des tunnels à revêtement segmentaire, qui affecte le fonctionnement et la sécurité, pendant l'installation des pieux n'a pas reçu une attention significative. Cette étude a examiné la déformation du tunnel pendant l'installation des pieux en utilisant la méthode Lagrangien Eulerien Arbitraire (ALE), qui a été validée par rapport à des données publiées. Trois cas avec un pieu circulaire de 0,6 m de diamètre et de 20 m de longueur près d'un tunnel revêtu en continu de béton avec un diamètre de 6 m et une profondeur d'enterrement de 12 m dans un sol sablonneux ont été étudiés. Dans ces cas, la section transversale du tunnel passe d'une forme circulaire à une forme ovale verticale avec une contraction horizontale d'environ 0,02% à 0,03% D, D étant le diamètre extérieur du tunnel. Les résultats ont montré que la déformation varie approximativement de manière linéaire par rapport à la distance entre le tunnel et le pieu. De plus, le centre du tunnel s'éloigne horizontalement tout en s'installant d'abord, puis en se soulevant verticalement à une certaine profondeur d'insertion du pieu. Plus le pieu est éloigné du tunnel, moins la profondeur d'insertion du pieu à laquelle la section commence à se soulever est importante. Les résultats ont montré que la méthode de simulation peut capturer avec précision le comportement du tunnel pendant l'installation des pieux. Les résultats fournissent davantage d'informations concernant la conception des pieux lorsque l'installation des pieux se produit à proximité d'un tunnel.

Keywords: Driven pile construction; existing tunnel; ALE method; pile-soil-tunnel interaction.

1 INTRODUCTION

Urbanisation and population growth stimulate more and more exploitation of underground space in many big cities (Schroeder et al., 2002; Shen et al., 2014; Wu et al., 2018). New construction and reconstruction projects are expected to use pile foundations extending to competent strata, because many cities sit on top of soft soil, in order to support the significant surface loads from large structures. The installation of piles will inevitably induce disturbances to the surrounding soil which will be transferred to adjacent buried infrastructures and assets including tunnels. These tunnels are used for transportation, water conveyance and as utility pipelines. The disturbance induced by pile installation potentially influences the operation

and serviceability of the existing tunnels. Previous studies have shown that the impact of driven pile installations on the surrounding soil is more pronounced compared to bored piles (Huang et al., 2018; X. Liu et al., 2019). However, the way the tunnel section deformation develops as a result of the installation of driven piles has not been fully investigated.

During the past years, studies have focused on the interaction between pile installation and existing tunnels. In contrast to bored piles though, studies on driven pile installations are limited (Salim and Lafta, 2020). Physical tests have been conducted to explore the strain and stress distribution along the tunnel induced by nearby pile insertion, and the influence of the clearance between the pile and tunnel (Kong et al., 2021; Standing & Leung, 2005), as well as the soil properties (Salim and Lafta, 2017), were considered. However, the scaling law was not fully considered in these experiments which can impact the accuracy of the results. On the other hand, theoretical deduction based on a beam model with elastic foundation to consider the effect of pile groups has been carried out. However, it is difficult to incorporate many critical conditions in these simplified theoretical models such as the failure of soil and the tunnel section distortion. This will lead to differences between modelling results and real observations. Numerical simulation techniques provide opportunities to account for more complex interactions between a pile and a tunnel. Ding and Zhang (2019) and Liu et al. (2019) incorporated Finite Element Modelling (FEM) and cavity expansion theory (CET) to investigate the effect of soil compaction induced by pile insertion on an existing tunnel in clay. However, these simulations ignored the friction between the pile and the soil. Also, the development of the tunnel deformation could not be explored based on these simulations. Fall et al. (2021) coupled the Arbitrary Lagrangian Eulerian (ALE) method and the element deletion technique to investigate the impact of vibration induced by the pile installation on an existing tunnel. In their study, the soil failing around the pile was ignored which is in contrast to the real contact between the soil and the pile. Additionally, the development of tunnel deformation was also ignored. Above all, previous studies have not fully considered the contact between the soil and the pile resulting in less reliable results. Furthermore, the development of tunnel deformation has not received sufficient attention.

This study aims to investigate the development of tunnel deformation during a nearby single pile installation in sandy soil. A more realistic strategy coupling ALE and CET is developed to develop the numerical simulation of the pile installation. The effectiveness of the strategy is validated by published physical tests. A parametric study is carried out to investigate the influence of clearance between the tunnel and the pile on the deformation of the existing tunnel.

2 NUMERICAL MODELS

2.1 Model's details

The ALE method has been proven to be an effective and efficient numerical method to cope with potential mesh distortion in geotechnical problems involving large deformations (Fu et al., 2023). Figure 1 shows the FEM mesh and layout of the numerical model for the focused problem where the pile installation happens next to an existing tunnel with continuous lining. The model is developed based on physical tests from Arshad et al., (2014) to validate the numerical simulation strategy.

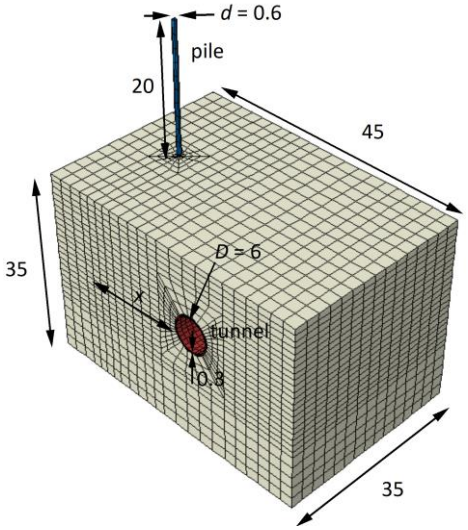

Figure 1. Geometry of the numerical model (units: m).

The model is 45 m in length, 35 m in width and 35 m in height. The outer diameter and the thickness of the tunnel lining are D = 6 m and t = 0.3 m, respectively. The depth of the tunnel axis is $H_t = 2D$ to the centre of the tunnel. The pile diameter is d = 0.6 m. The pile length is 20 m. A square area around the pile with a length of 10 d is assigned as the ALE region. The remeshing frequency is set at 1 per increment and the remeshing sweep is set at 25 per increment, which means the mesh in the ALE region will be remapped every increment and the mesh will be remapped 25 times per increment.

The properties of the soil and the tunnel are shown in Table 1.

C3D8R (8-node linear hexahedral reduced integration) elements are employed for the soil mass

and the existing tunnel while R3D4 elements are adopted for the pile. Besides, hourglass control is adopted for the ALE region to avoid elements without stiffness in numerical calculations. The soil mass and the tunnel are defined using solid elements while the pile are defined using shell elements. The soil is modelled as linear elastic-perfectly plastic with Mohr Coulomb strength and non-associative flow. The tunnel is modelled as linear elastic and the pile is modelled as discrete rigid elements.

*Table 1. Parameters used in the model (Note, * from Arshad et al., 2014).*

Header	Parameter	Unit	Value
soil	Density*	kg/m^3	1680
	Young's modulus *	MPa	60
	Poisson's ratio *		0.25
	Friction angle *		39
	Dilation angle *		5
	Cohesion *	Pa	0
Tunnel lining	Density	kg/m^3	2450
	Young's modulus	GPa	30
	Poisson's ratio		0.25

The surface-to-surface contact is used to simulate the interface between the pile and the soil. The surfaces of pile are master face while the surface of the soil is the slave surface. The contact between the pile and soil is defined as 'hard contact' in the normal direction with a friction coefficient of 0.2 in the tangential direction.

2.2 Simulation of the pile installation

The strategy to simulate the pile installation is derived from the work by Carter et al. (1979) where it is stated that expanding a cavity with the radius from a_0 to $2a_0$ can be used to give an adequate approximation to what happens in soil when a cavity expands from 0 to r occurs.

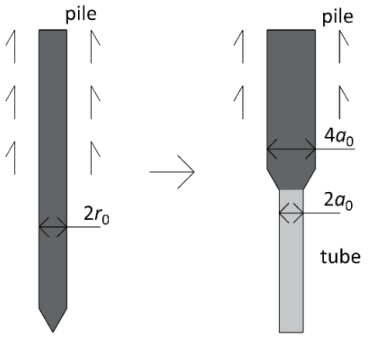

Figure 2. demonstration of the pile installation strategy in numerical modelling.

To achieve this, in the numerical model, a pre-installed virtual tube is installed ahead of the pile where the radius of the tube is a_0 while the diameter of the pile is refined as 2 a_0, as shown in Figure 2. The relationship between the real pile diameter d and a_0 is:

$$d/2 = \sqrt{3}\, a_0 \qquad (1)$$

In the numerical model, the tube is modelled as discrete rigid elements and the contact between the soil and tube is defined as frictionless.

2.3 Validation of the pile installation strategy

To test the reliability of the simulation strategy of the pile installation, another numerical model was developed with a penetrometer insertion into the sandy soil where the properties of the materials and geometry are exactly the same as those in the well-instrumented CPT (cone penetration test) tests (Arshad et al., 2014).

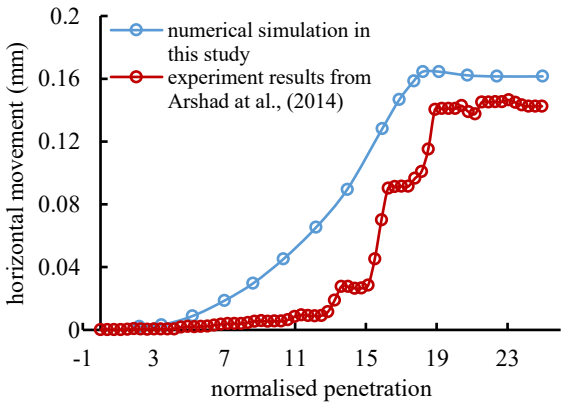

Figure 3. Comparison of the results from the numerical simulations and experimental data for the horizontal movement of the soil particles.

As shown in Figure 3, the numerical simulation results for the horizontal movement of the monitored point (The depth of the point is 18.5 r_c while the distance from pile centre is 3 r_c with r_c be the penetrator radius) can capture the trend of the observation from physical tests in spite of differences. The ultimate difference between the results is 13% with the numerical simulation predicting slightly larger values. According to the simulation results, it is indicated that the simulation strategy for pile installation is reliable enough to replicate the soil movement induced by pile penetration.

3 DEVELOPMENT OF TUNNEL DEFORMATION

Three cases are considered in this study with different clearances x between the tunnel and the pile: 2 D, 2.5

D and 3 *D* while all other parameters remain the same. The focus will be on the deformation of the middle of the tunnel.

3.1 Deformation of the tunnel circumference

Figure 4 to Figure 6 demonstrate the development of the tunnel section shape during the nearby pile installation with different clearances between the tunnel and the pile. The final aggregated displacements (u_x, u_y) of the tunnel crown, spring line and invert are marked with u_x the horizontal and u_y the vertical displacement. To facilitate the presentation of the results, the displacements are multiplied by 100. Besides, the normalised pile insertion depth, H_r, is defined as:

$$H_r = (H - H_t)/D \qquad (2)$$

with H the pile tip depth and H_t the tunnel centre depth.

Figure 4, Figure 5, and Figure 6 demonstrate the evolution of the tunnel section shape during the pile installation when the separation is 2 *D*, 2.5 *D*, and 3 *D*. In these cases, the tunnel section keeps moving horizontally away from the pile with the procedure of pile installation. The final horizontal deformation is the largest at the left springline while it is smallest at the right springline and is nearly the same at the crown and the invert. The vertical deformation is relatively small compared with the horizontal deformation, especially at the right springline. The crown keeps moving upward while the invert keeps moving downward. The resultant horizontal contraction and vertical extension of the tunnel section keep increasing during the pile installation. The horizontal contraction is prone to be slightly more than the vertical extension.

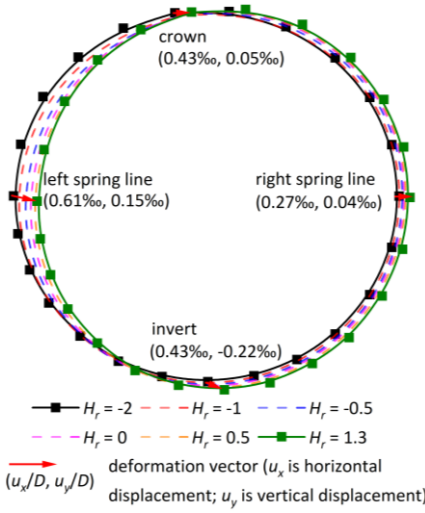

Figure 4. Progressive change in tunnel section shape with a pile clearance of 2 D with D = tunnel diameter. Note: the displacements are multiplied by 100 for visualisation.

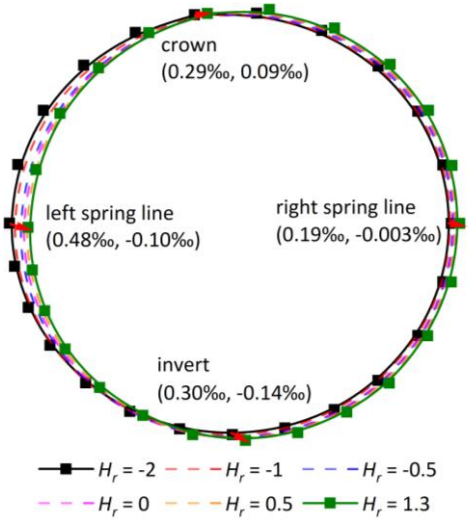

Figure 5. Progressive change in tunnel section shape with a pile clearance of 2.5 D with D = tunnel diameter. Note: the displacements are multiplied by 100 for visualisation.

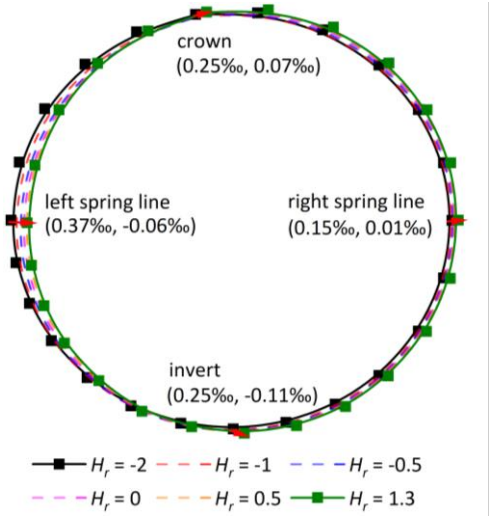

Figure 6. Progressive change in tunnel section shape with a pile clearance of 3 D with D = tunnel diameter. Note: the displacements are multiplied by 100 for visualisation.

The horizontal tunnel axis keeps contracting while the vertical axis continues to extend. The final changes of the horizontal and vertical diameters are shown in Table 2. As the clearance between the tunnel and the pile decreases, the diameter change tends to get larger.

Table 2. Diameter change in horizontal and vertical directions.

Header	Horizontal direction	Vertical direction
Clearance = 2 *D*	0.34‰ *D*	0.27‰ *D*
Clearance = 2.5 *D*	0.27‰ *D*	0.23‰ *D*
Clearance = 3 *D*	0.22‰ *D*	0.18‰ *D*

3.2 The displacement of the centre of the tunnel section

Figure 7 demonstrates the displacement of the tunnel section centre for the three different separations between the tunnel and the pile. The square markers represent the position change of the centre when H_r equals -2 *D*, -1.7 *D*, -1.3 *D*, -1 *D*, -0.7 *D*, -0.5 *D*, -0.3 *D*, 0 *D*, 0.3 *D*, 0.5 *D*, 0.7 *D*, 1. *D*, 1.3 *D*.

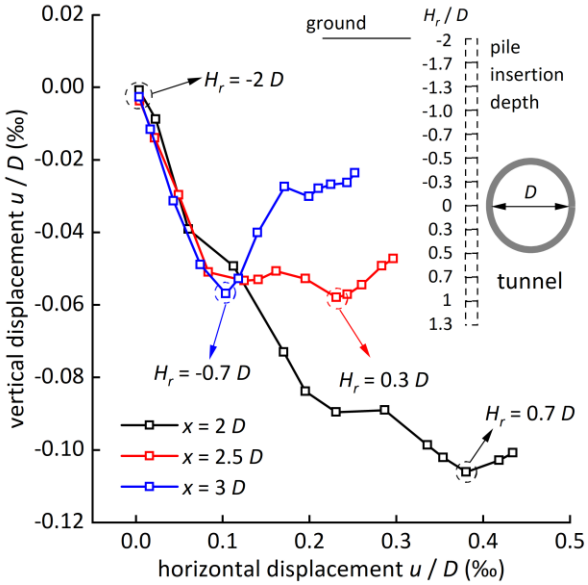

Figure 7. Movement of the tunnel section centre for pile clearances of 2 D, 2.5 D and 3 D with H_r = normalised pile depth.

It can be observed that the section centre continues to move away from the pile horizontally with final displacements of 0.43‰ *D*, 0.29‰ *D* and 0.25‰ *D* with clearances for 2 *D*, 2.5 *D* and 3 *D* respectively. With respect to the vertical displacement, the centre settles downward first and then uplifts until the pile tip reaches a certain depth. The critical pile tip depth is H_r = 0.7, H_r = 0.3 and H_r = -0.7 with clearances of 2 *D*, 2.5 *D* and 3 *D* respectively. The maximum settlement is 0.11‰ *D*, 0.06‰ *D* and 0.06‰ while the final settlement is 0.10‰ *D*, 0.05‰ *D* and 0.02‰ with clearances of 2 *D*, 2.5 *D* and 3 *D* respectively.

The horizontal displacement of the tunnel section centre is more than the vertical displacement at each pile installation depth. The tunnel tends to settle first and then heave. The pile tip depth changes from 0.7 D to -0.7 D at which tunnel begins to heave with the increase in clearance between the tunnel and the pile. During the design stage of a pile installation next to an existing tunnel, it is not sufficient to focus on the final stage of the pile installation. The maximum vertical displacement of the tunnel section may happen the pile tip at a certain depth.

Above all, despite the low magnitudes, the non-uniform displacement may potentially impact on the facilities inside the tunnel. In the case with clearance being 2 *D*, the horizontal displacement of sectional centre is 2.58 mm, which exceeds the limit for a train tunnel with the ballastless track structure (Liu et al., 2022). As a result, it may induce disturbance of the serviceability of the tunnel.

4 CONCLUSIONS

This study developed a numerical model to investigate the development of the deformations of an existing circular tunnel lining during the installation of a single circular driven pile in close proximity. A numerical strategy to simulate pile insertion into soil was developed based on the ALE method and CET. The main conclusions are as follows:

- The numerical model developed for the pile installation captured the behaviour of the surrounding soil well in terms of soil displacement.
- The pile installation caused the section at the middle of the tunnel to keep moving away from the pile horizontally. The maximum deformation happens at the left spring line. The crown keeps moving upward while the invert keeps moving downward.
- The horizontal contraction and vertical extension happen due to the pile installation. The contraction and extension keep increasing as the pile installation processes. The final horizontal contraction and vertical extension are 0.34‰ *D*, 0.27‰ *D*, 0.22‰ *D* and 0.27‰ *D*, 0.23‰ *D* and 0.18‰ *D* when the clearance is 2 *D*, 2.5 *D* and 3 *D*. It is indicated that the deformation is relatively small compared with the case in Liu et al., (2019), which is due to the single pile in this study instead of pile group and the lining of the tunnel is simplified as contiunous where the joints are not considered.
- The section centre keeps moving away from the pile with a final horizontal deformation of 0.43‰ *D*, 0.29‰ *D* and 0.25‰ *D* when the clearance is 2 *D*, 2.5 *D* and 3 *D*. While the centre moves downward first and then upward when the pile tip reaches a certain depth. The farther the pile is away from the tunnel, the less the pile insertion depth at which the section begins to uplift. The maximum settlement is 0.11‰ *D*, 0.06‰ *D* and 0.06‰ while the resultant final settlement is 0.10‰ *D*, 0.05‰ *D* and 0.02‰ when the clearance is 2 *D*, 2.5 *D* and 3 *D*.

- The tunnel tends to settle first and heave at a certain pile installation depth where the maximum tunnel settlement happens.

Earth mounds construction in York's Norman castles: Implications for current performance and protection

Construction de monticules de terre dans les châteaux normands de York: Implications pour les performances et la protection actuelles

ABSTRACT: This paper aims to review the construction technologies that would have likely been adopted in motte and bailey type of castles, in particular those adopted in construction of earth mounds of the Clifford tower and Baile Hill, built circa the 11th century. While Norman builders having presumably rudimentary knowledge of soil behaviour built these structures, their durability compares favourably with more recently built uncontrolled geostructures using heavier plant (e.g., Victorian earth retaining structures and embankments). This seems to suggest that the level of expertise of building with soil may have been greater than it is typically assumed for these periods. A comparison with modern construction techniques adopted in earthworks and influence of vegetation cover is also included in a bid to explain its remarkable durability. Results of a recent non-destructive site investigation campaign carried out at Baile Hill are also included to assist in the assessments of their current performance and evaluate its vulnerability. Some insights on the use of protection measures for enhanced resiliency against climate change are also included.

RÉSUMÉ: Cet article vise à passer en revue les technologies de construction qui été adoptées dans les châteaux de type motte et bailey, en Clifford et de Baile Hill, construits vers le 11ème siècle. Bien que les Norman constructeurs ayant vraisemblablement une connaissance rudimentaire du comportement du sol ont construit ces structures, leur durabilité se compare avantageusement à celle des géostructures non contrôlées construites plus récemment utilisant des installations plus lourdes (par exemple, les structures de soutènement et les remblais de l'époque victorienne). Cela semble suggérer que le niveau d'expertise en matière de construction avec du sol pourrait avoir été supérieur à ce qu'on suppose généralement pour ces périodes. Une comparaison avec les techniques de construction modernes adoptées dans les travaux de terrassement et l'influence de la couverture végétale est également incluse dans le but d'expliquer sa remarquable durabilité. Les résultats d'une récente campagne d'investigation non destructive du site menée à Baile Hill sont également inclus pour faciliter l'évaluation de leurs performances actuelles et évaluer leur vulnérabilité. Certaines informations sur l'utilisation de mesures de protection pour renforcer la résilience face au changement climatique sont également incluses.

Keywords: Heritage; geostructures; Norman castles; compacted soils.

1 INTRODUCTION

Heritage geostructures across the UK are being subjected to increasingly erratic environmental and climatic conditions due to climate change. This is predicted to worsen in the future which could lead to a higher risk of failure and collapse. This is mainly because the modern principles of compaction were not employed at the time of construction and thus it is likely that these geostructures were placed in a relatively loosely compacted condition. This in turn increases their vulnerability to climatic action, i.e., sudden wetting proceeding intense periods of rainfall and drying causing the onset of desiccation cracking (e.g., Heitor et al., 2015, and Walker et al, 2023).

2 CONSTRUCTION OF MOUNDS IN NORMAN CASTLES

During the Norman invasion, the motte and bailey was a common design geometry adopted in the

construction of castles by Norman builders (Pounds, 1994). Much like the castles in York there were numerous similar structures built across England during that time to support the Norman invasion effort and deal with local uprisings. Mottes were large conical earth mounds that were constructed by pilling layers of soils and stones and flattened on top. The top of the mound typically accommodated a tower or keep either constructed in wood or stone to enhance the castle defensibility (Toy, 1985). Some were also built over older man-made geostructures, such as Bronze Age barrows or Roman infrastructure (Kenyon, 2005).

In England and Wales, only 7% of mottes were taller than 10 metres high; 24% were between 10 and 5 metres, and 69% were less than 5 metres tall (King, 1972). The motte was often protected by a moat, i.e., a channel dug a few meters deep which usually surrounded the castle perimeter which provided further protection. The excavation of the moat would have typically been a source of the soil for constructing the mound itself. Considering the likely manpower and construction tools available during that period, i.e., rudimentary picks and shovels (Figure 1), it is estimated that the larger mottes might have taken up to a year to build (Kenyon, 2005).

Figure 1. Building of the Motte at Hastings (modified after Bayeux Tapestry, source: City of Bayeux).

The type of soil available locally would have largely governed the design of the motte (DeVries, 2003). Those built from fine grained soils (e.g. clays and silts) could support a steeper slope as the soil would be pilled and lightly compacted in unsaturated condition (i.e. greater magnitude of capillary stresses), whilst coarse grained soils (e.g. gravel, sands) would exhibit a gentler incline typically controlled by their angle of repose. Several accounts after their construction, report that these geostructures required frequent maintenance (e.g. Pounds, 1994). The main issues reported were associated with superficial erosion and washouts during flooding, particularly with steeper mounds. This is consistent with the placement of soils in a relatively loose condition. Over time however, some mottes suffered from subsidence and localised damage caused by flooding, which required repairs and stabilisation work (Cooper, 1911). Nonetheless, despite these specific localised issues most of these geostructures are in remarkable condition, compared to those built in Victorian time. Figure 1 depicts the construction of a mound and indicates that the mound would have been built in layers which is similar to the practices adopted today compared to Victorian times when fills were just tipped (Walker et al, 2022). In addition, the soil is represented as a particulate material which may indicate the level of expertise of building with soil would have been greater than typically assumed. In this paper, the site investigation works undertaken at Baile Hill mound conducted as part of pilot study to support a preliminary engineering assessment of the stability of a motte and bailey mound are showcased.

3 SITE INVESTIGATION

3.1 Baile Hill site

The site is currently a steep vegetated mound present to the south of Cromwell Road and the east of Baile Hill Terrace, roughly centred around 460266E, 451274N (British National Grid). Neither the bailey nor the ditch at the base of the hill are still present. Baile Hill is one of two castles constructed by William the Conqueror in 1069 in York (Figure 2).

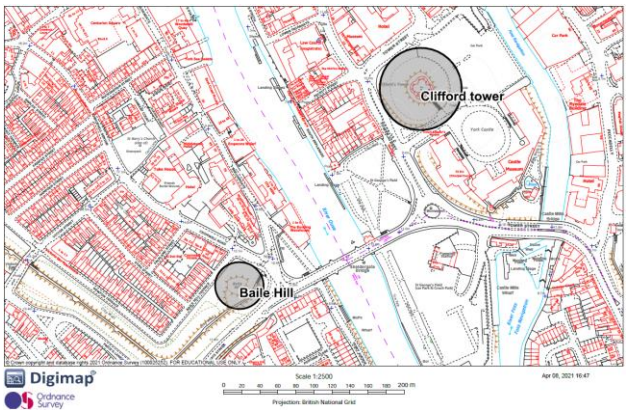

Figure 2. Ordnance map from York (Source: Digimap Ordnance survey collection, 2021).

The encircling ditch at the base of the hill, which is no longer present, is considered to have been 21m wide and 12m deep based on findings obtained by excavations undertaken during the 1960s. Addyman and Priestley (1977) speculated that the ditch is filled with soil (glacial till from the York Moraine member)

that may have washed out or resulted from localised shallow landslides from the Baile Hill mound. However, it is also likely that it may have been backfilled to support the rapid expansion of the town of York during Victorian times (Winslow and Heitor, 2024).

3.2 Methods

A combination of destructive and non-destructive methods were used. Georadar was proposed for an initial survey to identify the main composition layers within the mound and for identifying any buried structures. Advanced Continuous Surface Wave (ACSW) relies on the measurement of subsurface propagation of surface waves. The velocity of Rayleigh waves is monitored over a range of frequencies; starting at higher wave frequencies (shallow) to low frequencies (deep). The velocity of the Rayleigh waves (V_R) can be used to derive the velocity of shear waves (Vs) considering Poisson ratio (ν) as follows (Heymann, 2007):

$$\frac{V_R}{V_s} = \frac{0.874 + 1.117\nu}{1+\nu} \quad (1)$$

Electrical Resistivity Tomography (ERT) was undertaken to assist with the identification of moisture in the mound. While moisture content cannot be directly extracted from the ERT, their values are generally proportional (e.g. Archie's law). In addition, ERT is also sensitive to variation in soil density and grain size thus where the moisture regime is likely to be similar (at the same depth), lateral changes in density can be identified. A borehole was also drilled on the top of the Baile Hill to a depth of 5.45mbgl with window sampling and follow-on by dynamic Probe to 10.00mbgl.

4 RESULTS AND DISCUSSION

The Baile Hill site geology is dominated by the deposits of the York Moraine member consisting of clay, sand and gravel formed during the quaternary period. There are also alluvium deposits approximately 10m to the east of the site (British Geological Survey viewer), thus it is also possible that alluvium deposits underlie the base of the mound.

The quality of the results obtained by Georadar is relatively poor because the mound readily absorbed the radar energy. This behaviour is typically observed in clay rich formations, which indicates the mound consists of mainly clayey soils. Unfortunately, no stratification details or features were identified.

At the top of the hill the values of shear wave velocity obtained are generally between 200 and 300m/s with occasional outliers over 300m/s that may represent either areas that are denser or drier (Figure 3). These results indicate that the soils in the hill are considerably better compacted compared to the ground in the surrounding area (maximum values around 200m/s). The larger shear wave velocities can be the result of compression due to the self-weight of the fill material over time and some degree of ageing.

The ERT data is displayed in Figure 4. Generally, the electrical resistivity increases as the water content of a soil decreases and as the air voids increase (i.e., poorly compacted). On the top of the mound (0 to 19m), higher resistivity values were observed typically above 300 Ω.m for depths up to 2.5m (dry or perhaps loosely compacted). From the shear wave velocity surveys, it would seem the resistivity values may be combination of both, as shear wave velocities of about 200m/s (Figure 3) are typically considered relatively low for compacted materials.

The overall high resistivity region identified from 16-19m chainage is likely due to the moisture deficit caused by root water uptake and evapotranspiration processes of a nearby mature tree. The area of low resistivity between chainage 16 to 19 is anecdotally the location of the archaeological excavation (Addyman and Priestley, 1977). Similar values of electrical resistivity were also detected at the top of the mound at a depth of 3mbgl, which is likely the same material. At this level, the intrusive works at the top of the mound revealed the presence of a gravelly sandy clay layer with a high water content. It is likely that the beyond this depth the material is stiffer and has a high-water content as expected given the clay large water retention capacity. This is in line with the very low electrical resistivity levels recorded (below 30 Ω.m). It should be noted that while the gravelly sandy clay observed beyond 3mbgl appeared to be stiffer it is still likely made ground constructed with local glacial tills from the York Moraine member considering local geomorphology.

At chainage of 38 to 40m, a bulb of high resistivity is noted. As the line of ERT electrodes traversed a Rowan tree at this location, it is likely that the bulb indicates the presence of an area of low moisture content caused by root water uptake. These contours are also in agreement with field studies for direct moisture measurements conducted by Biddle (1998).

5 POTENTIAL PROTECTION MEASURES

The results from ERT indicated that high resistivity values were obtained in the vicinity of mature trees. At

the moment the mound is well vegetated and that may be the reason for its remarkable condition, i.e. no apparent deep seated failures. This seems to indicate that the use of well managed vegetation could be a cost effective and environmentally friendly protection measure for these geostructures. The vegetation use in this context can have multiple purposes, i.e. surface erosion mitigation, physical reinforcement of the superficial layers that are less compacted and increase in the soil shear strength driven by root water uptake (e.g., Pallewatta et al., 2019 and Pathirage et al., 2019). Where slope failures are frequent the use of capillary barrier system together with vegetation (e.g. grasses) could be effective in managing increased risk due to climate change (e.g. Scarfone et al., 2020).

Nonetheless, while the use of vegetation is attractive from a geotechnical standpoint, it should be noted that from an archaeological perspective it can hinder the conservation efforts as roots can damage buried heritage artifacts. In addition, for urban areas such as Baile Hill, the use of vegetation can have an unintented negative impact of the social landscape of the site (e.g. antisocial behaviour).

6 CONCLUSIONS

The results of this preliminary study, show that the shear wave velocity values measured and observations from the borehole, that the fill material in the mound may be loose to moderately compacted.

This is not surprising considering historical accounts of the construction methods employed and soil ageing and compression during the past 10 centuries. It is postulated that despite some localised evidence of soil movement, the vegetation via root reinforcement and moisture deficit induced by root water uptake may be playing a critical role to ensure the stability of the mound. However, more detailed investigations are required to ascertain the level of moisture deficit and the changes in stability between seasons driven by differences in the evapotranspiration processes in the vegetation.

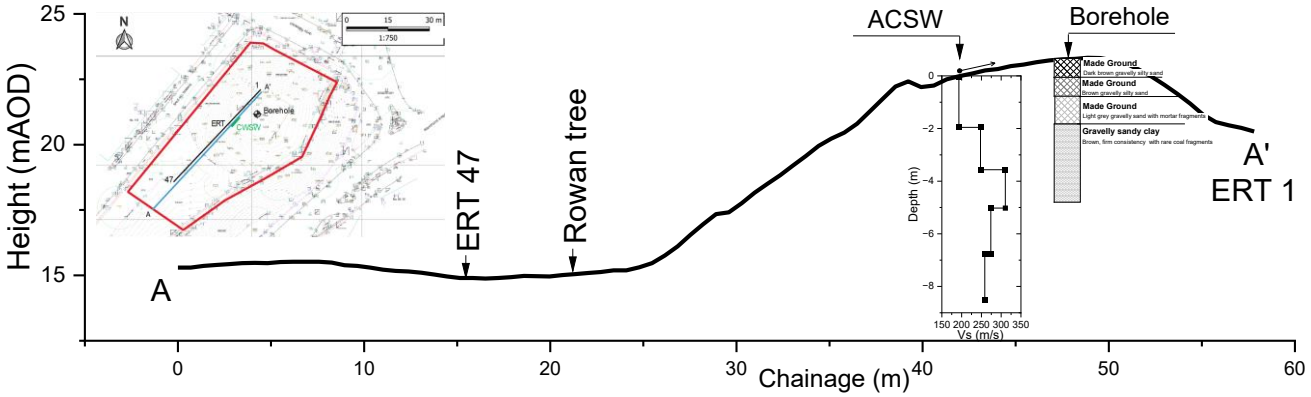

Figure 3. Shear wave velocity and borehole log profile obtained on top of the mound.

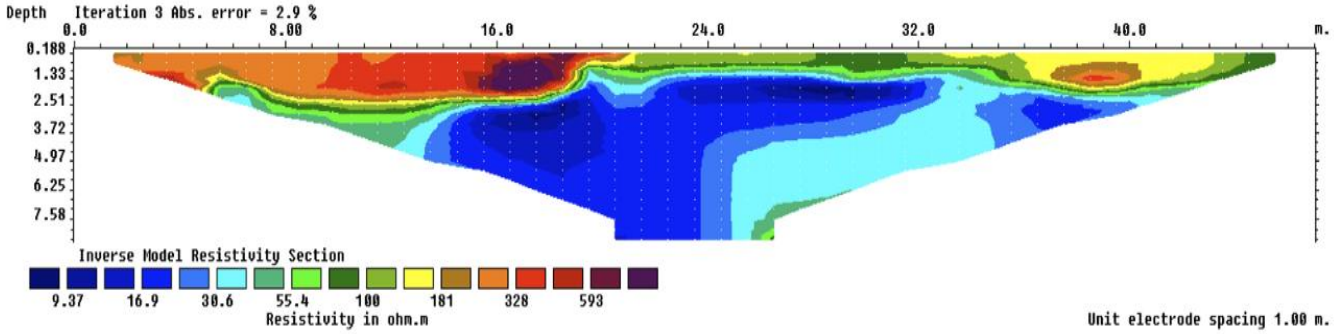

Figure 4. Electrical Resistivity values with depth section noted in Figure 3 (top of the mound 0 to 19m, inversion by RES2D).

ACKNOWLEDGEMENTS

Financial support provided by the Worshipful Company of Constructors Sir Ian Dixon scholarship awarded to P. Winslow is gratefully acknowledged. Technical assistance with geophysical techniques provided by Dr Adam Booth (Georadar) and James Blyth (ACSW, Soil safe) is appreciated. Assistance provided by Keith Emerick (Historic England) and by

York Archaeological Trust (archaeological watching brief) are also gratefully acknowledged.

Seismic response of the Kathmandu basin from 3D physics-based numerical simulations

Réponse sismique du bassin de Katmandou à partir de simulations numériques 3D basées sur la physique

V.M. Hernández-Aguirre*, R. Rupakhety

**vmh5@hi.is*

ABSTRACT: During the 2015 Mw7.8 Gorkha earthquake, which is the largest to have struck Kathmandu in the last 80 years, the ground motion inside the basin exhibited a notable amplification at low frequencies (<0.9 Hz). Different factors, including source, path as well as site effects, were responsible for the unusual recorded ground motion characteristics. To shed light on the site effects contribution, we study the seismic response of the Kathmandu basin by means of 3D physics-based numerical simulations of some of the aftershocks of the Gorkha earthquake, using the open-source high-performance spectral element code SPEED. To this aim, we developed a large 3D numerical model for the central part of Nepal, including the most recent data for the Kathmandu basin geometry and soil stratigraphy. With the ever-increasing computational power, 3D numerical simulations are becoming increasingly appealing to study the seismic response of complex tectonic and geological systems. The 3D model presented here could support future studies on the seismic response of the Kathmandu basin.

RÉSUMÉ: Lors du tremblement de terre de Gorkha de 2015 (Mw7.8), qui est le plus important à avoir frappé Katmandou au cours des 80 dernières années, le mouvement du sol à l'intérieur du bassin a présenté une amplification notable aux basses fréquences (<0.9 Hz). Différents facteurs, dont la source, la trajectoire et les effets de site, sont responsables des caractéristiques inhabituelles des mouvements du sol enregistrés. Pour mettre en lumière la contribution des effets de site, nous étudions la réponse sismique du bassin de Katmandou au moyen de simulations numériques 3D basées sur la physique de certaines répliques du tremblement de terre de Gorkha, en utilisant le code d'éléments spectraux haute performance SPEED. À cette fin, nous avons développé un vaste modèle numérique en 3D pour la partie centrale du Népal, incluant les données les plus récentes sur la géométrie du bassin de Katmandou et la stratigraphie du sol. Avec l'augmentation constante de la puissance de calcul, les simulations numériques en 3D deviennent de plus en plus attrayantes pour étudier la réponse sismique de systèmes tectoniques et géologiques complexes. Le modèle 3D présenté ici pourrait servir de support à de futures études sur la réponse sismique du bassin de Katmandou.

Keywords: Kathmandu basin; Wave propagation; Site effects; Physics-based simulations; Gorkha earthquake.

1 INTRODUCTION

Kathmandu is located on an oval intermontane valley of approximately 30 km long in the east-west direction and approximately 25 km wide in the north-south direction. The valley floor is overlain by soft, thick fluvial, fluvio-lacustrine, and fluvio-deltaic sediments, that reach thicknesses of around 600 m in the central part of the valley (Moribayashi & Maruo, 1980; Sakai, 2001).

Given the characteristics of the Kathmandu basin, the ground motion from the 25 April 2015 Mw7.8 Gorkha earthquake, that broke the bottom portion of the locked zone of an eastern segment of the Main Himalayan Thrust (Avouac et al., 2015), and from some of the aftershocks, was strongly amplified at low frequencies (e.g., Asimaki et al., 2017; Rupakhety et al., 2017) due to site effects arising from the basin geometry and soil stratigraphy. The ground motion in the Kathmandu basin from the mainshock (Takai et al., 2016) and from some of the aftershocks (Shigefuji et al., 2022) was recorded by a network installed by the Hokkaido University in collaboration with the Department of Geology from Tribhuvan University.

In the recent years, 3D numerical simulations of the 2015 Gorkha mainshock, and/or some aftershocks, have been carried out (e.g., Bijukchhen, 2018; Shen et al., 2022; Sreejaya & Raghukanth, 2022; Wei et al., 2018), however, these studies were limited to very low frequencies (<0.5 Hz), or modelled the 3D structure of basin in a simplified way.

In this work we present a 3D numerical model for the central part of Nepal that includes the surface topography and the most recent data for the Kathmandu basin geometry and soil stratigraphy. Moreover, we compare the results from 3D physics-based numerical simulations of some of the aftershocks with the respective recorded motion.

2 SETUP OF THE 3D NUMERICAL MODEL FOR CENTRAL NEPAL

2.1 The spectral element code SPEED

Three-dimensional physics-based numerical simulations were carried out using the open-source computer code SPEED (http://speed.mox.polimi.it), suitable for the simulation of seismic wave propagation problems including the coupled effects of the seismic source and the propagation path through heterogeneous Earth's media (Mazzieri et al., 2013). SPEED allows treating different seismic sources, including kinematic (either double couple point source or extended fault) and dynamic rupture models, as well as incoming plane waves.

2.2 Crustal structure

The adopted crustal structure (Table 1) is the 1D model developed by Mahesh et al. (2013), which has been used in locating local events and tested against more complex structures, with the addition of a layer of approximately 600 m thickness (H) with a lower stiffness at the top of the model.

Table 1. Crustal model adopted in the 3D model.

H [km]	ρ [kg/m^3]	Vs [m/s]	Vp [m/s]	Qs	Qp
0.6	2400	2200	4000	200	400
15.4	2530	3200	5500	320	640
4.0	2690	3500	6000	350	700
6.5	2830	3700	6450	370	740
10.0	2900	3850	6650	385	770
5.0	3070	4150	7200	415	830

2.3 Velocity model for the basin

Recently, Gilder et al. (2020) collected databases of ground conditions, in situ and laboratory geotechnical tests, and geophysical tests carried out in Kathmandu. Based on this information they created a 3D model of the sediment/bedrock boundary.

Based on a modified version of the sediment/bedrock boundary model of Gilder et al. (2020), and on the 3D velocity structure for Kathmandu defined by Bijukchhen (2018), we created a 3D model for the basin that has a linearly increasing Vs with depth. The shear-wave velocity at the ground surface decreases from 300 m/s at the edges of the basin, to 200 m/s at the locations where the basin thickness is larger than 100 m. For the whole basin Vs at the contact with the first crustal layer is 550 m/s. Figure 1 shows an E-W cross section of the velocity model for the basin.

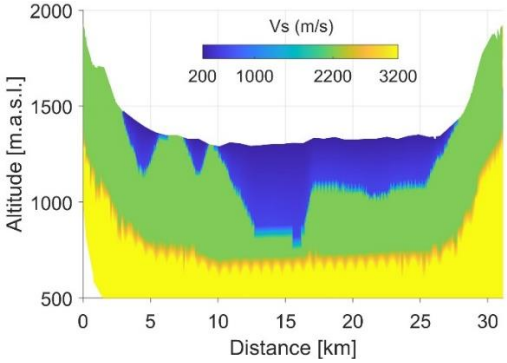

Figure 1. Cross section showing the shear-wave velocity model used for the basin. The location of the cross section is shown with a blue dashed line in Figure 2.

2.4 Numerical model

The mesh, shown in Figure 2, was created using the software CUBIT. It extends over a volume of about 196x98x42 km^3, and it is discretized using an unstructured hexahedral conforming mesh. The mesh is designed so that simulations are accurate up to about f_{max} = 0.9 Hz, to limit the computational load. The order of the spectral polynomials (N) is 4. Overall, the mesh consists of 614'752 spectral elements, resulting in approximately 40.4x10^6 degrees of freedom. The numerical simulations were performed on the Elja cluster from the University of Iceland. A linear viscoelastic model was used for all the materials present in the model.

3 RESULTS FROM THE 3D PHYSICS-BASED SIMULATIONS

Two aftershocks were simulated using point sources, the 25/04/2015 6:53 M4.9 and the 12/05/2015 7:36 M6.1, with depths of 8 and 9 km, respectively. Their epicenters are shown in Figure 2. For the sake of brevity, just some results for the M4.9 simulation are presented here.

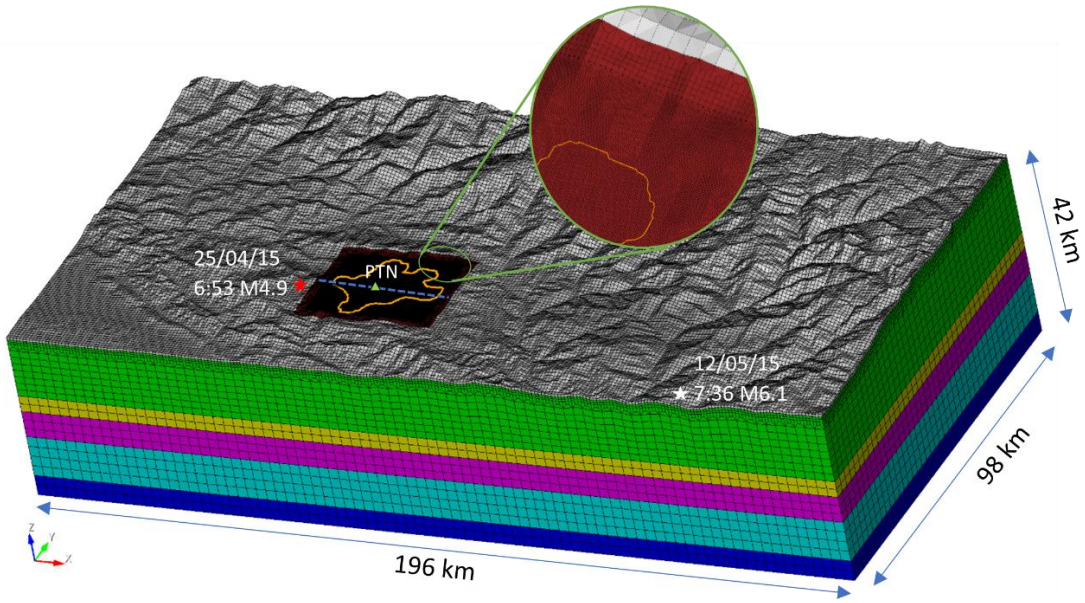

Figure 2. Three-dimensional mesh for Nepal. The contour of the Kathmandu basin is highlighted with an orange line. The blue dashed line represents the location of the cross section presented in Figure 1. For reference the location of station PTN is shown with a green triangle.

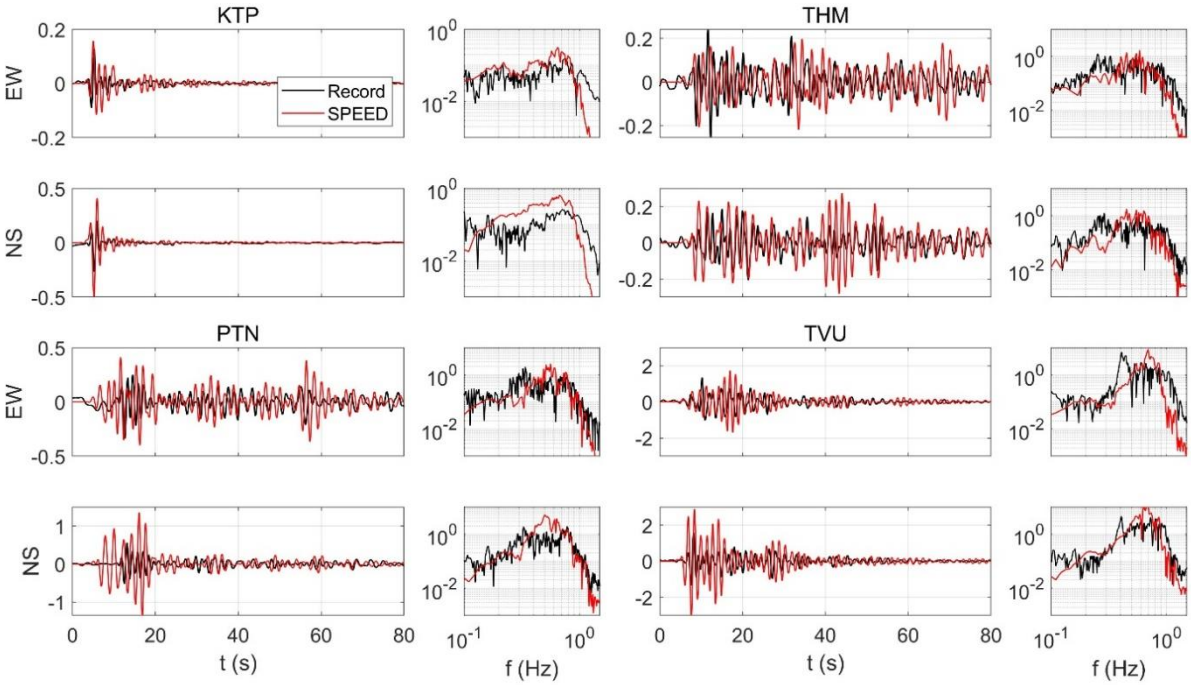

Figure 3. Comparison between recorded (black lines) and simulated (red lines) velocity waveforms (in cm/s) and their corresponding FAS (in cm) for the 25/04/2015 6:53 M4.9 earthquake.

In Figure 3 velocity waveforms are presented. The locations of the stations are shown in Figure 4. Synthetics and records have been low-pass filtered at 0.9 Hz, for consistency with the spatial resolution of the mesh While there is an overall good agreement between simulated and recorded ground motion, the peaks in the Fourier spectra (FAS) of the simulated motions appear at slightly higher frequencies. It is interesting to note the differences in strong ground motion duration; for instance, at station KTP, located in outcropping bedrock, the duration is of less than 10 s, while for station THM, located in a deeper part of the basin, the duration is of more than 50 s.

In order to highlight the effect of the basin on the ground motion, Figure 4 shows a map of geometric mean of horizontal peak ground velocity (PGV), from which the amplification of ground motion is evident inside the basin. Moreover, it's clear that for this case, PGVs are larger at the western part of the basin, since the simulated earthquake is located to the west. Using simple 1D simulations it is not possible to obtain the observed spatial variation of the ground motion.

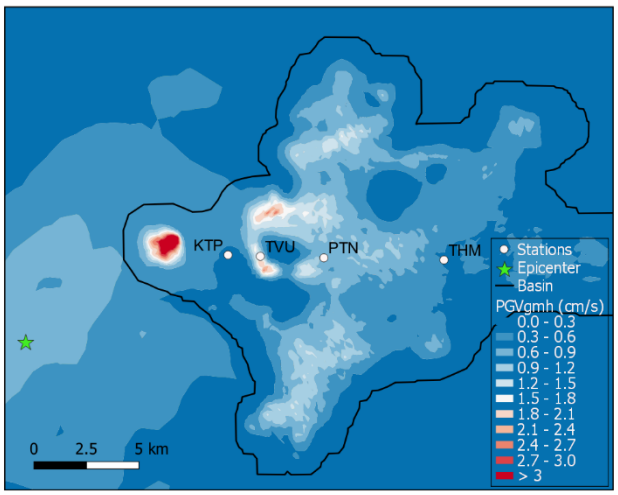

Figure 4. Ground motion map of PGV for GMH (geometric mean of horizontal) components.

4 CONCLUSIONS

Three-dimensional physics-based numerical simulations of two aftershocks of the 2015 Gorkha earthquake were produced by the open-source spectral element code SPEED. A 3D numerical model covering an area of 196x98 km^2 was constructed, based on the geological and geophysical investigations available, with special emphasis on the Kathmandu basin. While the maximum frequency that our model is able to propagate is relatively low (0.9 Hz), we were able to realistically simulate the basin effects, evident in the long-duration ground motion inside the basin with strong amplification at low frequencies.

At this point we did not attempt to simulate the Mw7.8 mainshock or the largest aftershock, since it has been shown that for these events soil non-linearity was present, and the model used here is linear viscoelastic. However, in the near future we expect to simulate also the mainshock.

ABSTRACT: Skempton and Brown (1961) presented a well-documented landslide case study involving a heavily overconsolidated boulder clay deposit in Selset, Yorkshire, UK. While the laboratory testing program revealed significant inherent variability in soil parameters, their analyses were limited to deterministic approaches. This study revisits their work within the framework of probabilistic analysis. We employed Monte Carlo Simulations (MCS) alongside Random Field Finite Element Limit Analysis (RF-FELA), which explicitly accounts for spatial variability. Additionally, we conducted MCS using a closed-form solution, implicitly neglecting spatial variability, i.e., assuming a scale of fluctuation tending towards infinity. Our analysis revealed that neglecting spatial variability can lead to an overestimation of the probability of failure. Nevertheless, MCS with the closed-form solution substantially reduces the computational time required by RF-FELA from hours (or even days) to minutes, making it an efficient tool for preliminary probabilistic analysis. The case study also demonstrate that probabilistic slope stability analysis provides more profound insights, offers a more transparent means of quantifying slope risk, and better captures the rapid increase in risk as the verge of failure is approached.

RÉSUMÉ: Skempton et Brown (1961) ont présenté une étude de cas bien documentée sur un glissement de terrain impliquant un dépôt d'argile à blocs fortement surconsolidée à Selset, Yorkshire, Royaume-Uni. Alors que le programme d'essais en laboratoire a révélé une variabilité inhérente significative des paramètres du sol, leurs analyses se limitaient à des approches déterministes. Cette étude réexamine leur travail dans le cadre de l'analyse probabiliste. Nous avons utilisé des simulations de Monte Carlo (MCS) en conjonction avec l'Analyse de Limite d'Éléments Finis de Champ Aléatoire (RF-FELA), qui prend explicitement en compte la variabilité spatiale. De plus, nous avons effectué des MCS en utilisant une solution en forme fermée, négligeant implicitement la variabilité spatiale, c'est-à-dire en supposant une échelle de fluctuation tendant vers l'infini. Notre analyse a révélé que le fait de négliger la variabilité spatiale peut conduire à une surestimation de la probabilité de défaillance. Néanmoins, les MCS avec la solution en forme fermée réduisent considérablement le temps de calcul nécessaire par RF-FELA, passant de heures (voire jours) à quelques minutes, en en faisant un outil efficace pour une analyse probabiliste préliminaire. L'étude de cas démontre également que l'analyse probabiliste de la stabilité des pentes offre des perspectives plus approfondies, fournit un moyen plus transparent de quantifier le risque de pente et capture mieux l'augmentation rapide du risque à l'approche de la défaillance.

Keywords: Slope stability; deterministic analysis; probabilistic analysis; Monte Carlo Simulation; Spatial variability.

1 INTRODUCTION

Soils are naturally occurring materials and exhibit inherent variability. When addressing slope stability issues, deterministic analysis is a commonly employed method. However, deterministic analysis falls short in adequately addressing the inherent uncertainties and variations in soil properties. The key advantage of employing probabilistic analysis lies in its ability to effectively quantify parameter uncertainties.

In this research, we revisit a well-documented landslide case that occurred in Selset, Yorkshire, UK,

using a probabilistic approach. This paper is structured as follows. First, we present a closed-form solution suitable for integrated deterministic and probabilistic analysis. Following this, we provide a brief overview of the Selset slope failure, and subsequently, we delve into both deterministic and probabilistic analyses.

2 CLOSED FORM SOLUTIONS FOR SLOPE STABILITY ANALYSIS

Taylor (1937) found that solutions of homogeneous slopes can be presented as dimensionless charts. Since then a large number of slope stability charts have been presented in the literature (e.g., Bishop and Morgenstern, 1960; Barnes, 1991; Michalowski, 2002; Steward et al. 2011). Slopes are rarely homogeneous. However, site investigation is often limited at early design stage or for analyses at regional and network scales. For such situations, simplification and assuming homogeneous ground condition become necessary. For the Selset slope failure revisited in this study, the slope is relatively simple and homogenous, use of stability charts gives accurate stability assessment (Skempton and Brown, 1961).

Slope stability charts are a product of 20th century, and it does not comply with the digital design workflow in the 21st century (Huang, 2023a). Instead of presenting dimensionless stability solutions as charts, Huang (2018, 2023b) further carried out regression analyses and innovatively developed a series of closed form solutions for dry, saturated and unsaturated slopes. The closed form solution for saturated slopes, which can be used to back analyse Selset slope failure, is given below:

$$F = A\left(\frac{c'}{\gamma H \tan\phi'}\right)^{B} \tan\phi' + \frac{\tan\phi'}{\tan\alpha} - \left(\frac{c'}{\gamma H}\frac{1}{\tan\alpha} + \frac{\tan\phi'}{\sin\alpha\cos\alpha}\right) r_u \quad (1)$$

where F = factor of safety, c' = effective cohesion, ϕ' = friction angle, γ = soil unit weight, H = slope height, α = slope angle. Parameters A and B are the two curve-fit parameters in regression analyses and they can be calculated as

$$A = 10.50\exp(-0.009\alpha) \quad (2)$$

If $0 \le \frac{c'}{\gamma H \tan\phi'} \le 1$:

$$B = 0.72 - 3.5\times10^{-5}\alpha^2 + 0.0031\alpha \quad (3a)$$

If $1 < \frac{c'}{\gamma H \tan\phi'} \le 3$:

$$B = 0.83 - 2.2\times10^{-5}\alpha^2 + 0.0026\alpha \quad (3b)$$

The slope angle α should be input as degree in Eq. (2) and (3). The applicable range of Eq. (1) is α = 11°~65° and $\frac{c'}{\gamma H\tan\phi'}$ = 0~3, which should cover most slopes encountered in practice. Closed form solution for α > 65° is also provided by Huang (2023b).

The advantages of closed form solutions over slope stability charts are (Huang, 2023a):

- The slope parameters are continuous within the defined range (rather than being restricted to discrete values necessarily dictated by the use of stability charts), therefore the user has more flexibility on the choice of parameter value.
- Closed form solutions can easily be incorporated into modern digital design workflows, such as Excel spreadsheets.
- Closed form solutions can be used for both deterministic and probabilistic slope stability analyses, as demonstrated in Sections 4 and 5.

3 SELSET SLOPE FAILURE

Skempton and Brown (1961) presented a case study on a slip at the river valley side in Selset, Yorkshire, UK. Figure 1 illustrates a cross-section of the landslide, with a slope height of H = 12.8 m and a slope angle of α = 28°. The slip occurred in Boulder clay, a heavily overconsolidated clay (OC) that likely deposited about 45,000-50,000 years ago during an early stage of the Last Glaciation. Alongside the hill slope's toe, a river has been flowing for at least a century, potentially causing erosion during floods. As per Skempton and Brown (1961), the slope may have remained in or near a state of limiting equilibrium for an extended period.

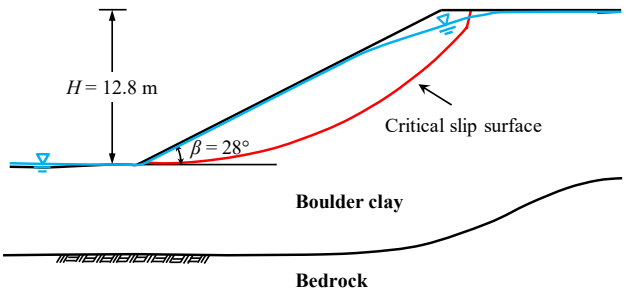

Figure 1. Cross-section of Selset slope failure.

The site investigation revealed the following basic soil properties: natural water content = 12%, clay fraction (< 2μ) = 25%, liquid limit w_L = 26, plastic limit w_P = 13, plasticity index I_P = 13. Eight samples were collected from the site, and consolidated drained

triaxial tests were conducted on these samples. Each sample had a diameter of 38mm and a height of 76 mm. The soil parameters are summarised in Table 1. Figure 2 displays the statistical distributions of the soil properties as presented by Skempton and Brown (1961), along with the Normal and Lognormal fits. Due to the limited amount of data, no consideration was given to the correlation between the random variables.

Table 1. Summary of soil properties.

	Mean (μ)	**Standard deviation (σ)**	**Coefficient of variation (COV)**
Saturated unit weight (γ)	21.8 kN/m^3	0.44 kN/m^3	2.0%
Cohesion intercept (c')	8.7 kPa	3.1 kPa	35.6%
Friction angle (ϕ')	32.0°	1.8°	5.5%

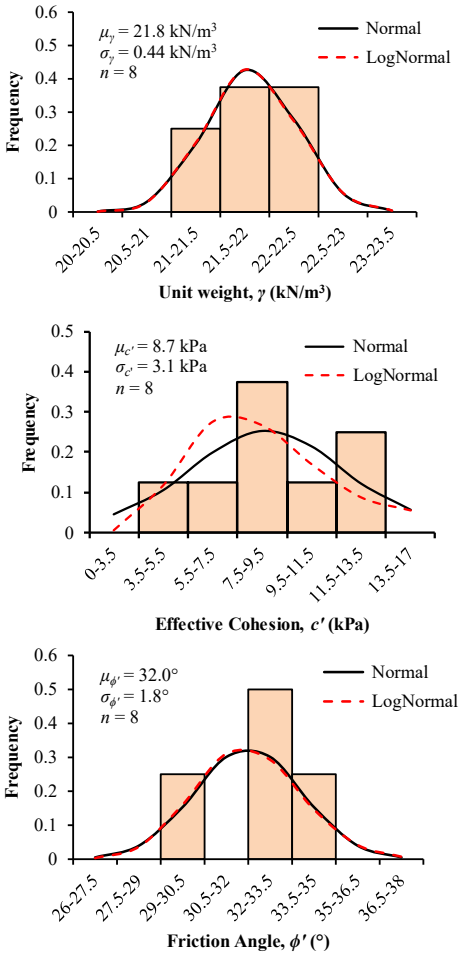

Figure 2. Statistical distribution of the soil properties for Selset Slope (data from Skempton and Brown, 1961).

The slip surface passes through intact Boulder Clay. Consequently, the field value of the cohesion intercept c' is approximately equal to the laboratory value measured in drained triaxial test. This observation stands in stark contrast to the outcomes typically observed in long-term slips occurring in overconsolidated fissured clays, where cohesion diminishes over time and eventually tends towards zero (Skempton, 1970).

4 DETERMINISTIC ANALYSIS

The highest water level measured at winter months, as shown in Figure 1, is practically at the ground surface except at the top of the slope. If the water level is simply taken as at the ground surface, preliminary analyses can be carried out at two extreme pore-water pressure conditions (Skempton and Brown, 1961): 1) hydrostatic condition, pore-water pressure ratio $r_u = \frac{\gamma_w}{\gamma} = \frac{9.81}{21.8} = 0.45$; and 2) steady state seepage with flow parallel to the slope surface, $r_u = \frac{\gamma_w}{\gamma}\cos^2\beta = 0.35$. Given the water level depicted in Figure 1 and in accordance with the two-dimensional critical slip surface presented by Skempton and Brown (1961), the area of the failure mass is about 103 m^2 and the submerged failure mass is about 96 m^2. Therefore, the pore-water pressure ratio can be approximated as $r_u = \frac{96}{103}\frac{\gamma_w}{\gamma} = \frac{96}{103} \times \frac{9.81}{21.8} \approx 0.42$ at hydrostatic condition.

Table 2. Deterministic analysis results.

	Factor of safety			
	r_u = 0.35	**r_u = 0.42**	**r_u = 0.45**	**Method**
Skempton and Brown (1961)	1.14	1.05	0.99	Stability chart
Miller and Hamilton (1989)	1.14	1.02	0.97	UBLA
This study	1.12	1.01	0.96	by Eq. (1)

Back analyses of Selset slope failure have been carried out by Skempton and Brown (1961), Miller and Hamilton (1989) and in this study. Deterministic analyses were carried out with mean values of soil parameters given in Table 1. The results are summarised in Table 2. The geometry of the Selset slope is relatively simple and critical slip surface in a relatively uniform material. Therefore, slope stability analysis can be carried out accurately with slope stability charts, and the charts developed by Bishop

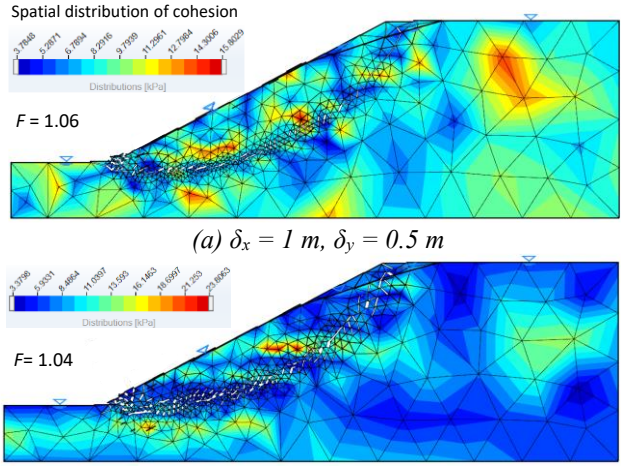
and Morgernstern (1960) was used by Skempton (1961) in back analyses. Miller and Hamilton (1989) reanalysed the Selset slope failure using upper bound limit analysis with rigid-body rotation mechanism. In this study, Eq. (1) is used for the back analyses. Factors of safety reported in the literature and obtained by Eq. (1) are remarkably consistent, with F = 1.12~1.14 at r_u = 0.35, F = 1.01~1.05 at r_u = 0.42, and F = 0.96~0.99 at r_u =0.45. The low safety margin or with F < 1 has, to some extent, explained the slope failure. However, laboratory testing of the soil, as shown in Figure 2, reveals soil variability and uncertainty. Yet, this is not captured by deterministic analysis. Therefore, probabilistic analysis would be carried out to bring additional insights.

5 PROBABILISTIC ANALYSIS

5.1 Random Field Finite Element Limit Analysis

Random field finite element limit analyses (RF-FELA) were carried out using the software Optum G2 (version 2021 2.1.6). Finite element limit analyses can be carried out by lower or/and upper bound. Agbaje et al. (2022) showed that the difference in probability of failure calculated by lower/upper bound is generally less than 2%. Therefore, lower bound limit analysis, which is slightly on the conservative side, is adopted in this study. Variability of the soil properties (Table 1), quantified by coefficient of variation (COV), is explicitly modelled. As COV of cohesion is 35.6%, the soil parameters are assumed to follow Lognormal distribution to avoid negative inputs (physically impossible). The spatial variation/random field modelling was generated using the Karhunen-Loeve (KL) expansion method. Huang et al. (2022) investigated vertical scale of fluctuation (δ_y) of London Clay with CPT data, and reported that δ_y ranges from 0.24 to 1.01 m with a mean of 0.48 m. No analysis has been found on Boulder clay. In this study, δ_y of Boulder clay is simply taken as 0.5 m. For the soils that have gone through normal deposition process, horizontal scale of fluctuation (δ_x) is generally much greater than δ_y, but the values of δ_x are rarely reported due to the scarcity of site investigation data collected at closely spaced horizontal intervals. Therefore, parametric studies are carried out with δ_x =1 m, 5 m, 50 m, respectively. The number of element of the finite element mesh is set to 1000, and mesh adaptivity is enabled with 3 adaptive iterations, so that the mesh is automatically refined along the critical slip surface. A typical set of results is shown in Figure 3(a) for δ_x = 1 m, δ_y = 0.5 m, and Figure 3(b) for δ_x = 50 m, δ_y = 0.5 m.

Probabilistic analysis was completed using the Monte Carlo Simulation (MCS). Probability of failure (P_f) is calculated as the ratio of the number of slope failures (F < 1) to the total number of simulations. The number of simulations is set to be 1000, which is considered as sufficient when the probability of failure is relatively high and used by Agbaje et al. (2022). The results are presented in Section 5.3.



(a) δ_x = 1 m, δ_y = 0.5 m

(b) δ_x = 50 m, δ_y = 0.5 m

Figure 3. Illustration of random field finite element analysis (the contours show spatial distribution of cohesion).

The time required for 1000 simulations with RF-FELA takes about 7.4 hours on a computer with i7-9750H CPU@2.60GHz and 16 GB of RAM. In cases involving slopes with lower P_f, greater number of simulations would be required to ensure accuracy of MCS. Though MCS is widely regarded as a superior approach, the computational time requirement limits its application in industry practice.

5.2 Efficient Probabilistic analysis with closed form solutions

With the closed form solution Eq. (1), Monte Carlo simulation with 1,000,000 simulations can be completed in 3 minutes on a computer with i7-9750H CPU@2.60GHz and 16 GB of RAM. This stands in sharp contrast to the 7.4 hours required for 1000 simulations using RF-FELA. Probabilistic analysis with first-order reliability method (FORM) and first-order second moment (FOSM) method can be completed instantly. Excel spreadsheets and VBA scripts used to implement MCS, FORM and FOSM has been provided by Huang (2023a, 2023b). They are adapted for the back analysis of Selset landslide in this study. The results are summarized in Section 5.3.

5.3 Probabilistic analysis results

The results of MCS by RF-FELA, where δ_x varies from 1 m to 50 m (with δ_y held at 0.5 m), are shown in **Error! Reference source not found.**. Additionally, MCS with Eq. (1) are presented. In the case of MCS using Eq. (1), in each simulation the slope is homogenous, therefore it is equivalent to assume $\delta_x = \delta_y = +\infty$. The cumulative probability increases with the increase in F and shows a "S" shape. For each cumulative probability curve, the cumulative probability at $F = 1$ represents the probability of failure, as summarised in **Error! Reference source not found.**. For the MCS with RF-FELA, P_f increases with the increase in scale of fluctuation, from 5.2% to 27.7%. It should be noted that this observation is made when $P_f < 50\%$, and P_f may decrease with the increase in scale of fluctuation when $P_f > 50\%$ (Huang, 2020). The solution obtained by MCS with Eq. (1) should be viewed as an approximate solution, and a 20% is reasonable compared to those reported by MCS with RF-FELA.

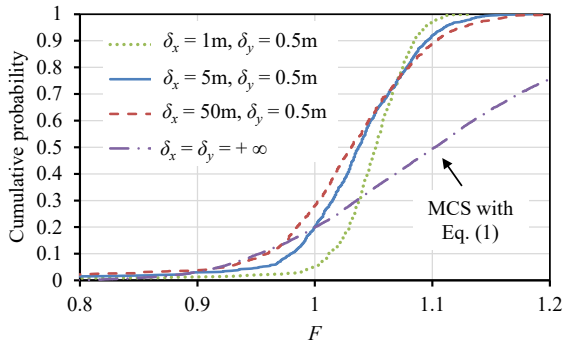


Figure 4. Cumulative probability of failure of Selset slope considering spatial variability (r_u = 0.35, Lognormal distribution).

Use of MCS with RF-FELA is limited to Lognormal distribution of the soil parameters and steady state seepage of water pressure (r_u is about 0.35). Further analyses were carried out using MCS with Eq. (1) considering both Normal and Lognormal distributions and r_u ranging from 0.35 to 0.45. The results are summarised in Table 4. The P_f obtained with Lognormal distribution is very closed to or slightly greater than Normal distribution. The P_f is about 20% at $r_u = 0.35$, increase to about 50% at $r_u = 0.42$, and further increase to more than 60% at $r_u = 0.45$.

With the closed form solution Eq. (1) parametric studies can readily be carried out for various r_u for both deterministic and probabilistic analyses, as illustrated in Figure 5. The P_f obtained by FORM and MCS with Normal and Lognormal distributions are almost identical (only those for Lognormal distribution are shown). Factor of safety F decrease linearly with the increase in r_u. When $r_u \leq 0.25$, P_f is practically zero, and P_f increase exponentially with the further increase in r_u. It can be concluded that probabilistic analysis better capture the increment of risk level of the slope.

Table 3. Effect of spatial variability on probability of failure (r_u = 0.35, Lognormal distribution).

Method	**Monte Carlo Simulation (MCS) with Random Field Finite Limit Analysis**			**MCS with Eq. (1)**
Scale of fluctuation	δ_x = 1 m, δ_y = 0.5 m	δ_x = 5 m, δ_y = 0.5 m	δ_x = 50 m, δ_y = 0.5 m	$\delta_x = +\infty$ $\delta_y = +\infty$
Probability of failure (P_f)	5.2%	19.8%	27.7%	20.0%

Table 4. Probabilities of failure by Monte Carlo Simulation with Eq. (1) ($\delta = +\infty$).

Distribution	**r_u = 0.35**	**r_u = 0.42**	**r_u = 0.45**
Lognormal	20.0%	52.8%	66.4%
Normal	20.3%	47.2%	61.0%

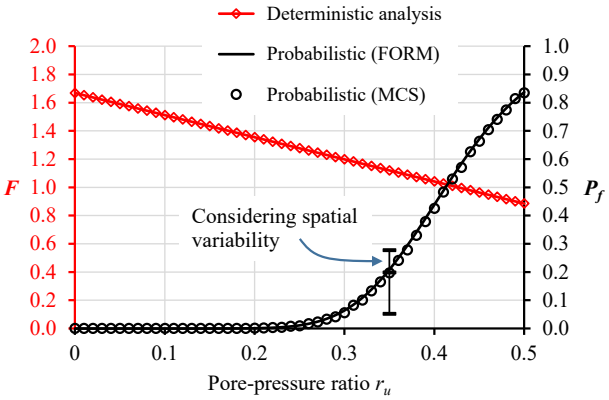

Figure 5. Comparison of deterministic and probabilistic analysis for Selset slope failure.

6 CONCLUSION

This study revisited the Selset slope failure. Despite the soil being situated within a single soil layer and consisting of relatively uniform Boulder Clay, it exhibits inherent variability. To address this, probabilistic analyses were conducted using Monte Carlo Simulation, employing Random Field Finite Element Limit Analysis, and a closed-form solution as defined in Eq. (1). The results from these back analyses demonstrate that probabilistic analysis provides a more accurate reflection of the slope's risk level through directly quantifies parameter variability

and more effectively captures the increase in slope risk with the change of triggering factors (e.g., pore-water pressures).

ABSTRACT: The common approaches to flood risk management are based on a top-down view, which, from our perspective, does not allow the adoption of effective solutions considering the different origins of this problem, such as insufficient drainage systems, surface water level, and impermeabilization. With this bottom-up approach, the idea is to consult the information available in municipal services to identify and delimit flooded areas. This mapping will allow the definition of flood zones in which subsequent actions will be promoted. An integrated analysis can be carried out for each affected area, which should include a definition of mitigation and/or adaptation measures to be implemented at a local scale. In some locations, given the constraints, it will only be possible to develop adaptation strategies, such as the placement of anti-flood barriers at the doors of affected buildings, which will allow for proactive rather than reactive actions. As a proof of concept, a street in the floodable area will be selected, barriers will be purchased, and an evaluation will be made in the next event. After this analysis and definition, the areas adjacent to the floodable areas should be analyzed to narrow the systems contributing to flooding in each location.

RÉSUMÉ: Les approches courantes de la gestion des risques d'inondation sont basées sur une vision descendante, qui, selon notre perspective, ne permet pas l'adoption de solutions efficaces en tenant compte des différentes origines de ce problème, par exemple les systèmes de drainage insuffisants, le niveau des eaux de surface, et l'imperméabilisation. Dans cette approche ascendante, l'idée est de consulter les informations disponibles dans les services municipaux pour identifier et délimiter les zones inondées. Cette cartographie permettra de définir des zones d'inondation sur lesquelles des actions ultérieures seront promues. Une analyse intégrée peut être proposée pour chacune des zones touchées, qui devrait inclure la définition de mesures d'atténuation et/ou d'adaptation à mettre en œuvre à l'échelle locale. Dans certains endroits, compte tenu des contraintes, il ne sera possible de développer que des stratégies d'adaptation, comme la mise en place de barrières anti-inondation aux portes des bâtiments affectés, ce qui permettra des actions proactives plutôt que réactives. Pour preuve de concept, une rue dans la zone inondable sera sélectionnée, des barrières seront achetées et une évaluation sera effectuée lors du prochain événement. Après cette analyse et définition, les zones adjacentes aux zones inondables devraient être analysées afin de réduire les systèmes contribuent aux inondations dans chaque localisation.

Keywords: Flood; risk management; bottom-up approach; precipitation; adaptation.

1 INTRODUCTION

The city of Lisbon, located at the confluence of the Tagus River with the Atlantic Ocean, is a major economic center in Portugal with a high population density. This location has given the city a prominent geostrategic position but also exposes it to natural and climatic hazards such as urban floods and an increasing occurrence of extreme weather events.

Whenever episodes of intense precipitation occur, exceeding the normal levels, parts of the city become completely flooded, with several centimeters of water, causing partial paralysis of the city and significant financial losses for both Lisbon and the country because many people are unable to go to their workplaces. During intense rainfall events, most urban flooding is caused by overflow in former watercourses that are occupied by buildings roads and pavements. These structures act as obstacles to the unimpeded flow of water, obstructing and hindering its movement and thereby creating a barrier-like effect.

According to a study conducted by Antunes et al. (2017), assessing vulnerability of sea level rising (MSL) in urban areas is crucial for defining and adopting strategies for climate change adaptation.

Based on the records of the Cascais tide gauge, in operation since 1882, it can be concluded that the MSL on the Portuguese coast has already risen about 22 cm

since the second decade of the 20th century, with 8 cm of this increase occurring in the last 25 years. The hypothesis that the MSL is in a process of increasing its rate of rise is supported by the most recent ocean observation data from satellites, altimetry, gravimetry, and the network of floats measuring the evolution of the average temperature of the top 300 m layer of the oceans, showing an acceleration in the rise of MSL in the last 10 years (Antunes, 2019).

Despite the uncertainty about the evolution of CO_2 and greenhouse gas emissions into the atmosphere, coupled with the complex dynamics of the oceans, a continuous rapid rise in MSL is expected. Global warming is the main contributor to the increase in melting of the largest continental ice reservoirs located in Antarctica and Greenland (Antunes et al., 2017).

With the increasing frequency of these intense precipitation episodes, 2022 was a critical year for the city, with December being an extremely warm month in terms of air temperature and very rainy in terms of precipitation. Classified in Portugal mainland as the warmest December in the last 92 years, the average value of the air temperature was 2.76ºC above normal. The average minimum air temperature was 9.58ºC, representing an anomaly of +3.53ºC. Meanwhile, the average maximum air temperature reached 15.87ºC, which is higher than the average value with an anomaly of +1.99ºC, being the second-highest value since 1931. The extreme precipitation value in 24 hours was 110.7 mm in Lisbon (Gago Coutinho on the 13th of December). The total average precipitation in December was 250.4 mm, which corresponds to 174% of the normal value, ranking as the 10th highest since 1931 and the 2nd highest since 2000 (IPMA, 2022).

In December, there were several instances of heavy precipitation, particularly on the 4th, 5th, 7th, 8th, 12th, and 13th, and at the end of the month. The two most extreme episodes of precipitation, on the 7th-8th and 12th-13th, accounted for approximately half of the total monthly precipitation.

2 METHODOLOGY, RESULTS AND DEVELOPMENTS IN PROGRESS

The work began with consulting operational services to identify and delineate the flooded areas during the floods in December of 2022. These floods prove to have a high return period, so their occurrence is comparable to those that happen every 100 years. Undertaking the drafting of this map will facilitate the delineation of the various zones in which the actions to be taken will take place. It is proposed that each of the affected areas be analyzed in an integrated manner, including the definition of a strategy with mitigation and adaptation measures to be adopted in the building or along the block. As this is on a local scale, it is recommended that measures be implemented at the level of urbanization plans and detailed plans, but also at the level of green areas and unoccupied public spaces.

2.1 Mapping occurrences

The Fire Department records all flooding incidents within the municipality. This record was made available to the authors of this work so that they could use this information as a basis for identifying vulnerable areas. The aim of this task was to identify the periods of flooding corresponding to the centennial rainfall values (with a return period or recurrence of 100 years). To this end, the events were filtered to periods that met these requirements, namely the rainfall events of December 7, 8, 12, and 13 of 2022 that affected Lisbon (Figure 1).

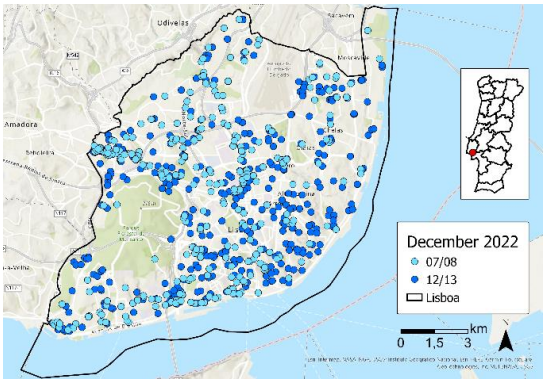

Figure 1. Flooding incidents reported to the Lisbon Fire Department Regiment on December 7, 8, 12 and 13 of 2022.

In addition, the tide values recorded during these periods were checked, and it was identified that the periods with the highest number of occurrences corresponded to high-tide periods. Thus, at the end of this phase, it was possible to obtain a list of events that occurred during the hours of greatest rainfall and with the highest tides, which were likely occurrences of centenary rainfall events. Duplicate occurrence records were also checked and excluded (sometimes the same occurrence was recorded twice, which is normal because firefighters receive information from more than one data source).

2.2 Mapping of flood-prone areas

Case studies:

- December 7-8: The weather in Portugal mainland was conditioned by the presence of a depression centered to the east of the Azores Island. This rainfall led to several flash floods in various urban areas of the Lisbon metropolitan

area, and two daily rainfall maximums were recorded by Instituto Geofísico (83.3 mm) and Gago Coutinho (78.9 mm) weather stations.

- December 12-13: The weather was conditioned by an intense SW flow associated with the passage of warm, humid, and unstable air masses with a high content of precipitable water. There was persistent rain, which was sometimes heavy, and caused flash floods, particularly in Greater Lisbon. During this period, there was an extremely high 3-hour rainfall at the Gago Coutinho (76.9 mm) and Relógio (73.5 mm) stations between 03:10 and 06:10 on December 13. As for the 24-hour figures, it is worth noting that the rainfall is close to the typical climatological values for the month at three weather stations.

The occurrences provided by the Lisbon Fire Department) are recorded on their platform in a point geometry. The analysis of the areas where the incidents were recorded depends on many factors, and the consideration of theoretical factors, such as soil type or geomorphology, proved to be ineffective in delimiting the areas of expected flooding, since Lisbon is a city that has most of its area sealed off and where water infiltration is essentially done through the sewage structure. It was therefore decided to meet with the firefighters who attended each event to find out which area was affected in each event. Additionally, it will be ascertained how high the water level reached at the stage of greatest flooding.

This information will be obtained from the fire brigade, and further data can be obtained from the residents of the affected areas by working with volunteers from the city's parish councils and filling in the information in the AGEO App, an application developed by the Lisbon Municipality as part of the AGEO Project, which aims to report occurrences related to risks of geological origin. This empirical process, which is currently underway, allows for the delimitation of the areas affected by the extreme rainfall events that occurred in Lisbon and is a reliable and credible way of transforming the occurrences in point geometry into areas that were actually flooded (polygons).

2.3 Flood map cartography

Once the relevant events are identified, corresponding to rainfall periods with a return period of 100 years, and the affected areas are delimited, it will be possible to create a new flood-vulnerability map. This map will identify the flood-prone areas based on the previously flooded ones, as well as define a level of susceptibility based on the height that the water has reached in the various locations.

2.4 Geological and geotechnical framework

Lisbon's geological formations range from the Cretaceous to the Holocene period. The Cretaceous formations are hard rocks, composed of limestone and basalts from the Lisbon Volcanic Complex, both of which with geotechnical aptitude. Above, there is a detritic Oligocene formation of continental origin, which is heterogeneous from a geological and geotechnical perspective. Most of Lisbon's urbanized area was raised above a sequence of Miocene formations classified as hard soils, composed of thick alternation of sandstone, limestone and claystone, reaching around 200m. These formations are generally geotechnically competent, except for the decompressed surface layers. Finally, the Holocene formations are made up of alluvium, which are distributed along the water courses (streams) and on the city's riverfront, where they can be up to 40 m thick. In addition, there are landfills of anthropogenic origin. The landfills and alluvial fans are poorly geotechnically competent and do not offer the capacity to support structural elements with prior improvement.

The city is heavily impermeabilized by anthropogenic action (except in the Monsanto area). Even so, the Cretaceous limestones have high permeability values (fracturing), while the volcanic complex and the Oligocene formation have lower permeability. In the Miocene system, permeability is quite variable, being lower in the clay formations and higher in the sand formations. Finally, the alluvial fans have very variable permeability values depending on the main lithologies, although they tend to be high.

2.5 Identification of the type of measures to be implemented in each area

Lisbon Municipality is implementing the Lisbon General Drainage Plan 2016-2030, in which large collectors are being built so that the water drains into the river. In addition, increasing the acceptable flow rate of the drainage network is another action that should be taken to mitigate the impacts of extreme rainfall events. It is also recommended that actions be taken to clean the gutters, thus facilitating water infiltration. Studies are also underway to create water-retention basins.

Nevertheless, even when considering these measures, there are areas whose characteristics reduce the effectiveness of the planned mitigation measures. The riverside area of the city is affected by the presence of water at near-surface levels due to its proximity to the river. This effect is even more evident at high tide, as the water inside the estuary is still significantly affected by this phenomenon.

2.6 Development of a solution

In this work, the priority is to identify the most vulnerable areas for which it is estimated that general mitigation measures may be insufficient or ineffective. Therefore, the Lisbon Municipality is conducting a study to identify which adaptation solutions are available for the population to purchase, namely, anti-flooding barriers that can be implemented without technical knowledge or specialized material.

Flood barriers are designed to protect every room in a building and prevent water from entering through doors, garages, windows, gates, and/or underground floors. As well as homes, they can be used in public areas, stores, shopping centers, industrial buildings, churches, museums, historic buildings, and storage buildings. One of the models of this type allows one to adjust the width of the barrier, whereas another allows one to adjust its height. They do not require invasive construction work because they fit into the existing wall next to the access point frame and are secured by moving the lever or by inflating the seals on the sides and base of the structure (depending on the type of barrier, you will usually have one of two mechanisms). Installation is quick, easy, and accessible to anyone, and has been tested under extreme conditions. If it is necessary to protect a larger area in which the entry exceeds the maximum measures of applicability of a single barrier, several barriers can be joined together because of a removable element when unnecessary, leaving the anchoring base covered. There are also measures to be adopted to prevent theft and extend the life of the equipment. This type of solution allows the population living in areas frequently affected by flooding to adapt to areas where mitigation measures have proved ineffective. The idea is that whenever warnings are issued forecasting heavy rainfall events, people will be able to put up these barriers, avoiding flooding in their homes, with consequent material losses and their safety at risk. This is the definition of the type of reaction that the population is supposed to be able to acquire: proactive, rather than reactive.

2.7 Implementation

The effective implementation of adaptation solutions that protect everyone's home is ultimately the responsibility of everyone. However, the Lisbon Municipality, as a public management and governance body that cuts across the entire city, plays a role in supporting populations that are often affected by flooding caused by extreme rainfall events. Thus, the implementation of the products studied is up to everyone, but there are lists of options for solutions that can be purchased at reasonable prices, which everyone can install in their homes. A list will also be provided of the most effective solutions to be implemented in each area, depending on its level of vulnerability, as well as the effectiveness of the mitigation solutions currently being implemented. The evaluation of the success of the solutions implemented will be carried out by Lisbon Municipality after heavy rainfall events, again by collecting data on the level of water reached and the damage, namely the damage caused and the areas of the property or establishment affected, and this data will be entered and forwarded via the AGEO app.

3 CONCLUSIONS

The work in progress involves a micro-scale analysis, starting with the information obtained through access to the first responders' records of occurrences, which will then evolve into a macro-scale analysis so that it can be included in Lisbon's Municipal Master Plan. This will result in a map highlighting the areas that have flooded and are frequently impacted by it. For future reference, the ideal would be to have a dynamic map that is updated as more recent data comes in.

ACKNOWLEDGEMENTS

The authors are grateful for the support provided by internal and external partners and their availability to cooperate whenever required by the project team.

Climate change impacts on safety of levees: A Review

Impacts du changement climatique sur la sécurité des digues: un examen

J.K. Janga, K.R. Reddy*, J. Schulenberg
University of Illinois Chicago, Chicago, USA

**kreddy@uic.edu*

ABSTRACT: Levees are an important part of infrastructure, whose failure can have severe socio-economic consequences including loss of life. Levee failure can be due to various reasons including overtopping, erosion, structural, or geotechnical failures. Many of these failures can be associated with the magnitude and frequency of the occurrence of extreme flooding events. Given the wide-ranging factors affecting the safety of levees, a risk-based-approach accounting for various stability factors should be adapted. In most cases, risk-based analysis of the safety of levees, considers existing data on extreme weather events assuming stationary climatic conditions. However, it was proven that extreme weather events can become more frequent than usual because of climate change. The assumption of stationarity would no longer be valid. Hence, adaptation strategies for levee remediation must be designed based on realistically predicted future weather events considering the non-stationarity of climate. One can employ techniques such as downscaled general circulation models (GCMs) using static or dynamic downscaling, and considering time-varying exceedance probabilities of return levels in order to realistically model future weather patterns. These climate predictions, coupled with detailed hydro-mechanical analyses of levees, can be an effective way to design levee remediation strategies that are adaptive and resilient to future climate change.

RÉSUMÉ: Les digues sont une partie importante de l'infrastructure, dont la défaillance peut avoir de graves conséquences socio-économiques, y compris la mort. La défaillance d'une digue peut être due à diverses raisons, notamment le dépassement, l'érosion, les défaillances structurelles ou géotechniques. Bon nombre de ces défaillances peuvent être associées à l'ampleur et à la fréquence de survenue d'inondations extrêmes. Compte tenu du large éventail de facteurs affectant la sécurité des digues, une approche basée sur les risques tenant compte des différents facteurs affectant leur stabilité devrait être adaptée. Dans la plupart des cas, l'analyse de la sécurité des digues basée sur les risques tient compte des données existantes sur les phénomènes météorologiques extrêmes en supposant des conditions climatiques stationnaires. Mais il a été prouvé que les phénomènes météorologiques extrêmes peuvent devenir plus fréquents que d'habitude en raison du changement climatique, et l'hypothèse de stationnarité ne serait plus valide. Par conséquent, les stratégies d'adaptation pour l'assainissement des digues doivent être conçues sur la base d'événements météorologiques futurs prédits de manière réaliste, compte tenu de la non-stationnarité du climat. On peut utiliser des techniques telles que les MCG à échelle réduite utilisant une réduction d'échelle statique ou dynamique et en tenant compte des probabilités de dépassement des niveaux de retour variant dans le temps, afin de modéliser de manière réaliste les modèles météorologiques futurs. Ces prévisions climatiques, associées à des analyses hydromécaniques détaillées des digues, peuvent constituer un moyen efficace de concevoir des stratégies d'assainissement des digues qui s'adaptent et résistent aux futurs changements climatiques.

Keywords: Weather extremes; climate change adaptation; risk identification; risk attribution; levee resilience.

1 INTRODUCTION

Levees, also known as dikes or embankments, are structures built adjacent to lakes or rivers, to protect communities, agricultural lands, and other business areas from flooding. Although floodwalls, sheet pile walls, and other concrete structures can also serve as levees, levees are primarily earthen structures made of compacted soils. According to the National Levee Database, there are more than 24,500 miles of levees recorded. The National Levee Database (NLD) of the United States estimates that these levees safeguard approximately $2.3 trillion worth of property and a large portion of the country's critical infrastructure systems. However, with an average age of 57 years, most of the country's levees are in poor condition, below standard, with many components nearing the end of their service life. Many of these levees were constructed decades ago, and lack proper design guidelines, leaving them vulnerable to failure, in the face of severe weather events. In addition, the impact of climate change-induced weather extremes has become a significant threat to the infrastructure of the country. Therefore, there is a pressing need to focus on the development of climate-resilient infrastructure (ASCE 2018). Similarly, with an increase in the

frequency of heavy rainfall events, breaches in levees have become a frequent occurrence. There have been several instances of devastating levee breaches, such as the ones caused by Hurricane Katrina in New Orleans, which resulted in over $150 billion worth of property damage. Other notable examples include the levee breaches during the 2008 Midwest floods and 2011 Mississippi river floods, as well as more recent floods along the Salinas river in California. Given, the economic and social impacts that could result from a levee breach, it is crucial to prioritize the development of resilient levee systems capable of withstanding the effects of climate change (Wenger 2015).

Resilience is a critical attribute of systems, requiring the system's capacity to rapidly recover from damage and restore functionality while also adapting to future extreme events. Achieving such resilience in levee design necessitates a comprehensive risk-based approach, involving four essential steps: identifying potential disastrous extremes, assessing the risk of their impact, conducting site-specific vulnerability assessment, and developing an adaptation strategy based on the risk assessment (Reddy et al., 2019). Such risk-based strategies, which utilize probabilistic methods for determining the stability of earthen levees, generally make use of levee fragility curves to assess the vulnerability of a levee with respect to flood levels. Fragility curves are tailored to specific failure modes by taking into account the factors influencing that particular mode of failure (Rossi et al. 2021, and Mazzoleni et al. 2015). However, many of these strategies developed for levees consider stationary climatic conditions. It is widely acknowledged, based on recent events, and an abundance of scientific research that human-induced climate change is leading to an increase in the frequency and severity of extreme weather events (Arnbjerg-Nielsen, K et al. 2013), and the assumption of stationarity in climate is no longer valid (Reid 2022). Therefore, there is a pressing need to adopt a more comprehensive and realistic approach to modeling climatic conditions and incorporating them into risk-based strategies to mitigate levee risks.

2 RISK-BASED APPROACH FOR REMEDIATION OR DESIGN OF LEVEE SYSTEMS

Given that most levee systems have exceeded their intended lifespan, and are prone to various modes of failures such as overtopping, external erosion, slope instability, slump slides, and under-seepage or through-seepage (Hui et al. 2016, and Richards and Reddy 2014), using traditional deterministic methods to evaluate their stability may not accurately account for the risk of failure. Therefore, the use of probabilistic methods, which takes the uncertainties in the levee material properties and weather patterns into account, is desired in order to be more realistic (Wang et al. 2018). However, the uncertainties in the properties of a levee material are not easy to determine. To accurately model the uncertainty, a periodic comprehensive geodetic survey, which includes the determination of the shape and dimensions of a levee, as well as the measurement of material properties through geotechnical testing and identification of potential threats to stability is essential (Mirosław-Świątek et al. 2021).

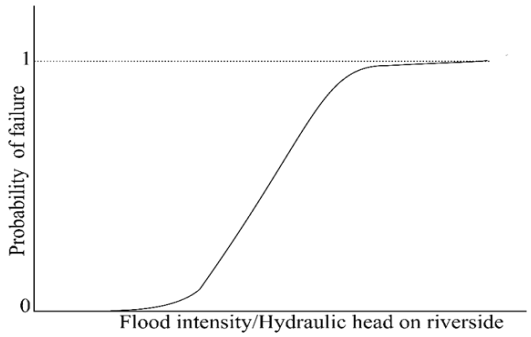

Figure 1. Typical levee fragility curve.

A fragility curve, as shown in Figure 1, is constructed by plotting the results of probabilistic analyses at different levels of river flow intensity, as represented by varying hydraulic heads, which are used to show the vulnerability or resilience of a levee structure, or system under different flow conditions. The steeper the curve, the more susceptible the structure is to failure, with increased flow. Furthermore, fragility curves are generated for each mode of failure in order to provide a comprehensive understanding of the system's vulnerability to failure (Hui et al. 2016, Rossi et al. 2021, and Mazzoleni et al. 2015). Several Researchers have integrated multiple failure modes together in order to consider the combined effects of various failure methods leading to a more comprehensive risk assessment (Fu et al. 2018, and Rahimi and Shafieezadeh 2020).

When performing the risk assessment of levees, both the vulnerability quantified through fragility curves, as well as the potential consequences and costs of failure should be accounted for. A risk-based approach to levee remediation involves a comprehensive risk assessment, prioritizing critical issues, and developing long-term maintenance plans for optimal resource allocation and levee sustainability. Given that levees can fail in multiple ways, such as overtopping or through intermediate geotechnical failures like through-seepage, a risk assessment is usually conducted by evaluating the

likelihood of failure for each mode of failure, and assessing the potential impacts and consequences resulting from it (Hui et al. 2016). A general risk assessment framework adapted for levees is shown in Figure 2. From an engineering standpoint, the most vital components of this risk assessment include forecasting the maximum hydrological load and its likelihood of occurring, as well as evaluating the condition of a levee and identifying potential weaknesses.

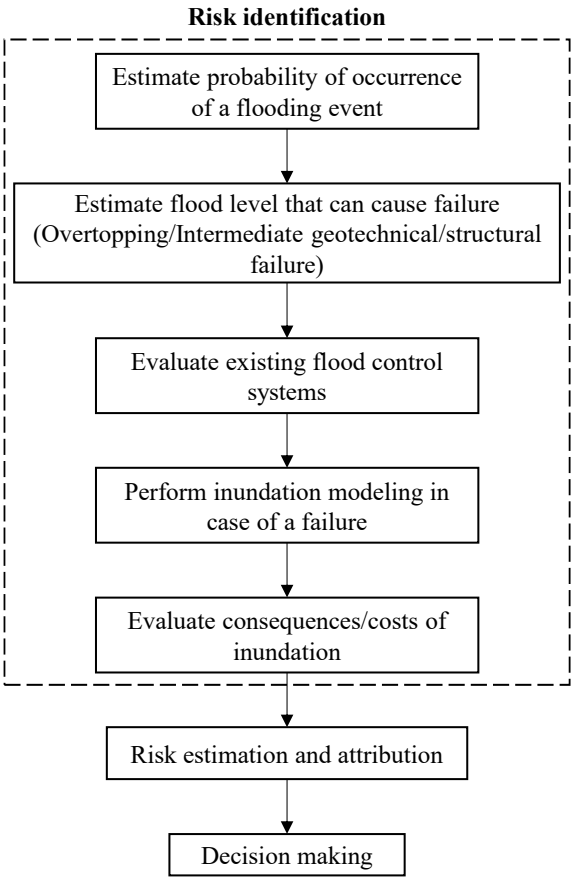

Figure 2. A general risk assessment framework for safety of levees and levee-protected systems (Steps inside the dotted box indicate steps for risk identification).

3 PREDICTION OF PEAK HYDROLOGICAL LOADS USING CLIMATE MODELS

Floods can be understood as the loads to which levees are subjected to, and are designed to withstand. These loads are typically characterized by a peak flood level, and an associated returning period (T), and are often related to the inflow hydrographs or the runoff into a river (Fluixá-Sanmartín 2018). In order to generate flood hydrographs, gridded hydrological models are used which divide an area into a grid of cells of specific size. These models use weather data such as temperature, wind, and precipitation to simulate the amount of runoff that is generated from each cell of the grid, taking into account variations in topography and other factors (Arheimer, and Lindström 2015, Dankers and Feyen 2008, and Herbozo *et al*. 2022). Multivariate hydrological models can also be used in order to address the interdependence of hydrological variables such as peak discharge and flood duration in order to consider issues such as long-term erosion, and fatigue induced weakening of levee systems leading to a potential breach (Balistrocchi *et al*. 2019). A general framework for predicting the peak hydrological load on a levee is presented in Figure 3.

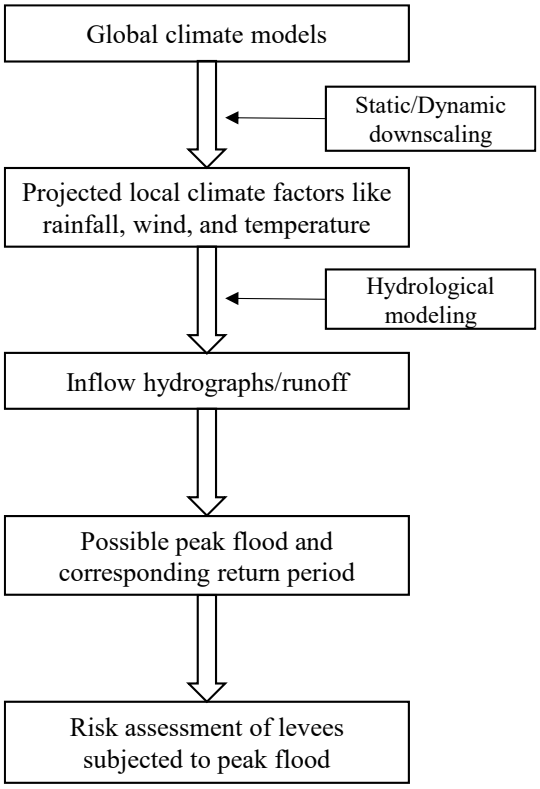

Figure 3. Example flowchart for determination of flood frequency under different climate scenarios based on downscaled projections.

General circulation models (GCM) are commonly downscaled and bias-corrected to generate more accurate local weather information, for use in hydrological models, and forecasting future weather patterns. The Inter-government Panel on Climate Change (IPCC) in its latest assessment report (IPCC 2014) recommends using 4 different representative concentration pathways (RCPs) to simulate future weather patterns. These RCPs include RCP 2.6, RCP 4.5, RCP 6, and RCP 8.5, and each one is based on a set of assumptions about the driving forces for greenhouse gas emissions, such as policies and socio-economic factors (Wayne 2013). For example, RCP 2.6 assumes that stringent policies will be

implemented to reduce emissions, resulting in a peak radiative forcing of 3 W/m^2 at some time before 2100, and it will reduce to 2.6 W/m^2 by 2100. On the other hand, RCP 8.5 assumes no change in the rate of emissions, and relatively lenient guidelines, resulting in an increase in radiative forcing up to 8.5 W/m^2 by 2100. The other two scenarios are intermediate stabilization scenarios. These scenarios can be used by researchers and engineers to realistically predict future weather patterns (Fluixá-Sanmartín 2018).

4 ACCOUNTING FOR NON-STATIONARITY IN CLIMATE FOR RISK ASSESSMENTS

The current practice for developing fragility curves to assess levee risk assumes a stationary climate. In other words, it is assumed that although the frequency and intensity of extreme events will increase, it will remain constant at the increased level for the design life of the levee. However, owing to the changes in climate patterns it is understood that climate cannot be considered stationary (ASCE 2018). Consequently, the probability of occurrence of a T-year flood cannot be accurately estimated using a simple 1/T probability model for the design life of a levee. To address this issue, it is crucial to consider the non-stationarity of climate when assessing the risk of levees. Several researchers have proposed frameworks for estimating non-stationary and time-varying return levels, return periods, and risks of climatic extremes in the face of changing climate (Cheng *et al.* 2014, Mentaschi *et al.* 2016, and Renard *et al.* 2013). These frameworks can inform levee remediation strategies based on the design life by estimating the change in exceedance probability of a standard return level with time. Alternatively, the non-stationarity of climate can be accounted for by dividing the design life into reasonable time periods and determining the return levels and exceedance probabilities of climate parameters for each period, which can be incorporated into the risk-analysis (Dhanai et al. 2022). Several researchers suggest that the structures should be designed for temporary conditions and then be flexible enough to be adjusted after a few years, depending on the climatic conditions at that point of time (Reid 2022). Hence, it is imperative to consider non-stationarity of climate into risk-based remediation strategies in order to truly achieve resilience.

5 CLIMATE CHANGE IMPACTS ON STRUCTURAL INTEGRITY OF LEVEES

Global warming and climate change have proven to increase the frequency and duration of extreme weather events. While some areas are experiencing frequent floods as a result of extreme precipitation, other areas are experiencing drought-like conditions, and higher temperatures. For instance, the State of California, in the US, has experienced extreme drought conditions for almost three years until recent rains. Such prolonged droughts can challenge and deteriorate the structural integrity of earthen embankments by reducing their strength, causing desiccation cracks, and ground subsidence due to drawdown of water levels (Robinson and Vahedifard 2016, and Vardon 2015). According to Dettinger et al. 2016, as a result of climate change, droughts can become longer, and rainfall due to storms can become more intense, which can result in larger peak discharges in rivers, when the levees are at their most vulnerable state. Levees subjected to such wet and dry cycles can get weakened, and their structural integrity might get compromised, leading to slope instability, seepage induced piping, earth subsidence, external and internal erosion and other forms of deterioration. Hence, a need arises for constant monitoring of levees, using technologies like LiDAR, and PoISAR to scan for structural deformities in the levee systems (Liu et al. 2020, and Sehat et al. 2014).

In view of the possible deterioration, a comprehensive stability analysis, including the hydro-mechanical response of the levee systems to extreme droughts or floods, needs to be modeled and performed periodically. Several studies (Dwornik et al. 2016, and Tracy et al. 2020) have focused on coupled 2D modeling for transient seepage analysis at extreme flood loads, and it was observed that the climate change impacts the performance of levee systems significantly. Therefore, a thorough examination that incorporates climate change projections to calculate future flood loads/drought conditions, combined with a thorough analysis of the probability of failure due to seepage, uplift, and slope instability, when subjected to those extreme loads, can be an effective method for conducting a comprehensive risk assessment.

If the levee systems were found to be unstable under any projected future flood event, remedial measures might be required in order to keep the levees from breaching. According the United States Army Corps of Engineers Manual on Design and Construction of Levees (USACE, 2000), there are several methods to control excessive seepage, and prevent piping or uplift failures. The following remedial measures can be adopted, based on site-

specific conditions: cutoff walls, riverside blankets, landside seepage berms, pervious toe trench, pressure relief wells, pervious toe drains, and horizontal/inclined drainage layers. If the slope stability analysis gives a factor of safety less than the acceptable standards, at any future weather extremes, slopes can be stabilized either by flattening the slopes or by using stability berms. In order to protect the riverside slope from erosion, various slope protection measures like grass cover, articulated concrete mat, concrete paving, among others, might have to be undertaken to avoid slope instability.

6 CONCLUSION

The study aimed to address the limitations of traditional risk assessment strategies for levees and propose a more comprehensive approach to enhance the resilience of these crucial infrastructure systems against climate change. Conventional risk assessment methods typically assume stationary climatic conditions to determine the likelihood of a levee failure and associated risks. However, given the changing climate, this approach may not be adequate. Therefore, this study suggests utilizing global climate models (GCMs), for different representative concentration pathways (RCP) scenarios, as an alternative approach to predict future weather patterns. As GCMs often have coarse spatial resolution (250-500 km), localized predictions require downscaling techniques. Climate indicators such as precipitation, wind, humidity, among others, obtained from these downscaled models, can then be used to develop flood hydrographs that correspond to specific levees.

The resulting peak flood levels can be utilized to assess the vulnerability of the levee to failure utilizing coupled hydro-mechanical analyses for greater reliability and a more realistic risk assessment. The study suggests that relying solely on a stationary return period to forecast future extremes might be inadequate, and instead recommends taking into account the non-stationarity of climate when evaluating the risk associated with levees. Finally, the study discussed the vulnerability of levee systems when subjected to extreme weather conditions to emphasize the importance of considering climate change in risk assessments. Various remedial measures were then listed to remediate vulnerable levees, and make them resilient to climate change.

Overall, this study provides a comprehensive approach to evaluating the risk of extreme weather events on levee systems. It emphasizes the significance of incorporating the effects of climate change in the design and maintenance of these critical infrastructure assets. By doing so, we can better safeguard communities and assets from potential damage caused by climate change induced levee failures.

Evaluation of unsaturated slope stability under rainfall infiltration based on experimental and numerical modeling

Évaluation de la stabilité des pentes non saturées sous infiltration de pluie basée sur une modélisation expérimentale et numérique

ABSTRACT: The presented paper contributes to the definition of the hydro-mechanical behavior of unsaturated soils while evaluating the problem of rainfall-induced slope instabilities. The slope instabilities in the Western Balkan countries have significantly increased in the past couple of years, due to climate change effects and its influence on the slope stability. Besides the arid climate, the increased manifestations of intense rainfalls often equal to monthly precipitation are the main contributing factors. Therefore, in North Macedonia, an assessment study has been initiated to re-evaluate the safety and define the risk level of the engineered slopes. To define the slope stability of such a system, the phenomenon of soil-atmosphere interaction is necessary to be analyzed. The slope stability will be governed by a coupled system's thermal, hydro, and mechanical conditions. Moreover, the vegetation as a factor that has additional effects on rainfall infiltration water and evapotranspiration is not considered in this study. The paper presents an analysis of an ideal slope example subjected to intense rainfall, for which both physical and numerical models were employed. The aim was to assess the impact of infiltrated water on moisture and suction as the main factors that lead to instability. The sandy soil slope with an angle of 51 degrees is subjected to a rainfall intensity of 30mm/h until the failure occurs. The comparison of the experimental and numerical results has shown very good agreement. In conclusion, the results have shown that intensive rainfalls might have a significant impact on the surface layers of the slopes causing serious erosion and local instability which after a prolonged duration is transformed into a global slope failure mechanism.

RÉSUMÉ: L'article présenté contribue à la définition du comportement hydromécanique des sols non saturés tout en évaluant le problème des instabilités de pente induites par les précipitations. Les instabilités des pentes dans les pays des Balkans occidentaux, ont considérablement augmenté ces dernières années, en raison des effets du changement climatique et de son influence sur la stabilité des pentes. Outre le climat aride, les manifestations accrues de précipitations intenses, souvent égales à des précipitations mensuelles, sont considérées comme les principaux facteurs contributifs. C'est pourquoi, en Macédoine du Nord, une étude d'évaluation a été lancée dans le but de réévaluer la sécurité et de définir le niveau de risque des pentes aménagées. Pour définir la stabilité de pente d'un tel système, il est nécessaire d'analyser le phénomène d'interaction sol-atmosphère. La stabilité des pentes sera régie par les caractéristiques thermiques, hydroélectriques et mécaniques dans un système couplé. De plus, la végétation comme facteur ayant des effets supplémentaires sur l'eau d'infiltration des précipitations et l'évapotranspiration n'est pas prise en compte dans cette étude. L'article présente une analyse d'un exemple de pente idéale soumise à des précipitations intenses, pour lequel des modèles physiques et numériques ont été utilisés. L'objectif était d'évaluer l'impact de l'eau infiltrée sur l'humidité et la succion comme principaux facteurs conduisant à l'instabilité. La pente du sol sableux avec un angle de 51 degrés est soumise à une intensité de pluie de 30 mm/h jusqu'à ce que la rupture se produise. La comparaison des résultats expérimentaux et numériques a montré un très bon accord. En général, les résultats ont montré que les pluies intensives ont un impact significatif sur les couches superficielles des pentes, provoquant une grave érosion et une instabilité locale qui, après une durée prolongée, se transforment en un mécanisme global de rupture des pentes.

Keywords: Unsaturated soil; rainfall; slope stability; physical model; numerical model.

1 INTRODUCTION

The intense rainfalls due to climate variations and change are more often seen as a triggering factor for instabilities, such as soil sliding and erosion of natural and engineering slopes. This phenomenon widely known as soil-atmospheric interaction is very often neglected by the engineers during the design. This interaction is realized through the wetting or drying of soil as a result of atmospheric, thermal, and hydraulic, conditions. In the case of rainfall, the water infiltrates through the surface of the slope thus causing an

increase in the soil water content and pore pressure, while reducing the suction, thereby reducing the shear strength, and increasing the probability of sliding.

Figure 1 shows slope sliding and erosion that occurred on the Miladinovci – Shtip highway in the central part of Macedonia after heavy rainfall on 29 May 2022 (Susinov and Josifovski, 2022). The nearest weather station measured 52 and 43mm/h for two consecutive 12-hour periods. The national weather monitoring station measured 25.2mm in one hour and 40.1mm in two hours.

Figure 1. Erosion on the slopes between the 2 extreme rainfall events on May 29, 2022.

The rise in the soil water content significantly influences the behavior of soils to the extent that the classical theory of soil mechanics is no longer appropriate. Hence, to understand the behavior of unsaturated or partially saturated soils it is necessary to introduce additional parameters, dependencies, and theories. Moreover, for a comprehensive solution to the problem of rainfall-induced slope instabilities, coupled thermo-hydro-mechanical analyses need to be performed.

2 MATERIALS AND METHODS

To properly address the problem under consideration, it is necessary to use transient analysis which considers the mechanical and hydraulically soil models defining time-dependent material behavior. The most reliable and comprehensive method would be the so-called coupled flow-deformation analysis which is used in the present study. Successful application of this method requires knowledge of soil shear strength parameters, hydraulic parameters, and rainfall characteristics (Zhang et al., 2018). Then, not only the mechanical model but also the hydraulic model should be selected. It uses the relationship between soil suction and water content or saturation degree (Sr), the so-called soil water retention curve – SWRC, and the suction-relative permeability relationship.

A sandy soil material was used in the present study (Susinov and Josifovski, 2018) defined with the Mohr-Coulomb model for the mechanical part (γ=18.2kN/m^3, φ=30˚ and c=0kPa) and the user-defined (Spline) model for the hydraulic part. The SWRC and permeability function defining the relationship between the degree of saturation (S_r) – suction (ψ) and relative hydraulic conductivity (K_r) – suction (ψ) have to be determined with specific hydraulic laboratory testing.

A physical model representing an ideal slope subjected to intense rainfall with more than 30 mm/h intensity was adopted in this study (Susinov et al., 2019). An explanatory photo is shown in Figure 2. In particular, a large-scale model with the following dimensions 400 × 200 × 200 cm was instrumented with three sensors (volumetric water content, pore water pressure, suction) on five different locations in the slope. Additionally, the deformations were scanned by LIDAR equipment and camera (Figure 3).

The aim was to assess the role of infiltrated water on moisture and suction through installed sensors as the main factors that lead to instability.

Figure 2. Photo of the physical model.

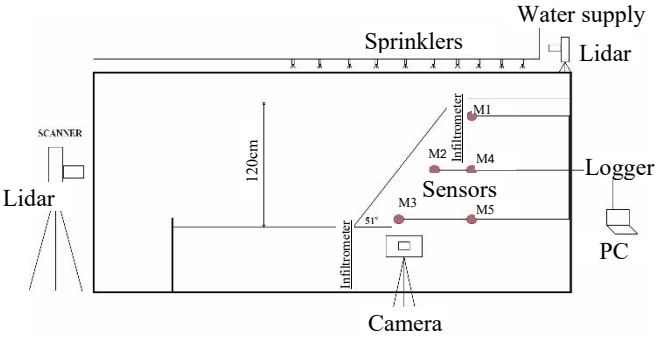

Figure 3. Schematic of the physical model and measuring sensors.

The change in volumetric water content (VWC) and suction during the rainfall event are presented in Figures 4 and 5, respectively.

Change in VWC was observed firstly at the M1 and M2 sensors placed near the slope surface. The value at the end of the test is lower in comparison with M3 and

M5 sensors which are placed near the phreatic level. It means that it is far from full saturation due to drainage of the infiltrated water into the lower layers. The lowest registered initial VWC is 0.050 m^3/m^3, while the highest at the end of the test is 0.422 m^3/m^3.

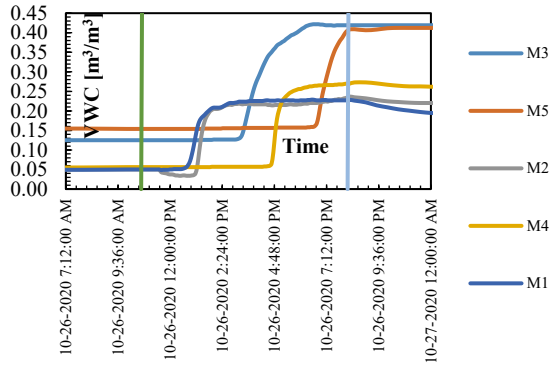

Figure 4. Changes in VWC during the rainfall event.

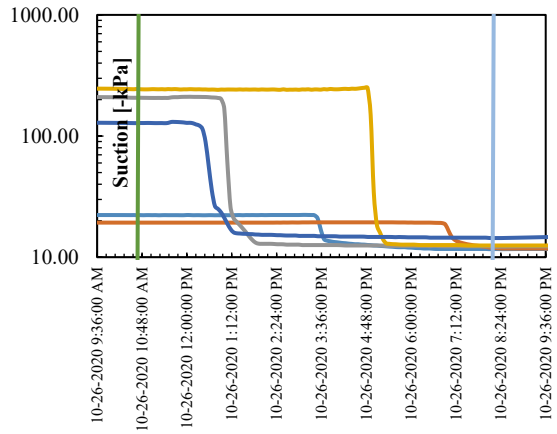

Figure 5. Changes in suction during the rainfall event.

The initial value of suction depends on the degree of saturation of the soil before the test. The sensors placed in the upper half of the slope (M1, M2, and M4) show the highest initial suction. A significant change – a drop in suction is observed when the infiltrated water reaches the sensor location. The largest registered initial suction is 244.7 kPa, while the lowest at the end of the test is 11.7 kPa. It can be concluded that the material loses suction relatively quickly during saturation.

3 NUMERICAL MODEL

Based on the data measured on the physical model during the rainfall test, a calibration of a numerical model subjected to constant rainfall was performed using FEM analyses by way of the PLAXIS code. For simulation purposes, a fully coupled flow-deformation analysis was adopted using the relationships presented in Figure 6.

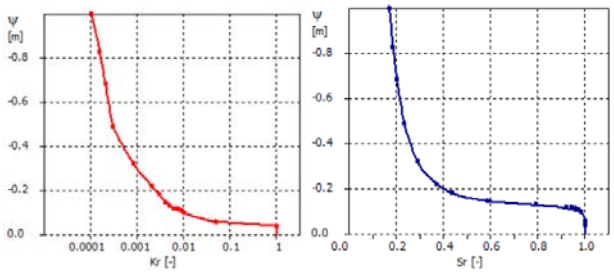

Figure 6. Used relationship for Spline model in PLAXIS.

In Figures 7 and 8 profiles of the saturation degree and suction before and after 3 hours of rainfall are respectively presented. The obtained results show a very good agreement with the measured ones.

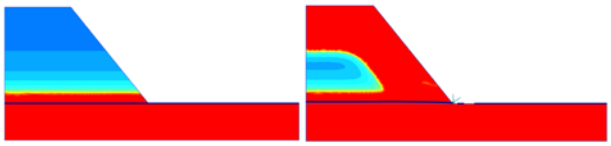

Figure 7. Degree of saturation before (left) and after (right) 3 hours of rainfall.

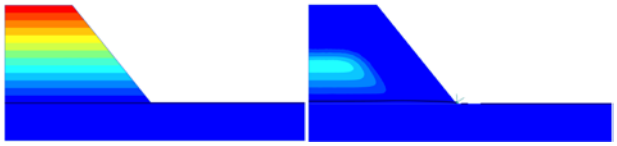

Figure 8. Suction before (left) and after (right) 3 rainfall.

The change in the saturation degree begins immediately after the beginning of rainfall as a result of the infiltration. In particular, the saturation zone increases and the suction decreases as the infiltration increases. The maximum saturation degree and suction changes were observed on the slope surface where the rainfall influence is the highest (Fredlund et al., 2012). The minimum value of the initial saturation degree at the top of the slope is 16.89%. As infiltration increases, the unsaturated zone decreases and matches that of the physical model. At the end of the test, the minimum value level of the saturation degree is 24.2%. The suction in PLAXIS is defined as negative pressure above the GWL and is related to the degree of saturation through the previously defined function which means that it cannot be compared directly.

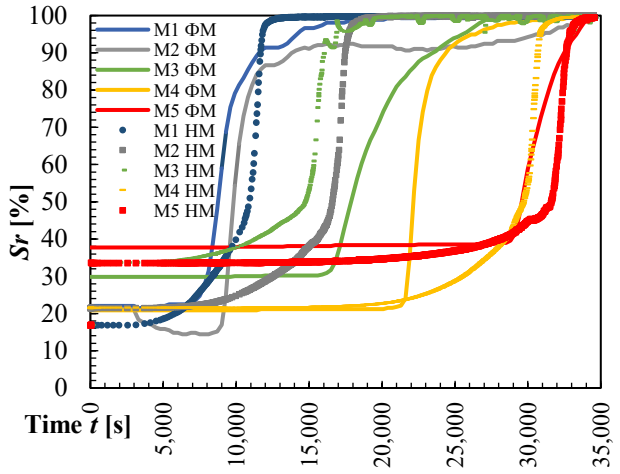

Figure 9. Comparison of S_r between the physical and numerical model.

Figure 9 presents the saturation degree value for both models. The initial degree of saturation in the characteristic points M1, M2, and M4 is lower compared to that in M3 and M5 where there is an influence from the groundwater due to the capillary effect. Compared over time, the degree of saturation at points M1 and M5 at the top of the slope and the lower part, respectively, show the best matching results. In points M2, M3, and M4, a minimal deviation is observed in the time when the change starts, although a sudden change is observed in both models. At the end of the analysis, all measuring points are completely saturated (S_r=100%).

Another aspect of the comparison between both models is the deformations and the geometry of the potential failure surface. Thus, in Figure 10 the slope deformations with the ultimate global Factor of safety (FoS) are presented. The maximum calculated deformations are 6.62 cm and the minimum FoS equals 1.037, which is very close to the slope limit equilibrium.

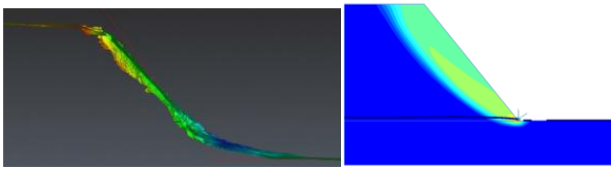

Figure 10. Slope deformation in physical (left) and numerical (right) models.

4 CONCLUSIONS

Comparing the measured data from the test on the physical model and results obtained with numerical analysis of slope stability, it can be concluded that there is very good agreement between them. In the initial phase of numerical analysis, the slope is partially saturated above the groundwater level, where the saturation is close to that in the physical model. From the influence of rainfall in the coupled analysis, the distribution of the degree of saturation and suction changes. The maximum suction occurs at the part above the groundwater level in the middle of the model, which is expected. Over time, maximum deformations develop in the lower part of the slope initiating its destabilization, as in the physical model.

If we compare the saturation degree value for both models, it can be concluded that the hydraulic behavior of the material in the physical model is similar to that of the numerical model.

Regarding the deformations, it can be concluded that there is very good agreement with the measured and calculated displacement although the soil erosion cannot be simulated by FEM.

The forecasting of future climate change scenarios is challenging, thus the prediction of slope-atmosphere interaction effects represents a demanding engineering task. Nevertheless, the presented successfully tests a concept that can re-evaluate the stability and reliability of the existing slopes on prescribed rainfall intensities, which are expected to be even more frequent in the future, thus more slope instabilities are eminent.

Impact of a spacing reduction in a fall cone test

Technique d'essai répétée du cone de chute

R. Khalili, C. Jommi

ABSTRACT: The paper investigates an adjustment to the fall cone test, where the same soil sample is reused for four extra tests. The analysis shows that the fall cone test inaccuracies are much higher than the effect of reusing the sample. Therefore, the proposed procedure may help to establish the soil properties more accurately without much extra effort and reduce the number of samples needed for testing.

RÉSUMÉ: L'article étudie un ajustement au test du cône de chute, où le même échantillon de sol est réutilisé pour quatre tests supplémentaires. L'analyse montre que les imprécisions du test du cône de chute sont bien supérieures à l'effet de la réutilisation de l'échantillon. Par conséquent, la procédure proposée peut aider à établir les propriétés du sol avec plus de précision sans trop d'effort supplémentaire et à réduire le nombre d'échantillons nécessaires aux tests.

Keywords: Fall cone test; statistical analysis; marine clay; sensitive clay.

1 INTRODUCTION

The fall cone test was initially devised by the Swedish state railways during the period from 1914 to 1922 and subsequently gained widespread adoption in Scandinavian countries (Hansbo, 1957). Currently, the ISO 17892-6:2017 standard contains the details of the procedure.

In general, the fall cone test requires that before its release the metallic cone is in direct contact with the surface sample. After the release, the cone penetrates the specimen. The undrained shear strength is correlated with the measured depth of penetration. The test relies on the lack of friction in the apparatus, hence the apparatus should be lubricated to minimise friction. The test accuracy is related to a number of factors, the interested reader may see Llano-Serna & Contreras (2020) for discussion on cone roughness influence and further references.

2 RESEARCH HYPOTHESIS

The ISO 17892-6:2017 standard requires that the test points should be distributed so that the distance between the outer boundaries of the cone penetration in two tests is at least 14mm, and the cone penetration closest to the perimeter is at least 7mm. For soft marine clays, for 60 deg 60g cone the penetration can reach 9mm, leading to the spacing requirement of 24,4 mm between centres of penetration and 12,2 mm from the sample perimeter. For common core diameters 50, 54 and – used in this study – 58 mm, these limitations lead to 3 sampling points on the single cross-section of the sample. Three points are the minimum required by ISO 17892-6:2017. However, ISO 17892-6:2017 requires that any test result deviating from the mean penetration by more than 0.5mm should be excluded. This means that often an extra point is needed, however, due to distance restriction, no more sampling points are allowed on the sample and another sample for testing should be taken. This may be difficult and affects the testing programme.

Recent research (e.g Mohapatra *et al*., 2023a; Mohapatra *et al.*, 2023b; Tran & Sołowski, 2019), has indicated that the impact of the fall cone penetration into a soft sensitive clay is contained to approximately double the radius of the 60-degree fall cone penetration mark, see Figure 1. Furthermore, the results have shown little sensitivity to lateral support, with no changes for full lateral support or lack of it. Based on those results we decided to check the hypothesis that a reduction of the spacing of the sampling points to double the radius of the penetration mark may have no influence on the results, while it allows for the increase of the number of sampling points on a standard 50 to 58mm sample cross-section, potentially increasing the accuracy of the findings. Additionally, the work aims to evaluate whether the

results of the test are statistically influenced by removing the lateral support. If the denser spacing or lack of lateral support has an effect, the depth of the penetrations closer to the sides of the sample should be higher compared to the first penetration in the middle of the sample.

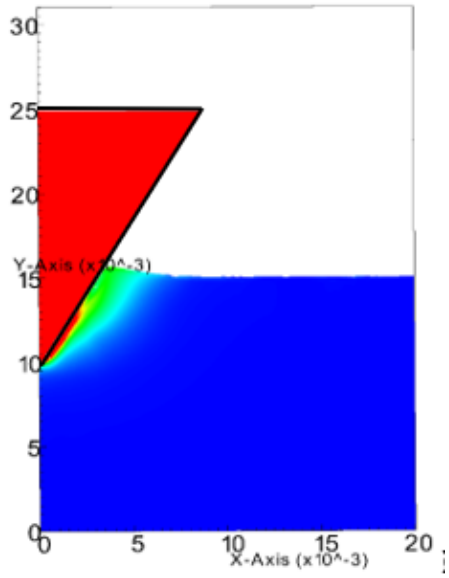

Figure 1. Numerical replication of a fall cone test in soft marine clay showing localised deformations around the cone, Mohapatra et al. (2023b).

3 CLAY SAMPLES

In this research, tested soil samples had a diameter of 58 mm and a height of 10 cm. The penetration test was conducted using a cone with a 60° angle and a mass of 60 grams. The observed penetration depths across all samples range approximately from four to 12 mm.

In this study, a total of 39 normally consolidated marine clay samples were tested with a fall cone. The samples came from four locations at the offshore Kytö site: KU2 (with depths ranging from 0.1 to 3.87 meters), KU3 (with depths ranging from 0 to 3.48 meters), KU1 (with depths ranging from 0 to 3.1 meters), and KU4 (with depths ranging from 0.15 to 3.75 meters). For a more detailed site description see Saresma *et al.* (2023), while for more details on properties and tests see Li *et al.* (2023).

The composition of these marine sediments exhibits some variations primarily attributed to the different stages of the Baltic Sea's evolutionary history. However, the stratification of these sediments is relatively weak and the samples were very similar. The clays are structured and sensitive. Their intact undrained shear strength varies, mainly due to differences in depth from which the samples originate.

4 METHODS

4.1 Fall cone test procedure

Figure 2 shows the position of each penetration for each sample in the testing programme, with numbers indicating the penetration sequence, leading to the spacing between the sampling points smaller than required by ISO 17892-6:2017. The sample used had a 58 mm diameter and the points 2-5 were positioned at least 10 mm from the side of the sample, with the impact point approximately in the middle of the line connecting the edge of the penetration 1 mark and sample perimeter, i.e. around 10-14mm from the sample perimeter. This means that the distance between the edge of the penetration mark was around 5-8mm to the sample perimeter, but there could be only about 8 mm between the edges of the penetration mark at test 1 and the subsequent test, instead of the required 14mm. Nonetheless, the spacing always was approximately 2 penetration radii, complying with the condition identified in numerical analyses. Besides the spacing, the testing procedure followed ISO 17892-6:2017, with tests done on thick 10cm extruded from plastic tubes. There was no lateral support at the sides.

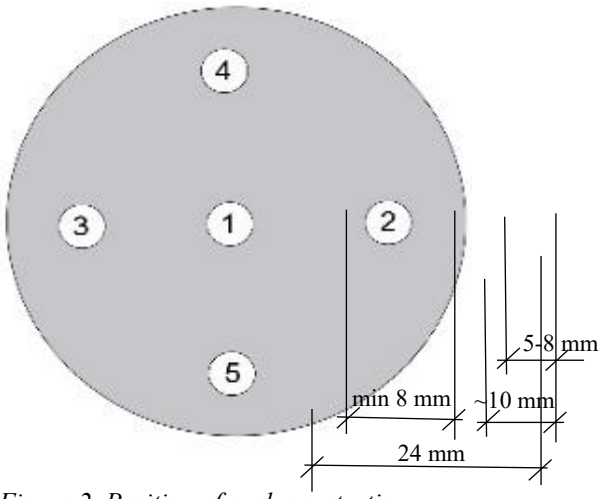

Figure 2. Position of each penetration.

4.2 Discussion of the testing procedure

An alternative would be to perform 3 tests according to ISO 17892-6:2017 and then one extra test in the middle with smaller distances to the other tests. However, that would lead to a distance between the middle test mark and any other test as low as 5mm, in which case the penetration distortion zones would likely overlap.

4.3 Statistical analysis

In case the spacing of the points was too close, the subsequent penetrations should be affected due to the disturbance of soil and the associated reduction in the

undrained shear strength. Hence, in case the soil is disturbed, we expect that there will be a statistically significant difference between the results obtained in the first penetration (middle point) and the subsequent 4 penetrations. Similarly, in case the lack of lateral constraint affects the penetration depth, the statistical analysis should reveal that.

Even though ISO 17892-6:2017 decides on the acceptance or rejection of the test based on penetration, in this contribution we decided to concentrate on the statistical analysis of the undrained shear strength. This is because the undrained shear strength is the key value obtained in the test and the important value for engineering. The results of the analysis performed based on the penetration depths are similar, but not included in this paper.

To analyse the data, first, all the undrained shear strengths were normalised with respect to the 'correct' penetration in the middle of the sample.

$$s_{n,i} = \frac{s_i}{s_1} \qquad i = 2,3,4,5 \qquad (1)$$

where $s_{n,i}$ is the normalised value of the undrained shear strength obtained from the i-th penetration with respect to the value s_1 obtained from the first penetration. This assumes the middle point is the correct one, with the four subsequent penetrations possibly deviating from it. First, we tried analysing the data for each penetration. Then, as the number of tests was small, we decided to pool the data together.

In this case, all the tests besides the first one are treated the same, leading to 39 sets of 4 deviating data points. Then, we first assessed whether the obtained data follows a normal distribution. Later, we checked whether the undrained shear strengths from the subsequent 4 penetrations deviated from the undrained shear strength obtained from the test done at the centre of the sample using the Student's t-test. The null hypothesis for the test is that the differences in the averages obtained from the other penetrations are not statistically significant when compared to the first penetration.

Finally, we also assessed whether the data with outliers removed (defined as data points with undrained shear strength deviating from the value obtained in the middle point by a certain percentage) would lead to any statistically significant result. The outlier cut-offs were 250% and 40% (marked 2.5), 200% and 50% (marked 2), 150% and 66.7% (marked 1.5) and 125% and 80% (marked 1.25).

We also assessed the data with tests following the acceptance/rejection strategy similar to that in ISO 17892-6:2017. In this case, if in the first three penetrations, there was a value deviating by more than 0.5mm, the value most deviating from the average was discarded (excluding the test from the middle of the sample) and another value was taken to compute the average.

5 RESULTS

5.1 Statistical distribution of the normalised data and testing of the hypothesis

The data is first normalized with respect to the data from the first penetration. Assuming a normal distribution for data, data obtained for each penetration has a very high standard deviation, see Table 1. The difference in mean value, vs the middle penetration, is between 0,68% to 7.84%, while the standard deviation is between 30,76% to 78.08%. These are very high values, indicating much scatter in the data. In this case, for each penetration point, we had 39 tests. The results of the Student's t-test show that the differences in obtained undrained shear strengths for each test point location are not statistically significant. The t-test suggests that the mean values differences are not statistically meaningful and cannot be taken as evidence that the adjusted test procedure leads to differences in the obtained values of undrained shear strength. Unfortunately, the amount of data points for each penetration location is not sufficiently large to make a meaningful discussion about whether the assumption of normal distribution is correct.

Table 1. Mean value, standard deviation and t-test result for each penetration location.

Location	Mean	Standard deviation	T-test	Significant?
2	1,0186	0,3869	0,3005	NO
3	1,0784	0,7808	0,6267	NO
4	0,9932	0,3076	0,1389	NO
5	1,0730	0,4614	0,9874	NO

To increase the amount of data, we decided to pool the data from all the points together, leading to 155 data points, due to cutting one outlier (see Figure 3). This full data, as well as data with cut outliers, is assessed for the normal distribution based on histograms and QQ plots, see Figures 4 and 5. The plots are similar and suggest that the normal distribution is an acceptable assumption. The results of a statistical analysis based on the assumption that the data follows normal distribution are in Table 2. The same table contains also mean and standard deviation values, as well as the Student's t-test values.

An alternative is to use lognormal distribution, with the QQ plots, see Figure 6. Both distributions are visually confirmed based on histograms, see Figure 7,

with perhaps lognormal distribution being a slightly better assumption.

The full data, as well as data prepared according to ISO 17892-6:2017, and data with outliers cut, were tested against the null hypothesis using Student's t-test. We checked both normal and lognormal distributions for statistical significance for the hypothesis that the undrained shear strength results obtained from tests done at the sides of the sample are statistically meaningfully different to the undrained shear strength values obtained from the tests done in the middle of the sample, Tables 1-3 contain the analysis results.

Table 2. Mean value, standard deviation and t-test values for the combined data, normal distribution assumption.

Cut-off	Data points	Mean	Standard deviation	T-test	Significant?
No	155*	1.041	0.5127	0.3221	No
ISO	77	1.033	0.2349	0.2150	No
2.5	153	1.001	0.3389	0.0505	(No)
2	146	0.979	0.2713	0.0114	No
1.5	121	1.007	0.1881	0.5530	No
1.25	88	1.006	0.1153	0.6464	No

*Cutoff – preparation of the data, with the cut-off indicating cut-off values – 2.5- values below 40% and above 250% of the average value cut, 2 – 50% and 200%, 1.5 – 150% and 66,7%, ISO – according to ISO standard/ N- assumed normal distribution, L – lognormal. T-test confirms the hypothesis when p<0.05. *one point cut out, see Figure 3 for an explanation.*

5.2 Analysis of the results

The results confirm that there is no statistically meaningful effect indicating that the undrained shear strength obtained for the samples at the sides is different from those in the middle. The confirmation of the hypothesis for the cut-off value of 2.0 is due to the different number of points cut from both sides of the distribution. The results for this case, see Figure 5, indicate that the penetration depths at the sides are smaller than in the middle, which has no physical sense. This perhaps shows how tricky it is to cut the outliers in the data and that such action should be avoided, as it may lead to incorrect results.

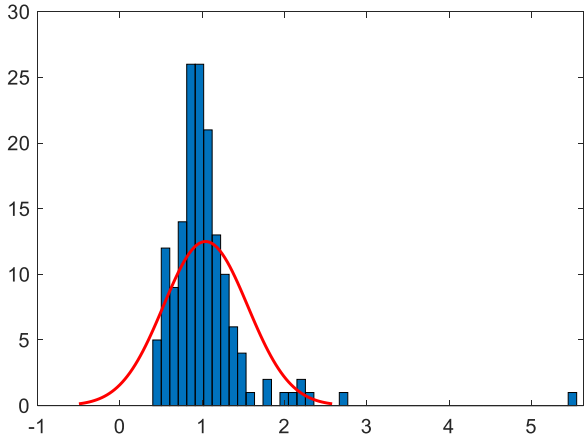

Figure 3. Histogram of all the data. The outlier pointed out by the arrow is cut off for analysis, as it is a clear testing error (insufficient penetration due to excessive friction in the apparatus).

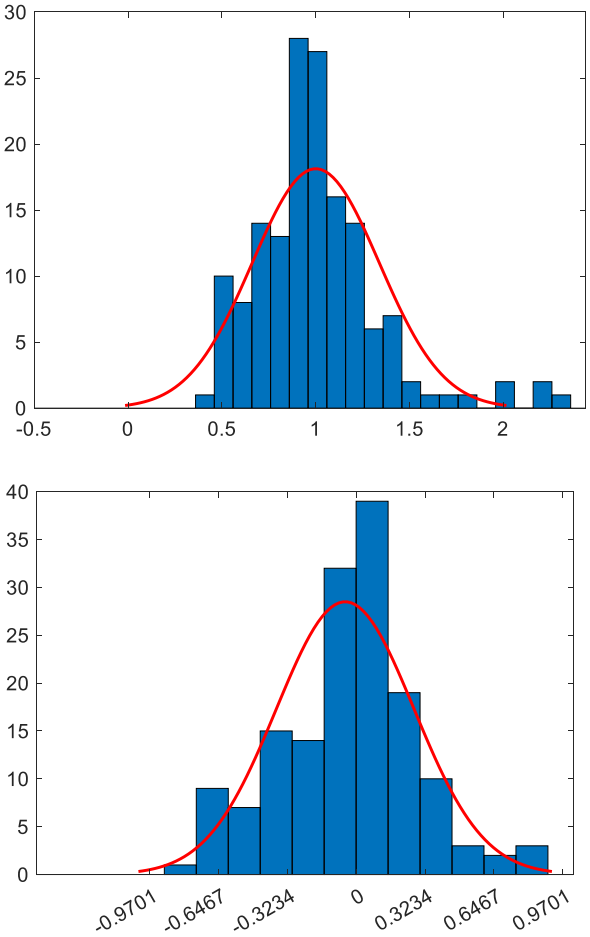

Figure 4. Histogram of data with outliers cut off (cut of value 40% and 250% of the average value), shown vs normal distribution (top) and lognormal distribution (bottom) In lognormal distribution numbers correspond to standard deviations.

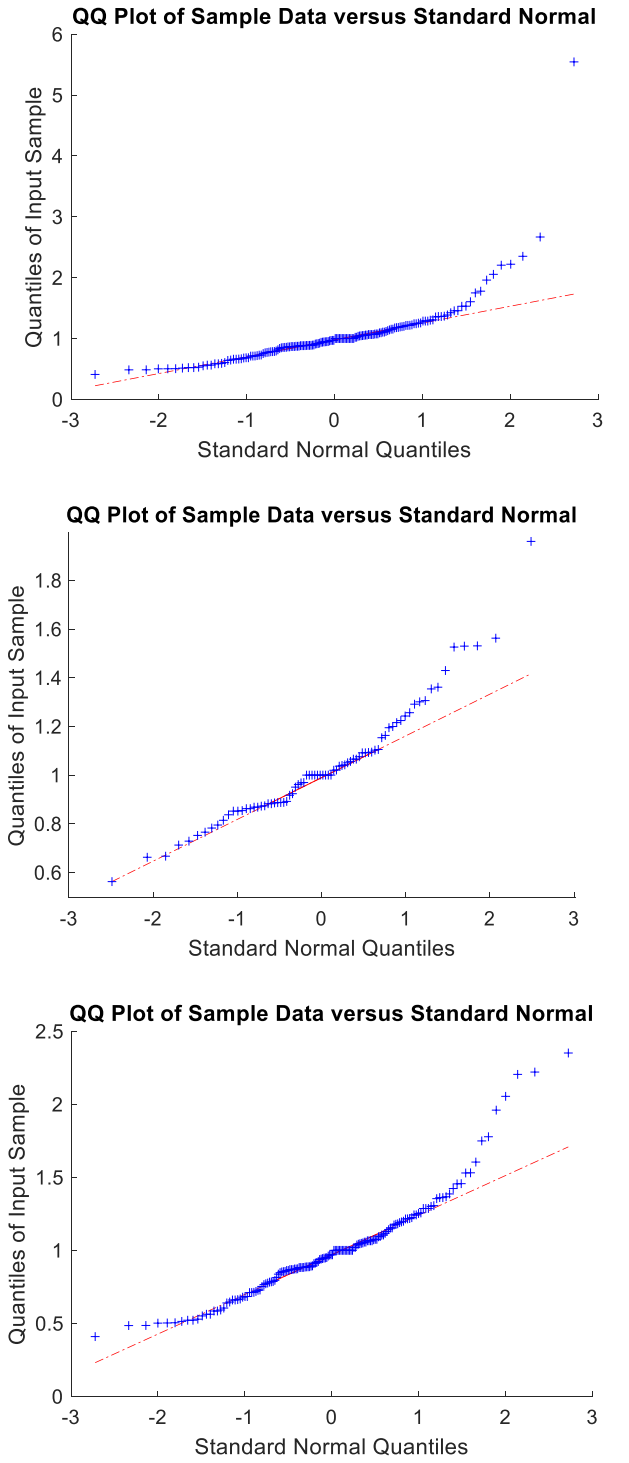

Figure 5. QQ plots of data assuming normal distribution: full data (top), data prepared according to ISO 17892-6:2017 (middle) and with outliers cut off (cut of value 40% and 250% of the average value)(bottom).

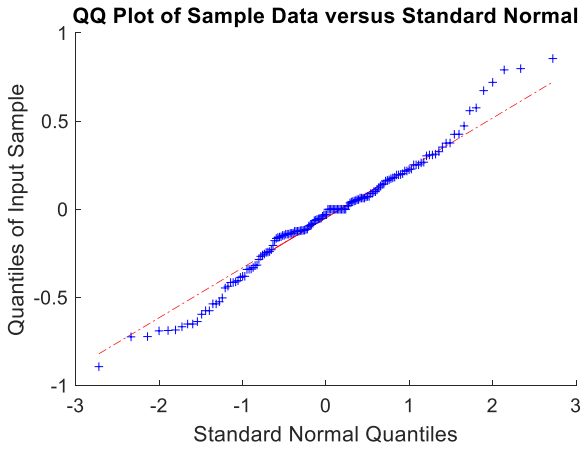

Figure 6. QQ plot of data vs lognormal distribution line with outliers cut off (cut of value 40% and 250% of the average value).

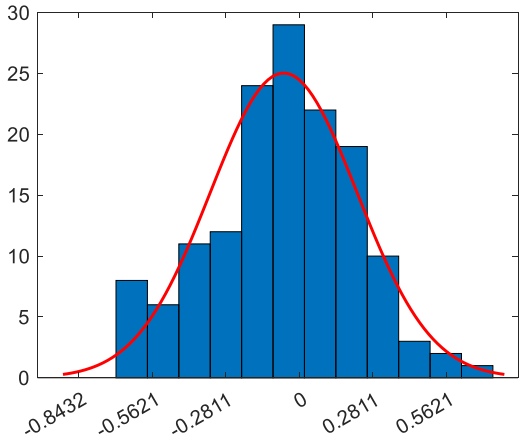

Figure 7. Histogram of data with outliers cut off at 50% and 200% of the average value, shown vs lognormal distribution, with numbers indicating standard deviations. Data is skewed towards lower values of undrained shear strength due to the cut-off value selected.

Table 3. Student's t-test values, lognormal distribution.

Cut-off	t-test p-value	Confirmed (Y/N)
No	0.2484	N
ISO	0.7120	N
2.5	0.0505	(N)
2	0.0114	**Y**
1.5	0.5530	N
1.25	0.9479	N

Cutoff – preparation of the data, with the cut-off indicating cut-off values – 2.5- values below 40% and above 250% of the average value cut, 2 – 50% and 200%, 1.5 – 150% and 66,7%, ISO – according to ISO standard/ N- assumed normal distribution, L – lognormal. T-test confirms the hypothesis when $p<0.05$.

6 CONCLUSIONS

The data we have does not support the hypothesis that the undrained shear strength values from tests on the

sides of the sample are different to the undrained shear strength values obtained from the tests in the middle of the sample, even when the distances of the penetrations are smaller than those required by ISO 17892-6:2017. Instead, the statistical analysis of the data indicates that there is no meaningful difference between the results of the tests in the middle and on the sides of the samples. The data used is still small in the statistical sense (a total of 39 tests, with each test giving 5 data points), and the test results for each sample are quite scattered. As such, in the future, the analysis may be redone with a larger set of data, ideally with data which exhibits smaller variation. Such analysis may give a more definite answer to the posed hypothesis. Additionally, the tests may also be extended to plastic limit tests.

The proposed approach is very convenient and may improve the uncertainty of the testing results, due to the larger amount of obtained values of undrained shear strength. Further investigations and comparisons to other methods of obtaining undrained shear strength will give further arguments on whether the proposed approach is beneficial, and what is the best strategy to obtain the accurate undrained shear strength values based on fall cone tests.

ABSTRACT: This paper describes a method of using Monte Carlo simulation for the probabilistic analysis of the shaft structure of a projected metro line in Vienna. The paper presents a discussion of the quality of the input data in the context of their probabilistic variability and their influence on the stress-strain state of the structures. A variant of the problem using the Hardening Soil (HS) and Hardening Soil Small (HSS) models and representing an improved elastic-plastic model was selected for statistical modelling. As a result of multiple variational modelling of the initial data of the soil in which the considered reinforced concrete structures of the tunnel are located, coefficients of variation for the main package of forces and deformations occurring in the reinforced concrete structures and in the soil mass were obtained. These coefficients of variation can then be used in the design process of reinforced concrete structures of this type. The probability of failure according to the criterion of additional settlement for buildings located near the construction site was determined. The degree of influence of certain initial data on the stress-strain state of the structure was also determined using regression analysis.

RÉSUMÉ: Cet article décrit une méthode d'utilisation de la simulation Monte Carlo pour l'analyse probabiliste de la structure d'un puits d'accès d'une ligne de métro projetée à Vienne. L'article présente une discussion sur la qualité des données d'entrée dans le contexte de leur variabilité probabiliste et de leur influence sur l'état de contrainte-déformation des structures. Une variante du problème utilisant les modèles Hardening Soil et Hardening Soil Small et représentant un modèle élastique-plastique amélioré a été sélectionnée pour la modélisation statistique. La modélisation variationnelle multiple des données initiales du sol dans lequel se trouvent les structures en béton armé du tunnel a permis d'obtenir des coefficients de variation pour les principaux ensembles de forces et de déformations se produisant dans les structures en béton armé et dans la masse du sol. Ces coefficients de variation peuvent ensuite être utilisés dans le processus de conception des structures en béton armé de ce type. La probabilité de rupture selon le critère du tassement additionnel pour les bâtiments situés à proximité du site de construction a été déterminée. Le degré d'influence de certaines données initiales sur l'état de contrainte et de déformation de la structure a également été déterminé à l'aide d'une analyse de régression.

Keywords: Probability approach; reliability; Monte Carlo simulation; regression analysis.

1 INTRODUCTION

In solving the problems of reliability theory, it is particularly difficult to determine the value of the risk of reaching a limit state on the basis of solving the corresponding statistical dynamics task. To solve such a problem today, the following methods are used: numerical integration techniques, Monte Carlo simulations, and First and Second Order Reliability Methods (FORM/SORM). The Monte Carlo statistical testing method (Monte Carlo Simulation) is a numerical method for solving mathematical problems based on modelling random variables and performing a significant number of statistical tests using random variables according to known distribution laws. The statistical test method is quite universal and is used to assess the reliability and safety of building structures and bases when solving reliability theory problems based on modelling random variables and constructing statistical estimates, as well as to develop possible (probable) processes or results using various random number generation methods, which are then applied to a real model. The Monte Carlo method is successfully implemented in geotechnical design practice (Pereira and Caldeira, 2011; Griffiths and Fenton, 2007,

Chalermyanont and Benson, 2004; Baecher and Christian, 2003, etc.).

The reliability of structural and geotechnical systems, as well as individual structures, cannot be fully assessed by neglecting the probabilistic nature of external loads and impacts, as well as the properties of structural materials and soils. This is especially true for structures that are located in an aggressive environment – for buried structures in contact with wet soil and water.

Description, modelling, calculation and analysis of the results of these processes is a complex task, the solution of which is impossible without the use of numerical methods and construction of correct calculation schemes. For structures operating in conditions of significant ground contact, the choice of ground model must be justified to a sufficiently high degree. In turn, obtaining adequate results is impossible without thorough geotechnical surveys and appropriate soil tests. This paper describes the experience of using probabilistic-statistical apparatus (Monte Carlo simulation) in determining and analysing the stress-strain state (SSS) of the geotechnical system of the underground construction site in Vienna – Schacht Triester Straße (U2/18 Matzleinsdorfer Platz, Figure 1).

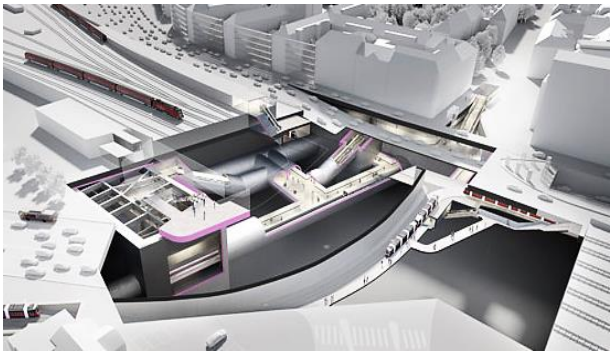

Figure 1. Visualization of Matzleindorfer Platz station (© OLN – Office Le Nomade 2018).

2 MODELING AND CALCULATION

2.1 Soil model

Adequate choice of the ground model is one of the important components in modelling complex technical systems. For statistical modelling, a variant using the Hardening Soil (HS) and Hardening Soil Small (HSS) models was chosen to represent an advanced elastic-plastic model. The actual stiffness characteristics are calculated by PLAXIS software from the achieved stresses, taking into account the development of the stress-strain state of the soil according to a hyperbolic relationship. The coefficients of variation for the varied characteristics were adopted according to the JCSS Probabilistic Modelling Code and in accordance with the scientific studies of Phoon and Kulhawy, 1999, and Griffiths and Fenton, 2007.

2.2 Calculation scheme

The calculation scheme of the system "underground structure – soil" of the metro section was performed and calculated in the PLAXIS programme (Figure 2).

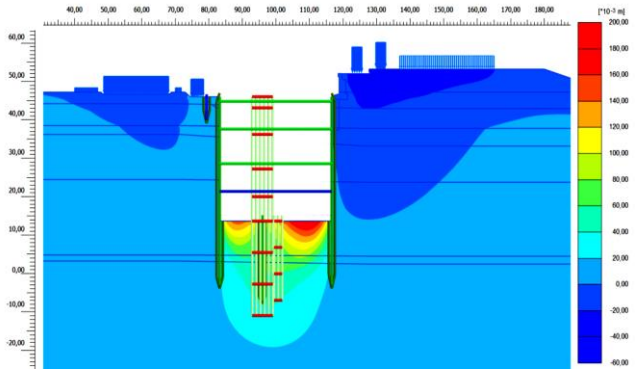

Figure 2. The calculation scheme of the system "underground structure – soil" and one the calculation variant (vertical displacement distribution).

The specified distributions for loads and materials are mainly taken from the Probabilistic Model Code, draft Eurocode 7 prEN 1997-1:2022 (E), and from some other sources of scientific literature (Griffiths and Fenton, 2007; Misra and Roberts, 2007; etc.). Geometric dimensions of building structures and their physical and mechanical characteristics are accepted in accordance with the design data.

2.3 Calculation algorithm

The conducted numerical experiment determines all the parameters of the stress-strain state of the system using Finite Element method and Monte Carlo method in the following order.

1. Values of some parameters of the soils used in the calculation (γ, φ, c, E_{50}^{ref}, E_{oed}^{ref}, E_{ur}^{ref}) and laws of distribution of values are shown in Table 1. The SSS random values of the system are fixed.

2. In the design and construction of underground structures in dense urban areas, one of the main requirements is to ensure the preservation of the surrounding buildings. This requirement is more stringent than the usual assignment of the subsidence level (SLS), as the deformations allowed for the surrounding buildings are always smaller than for

Table 1. Parameters of soils accepted for calculation.

Parameters	Desig-nation	Distri-bution	COV	Mean (1 layer)	Mean (2 layer)	Mean (3 layer)	Mean (4 layer)	Mean (5 layer)	Units
Weight density	γ	normal	0.05	19	21	20	20	20	kN/m^3
Angle of friction	φ	normal	0.1	25	35	25	25	25	°
Specific cohesion	c	normal	0.1	1	1	30	30	30	kPa
Secant stiffness modulus	E_{50}^{ref}	log-normal	0.2	10	60	20	20	20	MPa
Oedometer tangent stiffness modulus	E_{oed}^{ref}	log-normal	0.2	10	60	25	25	25	MPa
Young´s modulus for unloading and reloading	E_{ur}^{ref}	log-normal	0.2	40	240	100	100	100	MPa

new construction. Therefore, when designing underground structures, design solutions must be adopted that ensure not only the reliability of the structure itself, but also the safety of the neighbouring development. In this case, as a quantitative expression of the risk measure for existing buildings, we can use a criterion that limits the additional settlement of urban buildings to a certain permissible level: the value of additional deformations should not exceed the maximum permissible value. To determine the probability of exceeding additional deformations, it is advisable to adopt the method of statistical tests (Monte Carlo method) using the calculation results obtained by means of the PLAXIS program.

3. In this case, the following laws of distribution of input parameters are adopted: 1) distribution of the random variable $P_{S_{add}} = P_{S_{add}}(S_{add})$ additional vertical deformations, adopted with the normal distribution law with mean value $m_{S_{add}}$ = 0.03 m and standard deviation $\sigma_{S_{add}}$ = 0.003 m. The values of this parameter are determined by analysing FEM calculations. 2) The distribution of the random variable $P_s = P_s(s)$ of the limiting additional deformations, which is assumed with the normal law of distribution respectively with m_s and σ_s. The mean value is taken based on the analysis of monitoring of buildings and structures, literature and common sense.

4. According to this method, N statistical tests (N = 10^5) are conducted according to this algorithm. 1) Determination of random values of vertical deformation s (FEM). 2) In each case the condition $s \leq S_{add}$. 3) After conducting all N tests, the probability of exceeding the limit additional deformations during the design life is calculated as the ratio of the number of tests at which $S_{add} - s < 0$ to the number of all tests. Figure 3 shows the probability density functions of estimated additional settlement and allowable additional settlement.

5. It is highly likely that the surrounding development is mainly in the CC2 impact class, for which the minimum value β is 2.9 for a time period of 1 year and β = 1.5 for a time period of 50 years (Table C2 of EN1990:2002).

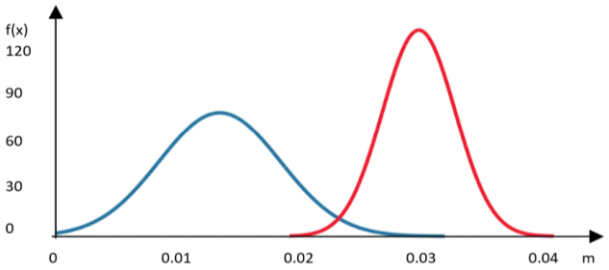

Figure 3. Density functions of the distribution of calculated additional settlement s (blue curve) and allowable additional settlement S_{add} (red curve).

2.4 Results

1. So, according to the results of FEM calculations with varying initial data, all characteristics of the stress-strain state of the "underground structure – soil" system were obtained, as well as the coefficients of variation of these characteristics, which are as follows:

- for longitudinal forces $N - v = 0.08$ (8%);
- for bending moments $M - v = 0.09$ (9%);
- for shear forces Q – $v = 0.11$ (11%);
- for vertical displacement $u_y - v = 0.237$ (≅24%);
- for horizontal displacements $u_x - v = 0.2$ (20%).

2. After checking the obtained values of all aforementioned parameters by the criterion of agreement at the significance level of 0.05, it was determined that they have normal distribution.

3. Probabilistic calculations performed in the Mathcad Prime software package showed that the probability of system failure by the criterion of additional vertical deformations is p_f = 0.002, and corresponds to the safety index β = 3.0, which is quite

acceptable and complies with the normative document "Probabilistic Model Code".

2.5 Regression Analysis

Regression analysis of the influence of varying factors on the main parameters of the stress-strain state obtained from the FEM calculation was performed. Regression analysis is a set of statistical methods to assess the relationship between variables and the degree of this relationship, as well as modelling of future dependence. Linear, multilinear and nonlinear models are the most common models of analysis. In this case, the first two models were used, and regression analysis was carried out on the basis of the least squares method.

After enumerating many variations, an interesting pattern was identified – the magnitude of the longitudinal force N in the shaft wall can be satisfactorily described by a linear regression model, as 90.1% of the percentage variability of the longitudinal force values is explained by this model. In this two-factor experiment, the independent variables were the specific gravity of the soil γ and the angle of internal friction of the soil φ, and the dependent variable was the value of the longitudinal force N. Further calculations were carried out only to establish the relationship between soil specific gravity and longitudinal force values, and it was found that 86% of the variability of longitudinal force values can also be described by a linear regression model.

An experiment was also conducted to establish the relationship between the vertical strain values and the values of soil specific gravity γ and elastic modulus E_{50}^{ref}. It was found that the percentage of variability of vertical deformation values also depends linearly on these two independent variables, but only 54.2% of the variability of values is described by a linear model.

3 CONCLUSIONS

Modelling of empirical distributions of initial data parameters of the system "underground structure – soil" was carried out, after which multiple variation calculations of this system were performed in the PLAXIS software package. As a result, the values of variation coefficients for the main set of forces and deformations were obtained, which can be used in reliability calculation after selection of cross-section and reinforcement of reinforced concrete structures of similar type.

The range of displacement values of the buildings during construction was also obtained and the reliability calculation was carried out using Monte Carlo numerical modelling using the criterion of additional settlement of the buildings surrounding the Schachtes Triester Straße (Baulos U2/18 Matzleinsdorfer Platz). The probability of failure was 0.002 and the reliability index β = 3.0, which are quite acceptable values for the SLS condition.

Regression analysis of the influence of changing soil characteristics on the main parameters of the stress-strain state was carried out. Regression analysis of the influence of varying soil characteristics on the main parameters of the stress-strain state has been performed. Correlation dependences between some parameters were established.

Effect of flood duration on levee stability

Effet de la durée de l'inondation sur la stabilité d' une digue

E. Koch*, R.P. Ray
Széchenyi István University, Győr, Hungary
**koche@sze.hu*

ABSTRACT: During the last decades, flood events in Hungary and other European countries have become an unprecedented challenge to geotechnical engineering due to the increase in frequency and severity. Construction of the flood protection system has been started in the middle of the 19th century. Their construction materials and methods do not meet current standards and require constant inspection and maintenance. The three most significant historic floods (i.e., characterized by the largest yield) along the main Hungarian Rivers have occurred in the last 20 years. During these events, soil instability and embankment failure occurred along the levees at several locations. The paper focuses on the effect of water levels on levee stability at a selected site along the Tisza River that failed during the 2006 flood events. To model the failure induced by extremely high water level, transient seepage analysis was carried out. The input parameters were determined based on the results of site investigations and laboratory tests. The study showed that with increasing water levels and time of flood, the stability of the levees decreased.

RÉSUMÉ: Au cours des dernières décennies, les inondations en Hongrie et dans d'autres pays européens sont devenues un défi sans précédent pour l'ingénierie géotechnique en raison de l'augmentation de leur fréquence et de leur gravité. La construction du système de protection contre les inondations a commencé au milieu du 19ème siècle. Les matériaux et les méthodes de construction ne répondent pas aux normes actuelles et nécessitent une inspection et un entretien constants. Les trois inondations historiques les plus importantes (c'est-à-dire caractérisées par le plus grand débit) le long des principales rivières hongroises se sont produites au cours des 20 dernières années. Au cours de ces événements, l'instabilité du sol et la rupture des digues se sont produites à plusieurs endroits. L'article se concentre sur l'effet des niveaux d'eau sur la stabilité des digues sur un site sélectionné le long de la rivière Tisza qui s'est rompu lors des inondations de 2006. Pour modéliser la rupture induite par un niveau d'eau extrêmement élevé, une analyse transitoire des infiltrations a été réalisée. Les paramètres d'entrée ont été déterminés sur la base des résultats des enquêtes sur le site et des tests en laboratoire. L'étude a montré que la stabilité des digues diminuait avec l'augmentation des niveaux d'eau et du temps d'inondation.

Keywords: Flood duration; levee; slope stability; transient seepage analysis; numerical simulation.

1 INTRODUCTION

Flooding is a natural hazard that probably has the highest occurrence in time and space worldwide, causing considerable damage in terms of loss of life and property every year (Loat, 2009).

There are many reasons and triggering processes that may cause levee failure. For flood risk reduction, CIRIA (2013) defines failure as the inability to achieve a defined performance threshold for a given function.

A levee can fail through structural or hydraulic mechanisms or both. Structural failure occurs by a breach in the levee system that results from damages affecting at least one system segment. Hydraulic failure (non-structural) occurs if water ingress into the leveed area (by through-flow, overflow or overtopping of the levee) before the planned protection level is reached and without prior damage to the system element. Structural failure can induce hydraulic failure and vice versa.

Slope failure occurs when the driving loads applied on the levee (weight of the materials, hydraulic forces) exceed the shear strengths of the materials in the embankment body and foundation (Tourment et al., 2019). Sliding can occur both on the inner slope and on the outer slope, the latter typically occurs after a high-water event when the water level falls but pore water pressures in the levee remain high.

Nagy and Toth (2005) conducted an extensive study of levee breaches in Hungary during the last 50 years (1954-2004). Based on analyses of 117 breaches, they determined that 98% of all breaches were caused by overtopping, piping and loss of slope stability (Figure 1).

Flooding due to hydraulic loading is often the result of the interaction of multiple phenomena, which may follow different failure paths. Engineers designing embankments consider separate, individual failure paths. However, back analysis of failure events often

indicates that flooding resulted from a combination of phenomena and that site-specific characteristics play a significant role in the occurrence of different events.

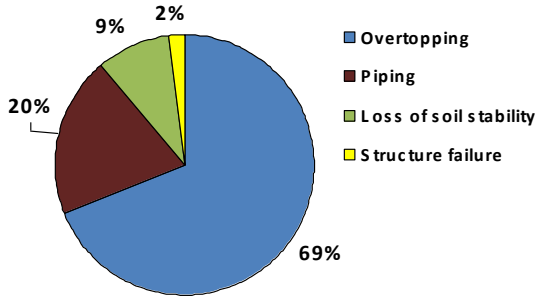

Figure 1. Distribution of failure mechanisms for levee breaches in Hungary between 1954-2004 (Nagy and Toth (2005).

This paper presents a back-analysis of a slope failure induced by the April 2006 flood near the Tisza River. The failure occurred on the landside of the levee (Figure 2) and required immediate stabilization by a sandbag revetment at its toe.

Figure 2. Stability problem along the Tisza River.

2 STUDY AREA

The Tisza River (catchment area: 157,000 km2) in Central Europe drains the eastern half of the Pannonian Basin, where river systems have a long history of evolution. The oldest fluvial deposits date back to the Late Miocene. The courses of the rivers, including the Tisza, are influenced by several sinking grabens. One of the most active ones is the South Tisza Graben, where approximately 700-m-deep fluvial sediments have accumulated. Until the Late Pleistocene, the graben subsidence was continuous but fluctuating; during the Holocene, it terminated as Early Holocene floodplain forms were not buried by younger sediments (Sheishah et al., 2023).

The original length of the Tisza River was 1.400 km from its spring in the north-eastern Carpathian Mountains in Ukraine to its mouth at the Danube. During the second half of the 19th century, extensive measures on the river and flood control were undertaken along the river. As a result of these works, the river's total length was shortened by approximately 30%, and today, it is 966 km.

Constructed in the 1880s, artificial levees (length = 2940 km) created flood-safe areas and decreased flood duration. They confined the floodplain width to 0.4–5 km. Over time, their further construction raised their heights to counteract higher flood levels (Lóczy et al., 2009). A typical levee cross-section reveals many different zones (Figure 3).

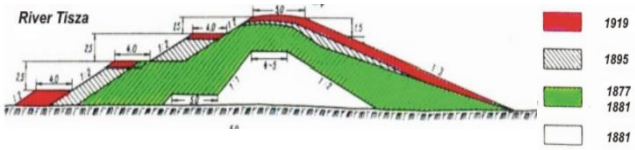

Figure 3. Typical cross-section along the Tisza River (Sheishah, 2023).

The groundwater elevation follows the river elevation changes and is close to the surface; as a result, the foundation soils are almost always saturated.

Figure 4 shows the water level elevation during the flood event in 2006. The typical zero water elevation reading on the river at Csongrád is ~75 m above the Baltic Sea level. During the 2006 spring flood, the peak level reached 1062 cm. The flood wave started at the end of March and peaked four weeks later. The figure also shows the flood warning levels I., II., and III. (650, 750, 850 cm).

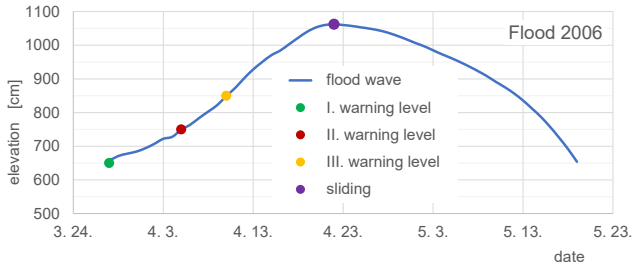

Figure 4. Water elevations during the 2006 April flood wave along the Tisza River.

3 MODELING APPROACH

Due to the levee evolution, the cross-section is inhomogeneous and anisotropic. PLAXIS 2D geotechnical software can analyse the time-dependent water level raising and the stability of the levee. Design approach 3 has been selected in the Hungarian national annexe of Eurocode 7 (EC7) for overall stability problems as in other countries. The choice is exceptionally reasonable for levees because design actions should receive no partial factor. The partial

factor for shear strength parameters for resistance is 1.35 (Szepesházi et al., 2015).

Geotechnical finite element software performs stability analysis using the ϕ-c reduction method, also called Safety Analysis by Plaxis, corresponding to design approach 3. The resulting safety factor must be compared with the partial factors defined by the standard, $\gamma_{\phi,c}$=1.35.

An extensive geotechnical investigation of ten boreholes determined soil stratification and parameters. The geotechnical laboratory of Széchenyi University tested disturbed and undisturbed samples to determine their physical and mechanical characteristics. Figure 5 shows the results of the triaxial test and shear tests of the high-plasticity clay. The figure also represents the characteristic shear stress value of the clay material.

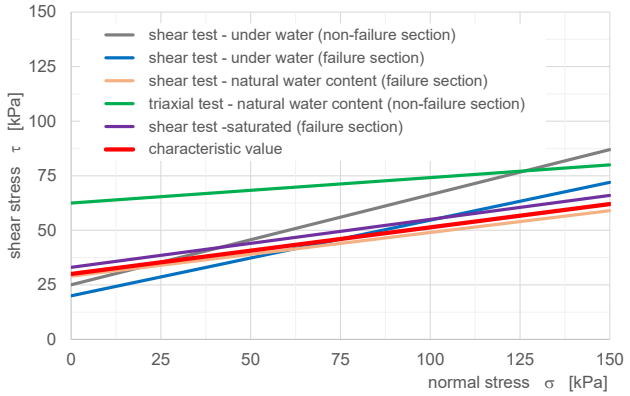

Figure 5. Results of the laboratory tests.

The soil properties are summarized in Table 1. The top layer was modeled as low-plasticity clay, the foundation and core as high-plasticity clay, and the bottom layer as silt and sandy soils.

The measured levee's present height is 6.5 m, and the base width is 45 m, with a crest 4.5 m wide. The landside slope of the levee is 1:3, and at 2/3 of the height, there is a 3.5 m wide berm.

We applied a fully coupled flow-deformation analysis to simulate the water level raising and followed by the overall stability using phi-c reduction method. The applied constitutive model was Mohr-Coulomb. The finite element mesh is shown in Figure 6. Stability was modeled with four water levels: warning levels I, II, and III, and the maximum water level (max) (Figure 6).

Before the flood, the levee was in good condition, showing overall stability MSF=2.6, much higher than the required value by the EC-7, MSF=1.35. Figure 7. shows the possible failure mechanism related to the condition without flood.

Observations of field performance pointed to the apparent failure mechanism where seepage helped to generate reduced effective stress and strength. The slope (berm) moved just as the water level peaked, rising 1.5 m in about a week. The water seeped over the lower, less permeable black clay material and through the upper, more permeable yellowish-brown zone. This process weakened the strength of the black clay interface and, to some extent, the yellowish-brown layer. At the same time, seepage gradients almost parallel to the downslope direction increased the sliding forces.

Table 1. Soil properties

parameters	Sand	Silt	HP Clay	LP Clay
γ_{unsat} [kN/m^3]	20.0	20.0	18.5	21.0
ν [–]	0.3	0.3	0.35	0.35
E_{oed} [MN/m^2]	15.0	7.0	5.0	3.0
c_{ref} [kN/m^2]	1.0	25.0	30.0	50.0
ϕ [°]	32.0	23.0	10.0	10.0
k [m/day]	1.5	8E-3	2E-4	8E-4

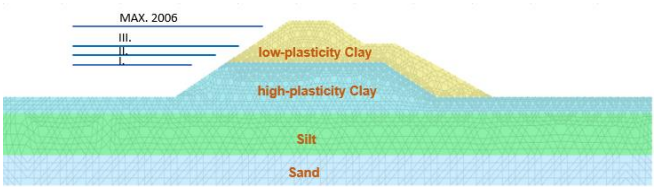

Figure 6. Finite element mesh and water elevation at the outer side of the levee.

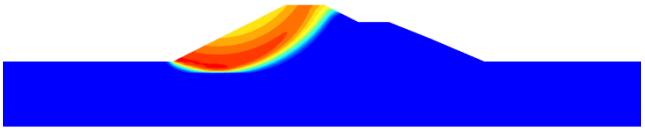

Figure 7. Possible failure mechanism before the flood (blue is no deformation; red maximum).

4 RESULTS

The stability of the levee was evaluated as a function of water level elevation and duration of rising water level. After 10 days of water level rising to 450 cm, the slope safety factor was MSF=2.3. During the next 10 days, reaching I. warning level (650 cm), the safety factor decreased to 1.88. With another 100 cm increase in water elevation (II. warning level=750 cm), it decreased to MSF=1.56. On the 35th day of the flood, reaching the III. warning level (850 cm), the safety factor decreased to MSF=1.32. With an additional 200 cm increase in water level elevation (MAX=1062 cm) the levee became unstable.

The factor of safety for stablity of the levee decreased with time and increasing water elevations. Figure 8. shows the failure mechanism at the peak water level with the safety factor MSF=1.03. The modelled slip surface matches the real failure observed

at the site. The factor of safety was plotted as a function of water levels and duration of the flood (Figure 9).

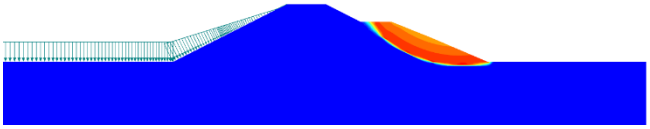

Figure 8. Possible failure mechanism at peak water level during flooding.

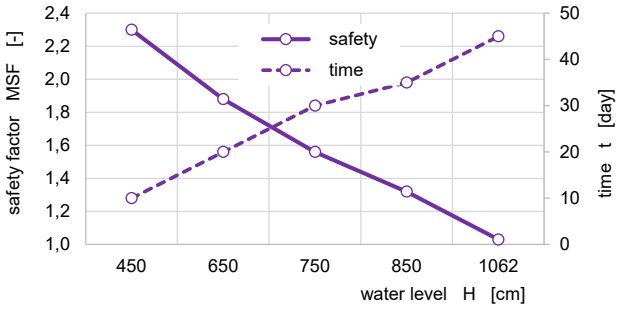

Figure 9. Factor of safety as a function water level and time of flooding.

After the flood, the failed slope was reinforced using a revetment on the land side. The applied material was coarse-grained and a drainage system was also constructed along the landside levee toe. After simulation of a longer, 60 day flood with the same peak water level (1062 cm), the stability shows MSF=1.37. The possible failure mechanism is shown in Figure 10. The slip surface seems similar to the surface related to the failure, but due to the coarse-grained revetment and the drainage system at the levee toe, the water flow through the levee had accelerated. Reducing the shear strength of the levee foundation and core might be avoided.

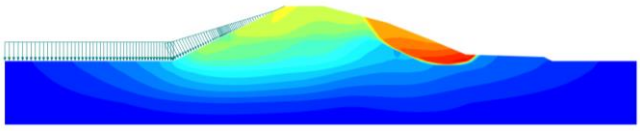

Figure 10. Failure mechanism after reinforcement.

5 CONCLUSIONS

Levee breaches are decreasing due to recent improvements in the levee systems. However, the safety of the levees can decrease because of other problems, such as instability due to the increase in the frequency of floods and longer and higher flood waves. Our study showed that with increasing water levels and the duration of rising water level, the stability of the levees decreased.

For the past 15 years, flood water elevations in the Tisza River have exceeded the previously determined maximum water levels. Higher levels have destabilized levees at unpredictable locations. Other new improvements are necessary since former solutions, such as increasing the crest and the width of the levee, can lead to structural problems. Thoroughly evaluating stability under the new flooding conditions and their impact on effective stress and strength of slopes during transient seepage loads represents a new challenge to the geotechnical engineer. Accurately modeling the transient seepage regime, global, and local stability is necessary to evaluate the performance of the levee system and any proposed improvements.

Deformations assessment of phosphogypsum waste heap in Wiślinka after 15 years of its reclamation

L'évaluation de la déformation du terril de phosphogypse à Wiślinka après 15 ans de remise en état

A.P. Korzec*, W. Świdziński
Institute of Hydro-Engineering/Polish Academy of Sciences, Gdańsk, Poland
*a.korzec@ibwpan.gda.pl

ABSTRACT: The article presents an analysis of the long-term response of the phosphogypsum waste heap in Wiślinka, Poland, almost 15 years after its reclamation. The behaviour of such heaps is an important issue since phosphogypsum has no industrial application so far and, consequently, such structures will become a part of the landscape or even a substructure. The heap deformations are assessed based on the results of two monitoring systems consisting of survey markers and inclinometers installed at various periods. In the analysis, available historical records combined with the most current records obtained in the course of the ongoing project are implemented. The crest of the slope of the oldest part of the heap settled by 2.5 m over the last 20 years. The settlement progresses with rate of up to 66 mm/year, which is 75% lower than in 2007. Horizontal displacements of the heap slope are also observed with the rate 11 mm/year and have remained constant since at least 2019. Based on these results and further investigations being currently carried out, the hypothesis concerning the existence of 3 different mass movements of some parts of the heap has been stated. To verify the hypothesis, a monitoring system has been developed and new results will be analysed during the course of the project that is still ongoing.

RÉSUMÉ: Cet article présente une analyse de la réponse à long terme du terril de phosphogypse localisé à Wiślinka en Pologne, près de 15 ans après sa remise en état. Le comportement de tels amas est une question importante puisque le phosphogypse n'a jusqu'à présent aucune application industrielle et, par conséquent, de telles structures deviendront une partie du paysage ou même une sous-structure. Les déformations du tas sont évaluées sur la base des résultats de deux systèmes de surveillance installés à différentes périodes de temps, constitués de balises d'enquête et d'inclinomètres installés à différentes périodes de temps. Dans l'analyse, les enregistrements historiques disponibles combinés avec des enregistrements actuels obtenus au cours du projet en cours sont mis en œuvre. La crête du talus de la partie la plus ancienne du terril s'est tassée de 2,5 m au cours des 20 dernières années. La sédimentation continue de se produire à un rythme pouvant atteindre 66 mm/an et est 75% inférieur à celui de 2007. Des déplacements horizontaux de la pente du tas sont également observés à raison de 11 mm/an et sont restés constants depuis 2019. Sur la base de ces résultats et d'autres investigations en cours, l'hypothèse concernant l'existence de 3 mouvements de masse différents de certains des parties du tas ont été indiquées. Un système de suivi a été développé et de nouveaux résultats seront analysés au cours du projet qui est toujours en cours afin de vérifier l'exactitude de l'hypothèse.

Keywords: Heap; landslides; mass movement; deformations; monitoring systems.

1 INTRODUCTION

The paper regards the performance of the reclaimed phosphogypsum heap located in Wiślinka, in Pruszcz Gdański district, Poland, Figure 1. The heap belongs to the Azoty Group Fosfory, Gdańsk, a producer of mineral fertilizers widely used in agriculture. The phosphogypsum is a by-product of the phosphoric acid made of phosphate rock. As such it is not considered as hazardous waste and can be utilized by its deposition. The location decision issued in 1969 defined the area occupied by the heap to be 26 ha. In 1983, it was established that a maximum of 16.6 Mt of chemical industry waste could be stored on the heap, and its height could not exceed 41 m. In order to facilitate the transportation process of phosphogypsum (Ph) using a waterway, the heap has been located nearby *Martwa Wisła* River. The deposition of phosphogypsum in the heap was carried out in the years 1972-2009.

The closure of the heap had been performed based on the detailed documentation. Reclamation works were carried out in 2008-2009. The main goal of the procedure of heap closure was to define its final geometry which minimises the negative impact of the heap on surface and ground waters, neighbouring agriculture lands and air as well as to assure lifetime

stability of the heap's slopes. The long-term behaviour of such heaps is an important issue since phosphogypsum has no industrial application so far (Bilal et al., 2023). According to Polish law, the behaviour of the heap should be monitored for 50 years after closure.

The essential part of the closure documentation consisted of the project and implementation of the monitoring system to follow the response of the heap in time and to assess its environmental impact and stability. The monitoring system, intended for stability assessment, consisted of 33 benchmarks to monitor the surface deformations accompanied by 2 inclinometers for investigation of deeper earth movements. On-site inspection revealed that 5 survey markers installed in 2004, before heap reclamation, still exist. Since the measurement records are also available, in this paper, the heap deformations monitored for almost 20 years are analysed.

Figure 1. Southern Slope of Wiślinka heap (October 2022).

2 GENERAL CHARACTERISTICS

2.1 Heap geometry and material

The base of the heap has an irregular shape. For the sake of the analysis, four parts of the heap corresponding to the cardinal directions have been distinguished, Figure 2. Next, based on satellite technology characteristic cross-sections of the heap slopes together with current geometry have been defined, Figure 3 and Figure 4. The maximum elevation of the heap's top plateau is 42.3 m asl. The heap is surrounded by dikes with a crest at the elevation of 5.8 m asl. The ground level from is 2.5 m asl from the *Martwa Wisła* river side and 0.5 m asl from the south side. Currently, the Western Slope is the most inclined slope of the heap. Its inclination is 37° (*V:H* = 1:1.3). The Eastern and Southern Slopes have similar geometry with a 10 m wide intermediate bench located at the elevation of 11 m asl and the average inclination of the upper slope 35° ± 5% (1:1.4). The Northern Slope has the lowest inclination of 25° (1:2.1). The original steep slope was reconstructed to form technical access road and to improve its stability.

Based on documentation analysis, site interviews and analysis of boreholes made in 2022, the method of phosphogypsum deposition has been concluded. Initially, the phosphogypsum (of white colour) had been deposited in a basin formed between surrounding dikes which resulted in the formation of laminations of mineral soil (Phl). After reaching the elevation of 2.5 m, phosphogypsum was deposited as a dry stack in 5 to 15 m thick layers without any compaction.

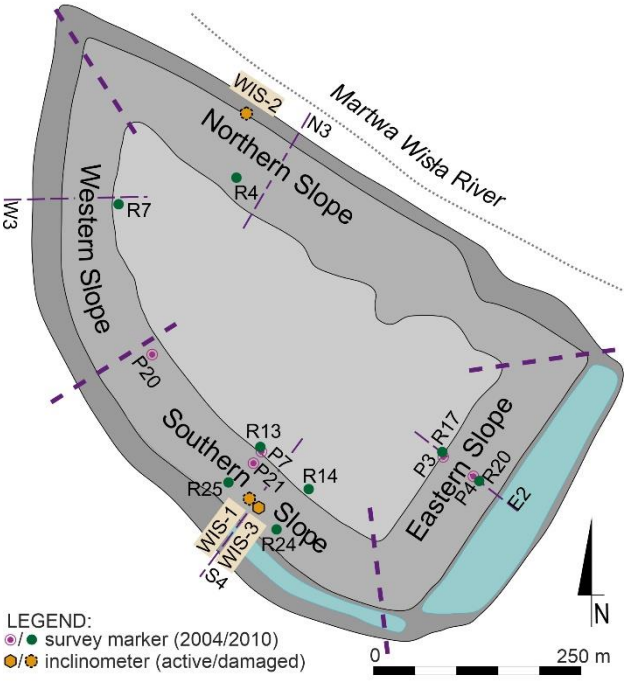

Figure 2. Scheme of Wiślinka waste heap.

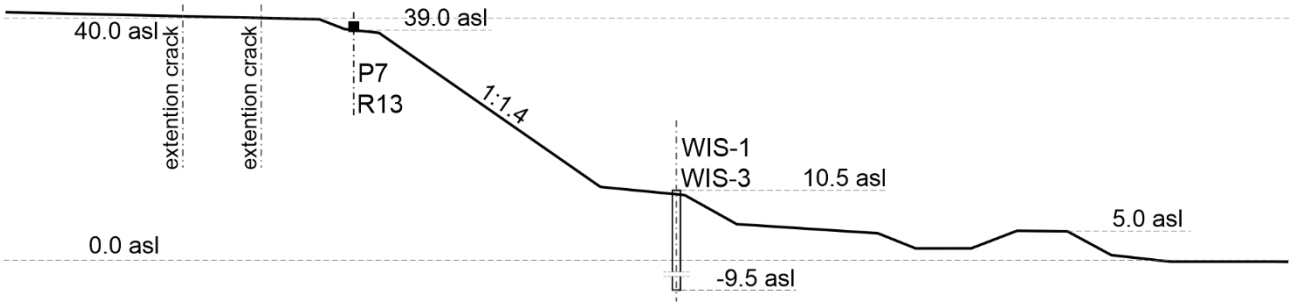

Figure 3. S4 profile of Southern Slope of Wiślinka waste heap.

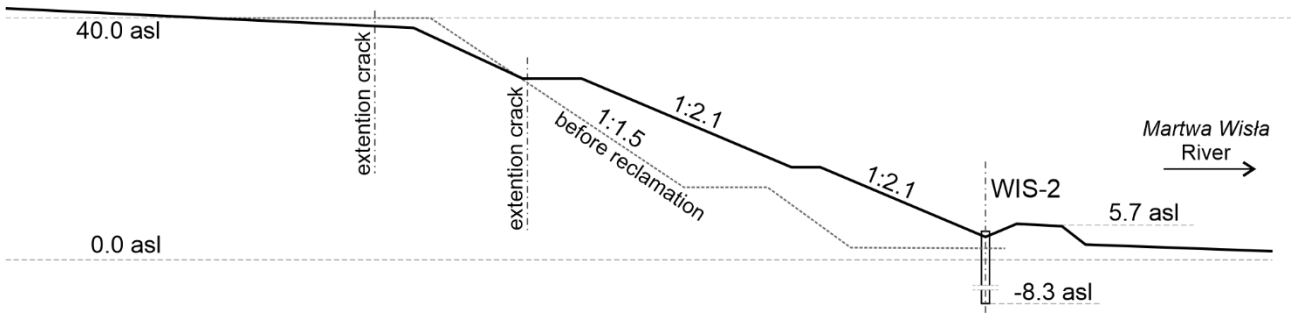

Figure 4. N3 profile of Northern Slope of Wiślinka waste heap.

The initial angle of external slopes might have reached even 63°, which has been confirmed by the photogrammetric measurements carried out in 1996. The variety of colours identified in phosphogypsum cores (from yellow-grey by grey to brown-grey), as well as their consistency (from very firm to loose) and moisture content, allows us to conclude that the raw material and the superphosphate production process had been changing over the years. The final elevation of the deposition was first reached in the eastern and southern parts of the structure (1999) whereas the rest of the heap was formed just prior to the closure.

2.2 Subsoil characteristic

The foundation under the heap, to the depth of the recognition carried out in the course of the ongoing project (19.6 m bsl), is strongly stratified. Such a stratification is characteristic of alluvial regions located near the rivers. Finally, three layers of organic soils interbedded by mineral soils have been identified. The first two organic layers are composed of mud and peat. The second, 3.1 m thick organic layer, seems to be decisive from the slope stability point of view. It consists of loose organic silts underlain by plastic clays.

3 DEFORMATION MONITORING SYSTEM

3.1 Surface deformations

Historically, the monitoring of the heap deformations measured during the development of the structure practically served to control its top elevation. In 2004, 21 benchmarks were installed in order to monitor the heap deformations in those parts which have been assumed to be completed. The surveying was carried out up to 2007 using an electronic tachometer with ±3 cm accuracy. The inventory of the existing monitoring infrastructure performed in the course of the project and initiated by the Authors of the paper showed that there are only 5 benchmarks left: three are located at the Western Slope (1 on the crest and 2 on the slope) whereas remaining two at the Eastern Slope (on the crest and slope, respectively), Figure 2. In the paper, these benchmarks are marked by the letter P. Measurements have been resumed since the autumn of 2022.

In 2010, a new monitoring system of heap deformation, consisting of 33 benchmarks, was installed. Benchmarks from that system are marked by the letter R. Measurements were initially carried out once every half a year, then once a year. The accuracy of the horizontal displacements was ±2 cm, whereas for vertical ones ±3 cm.

Initially, the surveying was carried out with reference to the Gdańsk70 coordinate system and the Kronsztadt86 elevation system. Since 2010, measurement has been performed using the 2000 and the Kronsztadt86 reference systems. Therefore, to obtain a continuous history of heap deformation, measurement data from the years 2004-2007 and 2010-2021 were converted to reference systems currently legally permitted in Poland, i.e. 2000 and EVRF2007 (Amsterdam 2007).

In three locations, the benchmarks from both above-mentioned systems are located close to each other; P3-R17 pair on the crest of the Eastern Slope, while P7-R13 and P4-R20 pairs on the crest and bench of the Southern Slope, respectively. Combining the results of geodetic measurements from both systems allowed us to obtain the deformation pattern over a longer period. It also enables the identification of possible displacements and their rates that might have occurred in parts of the heap formed later.

Starting from 2004, the top of the Eastern Slope settled by 2.32 m. Currently, the rate of subsidence is 66 mm/year. The vertical displacement u_Z rate in the period of 2004-2007 was as high as 260 mm/year. Similar values regard the Southern Slope i.e. u_Z = -2.52 m, Δu_Z = 40 mm/year, Figure 5. Over such, relatively long, observation periods some kind of stabilisation can be identified.

In Figure 6 the settlement's time-histories of four R benchmarks representing the crest of each slope were compared. The R7 benchmark settled 2.59 m since 2012. The settling rate of the youngest part of the heap

is 160 mm/year. Thus, some settlements are still expected to occur. A large settlement was recorded on the reconstructed northern part of the heap. However, if we ignore the first increment of the settlement, R4 behaves quite similarly to the older part of the heap.

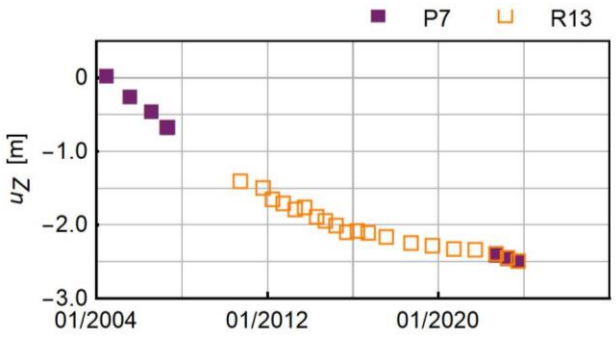

Figure 5. Settlements of P7 and R13 control points located at Southern Slope.

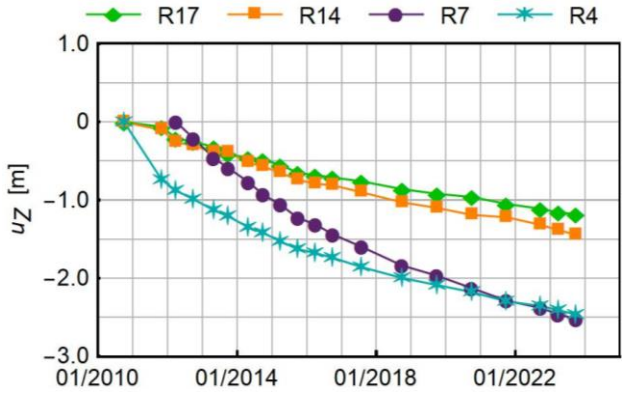

Figure 6. Settlements of control points installed in 2010 (R) representative for each slope.

The directions of horizontal displacement vectors of benchmarks installed in 2010 indicate an occurrence of mass motions observed along three slopes. Only the Eastern Slope has not been moving horizontally. It can be noticed that the values of displacements, as well as, their rates are different which mainly results from the different times of the construction of the heap parts.

The total horizontal displacements u_{XY} of Eastern Slope (P3-R17) recorded from 2004 reached merely 0.08 m and currently, the changes fall below measurement accuracy. In the same period, the top of the Southern Slope moved downstream by 0.47 m, Figure 7. The current displacement rate is 11 mm/year. In the time-history plot, the reduction of displacements u_{XY} can be observed in 2008. It is an effect of the construction of 2.5 m high embankments on the heap's top during the reclamation process.

The highest rates of horizontal displacements are observed along the Western and the Northern Slopes which from the start of the measurements reached the value of 0.9 m, (Figure 8) with the average rates of 30 mm/year and 50 mm/year, respectively.

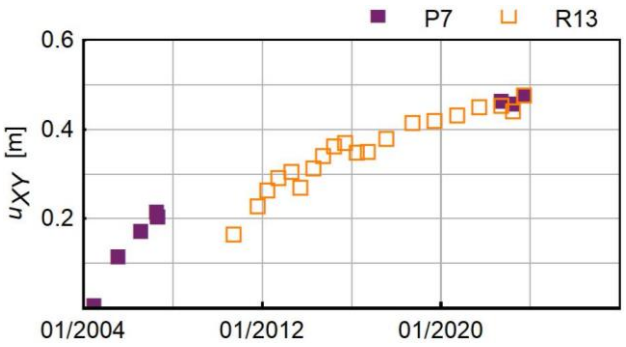

Figure 7. Horizontal displacements of P7 and R13 control points located at Southern Slope.

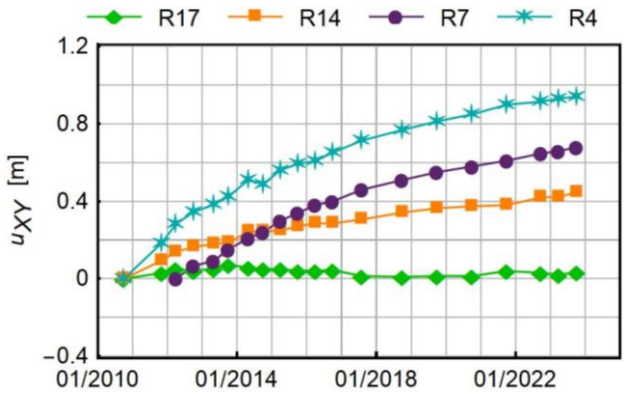

Figure 8. Horizontal displacements of control points installed in 2010 (R) representative for each slope.

Horizontal displacements u_{XY} of the R24 benchmark located along the Southern Slope were 198 mm at the rate of 9.98 mm/year, observed between 2016 and 2023. In previous years the rate was almost twice as high, reaching 18.2 mm/year with much notable fluctuations, Figure 9. The deformations that occurred in periods 2010-2016 (0.10 m) and 2019-2023 (0.03 m), have been confronted with the deformations of inclinometer WIS-1 and inclinometer WIS-3 which will be a subject of discussion presented in the next section of the paper.

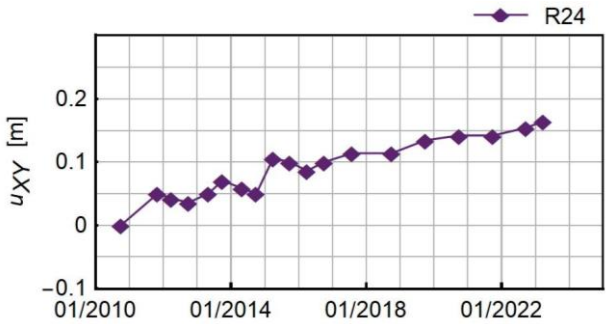

Figure 9. Horizontal displacements of R24 control poins located at Southern Slope.

3.2 Inclinometers

In 2007 two inclinometers for monitoring the potential mass movement were installed, one within the inland

side and the other on *Martwa Wisła* riverside (see WIS-1 and WIS-2 in Figure 2). The grooves of the inclinometer housing were orientated to directly measure the main direction of potential mass movement (Cornforth, 2005). Periodic measurements, at least once a year, have been carried out using a two-directional probe with an accuracy of ± 0.13mm/rm.

16 m long inclinometer WIS-1 was installed at the bench on the Southern Slope. In the fall of 2016, it was found damaged by the probe which was blocked at a depth of 8 m. Total cumulative displacements Δu_A of the inclinometric pipe at this depth were 173 mm. The records revealed a linear trend of this displacement over 9 years. The estimated displacement rate was 18.4 mm/year. In the period from fall 2010 to fall 2016 the displacement of the inclinometer head was 86.5 mm.

In 2019, a new 20 m deep inclinometer was installed in close vicinity to the sheared one (marked as WIS-3). The first measurement was taken in June 2019. Since 2020, the measurement of inclinometric displacements has been performed by another company with a similar two-directional probe equipped with a MEMS gauge. In both cases, the measurement error was ± 0.08 mm/rm. Fortunately, the raw data from all these measurements were available. Therefore, an attempt was made to assemble the data. Firstly, the measurements carried out in December 2022 by two different companies were compared. The maximum difference was 0.184 mm along 0.5 m of pipe length, whereas the cumulative difference of the head was 0.422 mm. It was deemed, that such a difference would not affect the conclusions.

The cumulative displacement obtained from all measurements relative to the very first one from 2019 is shown in Figure 10. The maximum values of horizontal displacements of the order of 50 mm occur at a similar elevation as in the case of damaged inclinometer WIS-1 with a practically constant deformation rate of 11.1 mm/year, Figure 11. According to the Cruden and Varnes classification (Zabuski, 2022), movement with this rate of displacement is classified as extremely slow. Cumulative horizontal displacement as a sum of total displacements recorded in both inclinometers WIS-1 and WIS-3 was estimated to be 232 mm (164.5 mm since 2010).

In the period 2019-2023, the horizontal displacements of WIS-3 inclinometer head were 27.4 mm whereas the observed corresponding displacement of the benchmark located on the bench was 30 mm. Therefore, it can be assumed that displacements of both inclinometers WIS-1 and WIS-3 reflect the main deformation mechanism of the Southern Slope.

The rotational character of the movement can be assumed from the cumulative displacement curve. The displacements of the inclinometer head are almost 40% lower than at 7 m depth. The largest pipe deformations occur in the organic soil and laminated phosphogypsum (Phl), (soil profile in Figure 10).

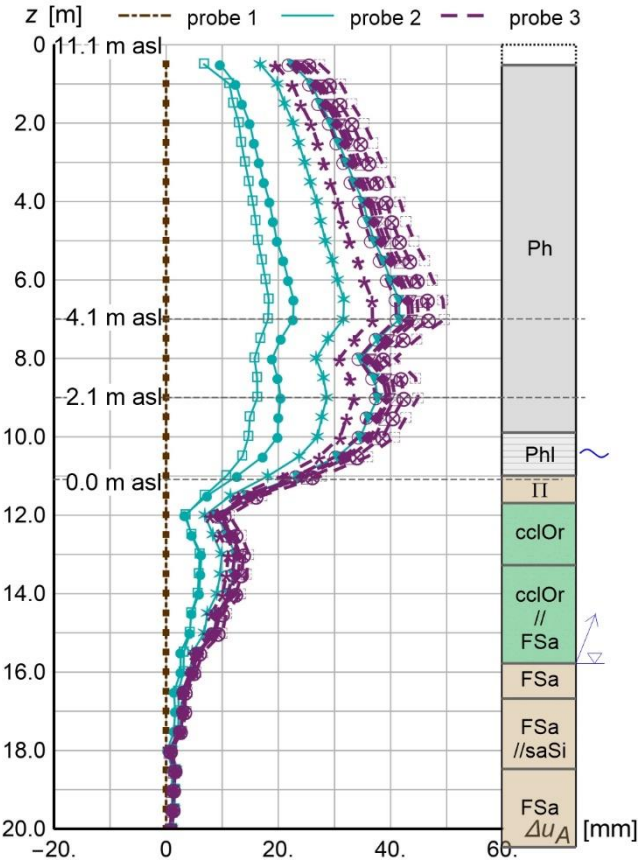

Figure 10. Cumulative displacement in A direction of WIS-3 inclinometer in relation to measurement of 27th June 2019.

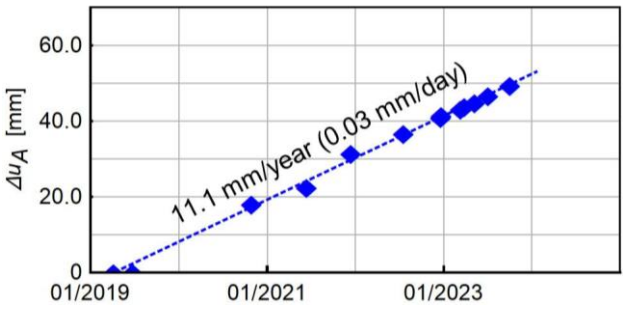

Figure 11. Cumulative displacement at 7 m of WIS-3 inclinometer in relation to measurement of 27th June 2019.

The second inclinometer from those two installed in 2007 was unfavourably installed in the internal trench of the Northern Slope, Figure 1. The largest displacements of the inclinometer casing were cumulated in the second layer of organic soils, with the maximum at the depth of 11 m. This movement practically disappeared in 2012 after dissipation of excess pore pressures which were generated during construction of the buttress. In the years 2012-2017,

the displacement rate was merely 1.4 mm/year. In 2021, the pipe was clenched at the depth of 2.5 m. No raw data from the period of 2012-2023 are available which could help to understand the slope displacement revealed by geodetic measurements.

4 CONCLUSIONS

In the paper, the results of the analysis of long-term deformation measurements of the phosphogypsum waste heap are presented and discussed. A trivial, however important, conclusion coming from such analyses is the importance of preserving the continuity of measurements and archiving data. In the presented case, the implementation of the original procedures for combining historical data obtained by various companies made it possible to extend the time window of the analysed deformations.

20 years after reaching the final height of the Eastern and the Southern Slope of the heap, continuous settlements at the rate of 66 mm/year are still observed. The current settlement rate is 75% lower than that observed in 2004-2007. As far as horizontal displacements are concerned, creep mass movements at the rate of 11 mm/year are recorded along the Southern Slope. From comparison of geodetic and inclinometric results, it was concluded that the WIS-1 and WIS-3 describe the main deformation mechanism of the Southern Slope.

The Eastern Slope does not move horizontally, however settlement occurs.

The rates of both horizontal and vertical displacements are the highest along Western Slopes which is due to the latter time of its formation.

The displacements observed in the inclinometer installed at the base of the Northern Slope did not contribute to the explanation of horizontal slope displacements. In order to reliably assess the stability of the Western and the Northern slopes, it was necessary to develop a monitoring system. Four inclinometers were installed, among other devices, to collect more data required for detailed identification of failure mechanisms driving the observed deformations.

ACKNOWLEDGEMENTS

The authors are grateful for the financial support for the project *'Safety assessment of phosphogypsum waste heap in Wiślinka, Poland'* provided by the Provincial Fund for Environmental Protection and Water Management (Gdansk, PL). www.wfos.gdansk.pl).

The authors are grateful to companies *GEOTEKO*, Warszawa and *GEO-EKSPERT*, Gdansk for providing raw data from inclinometer measurements.

Representative values of geotechnical parameters derived from dynamic penetration test

Valeurs représentatives des paramètres géotechniques dérivées de l'essai de pénétration dynamique

E. Kucova*, M. Kuvik
Department of Geotechnics, Faculty of Civil Engineering, Slovak University of Technology in Bratislava, Slovakia

*eliska.kucova@stuba.sk

ABSTRACT: Dynamic penetration test is a relatively simple field test, which is frequently used for testing of soil resistance. From the results of this test, it is possible to derive physical and mechanical geotechnical parameters of coarse-grained soils, namely relative density, angle of shear strength and deformation modulus. The representative values of these parameters can be furthermore used in design of geotechnical structures. The new Eurocode 7 provides a set of equations that should be followed to establish the characteristic value if the data is considered sufficient. In this article the results of dynamic penetration tests, performed in the locality of the capital city of Slovakia, were used for determination of mechanical properties of Danube gravels. Afterwards, results were statistically processed, and characteristic value was estimated according to Eurocode 7. The characteristic values of geotechnical parameters were compared with traditional evaluation procedures, where the average value is determined for each soil layer.

RÉSUMÉ: Le test de pénétration dynamique est un test sur le terrain relativement simple, fréquemment utilisé pour tester la résistance du sol. A partir des résultats de cet essai, il est possible de déduire des paramètres géotechniques physiques et mécaniques des sols à gros grains, à savoir la densité relative, l'angle de résistance au cisaillement et le module de déformation des graviers et des sables. Les valeurs représentatives de ces paramètres peuvent en outre être utilisées dans la conception de structures géotechniques. Le nouvel Eurocode 7 donne des lignes directrices pour l'estimation de la valeur représentative en tant que valeur caractéristique. Dans cet article, les résultats de tests de pénétration dynamiques, réalisés dans la localité de la capitale de la Slovaquie, ont été utilisés pour déterminer les propriétés mécaniques des graviers du Danube. Ensuite, les résultats ont été traités statistiquement et la valeur caractéristique a été estimée selon l'Eurocode 7. Les valeurs caractéristiques des paramètres géotechniques ont été comparées aux procédures d'évaluation traditionnelles, où la valeur moyenne est déterminée pour chaque couche de sol.

Keywords: Representative value of geotechnical parameter; coarse-grained soil; dynamic penetration test; statistics.

1 INTRODUCTION

In Slovak geotechnical practice the dynamic penetration test (DP) is frequently used in engineering geological surveys. The test is primarily intended for testing of coarse-grained soils due to less skin friction on the rod. The penetration rod is driven into the ground by dynamic force and the resistance of soil is measured.

From the measured data, it is possible to determine specific physical and mechanical properties of sands and gravels. These properties can be determined by using correlations of international and national significance (EN 1997-2:2008, DIN 4094-3:2002, EN ISO 22476-2, PN-B-04552:2002, STN 72 1032: 1997, Matys et al., 1990). The given literature offers both direct and indirect correlations to choose from.

Standards (EN 1997-2:2008, DIN 4094-3:2002, EN ISO 22476-2, PN-B-04552:2002, STN 72 1032: 1997) mention mainly direct correlations for the relative density (I_D) of sands and gravels that are directly derived from number of blows (*N)* measured during the penetration test. The indirect correlation is expressed for the angle of internal friction, that is evaluated based on the relative density of coarse-grained soil (Schnaid, 2009; Carter, Bentley, 2016; Sanglerat, 1972, Bolton, 1979; Robertson, and Hughes 1986, EN 1997-2:2008).

More direct correlations for the determination of coarse-grained soil geotechnical parameters are published in regional (Slovak) literature. These correlations are based on the results of dynamic penetration resistance (q_{dyn} in MPa).

From the derived geotechnical parameters, it is possible to determine a representative value, which is essential for the design of geotechnical structure. The new generation of Eurocode 7 (prEN 1997-1:2024) defines that the representative value can be either nominal or characteristic value.

In the previous Eurocode 7 (EN 1997-2:2008) the the characteristic value was referred to as cautious estimate of the value affecting the limit state and the statistical procedure for its estimation was not precisely specified. This assessment was analysed by various authors (e.g. Schneider 2010, Orr 2019, Prästings et al. 2019). The conclusion of these studies was that procedure did not consider the uncertainty of geotechnical properties. Authors also pointed out that the statistical procedure was not clearly defined and the same statistical rules as for man-made materials cannot be followed.

Therefore, in the new Eurocode 7 (prEN 1997-1:2024) the characteristic value is defined using a statistical procedure that includes basic statistical characteristics as mean, standard deviation, and coefficient of variation.

In our research we used the statistical procedure from the new EC 7 to determine the characteristic value as a representative value of the angle of internal friction. The angle of internal friction was derived from the results of dynamic penetration resistance using Slovak correlations for Danube gravels.

The obtained results were compared with other foreign correlations and nominal values used in Slovakia with the intention to investigate appropriateness and accuracy of the regional correlations.

2 METHODOLOGY

To determine the representative value of the angle of internal friction we analysed 120 heavy dynamic penetration tests performed in gravels near the Capital of Slovakia.

2.1 Material

Investigated gravels belong to Quaternary sediments of Danube River. The river has in the region accumulative and sedimentary activity, due to which the gravel particles are fine, smooth, well rounded with size of 1 – 5 centimetres.

In this article we focused on the analysis of the poor-graded gravel (G2/GP) which is together with gravels G3/G-F, the most represented gravel class in the area. Poor-graded gravels of the investigated area consist of 54 – 77% of gravel fraction. Grading of gravel particles at d_{60} is from 5 – 15 millimetres (Figure 1).

2.2 Determination of the angle of internal friction and its characteristic value

The angle of internal friction (φ_{eff}) was derived from results of dynamic penetration test. Its values were derived from the number of blows (N_{10}) using correlation from to Slovak standard (STN 721032:1997) and dynamic penetration resistance using correlations according to Švasta (Matys et al., 1990). The mentioned correlations are summarized in Table 1 and Table 2.

The characteristic value of the angle of internal friction was determined by following recommended approach from the second generation of Eurocode 7 (prEN 1997-1:2024).

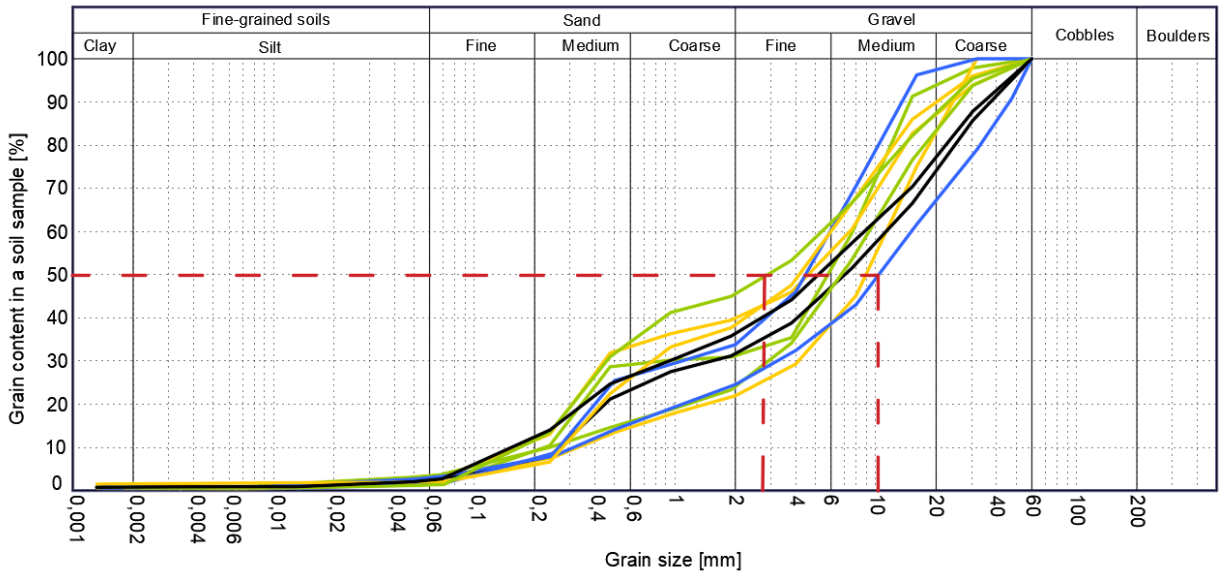

Figure 1. Grading curves of poor-graded gravel (G2/GP).

Table 1. Correlation between φ_{eff} and N_{10}.

Reference	Soil	Correlation	
		N_{10}	φ_{ef} (°)
STN 72 1032	Gravels	< 3	< 30
		3 – 6	30 – 35
		6 – 17	35 – 40
		17 – 30	40 – 45
		> 30	> 45

Table 2. Correlation between φ_{eff} and q_{dyn}.

Reference	Soil	Correlation	
Švasta	Gravels & Sands	$\varphi_{ef} = p\,(q_{dyn})^{r}$	[°]

Note: unitless coefficient p equals to 24
unitless coefficient r equals to 0,16

The characteristic value, denoted as X_k, corresponds to a specific quartile of the assumed statistical distribution of assessed soil parameter.

The second generation of Eurocode 7 recommends determining the characteristic value according to given formula:

$$X_k = X_{mean}[1 \mp k_n V_x] = X_{mean}\left[\frac{1 \mp k_n s_x}{X_{mean}}\right] \qquad (1)$$

where X_{mean} is an average of measured values of soil parameter, V_x is coefficient of variation of the measured values of soil parameter, k_n is the coefficient depending on the number of the measured values (n) of the soil parameter and s_x is the standard deviation of the measured values of soil parameter.

The procedure is applicable for both, known and unknown coefficient of variation, which is decisive when evaluating the coefficient k_n (prEN 1997-1:2024).

3 RESULTS

The values of the angle of internal friction obtained from the results of dynamic penetration are shown in Figure 2. The values of φ_{ef} were categorized according to relative density to three categories - φ_{ef} of loose, medium dense and dense poor-graded gravels. For each category the corresponding characteristic value was evaluated (Figure 2, Table 3).

Compering the results the difference between the two correlations is approximately 2° for medium and dense gravels while correlation according to STN 72 1032 being more optimistic. The difference between the two correlations for loose gravels is bigger.

The results in Table 3 are furthermore compared with other foreign correlations and nominal values published in cancelled Slovak standard, which are still in use as comparable experience.

Analysing Table 3 we can see that in regional (Slovak) literature there is no recommendation of nominal values for loose gravels. But European standards (BS 8002, Eurocode 7, DIN 4094-3) recommend an indicative value of 30° for φ_{ef} of loose gravels. This value is higher than our characteristic value derived by regional correlations.

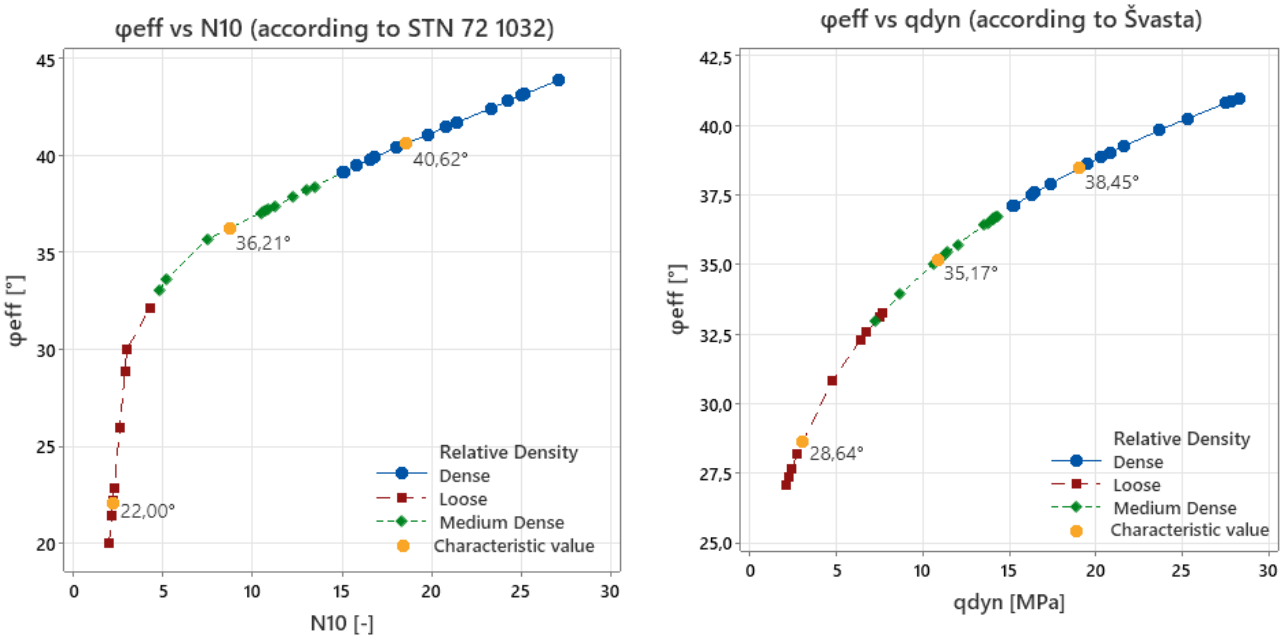

Figure 2. Evaluation of the angle of internal friction G2/GP according to regional correlations.

Table 3. Comparison of the characteristic and nominal values of φ_{eff}.

Soil	Relative density	φ_{eff} [°]				
		Characteristic values		Nominal values		
		Švasta	STN 72 1032	BS 8002	EC7/ DIN 4094-3	STN 73 1001
G2/GP	Loose	28,64	22,00	30,00	30,00	-
	Medium dense	35,17	36,21	32,50	34,00	35,50
	Dense	38,45	40,62	35,00	38,00	38,50

The characteristic values for medium dense gravels are in accordance with used nominal values and are more optimistic than the foreign correlations.

Dense G2/GP were also tested in laboratory using large-scale shear box machine, where we measured the values of φ_{eff} in range of 41,00° – 48,50°. Comparing the results, we can see that the British standard indicates the lowest value, and the laboratory tests designates the highest values for the angle of internal friction.

4 CONCLUSIONS

The article analyses the representative values of angle of internal friction for poor-graded river gravel.

Results of φ_{ef} were categorized according to the relative density of the soil and were compared with the laboratory test results, other correlations and nominal values used as comparable experience in Slovakia.

Characteristic values of φ_{ef} for loose G2/GP reaches according to Slovak correlations lower values than those specified by European standards. Moreover, there is no recommendation for nominal values in the Slovak standard.

Correlated results (according to Švasta in Matys et al. 1990, and STN 72 1032:1997) of medium dense and dense gravel show a good match with nominal values. Dense poor-graded gravels were also tested in laboratory and the results shows higher values of angle of internal friction. This can indicate that even higher values of φ_{eff} could be used as nominal values for Danube gravels in Slovakia.

To optimize regional correlations and suggest nominal values for the national appendix of new EC 7 the research will be complemented with the data from other localities in Slovakia by studying the coarse-grained soils of another genesis.

3-D geotechnical modelling contributing to the risk management in a road construction project - a case study

Modélisation géotechnique tridimensionnelle contribuant à la gestion des risques dans un projet de construction routière - une étude de cas

ABSTRACT: A case study of reliable 3-D geotechnical modelling based on drilling and geophysical survey data is presented. In this study, the distribution of a soft alluvial clay deposit having the risk of consolidation/deformation/subsidence was required for a new road planning. It was first estimated based only on drilling data. Then, a 2-D microtremor survey was conducted for more detailed modelling and resulted in the detection of a deeply buried valley filled with soft sediments, which have potential risks. The buried valley was confirmed by the additional drilling. The scale and direction were detected using a 3-D microtremor array measurement. The direction of the buried structure was oblique to the planning line of the road. It means that only drilling and a geophysical survey in 2-D were insufficient, and a 3-D survey was necessary to capture the geometry of the buried structure. These investigation results have been reflected in the 3-D geotechnical model. This study demonstrated the effectiveness of the geophysical survey for geotechnical modelling. The updated model, including the risk information, can be handed over to the owner and designers and planned to be used as a BIM model.

RÉSUMÉ: Une étude de cas de modélisation géotechnique tridimensionnelle fiable basée sur des données de forage et d'étude géophysique est présentée. Dans cette étude, la distribution d'un dépôt d'argile alluviale molle présentant un risque de consolidation/déformation/affaissement était nécessaire pour la planification d'une nouvelle route. Elle a d'abord été estimée sur la base des seules données de forage. Ensuite, une étude de microtremor 2-D a été menée pour une modélisation plus détaillée et a permis de détecter une vallée profondément enfouie remplie de sédiments mous, qui présentent des risques potentiels. La vallée enfouie a été confirmée par des forages supplémentaires. L'échelle et la direction ont été détectées à l'aide d'un réseau de mesure microtremor tridimensionnel. La direction de la structure enfouie était oblique par rapport à la ligne de planification de la route. Cela signifie que le forage et l'étude géophysique en 2−D étaient insuffisants et qu'une étude en 3-D était nécessaire pour saisir la géométrie de la structure enfouie. Les résultats de cette étude ont été pris en compte dans le modèle géotechnique tridimensionnel. Cette étude a démontré l'efficacité de l'étude géophysique pour la modélisation géotechnique. Le modèle mis à jour, y compris les informations sur les risques, peut être remis au propriétaire et aux concepteurs et il est prévu de l'utiliser comme modèle BIM.

Keywords: 3-D geotechnical model; geophysical survey; 3-D microtremor array measurement; risk information; BIM.

1 INTRODUCTION

Geological and geotechnical model of the underground plays an important role throughout all the phases of a construction project and is relevant for decisions and design solutions. This is because some types of risks are associated with geological conditions and uncertainties of predicting the ground conditions and have a significant impact on the cost of construction projects (Anan, 2021). However, in Japan, there have been a number of accidents during and after construction due to the models that does not satisfactorily represent geological/geotechnical uncertainties and risk information, or the underestimation of information by designers and builders (PWRI, 2017).

BIM (Building Information Modelling) is a process to achieve the improvement in productivity, safe construction, quality control and reduction of total cost over the lifecycle of a structure. BIM has been partly mandatory for public works since 2023 in Japan. In this process, digital models consisting of physical representations of the shape of the objects and semantics, like functions, dimensions, strength, and price, are created and shared to support decision-making and management from planning through design to construction and operation. Recommended data exchange standards for BIM have been

established by buildingSMART International (bSI), a non-profit international organization, and those for geotechnical data are under development (Rives, 2023). Demonstrations of various successful examples of risk management using 3-D geotechnical modelling can help to reduce the number of accidents caused by geotechnical conditions during the life of a structure and promote BIM in the geotechnical field.

In this paper, we present an example of successful risk management in road construction work in which a combination of borehole surveys and geophysical exploration resulted in a more reliable model, which in turn contributed to reducing the risk of rework and accidents in the projects.

2 PROJECT OVERVIEW

A new bypass was planned to run straight through a winding valley in a lowland where there are agricultural fields and residential areas. The construction of road embankments and soil reinforcement walls was planned in some sections of the bypass, and the site investigations were carried out for the preliminary design in order to reveal the distribution and thickness of the soft alluvial deposits such as cohesive and humic soils.

The survey locations are shown in Figure 1 and the survey sequence is shown in Figure 2 (Ito et al., 2023). First, two boreholes were drilled in each of the areas A and B shown in Figure 1. Then, 2-D microtremor surveys were conducted to evaluate the geotechnical conditions around two boreholes.

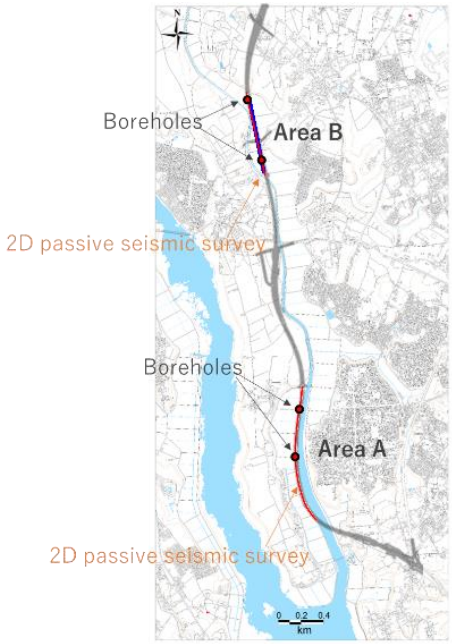

Figure 1. The survey locations.

In Area A, the geophysical survey detected a valley-shaped concavity with low-velocity, so additional drilling and a 3-D microtremor array measurement (Hayashi et al., 2021) were carried out to determine its detailed 3-D structure, following the flow shown in Figure 2.

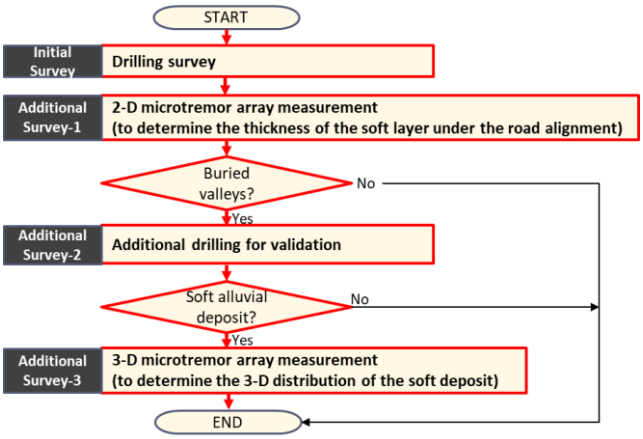

Figure 2. The survey sequence.

3 SURVEY RESULTS AND ESTIMATION OF UNDERGROUND STRUCTURE

The results of the investigation in Area A, where the buried valley was found, are described in detail. The locations of the boreholes, 2D and 3D geophysical surveys in Area A are shown in Figure 3 (Ito et al., 2023).

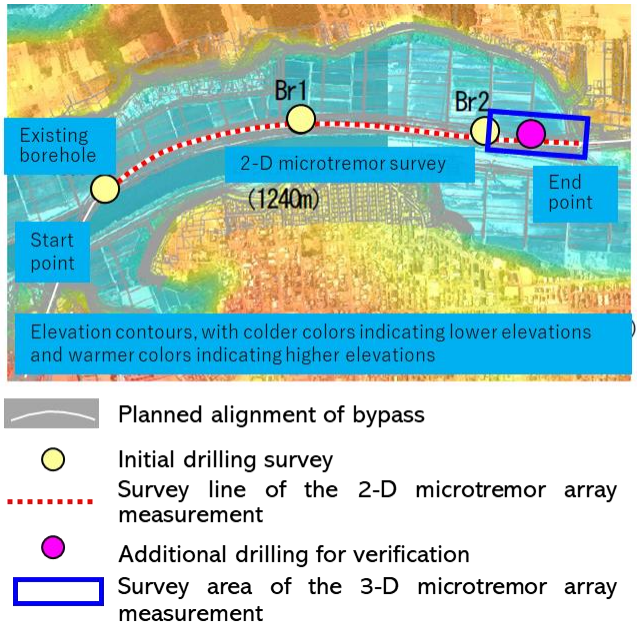

Figure 3. The survey locations in Area A.

The thickness of the soft alluvial deposits, shown in light blue, decreases towards the end of the cross-section (right side), as shown in Figure 4(a). Next, a 2-

D microtremor survey was carried out. The obtained S-wave velocity cross-section is shown in Figure 4(b). The relationship between N-value and S-wave velocity (Vs) suggests that Vs less than 100 m/s corresponds to alluvial layers, and the geological cross-section estimated on this basis is shown in Figure 4(c). A buried valley was expected to exist in the area in concave shape with a low S-wave velocity, where the stiff ground consisting of diluvial sand had been estimated in Figure 4(a). A borehole survey was therefore carried out at the location for verification. The results showed that the depression was filled with alluvial clay with an *N*-value close to 0-1, demonstrating the existence of a buried valley as shown in Figure 5. A 3-D geotechnical model was constructed based on the results of the investigations up to that point, as shown in Figure 6(a) and (b).

A 3-D microtremor survey was then carried out in the area indicated by the blue rectangle in Figure 3 to reveal the 3-D geometry of the buried valley and to accurately determine the extent of the ground improvement.

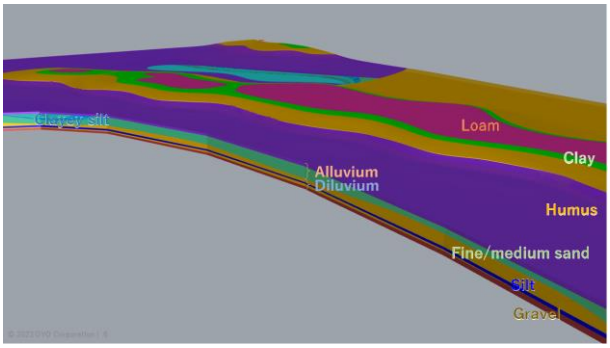
(a) The surface model of each layer.



(b) The solid model.

Figure 6. The 3-D geotechnical model of entire survey area of the project.

The distribution of depths at Vs = 80 m/s estimated from the 3-D velocity model is shown in Figure 7. The survey result indicated that the direction of the buried valley would intersect the planned road. Since this direction agrees with the distribution of the floodplain of the small river, it could be an old river channel. Based on this result, the 3-D geotechnical model was updated for use in the design.

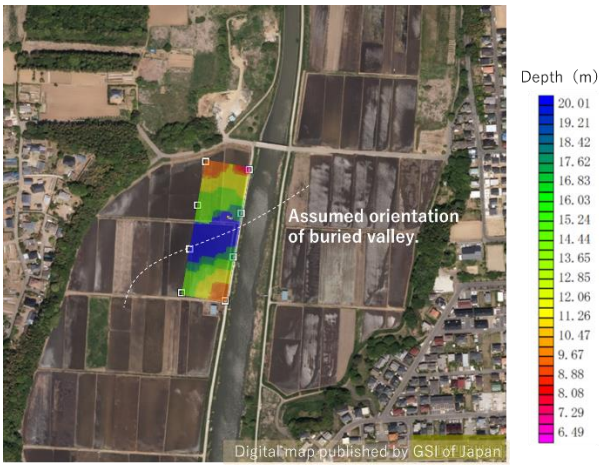


Figure 7. The distribution of depths at Vs = 80 m/s by 3-D microtremor survey.

4 CONSIDERATION

In this project, borehole investigations were combined with geophysical surveys in order to obtain continuous and accurate information on the subsurface in and around the vicinity of the linear structure. The detection of the buried valley filled with soft alluvial deposit resulted in a reduction in the risk of business such as unequal settlement after road fill construction, pavement cracks and their countermeasures. The 3-D model of the survey results also makes it easier to visually understand the positional relationship between the structure, ground conditions and potential risks, and simplifies communication and risk sharing between the parties involved.

One of the difficulties of applying geotechnical models in BIM is that models cannot be treated as a whole, as they are interpreted models and contain uncertainties, whereas the structure model shows the substance. Improving the reliability of geotechnical models by considering the results of geophysical surveys would contribute to the application and spread of geotechnical models in BIM.

5 CONCLUSIONS

The combination of borehole investigations and geophysical surveys detected a buried valleys that was not identified by borehole investigations alone. It resulted in a reduction in project risks such as rework during construction and unequal settlement and deformation of structures after construction. Furthermore, the improved reliability of the geotechnical model incorporating geophysical exploration must contribute to the application and dissemination of the geotechnical model in BIM.

ABSTRACT: In the context of the Grand Paris Express (GPE) metro project, a large number of pressuremeter tests were collected to improve knowledge of subsoil properties and to design underground structures. Despite the standardized nature of pressuremeter testing, many factors can influence the quality and reliability of the results. This article proposes a multi-criteria analysis methodology to assess the reliability of pressuremeter tests by calculating a reliability index for the pressuremeter modulus. Applying the evaluation process to 300 GPE pressuremeter tests, we classify them into different rating groups, identify suspicious tests and establish characteristic curves that can be extremely useful to the geotechnical profession.

RÉSUMÉ: Dans le cadre du projet de métro du Grand Paris Express (GPE), un grand nombre d'essais pressiométriques ont été collectés afin d'améliorer la connaissance des propriétés du sous-sol et dans un but de conception des ouvrages souterrains. Malgré la procédure standardisée de l'essai pressiométrique, de nombreux facteurs peuvent influencer la qualité et la fiabilité des résultats. Ainsi, une méthodologie d'analyse multicritères est proposée dans cet article afin d'évaluer la fiabilité des essais pressiométriques en calculant un indice de fiabilité du module pressiométrique. L'application du processus d'évaluation à 300 essais pressiométriques du GPE permet une classification en différents groupes de notations, l'identification des essais suspicieux et l'établissement de courbes caractéristiques qui peuvent s'avérer être très utiles à la profession géotechnique.

Keywords: Pressuremeter test; pressuremeter modulus; Reliability index; characteristic curves.

1 INTRODUCTION

In the context of large-scale underground projects such as the Grand Paris Express (GPE), a huge amount of data is collected to better characterize the underground, design structures and minimize risks. Within these high-volume databases, the quality and reliability of the data is very often heterogeneous, and it is not always easy to identify the suspicious data.

In engineering geology, it is common practice to establish borehole quality assessment systems to screen out poor-quality boreholes (Gunnink et al., 2013; Jørgensen et al., 2015). Nevertheless, concerning geotechnical information and more specifically pressuremeter testing, reliability rating systems are scarce or even absent.

The aim of the work presented in this paper is to develop and propose a reliability rating system for pressuremeter testing, a highly strategic geotechnical test for underground projects such as the GPE.

First, a description of the pressuremeter test and the pressuremeter data available is given. A step-by-step presentation of the multi-criteria pressuremeter modulus evaluation system is then undertaken and applied to 300 tests from a specific sector of the GPE. Finally, the reliability results obtained are analyzed, and characteristic curves for pressuremeter modulus reliability are presented.

2 PRESSUREMETER TEST AND AVAILABLE DATA

2.1 Pressuremeter test and parameters

Firstly introduced by Louis Ménard in 1955, the pressuremeter test is a static loading *in-situ* test in soil, in which a cylindrical probe is expanded in a borehole to measure the expansion of the borehole wall due to the pressure applied by the probe (Gambin et al., 2005). It has the advantage of characterizing both soil deformability and rupture. This distinction enables it to provide an estimate of soil properties for geotechnical studies (Clarke, 1994), while also being useful for the design of geotechnical structures (Arscop, 2023).

The pressuremeter test is performed by applying a loading program that progressively expands the pressuremeter probe within the borehole in successive pressure steps. The pressures applied to the wall and the volumes injected into the probe are recorded at 30 and 60s to construct two curves: the pressuremeter curve for volume variations at 60s as a function of applied pressures (Figure 1, blue curve) and the creep curve, plotting the volume variation measured between 30 and 60s at pressure steps (Figure 1, orange curve). Analysis of both experimental test curves should enable us to distinguish three distinct phases: contact between the pressuremeter probe and the borehole wall, the pseudo-elastic phase and the plastic phase. Test curves can be used to determine two main soil parameters:

- The pressuremeter modulus Em: derived from the pseudo-elastic phase;
- The limit pressure Pl: determined from the plastic phase.

These soil parameters are very useful for tunnel design (e.g. dimensioning), characterization of the spatial variability of the soils crossed (e.g. geostatistical interpolation, see Lachérade et al. 2023) and risk analysis (e.g. settlement prediction).

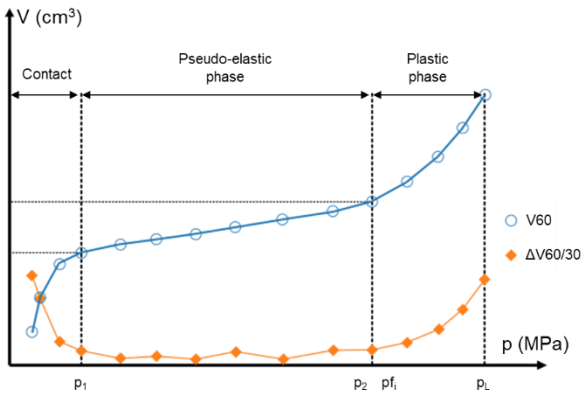

Figure 1. Representation of pressuremeter test results.

2.2 Available pressuremeter data

This study focuses on a specific sector of the Grand Paris Express project. Within the framework of this tunneling project, more than 6,000 pressuremeter tests were carried according to the European standard NF EN ISO 22476-4. Preliminary checking test are used to identify suspicious tests and eliminate outliers (Thierry et al., 2009; Dong et al., 2015, Lachérade et al., 2023). However, these controls are insufficient to detect all unreliable assays. This is the case, for example, with Plastic Clays, whose swelling behavior can result in Em values of a satisfactory order of magnitude when, in reality, the Em given is not correctly determined (Bergere and Ropers, 2018). These findings raise the need to better quantify the reliability of pressuremeter parameters. For this purpose, in this study we have chosen to focus on the Em.

3 METHODOLOGY OF RELIABILITY ASSESSMENT

Reliability criteria are established from the recommendations for good practice in pressuremeter testing provided by standard NF EN ISO 22476-4. For the Em, the criteria are determined by checking the content of the test reports, and in particular the pressuremeter/creep curves, more specifically the contact phase and the pseudo-elastic one (cf. §2.2.). Each criterion is scored binary according to its achievement, with two possible combinations: (0)/(+1) or (-1)/(0) depending on the criterion's positive or negative impact.

The general shape of the test to be assessed must first be analyzed to determine whether or not assessment can be started. If the test shows a pressuremeter curve with large variations in volume at low pressures, it is classified as incorrect, rejected and the rating process is not started.

The contact phase, which determines the quality and reliability of the parameters determined later, covers 4 criteria:

- Significant increase in volumes at 60s (V60) on first pressure steps (+1);
- High creep values (ΔV60/30) (> 5 cm³) with a peak at the beginning of the curve (+1);
- Contact made in a single step (+1);
- The p1 point, which materializes the transition to the pseudo-elastic phase, if found on the first step, means that the contact phase is not distinguished (-1).

The pseudo-elastic phase combines 6 criteria:

- Visible linear part, progressive evolution of volume with pressure increase (+1);
- Number of steps >= 2 (+1);
- End of linear part materialized by p2, if not before the beginning of the increasing part (-1);
- Operator indicates doubtful Em (-1);
- Creep low and close to 0 with +50% bearings with creep less than 10 cm^3 (+1);
- Recurrent negative creep (i.e., +50% steps < 0 cm^3) (-1).

These criteria are grouped together to create a pressuremeter module reliability rating scale (Figure 2), which results in a maximum Em rating of 6 points.

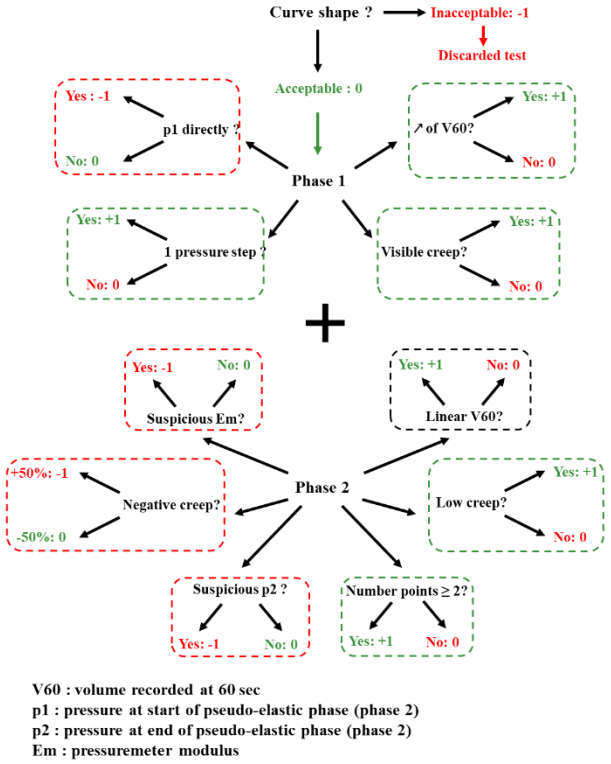

Figure 2. Pressuremeter modulus rating system workflow.

4 RELIABILITY RESULTS AND ABACUSES

4.1 Reliability results

The rating scale is applied manually to 300 tests randomly selected on the metro line, in order to check the consistency of the rating system and analyze the scores obtained.

The range of scores is from 2 to 6, and the distribution of the 300 tests within the scores is shown in Table 1. The reliability index for Em scores corresponds as follows:

- Em score = 2: very unreliable Em;
- Em score = 3: not very reliable Em;
- Em score = 4: moderately reliable Em;
- Em score = 5: reliable Em;
- Em score = 6: very reliable Em.

Tests with an "extreme" Em reliability rating, i.e. very unreliable and very reliable, are poorly represented, with proportions of 6.7% and 7% respectively. If scores 2 and 3 are combined to form a single unreliable score, and scores 5 and 6 to form a reliable score, then 33% of tests are unreliable and 44% reliable.

Table 1. Number of tests within reliability scores.

	Score 2	**Score 3**	**Score 4**	**Score 5**	**Score 6**
Proportion	6.7%	26.3%	22.7%	37.3%	7%

An example of a test for score Em = 3 and score Em = 6 is shown in Figure 3. A high degree of heterogeneity is observed between the pressure and creep curves for both scores. The contact phase is very well represented on score Em = 6 which is not the case for score Em = 3. Based on these observations of heterogeneity on individual tests, the relevance of developing a system of characteristic curves per note is raised.

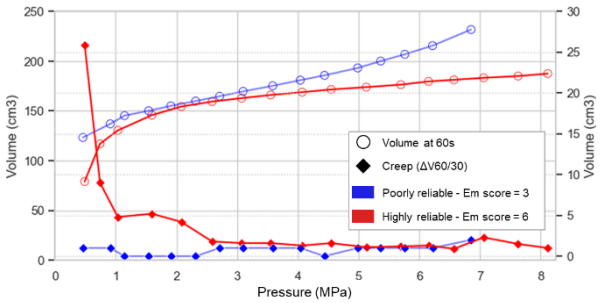

Figure 3. Experimental curves examples of tests of poor reliability (Em score = 3) and high reliability (Em score = 6).

4.2 Characteristic curves

Characteristic curves are built independently for each Em score group by dividing the 300 tests into their respective score groups. Three main steps are involved in constructing the characteristic curves:

- A min-max normalization of pressures and volumes;
- Homogenization and densification of pressure levels to obtain 100 steps of regular increments;
- Aggregation of curves by score group.

The results of the process of constructing characteristic curves by note group are shown in Figure 4. The differences between the curves for each note are clearly shown for both V60 and ΔV60/30.

Characteristic curves of low reliability (Em scores = 2 and 3) show no vertical part on the first part of the V60 curve and have a non-linear second part on pressure close to 1, meaning that the plastic phase has undoubtedly already begun. With regard to ΔV60/30, the creep peak normally expected at the start of the test is not always observed, and creep is not low during the pseudo-elastic phase. The opposite is true of curves with good reliability (Em rating = 5 and 6). The Em = 4 curves, perfectly localized between the two groups described, offer intermediate reliability. These characteristic curves can be a powerful tool for quickly assessing the reliability of a test by superimposing its standardized test curves.

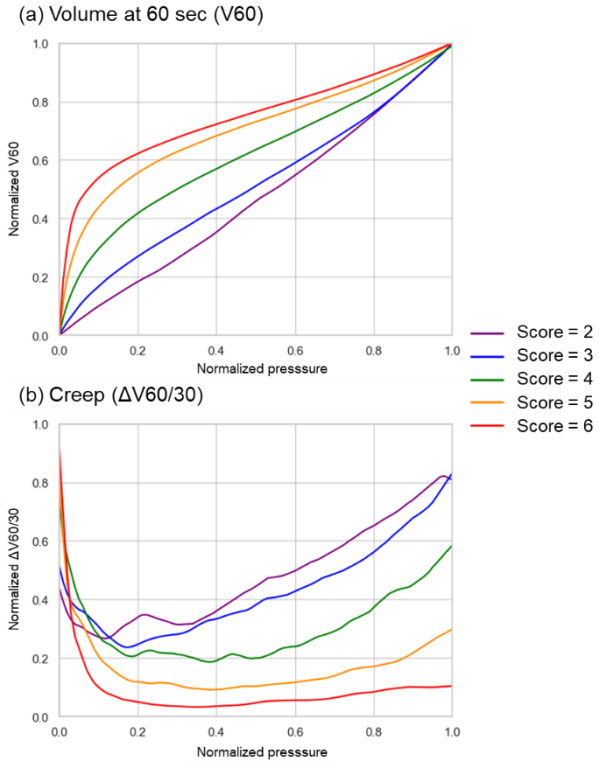

Figure 4. Characteristic curves for normalized (a) Volume at 60 sec (V60) and (b) Creep (ΔV60/30).

5 CONCLUSION

The aim of this study was to develop a system for assessing the reliability of Em from pressuremeter testing. This was achieved through the presentation of a multi-criteria scoring approach, which results in a reliability score for the pressuremeter modulus Em. Applying the evaluation process from 300 pressuremeter tests collected on a section of the Grand Paris Express, we were able to provide an overview of test reliability on the overall scale of the metro line. The results highlight the heterogeneity of test reliability, with a significant proportion of tests considered unreliable: 43% reliable and 33% unreliable. The scoring results have also been used to build characteristic curves for each group of scores, which can be assimilated to reliability "abacuses".

Prospects for improvement have been identified, in particular by extending the scoring system to the plastic phase of the pressuremeter test, in order to obtain a limit pressure rate. The time-consuming of the notation method also prompts reflection on automating the process, to help generalize it to new data. Questions are also being raised about the integration of reliability information into the geotechnical design and risk analysis processes. Finally, with regard to the characteristic curves, a study on the influence of the lithology may prove useful, as despite the diversity of the geological units represented by the selected tests, their distribution within them is not homogeneous.

ACKNOWLEDGEMENTS

We would like to thank the Société du Grand Paris for the access to its database and the interest shown in this work, as well as the Bureau de Recherches Géologiques et Minières (BRGM) for its financial support for this research project.

ABSTRACT: Tailings dam failures are one of the most destructive phenomena, both in terms of number of victims and of generated environmental impact. Over the years, different causes have been identified, with flow liquefaction being a prominent factor to consider when assessing the stability of tailings deposits. Due to the complexity of these events, numerical models are crucial for the analysis and design phases, where appropriate advanced soil constitutive models must be selected to reproduce the relevant features of the soil behaviour. In this paper, the Clay And Sand Model (CASM), originally proposed by Yu (1998) and later modified by Arroyo and Gens (2021) and Manica et al. (2021), has been adopted for the simulation of flow liquefaction of tailings deposits. The model incorporates the state parameter concept (Been and Jefferies, 1985) and has been implemented as a User-Defined Soil Model (UDSM) into the finite element code PLAXIS; thereby, it becomes generally applicable to a wide range of geotechnical applications. Due to its versatile yield surface and plastic potential formulations, CASM can be used to model the behaviour of a wide range of soils, from fine-grained (e.g., clays) to coarser-grained soils (e.g., silts and sands). This paper shows the capability of the model, as well as the robustness of the finite element formulation, to reproduce the soil flow liquefaction observed in boundary value problems.

RÉSUMÉ: Les ruptures de barrages de résidus miniers sont l'un des phénomènes les plus destructeurs, tant en termes de nombre de victimes que d'impact environnemental généré. De différentes causes ont été identifiées, parmi eux la liquéfaction statique étant un facteur important pour l'évaluation de la stabilité des dépôts de résidus miniers. En raison de la complexité de ces événements, les modèles numériques sont cruciaux pour les phases d'analyse et de dimensionnement, où des modèles constitutifs avancés doivent être utilisés pour reproduire les caractéristiques pertinentes du comportement du sol. Dans cet article, le Clay And Sand Model (CASM), proposé originalement par Yu (1998) et modifié par Arroyo et Gens (2021) et Manica et al. (2021), a été adopté pour la simulation de la liquéfaction statique des résidus miniers. Le modèle intègre le concept de paramètre d'état (Been et Jefferies, 1985) et a été implémenté en tant que User-Defined Soil Model (UDSM) dans le code des éléments finis PLAXIS; de ce fait, il devient généralement applicable à un grand nombre d'applications géotechniques. Grâce à la flexibilité de la formulation de la surface de charge et du potentiel plastique, CASM peut être utilisé pour modéliser le comportement de plusieurs types de sols, des sols à grain fin (comme les argiles) aux sols à grain plus grossier (comme les limons et les sables). Cet article montre la capacité du modèle, ainsi que la robustesse de la formulation par éléments finis, à reproduire la liquéfaction statique du sol observée dans les structures géotechniques.

Keywords: CASM; flow liquefaction; static liquefaction; tailings dams.

1 INTRODUCTION

Over the last 50 years, several failures of tailings facilities have been recorded around the world, resulting in hundreds of fatalities, and damage to infrastructures and environment. Static (or flow) liquefaction has often been identified as either the main cause of failure, as in the case of the Fundão tailings dam (Morgenstern et al., 2016), or as the major contributor to the devastating consequences of failure, as in the case of the Aznalcóllar dam (Alonso and Gens, 2006). The mechanism underlying flow liquefaction is undrained softening, which occurs when the soil undrained strength reduces significantly after a peak (instability point). This phenomenon is observed in tailings and, more in general, in hydraulic fills that are deposited in a loose state, and may be caused by different triggering mechanisms, such as undrained loading, drained lateral stress reduction, or a change in the hydraulic conditions.

To back-analyse known failure events, evaluate the status of existing tailings dams, or design new tailings facilities, advanced numerical analysis accounting for large deformations, soil non-linearity and softening should be performed. A key element in the numerical simulation of flow liquefaction is the choice of the constitutive model. The Clay And Sand Model (CASM) has been developed by Yu (1998) in the framework of Critical State Soil Mechanics (Schofield and Wroth, 1968) as a versatile constitutive model able to simulate the behaviour of both clays and sands. CASM can simulate static liquefaction and has been successfully employed to analyse the Brumadinho (Arroyo and Gens, 2021) and Merriespruit dam failures (Mánica et al., 2022).

CASM has been implemented as a User-Defined Soil Model (UDSM) in PLAXIS (Bentley Systems Inc, 2023). Compared to the original formulation, this version of CASM includes Lode's angle dependency, an alternative plastic potential equation (Arroyo and Gens, 2021) and the possibility to use it as either a rate-independent plastic model or as an elasto-viscoplastic model accounting for time-dependency (Manica et al., 2021).

In this paper, the Tar Island Dyke failure (Plewes et al., 1989) has been chosen as a case study to be modelled using the rate independent CASM model. After describing the constitutive equations, the finite element model is presented together with the strategy adopted to calibrate the model parameters and the results of the numerical analysis.

2 CONSTITUTIVE EQUATIONS

In the following, soil mechanics convention is used, i.e. stresses are positive in compression. Vectorial and tensorial quantities are denoted in bold, while scalars are in normal character.

2.1 Main concepts

As in the classical elasto-plasticity theory, the total strain rate is decomposed into an elastic $\dot{\boldsymbol{\varepsilon}}^{\boldsymbol{e}}$, and a plastic part $\dot{\boldsymbol{\varepsilon}}^{\boldsymbol{p}}$:

$$\dot{\boldsymbol{\varepsilon}} = \dot{\boldsymbol{\varepsilon}}^{\boldsymbol{e}} + \dot{\boldsymbol{\varepsilon}}^{\boldsymbol{p}} \tag{1}$$

Both strain rate tensors consist of a volumetric part $\dot{\varepsilon}_v$, and a deviatoric part $\dot{\boldsymbol{e}}$:

$$\dot{\boldsymbol{\varepsilon}} = \frac{1}{3}\dot{\varepsilon}_v\boldsymbol{\delta} + \dot{\boldsymbol{e}} \tag{2}$$

where $\boldsymbol{\delta}$ is the second-order identity tensor.

Similarly, the effective stress tensor $\boldsymbol{\sigma'}$ can be decomposed into a hydrostatic part p', and a deviatoric part $\boldsymbol{s}$:

$$\boldsymbol{\sigma'} = \frac{1}{3}p'\boldsymbol{\delta} + \boldsymbol{s} \tag{3}$$

The model has been derived from a reformulation of the original Cam-Clay model in terms of the state parameter ξ, defined as the difference between the specific volume υ at the current state and the specific volume on the critical state line at the same mean pressure p'. A positive value of the state parameter indicates a loose material that, under shearing, shows a volume contraction in drained conditions or an increase in pore pressure and a reduction of p', leading to flow liquefaction, in undrained conditions. The distance between the critical state line (CSL) and the reference consolidation line corresponds to the reference state parameter ξ_R.

2.2 Model formulation

CASM adopts a general stress-state relation to describe the yield surface for a variety of soils:

$$f = \left(\frac{q}{M_\theta p'}\right)^n + \frac{\xi}{\xi_R} - 1 \tag{4}$$

where q is the deviatoric stress, n is a parameter that controls the shape of the yield function, and M_θ is the stress ratio at critical state, dependent on Lode's angle θ according to (Sheng et al., 2000):

$$M_\theta = M\left(\frac{2\alpha^4}{1+\alpha^4+(1-\alpha^4)\sin 3\theta}\right)^{1/4} \quad (5)$$

In Equation 5, M is the critical stress ratio in triaxial compression and α is a parameter controlling the shape of the yield function in the deviatoric plane, both depending on the friction angle φ:

$$M = \frac{6\sin\varphi}{3-\sin\varphi}; \qquad \alpha = \frac{3-\sin\varphi}{3+\sin\varphi} \quad (6)$$

Finally, $\sin 3\theta$ is equal to:

$$\sin 3\theta = -\left(\frac{3\sqrt{3}}{2}\frac{J_3}{J_2^{3/2}}\right) \quad (7)$$

where J_2 and J_3 are the second and third invariant of the deviatoric stress tensor $\boldsymbol{s}$, respectively.

In the model implementation, it is preferred to use an alternative equivalent equation for the yield surface:

$$f = \left(\frac{q}{M_\theta p'}\right)^n + \frac{1}{\ln r}\ln\frac{p'}{p'_0} \quad (8)$$

where r is the spacing ratio and p'_0 is the preconsolidation pressure (Figure 1).

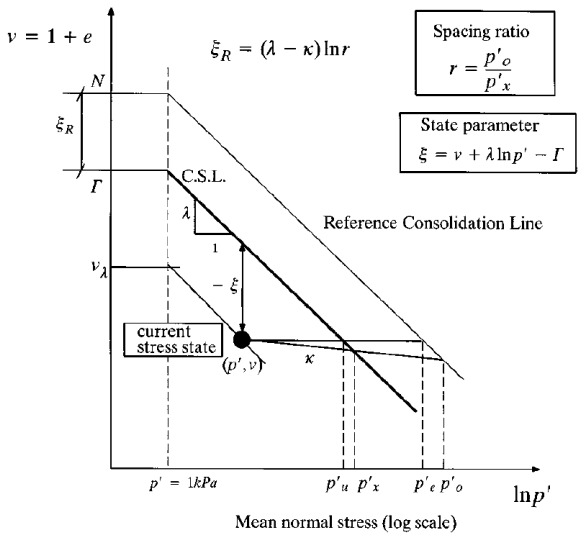

Figure 1. Definitions of state parameter, critical state constants, and reference state parameter (Yu, 1998).

Inside the yield surface, the behaviour is elastic and isotropic, defined by the bulk stiffness K', and the shear stiffness G. K' depends linearly on the mean effective pressure p', while G is a function of the bulk modulus and the coefficient of Poisson ν' (constant):

$$K' = \frac{p'(1+e_0)}{\kappa}; \qquad G = \frac{3(1-2\nu')}{2(1+\nu')}K' \quad (9)$$

where e_0 is the initial void ratio and κ is the slope of the swelling line in the ($\ln p'$, υ) space.

Instead, the plastic strains are calculated based on a non-associated flow rule. The plastic potential g can be described by either the original equation derived from Rowe's stress-dilatancy relationship (Rowe, 1962), or by the one introduced by Arroyo and Gens (2021), overcoming the limitations of the first one for stress paths with low stress ratios. The latter (Eq. 10) has been adopted in this paper:

$$g = \left(\frac{q}{M_\theta p'}\right)^m + m - \frac{p'_c(m-1)}{p'} - 1 \quad (10)$$

where m is a parameter controlling the shape of the plastic potential and p'_c must be solved for the current stress state such that the plastic potential passes through it.

Finally, the same isotropic volumetric hardening rule as in the Cam-Clay models is adopted:

$$\dot{p}'_0 = \frac{\upsilon\,\dot{\varepsilon}_v^p}{\lambda-\kappa}p'_0 \quad (11)$$

where λ is the slope of the CSL and reference line in the ($\ln p'$, υ) space, and $\dot{\varepsilon}_v^p$ is the plastic volumetric strain increment.

3 FINITE ELEMENT MODELLING OF THE TAR ISLAND DYKE

The Tar Island Dyke is a tailings structure built to retain sand tailings for the Suncor oil sand mine in Canada. Plewes et al. (1989) describe that, after an initial construction phase with the centreline method, the upstream construction method with compacted sand has been used for the subsequent phases. Adjacent to it, sand beaches were formed by discharging tailings from the upstream dyke crest.

Failure events of different entities have been registered during the construction, with the largest one occurring in 1974 due to flow liquefaction. When this slump occurred, a compacted cell 12.8 m high and about 36 m wide with a front slope of 1V:1H, was being placed on an approximately 9 m thick layer of loose sand recently deposited. The cell was placed in five lifts over the period from May 14 to August 22, 1974. During the construction of the first four lifts, no failure signals were observed, while the slump started near the completion of the last lift when the final compaction works were being carried out. The compacted cell did not liquefy and behaved as a rigid slab, while the beach sand below the cell liquefied and flowed out into the pond, generating a rapid failure. According to Plewes et al. (1989), the increased

construction rate and the considerable height of the compacted cell may have been the reasons for inducing static liquefaction.

The geometry of the model is shown in Figure 2, with the water table indicating the pond level on the upstream and falling within the dyke due to the downstream drainage system (Shuttle et al., 2021b). The bottom of the model is fully fixed, while the two lateral boundaries are normally fixed.

The finite element model has been discretised using a very fine mesh with 15-noded triangular elements, and with different degrees of local mesh refinement where significant changes in stresses and strains are expected during the analysis (i.e. in the loose beach sand below the compacted cell).

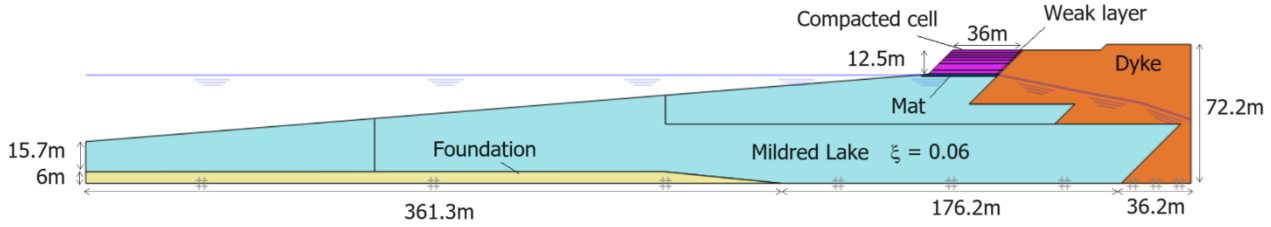

Figure 2. Model geometry in PLAXIS 2D.

The compacted dyke embankment, the compacted cell and the foundation layer have been modelled using drained Mohr-Coulomb model (Table 1).

Table 1. Parameters values for Mohr-Coulomb model.

γ_{unsat}	γ_{sat}	G	ν'	c'	φ'
18.6	19.6	33.3	0.2	5	48
kN/m^3	kN/m^3	MPa	-	kPa	°

For the foundation layer, an increased stiffness (G equal to 80 MPa) and strength (cohesion equal to 1 MPa) were assumed to simulate a rigid bedrock. The influence of a tension crack was considered by including a weak layer in between the compacted cell and the dyke, with a tension cut-off of 10 kPa and a friction angle of 5° (Shuttle et al., 2021b).

In this paper, the beach sand is assumed to consist entirely of loose material, modelled using CASM with a state parameter ξ of 0.06, while the mat at the bottom of the compacted cell consists of the same material but characterised by ξ equal to -0.1 (Shuttle et al., 2021b).

Since there were no investigations at that location at the time, Shuttle et al. (2021b) have selected the Mildred Lake data among test results available for tailings from existing mines in the area, determining the slope λ equal to 0.02826, the specific volume Γ of the CSL at a mean effective stress of 1 kPa equal to 1.89, and the stress ratio M equal to 1.29, i.e. a friction angle of about 32°. Additionally, the value of κ has been estimated equal to 0.004, based on the experimental data reported by Shuttle et al. (2021b).

The remaining model parameters characterising the shape of the yield surface and of the plastic potential should be calibrated based on laboratory tests. However, no tests are available for loose Mildred Lake material, which would be required for the calibration of CASM in problems involving flow liquefaction. For this reason, the calibration of the CASM parameters has been performed comparing the triaxial tests simulation results with those obtained with the NorSand (Jefferies, 1993) data set calibrated for the same application (Shuttle et al., 2021b). This results in a value of 20.4 for the spacing ratio r, 2 for n and 2.05 for m.

The initial stress state is generated assuming a coefficient of earth pressure at rest K_0 equal to 0.6, based on self-bored pressuremeter data at other tailings facilities, representing the case of normally consolidated tailings (Shuttle et al., 2021a, Shuttle et al., 2021b). The CASM parameters values are summarised in Table 2.

Table 2. CASM parameters values.

γ_{unsat}	γ_{sat}	λ	κ	ν'	φ
18.6	19.6	0.02826	0.004	0.2	32
kN/m^3	kN/m^3	-	-	-	°
n	r	m	Γ	ξ	K_0
2	20.4	2.05	1.89	0.06	0.6
-	-	-	-	-	-

The numerical analysis consists of six phases. In this study, we focus on reproducing the reported failure during the construction of the last tailings layer of which the increased of construction rate (Plewes et al., 1989) might be a contributing factor to flow liquefaction. Therefore, after the stress initialisation, the first four compacted layers are built in drained conditions, while the last one is built in undrained conditions. Considering the large strains expected in flow liquefaction problems, large deformation theory is taken into account in the construction phases through the Updated Lagrangian formulation (Bathe, 1982). Additionally, the arc-length control procedure

is adopted to improve the robustness of the analysis when dealing with failure in non-linear problems.

Three stress points have been selected to show the stress path evolution in the last phase, at the locations shown in Figure 3.

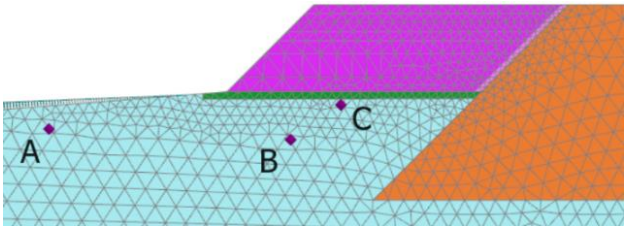

Figure 3. Selected stress points.

4 RESULTS

The first four construction stages are completed successfully while failure is detected during the activation of the top layer in undrained conditions.

During the last phase, prior to the occurrence of liquefaction, very small values of the deviatoric strain increment (in the order of 10^{-3}) are shown in Figure 4a. As expected, at the same step, the state parameter is positive in the loose beach sand, ranging from 0.04 to 0.06, approximately (Figure 4b).

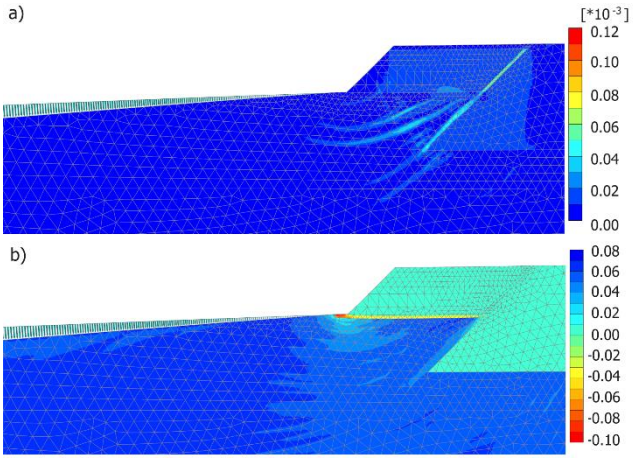

Figure 4. Contours prior to liquefaction occurrence: a) Deviatoric strain increment; b) State parameter.

In a subsequent step, shear bands develop (Figure 5a), along which the value of the state parameter approaches zero (Figure 5b), indicating that flow liquefaction has occurred.

Finally, at a later stage of liquefaction propagation, the deviatoric strain increment contours show multiple shear bands that extend to larger areas in the beach sand below the cell (Figure 6a). The state parameter is approximately zero in the same area (Figure 6b), showing that critical state has been reached. At the same step, the total displacement contours (Figure 6c) show that the compacted cell moves downwards, and that the depth of the collapsing mechanism extends to about 30 m below the cell.

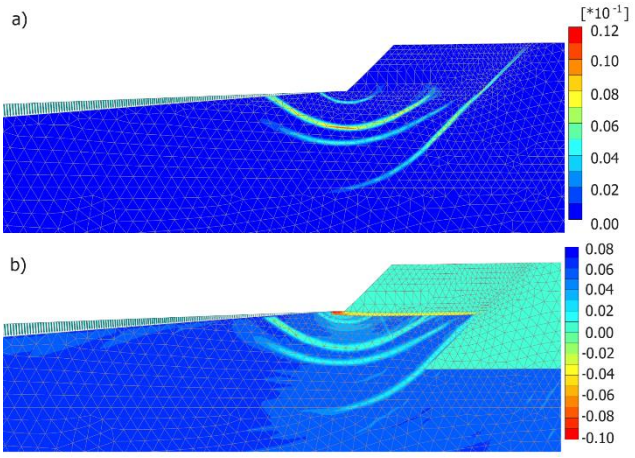

Figure 5. Contours at an early stage of liquefaction propagation: a) Deviatoric strain increment; b) State parameter.

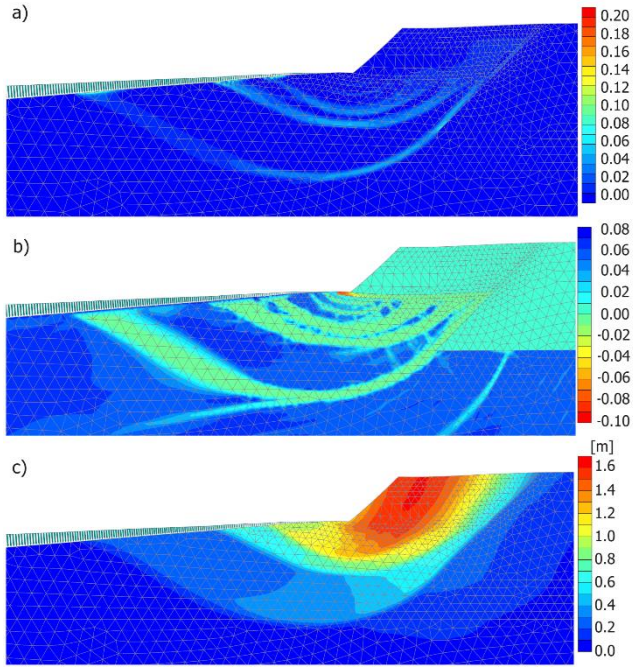

Figure 6. Contours at a later stage of liquefaction propagation: a) Deviatoric strain increment; b) State parameter; c) Total displacements.

A sharp decrease in terms of both deviatoric stress and mean pressure is observed along the shear bands, as shown by plotting the stress paths of the preselected stress points (Figure 7a). Starting from a relatively high value of p' and q, both stresses reduce, even to a value close to zero for point A, and reach the critical state line with a typical path indicating flow liquefaction. In the stress-strain plot (Figure 7b), undrained softening can be observed after a peak deviatoric stress is reached in each point.

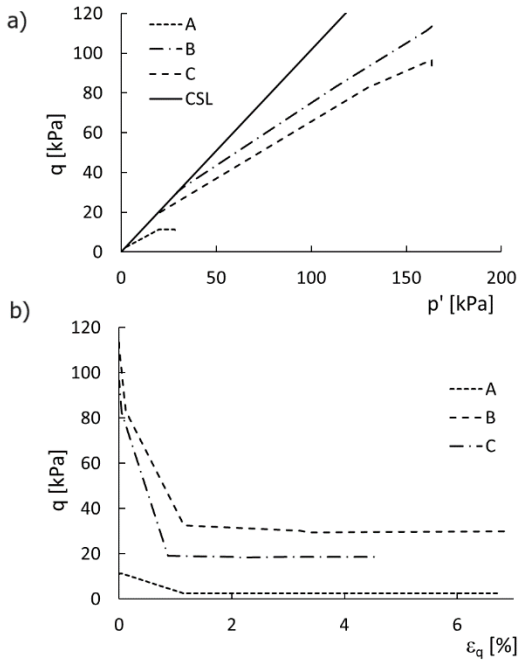

Figure 7. Results in preselected stress points: a) Stress paths; b) Stress-strain response.

5 CONCLUSION

This paper shows the capabilities of CASM to simulate undrained softening and reproduce the behaviour of soils susceptible to flow liquefaction. The model has been implemented as a user-defined soil model in PLAXIS and includes some improvements with respect to the original formulation, such as Lode's angle dependency, an alternative plastic potential equation and the possibility to account for creep effects.

In this paper, CASM has been calibrated based on available data and triaxial tests simulations on loose tailings. The Tar Island Dyke has been selected as a case study, where a major failure event caused by flow liquefaction of loose beach sand has been recorded in 1974. The results of the finite element analysis are consistent with the observations and show that CASM is capable of reproducing the behaviour of loose tailings in both drained and undrained conditions. In particular, the model is suitable for applications in which flow liquefaction may occur.

Brief insights: In-situ permeability test in weathered and poorly-graded rockfill

Essai de perméabilité in-situ dans un enrochement altéré et mal calibré

C. Laina-Gómez*, D. Escudero-Merino, E. Asanza-Izquierdo

*carlos.laina@cedex.es

ABSTRACT: Rockfills safeguard the core of engineered earth structures, enhancing strength and mitigating pore pressure accumulation. Factors such as significant thermal oscillations, severe frost/thaw, wetting/drying cycles, and shifts in rainfall patterns are likely to speed up the weathering of in-place rockfill particles. Throughout the past decade, investigations at CEDEX have revealed signs of particle alteration, including potential crumbling in aged dams, harbors, and embankments. These alterations result in significant changes in particle size distributions, consequently leading to a decline in drainage efficiency and overall structural strength. While large-scale laboratory tests such as permeameter, triaxial tests, or Rowe's cell, are able to assess the permeability of coarse-grained soils, in-situ tests performed on a larger scale appear to yield even more reliable results. These tests replicate natural conditions, including porosity, compaction, true grain-size distribution, and boundary conditions. This paper presents a case study on the in-situ measurement of permeability in a weathered, poorly-graded rockfill, providing valuable insights into real-world conditions.

RÉSUMÉ: L'enrochement protège le noyau des structures en terre, offrant de la résistance et minimisant l'accumulation de pression interstitielle. Les grandes oscillations thermiques, les cycles sévères de gel/dégel et de mouillage/séchage et les changements dans les régimes de précipitations sont des facteurs susceptibles d'accélérer l'altération des particules de l'enrochement. Ainsi, au cours de la dernière décennie, les cas de barrages, de ports et de remblais vieillissants étudiés au CEDEX ont montré une tendance à l'altération des particules (même d'effritement), entraînant des changements notables dans leur distribution granulométrique et, par conséquent, une dégradation de l'efficacité du drainage et de la résistance du matériel. Bien que des équipements d'essai de laboratoire soient disponibles pour évaluer la perméabilité des sols à grains grossiers (perméamètre, test triaxial ou cellule de Rowe), les essais à grande échelle in-situ semblent fournir des résultats encore plus fiables, car ils testent les conditions naturelles, c'est-à-dire la porosité, le compactage, la distribution granulométrique réelle et les conditions aux limites. Cet article traite d'une étude de cas de la mesure in-situ de la perméabilité dans un enrochement altéré mal gradué.

Keywords: In-situ; measurement; permeability; trench; weathered; rockfill.

1 INTRODUCTION

This communication presents a singular in-situ test carried out by CEDEX Geotechnics Laboratory, whose purpose was to assess how much the weathering and breakdown of the rockfill particles of an earth structure reduces its permeability. The rockfill basically consists of cobbles and gravels from a nearby quarry in a dolomite rock with sugary (saccharoidal) texture, yet partially dedolomitized into a somehow sandstone-like.

The study of the degradation of its particles, that had been addressed by CEDEX in the past, did not lead to sound conclusions regarding frost/thaw and wetting/drying cycles; however, those laboratory test that entailed direct mechanical stresses, showed that the particles were highly prone to crumble (into sugary sand). It was apparent that the mere rough mechanical handling at the lab led to fine production. For instance, dropping a particle onto the concrete floor might cause its crumbling.

After four decades as the upstream slope that protected the clay core of a large dam, a keen eye could recognize certain weathering features in the rockfill (bulgy profile, dying dusty, sandy patches). Since an expert assessment after on-site inspection had stated that the current bulk permeability of the rockfill could be as low as k≈0.01cm/s and that, therefore, the upstream slope stability during a rapid drawdown might be at risk due to excess pore pressures, CEDEX Geotechnics Laboratory engineered a full-scale test aimed at measuring the permeability on site.

2 THEORETICAL FRAMEWORK

2.1 On the in-situ measurement of permeability

Some formulations and tables the compute permeability based on non-comprehensive soil features (grain size and size distribution) can be found in the literature, such as the classical equations of Hazen (1911 and 1930) or Sherard (1984). Note that many of them neglect the degree of soil packing (void ratio), thereby the permeability of a shallow normally consolidated soil would erroneously remain constant until its maximum dry density.

Thus, such desk appraisal fails to take into account in-situ conditions (dry density, particle degradation and boundary conditions). Unfortunately, laboratory permeability tests with coarse soils fail again to reproduce the in-situ conditions, not to mention the drawbacks concerning the maximum grain size (a few inches) to meet standards. Soil resampling would force the coarse fraction to be excluded, changing the natural soil structure and, therefore, its porosity, which is a key issue in this study.

On the contrary, in-situ tests hardly disturb the natural conditions and allow a large mass of material to be tested, so its representativeness is much more reliable. In-situ measurements of permeability can be divided into two groups: tests carried out inside a borehole (Gilg-Gavard, Lugeon and Lefranc tests) and percolation tests on the surface through a trench in the soil (Haefeli and Matsuo tests).

In-situ measurements of the permeability inside a borehole were discarded, due to the major difficulties of placing a drilling machine on a steep slope and drilling into a coarse granular material. Additionally, a standard drilling diameter is not large enough in relation to the pore size of the rockfill skeleton. Furthermore, taking into account that the particles are prone to crumble, drilling works would likely produce an undesired amount of fines.

According to Fell et al. (2015), drilling works in such materials tend to cause the soil pore structure to close and become clogged, leading to highly biased permeability results, one or two orders of magnitude lower than that of the original soil.

2.2 Vedernikov´s solution (1934)

The percolation tests carried out on the surface through a trench seem to be an appropriate alternative when it comes to coarse materials. The State of the Art on percolation tests refers to several geometry arrangements of the trench or pit, but all of them assume a deep impermeable layer, are based on the Vedernikov's solution (1934), a 2D percolation model (q) from trapezoidal canal, given by Equation 1:

$$q = k \cdot (W + A \cdot y) \qquad (1)$$

where: q, is the flow rate [$L^2 \cdot T^{-1}$]; k, the permeability coefficient [$L \cdot T^{-1}$]; W, the width of the free water surface (L); y, the height of the trench from the discharge level; and A, a parameter that accounts for the maximum widening experienced by the downward flow [-].

As the close-form solution for the parameter A is rather complex, Vedernikov presented a chart for a wide range of shapes of trapezoidal canal (Figure 1).

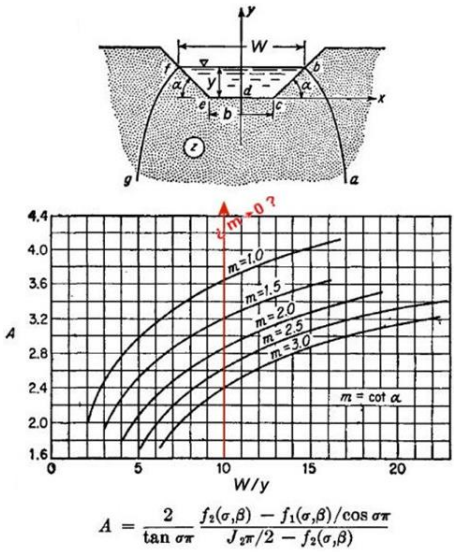

Figure 1. Percolation from a trapezoidal canal, Vedernikov's model (Harr, 1990).

However, this chart falls short to solve upper or lower bound cases, thereby vertical face (m = 0), perhaps the simplest, the geometry selected by the CEDEX Geotechnics Laboratory. For this reason, the article by Chahar (2001) has been used, which extends this abacus for extreme geometries (Figure 2).

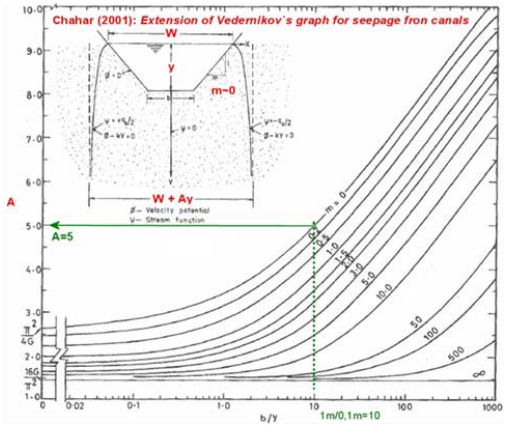

Figure 2. Chahar's chart (2001); generalization of Vedernikov's chart for obtaining A.

3 IN-SITU MEASUREMENT OF THE PERMEABILITY

3.1 Definition and scope

Figure 3 is a general layout of the in-situ permeability test that the Laboratory drew up. The aim was to measure the permeability of a large mass of the rockfill in the upstream slope, preferably in a zone with clear evidence of crumbling a weathering.

Vedernikov's model was taken on as the reference theoretical framework. In fact, it has been proven that percolation tests are in close agreement with theory as long as $H>3W$.

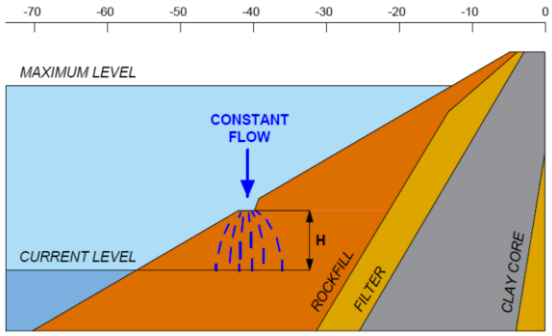

Figure 3. Layout of in-situ measurement of the permeability.

In this case, CEDEX set the base of the trench 3m above the discharge level, considering a trench width of W=1, due to constrains by the limited number and capacity of the available pumps. It is worth pointing out that in-situ tests long enough ($L>>W$) to meet 2D conditions turn out impractical for many other reasons. Thus, CEDEX concluded that even a square shallow pit would result cost-effective, regardless of minor fitting to match a 2D model with a 3D.

Bearing in mind the available pumps, pressure losses and preliminary judgement on the permeability expected, the in-situ test carried out by CEDEX was based on digging a shallow trench (W = 1m, y = 10cm), reaching total area between 1 and 3m².

Figure 4. Equipment calibration in CEH Laboratory.

3.2 Equipment calibration and mock test at CEH Laboratory

Due to the novelty of the test design, the large volume and flow rates of water and the specific devices (4 pumps operating in parallel, electronic flowmeters and connecting elements), the calibration, setting up and even a mock permeability test were carried out at CEDEX Hydraulics Laboratory (CEH), with ample resources and expertise in this field (Figure 4).

3.3 Description, details, and results of the in-situ test

The first preliminary works consisted of clearing and levelling a trail through the upstream slope with a backhoe to the approved testing spot. Next, CEDEX technicians contoured and prepared manually the trench. Finally, they proceeded to fix the pumps and the hoses, with special care with the intake from the reservoir, as well as the rest of the elements (Figure 5).

The design included the trench be lined with a macro-perforated sheet, in order to avoid potential erosion from the water squirting from the hose without loss of percolation capacity.

First test: Trench 1m x 3m in size.

A rectangular trench was meant to reduce somehow the 3D effect. Thus, the principle of the test was to adjust a flow of water just capable of maintaining a target height of water (10cm) in the trench.

However, it was soon recognized that with a size of 3m² the array of pumps at its maximum water flow rate ~ 13.6 l/s (~ 820 l/min) failed to fill the trench at all. In any case, the percolation capacity (permeability) in those 3m² exceeded 820 l/min. These results made possible to set a lower bound of the permeability of the rockfill (it was an order of magnitude higher than assumed, of k = 0.01cm/s), and therefore, dissipating all the doubts raised about the hypothetical loss of permeability due to the material "sanded".

Second and final test: Trench of 1m x 1m.

The technicians of the CEDEX Geotechnics Laboratory dissatisfied with the results, decided to repeat the test in a smaller trench (1m x 1m), even though this geometry maximized the three-dimensional effect.

Finally, following a very similar methodology this test was completed successfully. The main advantage was to obtain the order of magnitude flow rate associated with a steady height of water, which was maintained for several minutes in the trench.

The final flow rate of water, using three of the four available pumps, was 8.7 l/s (520 l/min).

Figure 5. Stages of testing; A) access road into the rockfill; B) installation of the 4 hydraulic pumps; C) preparation of the trench of 3m x 1m; D) preparation of the trench of 1m x 1m; E) detail of the trench of 1m x 1m; F) Trench of 1m x 1m with the level of water stabilized in 10cm.

4 ANALYSIS RESULTS

4.1 Approach

The difference in level between the trench and the water surface of the reservoir (about 3m) is sufficient to accept that the widening of the percolating flow is very close to its asymptotic value; in other words, the flow is almost vertical when it reaches the reservoir level.

The flow rate required to obtain a steady percolation flow in the trench of 1m x 1m was about 520 l/min. It is a three-dimensional flow and very similar to the case of an axil-symmetric problem (assuming a circular surface of area 1m²).

An approximation with the two-dimensional flow model could also be accepted, understanding that the asymptotic border does not influence whether it is a square trench or one of infinite length of equal width.

4.2 In-situ measurement

If there were a two-dimensional flow in a trench with vertical faces ($m = 0$), width (W) of 1m and water depth (y) of 0.1m, the flow would widen to an asymptotic value ($L_{asymptote}$) of:

$$L_{asymptote} = W + A \cdot y = 1m + A \cdot 0.1m$$

As seen in the above Figure 2, the present case it results that $A = 5$. Then:

$$L_{asymptote} = W + Ay = 1m + 5 \cdot 0.1m = 1.5m$$

It can be accepted that the flow is already practically vertical once it has descended the 3m difference between the trench and the reservoir's water surface, with a width equal to its asymptotic value.

As it is a square trench, three assumptions can be made about the dimensions and shape of the flow section when it intersects the level of the reservoir. The three options are represented in Figure 6.

Hypothesis 1: (upper bound) it is a square section with side $L_{asymptote} = 1.5m$.

$$S_{max} = 1.5m \cdot 1.5m = 2.25m^2$$

Then, the apparent speed for 520 l/min flow is:

$$v = 0.52m^3/min / 2.25m^2 = 0.39cm/s$$

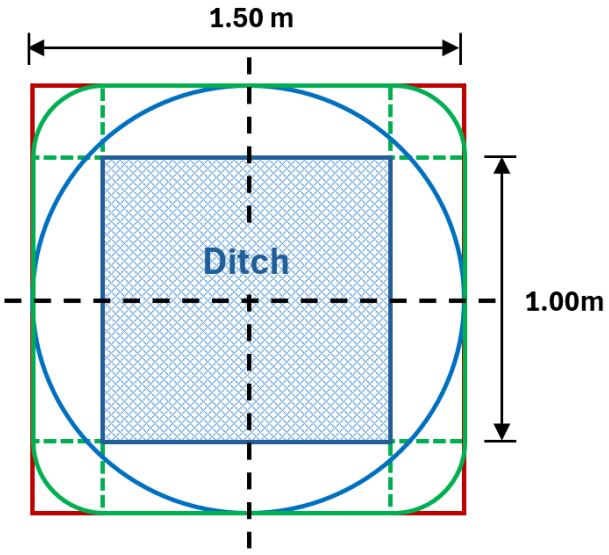

Figure 6. Possible sections formed by the flow when it intercepts the reservoir level.

Hypothesis 2: (intermediate bound) it is a square section with side $L_{asymptote} = 1.5m$ and the corners rounded.

$$S_{max} = 1.5m \cdot 1.5m - 4 \cdot 0.25^2 + \pi \times 0{,}25^2 = 2.20m^2$$

Then, the apparent speed for the same flow is:

$$v = 0.52m^3/min / 2.20m^2 = 0.39cm/s$$

Hypothesis 3: (lower bound) it is a circle section with a diameter of $L_{asymptote} = 1.5m$.

$$Smax = 0.25 \cdot \pi \times 1.5^2 = 1.77m^2$$

Then, the apparent speed for the same flow is:

$$v = 0.52m^3/min / 1.77m^2 = 0.49cm/s$$

It can be accepted with reasonable approximation that the area of the flow, when it reaches the level of the reservoir, will be that of the intermediate value between the different hypotheses raised. Therefore, it can be considered valid to approximate the apparent velocity to 0.4cm/s.

As the gradient in this percolation problem is $i = 1$, according to Darcy's law ($v = k \cdot i$), permeability is equal to the flow rate: $k \sim 0.4cm/s$.

5 CONCLUSIONS

The CEDEX Geotechnics Laboratory suggested this purpose-built permeability test in the poorly-graded weathered rockfill at upstream slope of the earthfill

dam, since an expert assessment had stated that its current permeability could be as low as $k \approx 0.01$cm/s.

For this purpose, the Laboratory took the Vedernikov solution, described by Harr (1990). In these “percolation" problems the gradient reaches i ~1 and the seepage turns soon downwards and tends to a constant "seepage area".

The setting up of this novelty model needed prior levelling and pumps capable of supplying a flow rate that would maintain the water level at the ditch. This calibration was carried out at CEDEX Hydraulics Laboratory under the support of its staff.

Although, an attempt was made to carry out the test as planned: a 3x1m ditch, it was soon recognized that the array of pumps at its maximum water flow rate failed to fill the trench at all. Finally, test was completed successful in a smaller trench of 1x1m with a final flow rate of water of 520 l/min.

As a conclusion and assuming a laminar flow (the true permeability would be higher than that derived from the test, as inertial loses are neglected), permeability equals the flow rate results: k ~0.4cm/s, and accordingly all the doubts raised about the hypothetical loss of permeability due to the material "sanded" were dissipated.

ABSTRACT: Developing the second generation of the structural Eurocodes is now reaching its final steps. The title of the revised Eurocode EN 1990 ("Basis of structural and geotechnical design") reflects the specific identity of geotechnical problems. While the original version of the geotechnical Eurocode EN 1997 ("Geotechnical design") was developed largely based on soil mechanics, the aim is that the revised version treats soil and rock on an equal basis. Thus, rock engineering aspects have been substantially revised and expanded. The paper presents the main changes to the Eurocodes as far as they affect rock engineering design and lists improvements that will still be necessary after this critical revision.

RÉSUMÉ: Le développement de la deuxième génération des Eurocodes structurels atteint désormais ses dernières étapes. Le titre de l'Eurocode EN 1990 révisé ("Bases du calcul structurel et géotechnique") reflète l'identité spécifique des problèmes géotechniques. Alors que la version originale de l'Eurocode géotechnique EN 1997 ("Conception géotechnique") a été développée en grande partie sur la base de la mécanique des sols, l'objectif était que la version révisée traite le sol et la roche sur un pied d'égalité. Ainsi, les aspects de l'ingénierie des roches ont été considérablement révisés et élargis. L'article présente les principales modifications apportées aux Eurocodes dans la mesure où elles affectent la conception technique des roches et répertorie les améliorations qui seront encore nécessaires après cette révision critique.

Keywords: Eurocode; geotechnical structures; rock engineering; design.

1 INTRODUCTION

This paper addresses new developments and changes in the forthcoming second generation of Eurocode 7 Geotechnical design with a focus on rock engineering, based on the nearly final drafts available in January 2024. It is based on a series of six papers published in a special issue of "Geomechanics and Tunnelling" (Lamas *et al*., 2023; Walter *et al*., 2023; Estaire *et al*., 2023; Stille *et al*., 2023; Maca *et al*., 2023; Harrison *et al*., 2023) and on the presentations at the workshop "The second generation of Eurocode 7 and the integration of rock engineering" organised in conjunction with the 15th International Congress on Rock Mechanics of the ISRM, in October 2023.

The Structural Eurocodes are a suite of European standards (EN 199x) for the design of buildings and civil engineering works, whose implementation started in 2010 when contradictory national standards were withdrawn. EN 1990:2002 sets the basis of structural design, with the other Eurocodes dealing with different materials and specific aspects of design. Geotechnical aspects of design are covered by EN 1997 Eurocode 7: Geotechnical design, with two parts: EN 1997-1:2004 General rules and EN 1997-2:2007 Ground investigation and testing.

The revision of the Eurocode system was initiated in 2012 by the European Committee for Standardization (CEN), after an invitation by the

European Commission, and responsibility for the revision of Eurocode 7 was assigned to sub-committee CEN/TC250/SC7.

The primary objectives of the evolution of the Eurocodes are to incorporate improvements that reflect the state-of-the-art in engineering design and the needs of the civil engineering market; to improve the ease-of-use of the standards; and to harmonize practice between countries. With regard to Eurocode 7, plans were laid to make the following changes:

- Restructuring to make it more consistent with other Eurocodes, easier to understand and navigate, more comprehensive in its technical coverage and easier to add new topics.
- Improve guidance on selecting characteristic ground parameters and design water pressures, application to numerical methods, rock engineering and dynamic design.
- Improve ease-of-use by clarifying existing clauses, removing repetitions and removing unnecessary information.

The need for enhancing support for rock engineering in Eurocode 7 was explicitly recognized. While the original version was developed largely based on soil mechanics, without involvement of rock mechanics experts, the aim was that the revised version of Eurocode 7 would treat engineering in soil and rock on an equal basis.

Successive working groups of rock engineering experts were formed to give input and accompany the development of the revision, and to comment on the successive drafts. These groups organised a workshop in 2014 in Vigo and published three collective papers. The current group is the Rock Engineering Platform (REP), which is formed by all experts working in the Eurocode 7 revision process with interest in rock engineering design. All authors of this paper are both co-authors on the series of six papers mentioned in the introductory paragraph and members of the REP.

2 RESTRUCTURING OF THE SECOND GENERATION OF EN 1997

The first generation of EN 1997 has two parts:

- Part 1 – General Rules (EN 1997-1:2004).
- Part 2 – Ground investigation and testing (EN 1997-2:2007).

For improved ease-of-use the second generation of the EN 1997 is organized in three parts:

- Part 1 – General rules (EN 1997-1).
- Part 2 – Ground properties (EN 1997-2),
- Part 3 – Geotechnical structures (EN 1997-3).

The contents of the current Part 1 (EN 1997-1:2004) are reconfigured in the following way:

- The basis of geotechnical design was moved to the revised EN 1990.
- The general rules that affect all geotechnical designs remains in Part 1 (EN 1997-1).
- The specific rules for particular geotechnical structures form the new Part 3 (EN 1997-3).

An important aspect of this restructuring is that the revised EN 1997-1 only covers aspects of geotechnical design that are common to all geotechnical structures. EN 1997-3 covers all aspects specific for the particular types of geotechnical structures. The existing Part 2 focusses primarily on data collection methods for laboratory and field data, while the revised EN 1997-2 focusses on obtaining ground properties of engineering interest. Calculation models based on tests presented in Annexes to the existing Part 2 have been moved to EN 1997-3. It is expected that this will improve the everyday usefulness of the code to practitioners, particularly to those working on rock engineering projects. EN 1997, as well as all the other Eurocodes, shall be read in conjunction with EN 1990.

3 GENERAL CHANGES CONCERNING ROCK ENGINEERING

Profound changes and additions have been made to EN 1997 with regard to rock engineering, namely:

- accepted definitions of rock, rock masses and discontinuities, as well as requirement to consider the discontinuous nature of a rock mass;
- recognition that rock mass geometrical properties (e.g. discontinuity spacing and orientation) may be considered probabilistically.
- recognition that ground properties (i.e. of rock masses) must consider the geometrical properties of the discontinuities when they affect the mechanical behaviour of the ground;
- recognition that reliability-based methods may be used in design situations not covered by the partial factor design format, due to the specific nature of actions and design scenarios, and in ground conditions such as rock, strongly affected by discontinuities and other geometrical phenomena;
- an understanding that risk-informed approaches may apply in design situations where uncertainties or consequences are outside common ranges;
- rock mass classification systems;
- the physical, and chemical properties relevant to rock, including relevant laboratory and field tests, and testing standards;

- the potential need to determine the *in situ* stress state and methods for its determination;
- specific strength envelopes for rock, rock masses and discontinuities and methods to determine their parameters, as well as specific aspects of rock and rock mass deformability;
- failure mechanisms relevant for rock masses;
- values of partial factors on ground properties to be used for rock, rock mass and discontinuities;
- increased attention given to the observational method and prescriptive rules for the design of rock engineering structures;
- rock anchors, rock bolts and surface support;
- groundwater control measures.

Table 1 shows the number of occurrences of the terms "rock", "rock mass" and "discontinuities" in the existing and revised versions of EN 1997. The increase in the use of "rock mass" and "discontinuities" is 36%, 412% and 522%, respectively. This is a clear sign of more material on rock issues, a better understanding of the discontinuous nature of rock masses and the relevance of discontinuities. With EN 1990 the corresponding numbers are modest: the occurrence of "rock" increased from 2 to 4, there is no occurrence of "rock mass", and the term "discontinuities" was not present but now occurs twice.

Table 1. Occurrence of rock related terms in the existing and the revised EN 1997.

	Rock	Rock mass	Discontinuities
prEN 1997-1:2023	52	10	27
prEN 1997-2:2023	284	91	105
prEN 1997-3:2023	278	76	35
Total	614	177	167
EN 1997-1:2004	136	22	18
EN 1997-2:2007	316	21	14
Total	452	43	32

Tunnels and other underground structures are not covered by the revised EN 1997-3, because they are complex geotechnical structures, where ground-structure interaction is critical, and involve different materials such as concrete and steel. However, steps in this direction are being taken by CEN/TC250/SC7.

4 DETAILED CHANGES CONCERNING ROCK ENGINEERING

4.1 General rules

The basis for ensuring reliability is distributed between EN 1990 and EN 1997-1. To facilitate straightforward application of the reliability model, three classifications have been introduced: Consequence Classes (CC) dealing with the consequences of a failure, Geotechnical Complexity Classes (GCC) that take into account the difficulties and uncertainties in obtaining ground conditions and parameters and modelling the ground behaviour, and Geotechnical Categories (GC) which combine the first two classifications. CC is introduced in EN 1990, where failure probabilities and modifications of partial factors depending on the CC of a (geotechnical) structure are specified. Examples of geotechnical structures in each CC are given in EN 1997-1.

GCC and GC are detailed in EN 1997-1, and are essential for appropriate handling of rock mass complexity. Tables are provided and aid in selecting the appropriate GCC and obtaining the resulting GC. The GC of a geotechnical structure (or part of it) has multiple consequences on the design. It shall be used to specify measures that cover the aspects of design and construction that are essential in ensuring the appropriate level of reliability, namely:

- appropriate extent of ground investigation;
- validation of ground investigation information;
- validation of the geotechnical design model;
- validation of calculation models;
- minimum designer qualifications and experience;
- minimum design checking level;
- appropriate implementation of design.

In EN 1990 and EN 1997-1 verification of ultimate limit states (ULS) using the partial factor method is dominant. However, in rock engineering, the observational method and prescriptive rules are also commonly used. Thus, the expression "validation of calculation models" should be interpreted more generally as "evaluation of verification method and of calculation models, and checking the applicability of the prescriptive rules".

For the verification of limit states of geotechnical structures by the partial factor method, so-called Design Approaches were used in the first generation of the Eurocodes. In the new EN 1990, which now contains all the partial factors on actions and action effects, four Verification Cases (VC) are defined.

Table 2 is an excerpt of Table 4.8 of EN 1997-1 with partial factors on material properties for persistent and transient design situations. Partial factors for rock mass, rock material and discontinuity properties have been added. τ_f is the effective shear strength, $\tan\phi'_p$ and $\tan\phi'_{cs}$ are the peak and critical state coefficients of friction, c_u is the shear strength in total stress, q_u is the unconfined compressive strength and $\tan\phi'_{dis,r}$ is the coefficient of residual friction. The values of γ are the partial factors of these material properties. The factor k_M is a consequence factor which depends on the

consequence class. For comparison, values for soil and fill are also presented. Which set (M1 or M2) of factors and which verification case have to be combined is specified in EN 1997-3 for the different types of geotechnical structures.

Table 2. Partial factors on material properties.

	Ground property	Symbol	Set M1	Set M2
Soil and fill	τ_f	$\gamma_{\tau f}$	1.0	1.25 k_M
	$\tan\phi'_p$	$\gamma_{\tan\phi,p}$	1.0	1.25 k_M
	$\tan\phi'_{cs}$	$\gamma_{\tan\phi,cs}$	1.0	1.1 k_M
	c_u	γ_{cu}	1.0	1.4 k_M
Rock material and rock mass	τ_f	$\gamma_{\tau f}$	1.0	1.25 k_M
	q_u	γ_{qu}	1.0	1.4 k_M
Rock discontinuities	τ_f	$\gamma_{\tau dis}$	1.0	1.25 k_M
	$\tan\phi'_{dis,r}$	$\gamma_{\tan\phi,dis}$	1.0	1.1 k_M

From a rock engineering perspective, one must be aware that application of the partial factor method according to the Eurocode may result in a false impression of safety, because actions and material strengths and resistances are factored, but geometry is not. In rock engineering geometric properties of discontinuities are frequently crucial in determining the probability of failure, and the uncertainties related to the geometric properties of discontinuities must be considered by alternative methods. This can be done by sensitivity analyses, namely considering different discontinuity orientations and spacings, or even using probabilistic descriptions of the discontinuities (and using partial factors or other method for the actions and the strengths and resistances). The use of discontinuity fracture networks (DFN) based on probabilistic descriptions of the geometric properties of discontinuity networks is one such methods.

4.2 Ground properties

Ground properties are dealt in the new EN 1997-2. In Clause 4 the concept of Ground Model (GM) is introduced, which comprises the geological, hydro-geological, and geotechnical conditions at the site, as well as the derived values of the properties of the geotechnical units, based on the ground investigation results. Clause 5 is organized to support the designer's need to obtain this information through the tasks accomplished during the ground investigation phases: desk study, site inspection, preliminary and design investigation, using field and laboratory tests.

Clauses 6 to 12 are focused on obtaining the ground properties of the geotechnical units included in the GM. They cover the main properties required to address all geotechnical materials, from soil and rock, such as: state, physical and chemical properties; strength, stiffness, compressibility and consolidation properties; cyclic, dynamic and seismic properties; geohydraulic and thermal properties.

EN 1997-2 presents the methods for determining those properties directly, by means of field or laboratory tests, and indirectly, using correlations. Direct and indirect methods are compiled in tables, with additional information on the applicable EN standards and the minimum quality class of the samples to be used, in the case of soils.

Besides the new contents concerning rock presented in section 3, reference is made in EN 1997-2 to the standard EN ISO-14689 for the description and classification of rock and its weathered profile, as well as to the ISRM Suggested Methods for laboratory testing of rocks and *in situ* testing of rock masses.

4.3 Slopes, foundations and retaining structures

The overall and local stability of slopes, cuttings and embankments in rock are addressed in Clause 4 of EN 1997-3. The following topics are included: rock excavation techniques and sequence; damaging effects of excavation by blasting; influence on local stability within slopes and cuttings of rock discontinuities and weathered zones; influence of strength anisotropy of the rock material; possible effect of local instability on the overall stability. Calculation models for analysing the stability of rock mass are provided in Annex A.4.

Prescriptive rules, often used in rock engineering, as well as methods based on classification systems, are referred to in EN 1997-3.

Spread foundations are considered in Clause 5, where the minimum extent of field investigation is specified, noting the influence of the presence of rock masses. Bearing resistance on rock is introduced and two cases are considered: either the rock mass behaves as a discontinuous or as an equivalent continuous medium. Recommendations regarding the type of analysis to be performed are included.

Clause 6 is devoted to piled foundations, with most of the provisions regarding piles on rock that deal with shaft and base resistance calculations included as suggested methods in Annex C. Model factors γ_{Rd} for verification of axial pile resistance by testing or assisted by testing, for piles installed in rock, are provided in this clause.

The design of retaining structures is the subject of Clause 7, but is also interconnected with nearly all the other clauses in EN 1997-3: among other aspects, it requires foundation design, supporting elements such as anchors and rock bolts, and groundwater control. This clause is written mainly for soils and fills. In order to incorporate rock, it is stated that the term earth

pressure shall be interpreted as ground pressure and also includes acting pressure from rock cuttings and slopes behind the retaining structure. It is also emphasized that rock pressure shall account for strength anisotropy of the rock material and that arising from the presence of the discontinuities.

4.4 Anchors, rock bolts, rock support and groundwater control

Anchors are addressed in Clause 8 of EN 1997-3. As the design rules for anchors were thoroughly revised in 2014, the changes mostly express the general changes within the Eurocodes and harmonization with other clauses. Crucially, there is no distinction in design principles between anchors in soil and rock.

One element of completely new content in EN 1997-3 is soil nailed structures, to which Clause 10 is dedicated entirely. Soil nails are used in weak or weathered rock masses, or in mixed ground conditions. The basic approach of resistance determination follows the concept of piles in tension. Further, the basis of design, as well as materials and testing are provided for commonly used rock engineering facing systems, such as wire mesh and sprayed concrete.

The inclusion of rock bolts and rock surface support are additions to the content, being the subject of Clause 11, focused on rock bolts for stabilization of slopes and excavations, but not covering underground structures. Clause 11 deals with the design of single rock bolt elements, and is thus strongly interconnected with other clauses of EN 1997-3 that deal with aspects of overall limit states. The verification of limit states for rock bolts is based on calculation, testing or prescriptive measures, giving the broad flexibility to use the most suitable method in any given conditions. The importance of the geometric relation of rock bolts to the orientation and location of discontinuities is highlighted. Rock surface support is to be verified by prescriptive rules. Additionally, materials and corrosion specifications concerning considering the nature of the rock mass are given. Finally, the clause provides the requirements regarding testing.

Groundwater control measures, relevant for all geotechnical structures, are dealt with in a new Clause 13. Generally, the limit states of structures requiring groundwater control measures are verified according to those clauses applicable to them. Criteria for serviceability limit states are presented, and Clause 13 indicates that verification of these criteria is primarily by the observation method or field tests. As for aspects of groundwater control specific to rock engineering, elements of ground investigation and rock testing methods for the design of rock grouting are provided.

5 PERSPECTIVES ON THE EVOLUTION TO THE THIRD GENERATION

The current Eurocode revision process has sought to improve EN 1997 for application to rock engineering, while including only techniques and procedures that are in widespread customary use. Unsurprisingly, this required detailed examination of customary rock engineering techniques in the context of limit state design (LSD) as implemented in the Eurocodes.

This work revealed many discrepancies between customary rock engineering practice and the basis of design implemented in the Eurocodes. Crucially, this in turn led to the germination of many ideas about how rock engineering practice may need to develop and evolve in order to embrace the principles on which the Eurocodes are based. In particular, aspects of determining the properties of rock masses, and design verification by observational methods, partial factors, numerical modelling, and prescriptive rules are all thought to require significant improvement or fundamental modification.

In the context of the Eurocodes, rock engineering practice is unique in terms of its reliance on classification schemes for obtaining design values. All rock mass classification schemes currently in general use require subjective qualitative assessments. Such assessments are unavoidably always biased, and generate ordinal data (*i.e.*, numeric values that are labels with a meaning of order). This latter point is crucial, as ordinal data cannot be used in the statistical sense needed for LSD. Also, no rock mass classification schemes have been calibrated against rock mass conditions or performance. This state of affairs suggests that the current classification schemes have no role to play in design verification by calculation. This is an immense challenge, as many design techniques and formulae traditionally used in rock engineering involve rock mass classification parameters: prediction of rock mass strength and stiffness are perhaps the two most common. Without doubt rock mass classification schemes will continue to play a significant role in rock engineering practice, but in the context of the Eurocodes this may need to be as input to prescriptive rules. Perhaps Eurocode 7 will need to evolve to better embrace the combined use of prescriptive rules, design verification by calculation and application of observational methods.

The fundamental geometrical and mechanical complexity of discontinuous rock masses presents an immense challenge to the application of LSD to rock engineering practice. Because of this, the authors hold the opinion that attaining perfection in the application of LSD to rock engineering is not feasible, but strongly believe that with a concerted effort by the rock

engineering community, the necessary developments can be made to ensure the potential future EN 1997:2035 (the tentatively, and cheekily suggested date for the next revision is 2035!) will contain rules that are both useful and good for rock engineering practice. Thus, the immediate challenge is one of mobilising this community to ensure this is the case.

6 CONCLUSIONS

Many changes were introduced in the forthcoming second generation of Eurocode 7 with regard to rock engineering, as a result of overall improvement to Eurocode 7: the restructuring into three parts, the introduction of an improved reliability model and the inclusion of a new EN1997-2 offering improved ease-of-use, but also enhanced guidance on obtaining properties for rock, rock masses and discontinuities, exemplify these.

Of particular value for rock engineering are clauses which recognise that partial factor approaches may be inappropriate or insufficient when occurrence of the limit state is governed by the geometry of discontinuities. Similarly, many clauses now recognise aspects particular to rock engineering, such as specific strength criteria, the necessity to use the observational method, and the common use of rock mass classification systems.

The revision process has revealed much about the discrepancies between customary rock engineering practice and the basis of limit state design as implemented in the Eurocode suite. In the coming years rock engineers will start gaining experience applying the Eurocodes for design and providing information on the advantages and the difficulties encountered, so that the targets for a subsequent revision can be defined.

An immediate challenge is that of mobilising the rock engineering community to develop techniques which will reduce any discrepancies. We expect the REP will play a central role in mobilising and coordinating this effort over the next few years.

7 ACKNOWLEDGEMENTS

Since the Eurocode 7 evolution, and then revision process began in 2011, well over 100 experts in rock mechanics and rock engineering from across Europe have contributed to the work. The authors of the present paper are immensely grateful to all of these colleagues for their contributions to this effort.

Analysis and simulation of a rainfall-induced landslide on Enna Area (Italy)

Analyse et simulation des glissements de terrain induits par les précipitations dans la région d'Enna (Italie)

V. Lentini*, K. Pinargote, F. Castelli
Faculty of Engineering and Architecture, University Kore of Enna, Enna, Italy
**valentina.lentini@unikore.it*

ABSTRACT: One of the most dangerous effects of climate change is heavy rainfall, often responsible for the triggering of natural phenomena, such as floods or landslides. In recent years, landslides and alluvial events had a strong impact on the road networks, creating the need to define criteria for management and mitigation of hydrogeological risk related with transport infrastructure systems. The reliability of transport infrastructures plays a key role since, in many cases, their inefficiency has caused serious damage to the anthropic system. In the paper the modelling of a debris flow occurred in the Enna area in the south of Italy is described. The area is prone to landslides, often consisting in shallow movements induced by rainfall. Starting from the study of the geological framework and the historical background for landslides of the Enna district, the research has focused on the causes triggering the landslides. In particular, the real case of 1st-2nd February 2014 which affected Enna city has been modelled. The event caused damage to private buildings and the interruption of the main infrastructure connecting Enna city to the motorway, due to the material on the road. The characterization of soil properties along the slope is based on a detailed geotechnical investigation in addition to a collection of topographical and hydrogeological data. The second part reports the results of the numerical analysis simulating the landslide event to assess the appropriate mitigation works, to reduce the damages to structures and infrastructures located in the area.

RÉSUMÉ: L'un des effets les plus dangereux du changement climatique est la forte pluie, souvent responsable de déclencher des phénomènes naturels tels que des inondations ou des glissements de terrain. Ces dernières années, les glissements de terrain et les événements alluviaux ont eu un impact important sur les réseaux routiers, créant ainsi la nécessité de définir des critères pour la gestion et l'atténuation des risques hydrogéologiques liés aux systèmes d'infrastructures de transport. La fiabilité des infrastructures de transport joue un rôle clé, car dans de nombreux cas, leur inefficacité a causé de graves dommages au système anthropique. Dans cet article, la modélisation d'une coulée de boue survenue dans la région d'Enna, dans le sud de l'Italie, est décrite. La région est sujette aux glissements de terrain, souvent dus à des mouvements superficiels induits par les précipitations. À partir de l'étude du cadre géologique et du contexte historique des glissements de terrain du district d'Enna, la recherche s'est concentrée sur les causes déclenchant les glissements de terrain. En particulier, le cas réel du 1er-2 février 2014, qui a touché la ville d'Enna, a été modélisé. Cet événement a causé des dommages aux bâtiments privés et l'interruption de l'infrastructure principale reliant la ville d'Enna à l'autoroute, en raison des matériaux sur la route. La caractérisation des propriétés du sol le long de la pente repose sur une enquête géotechnique détaillée en plus de la collecte de données topographiques et hydrogéologiques. La deuxième partie présente les résultats de l'analyse numérique simulant l'événement du glissement de terrain afin d'évaluer les travaux d'atténuation appropriés pour réduire les dommages aux structures et aux infrastructures situées dans la région.

Keywords: Landslides; debris flow; geo-hydrological.

1 INTRODUCTION

Landslides can be triggered by various factors, such as meteorological events and tectonic forces. In Italy, frequent landslides, often deadly and economically destructive, are primarily triggered by rainfall.

Evaluating landslide risk involves analysing the spatial and temporal likelihood of specific landslides occurrence. This includes assessing rainfall patterns, triggering factors, event dynamics, propagation areas, and rheology. Efforts over the past decades have focused on developing numerical models to create reliable landslide inventory maps. The information on hazard, elements at risk, vulnerability, as well as geological and geotechnical data is essential.

The aim of this paper is to present the results of the numerical analysis simulated with the model in the FLO-2D (Wu et al., 2013; Stancanelli and Foti, 2015) of the landslide event that struck Enna, Italy, on

February 1st-2nd, 2014, with the goal of evaluating debris flow behaviour.

2 LANDSLIDE INVENTORY IN ENNA AREA

A crucial component of landslide zonation is the creation of a landslide inventory map, which details the information. This inventory serves as a prerequisite for conducting analyses to establish relationships between landslide distribution and various influencing factors. The creation of a comprehensive landslide inventory map, as in Figure 1 (Castelli et al., 2016) in whiche the case study is highlighted in yellow, is pivotal for effective landslide zonation.

In the context of Enna (Sicily – Southern Italy region), a series of landslides triggered by rainfall events (Table 1) were examined and categorized, including the movement data, movement types and soil involved.

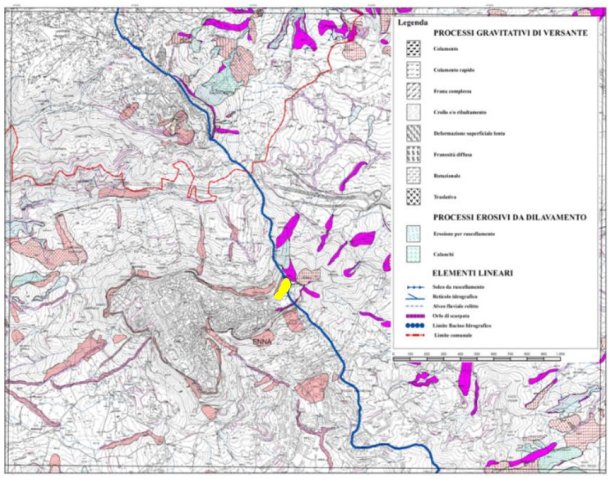

Figure 1. Landslide inventory map in the area of Enna, Sicily (Castelli et al., 2016).

Table 1. Cumulative rainfall, critical value and alert period for the landslides analysed and classified.

Event	Date of occurence
1	13/10/1991

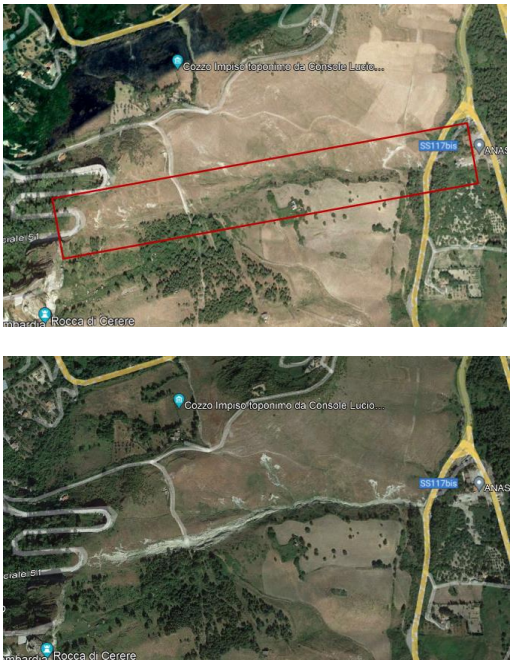
25	02/02/2014

3 CASE STUDY OF ENNA

Italy, particularly Sicily (Castelli and Lentini, 2013) is marked by a complex landscape and geology that results in a variety of potential instabilities. Enna, situated in the heart of Sicily, exhibits steep hill slopes (Castelli et al., 2016). The geological composition comprises the Numidian Flysch and Holocene-age river alluvium (Castelli et al., 2017). On the night of February 1st to 2nd of 2014, Enna experienced a heavy downpour that resulted in significant damage to structures. It took place in a basin covering 0.158 km², leading to a debris flow. The impact of the rainfall event can be assessed by comparing photos taken before and after the event (Figure 2).



(a)

(b)

Figure 2. (a) the area before the debris flow; (b) the area after the debris flow.

4 RAINFALL DATA

The focus is on identifying rainfall thresholds as potential triggers for landslides, and their significance in mitigating geo-hydrological risks. By continuously monitoring meteorological, hydrological, and geotechnical parameters and combining them with predefined threshold values.

Information of rainfall data collected by Enna Meteorological Station was used. Figure 3 presents the rain intensity of the event on February 2, 2014 in Enna. The landslide associated with this event was initiated after intense rainfall, with precipitation exceeding 116.6 mm in less than one hour.

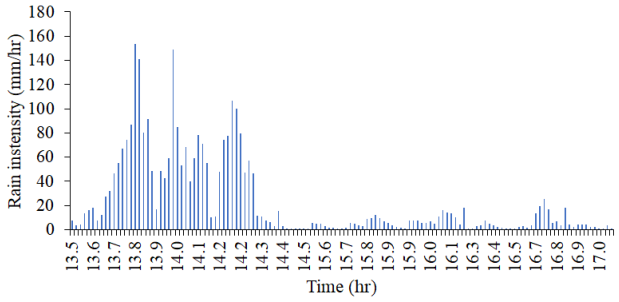


Figure 3. Rain intensity of the event of the 1st – 2nd February 2014 in Enna.

5 GEOTECHNICAL CHARACTERIZATION

The characterization of the foundation soil is an important key in the geotechnical study. That´s why the geotechnical parameters of silty clay (unsaturated soil), such as soil unit weight γ *(kN/m³)*, water content $w_{n\ (\%)}$, strength parameters in terms of friction angle $\phi'(°)$, cohesion $c'(kN/m^2)$, and undrained cohesion c_u *(kN/m²)* were obtained from in-situ tests and geotechnical laboratory tests, which have been used to subsequently define the geotechnical properties such as the consistence index I_C, presented in Table 2 (Castelli et al., 2017).

Table 2. Geotechnical parameters (Castelli et al., 2017).

Sample	γ $\left(\frac{kN}{m^3}\right)$	w_n (%)	c' $\left(\frac{kN}{m^2}\right)$	φ' (°)	c_u $\left(\frac{kN}{m^2}\right)$	I_c
S1C1	20.1	21.0	-	-	-	-
S1C2	20.9	20.4	39.44	25	-	1.50
S1C3	19.5	20.0	-	-	223.0	1.23
S1C5	20.2	26.0	25.36	24	255.0	0.67

6 NUMERICAL MODELLING AND RESULTS

The primary aim of the present numerical analyses is: to assess the ability of computational models to replicate the dynamics of debris flow.

To model the debris flows, it is required: a digital terrain model (DTM), hydrological data, and the rheological properties. The DTM was constructed using a grid system in FLO-2D, developed by O´Brien (1986). For this case, it assumed a single-phase modeling approach. The hydrological input was applied where the debris flow initiation was observed (Armanini et al., 2009).

In the simulations based on the literature reference (O´Brien and Julien, 1988; Bertolo and Wieczorek, 2005; Boniello et al., 2010; Wu et al., 2013) utilizing the FLO-2D model, specific parameter values of the rheological coefficients have been chosen from those available in the literature of Stancanelli and Foti (2015) that are closely resembling of the geomorphological and lithological characteristics of the study area α1= 0.006032, β1= 19.9, α2= 0.000707, and β2= 29.8.

A reconstructed representation of the area was yielded (Figure 4). The following important data were obtained:

- The maximum flow depths observed during the event, derived from the FLO-2D simulation, are presented in Figure 4a, with the highest predicted flow depth reaching approximately 1.10 meters.
- Figure 4b illustrates the final flow depths, with the highest predicted value at around 0.20 meters.
- Furthermore, Figure 4c displays the predicted maximum velocities, indicating that the greatest velocities were recorded in the upper regions of the basins, where the slopes were steeper, ranging from 4 to 6 m/s.

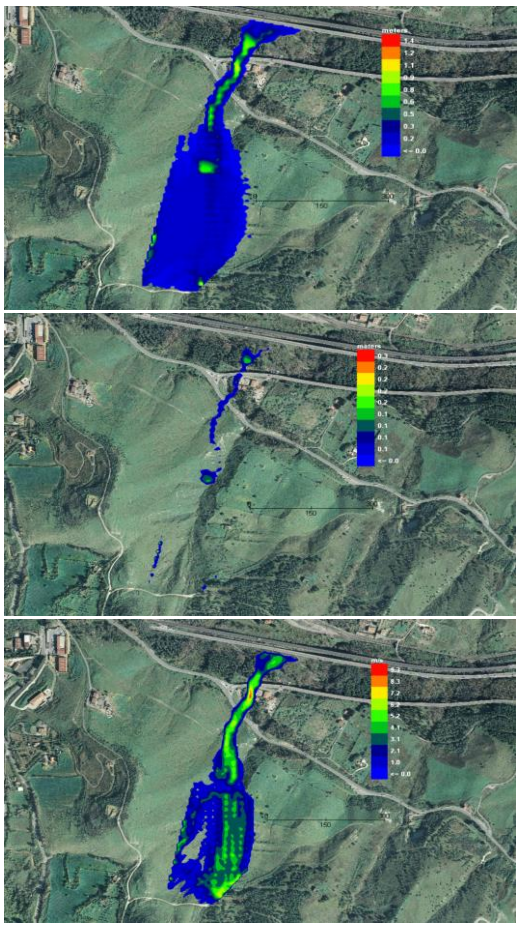

Figure 4. The simulation model carried out with the FLO-2D: (a) maximum flow depth; (b) final flow depth and (c) maximum velocity.

7 CONCLUSIONS

The results presented from a geological, geomorphological, and geotechnical survey of a real case in Enna, demonstrating that predicted values align closely with observed data and were reported in terms of the maximum flow depth, final flow depth and maximum velocity.

The study utilizes FLO-2D to simulate the case of the 1st-2nd of February 2014 create reliable numerical models for debris flows (Figure 4), which aid in assessing the set of variable direct infiltration of intense rainfall and runoff into cover materials. Likewise, was also possible to appreciate the key role that pore water pressure plays for the propagation stage, making dispersion patterns more complex. Ultimately, a precise representation of the topography in the system being a needed step to obtain a rational replication of the observed deposition patterns and to be able to carry out specific mitigation work for the area.

ACKNOWLEDGEMENTS

This study was carried out within the RETURN Extended Partnership and received funding from the European Union Next-GenerationEU (National Recovery and Resilience Plan - NRRP, Mission 4, Component 2, Investment 1.3 - D.D. 1243 2/8/2022, PE0000005).

Eurocode 7 – second generation – spread foundations

Eurocode 7 - deuxième génération – fondations superficielles

K. Lesny*
University of Siegen, Siegen, Germany

T. Orr
Trinity College, Dublin, Ireland

**kerstin.lesny@uni-siegen.de*

ABSTRACT: In the new second generation version of Eurocode 7, Part 3 the limit state design for various geotechnical structures is outlined. Spread foundations are covered in Clause 5 of this part where requirements for the verification of ultimate and serviceability limit states are provided. In comparison to the current version of Eurocode 7 the requirements have been improved first by revising the structure of this clause so that it is now unified and consistent with the other clauses in this part and follows the design-path defined in Part 1. In addition, various aspects addressing the limit state design of spread foundations have been complemented or modified such as the inclusion of the well-known Terzaghi-Buisman method for calculating the bearing resistance in the main text, the explicit consideration of rock mass as well as various calculation models provided in Annex B, e.g. models for punching failure and foundation settlement evaluation. The present paper provides an overview of the design of spread foundations according to the new Eurocode 7. A simple design example illustrates the design procedure.

RÉSUMÉ: Dans la nouvelle version de deuxième génération de l'Eurocode 7, partie 3, la conception des états limites pour diverses structures géotechniques est décrite. Les fondations superficielles sont traitées par la clause 5 de cette partie, où les exigences relatives à la vérification des états limites ultimes et d'aptitude au service sont fournies. Par rapport à la version actuelle de l'Eurocode 7, les exigences ont été améliorées tout d'abord en révisant la structure de cette clause afin qu'elle soit désormais unifiée et cohérente avec les autres clauses de cette partie et qu'elle suive le chemin de conception défini dans la partie 1. En outre, divers aspects relatifs à la conception à l'état limite des fondations superficielles ont été complétés ou modifiés, comme l'inclusion de la méthode bien connue de Terzaghi-Buisman pour le calcul de la résistance à l'appui dans le texte principal, considération explicite des masses rocheuses ainsi que divers modèles de calcul fournis dans l'annexe B, par exemple des modèles pour la rupture par poinçonnement et l'évaluation du tassement de la fondation superficielle. Le présent document donne un aperçu de la conception des fondations superficielle selon le nouvel Eurocode 7. Un exemple simple de conception illustre la procédure de conception.

Keywords: Second generation Eurocode 7; spread foundations; design; ultimate limit state; serviceability limit state.

1 INTRODUCTION

The design of spread foundations is covered in Part 3, Clause 5 of the new second generation Eurocode 7 (prEN 1997-3:2023). Clause 5 is organized with design provisions following the unified structure of all the clauses in Part 3 which reflects the design requirements in Part 1 (prEN 1997-1:2023) as illustrated in Figure 1. Clause 5 also refers to Part 2 (prEN 1997-2:2023) for required derived ground properties.

The scope of Clause 5 is the limit state design of spread foundations, i.e. of pad, strip and raft foundations. Compared to the current version of Eurocode 7 (EN 1997-1:2004 + AC:2009 + A1:2013) the scope has been extended to include unreinforced working platforms.

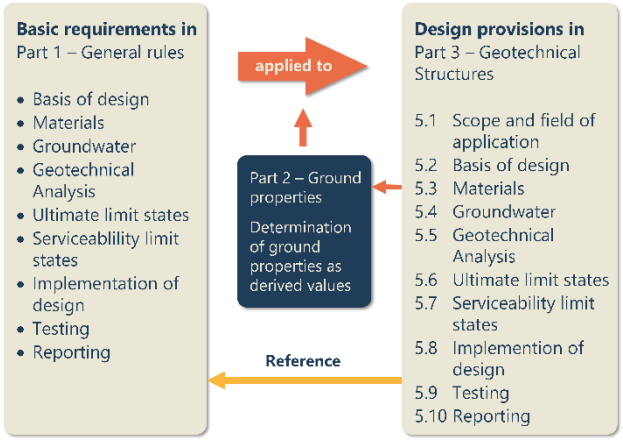

Figure 1. Structure of clause 5 – spread foundations.

While the design of load transfer platforms over rigid inclusions is covered in Clause 11 of Part 3,

Clause 5 is applicable to certain aspects as well. Furthermore, it is applicable to deep foundations such as caissons, which behave as spread foundations.

The present paper addresses the most important changes compared to the current version of the code with a focus on the basis of design, the geotechnical analysis and the verification of the ultimate and serviceability limit states. The procedure of design verification is illustrated using a simple design example at the end of this paper.

2 PHILOSOPHY AND DESIGN BASICS

2.1 Design philosophy

The head Eurocode EN 1990 (EN 1990:2023), Basis of structural and geotechnical design, states that the reliability required for structures within the scope of this document shall be achieved by design in accordance with all parts of the Eurocodes. Thus, the overall design goal is achieved if a design follows the requirements provided in Eurocode 7, Parts 1 to 3 together with those in EN 1990.

The new Eurocode 7, Part 1 provides a set of measures to achieve this reliability goal. These measures address not only the representation of design parameters and the accuracy of calculation models used, but also the prevention of errors in design and execution. They are defined at different levels, depending on the Geotechnical Category of the structure. The Geotechnical Category reflects the relationship between the Geotechnical Complexity Class, describing ground and groundwater conditions as well as ground-structure interaction, and the Consequence Class, considering the consequences of failure of the structure or the foundation. The provisions in Clause 5 address these requirements.

2.2 Basis of design

Clause 5, Subclause 5.2 summarizes the basic design information such as the design situations, geometrical properties, actions and environmental influences, limit states and ground investigations, which are spread over several subclauses in the current version of the code. Reliability, as outlined in 2.1, is addressed by reference to Part 1 only, so no specific provisions are given for spread foundations. However, the minimum extent (depth) of ground investigations defined here is one of the measures to achieve the required reliability. Table 1 shows the minimum depth values given for spread foundations. These values reflect the zone of influence of different types of spread foundations and are comparable to the recommendations in Annex B of the current Eurocode 7, Part 2. The width B is either the width of a single foundation or the width of a foundation group, depending on the considered system. The content of the table can be modified in the National Annexes.

Table 1. Minimum depth of ground investigations from Table 5.1 of prEN 1997-1:2023.

Types of spread foundations	Minimum depth
Square or circular footing	d_{min} = max (3B; 6m)
Strip footing	d_{min} = max (5B; 6m)
Raft or structure supported by a group of foundations	d_{min} = max (1.5B; 6m)

2.3 Materials and groundwater

Subclause 5.3 addresses the materials used in design. It mainly refers to Part 2 for the determination of ground properties and to Part 1, Clause 5.5 for concrete foundations. It further points out the use of effective or total stress ground properties, depending on the design situation.

Subclause 5.4 on groundwater demands explicitly the consideration of groundwater levels and pressures, which could affect the bearing behaviour of a spread foundation. Capillary rise inducing possible deterioration of footing material is mentioned as well.

3 GEOTECHNICAL ANALYSIS

The calculation models for verifying the limit states of spread foundations are the content of Subclause 5.5. The main changes compared to the current version of Eurocode 7 are related to the calculation of the bearing resistance. The well-known general Terzaghi-Buisman formulae for the bearing resistance of soils and fills for drained and undrained analysis (Terzaghi, 1943) are now presented in the code text of the new Eurocode 7. The parameters for the bearing resistance formulae are defined in Annex B.4.

The bearing resistance formulae for soil and fill were extended by depth factors and ground inclination factors. For the depth factors the formulae proposed by Brinch Hansen (1970) and adopted by Vesic (1973) and for the ground inclination factors the formulae provided by Vesic (1975) were adopted. More changes include the deletion of the cohesion term in the load inclination factors and a modification of the bearing capacity factor N_γ. For the latter the formulation provided by Caquot & Kérisel (1953) and Vesic (1973) was selected, which is slightly different from the formulae used in Annex D of the current Eurocode 7, i.e. $N_\gamma = 2(N_q + 1)\cdot\tan\varphi'$ instead of $N_\gamma = 2(N_q - 1)\cdot\tan\varphi'$. Figure 2 illustrates the effect of this modification and of the consideration of depth factors on the

foundation design width, B for a simplified design situation.

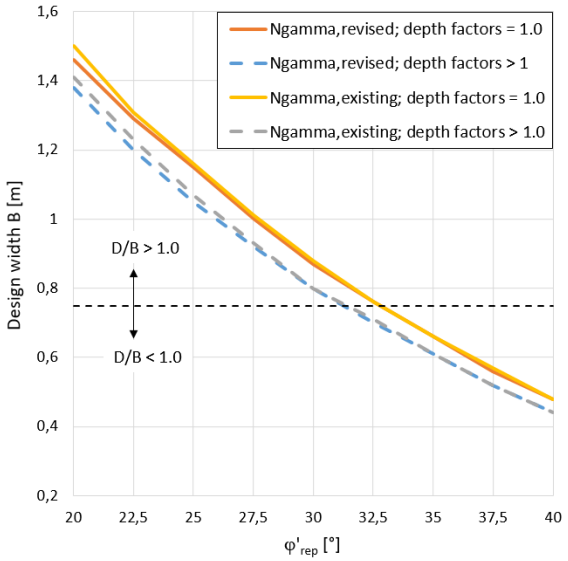

Figure 2. Design width B for a square foundation with 250 kN vertical load calculated using RFA for a dry coarse soil with γ = 18 kN/m³ and an embedment depth of D = 0.75 m (modified from M515/CEN/TC250/SC7/PT4, 2020).

Clearly, the modification of N_γ has negligible effect on B for φ‘ ≥ 27.5°. For φ‘ < 27.5° it results in widths B which are slightly smaller than with the existing formulation. No cohesion was considered here, which soils with small friction angles typically exhibit and which would increase the bearing resistance. In view of the scatter generally associated with the factor N_γ (see e.g. Paikowsky et al., 2010) the consequences of using the new N_γ formula are acceptable.

Compared to this, the effect of the depth factors is more significant. However, the depth factors should only be used with great care as the soil within the embedment zone is often disturbed. Consequently, the code states that they should only be used when the strength of the soil or fill in the embedment zone is equal to or greater than the strength of the soil below foundation level.

A further addition is that Subclause 5.5 includes some guidance on how to verify the bearing resistance of rock mass. It also allows the derivation of the bearing resistance from empirical models, provided comparable experience has shown their successful use. Annex B includes additional calculation models, e.g. for punching, a more detailed model for bearing resistance from pressuremeter test results and a model for bearing resistance of rock mass based on wedge equilibrium.

Regarding the calculation of sliding resistance and settlement or heave, no major changes have been made. Annex B provides various calculation models for settlement evaluation, e.g. based on the adjusted elasticity method and on pressuremeter or cone penetration test results.

Subclause 5.5 also includes recommendations for selecting appropriate distributions of bearing pressures for structural analysis.

4 DESIGN VERIFICATION WITH PARTIAL FACTORS

4.1 Limit states

According to Subclause 5.2.5 the design verification shall consider primarily the ultimate limit states (ULS) and serviceability limit states (SLS) shown in Figure 3.

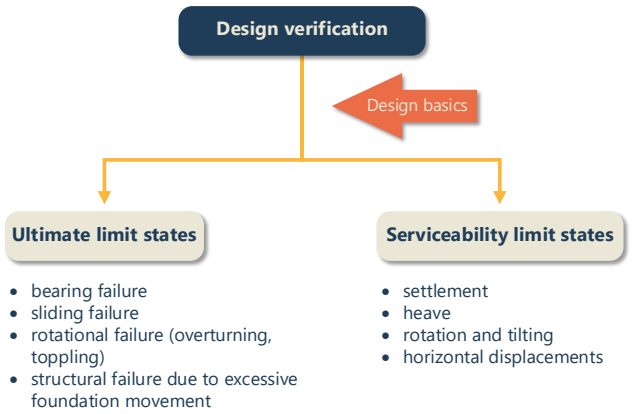

Figure 3. Ultimate and serviceability limit states of spread foundations.

Figure 3 also mentions failure by excessive deformations. However, Clause 5 does not provide recommendations on how to verify this limit state. Instead, this topic is addressed in Part 1.

4.2 Verification of the ultimate limit state

The new Eurocode 7 allows the material factor approach (MFA) and the resistance factor approach (RFA) to be used for ULS design verification. The partial resistance factors to obtain the RFA design resistances of spread foundations are provided in Subclause 5.6 of Part 3, Table 5.2, whereas the partial material factors to obtain the design MFA ground properties are given in Part 1, Table 4.8. The partial factors on actions and effects of actions are defined for different verification cases (VC) in EN 1990, Table A.1.8. The National Annexes will specify the factoring approach and partial factors to be used. The two approaches result in the combinations (a) to (c) for MFA and (d) and (e) for RFA (see Table 2). However,

combination (e) should be used only if the representative load inclination is not larger than 0.2.

Table 2. Partial factors for the ULS verification of spread foundations for persistent and transient design situations (Table 5.2, prEN 1997-3:2023).

Verification of	Partial factor on	Symbol	Material factor approach (MFA), either both combinations (a) and (b) or the single combination (c)			Resistance factor approach (RFA), either combination (d) or (e)[c]	
			(a)	(b)	(c)	(d)	(e)
Overall stability	See Clause 4						
Bearing and sliding resistance	Actions effects-of-actions	γ_F ,γ_E	VC1[a]	VC3[a]	VC1[a]	VC1[a]	VC4
	Ground properties	γ_M	M1[b]	M2[b]	M2[b]	Not factored	
	Bearing resistance	γ_{RN}	Not factored			1,4	
	Sliding resistance	γ_{RT}	Not factored			1,1	
	Passive resistance	$\gamma_{RT,face}$	Not factored			1,4	

[a] Values of the partial factors for Verification Cases (VCs) 1, 3, and 4 are given in prEN 1990:2023 Annex A.
[b] Values of the partial factors for Sets M1 and M2 are given in prEN 1997-1:2023, Table 4.8.
[c] Use combination (d) except where specified otherwise in 5.6.6 (2)

Combinations (a) and (b) correspond to the current DA1 Combination 1 and DA1 Combination 2, (d) corresponds to DA2, (e) to DA2* and (c) to DA3 with VC3 partial factors on structural actions. The new Eurocode 7 offers the possibility of reducing the partial material and partial resistance factors for transient design situations by multiplying them by a reduction factor, k_{tr} provided the products are not less than 1.0 and any constraints on its use are satisfied. It should also be noted that all tables with partial factors are Nationally Determined Parameters (NDPs) and therefore can be adjusted based on national practices and given in National Annexes.

Overall, the verification procedures for undrained and drained bearing and sliding resistances have not changed. Nevertheless, in addition to verification of the undrained sliding resistance in MFA and RFA, it still has to be checked that $R_{tud,base} \leq 0.4 \cdot N_{rep}$ ($R_{tud,base}$: design undrained base resistance; N_{rep}: representative value of the force acting normal to the foundation base (considered as favourable action)). This condition limits the load inclination when there is an irregular bearing surface with poor contact between the base of the foundation and the ground and, thus a reduced contact area, to ensure that simultaneous shearing and bearing failure does not occur. This limit corresponds to a maximum load inclination angle of 21.8° in such a design situation.

In case of eccentrically loaded spread foundations the new Eurocode 7 clearly distinguishes between the limit states of overturning and toppling. Overturning involves failure of the ground caused by rotation of the footing, whereas toppling describes a pure loss of static equilibrium without failure of the ground.

According to Subclause 5.6 the verification against overturning is covered by the bearing resistance verification. It is stated further on that the designer should note the following:

- Reduction of the plan area A to the effective plan area A' should be limited so that rotation does not cause a limit state in the foundation or the overlying structure;
- National Annexes can provide limiting values for the design eccentricity in the ULS;
- Precautions should be taken in the design if the eccentricity exceeds 1/3 of the footing width (or length) or 0.59 times the foundation radius.

It is also indicated that numerical methods can be more appropriate than the conventional bearing resistance formulae if the eccentricity is large.

For verification of the limit state of toppling reference is made to Part 1 and EN 1990. The verification includes a comparison of design stabilizing and destabilizing moments.

Finally, Subclause 5.6 provides guidance on ULS verification by prescriptive rules, testing and the observational method.

4.3 Verification of the serviceability limit state

Not many changes have been made to the verification of the serviceability limit state, which is covered in Subclause 5.7. Nevertheless, a clear distinction is now made between settlement and tilting caused by load eccentricity.

For eccentrically loaded foundations it shall also be verified that the load eccentricity remains within certain limits to confine the occurence of a physical gap at the edge of the foundation (see Table 3).

Table 3. Limits of the representative load eccentricity in SLS verification (Table 5.3, prEN 1997-3:2023).

Loading effects	Strip foundation	Circular foundation	Rectangular foundation
Permanent action effects only (No tension gap)	$\frac{e_B}{B} \leq \frac{1}{6}$	$\frac{e}{R} \leq \frac{1}{4}$	$\frac{e_L}{L} + \frac{e_B}{B} \leq \frac{1}{6}$
Permanent and variable action effects	$\frac{e_B}{B} \leq \frac{1}{3}$	$\frac{e}{R} \leq 0{,}59$	$\left[\frac{e_L}{L}\right]^2 + \left[\frac{e_B}{B}\right]^2 \leq \frac{1}{9}$

5 DESIGN EXAMPLE

The application of the design procedure outlined above will be illustrated using the example of a spread foundation under combined loading embedded in sand. For this purpose Example A2 prepared by CEN/TC250/SC7TG B2 in the course of analysing the applicability of the new Eurocode 7 (Bogusz, 2022) was selected and slightly modified. Figure 4 shows the design situation. In the following, only the ULS verification is presented.

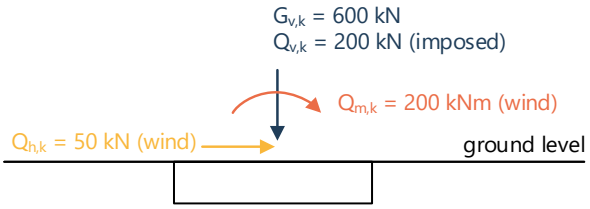

Figure 4. Design situation of a spread foundation on sand according to TG B2 example A2 by Bogusz (2022).

The cast-in-place square footing (weight density 25 kN/m³) has a width of 1.45 m and a thickness of 1.0 m which is equal to the embedment depth. The ground comprises a medium dense silty sand to significant depth and the groundwater level is located at the footing base. The representative weight density of the soil is 19 kN/m³ above and 9 kN/m³, the buoyant weight density, below groundwater level. The peak effective angle of internal friction of the silty sand is 39°. The foundation carries a vertical central permanent load of 600 kN, an imposed central vertical variable load of 200 kN, a horizontal wind load of 50 kN and a moment due to wind of 200 kNm. In the following, the ULS of the foundation is verified for Consequence Class 2 (CC2).

Table 4 summarizes the partial factors adopted in the various MFA and RFA approaches recommended for CC2 (see Section 4.2). In Combination (e) (RFA/VC4) the factor γ_Q results from $\gamma_Q = \gamma_Q/\gamma_E = 1.5/1.35 = 1.11$ (see EN 1990, Table A.1.8).

Table 4. Partial factors for the design example for the different combinations.

	MFA			RFA	
	a	b	c	d	e
	VC1	VC3	VC1	VC1	VC4
γ_G	1.35	1.0	1.35	1.35	1.0
$\gamma_{G,fav}$	1.0	1.0	1.0	1.0	1.0
γ_Q	1.5	1.3	1.5	1.5	1.11
γ_E	1.0	1.0	1.0	1.0	1.35
$\gamma_{\tan\varphi,p}$	1.0	1.25	1.25	1.0	1.0
$\gamma_{\tan\delta}$	1.0	1.25	1.25	1.0	1.0
γ_{RN}	1.0	1.0	1.0	1.4	1.4
γ_{RT}	1.0	1.0	1.0	1.1	1.1

To determine the representative load, combination factors according to Table A.1.7 of EN 1990 need to be considered, which are $\psi_0 = 0.7$ for imposed loads on buildings and $\psi_0 = 0.6$ for wind actions. With that, the following two load combinations were considered here for the bearing resistance verification: LC1 when the imposed load is the leading variable action and LC2 when wind effects are the leading variable actions (horizontal load and moment resulting from the same source). For the sliding resistance, load case LC3 is used with the permanent load assumed to act favourably ($\gamma_{G,fav}$ = 1.0 for all combinations). Since only wind effects are considered, the imposed load must be neglected.

Table 5 presents the resultant design loads for bearing and sliding resistance verification. For bearing resistance only the LC2 design loads are provided. The table also indicates which value (representative or design, unfactored or factored) of the soil shear strength (tan φ') and the strength in the footing interface (tan δ) must be considered. Note that the footing is cast-in-place so tan δ = tan φ'.

Table 5. Design loads for bearing resistance (LC2 only) and for sliding resistance (LC3) verification and relevant strength parameters for soil and footing interface (all numbers are rounded).

	MFA			RFA	
	a	b	c	d	e
	VC1	VC3	VC1	VC1	VC4
Design loads for bearing resistance [kN] or [kNm]					
$G_{v,d}$	881	653	881	881	653
$Q_{v,d}$	300	260	300	300	222
$Q_{h,d}$	45	39	45	45	33
$Q_{m,d}$	225	195	225	225	167
Design load for sliding resistance [kN]					
T_d	75	65	75	75	75
Relevant shear strength [-]					
$\tan\varphi'_{rep}$	-	-	-	0.81	0.81
$\tan\varphi_d$	0.81	0.65	0.65	-	-
$\tan\delta_{rep}$	-	-	-	0.81	0.81
$\tan\delta_d$	0.81	0.65	0.65	-	-

Table 6 shows the results of the design verifications for the assumed footing width of 1.45 m. Figure 5 illustrates these results by comparing the utilization achieved by the different combinations (a) to (e). The utilization is defined as the ratio of N_d/R_{Nd} and T_d/R_{Td}.

The results indicate that for this design example the RFA, with combinations (d) and (e), leads to consistent results for both the bearing and sliding resistance verification. For MFA, combination (a), in which the shear strength is not factored, leads to a much lower utilization than combination (b), in which the strength and the variable actions are factored, and so combination (b) controls the design in this case. Combination (c), in which both the strength and all the actions are factored and which can be used alternatively to (a) and (b) (see Table 2), leads to the highest utilization in MFA and hence to more conservative designs.

Table 6. Design values of effects of actions and resistances as well as resultant utilization for bearing resistance and sliding resistance verifications (all numbers are rounded).

	MFA			RFA	
	a	b	c	d	e
	VC1	VC3	VC1	VC1	VC4
Bearing resistance verification					
N_d	1181	913	1181	1181	1181
R_{Nd}	3738	1634	1744	2670	2670
N_d/ R_{Nd}	**0.32**	**0.56**	**0.68**	**0.44**	**0.44**
Sliding resistance verification					
T_d	75	65	75	75	75
R_{Td}	528	423	423	480	480
T_d/ R_{Td}	**0.14**	**0.15**	**0.18**	**0.16**	**0.16**

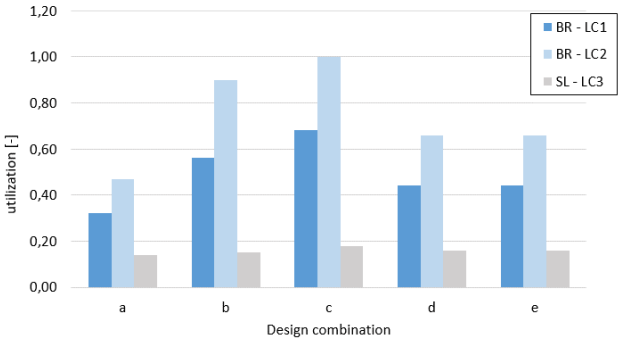

Figure 5. Comparison of the utilization achieved for the different combinations of partial factors for bearing resistance (BR) and sliding resistance (SR).

6 CONCLUSIONS

This paper addresses the design of spread foundations according to the new Eurocode 7. Overall, it can be stated that the design methodology has not changed in comparison to the current version of the code. On the other hand, improvements have been reached e.g. by a clear and unified structure of the code, by an increased harmonization in regard to the calculation of the bearing resistance, by the explicit distinction between soil/fill and rock and by a significantly extended informative Annex B including more calculation models.

Also the new code allows sufficient flexibility to accommodate national design practices and traditions through modification of existing or inclusion of additional tables with NDP values. However, the design example showed that the different alternatives of combining the partial factors lead to significant differences in the design results. So, these factors need to be defined with great care reflecting national design requirements and experiences.

ABSTRACT: Hybridnamic Rapid Load Test (Hybridnamic RLT) and Static Load Test (SLT) were carried out on three identical open-ended steel pipe piles (SPPs), named Piles No. 2, No. 4 and No. 5, in the Jibanshikenjo test yard at Sashima, Ibaraki Prefecture, Japan. The test piles had an outer diameter of 318.5 mm, a wall thickness of 6.6 mm and an embedment length of 11.0 m. In the RLTs, the classic UnLoading Point Connection (ULPC) method and a new interpretation method: UnLoading Point Connection method invoking Case Method (ULPC_CM) proposed by the authors, were used to obtain "static" load-displacement curves. According to the Japanese RLT standards, the relative loading duration $T_r = t_L/(2L/c)$ (t_L is loading duration, L is pile length, c is bar wave velocity in the pile) shall be greater than 5. In Pile No. 4, RLTs with T_r = 5 were caried out after SLT. In Pile No. 2, RLTs with T_r = 3 were carried out intentionally prior to SLT. In Pile No. 5, RLTs with T_r = 3 were caried out after SLT. In this paper, test conditions and test results are presented in detail. It will be shown that the static load-displacement curves from the ULPC method overestimate the SLT results, while the static load-displacement curves from the ULPC_CM method conform to the SLT results well even if T_r decreased to 3.

RÉSUMÉ: Des tests de charge rapide Hybridnamic (Hybridnamic RLT) et des tests de charge statique (SLT) ont été réalisés sur trois pieux en acier à extrémité ouverte identiques (SPP), nommés Pieux n°2, n°4 et n°5, dans la cour d'essai de Jibanshikenjo à Sashima, préfecture d'Ibaraki, au Japon. Les pieux d'essai avaient un diamètre extérieur de 318,5 mm, une épaisseur de paroi de 6,6 mm et une longueur d'enfouissement de 11,0 m. Dans les RLT, la méthode classique de Connexion du Point de Déchargement (ULPC) ainsi qu'une nouvelle méthode d'interprétation, la méthode de Connexion du Point de Déchargement invoquant la Méthode de Case (ULPC_CM) proposée par les auteurs, ont été utilisées pour obtenir des courbes de charge-déplacement "statiques". Conformément aux normes japonaises en matière de RLT, la durée relative de chargement T_r doit être supérieure à 5. Dans le Pieu n°4, des RLT avec T_r = 5 ont été effectués après le SLT. Dans le Pieu n°2, des RLT avec T_r = 3 ont été intentionnellement réalisés avant le SLT. Dans le Pieu n°5, des RLT avec T_r = 3 ont été effectués après le SLT. Dans cet article, les conditions d'essai et les résultats sont présentés en détail. Il sera démontré que les courbes de charge-déplacement statiques obtenues par la méthode ULPC surestiment les résultats du SLT, tandis que les courbes de charge-déplacement statiques obtenues par la méthode ULPC_CM sont en bonne concordance avec les résultats du SLT, même lorsque T_r est réduit à 3.

Keywords: Rapid load test; static load test; steel pipe pile; interpretation method; case study.

1 INTRODUCTION

The first standards for the method for Rapid Load Test (RLT) of single piles were published in 2002 (JGS, 2002). In the standards, load test with relative loading duration $T_r \geqq 5$ is defined as RLT, because it is thought that the wave propagation phenomena can be negligible. In the conventional interpretation method, UnLoading Point Connection method (ULPC), the pile body is modelled as a rigid single mass.

Aiming at widening the range of application of RLT, a new signal interpretation method, the

UnLoading Point Connection method invoking Case method (ULPC_CM) was proposed (Lin et al., 2023).

In this study, RLTs were carried out on three steel pipe piles (SPPs) with different relative loading durations, T_r = 5 and 3. Furthermore, Static Load Test (SLT) and RLT were carried out in different order. Load-displacement curves obtained from SLT and RLT using two interpretation methods, ULPC and ULPC_CM, were compared to examine the advantages and reliability of the new interpretation method over the conventional ULPC method.

2 OUTLINE OF PILE LOAD TESTS

2.1 Site conditions

Load tests were carried out in Sashima test yard of Jibanshikenjo Co. Ltd., Japan. Figure 1 shows the arrangements of soil investigations and test piles. One Standard Penetration Test (SPT) and Electric Cone Penetration Tests (CPTs) were carried out at just points of test piles.

Figure 2 shows the results of soil investigations, and embedment of the instrumented test piles. SPT *N*-values from the ground level to a depth z = 5 m are 1 to 3. Below this depth, *N*-value increases with depth. Below z = 10 m, a sand layer with $N \approx 33$ exists. The test piles were driven to z = 11 m. Groundwater table is at z =3.5 m. It can be seen from the distributions of SPT-*N* and CPT q_t (cone resistance corrected for pore pressure at filter) that ground conditions are similar in each test pile location.

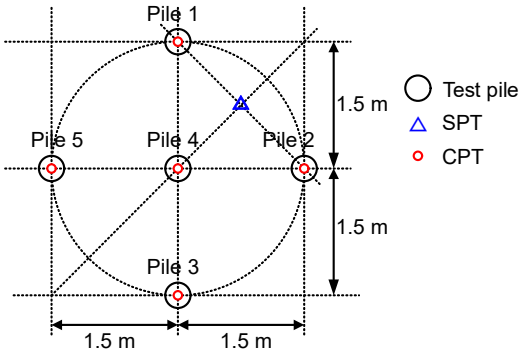

Figure 1. Locations of SPT, CPTs and test piles.

2.2 Test piles

Table 1 shows the specifications of 5 test steel pipe piles (SPPs). Channel steels were welded on the outer surface of the test SPPs for protecting strain gages and accelerometers.

Table 1. Specifications of test piles.

Item	Value	
	Original	with protection
Pile length, L (m)	11.8

2.3 Test cases

Table 2 shows the test sequence of each test pile. Dynamic Load Tests (DLTs) were carried out during initial pile driving. After curing period of 1 day, DLTs were carried out again on Pile No. 1 and Pile No. 2 to grasp "set-up" phenomena. RLTs with the relative loading duration $T_r = t_L/(2L/c) = 5$ (t_L is the loading duration, L is pile length, c is bar wave velocity in the pile) were carried out on Pile No. 1 and Pile No. 4, according to the JGS standards (JGS, 2002) in which $T_r \geqq 5$ is required. RLTs with $T_r = 3$ were carried out on Piles No. 2 and No. 5 intentionally. If RLT with shorter T_r is reasonable, it will be possible to apply RLT to piles with longer length and greater bearing capacity using the current RLT devices.

3 INTERPRETATION METHODS OF RLT

In this section, interpretation methods of RLT signals used in this research are described.

3.1 ULPC method

The ULPC method is an extension method of UnLoading Point (ULP) method. In ULPC, the pile is treated as a rigid single mass. To obtain soil resistance R_{soil}, the pile inertial force $R_a = m\alpha$ (m = the pile mass and α = acceleration at pile head) is subtracted from the rapid load F_{rapid}. ULP is the point of R_{soil} at the maximum pile displacement w, where pile velocity v = 0. Hence, R_{soil} at ULP is equal to the static soil resistance R_w. By connecting ULPs from multiple blows, static load-displacement relation is easily obtained.

3.2 ULPC_CM method (Lin et al., 2023)

The Case method (Raushe et al., 1985) is a method based on the one-dimensional stress-wave theory, in which the penetration resistance R_t (= R_{soil}) of a pile during driving is estimated.

First, the downward traveling wave F_d and the upward traveling wave F_u are calculated from the measured dynamic signals (axial force F and pile velocity v) by means of Eqs. (1) and (2), respectively; then, by using Eq. (3), the time variation of R_t (= R_{soil}) is obtained (Figure 3):

$$F_d(x_m,t) = \frac{F(x_m,t) + Z \cdot v(x_m,t)}{2} \quad (1)$$

$$F_u(x_m,t) = \frac{F(x_m,t) - Z \cdot v(x_m,t)}{2} \quad (2)$$

$$R_t(x_m,t) = F_d\left(x_m, t - \frac{L_m}{c}\right) + F_u\left(x_m, t + \frac{L_m}{c}\right) \quad (3)$$

where, x = coordinate along the pile axis (pile head = 0), x_m = measurement position, L_m = pile length from x_m to pile tip, Z = impedance (=EA/c).

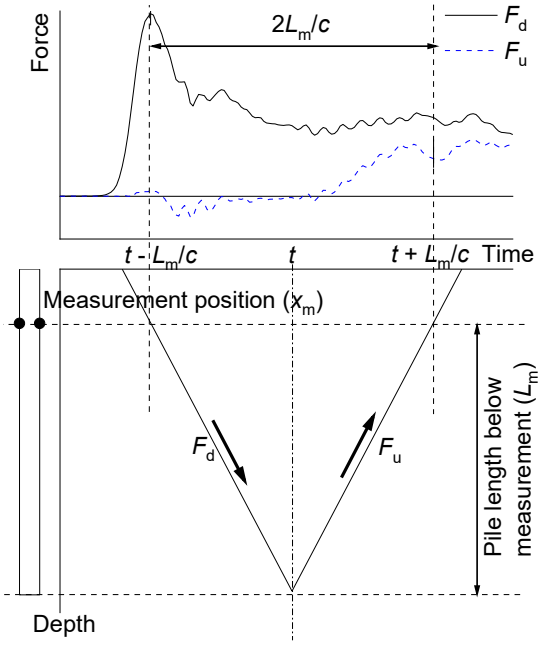

Figure 3. Case method (Raushe et al. 1985).

The Case method evaluates the penetration resistance of the pile during driving, but the load-displacement relationship of the pile cannot be obtained by this method alone. Since the Case method is based on the one-dimensional wave theory, the penetration resistance of the pile can be evaluated correctly regardless of the pile length.

In the ULPC_CM method, multiple blows (rapid load tests) are applied to a pile. The time variation of soil resistance R_{soil} is obtained from the Case method, and the time variation of pile displacement w is directly measured. Hence, $R_{soil} - w$ relation is easily obtained. R_{soil} at the maximum pile displacement can be regarded as the static resistance R_w. Similar to the ULPC method, static load-displacement curve is constructed by connecting ULPs from the multiple blows.

As the ULPC_CM method is based on the one-dimensional stress-wave theory, it has the advantage of not requiring correction for pile inertia R_a. Hence, the ULPC_CM method would be applied to RLTs on piles with $T_r < 5$.

4 COMPARISON OF RESULTS OF SLT AND RLT

4.1 SLT

SLTs were carried out on Piles No. 4, No. 2 and No. 5. The results of SLT will be shown in comparison with the RLT results later.

4.2 RLT (Pile No.4, $T_r = 5$)

In Pile No. 4, RLTs were carried out after SLT. In RLTs, a hammer mass m_h = 3.5 ton was used and 8 blows (RLTs) were applied to the pile with increasing drop height h from 0.03 to 0.83 m. Loading duration t_L was adjusted by changing the stiffness of cushion placed on the pile head to have $T_r \geqq 5$.

Figure 4 shows the measured dynamic signals, rapid load F_{rapid}, pile head displacement w, velocity v and acceleration α, in the RLT at h = 0.83 m (8th blow). In the figure, soil resistance R_{soil} (ULPC) from the ULPC method, R_{soil} (ULPC_CM) from the ULPC_CM method are shown together with F_{rapid}. Furthermore, F_d and F_u are also shown.

R_{soil} (ULPC_CM) at the maximum w where $v = 0$ is defined as the static resistance R_w (R_{ULP}) in a similar way to the ULPC method. Static load-displacement relation can be obtained by connecting R_{ULP} from ULPC_CM from multiple blows (RLTs).

Figure 5 shows the static load-displacement relations from ULPC and ULPC_CM compared with the SLT result. It is seen from the RLT results that the static soil resistance R_w from ULPC is larger than that from ULPC_CM. The load-displacement relation from ULPC_CM matches with the SLT result very well.

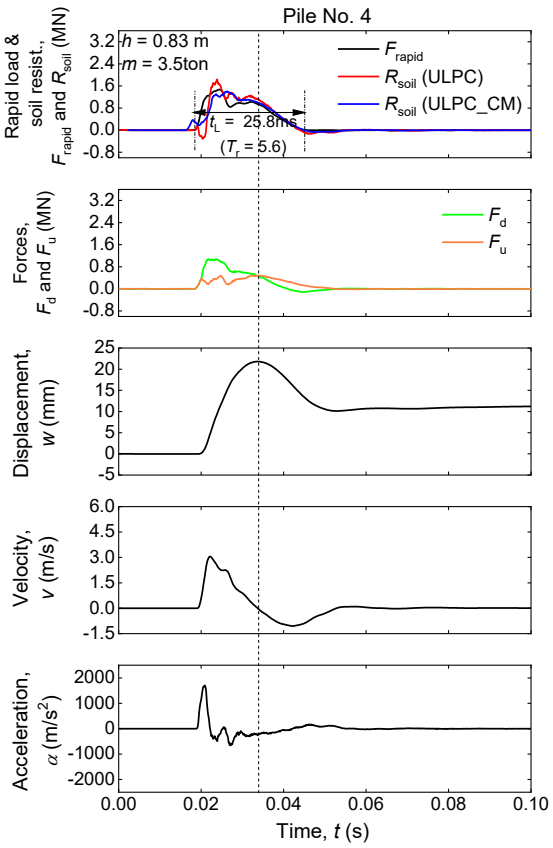

Figure 4. RLT signals (Pile No. 4, h = 0.83 m).

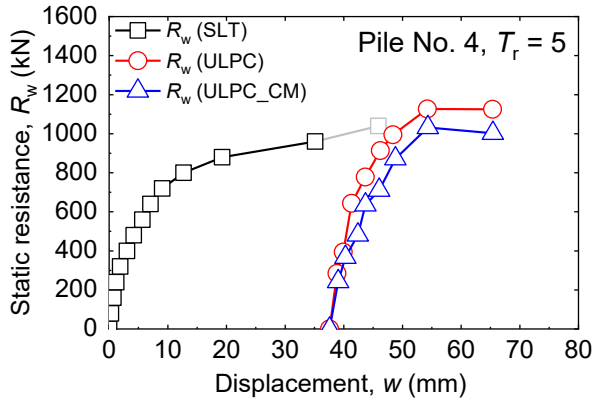

Figure 5. Comparison of load-displacement curves from SLT, RLTs with ULPC and ULPC_CM (Pile No. 4).

4.3 RLT (Pile No.2, $T_r = 3$)

In Pile No. 2, SLT was carried out after RLTs. In RLTs, a hammer mass m_h = 0.95 ton was used and 12 blows (RLTs) with $T_r = 3$ were applied to the pile with increasing drop height h from 0.02 to 3.84 m.

Figure 6 shows the measured F_{rapid}, w, v and α in the RLT in the 8th blow (h = 1.35 m) with T_r = 3.2. In the figure, R_{soil} (ULPC) and R_{soil} (ULPC_CM) are

shown together with F_{rapid}. Furthermore, F_d and F_u are also shown.

Figure 7 shows the static load-displacement relations from ULPC and ULPC_CM compared with SLT result. The load-displacement relation from ULPC_CM matches with the SLT result very well again, even for a shorter $T_r \approx 3$.

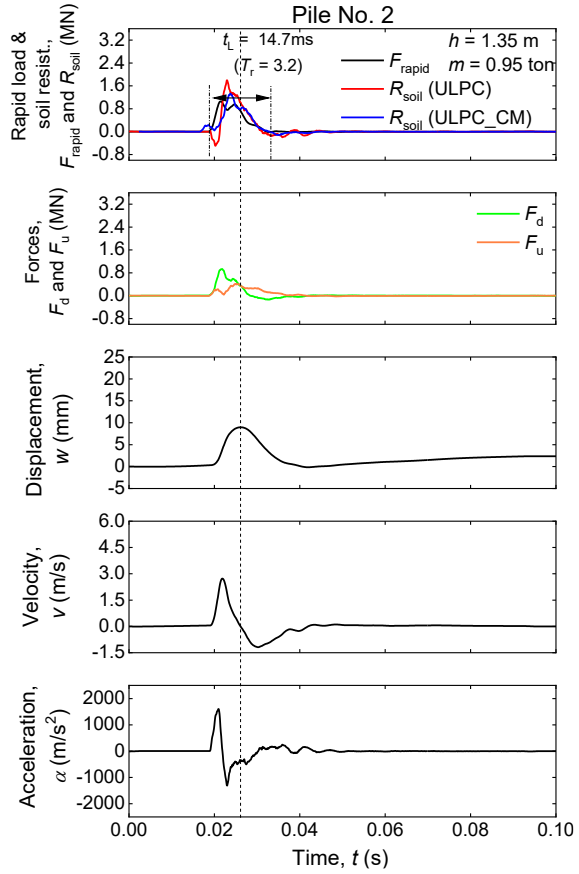

Figure 6. RLT signals (Pile No. 2, h = 1.35 m).

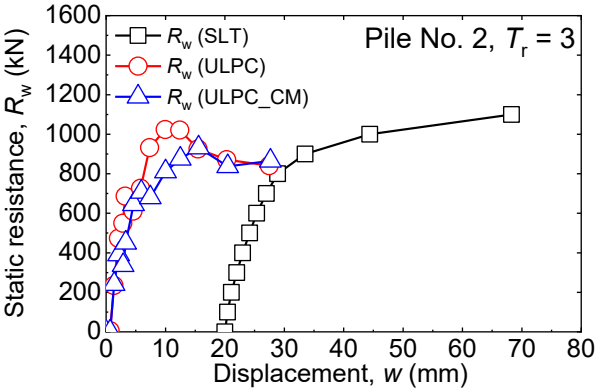

Figure 7. Comparison of load-displacement curves from SLT, RLTs with ULPC and ULPC_CM (Pile No. 2).

4.4 RLT (Pile No.5, T_r = 3)

In Pile No. 5, RLTs were carried out after SLT. In RLTs, a hammer mass m_h = 0.95 ton was used and 13 blows (RLTs) with T_r = 3 were applied to the pile with increasing drop height h from 0.02 to 3.84 m.

Figure 8 shows the measured F_{rapid}, w, v and α in the RLT in the 13th blow (h = 3.84 m) with T_r = 3.5.

Figure 9 shows the static load-displacement relations from ULPC and ULPC_CM compared with SLT result. The load-displacement relation from ULPC_CM matches with the SLT result very well again, even for $T_r \approx 3$.

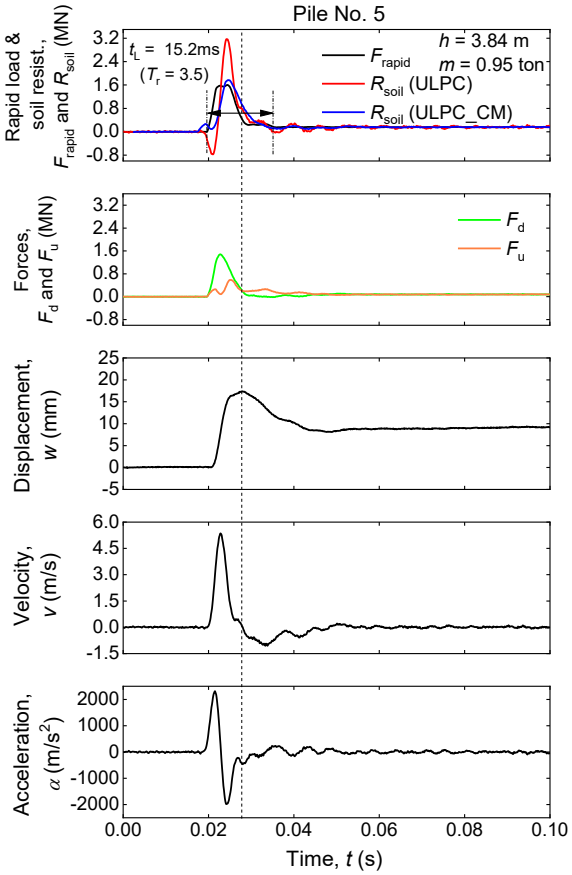

Figure 8. RLT signals (Pile No. 5, h = 3.84 m).

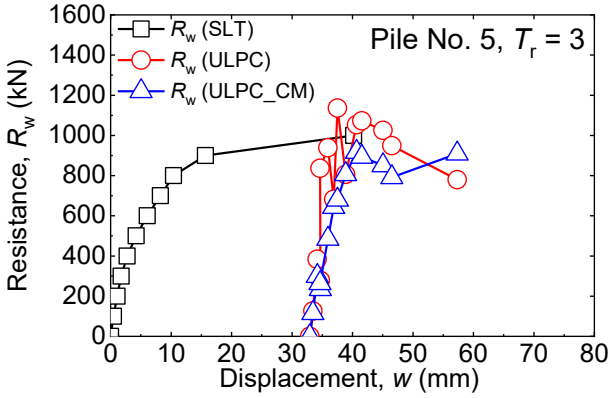

Figure 9. Comparison of load-displacement curves from SLT, RLTs with ULPC and ULPC_CM (Pile No. 5).

4.5 Comparison of results of RLTs having different relative loading durations

Figure 10 shows the comparison of load-displacement curves from SLT and RLTs with ULPC interpretation for the three test piles. ULPC result in case of $T_r = 5$ is consistent with the SLT result. However, the results in cases of $T_r = 3$ fluctuate and overestimate the SLT result. This suggests that ULPC is applicable for RLTs with $T_r \geqq 5$ as specified in the JGS standards.

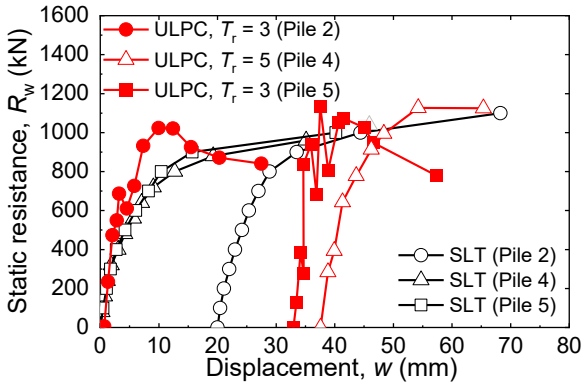

Figure 10. Comparison of load-displacement curves from SLT, RLTs with ULPC.

Figure 11 shows the comparison of load-displacement curves from SLT and RLTs with ULPC_CM interpretation for the three test piles.

Despite a slight underestimation, the load-displacement curves in both cases of $T_r = 3$ and 5 are comparable to the SLT results.

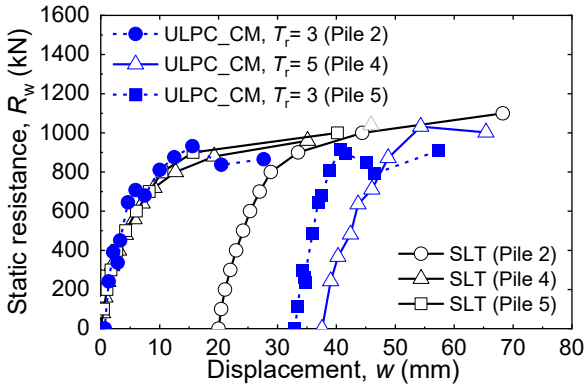

Figure 11. Comparison of load-displacement curves from SLT, RLTs with ULPC_CM.

Figure 12 shows an example of application ranges of RLTs with different T_r in case of m_h = 100 ton and h = 3.00 m. The stiffness of the cushion is varied so that required T_r is satisfied.

With the widened range of application of RLT by decreasing T_r in RLT with ULPC_CM method, it is possible to apply RLTs to a longer and higher capacity pile with the same loading device. On the other hand, it is possible to carry out RLT with the same load by using a lighter hammer, providing a more economical and convenient testing option.

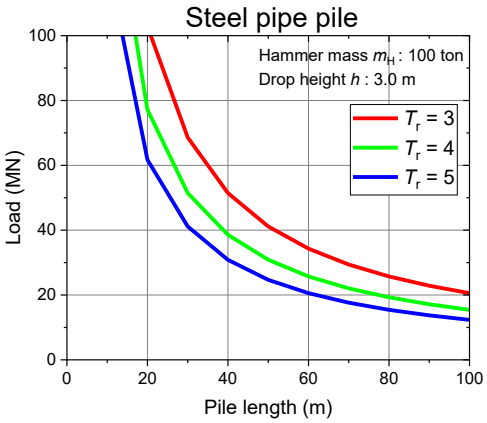

Figure 12. Application ranges of RLTs with different T_r.

5 CONCLUSIONS

In this study, comparative RLTs and SLTs were carried out on driven steel pipe piles to examine the validity of the new interpretation methods: ULPC_CM.

RLTs with $T_r = 5$ were carried out according to the JGS Standards in which T_r is required to be equal or greater than 5. Furthermore, RLTs with $T_r = 3$ were carried out to widen the application of RLT.

The static load-displacement relations from the ULPC_CM method matched with the SLT results very well even in cases of $T_r = 3$, regardless of order of SLT and RLT.

It can be said that it is possible to apply the RLT with ULPC_CM method to piles with longer length and greater bearing capacity using the current RLT devices.

The authors are planning to conduct similar comparisons between RLTs and SLT for different types of piles to examine the applicability of ULPC_CM method in the near future.

Various approaches to derive state of tailings materials on the basis of shear wave velocity measurement

Différentes approches pour dériver l'état des matériaux de résidus sur la base de la mesure de la vitesse des ondes de cisaillement

ABSTRACT: Undrained response of cohesionless soils to cyclic or monotonic loading might lead to liquefaction phenomenon, especially when material is in relatively loose or medium dense state. Such situations are often encountered in case of tailings storage facilities with special reference to those constructed by upstream method. High sensitivity of tailings material to sample disturbance create strong promise to look for alternative approaches than conventional sampling. The method based on laboratory measurement of shear wave velocity (V_S) on reconstituted sample and combined with relevant V_S values determined on undisturbed material *in situ* deserves special attention since V_S reflects changes in state of stress and void ratio as well. The important issue of such approach is a formula which links shear wave velocity, void ratio and state of stress. The paper presents a three conceivable formulae which were derived on basis of comprehensive triaxial test program carried out on two batches of tailings with various amount of fines. Logarithm and various power function regressions were considered. After a brief explanation of the derivation basis for all the considered formulas, the results of projecting the correlation for the tailings profile were shown for selected granulation.

RÉSUMÉ: La réponse non drainée des sols sans cohésion à une charge cyclique ou monotone peut conduire à un phénomène de liquéfaction, en particulier lorsque le matériau est relativement lâche ou moyennement dense. De telles situations sont souvent rencontrées dans le cas d'installations de stockage de résidus, en particulier celles construites par la méthode en amont. La grande sensibilité du matériau des résidus à la perturbation de l'échantillon incite fortement à rechercher des approches alternatives à l'échantillonnage conventionnel. La méthode basée sur la mesure en laboratoire de la vitesse des ondes de cisaillement (*Vs*) sur l'échantillon reconstitué et combinée avec les valeurs VS pertinentes déterminées sur le matériau non perturbé in situ mérite une attention particulière puisque la *Vs* reflète également les changements dans l'état de contrainte et d'indice de vides. La question importante de cette approche est une formule qui relie la vitesse de l'onde de cisaillement, d'indice de vide et l'état de contrainte. L'article présente trois formules concevables qui ont été dérivées sur la base d'un programme d'essais triaxiaux complet réalisé sur deux lots de résidus avec différentes quantités de fines. Des régressions logarithmiques et diverses fonctions de puissance ont été prises en compte. Après une brève explication de la base de dérivation de toutes les formules considérées, les résultats de la projection de la corrélation sur le profil des résidus ont été montrés pour une granulation sélectionnée.

Keywords: Soil liquefaction; state of tailings material; shear wave velocity; fines content.

1 INTRODUCTION

Liquefaction of soil is one of the most challenging issues in geotechnical engineering. Accumulated experience concerning this subject during the last sixty years has shown that mechanism of liquefaction is similar in case of cyclic and monotonic loading (e.g. Casagrande, 1975). This might be one of the reasons why critical state approach to soil liquefaction is so popular among engineers. This concept assumes that initial state prior to undrained loading determines the type of response of cohesionless materials to undrained loading – dilative (safe) or contractive (unsafe) response associated with liquefaction. Laboratory experience proves that in case of coarse sand characterized by relatively small slope of steady state line (SSL) the third type of response can be noticed i.e. limited strain softening also associated with liquefaction of soil. Strain rate during load controlled tests in which such a response of material appears is very high, as in the case of full collapse behaviour. In Figure 1 this type of response is shown

in the form of stress-strain diaphragm, stress paths and excess pore pressure charts. The same characteristics are shown for comparison for sample that revealed slightly dilative response. It is worth to emphasize the very small difference in value of void ratio (Δe= 0.011) between the samples. This proves how important is accuracy of void ratio determination in liquefaction problems. Sampling of cohesionless soils is inevitably associated with sample disturbance resulting in change in void ratio which might convert response of soil. Therefore, there is a need to look for an alternative approach to get soil of representative state.

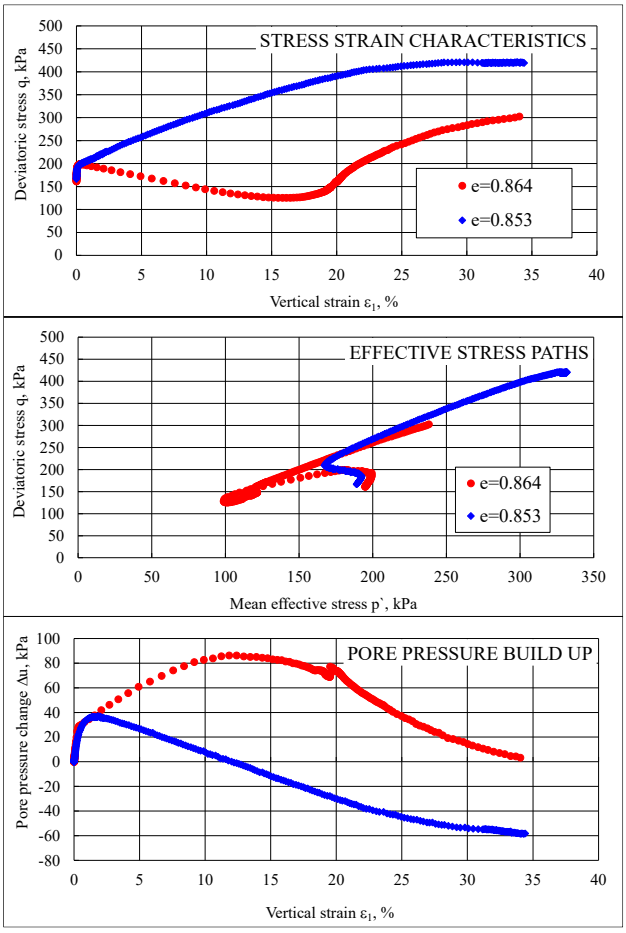

Figure 1. Sensitivity of undrained response of coarse sand to monotonic loading to small change in void ratio.

One of the conceivable solution of bypassing problems with sample disturbance is based on shear wave velocity measurement. The major argument for use of shear wave velocity (V_S) is that its value depends mainly on components of stress state and void ratio value i.e. both variables contributing to state of material. In addition shear wave velocity can be measured in the laboratory and in situ as well so that correlation obtained in the triaxial apparatus may be projected on a soil profile. Such combination of laboratory and field measurement is usually referred to as “hybrid method”. This approach is very convenient to use in case of tailings dams constructed by upstream method where liquefaction hazard is a major concern and high quality undisturbed sampling is not feasible. Additional difficulty associated with such constructions is considerable spatial variability of tailings materials containing various amount of fines. The latter controls compressibility characteristics and position of steady state lines which strictly contribute to the value of state parameter ψ (Been and Jefferies, 1985).

The procedure of evaluating void ratio distribution in the tailings profile on the basis of hybrid approach can be found in other authors' papers (e.g. Lipinski et al., 2023). It should be pointed out that relations between shear wave velocity and state of stress can be described by various formulae. In the further paragraphs of the paper application of hybrid method is presented with the use of three different relations among shear wave velocity, void ratio and stress components. At first, the results of most popular approach based on normalized shear wave velocity with respect to vertical effective stress are presented. Next, shear wave velocities were approximated against mean effective stress by logarithm and power function regressions.

2 LABORATORY TEST PROCEDURE

Triaxial tests were carried out on reconstituted specimens which were 50 mm in diameter and 100 mm in height. Triaxial cell with internal linking bars and high resolution proximity transducers for internal measurement of deformation were used for the test (Lipinski et al. 2020). Specimens were prepared by moist tamping by undercompaction method which enables preparation of samples in a wide range of void ratio, especially for loose state. When a triaxial cell was assembled, a specimen was saturated by back pressure until Skempton's parameter B exceeded value 0.96. After saturation specimens were consolidated anisotropically with zero lateral strain. When consolidation was terminated, shear wave velocity was measured. Piezoelectric transducer of bender type was used for sending and receiving the signals.

Two kinds of predominantly silicious tailings batches were tested which represented sand like behaviour and transition zone material. The batches contained respectively 10% and 36% of fines content i.e. material passing sieve diameter 0,075 mm.

Shear wave velocity $V_{S(VH)}$ in the field was measured during seismic cone tests (SCPTu).

2 NORMALIZED SHEAR WAVE VELOCITY

Most popular approach allowing to extract components representing void ratio and soil structure from measured value of shear wave velocity is its normalization with respect to vertical effective stress (Robertson et al., 1992). The following formula was proposed:

$$V_{S1} = V_S \left(\frac{Pa}{\sigma_v'}\right)^{0.25} \quad (1)$$

where:

V_{S1} - normalized shear wave velocity (m/s)

V_S - shear wave velocity (m/s)

σ'_v - vertical effective stress (kPa)

Pa - reference pressure (usually 100 kPa)

By normalization of V_S with respect to vertical effective stress a unique relationship between normalized shear wave velocity and void ratio can be achieved. Normalization can be done with respect not only to vertical effective stress but also with respect to both components of principal effective stress. The results of both approaches with characteristics showing relationship between normalized shear wave velocity and void ratio were presented in paper (Lipinski et al., 2017). The formulae linking void ratio with shear wave velocity and vertical effective stress were the following:

for tailings with 10% of fines:

$$e = \frac{343.57 - V_S\left(\frac{100}{\sigma_v'}\right)^{0.25}}{189.02} \quad (2)$$

for tailings 36% of fines:

$$e = \frac{472.38 - V_S\left(\frac{100}{\sigma_v'}\right)^{0.25}}{432.69} \quad (3)$$

The comparison of measured and calculated values of void ratio on the basis of the above formulae for both kinds of tailings is shown in Figure 2.

The obtained comparison reveals significant difference between two kinds of soil. For sandy materials with 10% of fines the values of void ratio predicted by trend line are in a good agreement with the measured ones. For tailings with 36% of fines the calculated values are substantially higher than the measured ones, especially for denser state.

4 APPROACH BASED ON FIT CURVES

The analysis of the laboratory test results allowed us to determine that the relationship between the shear wave velocity Vs and the mean effective stress p' can be reflected by a power function of the form:

$$V_s = Ap'^B \quad (4)$$

or a logarithmic function of the form:

$$V_s = Alnp' + B \quad (5)$$

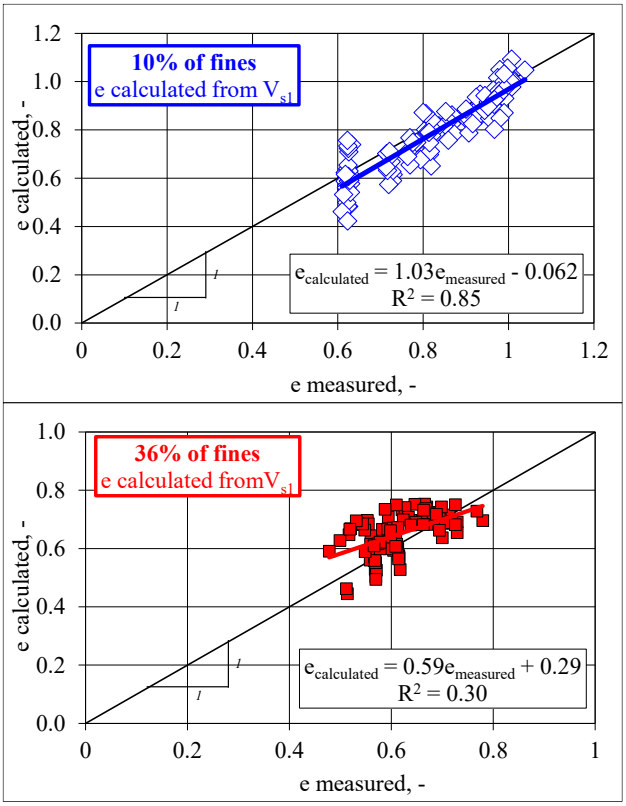

Figure 2. Calculated against measured values of void ratio on the basis of normalized shear wave velocity for material containing 10% and 36% of fines.

In order to show the differences between the two solutions, each of the above functions was determined for several ranges of void ratio and presented on a linear and logarithmic scale of the mean effective stress p'. Both types of regression have a high R-squared value - above 0.89 for the power function and above 0.92 for the logarithmic function. The data and the procedure for derivation of the formulae was presented in detail in authors' papers for power function (Lipinski and Wdowska, 2020) and for the logarithmic function (Lipinski and Wdowska, 2019), respectively. There is no clear answer to the question which function is better suited; function fit varies in different void ratio ranges. Due to the fact that the coefficient of the independent variable is proportional

to the void ratio, it is possible to obtain a procedure for determining the relationships enabling the calculation of the void ratio value. The procedure is shown in the diagram in Figure 3.

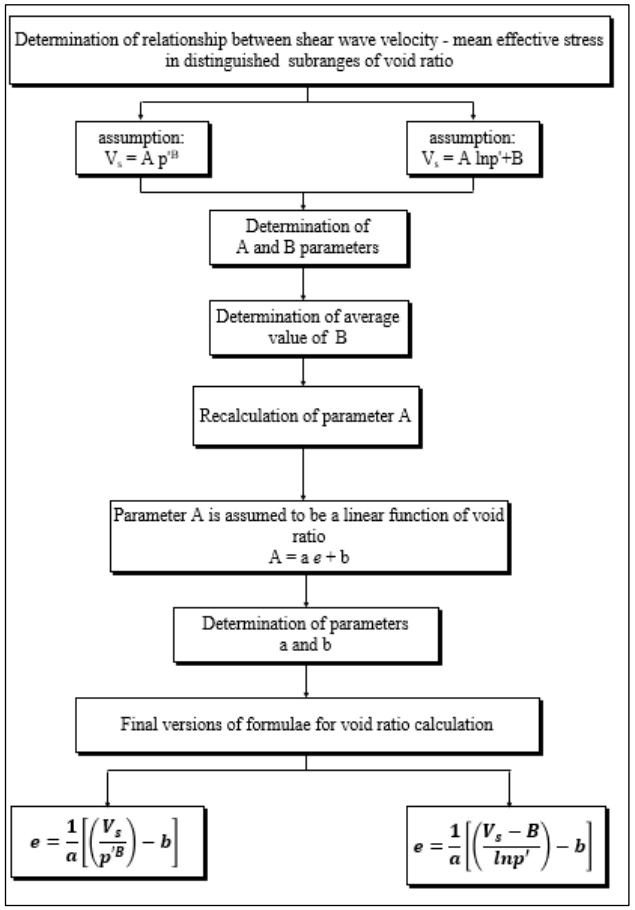

Figure 3. Procedure for determination of formulae for void ratio calculation based on logarithmic and power functions fit curves $V_s = f(p')$.

The derived formulae are the following:
for power function:

$$e = \frac{1}{a}\left[\left(\frac{V_S}{p'^B}\right) - b\right] \quad (6)$$

$$e = \frac{1}{a}\left[\left(\frac{V_S - B}{\ln p'}\right) - b\right] \quad (7)$$

Similarly, in the case of normalized shear wave velocity, the charts comparing void ratio calculated on the basis of both above formulae against the measured values were prepared. They are showed in Figure 4 for tailings with 10% of fines and in Figure 5 for finer material with 36% of fines.

For sandy materials R-squared values are high, (approximately 0.87 for both chars), although trend line in case of logarithmic function better fits the equal value line. In case of both formulae void ratio for loose material is better predicted.

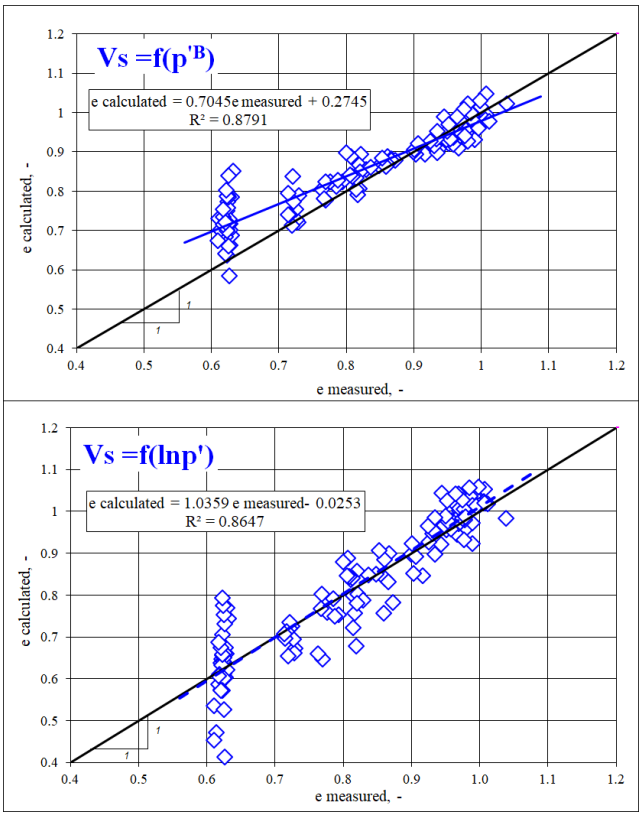

Figure 4. Comparison of measured and calculated (with both formulae) void ratio values for soils containing 10% of fines.

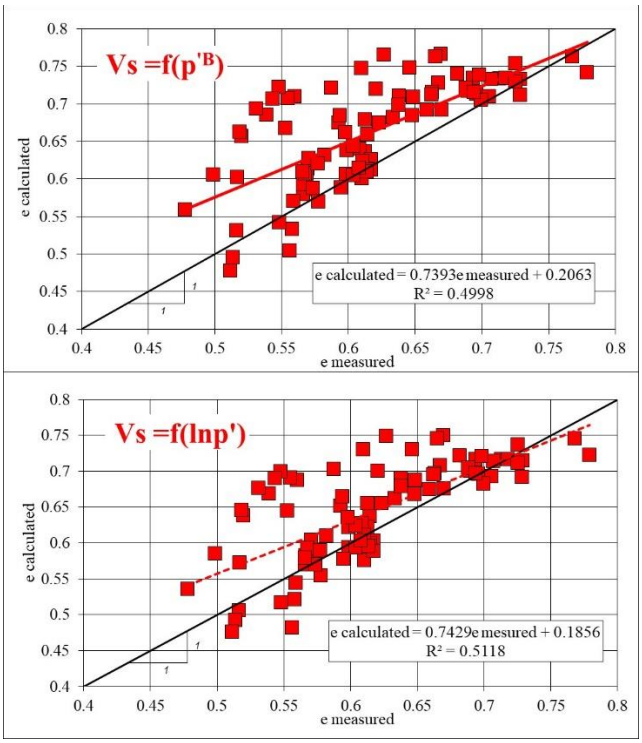

Figure 5. Comparison of measured and calculated (with both formulae) void ratio values for soils containing 36% of fines.

For transition zone material with 36% of fines content, the values predicted by both formulae are not

as good as in case of sandy material. The points on the both charts are more scattered. R-squared values are in the same order (approximately 0.50) with slightly higher coefficient for logarithmic function. In both cases predicted values of void ratio overestimated the measured ones, although, similarly as in the case of normalized shear wave velocity, convergence of trend lines is higher for loose state. It is worth to emphasize that R-squared values for that kind of soil for fit curves solutions are considerable higher (0.50) than for normalization procedure.

5 VOID RATIO DISTRIBUTION IN SITU

As it was aforementioned in the first paragraph, void ratio distribution was determined on the basis of hybrid method which assumes that various formulae derived from laboratory test results assuming different relations among void ratio, shear wave velocity and effective stress components, create the input for evaluation of void ratio values determined on the basis of the measurement of shear wave velocity carried out in non-homogeneous tailings profiles.

In order to compare results of all methods there is a need to notify an assumption concerning effective stress components contribution to the final results. In case of normalization procedure only vertical effective stress is considered in this research. However, for fit curves approaches mean effective stress p' is taken. This requires assumption concerning coefficient of earth pressure at rest. In case of tailings material deposited by discharge of slurry, the values of K_0 are in the range of 0.40-0.50, depending on granulation and void ratio. It was verified that maximum void ratio variation assuming extreme values of K_0 is 0.02 for sandy material and less than 0.01 for silty tailings. Therefore for further analysis fixed value of $K_0 = 0.4$ was assumed.

In order to compare effectiveness of all three approaches, the correlations obtained in the laboratory were projected on real profile of tailings. Thus one profile of shear wave velocity measured in the field generated six profiles of void ratio (3 formulae x 2 granulation). The results are shown in Figure 6.

The data shown in Figure 6 can be analysed according to various criteria. At first, general remarks concerning obtained values of void ratio can be presented.

- Void ratio values are less scattered than *e* values determined on cores retrived by Mostap sampler and void ratio distribution determined on the basis of CPT results.
- Profiles reflect the upper (approximately 5 m deep) zone densified by bulldozers forming the beach. Next, starting from the depth of 11 m, effect of densification caused be verical effective stress coming from gravitation is visible.
- Void ratio values for each tailings batch are approximately in the range observed during compressibility tests in the laboratory.
- Variability of void ratio value in a profile is bigger for material containing 10% of fines than in case of tailings having 36% of fines.

With regard to the three methods compared and the role of fines content, it is quite clear from the chart shown in Figure 6 that the change in fines content from 10 to 36% influences much more void ratio value than the differences resulting from applied method of data reduction. The differences of void ratio between the applied methods are smaller in case of sandy material.

For material with 36% of fines the biggest void ratio values in a profile are obtained for normalized shear wave velocity method and the smallest one for logarithmic function. However, even for that batch the difference between extreme values of void ratio is the range of 0.010-0.052 with average not exceeding 0.038.

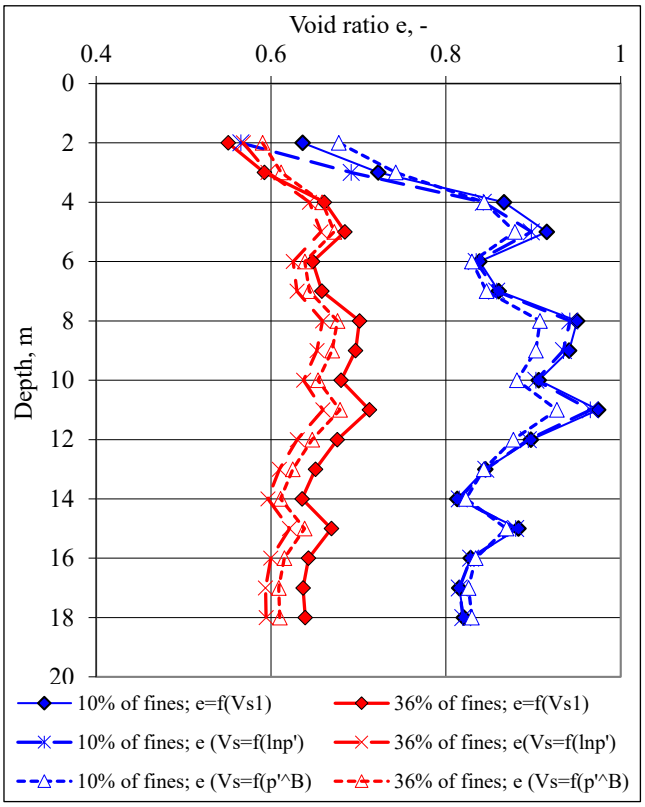

Figure 6. Comparison of void ratio profiles calculated on the basis of various approaches for tailings containing 10 and 36% of fines.

6 CONCLUSIONS

The high quality triaxial tests results combined with internal measurement of sample deformation and shear wave velocity measured in the laboratory and in the field make it possible to evaluate soil state for unaged and uncemented sands and silts with fines content up to 36%. Such approach delivers much more consistent results than any other based on static or dynamic probes, especially in case of tailings dams where non-homogeneous material containing various amount of fines prevails.

The relations among void ratio, effective stress components and shear wave velocity were obtained on the basis of laboratory tests results with use of three different approaches. One of them used very popular concept of normalized shear wave velocity and the other two were based on fit curves to relate shear wave velocity and mean effective stress p' approximated by logarithm or power function with distinguished void ratio categories. Although all three methods delivered good results for sandy material with 10% of fines, the methods based on fit curves better predict void ratio values for material with 36% of fines. Void ratio projected on field profile of tailings has shown that void ratio predicted on the basis of shear wave velocity measured in the laboratory and in the field has large potential to evaluate state of tailings in materials where undisturbed sampling of satisfactory quality is not feasible. The next step to improve void ratio prediction in a real tailings profile is associated with accounting for better reconstruction of laboratory specimen structure (slurry instead of moist tamping by undercompaction) and account for a real fines content change in a tailings profile.

Analysis of risk associated with failures of tailings storage facility

Analyse du risque associé à la rupture de digues à résidus

Z.Q. Liu*, S.S. Nagula, L. Piciullo, S. Lacasse
Norwegian Geotechnical Institute, Oslo, Norway

**zhongqiang.liu@ngi.no*

ABSTRACT: In view of the recent failures of tailings storage facilities (TSF) caused by static liquefaction, there is need for (1) a critical evaluation of the methodologies used for quantifying uncertainties and (2) increased use of advanced approaches to assess failure probability and consequences. The failure probability combined with the expected consequences will provide an estimate of the risk associated with the unsatisfactory performance of the TSF. A risk-informed framework was developed to analyse potential breaches of a TSF induced by static liquefaction of the tailings. The framework and the tools to estimate hazard and consequences are briefly discussed in the paper. The framework is then used to determine the probability distribution of instability, predict the mobility flow downstream, assess the vulnerability of buildings in the influence area and do a consequence assessment.

RÉSUMÉ: Compte tenu des récentes ruptures de barrages à résidus dues à la liquéfaction statique, il est nécessaire de faire une évaluation critique des méthodologies utilisées pour quantifier les incertitudes et d'utiliser davantage les approches pour évaluer la probabilité de défaillance et les conséquences d'une telle défaillance.. La probabilité de défaillance combinée aux conséquences fournit une estimation du risque associé à une défaillance d'un part à résidus. Une approche «risque-informé» générique est proposée pour des défaillances dues à une liquéfaction statique des résidus. L'approche et certains outils probabilistes pour estimer les dangers et les conséquences sont discutés dans l'article. L'usage de la méthodologie est démontrée pour une digue à résidus: on y démontre la probabilité d'instabilité, la prévision de la mobilité de résidus en aval, la vulnérabilité des bâtiments dans la zone d'influence et l'évaluation des conséquences et du risque.

Keywords: Failure probability; vulnerability; risk; tailings storage facility.

1 INTRODUCTION

Currently, thousands of tailings storage facilities (TSFs) exist around the world. The stored tailings are often highly toxic and the failure of a tailings dam and the uncontrolled release of the impounded waste can have disastrous consequences for the public, the environment and the owner or operator. Keeping the TSFs safe is one of the biggest challenges of the mining industry. A correct approach to long-term TSF management is crucial to the successful operation of facilities and for the reputation of the mining industry. Guidelines have been issued (e.g., ICMM, 2020), but few give details on how to do qualitative or quantitative risk assessment.

Tailings dam failures can occur due to several reasons: for example, foundation failure due to the raising of the dam; slope instability; internal erosion within the dam; earthquake-induced or static liquefaction of the tailings; and lack of or wrongful maintenance or operation. Examples of recent failures include the Fundão Tailings Dam in Minas Gerais, Brazil, on November 4, 2015, causing at least 19 deaths, destruction of 158 homes and contamination of three large rivers; and collapse of the decommissioned Córrego do Feijão dam in Minas Gerais in January 2019, causing 270 fatalities and destroying large sections of agricultural land.

A systematic approach to do the risk assessment of potential TSF failures is urgently needed as there are many active TSFs and many closed facilities with unknown risk conditions. The current approaches of TSF safety need to be critically evaluated and the procedures for risk assessment need to be improved. This paper proposes an integrated framework for the risk assessment of TSFs that includes new methods to analyse the stability and the mobility of tailings.

2 NEW RISK-INFORMED FRAMEWORK FOR TAILINGS STORAGE FACILITIES

Traditionally, the geotechnical design of a TSF has been based on a deterministic Factor of Safety (FoS).

The FoS is meant to implicitly account for all the uncertainties in external loads and resistance (strength) of the tailings, but it does not address the uncertainties in the analysis explicitly. Such approach is insufficient today. Two tailings storage facilities with nominally the same FoS can have vastly different safety margin and failure probability because of the different inherent uncertainties in the analyses (Lacasse and Höeg, 2019). Risk assessment is needed to assess the actual safety margin. The conventional design methods are also rapidly being transformed by advances in numerical analysis, constitutive modelling, real-time remote monitoring, data interpretation with machine learning and an increased ability to model and interpret deformation and seepage. These advances help reduce the uncertainties, thereby reduce the limitations of an overall FoS.

Figure 1 presents the integrated risk management framework for TSFs that brings together the required information and enables risk-informed decision-making. It systemizes the risk assessment and management in four parts: (1) gathering and assessing the information required for deterministic and probabilistic hazard and consequence assessment (green zone); (2) carrying out the risk assessment, qualitatively or quantitatively or both (yellow zone); (3) making risk-informed decisions on reducing risk (blue zone); and (4) regular and frequent re-assessment of risk loop (grey zone). The framework also requires layers of review, recurrent risk assessment and performance-based validation through the life of the facility, and can be described as "performance-based risk-informed TSF management". This study focuses on probabilistic methods used to assess hazard, vulnerability, and consequence in the yellow zone.

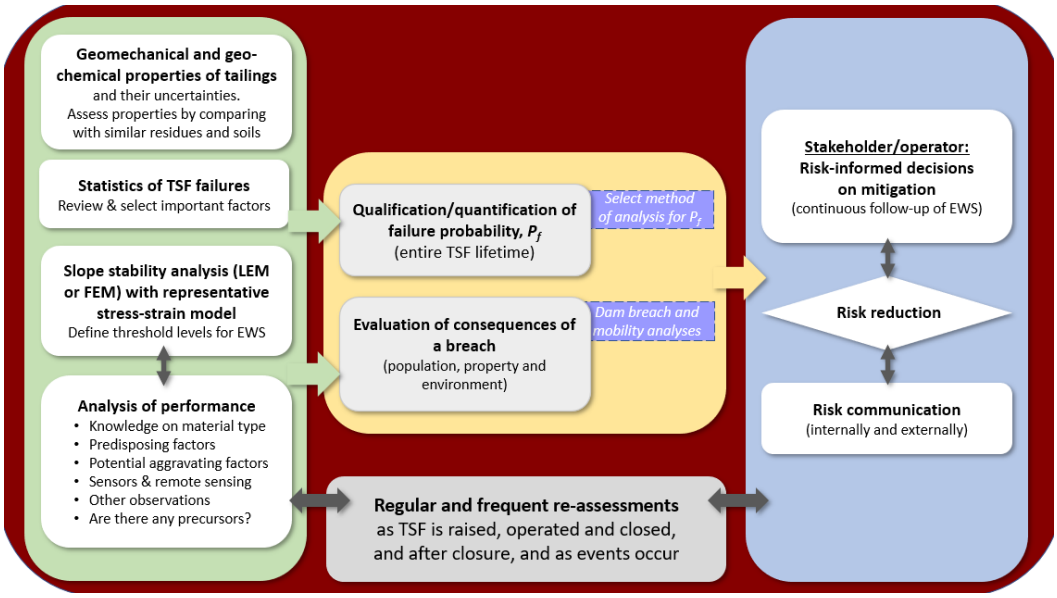

Figure 1. Proposed integrated framework for risk-informed management of tailings storage facilities.

3 PROBABILISITIC STABILITY ANALYSIS

For stability evaluation during the life of a TSF and safe tailings dams, it is necessary to consider the complete stress-strain behaviour of the soils, using appropriate and reliable constitutive models. For example, if the tailings are subjected to a shear stress higher than the undrained shear strength, the material becomes unstable, and a small pore pressure change can cause a progressive failure or static liquefaction. This failure mode can easily be overlooked if stability is assessed by conventional limit equilibrium analyses. The preferred approach is to use numerical modelling with the finite element method (FEM) and a constitutive model simulating softening and hence, the initiation of static liquefaction in tailings dams and provide an estimate of FoS against failure. However, significant uncertainties exist in the input parameters because of existing conditions in situ and in the way we calculate the factor of safety against failure. In such cases, probability-based approaches provide more insight than deterministic analyses.

3.1 Numerical modelling in PLAXIS

An idealised geometry for a TSF was numerically simulated (Reid and Fourie, 2023). The stability analyses were carried out in Plaxis 2D, using the NorSand model (Jefferies, 1993), as presented in Figure 2. The slope was 50 m high with 1V:3H side slope. A 10-m wide bench was included at a height of 25 m, making the overall average slope 1V:3.2H.

The model was divided into four layers of tailings to account for the variability in state parameter and variation of phreatic line (Figure 2). The bottom boundary of the model is fixed, and the vertical boundaries are fixed in the lateral direction. An initial phreatic line commencing from 30 m upstream of the toe till 26 m height as shown in Figure 1.

The state parameters ($\psi = e - e_c$, where e is the in-situ void ratio and e_c is the critical void ratio at same mean pressure p) were evaluated using the CPTU data, using the correlation after Been and Jefferies (1992). The mean and standard deviation for each layer are shown in Table 1. The standard deviation of ψ is very high in all four layers, and extremely high in Layer 1, making it difficult to determine whether is contractive or dilative. This reemphasises the need to analyse TSFs in a probabilistic framework.

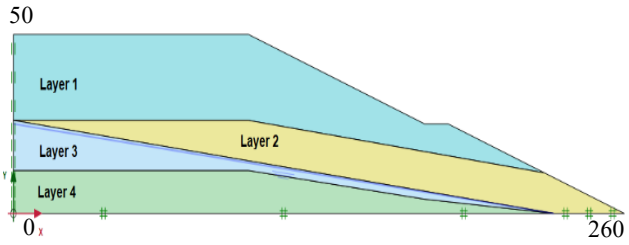

Figure 2. PLAXIS 2D model of tailings dam with 4 layers of tailings. Phreatic line is between Layers 2 and 3.

Table 1. Mean and standard deviation of state parameter for each layer.

Layer	Mean ψ (M)	Std. Dev. Ψ (D)
Layer 1 (x1)	-0.01756	0.04513
Layer 2 (x2)	0.05206	0.03794
Layer 3 (x3)	0.07968	0.02977
Layer 4 (x4)	0.07968	0.02977

3.2 Probability of failure

The first- and second-order reliability methods (FORM and SORM), enhanced with response surface method (RSM) modelling, were utilized to estimate failure probability.

Figure 3 describes the change in the failure probability for the idealized geometry and the highly uncertain state parameters in Table 1 as a function of the elevation of the phreatic surface at centreline of the modelled TSF. The results show that the failure probability increases from 1% to 32 % as the phreatic line rises from 26 to 50 m. Figure 4 illustrates with the FORM sensitivity coefficients (a^2 in the mini-table) that the state parameter in Layer 4 (a = 0.94) has the most influence on the calculated failure probability.

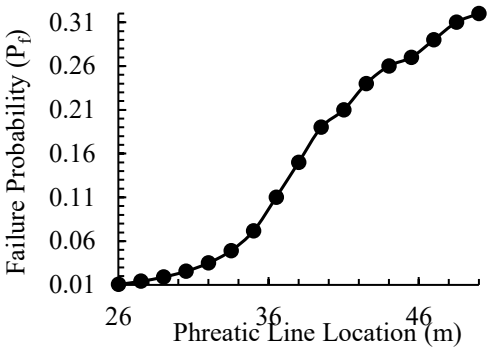

Figure 3. Variation of P_f with normally distributed state parameters for all layers as a function of the elevation of the phreatic line at the centreline of the Model (FORM results).

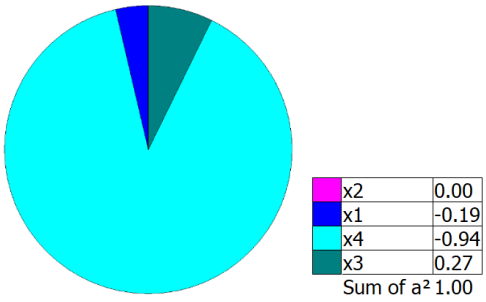

Figure 4. Alpha variables (a) for state parameters in each layer (SORM analyses).

4 RUNOUT AND CONSEQUENCES: MOBILITY ANALYSIS

4.1 Numerical simulations of runout

If a TSF fails, the tailings can travel long distances, posing a risk to life and health, infrastructure, and the environment. Modelling the mobility of tailings is a challenging, yet essential, task for estimating the elements at risk and consequences of a TSF failure. A flow slide following a static liquefaction event can be modelled by non-Newtonian fluid mechanics models, in particular the Herschel-Bulkley model. In the present study, the BingClaw model was used to predict the mobility of the Feijão Mine tailings dam.

The BingClaw model is a visco-plastic model with Herschel-Buckley rheology (Liu et al. 2021). The model is an extension of the Bing model (Imran et al. 2001) in Eulerian coordinates in two horizontal dimensions. Figure 5 presents an example of a BingClaw simulation of the runout distance of the Feijão Mine tailings dam.

Estimating the released volume for analyses that aim to predict the runout is a fundamental issue. Empirical correlations (e.g., Piciullo et al. 2022) can be useful for preliminary release volume estimation. In this study, the released volume was estimated by interpreting from satellite data the topography before

and after the failure. Figure 5 superposes the periphery of the deposited material at the end of the sliding with the simulated runout. The agreement between the simulated and observed runout distance and its spatial distribution after failure is excellent.

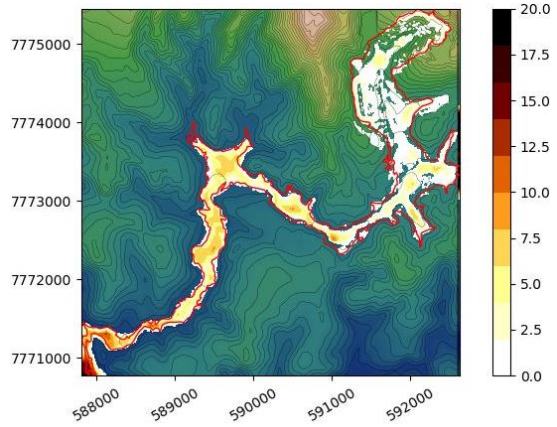

Figure 5. Tailings runout 133 minutes after failure of the Feijão Mine tailings dam: red curve is the mapped runout extent; white area is the calculated runout with BingClaw; scale on right is debris thickness in m.

4.2 Consequence analysis

The quantitative modelling of vulnerability and consequence is a central part of the quantitative risk assessment for a TSF. Vulnerability assessment for TSFs should consider the magnitude of potential failures and the variable nature of the elements at risk. Figure 6 presents an example of a simulation of the velocity of the Feijão Mine tailings dam and the buildings affected by the failure.

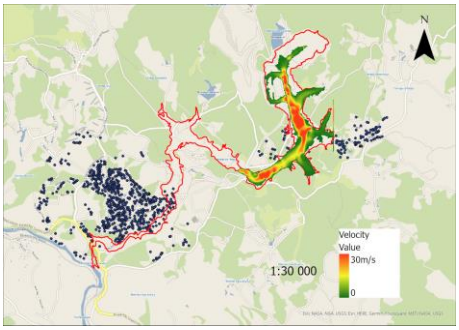

Figure 6. Simulated velocity of the Feijão Mine tailings at 10 minutes after dam failure and the mapped buildings affected by the failure.

Consequence analysis can be conducted based on the velocity and the exposure of buildings. Number of fatalities can be estimated from the path of the flow and the thickness of the wave and debris.

5 CONCLUSIONS

The paper outlines a risk-informed decision-making framework to estimate the failure probability and the consequence of tailings storage facilities. The recent catastrophic tailings dam failures necessitate the use of reliability-based methods to adhere to new regulations and make risk informed, and thereby more robust decisions.

Hydro-Mechanical response of a shale subjected to gas transport in the context of radioactive waste disposal

Réponse hydromécanique d'un schiste soumis au transport de gaz dans le contexte du stockage de déchets radioactifs

ABSTRACT: In the context of deep geological radioactive waste disposal, significant amount of generated gas is expected to migrate from the repositories into the surrounding host rock, affecting its hydro-mechanical state. In Switzerland, Opalinus Clay is the selected host geological formation and requires a comprehensive understanding of the relevant phenomena that characterize its behaviour associated with gas transport regarding the long-term safety assessment of the repository. In this context, water and gas injection tests were performed using a high pressure oedometer cell. The results suggest that gas-induced porewater displacement is a key feature during gas invasion processes in clay-rich host rock. Furthermore, water permeability was not impacted by gas transport and consistently found in the order of 10^{-21} (m^2) before and after the gas invasion tests. The experimental outcome of the study provided unique observations of the hydro-mechanical behaviour of Opalinus Clay when subjected to gas transport in the short-term and long-term.

RÉSUMÉ: Dans le contexte de l'enfouissement géologique profond des déchets radioactifs, une quantité significative de gaz sera générée et migrera vers la roche hôte environnante, influençant son état hydromécanique. En Suisse, l'argile à Opalinus a été choisie comme formation géologique hôte et nécessite une compréhension approfondie des phénomènes caractérisant son comportement lorsqu'elle est associée au transport de gaz, en vue de l'évaluation à long terme de la sécurité du dépôt. Dans ce contexte, des essais d'injection d'eau et de gaz à haute pression ont été réalisés à l'aide d'une cellule œdométrique spécialement développée. Les résultats suggèrent que le déplacement de l'eau interstitielle induit par le gaz est une caractéristique clé lors de l'invasion de gaz. De plus, la perméabilité de l'eau n'a pas été impactée par le transport de gaz avec des valeurs mesurées l'ordre de 10^{-21} (m^2) avant et après l'invasion de gaz. Les résultats expérimentaux de l'étude ont fourni de nouvelles observations sur le comportement hydromécanique de l'argile d'Opalinus lorsqu'elle est soumise au transport de gaz à court et à long terme.

Keywords: Radioactive waste; opalinus clay; hydro-mechanical behaviour; gas transport.

1 INTRODUCTION

Regardless of the national strategies concerning nuclear energy production, there is an urgent need to address the problem of disposing high-level nuclear waste produced by power plants. Switzerland foresees a deep geological repository which relies on a multi-barrier system to isolate the waste from the biosphere for dozens of thousands of years. However, uncertainties still exist about the late stage of the repository when a significant amount of gas will be produced due to various processes. This gas production may cause gas pressure build-up with a potential propagation of the gas front into the host rock. Those circumstances can result in the loss of the mechanical integrity of the multi-barrier system and may impact the long-term safety of the repository (Levasseur et al., 2021).

In Switzerland, Opalinus Clay has been selected as the host geomaterial for the underground disposal of radioactive waste. More experimental evidence for a comprehensive understanding of the relevant phenomena that characterize the hydro-mechanical (H-M) behaviour of Opalinus Clay (OPA) when subjected to gas invasion is thus required.

In this paper we are showing the results of an experimental campaign on OPA conducted with a high-pressure oedometer apparatus allowing the performance of water and gas injection tests while assessing the vertical deformation of the tested

material with the aim to better observe and understand the involved phenomena.

2 MATERIAL AND METHODS

2.1 Tested material

Opalinus Clay is a fine-grained sedimentary geomaterial with a mineral composition mainly consisting of silicates, carbonates and quartz. The tested material was retrieved from the deep borehole in Trüllikon in the Zürich Northeast siting region in Switzerland (Ammen and Palten, 2021) and was sourced at a depth of about 848 (m). Complete geotechnical characterization has been performed and included: bulk density ρ=2.50 (g/cm^3), density of solid particles ρ_s=2.78 (g/cm^3), water content w=0.05, void ratio e=0.15, degree of saturation Sr=0.63, initial total suction ψ=66 (MPa).

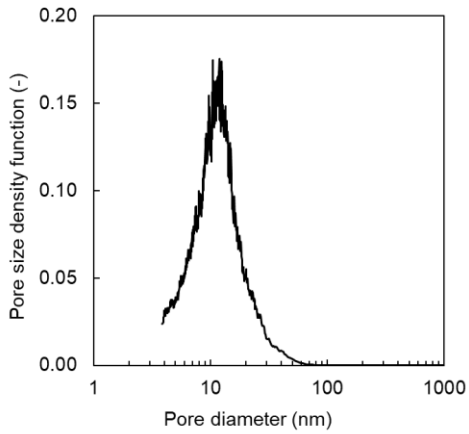

Figure 1. MIP test results.

The pore structure of Opalinus Clay was studied by Mercury Intrusion Porosimetry (MIP), using the freeze-drying technique for sample preparation. To overcome the conformance effect and the compressibility of the sample below the entry pressure of mercury, a correction was applied to the MIP data according to (Comisky et al., 2011). As depicted in Figure 1, a unimodal pore size distribution was obtained in the range of 8 to 16 (nm) with a peak value at about 12 (nm). The size of the detected porosity was from 4 to 60 (nm); 4 (nm) being the smaller pore size detectable with the apparatus. The results are in good agreement with values from the literature on the same material (e.g., Crisci et al., 2019; Minardi et al., 2021). From the larger detected pores, air is expected to enter the pore space of the initially saturated porous medium at a capillary pressure of about 5 (MPa) according to the Young-Laplace equation.

2.2 Experimental set-up and procedure

The experimental work used a high-pressure oedometer cell, as depicted in Figure 2, that allowed to apply a vertical total stress up to 100 (MPa) with the possibility to perform water and gas injection from the bottom and top side of the specimen with a fluid pressure up to 16 (MPa) and 20 (MPa), respectively (Minardi et al., 2021). The vertical deformation was assessed using three LVDTs with 0.2 (μm) resolution. The height and diameter of the specimen were 12 and 35 (mm), respectively. The specimen was tested with the vertical load and fluid injection perpendicular to the bedding planes (S-sample).

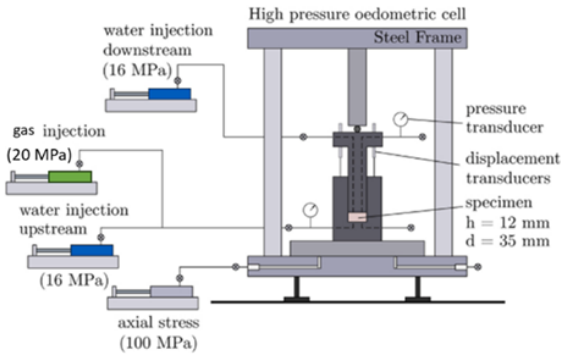

Figure 2. High pressure oedometer test set-up.

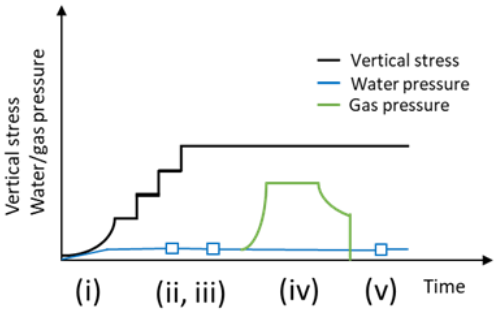

Figure 3. Sequences for the water and gas injection tests.

The experimental procedure was composed of five test sequences (phases i to v) which are illustrated in Figure 3 and described hereafter. (i) The experimental procedure included first a water resaturation in isochoric conditions with synthetic water mimicking the in-situ porewater (Aschwanden et al., 2021). (ii) Mechanical loading up to the target vertical effective stress was performed to simulate in situ conditions. To do so, constant water pressure of 1 (MPa) was applied at the bottom ($u_{w,bot}$) and top ($u_{w,top}$) and the vertical total stress (σ_v) was increased in steps up to 15 (MPa). (iii) Constant head water permeability tests were performed at different vertical effective stresses by applying a differential pressure of 1 (MPa). Then, in order to perform the gas injection test (iv), the water pump connected at the bottom side of the specimen

was replaced by the gas pump filled with nitrogen pressurized at 3 (MPa). The sequence comprised then a constant rate gas injection period (0.2 (ml/min) for an initial gas volume of 500 (ml) in the reservoir) during which gas pressure was increased from 3 MPa to 10 MPa. Gas pressure was then kept constant until steady state conditions were observed for both gas flow and volumetric response of the tested specimen. Finally, a shut-in phase was performed where the gas pump was stopped, ensuring constant gas volume at the inlet, and gas pressure decay was monitored. Water back-pressure at the top side of the specimen was kept constant during the entire phase at $u_{w,top}$=1 (MPa). (v) After the gas injection phase, water resaturation was performed under constant vertical total stress, followed by a second water permeability test in order to assess the evolution of the intrinsic permeability due to gas transport.

3 RESULTS

3.1 Hydro-mechanical results (phases i to iii)

During the resaturation phase, the vertical total stress was progressively increased ensuring isochoric conditions and minimizing damage due to swelling. The swelling pressure, S_p, developed during this phase was 3 (MPa) as shown in Figure 4.

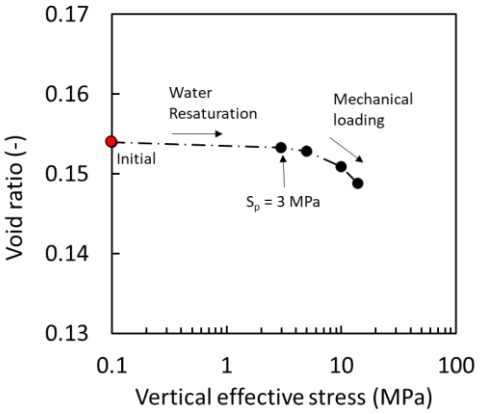

Figure 4. Oedometer curve for tested specimen.

The mechanical compression up to the target vertical effective stress allowed an assessment of the relationship between void ratio and the applied stress. The deformation of the oedometer system was accounted for every loading step (Ferrari et al., 2016). Figure 4 shows the compression of the specimen with increasing vertical effective stress. The water intrinsic permeability was computed from the constant head tests performed at different vertical effective stresses. The water intrinsic permeability was obtained in the range of $2\text{-}3\cdot10^{-21}$ (m^2) and is in good agreement with values reported in the literature for the same material (Crisci et al., 2019; Minardi et al., 2021).

3.2 Gas injection test (phase iv)

The gas injection test was performed at fast gas pressure build-up rate with the intention to favour an undrained response of the material. The applied boundary conditions, such as vertical stress and fluids pressures are shown in Figure 5 (top).

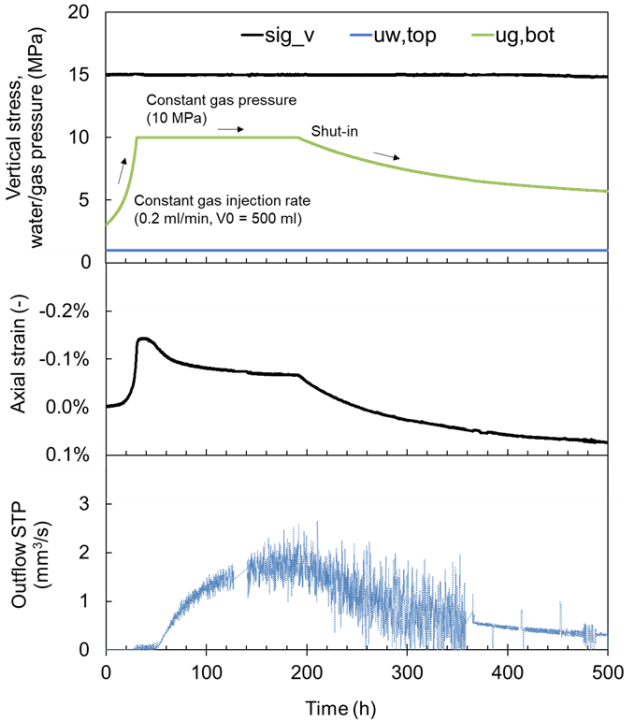

Figure 5. Gas injection test results.

The global axial strain of the specimen computed from the measurement of the vertical deformation, shown in Figure 5 (middle), indicates that almost no deformation was observed at the early phase as gas pressure was likely below the entry pressure and had not yet invaded the pore space. Once gas reached a pressure of about 5 (MPa) at t=17 (h), expansion of the specimen was observed, indicating the start of gas invasion, which was associated with porewater displacement and development of capillary pressure. The air entry value was consistent with the estimation from the MIP test. Expansion continued as gas pressure increased further. Once gas pressure was kept constant at 10 (MPa) from t=30.5 (h), expansion continued to slightly increase and reached a strain of -0.14% and was followed by a slow reduction and stabilization at about -0.07% until t=193 (h). As gas pressure decreased during the shut-in phase, t > 193 (h), the specimen experienced compression. Gas pressure after shut-in was measured at 5.7 (MPa).

The observed mechanical response was consistent with the measured outflow from the specimen. Gas breakthrough was observed only after the maximum gas pressure was reached (t = 50 h). This suggests that gas movement was impaired by the low permeability of the specimen. With time, as gas further invaded the pore space, the measured outflow increased until steady state conditions were observed at about t=193 (h). The gas outflow at standard temperature and pressure (STP) conditions was about 2 (mm^3/s). During the shut-in, gas outflow decreased until almost no flow was observed anymore.

3.3 Hydro-mechanical results (phase v)

No significant strain (less than 0.01%) due to water uptake was observed during resaturation at constant vertical stress. The water intrinsic permeability after resaturation was found very similar to prior to the gas injection, $2\text{-}3 \cdot 10^{-21}$ (m^2), suggesting that gas transport did not impair the intrinsic permeability of the tested material.

4 CONCLUDING REMARKS

In this study, the hydro-mechanical response of Opalinus Clay associated with gas transport was investigated. Water and gas injection tests have been performed using a high-pressure oedometer cell to replicate the in-situ stress conditions. In particular, the short- and long-term responses to gas invasion were assessed during fast gas pressure build-up.

The interpretation of the results in terms of drained/undrained behaviour is consistent with the general deformation behaviour of clayey geomaterials. If the tested material is subjected to fast gas pressure build-up, it is more likely that gas transfer is initially associated with larger deformation due to generation of excess porewater pressure during the transient phase. The results suggested that gas-induced porewater displacement is a key feature during gas invasion processes in clay-rich host rock.

Furthermore, the consistent water permeability values obtained before and after the gas injection test suggest that the involved gas transport processes are unlikely to impact the long-term barrier function of the host rock.

The experimental outcome of the study provided additional observations of the hydro-mechanical behaviour of Opalinus Clay associated with gas transport in the short-term and the long-term. Further experimental investigation, as well as numerical analysis, are required to better understand the involved processes, such as the development of non-uniform and localized strains associated with gas invasion.

Relevance of correlation length in geotechnical engineering

Pertinence de la longueur de corrélation en ingénierie géotechnique

Durham University, Durham, United Kingdom

**marti.lloret-cabot@durham.ac.uk*

ABSTRACT: Soils are heterogeneous in nature and as such, their properties inherently exhibit a distinct spatial variation that reveals past information of their geological history. This spatial variability is an important source of geotechnical uncertainty and hence its proper characterisation is of importance to geotechnical design. Random field theory provides a consistent mathematical framework to account for this soil's heterogeneity and it is a powerful computational tool to perform reliability analyses of geotechnical structures when combined with the finite element method. A key parameter in these stochastic analyses is the correlation length (or sometimes also referred to as scale of fluctuation) because it controls variations of a soil property in a given spatial direction. This spatial statistic can be estimated from in-situ data (e.g., cone penetration test CPT) and the quality of such estimation is the main question tackled in this paper.

RÉSUMÉ: Les sols sont de nature hétérogène et, en tant que tels, leurs propriétés présentent intrinsèquement une variation spatiale distincte qui révèle des informations passées sur leur histoire géologique. Cette variabilité spatiale est une source importante d'incertitude géotechnique et sa caractérisation appropriée est donc importante pour la conception géotechnique. La théorie des champs aléatoires fournit un cadre mathématique cohérent pour tenir compte de l'hétérogénéité de ce sol et constitue un outil informatique puissant pour effectuer des analyses de fiabilité des structures géotechniques lorsqu'il est combiné avec la méthode des éléments finis. Un paramètre clé dans ces analyses stochastiques est la longueur de corrélation (ou parfois également appelée échelle de fluctuation) car elle contrôle les variations d'une propriété du sol dans une direction spatiale donnée. Cette statistique spatiale peut être estimée à partir de données in situ (par exemple, test de pénétration du cône CPT) et la qualité d'une telle estimation est la principale question abordée dans cet article.

Keywords: Correlation length; scale of fluctuation; uncertainty; soil variability.

1 INTRODUCTION

Due to the geological/engineering processes by which soil is formed/deposited, its property values vary with position, meaning that soil is not homogenous. More interestingly, if a given direction within a soil domain is considered, higher correlation values are likely to be found in the geotechnical property values (e.g., undrained shear strength, S_u) measured at points that are closer to each other (small lag distance τ) because the soil conditions at these closer points are likely to be quite similar. In contrast, values of such property measured at points that are further away from each other (larger lags τ) will likely show bigger differences, because of a lower correlation. This decay of correlation in the property values at pairs of points along a given direction is described by the correlation function $\rho(\tau)$ and the sharpness of such decay is controlled by a key statistical parameter known as the correlation length, θ, (or also referred to as scale of fluctuation, SOF).

Such representation of the spatial variation of a geotechnical property in a given direction is useful because it facilitates a consistent approach able to capture the spatial heterogeneous nature of a soil property. It is also useful because it allows to incorporate in a relatively easily way the spatial variability of a soil property in geotechnical design via the random finite element method (RFEM) (e.g., Fenton and Griffiths, 2003) which combines the finite element method with the random field generator LAS (Local Average Subdivision method proposed by Fenton & Vanmarcke, 1990).

The RFEM has been used extensively in the literature to assess the structural response of a geotechnical system (Fenton and Griffiths, 2003; Hicks and Spencer, 2010; Griffiths et al., 2011). Interestingly, using the RFEM in any of these geotechnical problems facilitates a probabilistic assessment of their structural performance because, rather than solving the problem for a single realisation (considering an homogeneous soil), the same problem can be solved for a finite number of realisations within a Monte Carlo approach, so that the response of the geotechnical system can be assessed in probabilistic terms, allowing for the description of failure in terms

of a probability of failure (and not in terms of a single factor of safety, as historically done). In doing such probabilistic assessment, all these works above confirm the relevance of incorporating the spatial variation of soil properties in the geotechnical design of these structures and, more specifically, the relevance of the correlation length. Perhaps due to this importance, many studies in the literature have studied the concept of the correlation length (e.g., DeGroot and Baecher, 1993; Phoon and Kulhawy, 1999; Fenton, 1999ab; Jaksa, 1995; Uzielli et al., 2005; Cami et al., 2020; Lloret-Cabot et al., 2013, Ching et al. 2023) estimated from available in situ or artificially generated information (most commonly cone penetration test data, CPT). These studies, however, do not all use the same estimation method (not even the same theoretical correlation model), they often treat the trend in the data in different ways and they do not all estimate θ using the same specific in situ test or, if they do, the sampling interval is not necessarily the same. These differences in the available literature make challenging the comparison between the different estimated θs. Against this background, the current paper aims to provide some further insight (in terms of accuracy) of the computational performance of the most common estimation method of θ which consists in minimising the error between an assumed theoretical correlation model $\rho(\tau)$ (see Table 1) and the estimated experimental correlation function $\hat{\rho}(\tau)$ (calculated from the in-situ or artificially generated data). Various theoretical correlation models $\rho(\tau)$ are available in the literature but due to space constraints only the most common two are considered in this research. Their definition is given in Table 1.

Table 1. Most common theoretical correlation models.

Name	Expression
Markovian	$\rho(\tau) = \exp\left\{\frac{-2\lvert\tau\rvert}{\theta}\right\}$
Gaussian	$\rho(\tau) = \exp\left\{-\pi\left(\frac{\lvert\tau\rvert}{\theta}\right)^2\right\}$

Note: θ is the correlation length in a given direction and the τ lag distance

According to the method of moments, the experimental correlation function takes the following form:

$$\hat{\rho}(\tau_j) = \sum_{i=1}^{k-j} \frac{(X_i-\hat{\mu})(X_{i+j}-\hat{\mu})}{(X_i-\hat{\mu})^2}, \quad for\ j = 0, \dots k-1 \tag{1}$$

where $\hat{\rho}(\tau_j)$ is the experimental correlation function between two points separated by a lag distance τ_j, $\hat{\mu}$ is the experimental mean, k is the total number of measurement points and i is the total number of pairs of points (separated by τ_j).

Equation 1 can be re-written in terms of the experimental variance $\hat{\sigma}^2$ in the following two forms depending on wether an unbiased (Equation 2) or biased (Equation 3) estimator of the experimental variance $\hat{\sigma}^2$ is considered:

$$\hat{\rho}(\tau_j) = \frac{1}{\hat{\sigma}^2(k-j)} \sum_{i=1}^{k-j} (X_i - \hat{\mu})(X_{i+j} - \hat{\mu}), \quad for\ j = 0, \dots k-1 \tag{2}$$

$$\hat{\rho}(\tau_j) = \frac{1}{\hat{\sigma}^2 k} \sum_{i=1}^{k-j} (X_i - \hat{\mu})(X_{i+j} - \hat{\mu}), \quad for\ j = 0, \dots k-1 \tag{3}$$

Traditionally, Equation 2 has been most commonly used in the geotechnical literature. However, recent work by Cami et al. (2020) proposes using Equation 3 instead to prevent negative eigenvalues in the correlation matrices. In the context of the work presented here (primarily focussed on the estimation of the correlation length in the vertical direction from artificially generated CPT data), any of the three equations is likely to give very similar estimates because a CPT typically has a large number of data points available in the vertical direction (and the value of the experimental mean should be close to zero, when using de-trended and normalised data, Lloret-Cabot et al., 2014). This research has used Equation 3.

2 ACCURACY ASSESSMENT

The main goal of this investigation is to assess the accuracy of using two of the most common theoretical correlation models to estimate the vertical correlation length from CPT data (see Table 1). This section aims to address this issue by using an equivalent numerical strategy to that proposed in Lloret-Cabot et al. (2014). Rather a two-dimensional (2-D) random fields as used in Lloret-Cabot et al. (2014), this work uses LAS to generate 1-D random fields as a suitable representation of de-trended and normalised CPT tip resistances with known zero mean ($\mu = 0$) and unit variance ($\sigma^2 = 1$), and with a vertical correlation length of $\theta_v = 1.5$m (e.g, Fenton, 1999b). The total length considered is D = 20m and the sampling distance d_y is 0.1m. A typical example is illustrated in Figure 1.

From this random field data, the experimental correlation function $\hat{\rho}(\tau)$ can be estimated using Equation 3 as illustrated in Figure 2. The optimal value $\widehat{\theta_v}$ can be then estimated by best fitting $\hat{\rho}(\tau)$ to a theoretical correlation structure $\rho(\tau)$. A number n of estimated $\widehat{\theta_v}$ are obtained by repeating this process from j = 1 to n, (where n = 1,000 corresponds to the

number of realisations considered here). In order to assess the accuracy of the correlation model used, the obtained value of $\widehat{\theta_v}$ (averaged over the n estimated correlation lengths) is compared against the known value of θ_v used to generate each CPT.

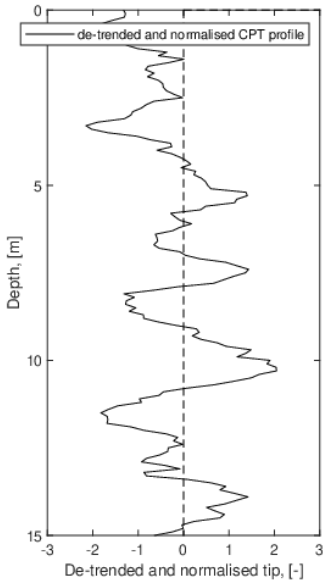

Figure 1. Typical CPT profile generated using LAS.

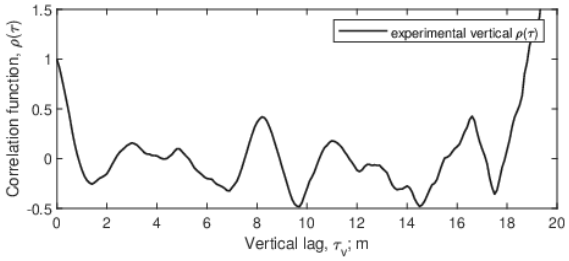

Figure 2. Typical experimental correlation structure.

The accuracy of estimating θ_v when using the approach discussed earlier with a Markovian or a Gaussian correlation structure is illustrated in Figures 3 and 4 respectvely. Each figure includes results for n = 1,000 realisations. In the figures, the representation of $\rho(\tau)$ with the corresponding optimized θ_v is represented as a thick solid line whereas the averaged experimental correlation model is indicated by a dashed thick line. The thinner continuous lines represent each of the individual $\hat{\rho}(\tau)$ estimated for each CPT. It is perhaps worth noting here that practically the same result for the optimal $\widehat{\theta_v}$ is obtained by best fitting the averaged experimental correlation structure and the theoretical one. Inspection of the figures shows that a very similar performance is achieved by the two correlation structures assumed, with an optimal $\widehat{\theta_v}$ of 1.55m and 1.54m for Markovian and Gaussian, respectively, corresponding to relative errors of 3.33% and 2.67%, which are values in line with similar analysis published in the literature (e.g., Lloret-Cabot et al., 2014). This similarity suggests that both theoretical correlation functions are equally valid for tackling this problem.

In addition to investigating the convergence of the estimation method to the true value of the vertical correlation length (Figures 3 and 4), it is also convenient to study the response of each individual estimated value of θ_v, as illustrated in Figure 5 in the form of a histogram.

Figure 5 includes also the true and estimated values of the vertical correlation length which are indicated, respectively, by a solid and a dashed line. For completeness the 90% confidence interval of LogNormal probability distribution fit is also plotted in the figures showing a reasonably good representation of the estimated θ_v. Inspection of the figure confirms that both approaches provide very similar results and, in particular, both show a right-skewed distribution which, interestingly, resembles well the histograms obtained from estimations of θ_v using real CPT data (e.g., Cami et al. 2020). Finally, it is worth noting that about two thirds of the estimated values of θ_v below the true value (1.5m) in agreement with the results from Nie et al. (2015) which illustrates well the challenge in estimating this parameter (as, clearly, the number of CPTs available in a specific site will be much less and hence the magnitude of the error might become quite important).

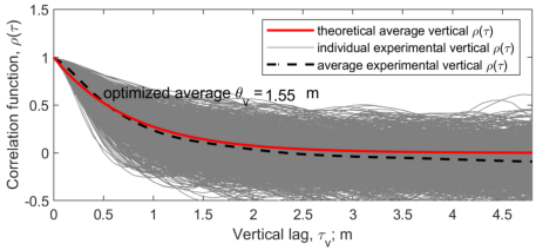

Figure 3. Estimation of the vertical correlation length with Markovian correlation structure and n = 1,000 realisations.

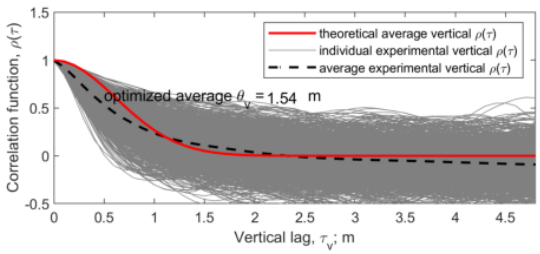

Figure 4. Estimation of the vertical correlation length with Gaussian correlation structure and n = 1,000 realisations.

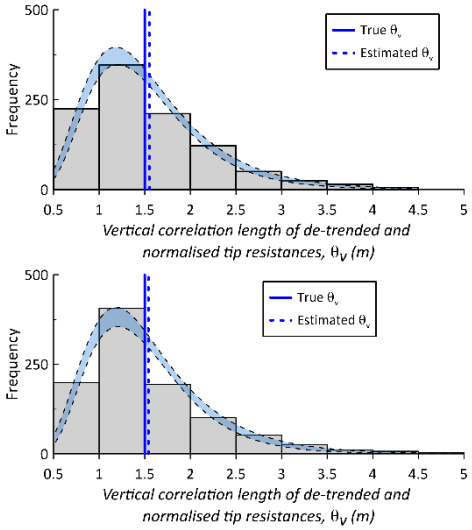

Figure 5. Histogram of estimated correlation lengths Markovian (top) or Gaussian (bottom).

3 CONCLUSIONS

The importance of the correlation length has been discussed in the context of probabilistic geotechnical analyses and its estimation has been assessed through a numerical investigation using artificially generated CPT data. The analyses showed that a very good accuracy is generally achieved when using a substantial number of realisations (1,000) demonstrating the applicability of the methods. However, a more detailed analysis on the individual estimated values of θ_v showed great variability which highlights the challenge and the potential error involved in the estimation process.

Challenges in the geotechnical characterisation of bauxite tailings (Red Mud)

Défis dans la caractérisation géotechnique des résidus de bauxite (Red Mud)

I. Lopes*, M. Garcia, G. Tavares

**isabel.lopes@tpf.pt*

ABSTRACT: The geotechnical characterisation of tailings from mining operations is a current challenge of great relevance. The geotechnical behaviour of tailings accumulation is very variable and depends on many factors, among others, the original mineralogy, the process used to obtain the ore, and the deposition form. Authors have studied tailings of various mineralogical origins, dealing with their geotechnical and geochemical particularities. The data presented in this paper comes from the study of Bauxite tailings, known as Red Mud. Tailings geotechnical characteristics are also a function of their disposal method, which depends on the percentage of solids, i.e. whether they were disposed as slurry (<50%), thickened (50% to 65%), paste (65% to 70%), or filtered (>70%), and if compaction processes were used. In this paper, the main Red Mud aspects and its geotechnical characteristics (obtained from literature) are presented, and the differences in the mechanical behaviour depending on the disposal method are discussed.

RÉSUMÉ: La caractérisation géotechnique des résidus miniers est un défi actuel de grande importance. Le comportement géotechnique des accumulations de résidus est très variable et dépend de nombreux facteurs, notamment de la minéralogie d'origine, du processus utilisé pour obtenir le minerai et de la forme du dépôt. Les auteurs ont étudié des résidus de diverses origines minéralogiques, en traitant leurs particularités géotechniques et géochimiques. Les données présentées dans cet article proviennent de l'étude des résidus de bauxite, connus sous le nom de *Red Mud*. Les caractéristiques géotechniques des résidus sont également fonction de leur processus de dépôt, qui dépend du pourcentage de solides, c'est-à-dire s'ils ont été déposés sous forme de boue (<50%), épaissis (50% à 65%), pâte (65% à 70%), ou filtrés (>70%), et si des processus de compactage ont été utilisés. Dans cet article, les principaux aspects de Red Mud et ses caractéristiques géotechniques (tirées de la littérature) sont présentés et les différences de comportement mécanique en fonction de la méthode de dépôt sont discutées.

Keywords: Tailings geotechnical behaviour; red mud; disposal method; CPTu.

1 INTRODUCTION

Red Mud results from the processing of bauxite ore to obtain alumina. To introduce and explain the site observations, based on literature, the main aspects, that are specific of the composition and behaviour of red mud are presented and are, also, described the different tailings disposal methods.

To show the differences in behaviour that will be presented in this case study, the results of CPTu tests will be used, as for the *in situ* geotechnical characterisation of tailings, is one of the tests established. One of the methods used for the separation between contractive and dilative behaviour is based on the Robertson (2016) charts.

In this paper is presented the separation between the different observed behaviours in the same red mud TSF, depending of the disposal method and are discussed the challenges felt on the TSF characterization and analysis.

2 RED MUD

2.1 Origin and composition

Red mud is a waste industrial product (tailing) from aluminium industries which is produced during the extraction of alumina from the bauxite ore. Bauxite is a weathered rock, typically with a soft structure (hardness between 1-3), containing two forms of hydrated aluminium oxide, in a quantity usually between 30-65%. These oxides are either predominantly monohydrate [AlO(OH)] or trihydrate [$Al(OH)_3$], represented by the minerals Gibbsite, Boehmite and/or Diaspore, which have a specific gravity (Gs) between 2.6-3.5. This ore has additional Fe_2O_3 as the main impurity. Although the minerals that compose bauxite ore have high Gs, the rock has a dry bulk density between 1.5 and 2.5 t/m^3 due to its high porosity.

The Bayer process is the commonly used process for the purification of this ore and it involves digesting the bauxite in a solution of NaOH at temperatures between 140 and 280°C (function of the mineralogy), under pressure. During the digestion process, aluminium reacts with the NaOH to form soluble sodium aluminate, leaving behind the Fe_2O_3 and other impurities. The process results in a highly alkaline pH=11-13 waste material, whose mineral components can include hematite, goethite, gibbsite, rutile, calcite, sodalite, and complex silicates. Notably, there is usually absence of quartz or clay minerals in this waste. The quantities of each mineral in the red mud are very variable and depend on the source bauxite and the original mineralogical composition of the ore is one of the most important factors influencing the red mud tailings properties (Table 1).

2.2 Geotechnical properties

Due to the high variability of combinations found it is difficult to generalize about red mud geotechnical behaviour. Both the original mineralogy, as the disposal method, strongly influence its behaviour. Nonetheless, some aspects are specific to its nature and can be found in literature (among others Newson et al., 2006 and Reddy et al., 2021):

- It is usually found in two grades: fine-grained "red mud" and coarse "red sand", being the "red mud" the more common type;
- Typical gradings show up to 20–30% clay sized, with most particles in the silt range, reason why some authors prefer the term *ferrosilt* to classify these materials, because of the high amount of red iron oxide and dominance of the silt size fraction. Despite that, some have been found with ≥50% of particles with less than 2 μm (clay sized), but it is a function of the digestion process used and of the characteristics of the ore body;
- Clay fraction grains microscopic analysis show equidimensional polyhedric grains with slightly rounded edges. Minerals of flat shape, typical of clay minerals, can hardly be found;
- They tend to have low plasticity (e.g., WL≈39-45%, IP≈10-15%) and are mainly ML in UCS. In spite of their IP and lack of clay minerals, they show many geotechnical properties similar to clayey tailings found in other mineral processing e.g. gold tailings;
- The specific surface area (BET) is between 10-30 m^2/g and the CEC (Cation Exchange Cap.) is comparable with kaolin or illite minerals;
- They present relatively high specific gravity (Gs=2.8-3.3), function of the strong presence of

iron minerals. Red mud tailings Gs is highly dependent on its mineralogical and chemical composition;

- Consolidation and settling has been found to be a function of the type and quantity of iron minerals i.e., Al-goethite, goethite, and hematite. In particular, very fine goethite can cause problems due to its relatively high Gs (=3.2) and high BET compared to the other oxide minerals;
- 1D compression tests indicate compression indices Cc=0.27-0.39, permeabilities k=(2-20)×10^{-7} cm/s and coefficients of consolidation c_v=(3-50)×10^{-3} cm^2/s and are therefore similar to silty-clay soils;
- Very high friction angles (ϕ') of 38-42° are also found for these materials, which are more typical of sandy soils;
- In situ undrained shear strengths are typically very high compared to uncemented clayey soils at equivalent liquidity indices (i.e. Su≥2 kPa for I_L>1) and sensitivities from 5 to 15 are commonly found (i.e. very low residual Su). Thixotropy has been observed with these materials and apparent preconsolidation pressures in excess of actual overburden pressures are found (apparent overconsolidation). Hence there is a strong indication that some red muds are cemented or aggregated;
- Leaching by freshwater and acid neutralization has been found to reduce in situ void ratios and compression indices.

Some examples values obtained for geotechnical properties and parameters, in different locations, are presented in Table 2, as extracted from literature. These values should only be used as reference as there is details about the tests made, and without indication, for instance, on the type of shear tests performed or on the disposal method used. This last point, as will be presented, has a big influence on the red mud tailings behaviour. To use the data here presented, or to obtain more information about the results and thier origins, it is strongly recommended to consult the original paper (Reddy et al., 2021).

Table 2. Examples of geotechnical parameters observed in different red muds produced in the world (adapted from Reddy et al., 2021).

Swelling property	**Free swell index (%)**	No swell	No swell	No swell	No swell	Very low	-	-

Other specific information is found in literature that is important to understand the red mud behaviour. For instance, Newson et al. (2006) observed the microstructure of a red mud specimen from a site in the UK and found that it is composed of a collection of small, apparently aggregated particles. Closer inspection shows a layer of material coating most of the particle surfaces (cementation?), composed of crystals with a cubic habit. X-ray analysis suggests that the coating is composed largely by hydroxysodalite (feldspar). Cementation can help to justify the high peak Su and the cohesion values obtained in shear testing.

Another important characteristic is red mud dispersivity. According with Rout et al. (2013), the results of the crumb tests, double hydrometer tests and turbidity tests made on red mud samples show that it is highly to extremely dispersive, with a dispersion ratio of 94% in the double hydrometer test.

One of the main parameters used to understand the tailings geotechnical behaviour is the void ratio (e), even though the huge difficulties in characterizing it in situ. In literature are found values for red mud bulk and dry densities, as being the parameter that gives the idea of their in situ state, but due to the high Gs of its grains, these parameters can be misleading. Newson et al. (2006), for the UK red mud analysed, obtained e values, both for intact and reconstituted specimens, varying between 1.76-1.45, but Carrier III et al. (1983) refers the value of 9 for the e_0 of red mud. Also here, the disposal method is very important for the void ratios obtained/observed.

3 TAILINGS DISPOSAL

Generally, tailings are the combination of the fine-grained solid materials (usually silt-sized), remaining after extraction from the ore of metals and minerals, with the water used in the recovery process. Depending on solid/liquid ratio of the tailings, they can be disposed (Figure 1 and Figure 2) as slurry (with the higher water content), as thickened tailings and paste, or as cake (often called dry stacking), that can be "wet" or "dry". The disposal can also be made in co-disposal with coarse wastes. The different solids concentrations are achieved by dewatering, and the concentrations vary for different tailings, since particle size distributions, clay mineral content, particle shape, mineralogy, electrostatic forces and flocculant dosing vary considerably and deeply influence the final result (Australian Government, 2016).

Tailings are commonly pumped as a slurry in a pipeline and discharged sub-aerially into a surface Tailings Storage Facility (TSF). The consistency of the slurry (% solids by mass) depends on the type of tailings, the particle size distribution and specific gravity, and the extent of thickening at the processing plant (Figure 1). Upon discharge (Figure 2), tailings slurry segregates, being the coarser and higher Gs particles deposited on the upper beach after which remains substantial supernatant water that carries finer and lower Gs particles forward into the decant pond. The segregation and settling of the tailing particles result in a significant curvature of the beach profile, i.e. more steep near the point of discharge and becoming flatter further down the beach profile. Thickened tailings still show some segregation, settling and bleed on placement, accompanied by some curvature of the beach profile, while paste tailings have a non-segregating, non-settling consistency that releases only small quantities of water after placement.

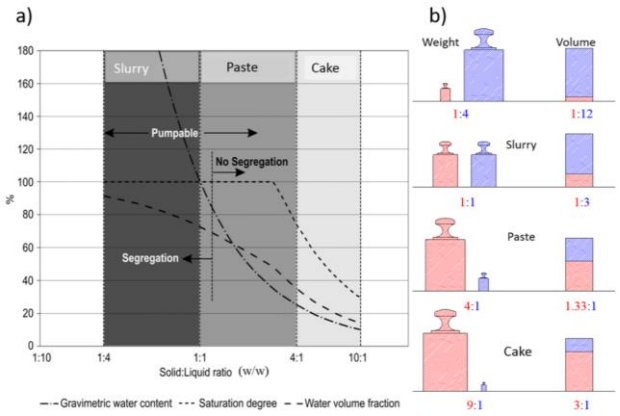

Figure 1. a) Types of mine tailings according to its solid/liquid ratio. including profiles for gravimetric water content. saturation degree. and water volume fraction and b) comparison between w/w and v/v ratios for a particle density of 3g/cm³ (Pacheco, 2018).

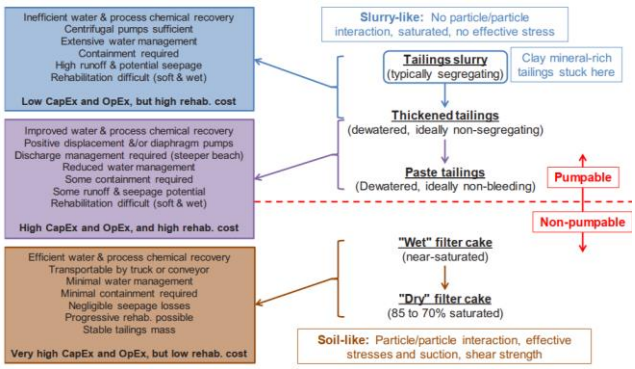

Figure 2. Tailings Continuum (Australian Government, 2016).

Thickening tailings reduces the quantity of water delivered to the TSF, which reduces the risks of overtopping, reduces seepage, evaporation losses, and reduces the risk of TSF embankment failure by

lowering the pond level and reducing the phreatic surface within the embankment. Thickening of tailings in the processing plant before disposal also enables process water to be recycled directly back to the plant, reducing water losses and reducing plant raw water demand.

Tailings can be also brought to a 'solid-like' state by centrifuging or filtration, producing a consistency that is potentially transportable by truck or conveyor. True dry stacking requires that the flocculated tailings be filtered, usually under pressure or possibly under vacuum to produce a product that is transportable and stackable using 'dry' material transportation and disposal techniques. In this state they may then be placed, spread and compacted to form an unsaturated, dense and stable tailings 'dry stack'.

4 SITE OBSERVATIONS

4.1 Site tailings disposal description

The site in analysis is a red mud TSF where there were 3 stages of deposition, one overlapping the other. At first, the operation started with the deposition of tailings in slurry form with 30% solids. During this 1st deposition stage, tailings were in liquid state and were pumped as a wet slurry through a pipeline and discharged sub-aerially. Due to the high specific gravity of the grains, the solid phase sedimented and there was supernatant water remaining ("pond").

In the 2nd deposition stage, after introduction of the use of drum filter and dumper in the installation, the red mud was transported in cake form, with a solid content of around 65-70%, but the discharge of the tailings was made by trucks into a "pond" (Beach Below Water Disposal - BBW).

When the surface of the TSF achieved a dry situation (without supernatant water), the 3rd deposition stage has started. At this stage, a almost dry material with 70 to 75% solids was transported using trucks and stacked, spreading and compacted using a bulldozer.

4.2 CPTu results

Two CPTu campaigns were made in the site, in different years. The CPTu data were processed following the state-of-the-art methodologies, one of which is detailed in Roberston (2016).

The results obtained were similar, allowing to separate the different stages. Nonetheless, as they were made in different moments of deposition, the number of points sampled in the red mud tailings of the different deposition stages is different, i.e. 53% in the 1st dep. stage, 31% in the 2nd and only 16% in the 3rd. An example of the results, separating the different stages of tailings deposition, above the natural soil, is presented in Figure 3.

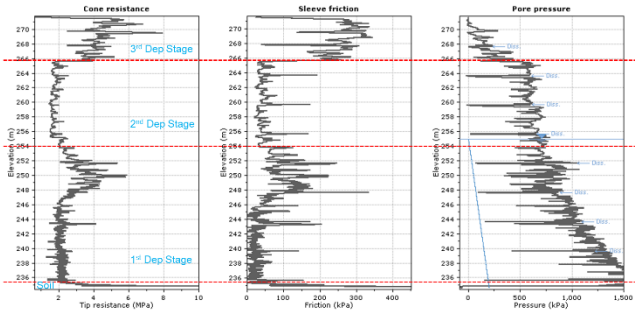

Figure 3. Example of a CPTu test made in study site, showing the division between the different deposition stages.

Being the grain size distribution of the red mud tailings, in the different deposition stages, similar, the main differences in the site are due to the disposal method and to the installed water level (WL), observed to be slightly above the top of the tailings of the 1st deposition stage.

When looking to the points plotted in the Robertson (2016) SBTn classification charts (Figure 4) it is evident the difference in the behaviour between the 1st dep. stage (slurry below the water table), where the data appear in the clay contractive (CC) area of the chart, but expanding to the CCS sensitive materials, and the dilative behaviour of the 3rd dep. stage (stacked filtered dry tailings above the WL). To note is the observed behaviour of the red mud tailings of the 2nd dep. stage, that were deposited with high solids content, but in BBW. These tailings, even though are not below the WL, are clearly close to saturation and present low resistance. When ploting in the SBTn chart they appear with a behaviour very close to the one observed in the slurry, mainly with clay contractive behaviour type.

As in all tailings, analysing and interpreting the behaviour od red mud, depends not only on the results of the site investigation tests, but also on understanding the TSF history.

5 CONCLUSIONS

Tailings studies are very challenging, and the difficulties start, frequently, with the difficulty to build the initial ground model, due to lack of data from construction period, and to define the TSF history. In the case of red mud, the challenges continue due to: its mineralogical content, that promotes cement mineral neoformation; the dominant silt fraction, that promotes partial drainage when tested; high Gs; sometimes high

e_0; and high sensitivity, with the observation of high peak strength and very low residual strength.

From the site, the results show that, as expected, the dry stacking presents mainly dilative behaviour and that slurry tailings present contractive behaviour. To note, in this site, is the clear evidence that the disposal of tailings in BBW conditions, even if they are filtered, fully saturates the materials resulting in contractive behaviour, showing the importance of the deposition on the geotechnical behaviour.

It is also important to note that, while the 3rd dep. stage materials are dilatant, there are no guarantees for the TSF stability, as stacking materials (with lower *e* and high unit weight) above contractive materials may induce excess pore pressures, being the contractive materials, the ones ruling the overall stability of the facility.

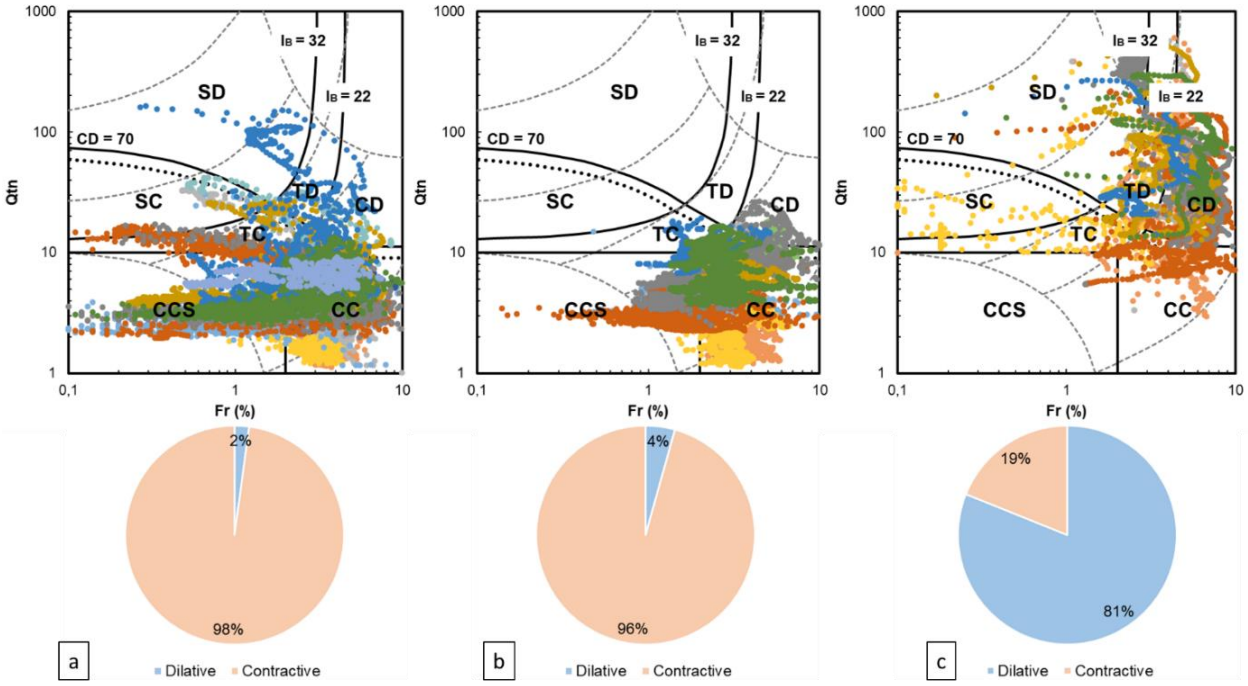

Figure 4. Red mud updated SBTn classification (Roberston, 2016) and percentage of points showing contractive or dilative behaviour in tailings disposed, in the same TSF, as: a. slurry (30% solids); b. filtered tailings (65% solids) disposed in beach below water; c. filtered tailings (70% solids) dry stacking.

Assessment of shear stiffness and damping variations in undrained cyclic triaxial tests of iron ore tailings

Évaluation des variations de la rigidité au cisaillement et de l'amortissement dans des essais triaxiaux cycliques non drainés de résidus de minerai de fer

ABSTRACT: Tailings dams pose severe risks to society and to the environment. Many failures occur worldwide, suggesting that their behaviour remains poorly understood. This is particularly true in the case of tailings dams built in seismically active regions, where the ability to properly understand and model the behaviour of ore tailings under cyclic loading is critical. This paper aims to clarify the undrained cyclic behaviour of iron ore tailings observed in triaxial tests on reconstituted samples of mining waste obtained from Torre de Moncorvo Iron Mine. Firstly, the undrained cyclic behaviour of this unconventional geomaterial is compared with that of other typical soils, including loose granular soils. Secondly, the degradation of the shear stiffness and the increase in the damping ratio with the number of loading cycles are assessed using suitable software created to compute the values of these properties relative to each hysteretic loading cycle automatically. In addition, the challenges in analysing real undrained cyclic triaxial tests on iron ore tailings are discussed in detail. Based on the results presented in the paper, the authors expect to shed further light on the undrained cyclic response of ore tailings under seismic loading and the degradation of the mechanical properties, namely the stiffness and the damping, caused in each loading cycle.

RÉSUMÉ: Les barrages de résidus miniers présentent des risques graves pour la société et pour l'environnement. De nombreuses défaillances surviennent dans le monde entier, suggérant que leur comportement reste mal compris. Cela est particulièrement vrai dans le cas des barrages de résidus miniers construits dans des régions sismiquement actives, où la capacité à comprendre et modéliser correctement le comportement des résidus de minerai sous chargement cyclique est cruciale. Cet article vise à clarifier le comportement cyclique non drainé des résidus de minerai de fer observé dans des essais triaxiaux sur des échantillons reconstitués de déchets miniers obtenus de la mine de fer de Torre de Moncorvo. Tout d'abord, le comportement cyclique non drainé de ce géo-matériau non conventionnel est comparé à celui d'autres sols typiques, y compris des sols granulaires lâches. Deuxièmement, la dégradation de la rigidité au cisaillement et l'augmentation du rapport d'amortissement avec le nombre de cycles de chargement sont évaluées à l'aide d'un logiciel approprié créé pour calculer automatiquement les valeurs de ces propriétés par rapport à chaque cycle de chargement hystérétique. De plus, les défis liés à l'analyse des essais triaxiaux cycliques non drainés réels sur les résidus de minerai de fer sont discutés en détail. Sur la base des résultats présentés dans l'article, les auteurs espèrent apporter davantage d'éclairage sur la réponse cyclique non drainée des résidus de minerai sous chargement sismique et la dégradation des propriétés mécaniques, à savoir la rigidité au cisaillement et l'amortissement, causée à chaque cycle de chargement.

Keywords: Tailings; earthquakes; cyclic liquefaction; stiffness degradation; damping variation.

1 INTRODUCTION

Tailings dams are enormous geotechnical structures built to contain the waste resulting from mining activities. Recently, due to significant failures around the world (e.g., Robertson et al., 2029), the safety of these structures has been under strict review. When tailings dams are built in seismically active regions, accidents are also common (e.g., Vergudo et al., 2012), not only due to the possible occurrence of cyclic liquefaction but also due to the inertial forces imposed by wave propagation within the dam. Thus, the degradation of tailings properties imposed during undrained cyclic loading must be assessed to ensure the safety of tailings dams under dynamic loading. As limited data exist in this field, this paper discusses interpreting the undrained cyclic behaviour of iron ore tailings collected from a Portuguese mine.

2 EXPERIMENTAL PROGRAM

Research Project GeoSusTailings aims to improve tailings management's safety and sustainability, applying a geotechnical approach to characterise and numerically model tailings behaviour. Herein, the cyclic behaviour of iron ore tailings is discussed.

2.1 Torre de Moncorvo iron tailings

Torre de Moncorvo iron tailings are used in this paper to assess the cyclic undrained behaviour of mining waste. The mine is in the North of Portugal (Figure 1) and was reactivated under the concession of Aethel Mining. Table 1 lists the main properties of the low plasticity iron-rich tailings from an old deposit with particles having dimensions in the silty-sand range. The unusually high values of G and γ_d are remarkable and result from the significant presence of high-density iron particles, which increases the risk of particle segregation during reconstitution.

2.2 Sample reconstitution of studied tailings

Slurry-based reconstituted samples of the studied iron ore tailings were tested and used for the analysis. The sample reconstitution method and the capability of reconstituted samples to qualitatively replicate the behaviour of undisturbed samples collected from the site are depicted by Coelho et al. (2022). Overall, the reconstituted samples obtained through consolidation of a uniform liquid slurry could avoid segregation and replicate the field behaviour satisfactorily.

2.3 Cyclic triaxial testing

Undrained cyclic triaxial tests are commonly used to address the behaviour of granular saturated soils under the effects of dynamic loading, namely if earthquake-induced liquefaction is a relevant phenomenon. Strain-controlled undrained cyclic triaxial tests with fixed deviator stress peaks were performed on reconstituted samples isotropically consolidated at 200 kPa. These were loaded and unloaded in each cycle between the fixed predefined minimum and maximum deviatoric stress values, imposing variable cyclic stress ratios.

Figure 1. Location of Torre de Moncorvo Iron Mine.

Table 1. Physical and identification properties of Torre de Moncorvo iron tailings.

Property	In situ range
γ_d [kN/m^3]	27~29
G [-]	4.4~5.1
e [-]	0.60~0.70
D_{50} (mm)	0.05~0.06
D_{10} (mm)	0.012~0.23
P.L. [%]	14~16
L.L. [%]	19~21
P.I. [%]	4~6

2.4 Undrained cyclic triaxial behaviour of Torre de Moncorvo iron tailings

The undrained cyclic triaxial behaviour of the studied tailings is similar to that of granular materials under similar loading conditions. In particular, the concepts of critical state and phase transformation lines (Ishihara et al., 1975) are valid for describing tailings' stress paths and stress-strain responses under undrained cyclic loading. More importantly, the progressive reduction of the effective confining stress up to near-zero values and the ensuing degradation of the tailings' mechanical behaviour in each cycle can be identified (Figure 2). This degradation is often assessed through the reduction of the shear stiffness and the variation of damping with the shear strain, as Seed et al. (1986) proposed. Even if the so-called degradation curves are more popular for describing the behaviour of natural granular materials, these can also be used for natural soils with variable plasticity (e.g., Okura & Ansal, 2007) or tailings (e.g., Urbano et al., 2017) under undrained cyclic loading causing liquefaction. However, some practical difficulties arise when evaluating the stiffness and damping of soils under cyclic loading, namely for large deformations. It is also true for the iron ore tailings tested, which motivated the creation of a numerical tool to calculate the stiffness and damping consistently for each cycle.

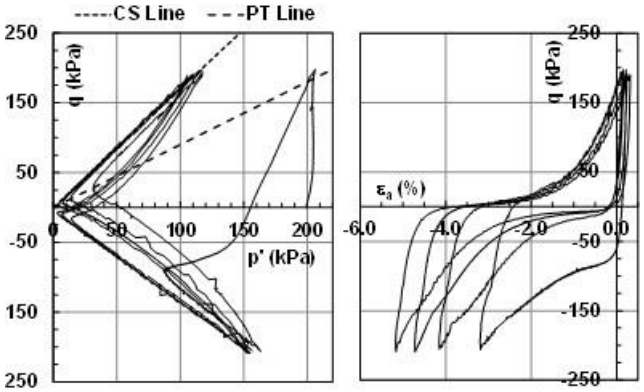

Figure 2. Undrained cyclic triaxial behaviour of Torre de Moncorvo Iron Tailings.

3 TOOL TO ASSESS THE STIFFNESS AND DAMPING RATIO VARIATIONS

The secant shear modulus (G) and damping ratio (ξ) for each cycle, defined in Figure 3, exhibit significant variation with the shear strain. A GNU/Octave script, detecting and individualising all the cycles, was developed to assess these variations. As the cyclic stress-strain responses are not closed, symmetrical, or as well-defined as the example shown in Figure 3, some processing is required in each cycle.

3.1 Numerical procedures

In undrained triaxial tests, no volumetric strain exists (1), and the shear strain relates to the axial strain, as described in (*2*). Moreover, the shear modulus (G) relates the shear stress with the shear strain (*3*):

$$\epsilon_v = \epsilon_a + 2\epsilon_r = 0 \quad (1)$$

$$\gamma = (\epsilon_a - \epsilon_r) = \frac{3}{2}\epsilon_a \quad (2)$$

$$G = \frac{\tau}{\gamma} = \frac{\frac{q}{2}}{\frac{3}{2}\epsilon_a} = \frac{q}{3\epsilon_a} \quad (3)$$

The script has the following sections:

i) detection of the global maximum and minimum values of deviatoric stress (q) for each cycle ($q_{max,i}$ and $q_{min,i}$), local extremes being discarded, in order to individualise all the cycles by detecting the starting point for the extension and compression stress paths;

ii) for the ith cycle, the script calculates the deviatoric strains that correspond to $q_{max,i}$, $q_{min,i}$ and $q_{end,i}$ (i.e., $\varepsilon_{d,qmax,i}$, $\varepsilon_{d,qmin,i}$ and $\varepsilon_{d,end,i}$); the extension path starts in $q_{max,i}$ point and ends at $q_{min,i}$ point, and the compression path starts in $q_{min,i}$ and ends in $q_{end,i}$;

iii) the extension closed cycle is built; the cycle deviatoric strain ($\varepsilon_{d,ext,i}$) for the extension section is given by $\varepsilon_{d,qmax,i}$ - $\varepsilon_{d,qmin,i}$; an extension symmetry line is formed by connecting points ($\varepsilon_{d,qmax,i}$, $q_{max,i}$) and ($\varepsilon_{d,qmin,i}$, $q_{min,i}$), the closed cycle results from mirroring the original extension path around the symmetry line; the cycle is translated to centre it in $\varepsilon_{d,i} = 0$ (Figure 4);

iv) the compression closed cycle is built; for the compression section, the cycle deviatoric strain ($\varepsilon_{d,comp,i}$) is determined by $\varepsilon_{d,qend,i}$ - $\varepsilon_{d,qmin,i}$; an extension symmetry line is formed connecting the points ($\varepsilon_{d,qmin,i}$, $q_{min,i}$) and ($\varepsilon_{d,qend,i}$, $q_{end,i}$), and the closed cycle is formed by mirroring the original compression path around the symmetry line; the cycle is translated to have its centre in $\varepsilon_{d,i} = 0$;

v) the shear stiffness (G) and the damping ratio (ξ) for the ith cycle are determined (Figure 4).

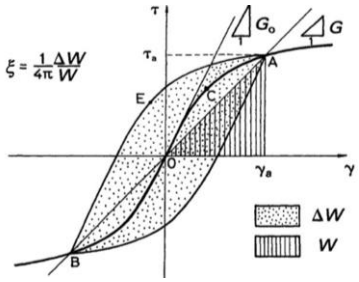

Figure 3. Definition of elastic (G_0) and secant (G) shear moduli and damping ratio (ξ), relating dissipated (ΔW) and elastic stored (W) energies (adapted from Ishihara, 1996).

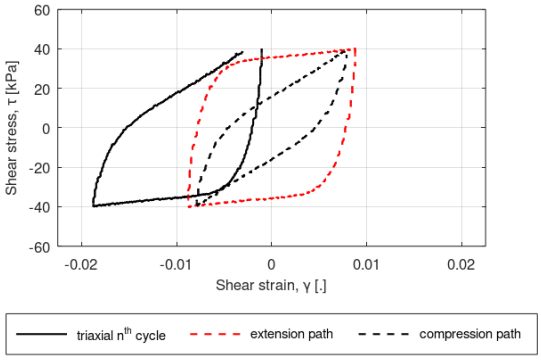

Figure 4. Extension and compression closed cycles, defined after a generic triaxial cycle.

3.2 Results obtained

Figure 5 illustrates the cyclic shear stress- shear strain responses for several cycles obtained after processing using the script, showing that the stiffness degradation resulting from the compression and extension sections is similar. On the contrary, the damping ratio depends more on the section of the curve considered during processing. Figures 6 and 7 highlight this qualitative assessment, the stiffness and damping values for all the cycles registered in the test being plotted against shear strain. In fact, the stiffness degradation with the shear strain (Figure 6, G_0 not available) has a shape typically observed in natural soils (e.g., Okura and Ansal, 2007) and is quite independent of the selected curve path.

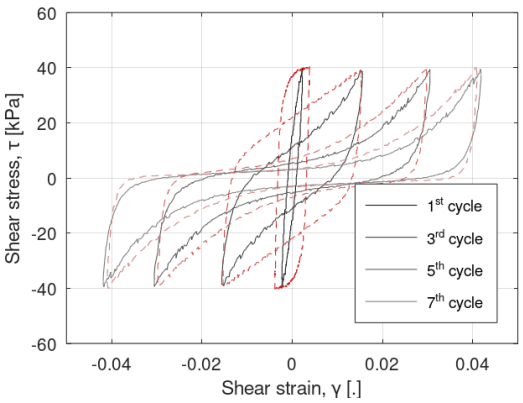

Figure 5. Cyclic shear stress- shear strain derived from the compression and extension sections after processing.

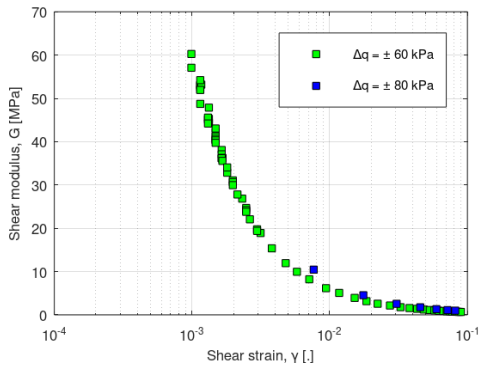
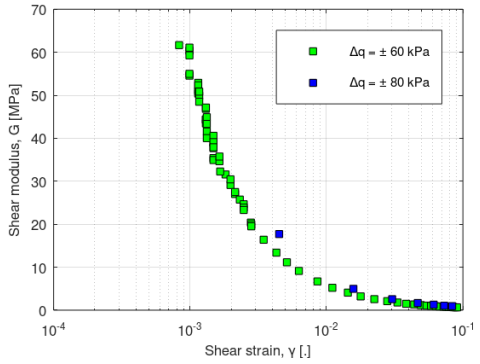
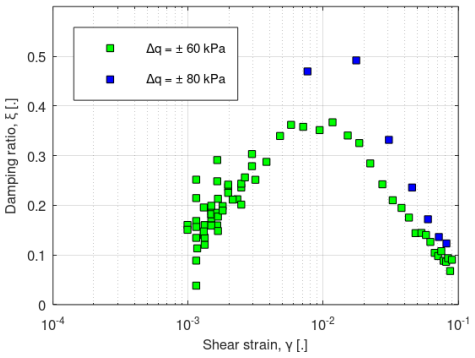


a) extension path

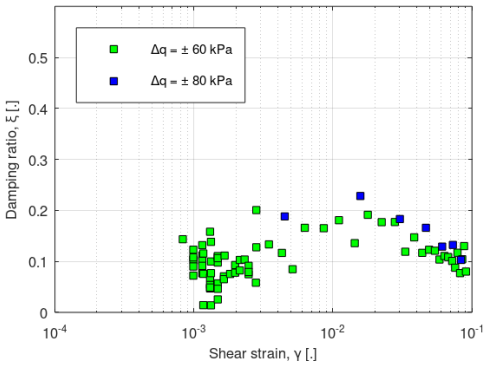


b) compression path

Figure 6. Shear modulus evolution with shear strain.



a) extension path



b) compression path

Figure 7. Damping ratio evolution with shear strain.

In contrast, the variation of damping with the shear strain has two parts: firstly, some scatter is observed at low strains, possibly due to calculation challenges; secondly, after reaching a peak at around 10^{-2} of shear strain, the damping decreases with shear strain. This latter behaviour is physically doubtful but may find some support in Okura and Ansal (2007), as damping stabilizes at 10^{-2} of shear strain. But as the shape of the stress-strain curves observed differs from usual curves (Figure 3), normal calculation methods may not apply.

4 CONCLUSIONS

A script is proposed to assess the shear modulus and damping ratio variation with shear strain observed in undrained cyclic triaxial tests on iron tailings. The results show that degradation curves match those observed in natural soils (e.g., Okura and Ansal, 2007) while damping variation is physically debatable and requires further validation through alternative tests.

Eurocode 7 – Second generation: anchors, rock bolts and soil nailed structures

Eurocode 7 – Deuxième generation - Ancrages, boulons de roche et structures clouées au sol

N. Maca*
TITAN POLSKA Sp. z o.o., Krakow, Poland
**natalia.maca@titan.com.pl*

ABSTRACT: Among the objectives of the second generation of Eurocode 7 was to consider developments in the industry, including the introduction of common geotechnical structures so far not covered in the Eurocodes, aiming towards harmonising geotechnical design. Among the new structures introduced in the EN 1997-3 are rock bolts and soil-nailed structures, which are the paper's focus. To complement the discussion on tension-supporting elements, the paper also briefly describes the anchor clause's revision. It provides an overview of significant aspects of geotechnical design, considering limit states, material and durability requirements and demonstrates verification methods. As the reliability of the structures in question in the whole process, from design through execution to testing, is to be harmonised, some guidance to the compulsory supplement standards is also provided.

RÉSUMÉ: L'un des objectifs de la deuxième génération de l'Eurocode 7 était de prendre en compte les développements dans l'industrie, y compris l'introduction de structures géotechniques communes jusqu'à présent non couvertes par les Eurocodes, dans le but d'harmoniser la conception géotechnique. Parmi les nouvelles structures introduites dans l'EN 1997-3 figurent les boulons de roche et les structures clouées au sol, qui font l'objet du présent document. Pour compléter la discussion sur les éléments de support de tension, le document décrit également brièvement la révision de la clause sur les ancrages. Il donne un aperçu des aspects importants de la conception géotechnique, en tenant compte des états limites, des exigences en matière de matériaux et de durabilité, et démontre les méthodes de vérification. Étant donné que la fiabilité des structures en question doit être harmonisée tout au long du processus, de la conception aux essais en passant par l'exécution, des indications sur les normes complémentaires obligatoires sont également fournies.

Keywords: Eurocode 7; standardisation; anchors; rock bolts; soil nails.

1 INTRODUCTION

The second generation of Eurocode 7 will consist of three parts, denoted here as prEN 1997-1 (CEN 2024a), prEN 1997-2 (CEN 2024b) and part 3 which contains design rules specific to a particular type of geotechnical structures prEN 1997-3 (CEN 2024c).

Among the objectives of the second generation of Eurocode 7 was to take account of developments in the industry, including the introduction of new chapters addressing commonly used geotechnical structures so far not covered in the Eurocodes, aiming towards the harmonisation of geotechnical design. It should be noted that even if the structures in the new content are widely used in Europe, a common design approach has yet to be available and national practices are considerably different. Thus, drafting the new clauses was challenging and ended with the current form of consensus.

The paper focuses on anchors, rock bolts and soil nailed structures. While anchors are familiar to the reader and the design requirements within their scope have been slightly revised, the remaining ones are entirely new content barely mentioned in the first generation of Eurocode 7 (CEN, 2004).

As a consequence of the changes in the entire set of Eurocodes and prEN 1997-3 itself, as well as the harmonisation of the general rules for structural and geotechnical design, the design aspects of geotechnical elements within the scope of the paper are closely linked to other parts of Eurocode 7, which should therefore be considered together.

2 COMMON ASPECTS OF DESIGN

2.1 Design concept in prEN 1997-3

One of the significant features in prEN 1997-3 is that it contains many references to the other two parts (CEN, 2024a, 2024b) and other structural Eurocodes, as well as the execution and testing standards. This is an effect of the increase of harmonisation of structural and geotechnical design, as well as the close linking of all stages of construction from design through to execution and testing.

Within the new Eurocode 7 itself, the design principles for all geotechnical structures are more consistent. Thus, in prEN 1997-3 anchors in Clause 8 and rock bolts in Clause 11 are described as single supporting elements being a part of a larger structure. Therefore, the load acting on these elements and general aspects of the design of the structures supported by these elements are defined in different clauses: Clause 4 (Slopes, cuttings, and embankments), 5 (Spread foundations), 7 (Retaining structures) and in some cases Clauses 6 (Piled foundations) or 9 (Reinforced fill structures). Soil nailed structures are defined in Clause 10, but general design aspects are referenced in the corresponding clause where the soil nails are used. Also, as structures in the scope are often rely on groundwater control, the guidance on its measures is given in Clause 13.

2.2 Different tension supporting elements – definitions and clarification

One of the aims of the revision of Eurocode 7 was to include and clarify all standard tension supporting elements, addressing their specifics in the design. As they can be constructed and executed in the same way and often in the same ground condition, clear distinction is necessary so that the proper design path for this application is used. Thus, the elements distinguishing features are defined as:

- Tension piles in Clause 6 are piles transferring axial tension force by friction between the surface of the pile and the adjacent ground;
- Anchors in Clause 8 are elements transmitting a tensile load from the anchor head through a free length to into the ground (soil, rock or fill);
- Soil nails in Clause 10 are reinforcing elements mobilising resistance with the ground along the entire length, working mainly in tension, creating composite soil nailed structures;
- Rock bolts in Clause 11 are reinforcing elements for stabilising rock excavations and slopes, transferring load from the unstable exterior to the confined interior of the rock mass, including doweling to prevent shear failure through discontinuities.

The summary of the mode of operation with the referenced standards is presented in Figure 1. Corresponding verification methods with regulations regarding execution and tests result in diverse safety factors of the given element.

element	anchor	micropile	soil nail	rock bolt
design	Clause 8	Clause 6	Clause 10	Clause 11
execution	EN 1537	EN 14199	EN 14490	[future EN 14490]

Figure 1. Comparison of tension supporting elements.

2.3 Transition between soil and rock

Following the above discussion on the definitions, one common question in the drafting process was whether the stabilised rock mass slope should be designed according to the rock bolt or soil nail clause and, consequently, which verification methods and partial factors are allowed. This question is justified as the structures in the scope of the paper could be applied in the whole spectrum of ground conditions: from soil (also fill) and weak to hard rock mass. In many cases, a clear distinction between soil and rock is impossible, and we can observe a smooth transition in the continuum between of soil and rock. Thus, if the precise categorisation of the ground condition is not feasible, the Eurocode leaves it up to the designer to choose what ground model and element behaviour, either rock bolt or soil nail, should be applied.

2.4 Material and durability

One of the improvements in the second generation of Eurocode 7 is the compilation and clarification of requirements for materials used for geotechnical structures. As the reliability of the structures, which are mostly covered underground, may be highly influenced by the durability issue, this aspect is also highlighted in the code. Consequently, information about assessing the corrosive potential based on the chemical properties of the ground and the ground water as well as the climate conditions, are provided.

Thus, for anchors, the current regulations have been maintained; however, they have mostly been moved from EN 1537 (CEN, 2012) to prEN 1993-5 (CEN, 2021). New clauses for soil nails and rock bolts introduce in an orderly fashion the various regulatory texts dealing with material and corrosion protection for steel soil nails and rock bolts, following the rules for

tension piles as in prEN1993-5), primarily consistent with the current EN 14490 (CEN, 2010). Moreover, the a set of requirements for facing are provided, with a particular focus on wire mesh including an exhaustive list of referenced standards and EADs (European Assessment Documents) is provided.

3 ANCHORS

The anchors clause was already completely revised in 2014. Thus, in prEN 1997-3, it was only slightly edited to fit the general changes of the entire set of the Eurocodes and further details and harmonisation with interdependent standards were introduced. The informative Annex E further supplements the content of Clause 8 with some practical guidance on the design considerations.

The calculation models to determine the required anchor force to prevent an ultimate or serviceability limit states are given in prEN 1997-3 Clauses 4 and 7 for supporting elements or prEN 1997-1 for uplift. It should be noted, that the effect of action E_{d} used in the design of anchors is the maximum result from ULS or SLS during the design service life of the supported structure.

In prEN 1997-3, the design path for geotechnical resistance determination has not been changed compared to the current version of Eurocode 7. The geotechnical design and construction are obligatorily verified by testing according to EN ISO 22477-5 (CEN, 2018), with the possibility of verification by comparable experience in the National Annex. The requirements to determine the geotechnical resistance are now clearly stated for both grouted and non-grouted anchors.

The partial factors for verifying geotechnical resistance and limiting criteria remain the same as in the current version, but are supplemented with the values for temporary anchors. It can be noted that Method 2 as specified EN ISO 22477-5 is no longer used in the design.

The structural resistance of the anchor shall comply with prEN 1993-5 and has to be checked for the proof load according to EN ISO 22477-5.

Regarding testing prEN 1997-3 addresses aspects of types of tests, proof load values, acceptance criteria and the number of tests, while EN ISO 22477-5 is referenced for the testing procedures.

4 SOIL NAILED STRUCTURES

4.1 General

prEN 1997-3 includes a new Clause 10 devoted entirely to soil nailed structures, which is intended to cover the requirements and design procedures comprehensively. It standardises different design methods used in the EU countries and takes over design-related aspects from EN 14490. Clause 10 is supplemented with informative annex G providing guidance on verification of pull-out resistance.

Clause 10 applies to "soil nailed structures - cutting, slope, or existing structure reinforced with soil nails" which form a composite structure usually including facing elements. There are no limitations regarding the technique or material of the soil nails. Facing systems in the scope of the clause are: wire mesh, plain and reinforced concrete, sprayed concrete, concrete panels and other facing elements.

As soil nailed structures are basically a reinforced cut or slope, embankment or retaining structure, the basis of desing follows the rules of Clauses 4, 5, or 7, respectively, Clasue 10 defines additionally only the requirements specific for the given elements in clause, as below.

4.2 Geotechnical analysis

The geotechnical analysis of a soil nailed structure is mainly related to pull-out resistance of soil nails and structural resistance of wire mesh and sprayed concrete, described in section 4.3.

The stability of a soil nailed structure should be verified using limit equilibrium methods (slope stability or multiple wedge methods) and/or numerical models. The details regarding the calculation models for stability analysis, are given in Clause 4 and Annex A. prEN 1997-3 allows verification using one design method, if it adequately addresses all relevant limit states, which is beneficial for the efficiency of designing, especially when using numerical models.

4.3 Ultimate limit states

The general limit states of soil nailed structures are to be analysed according to Clauses 4, 5, or 7, as appropriate, considering the beneficial effect of soil nails. Clause 10 focuses on ultimate limit states related to the single supporting element, which are necessary to analyse, among others:

- failure at the interface between the ground and the soil nail (pull-out) and/or between the soil nail and the grout (if present);
- structural failure of soil nails or any facing element and their connections.
- bearing failure beneath a head plate
- loss of force or resistance by deformation or loss of ground behind the soil nailed structure.

All verification methods are allowed to design the soil nailed structure:

- verification by the partial factor method;

- verification using prescriptive rules;
- verification by testing;
- verification using the Observational Method.

For soil nails the minimum of pull-out resistance $R_{po;d}$ (in the active and passive zone), structural resistance $R_{el;d}$ and the resistance of connection to the facing $R_{con;d}$ shall be verified against the effects of actions E_d:

$$E_{\mathrm{d}} \leq \min\left\{R_{\mathrm{po,d}}; R_{\mathrm{el,d}}; R_{\mathrm{con,d}}\right\} \qquad (1)$$

The basic approach of pull-out resistance $R_{po;d}$ determination is consistent with other tension elements, introducing verification by testing and by calculation based on the ground model method or model pile method, as defined in Clause 6 (Piled foundations). Additionally, design based on comparable experience allows continuing the current practice used in different countries. To ensure the proper reliability level, different methods are related to different sets of model and correlation factors and additional requirements regarding testing. For given methods the corresponding sets of factors for both Material Factor Approach MFA (sets VC3 and M2) or Resistance Factor Approach RFA (with VC1) are determined, conveniently allowing using wide range of design methods for the whole structure. The summary of the verification methods and safety factors as well as corresponding requirements regarding testing in the given method, is presented in Table 1.

Regarding the structural resistance the soil nail and resistance of the connection to the facing shall comply with prEN-1993, considering any anticipated loss of strength with time.

As currently dimension of the wire mesh is not standardised, Clause 10 gives the formulas for determining the tensile and puncture resistance, consistent with the general EC7 design philosophy and the current practice. A vague guidance regarding determining the loads acting on a facing element is also given with additional references to BS 8006-2 or FHWA.

Table 1. Summary of design verification methods for soil nails pull-out resistance determination

Method	The formula and factoring approach	Factors	Testing
By testing	RFA $R_{po;d} = \frac{1}{\gamma_{\mathrm{R,po}} \times \gamma_{\mathrm{Rd}}} \min\left\{\frac{R_{\mathrm{test;mean}}}{\xi_{mean}}; \frac{R_{\mathrm{test;min}}}{\xi_{min}}\right\}$	$\gamma_{\mathrm{Rd}} = 1.0, \xi = 1.0 - 1.4,$ $\gamma_{\mathrm{R,po}} = 1.25$	Recommendation for acceptance tests
By calculation - Model Pile method	RFA $R_{po;d} = \frac{1}{\gamma_{\mathrm{R,po}} \times \gamma_{\mathrm{Rd}}} \min\left\{\frac{R_{\mathrm{calc;mean}}}{\xi_{mean}}; \frac{R_{\mathrm{calc;min}}}{\xi_{min}}\right\}$	$\gamma_{\mathrm{Rd}} = 1.4, \xi = 1.0 - 1.4,$ $\gamma_{\mathrm{R,po}} = 1.25$	
By calculation – Ground model method	MFA for effective stress analysis: $R_{\mathrm{po;d}} = \frac{1}{\gamma_{Rd}} \int_0^{L_{\mathrm{po}}} P(x) \cdot \frac{\mu_{\mathrm{po}}}{\gamma_{\tan\varphi}} \cdot \sigma'_r(\mathrm{x}) \cdot dx$	$\gamma_{\mathrm{Rd}} = 1.2 - 1.6$ $\gamma_{\tan\varphi}$=1.25 γ_{cu}=1.40	Recommendation for verification by suitability tests
	MFA for total stress analysis: $R_{\mathrm{po;d}} = \frac{1}{\gamma_{Rd}} \int_0^{L_{\mathrm{po}}} P(x) \cdot \frac{c_u}{\gamma_{cu}} \cdot \alpha \cdot dx$		For GC3 $R_{po;d}$ shall be determined from investigation tests and verified by suitability tests only
	RFA for effective stress analysis: $R_{\mathrm{po;d}} = \frac{1}{\gamma_{\mathrm{R,po}} \times \gamma_{\mathrm{Rd}}} \int_0^{L_{\mathrm{po}}} P(x) \cdot \mu_{\mathrm{po}} \cdot \sigma'_r(\mathrm{x}) \cdot dx$	$\gamma_{\mathrm{Rd}} = 1.2 - 1.6$ $\gamma_{\mathrm{R,po}} = 1.25$	
	RFA for total stress analysis: $R_{\mathrm{po;d}} = \frac{1}{\gamma_{\mathrm{R,po}} \times \gamma_{\mathrm{Rd}}} \int_0^{L_{\mathrm{po}}} P(x) \cdot c_u \cdot \alpha \cdot dx$		Recommendation for acceptance tests
	with RFA for comparable experience: $R_{po;d} = \frac{1}{\gamma_{\mathrm{R,po}} \times \gamma_{\mathrm{Rd}}} \int_0^{L_{\mathrm{po}}} P(x) \cdot \tau_{\mathrm{po}}(x) \cdot dx$	$\gamma_{\mathrm{Rd}} = 1.2 - 1.6$ $\gamma_{\mathrm{R,po}} = 1.25$	

4.4 Serviceability limit states

In addition to general serviceability limit states (SLS) given in EN 1997-1 (CEN, 2024a) the specific ones for soil nailed structures are, among others:

- bulging and deformation of the facing;
- deformation adversely affecting the function or appearance of the structure or causing damage to existing structures;
- cracking or spalling of any concrete facing.

What is important, especially with calculation models based on limit equilibrium methods, the permission is given to omit SLS verification, provided that ultimate limit states are verified and there are no explicit serviceability criteria.

4.5 Testing

prEN 1997-3 addresses testing of the soil nails in terms directly related to design, particularly verification methods. The new soil nail content is primarily consistent with the current EN 14490, adding more guidance and ensuring compatibility with future prEN ISO 22477-6 (ISO, 2023) which will regulate the

testing procedures. Compared to EN 14490 the terminology and essential requirements regarding testing are harmonised for all tension elements.

According to the approach used in the design, soil nails should be tested using Investigation, Suitability, Acceptance tests with the minimum number of tests depending on the geotechnical category and type of the test. A per the design method, not all types of tests are obligatory. Values of proof load are also proposed. Acceptance criteria for tests are analogous to the ones for anchors with the addition of the new criteria for test methods with constant displacement rate.

5 ROCK BOLTS AND ROCK SURFACE SUPPORT

5.1 General

Clause 11 describes another new content to Eurocode 7: rock bolts and rock surface support. The text is supplemented with informative annex H providing guidance on verification of interface resistance.

According to the definition, rock bolts are used to stabilise rock mass. They primarily work in tension but also through open discontinuities to prevent shear failure through discontinuities with a dowelling effect. Rock surface support, such as wire mesh or sprayed concrete, "prevents potential rock falls and ravelling of the rock surface ".

At this stage, prEN 1997-3 does not cover rock bolt applications in tunnelling or other underground structures.

Rock bolts and the rock surface support in Clause 11 are considered as individual elements. The design questions for overall supported structures are considered in Clauses 4, 5 or 7.

5.2 Geotechnical analysis

The rock bolts shall be analysed considering the interaction between them and the rock mass, with particular attention on geometrical properties including any discontinuities and weathered zones with the direction of the action imposed on the supported structure.

It should be noted that tension and shear load development is governed by complex interaction between bolt and rock. However, it can be shown in particular geometrical arrangements between rock bolt and discontinuity that the effect of shear stresses on steel material's structural resistance can be ignored.

The geotechnical analysis of rock bolts also determines the interface resistance for two parts of the rock bolt: the anchoring length behind the discontinuity (in the stable zone) and the pick-up length in the zone in front of the discontinuity object of the reinforcement.

5.3 Ultimate limit states

The general limit states of structures supported by rock bolts are to be analysed according to Clauses 4, 5, or 7, respectively. The limit states to consider specifically for rock bolts and rock surface support are, among others:

- Rupture of the rock bolt cross section, the connection to the head plate or the plate itself;
- Failure at the interface between the ground and the rock bolt (for non-grouted bolts) or between the ground and the grout and between the grout and the rock bolt (for grouted bolts);
- Loss of force in the bolt or surface support owing to deformation or loss of ground behind the head plate;
- Rupture of the surface support and between the surface support and its fixing into or onto the rock mass.

Limit states of rock bolts may be verified by: calculations, testing or prescriptive rules, while the design of rock surface support shall be based on prescriptive rules. Regarding the complete supported structure, the observational method is in most cases the preferred approach.

As prescriptive rules are commonly used for rock bolt verification, it should be recalled that they must be used within their known limitations and that they are suitably conservative and justified by comparable experience. Examples of this method are the rules based on rock mass classification system.

For rock bolts it shall be verified that the design value of the effects of actions E_{d} satisfies:

$$E_{\mathrm{d}} \leq \min\{R_{\mathrm{ri,d}}, R_{\mathrm{el,d}}, R_{\mathrm{ro,d}}\} \qquad (2)$$

where $R_{\mathrm{ri,d}}$ and $R_{\mathrm{ro,d}}$ are respectively the design value of a rock bolt interface resistance for the pick-up and anchoring part and $R_{el;d}$ is the structural resistance.

The determination of the interface resistance follows the principles of other tension elements, introducing verification by testing and by calculation based on comparable experience. Specific verification methods are associated with strictly defined sets of safety factors and additional requirements. The summary of the verification methods and safety factors as well as corresponding requirements regarding testing in the given method, is presented in Table 2. It should be noted that while for overall stability verification only MFA is allowed, the rock bolts may be verified using only RFA approach.

Table 2 Summary of design verification methods for rock bolts interface resistance determination

Method	The formula and factoring approach	Factors	Testing
By testing	$\left.\begin{matrix}R_{\mathrm{ri,d}}\\R_{\mathrm{ro,d}}\end{matrix}\right\} = \frac{1}{\gamma_{\mathrm{Rr}}}\min\left\{\frac{R_{\mathrm{r,mean}}}{\xi_{mean}};\frac{R_{\mathrm{r,min}}}{\xi_{min}}\right\}$	$\xi = 1.0 - 1.4$ $\gamma_{\mathrm{Rr}} = 1.25$	In GC3, τ_f (the interface resistance) should be determined from investigation tests or verified by suitability tests. Recommendation for acceptance tests.
By calculation	$\left.\begin{matrix}R_{\mathrm{ri,d}}\\R_{\mathrm{ro,d}}\end{matrix}\right\} = \frac{1}{\gamma_{\mathrm{Rr}} \times \gamma_{\mathrm{Rd}}}\int_0^{L_{\mathrm{po}}} P(x)\cdot\tau_{\mathrm{f}}(x)\cdot dx$	$\gamma_{\mathrm{Rd}} = 1.5$ $\gamma_{\mathrm{Rr}} = 1.25$	In GC1 or GC2 τ_f may be determined from comparable experience, in GC 3 should be based on calculations.
Prescriptive rules	Prescriptive rules according to prEN 1997-1, 4.5;		Control tests shall be performed and inspection plan is required

For structural resistance, design shall comply with prEN 1993-1-1, considering tension and shear stresses and making corrosion allowance.

The details regarding special considerations of design in rock are discussed in (Maca et al., 2023).

5.4 Serviceability limit states

Serviceability limit states specifically for the rock bolt or surface support are, among others, deformation of the rock bolt or surface support that adversely affects the function or appearance of the supported structure or causing damage to existing structures, utilities, or ground in the zone of influence.

5.5 Testing

The approach for testing rock bolts in prEN 1997-3 is analogical to the ones described for soil nails with differences in the number of tests. For rock bolts the load testing according to prEN ISO 22477-6 is not obligatory. However, if design by prescriptive rules is used, the control tests, such as visual inspection grouting process, acoustic or ultrasonic testing or Rock Bolt Tester shall be performed. Control tests for rock bolts and rock surface support can be specified in the National Annex or agreed for a specific project.

6 CONCLUSIONS

The introduction of elements such as rock bolts and soil nailed structures, with the in-depth reorganisation and harmonisation of design rules for different geotechnical structures (including revision of the Anchors Clause) in the second generation of the Eurocode 7 provides a significant improvement. Even if, due to the complex challenge of compromising diverse national practices across the EU, the new content does not solve all the issues, it provides a solid framework for the design. The open character of the requirements enables the national standardisation bodies to decide on the preferred verification methods or calculation models and the designers to use the design tools according to the actual needs, conditions and experience. It also means that commonly used guidelines and manuals can be used after some adaptation with the second generation Eurocode.

ACKNOWLEDGEMENTS

Many people have contributed to developing the second generation of the Eurocodes. I am especially indebted to the members of Task Group CEN TC250/SC7 TG-D3, with whom I was privileged to work together from 2021 to 2023 and who provided a significant contribution to the development of the Clauses 10 and 11 of EN 1997-3.

Failure in cohesive soil due to hydraulically induced fractures

Rupture d'un sol cohésif due à des fractures d'origine hydraulique

H. Machacek*, B. Odenwald
Federal Waterways Engineering and Research Institute, Karlsruhe, Germany

K.J. Witt
Bauhaus University Weimar, Weimar, Germany

**helen.machacek@baw.de*

ABSTRACT: According to Eurocode 7 the verification against hydraulic heave on the downstream side of a sheet pile wall must be fulfilled independent from the ground properties. The mechanism of hydraulic heave is based on the soil behaviour of non-cohesive soil, in which the upward directed seepage forces on the downstream side can cause liquefaction if the effective stress is reduced to zero. However, other failure mechanisms are expected in cohesive soil due to additional binding forces. Laboratory experiments have shown, that the alternative failure mechanism in cohesive soil is triggered by the formation of fractures at the foot of the sheet pile where high hydraulic gradients occur. To further investigate the mechanisms of these hydraulically induced fractures in cohesive soils, a new triaxial test has been developed, in which the pore water pressure in the centre of the specimen is increased until failure by fracturing occurs. The pore water pressure at fracture initiation, the fracturing pressure, is a measure for the soil resistance against hydraulic induced fractures. In an extensive laboratory study the influencing factors on the fracturing pressure have been determined by variation of the sampling material, the rate of the pore water pressure increase, the stress and drainage conditions. Further insight into the stress state at fracture initiation could be gained by numerical calculations. It could be concluded, that the failure by fracture differs significantly from the failure mechanisms in cohesionless soil. Therefore new concepts are required to ensure the safety against hydraulic failure.

RÉSUMÉ: Selon l'Eurocode 7, la vérification contre le soulèvement hydraulique du côté aval d'un mur de palplanches doit être réalisée indépendamment des propriétés du sol. Le mécanisme de soulèvement hydraulique est basé sur le comportement du sol non cohésif, dans lequel les forces d'infiltration dirigées vers le haut sur le côté aval peuvent provoquer une liquéfaction si la contrainte effective est réduite à zéro. Cependant, d'autres mécanismes de rupture sont attendus dans les sols cohésifs en raison de forces de liaison supplémentaires. Des expériences en laboratoire ont montré que l'autre mécanisme de rupture dans un sol cohésif est déclenché par la formation de fractures au pied de la palplanche, là où les gradients hydrauliques sont élevés. Pour étudier plus avant les mécanismes de ces fractures d'origine hydraulique dans les sols cohésifs, un nouvel essai triaxial a été mis au point, dans lequel la pression de l'eau interstitielle au centre de l'échantillon est augmentée jusqu'à ce qu'une rupture par fracturation se produise. La pression de l'eau interstitielle à l'initiation de la fracture, la pression d'initiation, est une mesure de la résistance du sol aux fractures induites par l'hydraulique. Dans le cadre d'une étude approfondie en laboratoire, les facteurs influençant la pression d'amorçage ont été déterminés par la variation du matériau d'échantillonnage, le taux d'augmentation de la pression de l'eau interstitielle, la contrainte et les conditions de drainage. Des calculs numériques permettraient de mieux comprendre l'état de contrainte au moment de l'initiation de la fracture. On peut conclure que la rupture par fracture diffère considérablement des mécanismes de rupture dans un sol sans cohésion. Par conséquent, de nouveaux concepts sont nécessaires pour garantir la sécurité contre les ruptures hydrauliques.

Keywords: Hydraulic failure; fractures; cohesive soil; laboratory study.

1 INTRODUCTION

When dimensioning sheet piles for excavations in groundwater or along canals, the verifications against hydraulic failure mechanisms are often decisive for the required embedment depth. The current standardisation according to EC7 requires among other the verification against hydraulic heave, which is to be carried out on the basis of a force equilibrium from the soil's deadweight under buoyancy and the upward flow force, almost independent from the existing ground. However, this verification concept is based on the hydraulic failure mechanism in non-cohesive soils, where the flow force can cause soil liquefaction in the downstream area. Only in highly cohesive soils is it common practice to dispense with

the verification against hydraulic heave and instead to perform the verification against uplift. The actual hydraulic failure mechanisms in fine-grained soils have been little studied, which is why both verifications are not very accurate.

Laboratory tests by (Wudtke, 2014) on a wall in silt and clay conducted by undercurrent have shown that the hydraulic failure mechanism in fine-grained soils is triggered by hydraulically induced fractures at the base of the wall. Since the subsequent sequence of failure ending in the loss of the earth abutment can proceed quickly and unnoticed, the hydraulically induced fracture initiation is decisive for the design.

But currently there is neither practical experience nor sufficient theoretical basis to determine the resistance to hydraulic fracture failure in fine-grained soils. Although various fields of geotechnics and geomechanics have been dealing with the formation and propagation of hydraulically induced fractures in rock or sand for decades, no study has yet comprehensively considered a greater number of potentially relevant influencing factors on fracture formation in fine-grained subsoil (Günther, 2019). In order to formulate a design concept against hydraulically induced fractures in fine-grained soils, it is essential to investigate the main factors influencing fracture resistance of these soils experimentally.

2 EXPERIMENTAL STUDY

To fill this knowledge gap, a laboratory study was carried out in a new type of triaxial test. In this test, the failure of the cylindrical sample (height= diameter=100mm) is not caused by shearing, but by an excess pore water pressure applied in its centre. For this purpose, a cannula with a filter tip was attached to the top plate of the triaxial device, where the pore water pressure is increased until fracture occurs. As fractures initiate at flaws in the material (Jaworski et al., 1981), the samples must be as homogeneous as possible to ensure reproducible test results.

The test setup, test procedure and sample preparation are described in detail in (Günther, 2019), (Machacek, 2024) and (Machacek and Odenwald, 2023). The resistance of a sample to hydraulically induced fractures is determined by the pore water pressure at the filter tip required for the first fracture to form. This pressure is referred to as the fracturing pressure $p_{w,fr}$. At the moment of fracture initiation there is a significant pressure drop at the controller of the pore pressure at the filter tip and at simultaneously a sharp increase in the volumes flowing in and out of the sample at the top and bottom plate (in case of drained boundary conditions). This is exemplified in Figure 1 with diagrams of the pressure curves over the time for the filter tip and the end plates (left) and the corresponding volume curves over the pressure at the filter tip (right) during the hydraulic loading.

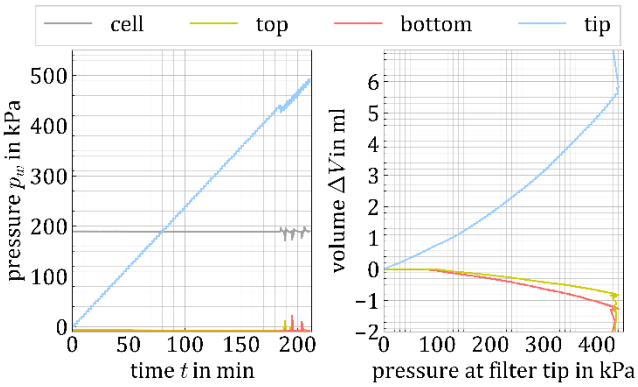

Figure 1. Typical results of the triaxial test with hydraulic loading. Left: pressure vs time for a pressure controlled loading phase with open drainage at the end plates, the pressure drop at the filter tip indicates the fracturing pressure. Right: volume change vs the pressure at the filter tip. The in- and outflowing volumes increase suddenly as the fracturing pressure is reached.

2.1 Variations

In order to investigate the soil-mechanical parameters influencing the resistance to hydraulic fractures and the fracturing pressure numerous variations with different initial and boundary conditions were carried out as part of the laboratory study.

To analyse the influence of the soil type and structure, test samples made of silt, kaolin or bentonite were loaded until fracture failure. These were either consolidated as described in (Günther, 2019) or produced by static compaction, whereby the compaction, in contrast to the consolidation, produces a soil structure with clear aggregate formation.

To vary the initial stress state, the samples were consolidated to different initial mean effective stresses p at isotropic ($\sigma_h = \sigma_v$) or anisotropic stress ratios ($K = \sigma_h/\sigma_v \neq 1$) prior to hydraulic loading. The effect of preloading by a consolidation pressure p_c was investigated by different overconsolidation ratios $OCR = p_c/p$. With regard to the hydraulic loading, variations were made between pressure and volume controlled loading with different pressure rates or volume flows. This rate of hydraulic loading must always be related to the hydraulic permeability of the sample material, so that the ratio between the flow velocity v and the permeability coefficient k is decisive.

Furthermore, tests were carried out with and without drainage at the end plates during the loading phase and the backpressure was varied during the

loading phase, which influences the speed of pore water pressure propagation.

To ensure the reproducibility of the tests with hydraulic loading each variation was repeated at least two to four times under identical conditions.

2.2 Results

The fracturing pressure $p_{w,fr}$ is reproducible. Depending on the test variant, the coefficient of variation is a maximum of 17.2% and, with a mean value of 5.7%, is below the coefficient obtained in undrained triaxial shear tests carried out on the same samples.

The fracture pattern and the expansion of the fracture surfaces can be visualised by injecting potassium permanganate into the cannula after removing the sample from the triaxial cell. However, no regularity with regard to the fracture formation can be determined. Yet Figure 2 shows some fractured samples to give a better idea of the failure patterns. Fracture propagation is very complex an depends on numerous factors, which is why the following investigation focusses exclusively on factors influencing the fracturing pressure $p_{w,fr}$.

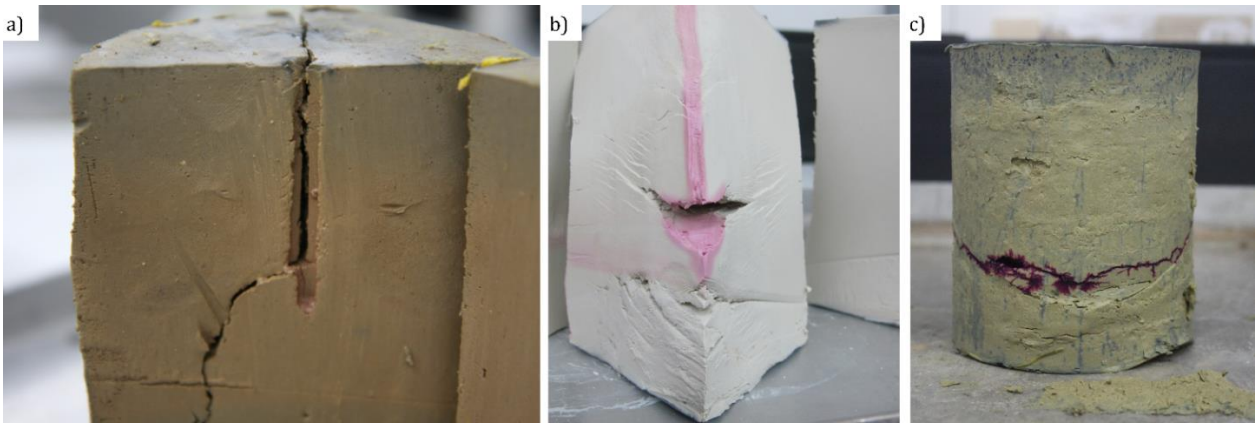

Figure 2. Examples of the fracture patterns observed by injecting potassium permanganate (purple) after removing the sample from the cell. a) A vertical fracture in a silt sample. b) Slightly horizontal fractured kaolin sample. c) A diagonal fracture through a bentonite sample.

The variations in the laboratory study showed that the magnitude of $p_{w,fr}$ was mainly influenced by the material, the initial stress state, the overconsolidation ratio OCR and the rate of the loading pore pressure (or the v/k-ratio). The other variations had minor influence on $p_{w,fr}$.

Regarding the sample material $p_{w,fr}$ increased with the amount of fines in the material. Hence the lowest fracturing pressures were observed in the silt samples and the highest in the bentonite samples. Only consolidated samples show reproducible results, in compacted samples the range of the fracturing pressures was comparatively large due to the larger aggregates and variation in pore size. Though under the same testing conditions the consolidated samples clearly show higher fracturing pressures than the compacted samples.

Further the fracturing pressure increases with the initial effective mean stress p and the overconsolidation ratio OCR. For the isotropic stress state there is an almost linear relationship between p and the fracturing pressure. The variation of the initial stress ratio K for normally consolidated samples ($OCR = 1$) shows that the fracturing pressure does not depend solely on the smaller principal stress σ_h, but on the stress state.

To compare the fracturing pressures resulting from tests with different OCR, $p_{w,fr}$ is normalised by p. The normalised fracturing pressure increases asymptotically and reaches a maximum value of $p_{w,fr}/p \sim 4$ at $OCR \sim 8$.

One of the most important influence factors is the pressure rate or the v/k -ratio. The higher the v/k -ratio, the higher the fracturing pressure. From the test results it can be assumed that the injected water does not infiltrate into the pores of the sample if the v/k -ratio is very high. Instead the soil around the filter tip is displaced and the expanding cavity is filled with the injected water.

A more detailed description of the quantitative results of the study would go beyond the scope of this article and therefore reference is made here to (Machacek, 2024).

3 NUMERICAL ANALYSIS

For the fracture failure by hydraulic loading from the centre of the sample, only the local stress state around

the filter tip where the fracture first occurs is of interest. So far no analytical can describe the stress changes around the filter tip due to the pore pressure increase regarding all the influence factors observed in the laboratory study. Hence, to analyse the stress state which leads to the fracture failure a numerical analysis is required which considers the transient coupling between soil as a continuum and pore water.

3.1 Numerical model

An axisymmetric FE-model of the sample was created to simulate the tests in the laboratory study. Thereby only the stress state in the soil as a continuum until the first fracture occurs was regarded. It is not the intention to model the fracture initiation or propagation. For the material behaviour the Modified Camclay-Model (MCC) was chosen and the material parameters were calibrated from standard compression and triaxal tests. The dimensions, the (loading) boundary conditions and the mesh are shown Figure 3. To start from realistic stress states, not only the hydraulic loading but also the consolidation phases were simulated.

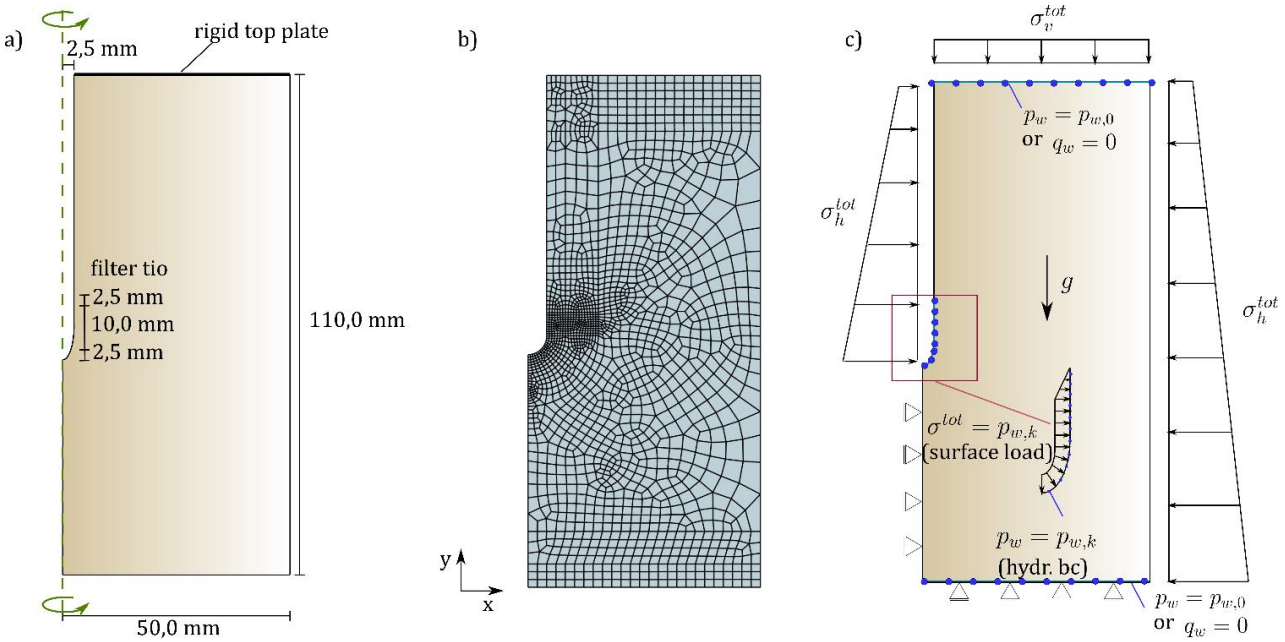

Figure 3. Axisymmetric FE-model of the triaxial test with hydraulic loading. a) Dimensions of the modelled sample. b) Mesh of the model. c) Boundary conditions (bc) and loading of the sample to model all phases of the triaxial test in different variations, e.g. pressure or volume controlled loading and drained or undrained conditions at the end plates.

To analyse the stress state around the filter tip at the moment the fracture occurs, the simulations were evaluated at the corresponding point of time t_{fr} at which the fracturing pressure was reached in the laboratory test variation.

3.2 Critical stress states

In the numerical calculations no failure criteria were given as the fracture criteria for fine-grained soil is unknown. But by using the MCC model the critical state line (CSL) is included. Fractures can be triggered by tensile and or shear stresses, hence in the postprocessing both were analysed at the moment of fracture initiation t_{fr}. The numerical analysis of the tests on consolidated samples show, that at $t = t_{fr}$ an area around the filter tip exists in which the minor principal stress σ_{min} becomes tensile stress or in which the shear stress ratio $\eta = q/p$ with the deviator stress q reaches the CSL. In the following these areas are called critical stress zones. The size of these zones as well as the maximum tensile or shear stress intensity within the zone correlate primarily with the sample's material and the overconsolidation ratio. In other words, the stress analysis of test variations with the same material and OCR show almost identical critical stress zones independent from the drainage condition, the backpressure and the v/k -ratio. Even the initial stress state has in fact little influence on these critical areas. This is demonstrated in Figure 4 by field plots of the stress ratio η at $t = t_{fr}$ for the test series on silt with different initial mean stresses of $p = 100$ kPa, 200 kPa and 300 kPa. The critical zones in which the stress ratio reaches the CSL of silt with $\eta \geq M_c = 1{,}4$ is displayed in grey. The size of the grey zone grows only slightly with p. In contrast Figure 5 shows the field plots of the test series on silt with $OCR = 1, 2$ and 4.

The grey zones of the c critical shear stress with $\eta \geq 1{,}4$ and of tensile stress $\sigma_{min} \leq 0$ kPa grow with the increase of OCR.

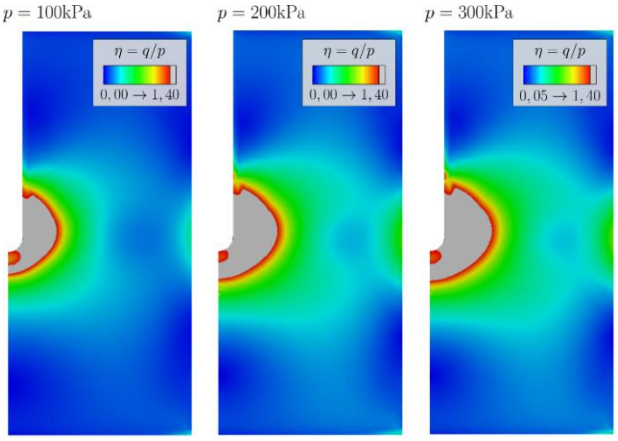

Figure 4. Stress ratio η at the moment of fracturing for test variations with different initial mean stresses p. The grey zone where the maximum stress ratio of $M_c = 1{,}4$ is reached increases only slightly with p.

The conclusion from this numerical analysis was drawn with a view on the basics of fracture mechanics.

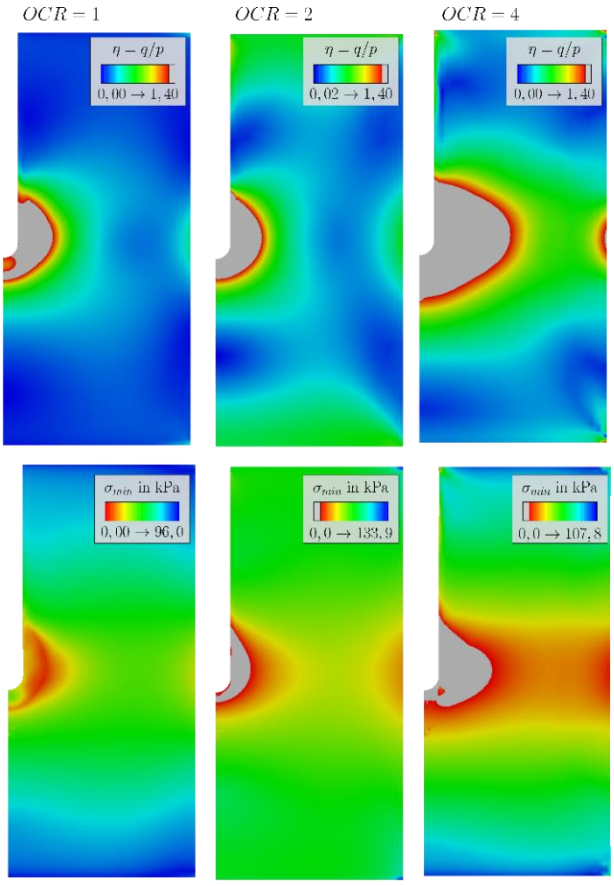

Figure 5. Stress ratio η (upper row) and minimum principal stress σ_{min} (lower row) at the moment of fracturing for test variations with different overconsolidation ratios OCR. The grey zone where the maximum stress ratio of $M_c = 1{,}4$ is reached or the σ_{min} is tensile increases with OCR.

According to these fractures initiate at an imperfection in the material, where high tensile or shear stress loads occur. If these stress intensities at an imperfection reach the materials specific critical value, the fracture extends from the imperfection. If the pore structure of a homogenous material in which larger pores, extraneous inclusions or little fissures represent imperfections, then the fracture initiates if in the critical stress zone around the filter tip the material strength is reached at one of these imperfections.

This results in a probabilistic issue: as the pore water pressure at the filter tip increases, the critical stress zone grows and with it the probability that there is an imperfection in this area where the material strength is exceeded. If this zone varies in its size when fracture occur, the material will either differ in strength or in the amount and size of imperfections.

4 CONCLUSIONS

With the newly developed triaxial test for hydraulic induced fractures in soil reproducible results regarding the fracturing pressure in consolidated fine-grained samples can be obtained. In an extensive laboratory study the material of the samples, the initial stress state, the overconsolidation ratio and the rate of the hydraulic loading were identified as the decisive factors influencing the fracturing pressure. A numerical analysis of the stress state at the time of fracture initiation in the test variations of the study show that there are similar zones of high tensile or shear stress around the filter tip. The size of this zone and the level of tension or shear depends only on the material, the overconsolidation ratio and slightly on the initial stress state.

Based on this numerical analysis and the fundamentals of fracture mechanics, it can be hypothesised that the hydraulically induced fractures in the samples are only influenced by three factors: the material resistance, the effective stress state and the defects in the material.

ABSTRACT: Copper mine tailings (CMT) are the waste material that remains after the economic fraction is extracted from the mineral ore and consist of a slurry of ground rock, water, and chemical reagents that remain after metallurgical processing. These tailings are considered toxic to the environment, so controlling their environmental toxicity and improving their mechanical properties are crucial. However, only a few studies have focused on assessing such performance by establishing the constitutive behaviour of the CMT. In this paper, we describe mine tailings properties and perform laboratory tests to calibrate clay hypoplasticity. Hypoplasticity is a constitutive model that includes concepts from Critical State Soil Mechanics, as a stress-dependent critical void ratio and a critical stress cone, according to Matsuoka-Nakai. The results show that hypoplasticity can well predict the mine tailings triaxial test behaviour.

RÉSUMÉ: Les résidus miniers de cuivre (CMT) sont les déchets qui restent après l'extraction de la fraction économique du minerai minéral et consistent en une boue de roche broyée, d'eau et de réactifs chimiques qui restent après le traitement métallurgique. Ces résidus sont considérés comme toxiques pour l'environnement, il est donc crucial de contrôler leur toxicité environnementale et d'améliorer leurs propriétés mécaniques. Cependant, seules quelques études se sont concentrées sur l'évaluation de ces performances en établissant le comportement constitutif du CMT. Dans cet article, nous décrivons les propriétés des résidus miniers et effectuons des tests en laboratoire pour calibrer l'hypoplasticité de l'argile. L'hypoplasticité est un modèle constitutif qui inclut des concepts de la mécanique des sols à l'état critique, comme un indice de vide critique dépendant de la contrainte et un cône de contrainte critique, selon Matsuoka-Nakai. Les résultats montrent que l'hypoplasticité peut bien prédire le comportement des essais triaxiaux des résidus miniers.

Keywords: Mine tailings; waste material; constitutive model; hypoplasticity.

1 INTRODUCTION

Mine tailings are the materials left over after the process of separating the valuable fraction of mined ores from the uneconomic fraction of the ore. Tailings can contain a variety of materials depending on the ore being mined. They often include finely ground rock particles, chemicals used in the extraction process, and water (Sarker et al., 2022).

Mine tailings pose significant environmental concerns. Proper storage in dams is crucial to mitigate their impact on surrounding ecosystems and water sources. The necessity of determining the behaviour of mine tailings is essential to design how it is deposited, which will influence their potential environmental impact and their management strategy (Cacciuttolo and Atencio, 2023). This assessment helps safeguard ecosystems, water sources, and communities from potential hazards such as acid mine drainage and other health risks, not to mention their mechanical stability (Rezaie and Anderson, 2020).

Constitutive models are indispensable for understanding and predicting the mechanical behavior of materials. Their importance extends beyond academic study to practical engineering solutions that drive innovation. Determining the behavior of mine tailings with constitutive models involves using mathematical representations to describe how these materials respond to various mechanical conditions (Qiu et al., 2018). These models are based on fundamental principles of material behavior, which are also determined through triaxial tests and can help predict stress-strain relationships, peak and critical shear strength, among other important aspects that control the overall response of tailing deposits. By applying constitutive models, users can simulate and

analyse the performance of mine tailings in different scenarios, aiding in the design of safe storage and containment systems (Bursa et al., 2023).

2 EXPERIMENTAL WORK

To assess the behaviour of copper tailings from the Neves Corvo mine located in Portugal, triaxial compression undrained tests (CU) were conducted to determine the shear strength characteristics of mine tailings. According to the ASTM unified classification (2006), the copper mine tailing was designated as CL—lean clay with liquid and plastic limits of 23% and 11%, respectively (Manaviparast et al., 2022).

For the purpose of simulating the deposition of mining waste in landfills and simulating deposition in layers, each test sample was molded in 6 layers, with a pre-established amount of mixture introduced into each layer and compacted. The compaction process of each layer was important since each layer was compacted with a different degree of compaction; as the layers progressed, the greater degree of compaction applied. However, in theoretical terms, all layers will have the same density due to the adjustments that the material makes with the different degrees of compaction applied to each of the layers.

According to the BS 1377-7 (1990) standard, tests were performed through three distinct phases of saturation, consolidation, and shear under confining stresses of 97 kPa, 188 kPa, and 277 kPa in normally to slightly overconsolidated conditions to be utilized as a pivotal foundation for the calibration of model parameters. The experimental results, including the trajectory of stress paths, deformation characteristics, the stress-strain relationship, and the evolution of pore pressure with axial strain, are shown in Figures 1 to 4, respectively.

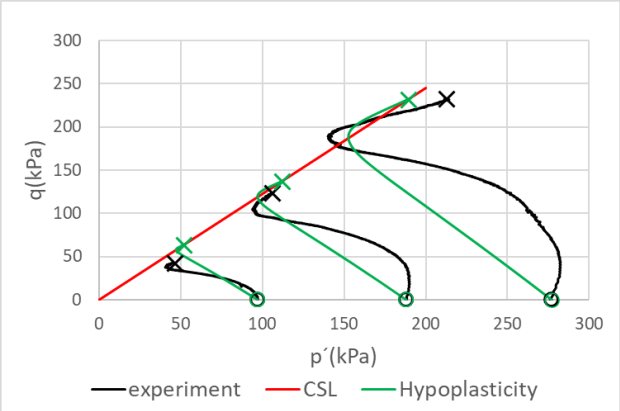

Figure 1. Experimental and hypoplastic stress paths observed in the q-p' plane for triaxial tests (CU) on mine tailing samples under slightly overconsolidated conditions.

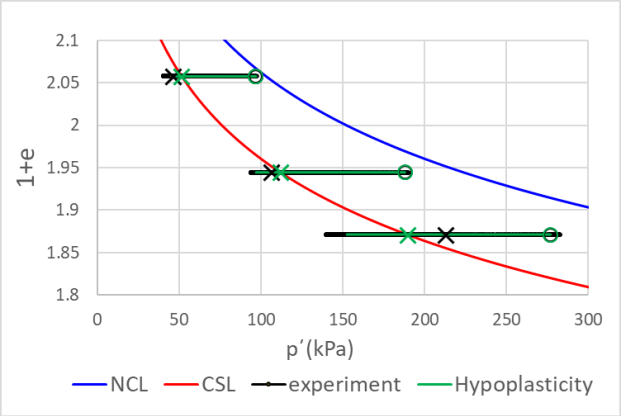

Figure 2. Experimental and predicted hypoplastic paths observed in the (1+e)-p' plane for triaxial tests (CU) on mine tailing samples under slightly overconsolidated conditions.

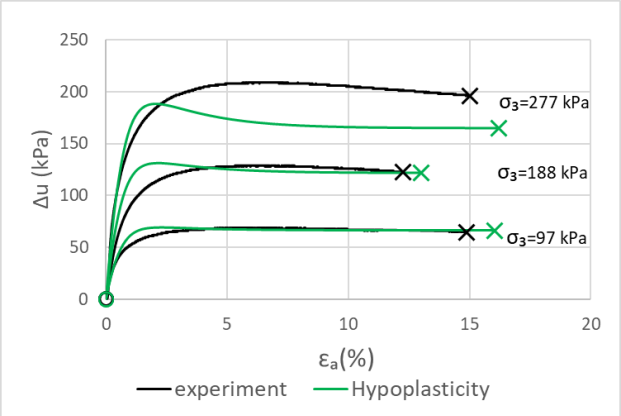

Figure 4. Evolution of pore pressure with axial strain in the experiments and the hypoplastic predictions.

3 PREDICTIONS WITH CLAY HYPOPLASTICITY

Clay hypoplasticity (Mašín, 2013) is a constitutive model in which the stress rate is formulated as a tensorial function of the current stress **σ**, void ratio *e*, and strain rate.

Hypoplasticity incorporates concepts from critical state soil mechanics, such as the critical stress cone, according to Matsuoka-Nakai, and a stress-dependent critical void ratio e_c, i.e., the critical state line (CSL) in the void ratio vs the mean effective stress plane. The strength and stiffness response is, therefore, dependent on the stress level and the overconsolidation ratio. Figure 5 shows the so-called asymptotic state boundary surface (ASBS) of clay hypoplasticity in the *p'-q-e* space (left) and in the *p'-q* and *e-p'* projections. All feasible states lie within the ASBS. In the *(1+e)-p'* projection, the Normal Compression Line (NCL), as well as the CSL are defined as follows:

$$\text{NCL: } ln(1+e) = N - \lambda^* ln\, p' \qquad (1)$$

$$\text{CSL: } ln(1+e) = N - \lambda^* ln(2p') \qquad (2)$$

The slope of the CSL in the *p'-q* projection is

$$M = \frac{6sin\,\varphi_c}{3-sin\,\varphi_c} \qquad (3)$$

for axisymmetric triaxial compression.

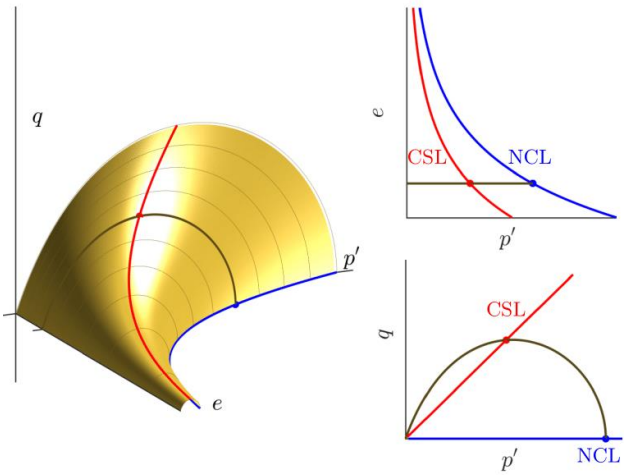

Figure 5. Clay hypoplasticity: Concepts from Critical State Soil Mechanics are included in the model. Left: Asymptotic state boundary surface (ASBS) of clay hypoplasticity in p'-q-e space, above right: e-p' projection, below right: p'-q projection [Link].

3.1 Calibration

For the calibration of some of the model's parameters, the automatic calibration software Excalibre, soilmodels.com/excalibre-en, developed by Kadlíček et al. (2022a, 2022b), available on the platform SoilModels (Gudehus et al., 2008) was used.

Due to the lack of compression data, the parameters to define the NCL have been estimated based on the initial states of the normally to slightly overconsolidated initial states of the CU tests, see Figures 1 and 2. The slope of the CSL in the *p'-q* plane is governed by the critical friction angle φ_c according to equation (3). The parameter ν was calibrated by parametric study to capture the shape of the undrained stress paths, see Figure 1. In the absence of isotropic unloading data, κ^* was set to the typical value of 0.1 (Mašín, 2013). All parameters of clay hypoplasticity are provided in Table 1.

Table 1. Calibrated model parameters.

Parameters	Value
Ordinate intercept of the NCL (N)	1.06
Slope of the NCL (λ^*)	0.073
Slope of unloading line under isotropic compression (κ^*)	0.01
Critical friction angle (φ_c)	30.6°
Poisson's ratio (ν): controls the shear modulus and affects the shape of undrained stress paths	0.25

3.2 Predictions with hypoplasticity

The samples are initially normally to slightly overconsolidated, with the initial states marked with o in Figures 1-4.

The critical strength q_c equals $M \cdot p'_c$, where p'_c follows from the location of the CSL in *(1+e) - p'* plane, see Figure 2. In hypoplasticity the position of the CSL in relation to the NCL is fixed by $p'_e/p'_c=2$, where p'_e is the so-called Hvorslev's equivalent pressure on the NCL and p'_c is the mean effective stress at critical state on the CSL. The final states of the simulations, as well as the experiments, are marked with x. The pore water pressure and the deviatoric stress of the experiments are not yet constant. This means that the samples are still approaching the critical state and have not yet reached it. The final points of the simulations already lie on the CSLs in Figures 1 and 2. Deviatoric stress *q* as well as the pore pressure at a given axial strain are well predicted by the model, see Figures 3 and 4. In order to predict the undrained strength of samples with different initial densities, it is necessary to use a constitutive model that incorporates the framework of critical state soil mechanics.

4 CONCLUSION

Understanding the behavior of mine tailings is of paramount importance for the safe and responsible management of these waste materials. Triaxial tests provide invaluable insights into the mechanical properties and stability of mine tailings under varying

stress conditions, offering essential data for the design of secure containment systems. Furthermore, employing constitutive models enhances our ability to predict and analyse the response of mine tailings, enabling informed decision-making in engineering practices. By leveraging both experimental testing and mathematical representations, we can effectively address environmental concerns and minimize potential risks associated with the disposal of mine tailings. This comprehensive approach underscores the significance of adopting responsible mining practices that prioritise the protection of ecosystems, water sources, and surrounding communities.

ABSTRACT: The application of physically based methods to areas affected by landslides requires the knowledge of geometric, geotechnical and rainfall input data. Once the geometric and rainfall data have been acquired, the geotechnical data are of relevant importance for the results obtained by method implementation. Indeed, if significant geotechnical properties on the soil involved by landslides are not available, any methodological application is a simplistic exercise. To overcome this issue, in the preliminary stage, data from the literature – for soils similar to those involved in the landslides – can be used in order to localize the in-site investigations in areas potentially affected by landslides. The paper shows an application of the physically based method TRIGRS to an area affected by rapid debris flows for the susceptibility assessment. Firstly, TRIGRS has been applied using as input geotechnical parameters those available in literature and the zones potentially affected by similar landslides have been identified. Detailed in-site investigations have been located and carried out in the so identified zones. By means of the results of in-site surveys and laboratory tests a reliable geotechnical slope model for the area has been created. Therefore, TRIGRS has been applied again to the study area using as input geotechnical parameters those obtained from the survey. The last application of the method provided the susceptibility zoning map of the area. The achievement of these results has been favored by the limited extension of the area and by availability of literature data for the involved soils.

RÉSUMÉ: L'application de méthodes physiques aux zones touchées par les glissements de terrain nécessite la connaissance des données géométriques, géotechniques et pluviométriques. Une fois les données géométriques et pluviométriques acquises, ces données géotechniques sont d'une importance pertinente pour les résultats obtenus par la mise en œuvre de la méthode. En effet, si des données géotechniques significatives sur les sols impliqués par les glissements de terrain ne sont pas disponibles, toute application méthodologique est un exercice simpliste. Pour surmonter ce problème, au stade préliminaire, les données de la littérature sur les sols - similaires à celles impliquées dans les glissements de terrain - peuvent être utilisées afin de localiser les enquêtes sur place dans les zones potentiellement touchées par les glissements de terrain. L'article montre une application de la méthode physique TRIGRS à une zone affectée par des écoulements rapides pour l'évaluation de la susceptibilité. Tout d'abord, TRIGRS a été appliqué en utilisant comme paramètres géotechniques d'entrée ceux disponibles dans la littérature et les zones potentiellement affectées par des glissements de terrain similaires ont été identifiées. Des enquêtes détaillées sur place ont été localisées et effectuées dans les zones ainsi identifiées. Grâce aux résultats des études sur site et des essais en laboratoire, un modèle géotechnique fiable de pente a été créé pour la région. Par conséquent, TRIGRS a été appliqué à nouveau à la zone d'étude en utilisant comme paramètres géotechniques d'entrée ceux obtenus à partir du levé. La dernière application de la méthode a fourni le tableau de zonage de sensibilité de la région. L'obtention de ces résultats a été favorisée par l'extension limitée de la zone et par la disponibilité de données documentaires pour les sols concernés.

Keywords: Shallow landslides; TRIGRS; in situ investigations; laboratory tests.

1 INTRODUCTION

In the wider frame of shallow landslide risk assessment, this paper is aimed to show the ability of a physically based model both to locate in a coherent scientifically based manner the in-situ investigations and to assess the susceptibility to shallow landslides in an area.

For this purpose, the "Transient Rainfall Infiltration and Grid-based Slope-Stability" (TRIGRS) deterministic model is applied to a study area periodically affected by rainfall-induced shallow landslides, located in Calabria (Southern Italy).

The implementation of TRIGRS needs of several data including rainfall, topographical and geomorphological data, mechanical and hydraulic properties of soils, pore water pressure regime. The database can be created starting from the data available from scientific literature on soils similar, for genesis and stress history, to those of the studied area (literature data) and it can be upgraded every time that a new data is available.

TRIGRS is applied twice, firstly using literature geotechnical data and secondly using in-site survey and laboratory test results. Particularly, literature data have been initially used to implement TRIGRS in order to individuate slopes potentially affected by shallow landslides. In these slopes in situ investigations, that included sampling and subsequent geotechnical laboratory tests, have been located on.

Once geotechnical data have been gathered, a reliable geotechnical slope model has been obtained and TRIGRS has been applied again to assess shallow landslide susceptibility of the area.

2 MATERIALS AND METHOD

2.1 Study area and landslide inventory

The study area, approximately 1 km^2, is located within the Costa Viola zone between Scilla and Bagnara Calabra (Reggio Calabria, Southern Italy).

From a geological point of view, the paleozoic basement of the area is manly made up of para- and ortho-gneiss, strongly tectonised and intensely weathered. Consequently, residual, colluvial and detrital soils (gneiss of Class VI according to Gioffrè et al., 2016) cover about 60% of the study area.

In the study area, several types of landslides periodically occur. The paper focuses on shallow landslides, involving class VI soils, that frequently propagated as debris flows affecting the urbanized area and transportation infrastructures. Two typical examples are debris flows occurred on 12 May 2001 and on 31 March 2005 (Figure 1).

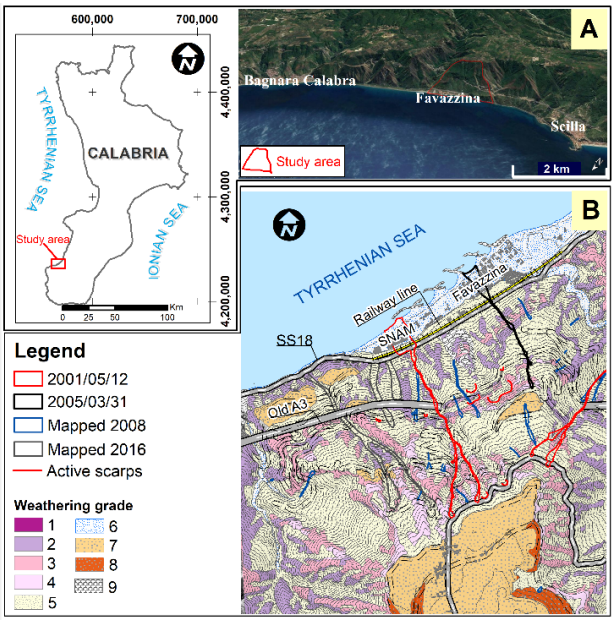

Figure 1. View of study area with debris flow location and weathering grade map (modified from Gioffrè et al., 2016). Legend of weathering grade: 1, gneiss of class II; 2, gneiss of class III; 3, gneiss of class IV; 4, gneiss of class V; 5, gneiss of class VI (colluvial and detrital soils); 6, coastal and alluvial deposits; 7, terraced marine deposits; 8, marine coarse sandstone deposits; 9, landslide debris.

The soil volumes triggered in source areas with sliding surfaces not exceeding 2 meters in depth rapidly moved along steep channels with strong entrainment of material and water; the deposition occurred on debris fans and the mass partially reached and deposited in the sea (Ciurleo et al., 2019a, 2019b).

The landslide inventory (Figure 1) has been made by combining these debris flows, the landslides mapped in 2008, the landslide inventory provided by the Calabria Region (dated 2016) and the landslide scarps identified by Moraci et al. (2017).

From a hydrological point of view, the Scilla rain gauge recorded rainfall of 20 mm over two consecutive days (on 12 May 2001) and 13.6 mm over two consecutive days (on 31 March 2005).

2.2 The methodology

The methodology consisted of two stages (I and II), in both stages, the method used to simulate shallow landslide triggering has been TRIGRS. It is a spatially distributed slope stability model coupled with a one-dimensional rainfall infiltration model. The input data of TRIGRS are: rainfall, topographical data, soil thickness, initial ground water table depth and mechanical and hydraulic properties of soils.

Referring to rainfall intensity, a rainfall of 20 mm over two consecutive days was considered because of it is the highest known value.

Referring to topographical data, a digital elevation model (DEM) of the study area with 5 m cell resolution has been used.

TRIGRS analysis is sensitive to initial steady state groundwater conditions, soil depths and geotechnical properties of soils (Godt et al., 2008; Salciarini et al., 2006; Sorbino et al., 2007, 2010).

To this regard, in stage I, TRIGRS was implemented using as input geotechnical parameters those available in literature. The aim of this stage has been the location of in-site investigations, included sampling, in slopes recognised as the most susceptible to the occurrence of shallow landslides (Ciurleo et al., 2019b, 2022).

By means of the results of in situ investigations and laboratory tests, a reliable geotechnical slope model of the study area has been obtained and used in the stage II.

In stage II, TRIGRS has been implemented again to assess shallow landslide susceptibility of the study area.

In this stage, owing to the lack of data on the initial steady state ground water position, several parametric analyses were performed in order to quantify the role of partially saturated conditions on the slope stability.

The performance of the model has been assessed by the true positive rate (TPR), also called sensitivity, and by the area under the receiver operating characteristic (ROC) curve (Swets, 1988).

3 RESULTS

3.1 Stage I

The input data used by TRIGRS in stage I are slope gradient and flow direction maps, derived by DEM, reported in Figure 2A and 2B. Referring to weathering grade map, gneiss of class VI (SOIL 1) and gneiss not involved by shallow landslides of slide type (SOIL 2) were identified (Figure 2C). Referring to ground water table location, according to Ciurleo et al. (2018), two different zones (Zone “A” and Zone “B”) with two different depths of ground water table were considered in the study area. Particularly, in Zone “A” (near the landslide source area) the water table was located at the ground surface, in the remain part of the study area (Zone “B”), it was considered at 1.5 m of depth from the ground surface (Figure 2D).

From a geotechnical point of view, in stage I, literature data have been used to carry out several parametric analyses in the Favazzina hamlet (Figure 2) with the aim to identify the combination of geotechnical parameters that best fit the available multi-temporal shallow landslide inventory.

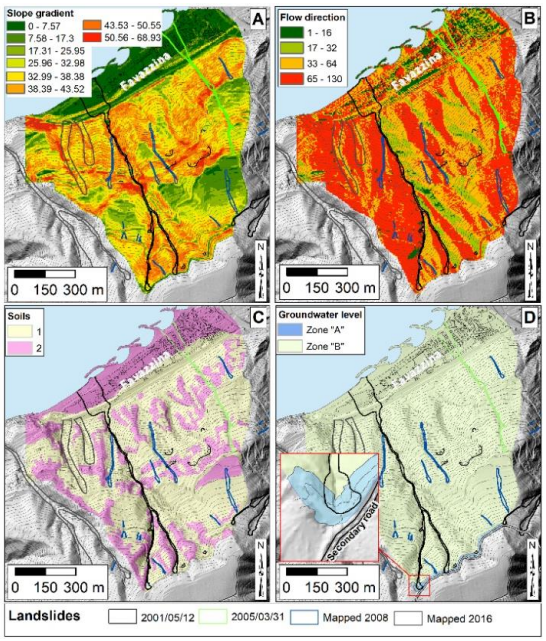

Figure 2. TRIGRS input data maps: (A) slope gradient; (B) flow direction; (C) weathered gneiss; (D) initial groundwater table depth (modified from Ciurleo et al., 2022).

The best obtained map in terms of sensitivity (TPR) is shown in Figure 3. It has been obtained using the literature mean values of hydraulic parameters (i.e., the saturated conductivity K_{sat} equal to 1.79E−05 m/s, the soil diffusivity D_0 equal to 7.92E−05 m^2/s, and the saturated water content θ_{sat} equal to 0.4); a constant value of soil cover thickness equal to 1.5 m; a value of cohesion (c') equal to 2.5 kPa and a value of shear strength angle (φ') equal to 30°. Several maps have been obtained changing the above mentioned geotechnical parameters but these maps did not fit the triggering areas mapped in landslide inventories.

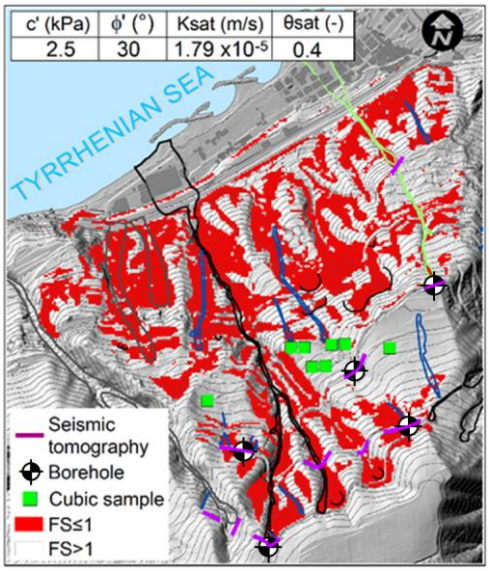

Figure 3. Map used to locate in situ investigations (modified from Ciurleo et al., 2022).

Starting from this map, in the slopes most susceptible to landslides, 10 seismic refraction tomographies, 5 boreholes with undisturbed samples have been located and performed (Figure 3). Cubic samples, due to the procedures of sampling, have been located in areas simply reachable by men and equipment (Figure 3). Tomographies and boreholes allowed us to identify the main soil cover thickness (gneiss of class VI) and confirmed that, in shallow landslide source areas, it is less than 2.0 m (about 1.5 m in most cases).

In order to develop a more detailed analysis, the results obtained by geotechnical laboratory tests performed on undisturbed specimens retrieved from the boreholes and the cubic samples have been considered in the following analyses.

The class VI gneiss involved in the shallow landslides have been classified, according to the Unified Soil Classification System (USCS), as silty sand (SM) and clayey sand (SC) with uniformity coefficient U = 76.05, 76.83, 113.51 and inorganic fine fraction of medium compressibility and not active. The value of LL ranged from 30.23 to 33.36% and PI from 3.25% to 11.36%. These soils have a solid unit weight (γ_s) varying from 25.9 to 26.1 kN/m^3; void ratio (e) variable from 0.9 to 1.17 and porosity (n) varying from 0.47 to 0.54.

Regarding the hydraulic properties of these soils, permeability tests have been performed in oedometer at different consolidation stresses ranging from 50.00, to 196.45 kPa, the obtained values of hydraulic saturated conductivity vary respectively from 3.64E-07 to 1.63E-08 m/s. The value of the hydraulic conductivity equal to 3.64E-07 m/s has been used for the analyses due to the expected (shallow) depths of the studied landslides.

The soil water characteristic curve has been obtained by a suction controlled oedometer test, and the laboratory data have been fitted with the Gardner model with a value of saturated volumetric water content (Θ_s) equal to 0.51, residual volumetric water content (Θ_r) equal to 0.23 and α parameter equal to 0.69 (Ciurleo et al., 2022).

Referring to mechanical properties, shear strength parameters have been obtained by drained triaxial compression tests on the undisturbed saturated specimens previously classified (i.e. SM) and they have been equal to c' = 1 kPa and $\varphi' = 35°$.

3.2 Stage II

In stage II several TRIGRS analyses have been performed in saturated and unsaturated conditions using the geotechnical input data obtained in stage I.

Regarding pore water pressure regime, different positions of the initial ground water table have been considered (Table 1). The first column of Table 1 shows a progressive identification number with the letter U, in case of unsaturated soil conditions, or S in case of saturated soil conditions. Cases 1U, 2U and 3U have been performed considering for the whole study area three different position of ground water table, respectively equalling 3.0 m, 2.5 m and 2.0 m.

Case 4S has been performed considering an initial steady state water table located at 1.5 m in the whole study area.

In case 5S the study area has been divided in two zones (Figure 2D): in zone "A" the depth of water table has been located at 0 m from the ground surface and in zone "B" a steady state ground water table at 1.5 m of depth has been considered.

Table 1. Ground water table location used in saturated and unsaturated soil conditions.

Case	Zone "A"	Zone "B"
1U	3.0	3.0
2U	2.5	2.5
3U	2.0	2.0
4S	1.5	1.5
5S	0	1.5

The simulation performed in unsaturated conditions with an initial water table located at 3.0 m (Figure 4 A) showed that only some cells of the study area are computed as unstable by the model and this initial configuration did not allow to simulate the real source areas mapped by multi-temporal landslide inventory.

When the position of the water table rose (Figure 4 B and C), the number of cells computed as unstable by the model increased even if the overall computed instability has been still very far from the simulation of the triggering areas mapped by the multi-temporal landslide inventory. This consideration has been supported by values of TPR equal to 0.08 and 0.14 for 1U and 2U cases. At the initial ground water table location of 2 m of depth, the value of TPR started to increase, reaching 0.45 (case 3U).

In saturated conditions, case 4S (Figure 4D) showed that the areas computed as unstable by the model well fitted the real source areas mapped by multi-temporal landslide inventory except the triggering area A_{01} that is one of the source areas that was triggered in the 2001 debris flow.

On the contrary, considering an initial ground water table located as reported in case 5S (Table 1, Figure 4E), TRIGRS has been able to correctly back-analyse the landslide source areas mapped by the inventory including the triggering area A_{01}.

The highest value of TPR, equal to 0.86, was reached for Case 5S that had a value of AUC equal to 86.4% so testifying a good ability of the model to back-analyse shallow landslide source areas.

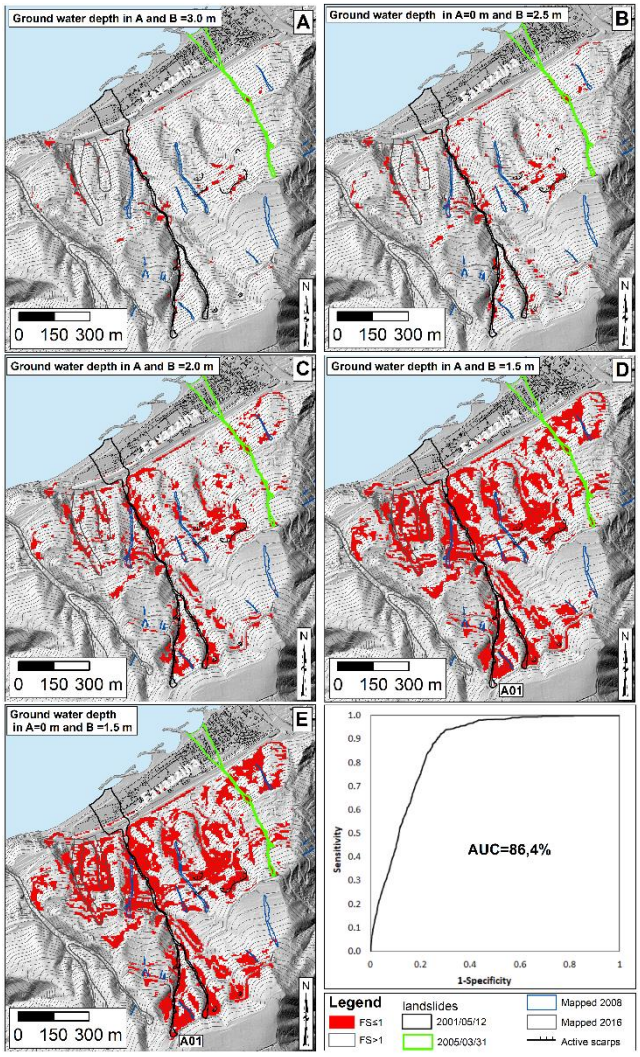

Figure 4. TRIGRS results in unsaturated and saturated soil conditions.

4 CONCLUSIONS

The paper showed for the first time in scientific literature the application of TRIGRS as tool to locate in-site investigation and laboratory tests.

The obtained results also show a good performance of the model in predicting shallow landslide occurrence.

Starting from the consideration that TRIGRS is a free software and the required input data can be found on literature, it is author opinion that the proposed methodology could become the common practice in landslide susceptibility assessment by using physically based models to locate in-site investigations so allowing the characterization of the soils potentially involved by landslides.

ABSTRACT: Pile Static Load Test (SLT) and Rapid Load Test (RLT) results at the Jibanshikenjo test site in Sashima were compared to the empirical pile resistances estimated based on SPT and CPT measurements proposed by different European (EC7 National Annexes) and Japanese codes. RLT requires an interpretation, however, it is quick to perform and for this case it was in close agreement with SLT. The empirical pile resistance calculations from SPT and CPT vary in terms of methodology, gave different results and no consistent trend, especially for the tip resistance. Concerning the shaft resistance BS code for shaft resistance from SPT and Unified CPT, AFNOR and DIN codes from CPT gave good results. SLT and RLT must be considered more accurate, while the empirical methods should always consider local experience and preferably be compared to SLT or RLT results.

RÉSUMÉ: Les résultats des tests de charge statique et des tests de charge rapide sur le site d'essai de Jibanshikenjo à Sashima ont été comparés aux résistances empiriques des pieux estimées sur la base des mesures SPT et CPT proposées par différents codes européens (annexes nationales EC7) et japonais. RLT nécessite une interprétation, cependant, elle est rapide à réaliser et pour ce cas elle a été en étroit accord avec SLT. Les calculs empiriques de résistance des pieux de SPT et CPT varient en termes de méthodologie, ont donné des résultats différents et aucune tendance cohérente, en particulier pour la résistance aux pointes. Concernant la résistance à l'arbre BS pour la résistance à l'arbre du SPT et du CPT Unifié, l'AFNOR et le DIN du CPT ont donné de bons résultats. SLT et RLT doivent être considérés comme plus précis, tandis que les méthodes empiriques doivent toujours tenir compte de l'expérience locale et être de préférence comparées aux résultats SLT ou RLT.

Keywords: Pile resistance; design codes; representative value; empirical methods; Rapid Load Test.

1 GENERAL

The ultimate limit state (ULS) bearing capacity check of a single pile includes the calculation of the Ultimate Pile Load (UPL) representative value (R_{rep}), which corresponds to the pile bearing resistance failure (according to EN 1997-1:2004) or to the failure of the ground surrounding the piles (according to the upcoming 2nd generation EN 1997-3). In most cases, the bearing capacity calculation is based on static load tests, or on dynamic impact tests, or on ground tests results (e.g. EN 1997-1:2004) and these three alternatives result in different computational models, i.e. methods of calculation.

The static load test provides a direct estimation of the in situ total bearing resistance (R_c) or separately base (R_b) and shaft (R_s) resistances (EN 1997-1:2004). The dynamic impact test provides R_c, R_b and R_s after an interpretation and according to EN 1997-1:2004 "the validity of the result shall have been demonstrated by previous evidence of acceptable performance in static load tests on the same pile type of similar length and cross-section and in similar ground conditions".

Regarding methods to be incorporated based on ground tests the calculation results "shall have been established from pile load tests and from comparable experience" EN 1997-1: 2004. Ground test results may be either laboratory or in-situ tests. In Europe each country may propose a different calculation methodology, which is influenced by the local experience, for instance the DIN 1054, AFNOR NF P 94-262 and BS 8004 National Annexes (NAs) for EN 1997-1. For instance, the BS 8004, adopts the α-method if laboratory determined undrained shear strength (s_u) is available, or the β-method if drained shear strength (Mohr – Coulomb effective cohesion c' and effective angle of shearing resistance φ') is available. Notably, in Japan a variance of methods are prescribed in different Japanese Codes adopted by different authorities for their applications (Architectural Institute, Road Association, Ports and Harbours Bureau and Railway TRI). Concerning the use of in situ results all codes propose totally different methodologies.

The calculation of the UPL design value (R_d) differs on the way the design codes apply the factors of safety: a) Material Factor Approach (MFA), in which partial factors of safety are applied to the material strength constants or b) the Resistance Factor Approach (RFA), in which overall factors of safety are applied to the representative UPL.

This work performs a comparative analysis of the EC7 DIN, EC7 AFNOR, EC7 BS and four Japanese Codes with regards to in situ tests results carried out at the Jibanshikenjo test yard in Sashima Japan (Lin et al., 2023b).

2 ULTIMATE PILE LOAD

A general definition of the Ultimate Pile Load (UPL) representative value ($R_{c;rep}$) is presented in to Equation (1). The design value ($R_{c;d}$) depends whether the MFA or RFA approaches are adopted, or Equations (2) and (3) respectively. Equation (3) directly relates to Equation (1) by the overall factor of safety on the resistance. The EN 1997 signs have been adopted, while $X_d = X_{rep} / \gamma_M$ and $F_d = \gamma_F F_{rep}$ correspond to the design values of strength and loads respectively.

$$R_{c;rep} = R\left(F_{rep}, X_{rep}\right) \quad (1)$$

$$R_{c;d} = R\left(\gamma_F F_{rep}, X_{rep}/\gamma_M\right) \quad (2)$$

$$R_{c;d} = R_{c;rep}/\gamma_R = R_{c;rep}/\gamma_t \quad (3)$$

If bearing capacity is further analysed into the base (R_b) and the shaft (R_s) resistances, then:

$$R_{c;d} = R_{b;rep}/\gamma_b + R_{s;rep}/\gamma_s \quad (4)$$

The selection of MFA (Equation (2)) or RFA (Equation (3)) relates closely on the methodolody applied to estimate the single pile bearing capacity:

- Static Load Test (SLT) or Dynamic Impact Test: If it determines $R_{c;rep}$ applies RFA. If it determines $R_{b;rep}$ and $R_{s;rep}$ apply MFA or RFA (Equations (4) and (3) respectively).
- Ground Tests (GT): $R_{b;rep}$ and $R_{s;rep}$ are determined (Equations (5) and (6)). Empirical correlations are applied to laboratory results (soil strength constants) or in situ results (CPT, SPT), to calculate the representative base bearing capacity ($q_{b;rep}$) and shaft unit bearing capacity ($q_{s;rep}$, or $q_{s;i;rep}$ for ith layers). Either MFA or RFA (Equastions (4) and (3) respectively) can be applied.

$$R_{b;rep} = A_b q_{b;rep} \quad (5)$$

$$R_{s;rep} = \sum_{i=1}^{n} A_{s;i} q_{s;i;rep} \quad (6)$$

The MFA and RFA for pile $R_{c;d}$ calculation will give similar results for calculations from GT because the computational models are practically linear functions of the soil strength (c_u or c' and $\tan\varphi'$) or the in situ measurements (corrected cone resistance q_t, or blow counts N_{SPT}). This is in strong contrast with the shallow foundation case under drained conditions (e.g. Kovaiou & Belokas, 2023), where the bearing capacity equation is non-linear function of $\tan\varphi'$. Next, the European and Japanese methodologies for R_{rep} calculation of steel pipes are compared based on SLT (Static Load Test), RLT (Rapid Load Test) and in situ GT (SPT and CPT) results.

3 CALCULATION METHODS

DIN 1054 applies model factors $\eta_b < 1$ and $\eta_s < 1$ on Eqs. (5) and (6), i.e. $R_{b;rep} = \eta_b A_b \; q_{b;rep}$ and $R_{s;rep}=\sum \eta_{si} A_{si} q_{s;i;rep}$. Bearing capacities estimations are based on a representative resistance-settlement curve, which uses empirical limit settlements for $q_{b;rep}$ and $q_{s;rep}$ full mobilization and empirical correlations for ultimate $q_{b;rep}$ and $q_{s;rep}$ values that depend on limit settlements and CPT or c_u values.

AFNOR: NF P 94-262 classifies Close-ended Pipe Piles (CPP) to "class 4" and Open-ended Pipe Piles (OPP) to "class 5". It employs $q_{b;rep} = k_c \; q_{ce}$ and $q_{s;rep} = \alpha f_{soil} \leq q_{smax}$, where q_{ce} is an equivalent CPT value, k_c varies according to soil type, pile geometry and pile class, while $0.2 \leq \alpha \leq 2.25$ and q_{smax} vary according to soil type and pile class.

BS 8004 classifies CPP to "high displacement class" and OPP to "low displacement class", which refer to the degree of installation disturbance. It allows calculation from SPT, CPT (both used herein) or soil strength data. The CPT calculation is $R_{b;rep(0.1)} = A_b c_{b;0.1} q_{c;b;rep}$ and $R_{s;rep}=\sum c_{s;i} A_{s;i} q_{c;i;rep}$, where $q_{b;0.1}$ is the measured cone resistance over 1.5D depth below base, $q_{c;i}$ is the measured cone resistance within the layer, while $c_{b0.1}$ and $c_{s;i}$ are empirical coefficients that depend on soil pile type and can be estimated from Tables. The SPT calculation is $R_{b;rep(0.1)} = A_b n_{b;0.1} p_{ref} N_b$ and $R_{s;i} = A_s n_{s;i} p_{ref} N_i$, where $p_{ref} = 100$ kPa, $n_{b;0.1}$ and $n_{s;i}$ empirical coefficients that depend on soil and pile type (typical tabulated values are given), N_b and $N_{s;i}$ the uncorrected N_{SPT} at the base and in layer i respectively.

Tables 1 and 2 summarise the Japanese codes AIJ (2019) of Architectural Institute, JRA (2017) of Road Association, MLIT (2020) of Ports and Harbours Bureau and RTRI (2012) of Railway TRI.

Table 1. q_b and q_s based on Japanese codes (in kPa) (1/2).

Code	Type	Soil type: Sand	Soil type: Clay
Railway	q_b	$210N$ (≤10000)	6.3c or $75N$ (≤20000)
		CPP: N = mean N-value $3D_o$ below pile tip	
		$175N$ (≤ 8000)	$55N$ or $5.5s_u$ (≤16000)
		OPP with w/ $D_o \leqq 0.8$ m and $l/D_o > 5$: N = N-value of ground at pile tip, l = equivalent embedment length into bearing stratum, $l = [5\ D_o\ (N_1+N_2)/2]/N$, N_1 = N-value at $5D_o$ above pile tip, N_2 = N-value of ground at pile tip, D_o = outer pile diameter	
		$35(l/D_o)N$ (≤8000)	$11(l/D_o)N$ or $1.1(l/D_o)s_u$ (≤16000)
		OPP with w/ $D_o \leqq 0.8$ m and $l/D_o \leqq 5$: N = N-value of ground at pile tip	
		$(140/D_o)N$ (≤8000)	$(44/D_o)N$ or $(4.4/D_o)s_u$ (≤16000)
		OPP with w/ $D_o > 0.8$ m and $l/D_o > 5$: N = N-value of ground at pile tip	
		$(28/D_o)(l/D_o)N$ (≤8000)	$(8.8/D_o)(l/D_o)N$ or $(0.88/D_o)(l/D_o)s_u$ (≤16000)
		OPP with w/ $D_o > 0.8$ m and $l/D_o \leqq 5$: N = N-value of ground at pile tip	
	q_s	$3N$+30 (≤150)	$6N$ or $0.4s_u$ (≤120)
		$3N$ (≤120)	$6N$ or $0.4s_u$ (≤120)

Table 2. q_b and q_s based on Japanese codes (in kPa) (2/2).

Code	Type	Soil type: Sand	Soil type: Clay
Port	q_b	$300\eta N$ (≤15000)	$6s_u$
		$N = (N_1+N_2)/2$, N_1 = N-value of ground at pile tip, N_2 = mean N-value $4D_o$ above pile tip, η = plugging efficiency	
	q_s	$2N$ (≤100)	$1s_u$ (≤100)
Archi.	q_b	$300\eta N$ (≤18000)	$6s_u$ (≤18000)
		$\eta = 0.16(L_B/D_i)$ for $2 \leq L_B/D_i \leq 5$; $\eta = 0.8(L_B/D_i)$ for $L_B/D_i > 5$; L_B = embedment into bearing stratum, D_i = inner pile diameter	
	q_s	$2N$ (≤100)	$0.8s_u$ (≤100)
Road	q_b	$130N$ (≤6500)	$90N$ (≤4500)
	q_s	$5N$ (≤100)	$6N$ or $1s_u$ (≤70)

4 COMPARISON OF PILE RESISTANCES

Results from an open-ended steel pipe pile (SPP) at Jibanshikenjo test site in Sashima, Ibaraki Prefecture, Japan are considered. It had an outer diameter of 318.5 mm, a wall thickness of 6.6 mm and an embedment length of 11.0 m. The Static Load Test (SLT) and Rapid Load Tests (RLTs) carried out are summarized in Figure 1. The RLT instrumentation is shown in Figure 2. To estimate the soil resistance R_{soil} (= static soil resistance R_w + dynamic soil resistance R_d) and R_w from the measured values of applied load F_{rapid} and pile head acceleration α, UnLoading Point Connection Method invoking CASE method (ULPC_CM) (Lin et al., 2023a) was used. The relative loading duration $T_r = t_L/(2L/c)$ (t_L= loading duration, L = pile length, c = bar wave velocity in pile) in RLTs was about 5 according to JGS (2002).

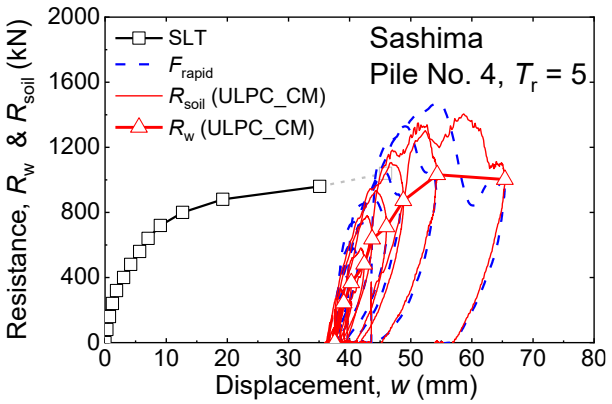

Figure 1. Static load-displacement relations from SLT and RLTs.

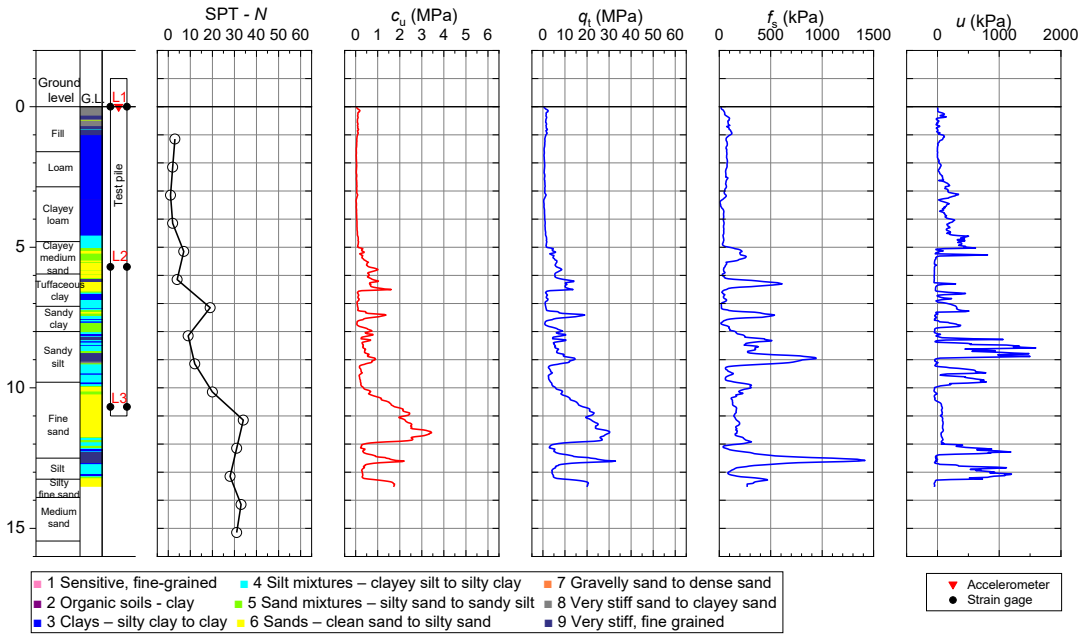

Figure 2. Site soil profile (undrained strength c_u is computed from q_t).

Figure 2 presents the soil profile and the in-situ results: a) SPT N-values obtained at 1 m intervals and b) electric Cone Penetration Test (CPT) measurements of corrected cone tip resistance q_t, sleeve friction f_s and pore water pressure u at 20 mm intervals. The undrained shear strength c_u was estimated using q_t. Notice that the estimated c_u is valid for only clayey soil layers.

Three EN 1997 National Annexes, namely DIN (including "Recommendations on Piling", DGGT (2013)), AFNOR and BSI and four Japanese codes, are applied to the test site results.

4.1 Calculation by SPT N-value

Four Japanese codes and EN 1997 Annex BS have been used. Figure 3 shows the distributions with depth of shaft resistance τ_f (or $q_{s;rep}$) from static Load Tests (SLT), Rapid Load Tests (RLT) with ULPC_CM and SULPC interpretations (Lin et al., 2023b), and various design codes. SULPC is an extension of ULPC. If the dynamic signals are measured at several levels of a pile, the pile is divided into several pile segments. ULPC interpretation is applied to each pile segment to obtain the static force-displacement relation of the segment. Response of the whole pile subjected to static pile head load is then calculated through a one-dimensional FEM using the static response of pile segments previously obtained (Kamei et al., 2023).

Notice that when the empirical equation using only cohesion (undrained shear strength) c is specified in the Japanese codes, $c = 6.25N$ (kPa) was assumed.

In Figure 3, the dotted lines are the shaft resistance τ_f estimated from the various design codes. The solid lines indicate the average values of τ_f along the pile segment, specifically Seg. 1 and Seg. 2. The thick solid lines are the measured τ_f in SLT and RLTs.

Concerning RPL, to estimate the soil resistance on each pile segment, ULPC_CM interpretation analysis was carried out using the measured signals at each measurement level (L1, L2 and L3). When the signal measured at L1 are used, the soil resistance below L1 is obtained. Similarly, when the signals measured at L2 are used, the soil resistance below L2 is obtained. When signals measured at L3 are interpreted, the soil resistance is the pile tip resistance. Hence, the soil resistance acting on each segment was obtained.

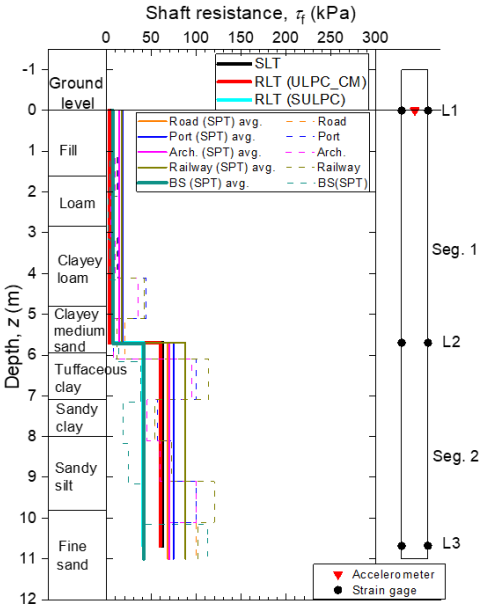

Figure 3. Distributions of shaft resistance τ_f from SLT, RLT and design codes (SPT).

Figure 4 shows the comparison of shaft resistance τ_f of two pile segments from SLT, RLT and the design codes. While Japanese codes show no significant differences, they tend to overestimate the SLT result. On the other hand, the shaft resistance τ_f from BS and RLTs are almost equal to the SLT result.

Figure 5 shows the comparison of maximum total shaft resistance Q_s and maximum total tip resistance Q_b from SLT, RLT and the design codes. The trend of Q_s is similar to that described in Figure 4. There is a wide variation in Q_b from the design codes. The plugging efficiency $\eta = 1$ in Port code and Road code, while $\eta = 0.52$ in Architectural code for this particular test pile condition. Q_b from RLT is the most reasonable estimation for the SLT result.

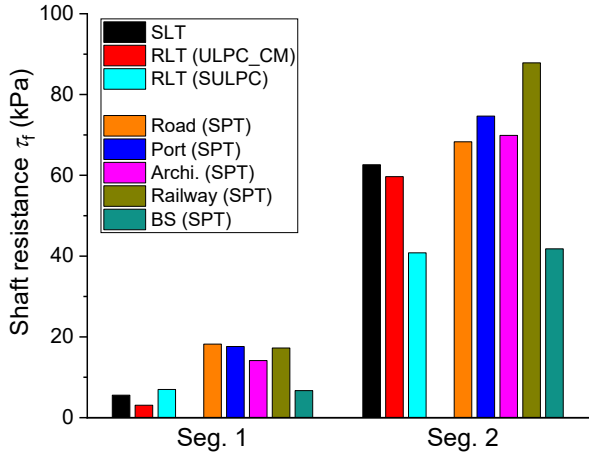

Figure 4. Comparison of average shaft resistance τ_f of two pile sections from SLT, RLT and design codes (SPT).

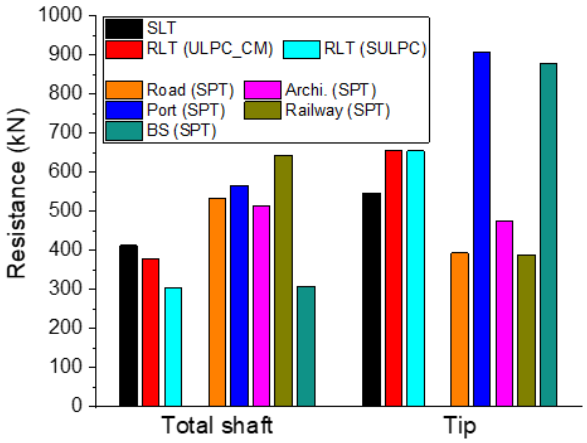

Figure 5. Comparison of maximum shaft resistance Q_s and maximum tip resistance Q_b from SLT, RLT and design codes (SPT).

4.2 Calculation by CPT

The Unified CPT method (Lehane et al., 2022a, b) and three EN 1997 Annexes (BSI, AFNOR, DIN) are applied to compare them to shaft resistances and tip resistance from SLT and RLT. The shaft resistances are estimated at 0.02 m intervals of CPT measurements. When CPT-based methods were used, soil classification from the borehole investigation (SPT) (Fig. 2) was used. Loam, clayey loam, tuffaceous clay and sandy clay were classified as "clay", and the other soil layers were classified as "sand".

Figure 6 shows the distributions with depth of shaft resistance τ_f from the SLT, RLT with ULPC_CM and SULPC interpretations (Lin et al., 2023b) and the various CPT codes (dotted lines). The solid lines indicate the average values of τ_f along the pile Seg. 1 and Seg. 2. Notice a coefficient F_{st} was set as 0.3 in the Unified CPT method.

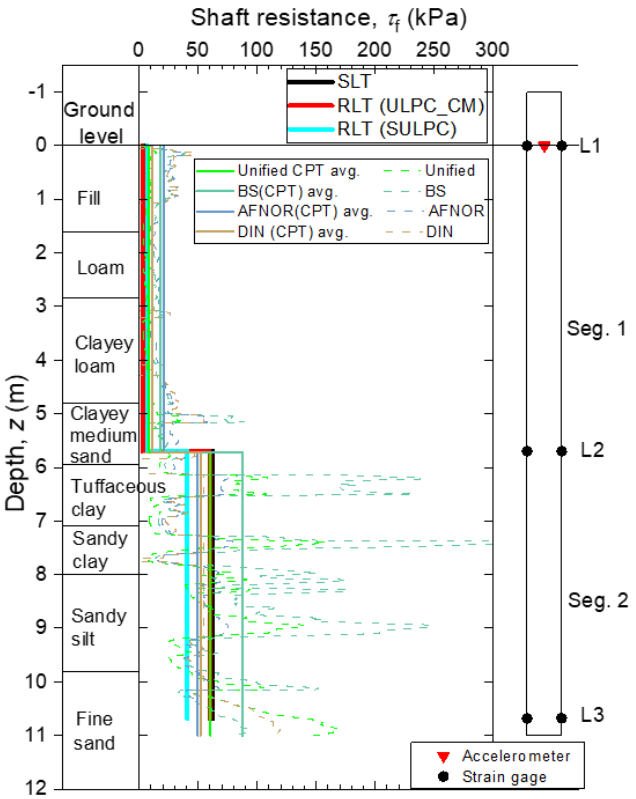

Figure 6. Distributions of shaft resistance τ_f from SLT, RLT and design codes (CPT).

Figure 7 shows the comparison of shaft resistance τ_f of two pile segments from SLT, RLT and the design codes. Shaft resistance from BS tends to overestimate the result of SLT. The shaft resistance τ_f from Unified CPT, DIN and RLT are almost equal to the SLT result.

Figure 8 shows the comparison of maximum total shaft resistance Q_s and maximum total tip resistance Q_b from SLT, RLT and the CPT codes. The Q_s of RLT, Unified CPT, AFNOR and DIN are almost equal to the SLT result. However, all the Q_b from CPT code underestimate the SLT result.

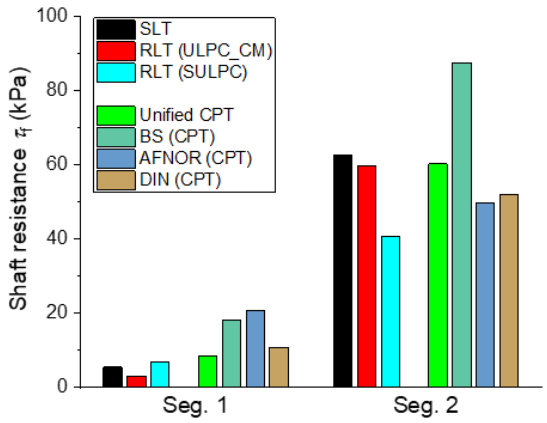

Figure 7. Comparison of average shaft resistance τ_f of two pile sections from SLT, RLT and design codes (CPT).

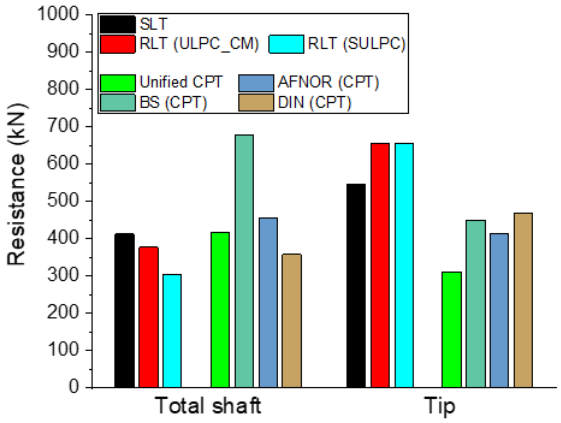

Figure 8. Comparison of maximum shaft resistance Q_s and maximum tip resistance Q_b from SLT, RLT and design codes (CPT).

5 CONCLUSIONS

Pile SLT and RLT results at the Jibanshikenjo test site in Sashima were compared to the pile resistance estimated based on SPT and CPT measurements for different European and Japanese codes. Test piles SLT and RLT showed close agreement. The different empirical pile resistance estimations from SPT and CPT varied considerable. Despite that some methods gave good results, e.g. BS for shaft resistance from SPT, Unified CPT, AFNOR and DIN for shaft resistance from CPT, there was not any consistent trend, especially for the tip resistance. SLT and RLT must be considered more accurate, while the empirical methods should always consider local experience and preferably be compared to SLT or RLT results.

ABSTRACT: The development of historical cities naturally consists in the development of underground space. The article considers an integrated approach to the preservation of buildings - monuments on the example of the city of St. Petersburg, which has a large capacity of weak soils in its geological structure and a significant building area, which is a World Heritage Site protected by UNESCO. The article analyzes the experience of using various geotechnologies to minimize the impact of underground construction on the surrounding buildings. The high role of geotechnical monitoring for the preservation of monuments located near the site of underground construction is noted. The use of modern laser scanning systems and traditional methods of assessing deformations of buildings allow us to take into account the features of a unique object during monitoring. Prospects for the use of high-precision spatial monitoring of architectural monuments suggest the introduction of a new tool for monitoring the state and risk analysis of historical heritage. The data on the implementation of the described studies are confirmed by the successful implementation of the construction of an underground space on weak soils in the historical districts of the city of St. Petersburg.

RÉSUMÉ: Le développement des villes historiques consiste naturellement en l'aménagement de l'espace souterrain. L'article considère une approche intégrée de la préservation des bâtiments - monuments sur l'exemple de la ville de Saint-Pétersbourg, qui a une grande capacité de sols faibles dans sa structure géologique et une zone de construction importante, qui est un site du patrimoine mondial protégé par l'UNESCO. L'article analyse l'expérience de l'utilisation de diverses géotechnologies pour minimiser l'impact de la construction souterraine sur les bâtiments environnants. Le rôle important de la surveillance géotechnique pour la préservation des monuments situés à proximité du site de construction souterraine est noté. L'utilisation de systèmes de balayage laser modernes et de méthodes traditionnelles d'évaluation des déformations des bâtiments nous permet de prendre en compte les caractéristiques d'un objet unique lors de la surveillance. Les perspectives d'utilisation de la surveillance spatiale de haute précision des monuments architecturaux suggèrent l'introduction d'un nouvel outil de suivi de l'état et d'analyse des risques du patrimoine historique. Les données sur la mise en œuvre des études décrites sont confirmées par la mise en œuvre réussie de la construction d'un espace souterrain sur des sols faibles dans les quartiers historiques de la ville de Saint-Pétersbourg.

1 INTRODUCTION

The development of historical cities naturally consists in the development of underground space. Consider the option of creating predominantly pedestrian streets, while developing transport infrastructure under existing roads, canals, buildings. Using the example of a city with a large capacity of weak soils and widespread existing buildings in the status of objects of cultural significance, geotechnical construction involves the study of not only complex soils, but also the structures of palaces and monasteries built hundreds of years ago. Under these conditions, over the past 10 years, experience has been accumulated and analyzed in the application of various technologies for the construction of piles, enclosing structures and strengthening the foundation soils (Mangushev and Nikiforova, 2017).

At the same time, significant expenditures of the construction budget were spent on measures aimed at ensuring the safety of historical buildings. The laws of construction in such areas require a practical lack

of impact from new construction. So, the additional sediment should not exceed 0.5 cm. On weak thixotropic clay soils, any construction work leads to the risk of destruction of the existing building (Mangushev et al., 2018). The answer to each of the technological challenges of underground space development is the appearance of a new technology on the construction equipment market, which allows solving a new range of tasks taking into account the requirements and peculiarities of local ground conditions. In this regard, we are convinced that even the most advanced technological methods should be adapted to local geotechnical conditions. For example, in the conditions of weak thixotropic clay soils of St. Petersburg, the modulus of deformation of which can be 2...3 MPa, the role of control of technological operations is enhanced. An example of such development can be considered the accumulation of research experience on the construction of pit fences by the "Wall in the ground" method and the immersion of the sheet pile by static and vibration method. Within the framework of these studies, criteria for the technological performance of work were determined, such as speed, sequence of operations and calculation method for a preliminary analysis of the safety of work.

In this regard, the role of monitoring the behavior of the object of protection and the instrument of operational control of its structures is being strengthened. At the same time, the role of soil surveys and structures of the cultural heritage object becomes a priority, determining the principles of modeling and implementation of construction. Improving the quality of risk assessment at the stage of project development is also ensured by improving the methods of monitoring spatial deformations of the building and its parts. Traditional monitoring systems monitor only certain points on the object. At the same time, an increase in the number of points will lead to an increase in the cost of geodetic works. The use of scanning systems to obtain a point cloud, as well as a digital double of an object, can be a useful tool that allows you to present a complete picture of deformation, including the presence of defects and cracks in the structure.

In addition, the building of historical buildings requires an individual approach both in design and monitoring. The use of laser scanning systems in interaction with scanning drones, and traditional methods for assessing movements and efforts in the structure, allow you to take into account all the details of a unique object when monitoring its safety.

Comparable modeling and monitoring capabilities of the facility allow for operational control of the stress-strain system. In addition, spatial monitoring using laser scanning provides an analysis of the impact of construction on cultural heritage sites, and the accumulation of such experience makes it possible to develop models of materials of load-bearing structures and verify the method of their modeling based on the results of comparison with actual deformations. In order for the scanning in the monitoring system to meet the requirements for measurement accuracy, it was necessary to develop a survey methodology that includes new types of geodetic signs (spherical prisms), the use of unmanned aerial vehicles to build an additional point cloud, as well as a method for processing a point cloud. The prospects of using high-precision spatial monitoring of architectural monuments suggest the introduction of a new tool for monitoring the condition and risk analysis of historical heritage. The data on the implementation of the described studies are confirmed by the successful implementation of the construction of an underground space on weak soils in the historical districts of the city of St. Petersburg.

2 LITERATURE REVIEW

Reducing the amount of additional deformations in the building of the surrounding building naturally leads to the choice of an enclosing structure of greater rigidity. At the same time, we are increasing the technological component of additional precipitation. A number of authors (Mangushev et al., 2020, Sapin, 2014) under the guidance of Professor Mangushev were engaged in studies of the nature and methods of calculating technological sediments in the construction of pit fences. In his research, D.A. Sapin (Sapin, 2015) showed that the technological component of the toughest enclosing structure – the trench wall in the ground reaches 80% of the total additional deformation of the building of the surrounding development. The results of field and laboratory modeling of static immersion of steel sheet piling, performed by A.V. Gursky, (Mangushev and Gursky, 2016), allowed us to conclude that additional technological deformations of the tongue-and-groove device will be less than in the case of a trench wall in the ground, however, the subsequent additional deformations of the building caused by the horizontal movement of the flexible retaining tongue-and-groove wall are comparable, and even exceed the technological risks from the trench wall in the ground. The main problem that forms these risks is a large thickness of weak clay soils, during the operation of equipment in which thixotropic structural disturbances begin to occur and are always

accompanied by large movements (Mangushev and Osokin, 2019). Under these conditions, the deformations of the surrounding historical buildings can be 150...600 mm (Ulitskiy et al., 2013, Paramonov, 2009). As we noted earlier, the permissible amount of precipitation is 5...20 mm. The negative effects of these values of deformations are always enhanced by the presence of a large unevenness of deformations, which leads to the formation of cracks and the destruction of the building.

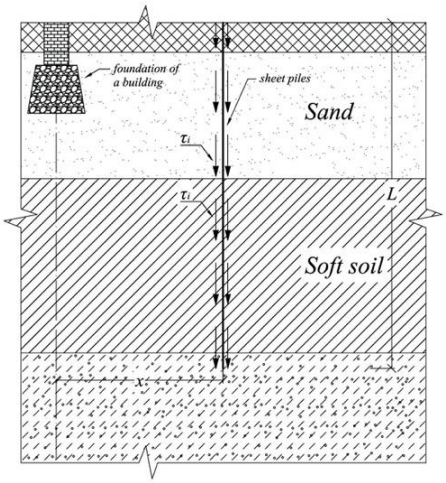

Figure 1. Additional settlement of an existing building under the technological influence of the device of the enclosing structure.

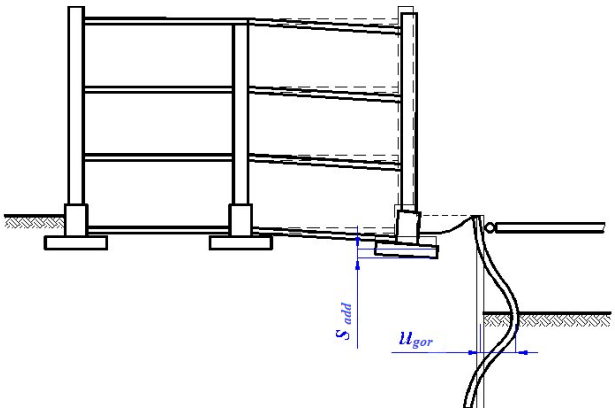

Figure 2. Additional settlement of the existing building from the horizontal displacement of the fence during excavation of the pit

In the case under consideration, a comprehensive solution is proposed, which consists in the construction of a fence structure "wall in the ground" of drill-cut piles d = 350 mm, performed under the protection of a geotechnical barrier with preliminary multi-stage reinforcement of the foundations and foundations of existing historical buildings (Osokin et al., 2019). Thus, at the stage of fencing construction, technological precipitation of manufacture was minimized. And in order to avoid negative consequences when digging a pit, jet–grouting technology was proposed as a spacer plate below the bottom of the pit.

Geotechnical monitoring plays an important role in assessing the effectiveness of the technology, operational adjustment of the speed and sequence of work. At the same time, the main role should be given to geodetic spatial observations of aboveground structures and structures of the pit fence, which can be performed using both classical equipment (leveling, total station) and modern scanning systems and aerial photography. Spatial monitoring allows you to get an interconnected field of points. The area where the field of points is built can include both the building itself and adjacent territories with structures and structures. Long-term satellite positioning of the points system can improve the accuracy of scanning with a measurement error of vertical deformations of 1...2 mm, horizontal displacements of 2...5 mm. This technology is indispensable in conditions of difficult accessibility to the object of observation. The complexity of the information obtained allows us to evaluate complex deformations of individual structures, the development of cracks. The basis for ensuring the accuracy of measurements by laser scanners and unmanned aerial vehicles (UAVs) is always the measurement procedure, the rules of which come out of geodetic standards. However, a significant increase in productivity can be considered the use of a list of equipment that allows you to get a point cloud of good quality, which will require less time for in-house processing. One of such developments is a new type of stamp developed by researchers of the Department of Geodesy of the St. Petersburg University of Architecture and Civil Engineering made on a polymer 3D photo printer that provides the necessary surface quality of the stamp. The effectiveness of the use of this type of stamps, which also consists in increasing the scanning speed, has been demonstrated in laboratory conditions, at research sites and has already been successfully implemented by us in construction production at the stages of spatial monitoring.

The results and application of spatial monitoring are increasingly in demand with the increasing use of joint calculations of the "building-base" system. In this situation, you can monitor the complex deformation of the entire building, with further comparison and refinement of the design model. For existing historical buildings built hundreds of years ago, only such an approach is possible, which can compensate for the lack of complete detailed design documentation, as is the case with new construction.

3. METHODS

The above design scheme of the excavation enclosure was used in the construction of an underground structure in the center of St. Petersburg. At the same time, the construction under construction was erected in close proximity to 6 buildings - objects of cultural heritage.

At the same time, the engineering and geological conditions of the construction site are represented by a significant thickness of weak clay soils. The construction project involved the development of a 3.5 m deep excavation in close proximity to existing cultural heritage sites. To ensure their safety, taking into account the above data, a device for fencing the pit using the technology of boring piles was chosen. This technology involves the construction of fencing from drilling piles under the protection of bentonite mortar. From the point of view of the preservation of buildings of the surrounding development, a significant advantage of this technology over the technology of trench wall in the ground is a significantly smaller amount of excavation for the device of one section of fencing, and before the technology of the device of tongue–and-groove fencing - the absence of transmission to the ground base of static or dynamic loads during immersion.

At the same time, a significant disadvantage of this technology can be called a significantly lower bending stiffness of the enclosing structure than in the cases of sheet piling and trench wall in the ground. To compensate for the insufficient rigidity of the fence, at the design stage, it was provided for the installation of a ground-cement jet-diaphragm below the bottom of the pit, contributing to an increase in the overall rigidity of the enclosing structure. The general scheme of the pit enclosure is shown in Figure 3.

The experience of the construction of pit fences using this technology in the conditions of St. Petersburg shows that the technological precipitation of the surrounding buildings, even when they are directly adjacent to the construction site, does not exceed 1 mm. In this regard, when assessing additional sediments of cultural heritage objects, only additional sediments caused by the excavation were evaluated.

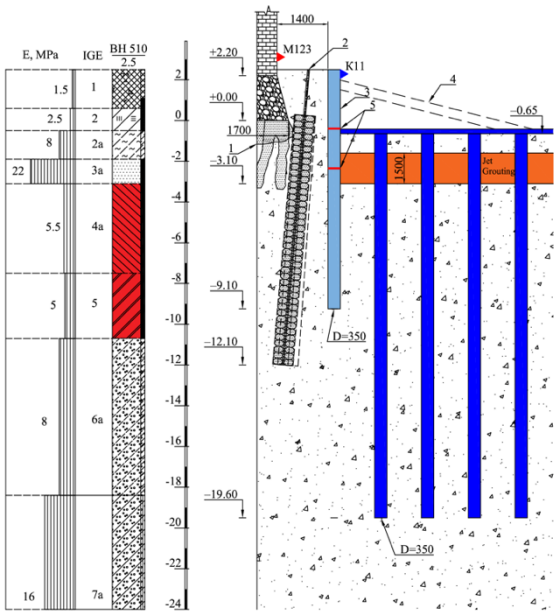

Figure 3. Applied structures of fencing, fixing of the pit, reinforcement of the existing building and geotechnical barrier device.

Figure. 4. The spacer system of the pit at the stage of excavation to the bottom of the pit.

When performing a computational analysis of the development of additional sediments, the following factors were taken into account (Kuznetsov et al., 2023):

1. The stage of work.
2. Nonlinear behavior of the foundation soils (using the Hardening Soil model).
3. Undrained behavior of weak clay soils (drainage type – undrained B).
4. Reinforcing effect of a pile field made for the projected building (using Embedded Beams elements)
5. Nonlinear behavior of reinforced concrete of the enclosing structure and the pile foundation (using the M-k diagram).

Due to the complexity of sampling of sufficiently high quality in the conditions of St. Petersburg, the specific resistance to undrained shear of weak clay soils was determined on the basis of static sounding

data according to the formula: $s_u=q_c / 19$ (Shashkin, 2014).

Construction of a graph of the dependence of the bending stiffness of reinforced concrete piles was performed numerical simulation of the cross section, taking into account the peculiarities of the work of concrete in tension and compression (Osokin et al., 2023). The calculated cross-section of the reinforced concrete pile and the obtained dependence of the bending stiffness on the acting bending moment are shown in Figure 5.

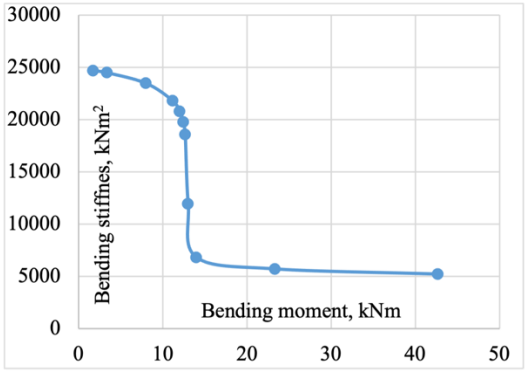

Figure 5. Dependence of the bending stiffness of the pit fence on the acting bending moment.

Below, Figures 6-7 presents the results of numerical modeling of the impact of the development of the pit on the buildings of the existing development.

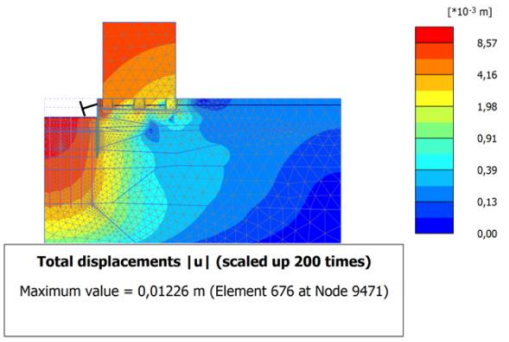

Figure 6. Isofields of complete displacements of the soil mass.

Figure 7. Diagram of deformations of the settlement of surrounding buildings.

4. CONCLUSIONS

1) The development of underground space is an integral part of the development of urban space in the central part of historical cities;

2) In the conditions of complex engineering and geological conditions, represented by a significant capacity of weak clay soils, one of the most important aspects of the preservation of historical buildings is the correct choice of technology for the construction of enclosing structures of the pit;

3) In order to ensure the preservation of the surrounding historical buildings, when developing pits up to 5 m deep in close proximity to existing buildings, a structural scheme of the enclosing structure is proposed, which is a combination of small diameter borehole piles, a spacer system and a deep jet diaphragm;

4) On the example of a real object in the conditions of the historical center of St. Petersburg, the effectiveness of this variant of the enclosing structure is shown;

5) To predict the development of additional sediments of the existing development, a design scheme is proposed that takes into account the undrained behavior of the foundation soils, the preliminary arrangement of the pile field within the contour of the pit, the nonlinear behavior of the soil mass and reinforced concrete enclosing structures.

ABSTRACT: The introduction of new technologies applied in unmanned aerial vehicles (UAV), to monitor civil engineering structures, substantially developed inspection techniques and deformation measurements in embankment dams. The use of UAV allows the acquisition of essential data on the behaviour of a structure, at a reduced cost. During a UAV flight, aerial photographs are recorded following a pre-defined route. They can be easily converted to orthophotos after processing. The quality of those orthophotos depends on many factors, namely, the photographs' quality (resolution, noise, distortion), their overlap, and the identification of enough control points, among other factors. To improve the accuracy of the orthophoto, and allow georeferencing, enough control points must be defined to allow for a high-quality orthophoto. Such control points, also called Ground Control Points (GCP), are positioned in situ with high-precision coordinates. Due to the great amount of aerial photographs recorded on each flight, it is essential to increase efficiency in GCPs identification in each photograph. This paper describes an open-source algorithm, developed by National Laboratory for Civil Engineering (LNEC) and NOVA University Lisbon, within the scope of a master's thesis, which automatically identifies GCPs and prepares data for processing in the WebODM platform.

RÉSUMÉ: L'introduction de nouvelles technologies appliquées aux véhicules aériens sans pilote (UAV) pour surveiller les structures de génie civil a considérablement développé les techniques d'inspection et de mesure de déformation dans les barrages en remblai. L'utilisation d'UAV permet d'acquérir des données essentielles sur le comportement d'une structure à moindre coût. Lors d'un vol d'UAV suivant un itinéraire prédéfini, des photographies aériennes sont enregistrées. Elles peuvent être facilement enregistrées avec des orthophotos après traitement. La qualité de ces orthophotos dépend de nombreux facteurs, notamment la qualité des photographies (résolution, bruit, distorsion), leur chevauchement, l'identification d'un nombre suffisant de points de contrôle, entre autres facteurs. Pour améliorer la précision de l'orthophoto et permettre la géoréférencement, un nombre suffisant de points de contrôle peut être défini pour permettre l'enregistrement, ainsi que le calcul de la proximité de l'ajustement obtenu dans le processus d'enregistrement. De tels points de contrôle, également appelés points de contrôle au sol (GCP), sont positionnés in situ avec des coordonnées de haute précision. En raison de la grande quantité de photographies aériennes enregistrées lors de chaque vol, il est essentiel d'augmenter l'efficacité de l'identification des GCP dans chaque photographie. Cet article décrit un algorithme open source, développé par le Laboratoire National de l'Ingénierie Civile (LNEC) et l'Université NOVA de Lisbonne, dans le cadre d'une thèse de maîtrise, qui identifie automatiquement les GCP et prépare les données pour le traitement dans la plateforme WebODM.

Keywords: UAV; dam; monitoring; safety; WebODM.

1 INTRODUCTION

The monitoring of civil engineering structures plays a fundamental role in analysing their behaviour and safety and predicting future performance. It also contributes to the development of new design methods. In the case of dams, given its high potential risk resulting from a dam failure, monitoring plays an increased role in safety control.

Monitoring essentially comprises two components: instrumental measurements and visual observations. Instrumental measurements involve collecting data

from instruments installed inside or on the surface of the dam observing specific aspects of the structure. The combination and integration of these two components with conceptual, statistical, and mathematical models provide decision support for ensuring dam safety.

In the context of visual inspections, it is important to underscore that numerous anomalies may manifest on dams, such as cracks, settlements, and seepages, often eluding detection, particularly in their early stages. Nevertheless, early detection of these anomalies can prove pivotal for remedial measures, safeguarding the structural integrity and safety of dams.

In this context, the application of Unmanned Aerial Vehicles (UAVs) and laser scanning in monitoring dams has seen a notable increase, primarily due to reduced costs in acquisition, development, and dissemination (Leite et al., 2020). This cost-effectiveness allowed the development of new monitoring techniques and displacement measurements. However, the quality of the data collected by UAVs relies on factors, such as, the quantity and quality of ground control points (GCPs). GCPs play a crucial role in correcting the position of objects in the three-dimensional model during the post-processing process. This paper presents an algorithm developed to enhance the efficiency of GCP identification and data preparation for processing on the WebODM platform (Freire, 2022).

2 THE USE OF UAVS FOR VISUAL OBSERVATIONS

The importance of visual observations in dam security is paramount, and UAVs can play a crucial role in the development and implementation of innovative visual observation methodologies. By collecting data from UAVs, it is possible to generate a dam model from a point cloud and subsequently reconstruct its geometric representation. Point clouds result from processing georeferenced images captured during the flight. These three-dimensional models exhibit geometric precision and enable the comprehensive modelling of the entire object to a certain extent. They provide the unique advantage of analysing perspectives of the dam that are typically inaccessible, such as views from above and upstream.

Beyond the evident benefit of capturing the entire geometry during the flight survey, these models, in an ideal scenario, promote a more thorough and phased inspection over time. Moreover, the data derived from the geometric model closely resembles that obtained through instrumental monitoring, offering a numerical representation stored in a database, devoid of subjectivity. The approach is not limited to the visible spectrum; alternative systems capturing data outside this range (thermal, infrared or ultraviolet) can also be employed. While the current study focuses on visible spectrum data, the developed technique can be applied for any sensor, as long as the maps obtained refer to the same positions in the image.

2.1 Developed technique

Regardless of the type of sensor, ensuring high geometric accuracy is essential to enhance the quality and efficiency of the model. To achieve this, in each data collection survey, points with known coordinates (GCPs) are used. These points, visible in a large number of photographs, provide each photograph with a set of GCP coordinates in pixels, aligning them accurately with the real-world coordinates. This procedure significantly enhances the model's quality. These points are used in object reconstruction algorithms that use photographs to correct the geometry.

In this study, an Open-Source Software (OSS) was used to apply UAV technologies in dam observation, since it allows for the development of applications avoiding dependencies on a specific supplier. The Open Drone Map (ODM) software was used in its version with a web interface (WebODM). WebODM serves as an GUI application interface for ODM, which, in itself, comprises a collection of open-source tools designed to process and convert aerial images captured by drones into various georeferenced outputs, including maps, point clouds, digital elevation models, and 3D textured models. When processing images, ODM performs a sequence of six operations: Structure from Motion (SFM), Multi View Stereo (Point Cloud Densification), Meshing, Texturing, Georeferencing, Orthophoto Processing, and Generation.

2.2 GCP finder

In SFM, when photographs are georeferenced, ODM uses this information to determine the camera's position at the time of capture. In the absence of this metadata, the camera's position can still be deduced approximately, albeit with some errors. However, even with georeferencing, factors such as image size, granularity, optical quality, or minor variations during the UAV's flight can induce considerable errors. This is where GCPs come into play. An effective GCP should be easily identifiable from a high altitude, possess shapes or colours that distinguish it from the surrounding environment, and feature a well-defined point for convenient GPS placement. Regardless of the GCP format, a matte non-reflective target is essential

to prevent light reflection, ensuring ease of identification in the photographs (Freire, 2022).

Creating a manual list of coordinates is a relatively straightforward task for a small number of photographs, but it becomes highly time-consuming and prone to errors when dealing with a large volume of images, as often encountered in real surveys. Thus, the developed algorithm is essential for the SFM phase, as it enables the automatic and high-quality generation of a comprehensive list of GCP coordinates in each image (Marcelino et al., 2022). The algorithm is freely accessible on the GitHub (t.ly/EhGIQ - in the console version) and on the web interface for server installations, found at (t.ly/quv7U). The platform provides the source code, installation instructions, and a practical application example.

3 CASE STUDY

3.1 Description of Lapa Dam

Lapa is an embankment dam with a maximum height of 24 m and a crest level at 174.0 m, as presented in Figure 1. The full reservoir level (FRL) is set at 170.0 m, while the Maximum Flood level (MFL) is positioned at 171.92 m and the dead storage level (dSl) is located at 162.2 m. The reservoir has a relatively modest volume (0.64 hm^3), and a flooded area of 9.5 ha. The upstream and downstream slopes exhibit ratios of 1:3.25 (V:H) and 1:2.5 (V:H), respectively. Additionally, the downstream slope incorporates a 2.5 m wide bench, positioned at 164.0 m.

3.2 UAV surveys carried out

Two UAV surveys of the Lapa dam were conducted in 2021 (Figure 1) and in 2022 (Figure 2). GCP were employed in both surveys, and in 2022, the GCP finder algorithm was used for their automatic detection.

Figure 1. Textured model of the Lapa dam, survey of 2021.

Figure 2. Textured model of Lapa dam and UAV positions, survey of 2022.

Figure 3 presents an image derived from the 2022 orthophoto, showcasing two different types of GCP: one traditional and one with a QR Code (Aruco marker). These GCPs are automatically identified by the GCP Finder and immediately classified, as the pattern of each GCP corresponds to its assigned number. For example, in the figure, the visible GCPs are numbered 3 and 11 (https://chev.me/arucogen/).

Figure 3. View of GCP – Aruco marker nº 3 and nº 11.

The disparity in the crest between the two surveys was assessed using point cloud visualization tools and algorithms (Figure 5). According to the figure, settlements occur at the base of the dam downstream and in the spillway channel.

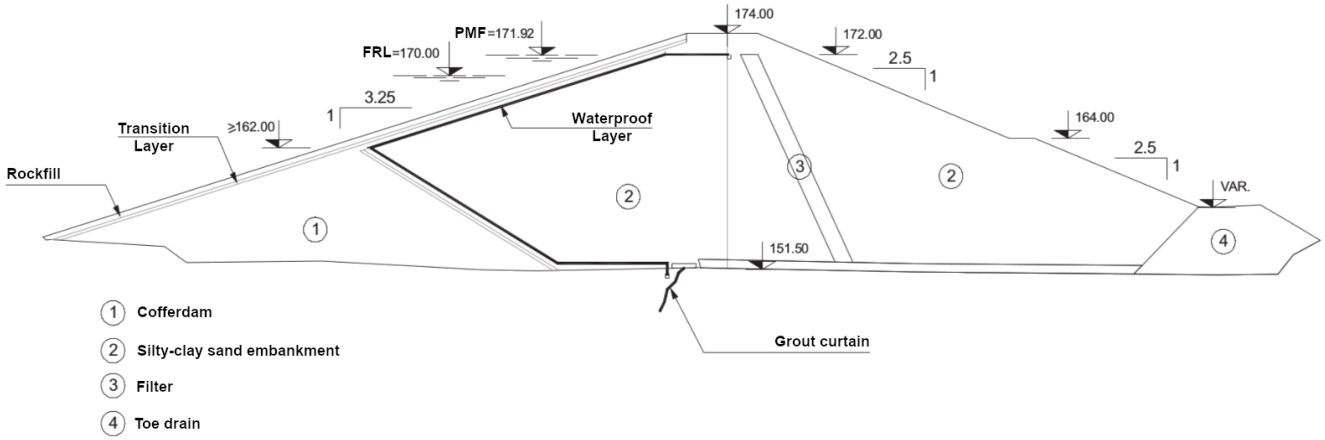

Figure 4. Cross-section of the Lapa dam.

Occasionally, there are also some movements on the downstream face, but these cases may correspond to errors due to deforestation (partial in 2021 and total in 2022). In the case of settlements in the spillway channel, it is necessary to take into account that the visualization of this area is less precise due to its geometry, so the displacement values obtained from the survey will be less accurate.

Figure 5. Settlements increments (2021-2022) in Lapa dam obtained by photogrammetric processing of high-resolution UAV images

4 CONCLUSIONS

The use of UAVs to support visual inspections of geotechnical structures has been increasingly significant, driven either by cost reduction or the development of more efficient post-processing software.

The quality of surveys and models obtained through post-processing depends heavily on various factors, such as the quality of the optics, image resolution, ambient light during photography, and also the existence of reference points with known coordinates that allow correction of the reconstructed model.

This paper outlines the development of an important tool designed to automate the identification of GCP in photographs derived from photogrammetric surveys. This tool was developed as part of a master's thesis at Universidade Nova de Lisboa, under the guidance of LNEC, is now accessible to any user under an open-source license, allowing unrestricted use.

In further developments, GCPs could incorporate GPS positioning modules, eliminating the necessity for individual position determination. Instead, these targets could communicate with each other, transmitting their positions to a centralized server for data consolidation.

The use of vane shear tests in granular materials for shear strength measurement

Utilisation d'essais de cisaillement à palettes dans des matériaux granulaires pour la mesure de la résistance au cisaillement

J. Meng, J. Laue*
Department of Civil, Environmental and Natural Resources Engineering, Luleå University of Technology, Luleå, Sweden
**jan.laue@ltu.se*

ABSTRACT: The field vane shear test offers a convenient way for assessing the undrained shear strength of fine soils. However, various factors, including the rotation rate, vane insertion disturbances, vane shape, soils' organic content and strength anisotropy, can affect the test results. Its application is largely limited to clays, and its suitability for other granular materials like tailings is questionable. Nonetheless, due to its simplicity and ease of use, ongoing theoretical developments and increased data reporting for other granular materials have become available. In the author's opinion, reviewing and summarising recent developments in the vane shear test for granular materials can help interested readers to find out the relevant papers on a specific topic and aid engineers in interpreting the available measured results.

RÉSUMÉ: L'essai de cisaillement à la girouette offre un moyen pratique d'évaluer la résistance au cisaillement non drainé des sols fins. Cependant, divers facteurs, notamment le taux de rotation, les perturbations d'insertion des aubes, la forme des aubes, la teneur en matières organiques du sol et l'anisotropie de résistance, peuvent affecter les résultats des tests. Son application est largement limitée aux argiles et son adéquation à d'autres matériaux granulaires comme les résidus est discutable. Néanmoins, en raison de sa simplicité et de sa facilité d'utilisation, des développements théoriques en cours et une augmentation des rapports de données pour d'autres matériaux granulaires sont devenus disponibles. De l'avis de l'auteur, passer en revue et résumer les développements récents dans l'essai de cisaillement aubes pour les matériaux granulaires peut aider les lecteurs intéressés à trouver les articles pertinents sur un sujet spécifique et aider les ingénieurs à interpréter les résultats mesurés disponibles.

Keywords: Vane shear tests; shear strength; field tests.

1 INTRODUCTION

The vane shear test is a commonly used field method for testing undrained shear strength. While sampling disturbance effects are avoided, the vane insertion causes excess pore pressure and changes the original stress conditions. Moreover, research has identified several factors that impact the test results: failure modes (Flaate, 1966), rotation rate (Sharifounnasab and Ullrich, 1985), anisotropy (Silvestri and Aubertin, 1988), waiting time (Watson et al., 2000) and organic content (Andersland et al., 1980). Nevertheless, despite these concerns, the vane shear test remains a common choice for geotechnical site investigations.

While its validity in clays is well recognized, recent studies have also applied the vane shear test to other granular materials, such as tailings (Reid, 2016), organic mud (Schlue et al., 2010) and Peat (Landva, 1980), and even to measure the friction angle of sands (Park et al., 2018). Furthermore, the vane device has seen development with new vane shapes and measurement systems and automation.

In this study, we will review the use of vane shear tests in granular materials for shear strength. Specifically, we will examine the main factors that influence test results and explore recent advancements in both theory and hardware related to this testing method. The objective is to help to assess its result reliability by considering its test conditions and assumptions and to encourage its further developments for broader applications in geotechnical field investigations.

2 FACTORS INFLUENCING THE TEST RESULTS

The principle of the vane shear test is described briefly in Figure 1. It assumes a cylindrical failure surface around the vane's perimeter, with uniform shear stress

along this surface. The torque necessary to rotate the vane under undrained conditions is measured to calculate the shear strength (ASTM, 2008). While the concept is straightforward, assumptions are made to interpret the results and reviewed here.

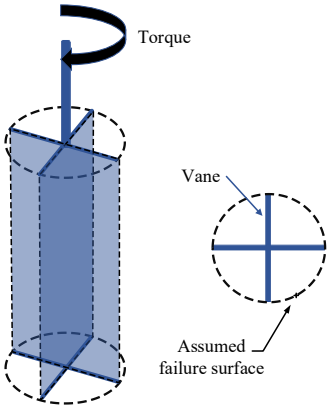

Figure 1. Sketch of the vane shear test.

2.1 Failure modes

Gylland et al. (2012) have performed experimental and numerical studies on soft sensitive clay finding the rounded square failure surfaces instead of the previously assumed circular shape. Numerical studies, employing a Eulerian approach is used to model the large deformation of clays, further supported these findings (Kundu et al., 2021, Shen et al., 2023). The circular failure shape is finally formed after peak torque with a large rotation. This implies a underestimation of 6-7% when using the assumed circular failure surface (Gylland et al., 2013).

Progressive failure in sensitive clay is another critical concern regarding the reliability of results given that the materials is assumed to reach their shear strength simultaneously. The finite element model is developed using an elasto-plastic constitutive law with strain-softening (De Alencar et al., 1988). The numerical results show the strength is mobilised non-uniformly and the stress is not uniform at peak torque.

2.2 Soil disturbance by vane insertion

The insertion of a vane into soils causes soil fabric disturbance and strength degradation (Chandler, 1988). The effect of vane insertion on the measured undrained strength exhibits a positive correlation with soil sensitivity and is also influenced by vane geometry factors. Moreover, experimental studies show that even a very slow vane insertion can generate high excess pore pressure (Kimura and Saitoh, 1983). As pore pressure dissipates, the consolidation can enhance the strength. To ensure fully undrained conditions, a delay time of no longer than 1 minute is advised to be used (Wilson et al., 2016).

2.3 Rotation rate

The measured shear strength is affected by the rotation rate due to the interplay of two conflicting factors: drainage and soil viscosity effects. The effect varies depending on soils' properties and test conditions, resulting into not unique relationship between the shear strength and rotation rate. Numerous experimental studies have been conducted on this effect such as in (Sharifounnasab and Ullrich, 1985, Peuchen and Mayne, 2007). A conceptional chart is proposed to illustrate this effect in (Quinn and Brown, 2011), defining mechanical responses of soils in four zones across a wide range of rotation rates.

2.4 Correction factor

After obtaining field vane shear strength data, it is important to correct the measured value before practical use. A correction factor is normally used as follows (ASTM, 2008):

$$\tau_u = \mu(S_u)_{fv} \quad (1)$$

where μ is the empirical correction factor, and its value depends on test conditions and soil parameters such as plasticity index (PI) and liquid limit (w_L). While many choose plasticity index based correction factors (Bjerrum, 1972, Chandler, 1988), the Swedish Geotechnical Institute recommends a correction factor based on the liquid limit (Larsson et al., 1984):

$$\mu = \left(\frac{0.43}{w_L}\right)^{0.45} \quad (2)$$

Recently, vane shear testing has been conducted to determine correction factors. For example, the values are presented for Swedish fine-grained sulphide soils (Westerberg et al., 2015), harbor mud with an emphasis on the rotation rate effect (Schlue et al., 2010) and certain fine-grained soils based on the liquidity index (Kayabali et al., 2015).

3 VANE SHEAR TESTS IN VARIOUS GRANULAR MATERIALS

While the vane shear test is usually used to measure the strength of clays, research has been conducted to explored its potential for being used in other granular materials. Typical examples include but are not limit to peat and organic soil (Andersland et al., 1980, Landva, 1980, Schlue et al., 2010, Boylan et al., 2011, Boylan and Long, 2014), silty soils (Long et al., 2010, Reid, 2016, Jana and Stuedlein, 2022) and even snow (Diamond and Hansen, 1956, Domine et al., 2011).

When applying the vane shear tests on intermediate permeability soils, partial drainage can occur at the standard rotation rate. Blight (1968) developed a model, validated with experimental data, that is widely accepted for practical applications in estimating drainage conditions (Chandler, 1988). Its pore pressure assumption for vane insertion is later corrected in a revision model (Morris and Williams, 2000). Recently, a theoretical model is developed for assessing partial drainage effects (Forcelini et al., 2020), drawing from the poromechanical theory of consolidation induced by the vane shearing process (Dienstmann et al., 2018). The model allows for the quantification of the rotation rate effect, enabling the prediction of undrained shear strength at standard rotation rate.

There are also a few studies on the application of vane shear tests in coarse granular materials (Park et al., 2016, Park et al., 2018). Laboratory vane tests are performed in sands, in which the torque and horizontal stresses are used to calculate the friction angle.

4 DEVICE DEVELOPMENT

The vane shear device has also seen further developments to enhance its usability. Changing the vane blade shape is likely the most straightforward concept to consider. Silvestri et al. (1993) proposed eighteen vane blade configurations including rectangular, rhomboidal, triangular and elliptic shapes. A so-called advanced vane shear test system is developed that can measure torque underground, directly above the vane, to minimize errors associated with rod friction (Peuchen and Mayne, 2007, Selänpää et al., 2017). Most recently, an automated vane shear tool is integrated into an unmanned ground vehicle for remote field tests, aiming to lower cost and reduce risks to workers (Olmedo et al., 2020).

5 CONCLUSIONS

The field vane shear test is a commonly used tool for testing the undrained shear strength of clays, relying on certain assumptions. There have been numerous studies on the use of vane shear test in granular materials involving field tests, numerical simulations, analytical equations, and device developments in the literature. These studies collectively enhance our understanding of the test's underlying assumptions, aiming for higher result accuracy and expand its applicability to a broader range of granular materials.

ABSTRACT: This paper presents a comprehensive seismic assessment of an existing building subject to induced seismicity in the Groningen region, a location with unique geological characteristics that pose significant safety concerns for building occupants. To assess the seismic response of the building more accurately, we incorporate non-linear dynamic soil-structure interaction (DSSI) through response-history analysis using a finite element global model. Our study demonstrates the importance of accounting for non-linear soil-structure interaction in the seismic assessment of combinations of rigid buildings and soft soils and highlights the need for more comprehensive approaches to building safety in such regions. We also show that the use of a holistic dynamic soil-structure interaction performance-based approach can improve the reliability of seismic assessments for existing structures and ensure cost-effective retrofit solutions with quantifiable levels of performance. Our results have important implications for building design and safety in the Groningen region and contribute to the broader field of seismic engineering by improving the understanding of the complex interactions between buildings and soil.

RÉSUMÉ: Cet article présente une évaluation sismique complète d'un bâtiment existant soumis à une sismicité induite dans la région de Groningen, un endroit présentant des caractéristiques géologiques particulières qui posent d'importants problèmes de sécurité pour les occupants du bâtiment. Pour évaluer plus précisément la réponse sismique du bâtiment, nous incorporons l'interaction dynamique no linéaire sol-structure (DSSI) par le biais d'une analyse temporelle à l'aide d'un modèle global à éléments finis. Notre étude démontre l'importance de la prise en compte de l'interaction non linéaire sol-structure dans l'évaluation sismique des combinaisons de bâtiments rigides et de sols mous et met en évidence la nécessité d'approches plus globales de la sécurité des bâtiments dans ces régions. Nous montrons également que l'utilisation d'une approche holistique de l'interaction dynamique sol-structure basée sur la performance peut améliorer la fiabilité des évaluations sismiques pour les structures existantes et garantir des solutions de réhabilitation économiques avec des niveaux de performance quantifiables. Nos résultats ont des implications importantes pour la conception et la sécurité des bâtiments dans la région de Groningen et contribuent au domaine plus large de l'ingénierie sismique en améliorant la compréhension des interactions complexes entre les bâtiments et le sol.

Keywords: Existing building; non-linear dynamic soil-structure interaction; performance based seismic design.

1 INTRODUCTION

Dynamic soil-structure interaction (DSSI) occurs when a structure and the soil on which it is founded interact during a dynamic event such as an earthquake. In the last decades, there is increasing evidence in literature that this interaction may induce unavoidably nonlinearities both in the soil around the foundation and at the soil-foundation interface (Kutter et al., 2003, Pecker et al., 2012, Gazetas, 2015). This fact, especially when we talk about rigid structures on soft soils, requires design engineers to include these nonlinearities in their analyses.

Traditional substructuring techniques rely on the superposition theorem (Kausel et al., 1978) and, consequently, are limited to linear elastic or viscoelastic domain. They can account for some nonlinearities, in particular those related to the

propagation of the seismic waves (equivalent linear soil behavior), but there is no possibility to introduce the nonlinearities specifically arising from DSSI.

This calls for other techniques, allowing nonlinearities to be captured in the vicinity of the foundation. A practical way to include them is the use of the direct approach through a 3D nonlinear finite element global model, which allows you to analyze in a single step the complete soil-foundation-structure system. These models can capture different nonlinearities in the structure and in the soil as long as the soil, the structure and the soil-structure interfaces are modeled appropriately.

Finite-element analysis programs such as LS-DYNA® (ANSYS, 2023) offer an integrated environment for complete soil-structure system analysis which enables the study in a single model of all the energy dissipation phenomena that take place in a seismic event.

This paper presents the case study of the dr. Aletta Jacobs College in Hoogezand, a village 10 km southeast of Groningen, sitting on soft soil and how different nonlinear mechanisms in the soil-foundation interface are activated during the analysis, leading to a more realistic seismic response characterization.

2 ANALYSIS APPROACH AND SEISMIC MODELLING

A wide range of analysis approaches, with differing degrees of reliability and conservatism, are available to the earthquake engineer. State of the art approaches to assess the seismic performance of structures use response history analysis, which requires solving the equation of motion at each time step for the structure (and soil) when excited by a ground-motion time series. Thanks to the improvement in the computational capabilities of cloud computing, advanced numerical dynamic simulations are catching on as an alternative approach to conventional approaches, eliminating the need for unrealistic simplifications.

A nonlinear response history analysis is thus carried out to assess the seismic performance of the system. The following sections describe the modelling strategy adopted to model all the elements necessary for conducting this type of analysis.

2.1 Bedrock motions development

The first step is to develop a suite of ground motion time histories representative of a sufficiently stiff layer beneath the surface where nonlinearities due to earthquake wave propagation are considered to be limited. It was defined in this case as a soil layer with a shear wave velocity equal to 300 m/s. The depth at which this layer appears is referred to as the reference depth and corresponds to 20 m below ground level.

This procedure involved selection and spectral matching of seed records to a target acceleration response spectrum at the reference depth, developed through a site-specific probabilistic seismic hazard assessment (PSHA).

A suite of eleven 2475-year input motions was applied at the base of the soil block underlying the structure.

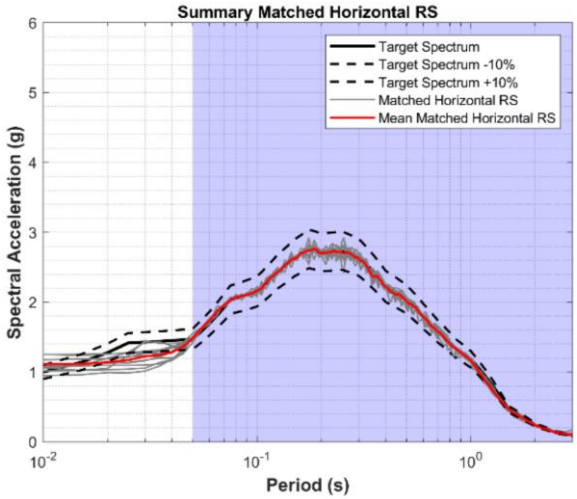

Figure 1. Horizontal spectrally matched components of the 11 earthquake acceleration time signals.

2.2 3D soil domain definition

Since the shallow soil layers in the Groningen region are typically soft and relatively weak, the response of the soil when subjected to significant earthquake shaking in performance-based analysis can be highly non-linear. Soil was modelled with 3D solid elements using a nested bounding surface plasticity model, which is suitable to reproduce the hysteretic, nonlinear behaviour of soils. At a minimum, it requires: density, bulk modulus, Poisson's ratio and a backbone curve of shear strain versus shear stress. These curves were derived using site-specific soil information and a shear strength matching routine at large strains using the hyperbolic fitting procedure provided in Groholski et al., 2016. The model follows the extended unload-reload Masing rules (Masing, 1926) to reproduce hysteretic behaviour.

In the near field domain (i.e., soil zone where localized shear induced nonlinearities due to soil-structure interaction are concentrated), the mesh was refined enough to explicitly capture local soil-foundation flexibility, bearing failure for shallow foundations, soil yielding and geometrical nonlinearities.

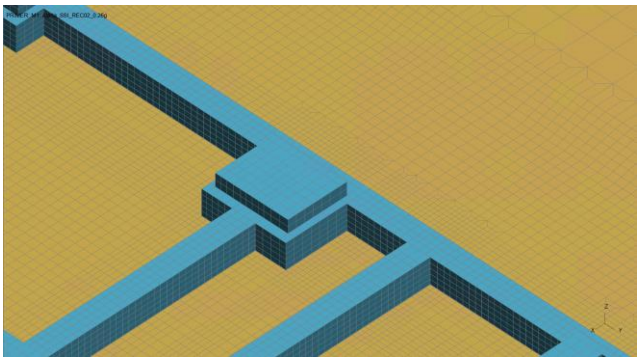

Figure 2. Soil mesh refinement in the vicinity of shallow foundations.

However, for piles, this would increase the computational cost of the model dramatically and thus, the interaction between the soil and the pile elements is modelled using nonlinear springs (see section 2.5).

2.3 Above-grade structure definition

The building is a 3 storey school (dimension in plan is about 80x66m) with a fully concrete structure, where some elements are cast in situ while others are precast, like columns and part of the floor system. The lateral stability system (mainly conceived for wind loads) consists of concrete shear walls located in 4 areas of the building, in both the principal directions. Finally, within the building, some steel structures are present (mezanine floor and staircases) together with several masonry non load bearing walls.

A detailed model of the structure was created (figure 3) to perform the as-built seismic assessment and to develop proposals for the seismic strengthening. In this case, the main retrofit measure was to add circular hollow steel bracings in some locations along the internal and external facade with an inverted V-shape layout. The upgraded building was also assessed to ensure this retrofit could effectively provide seismic stability and meet the target performance objective.

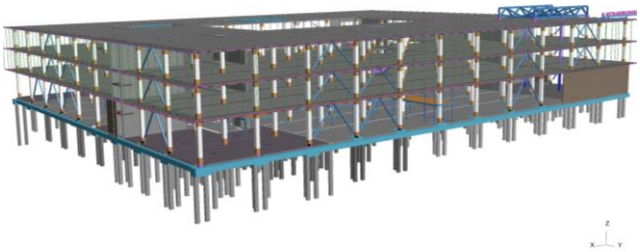

Figure 3. Building perspective view.

2.4 Below-grade structures definition

Foundation pads and beams are supported on groups of 1-to-4 piles, transferring the loads to a stiffer deeper sandy layer. Pads and beams are modelled using 3D solid elements.

1D beam elements are used to define the piles. These are 0.55m diameter concrete piles ranging from 3.5 to 7.5 m in length. A lumped-plasticity material model is used, which is able to capture axial-bending and axial-shear interaction.

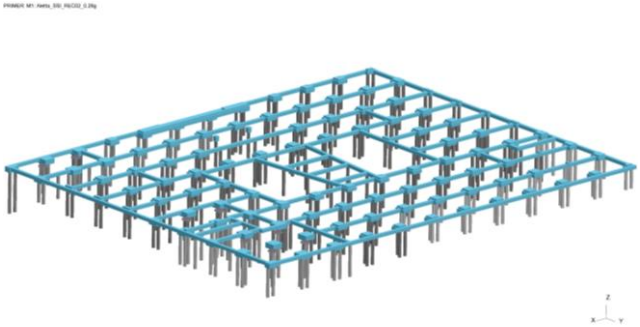

Figure 4. Foundation layout. Shallow and deep elements.

2.5 Soil-structure interfaces

Special attention was paid to the soil-structure interface modelling strategy. Different techniques, which are situation-dependent, can be applied.

The interaction between the footings and the soil is modelled using zero-thickness contact elements that allow relative shear displacements (sliding) and separation between the soil and foundation (gapping). Moreover, this does not require congruous meshes, allowing on each side of the contact different size of elements on the soil and on the foundation. The tangential behaviour of these contacts adopts a classical Coulomb model where the tangential frictional stress is taken proportional to the normal stress. A penalty algorithm is adopted for the contact behavior.

The soil-pile interaction, in place of using any joint element strategy to model the interface, uses a penalty-based coupling between the 1D beam elements (piles) and 3D solid elements (soil). The nodes of the 1D element are rigidly connected to a ring of nodes situated at the true diameter of the pile.

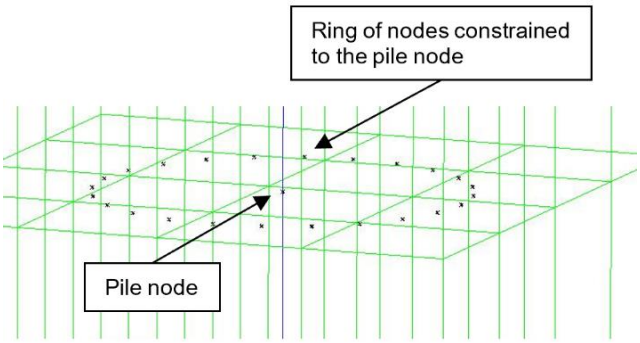

Figure 5. Pile nodes and surrounding soil elements.

These are constrained to the pile node translationally and rotationally. For each node in the ring of nodes, a new initially coincident "point" is created that will be constrained to move with the soil element within which it lies. The pile and soil move independently of each other during the analysis, so the new points (fixed within the soil element) will no longer be coincident with the nodes in the ring (figure 6). The difference in displacement between the pile node and the new point controls the stress on the soil/pile interface. Forces (equal to stress times area) are applied to the pile node and reacted onto the nodes of the soil element.

These nodes are attached to the soil mesh through nonlinear springs that are previously calibrated through separate soil-structure interaction analyses to obtain the desired lateral (p-y), skin friction (t-z) and end bearing (Q-z) behaviour.

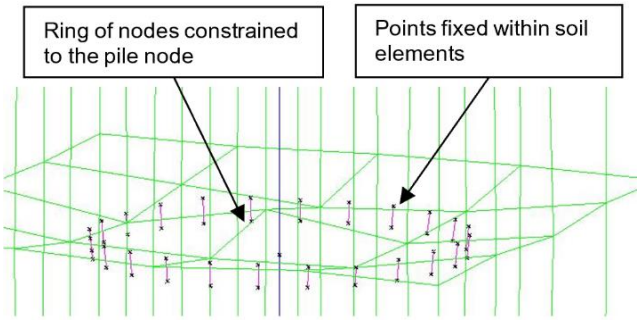

Figure 6. Ring of nodes and the new soil-constrained nodes.

The load on the base of the pile is spread over the pile area. The number and positions of points on the base was automatically defined by the software, with a spacing roughly equal to the spacing of points around the outer circumference.

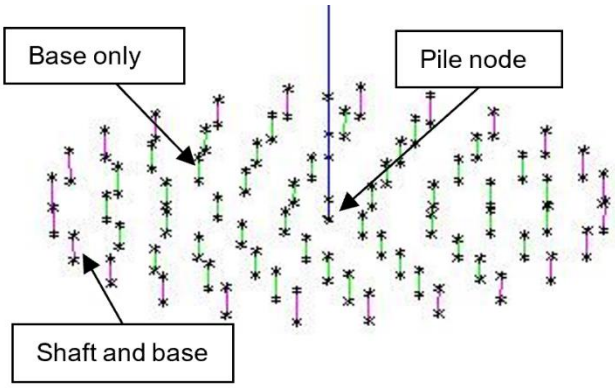

Figure 7. Base points created at the toe pile node level.

2.6 Boundary conditions

When using a global FE model, one of the cautions to be taken is that the boundaries used do not introduce spurious reflections in the model that may alter the results of the simulations.

For this purpose, we included absorbing boundaries (Lysmer dampers) at the base of the soil block. Lateral boundary nodes are tied together without relative movement and are located more than four times the distance from the surface to the reference depth away. This approach mitigates boundary effects at the edges and thus, avoids the need of transmitting boundaries at the lateral sides of the model.

3 NONLINEAR DSSI MECHANISMS

Due to the direct modelling approach of the nonlinear soil-structure interaction described in the previous section, all these sources of nonlinearities at the foundation level were included in the response of the system: soil (and structural) yielding, sliding and gapping of foundations. In the following, we give evidence of such mechanisms.

3.1 Residual displacements

At the end of the time history application, part of the deformation is not recovered, giving rise to residual displacements in the foundation. Figure 8 shows the horizontal displacement time histories of all pile heads, indicating that piles and surrounding soil undergo plastic deformations during the earthquake.

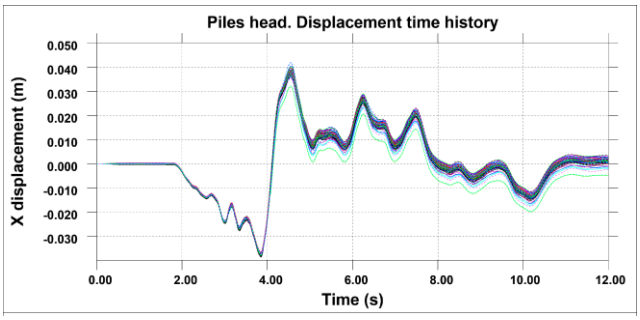

Figure 8. Residual foundation X displacements: pile heads.

3.2 Sliding and gapping of shallow foundations

Relative displacement between foundation elements and soil is the main geometric nonlinearity occurring at the foundation level. It can take place without losing contact between the soil-foundation system (sliding) or with separation of the two surfaces (gapping). Therefore, two nodes near each other, one in each element, may not show the same history of displacements.

3.2.1 Sliding

An important sliding occurs between the soil layer and the foundation pads and beams close to the areas where the concrete shear walls are concentrated. Due to the important shear loads attracted by the shear walls, the piles in these zones fail in shear at 4.2s, causing the pads and beams to work only as shallow foundations. This conservative design assumption increases vertical and differential settlements of these shallow elements, but it doesn't lead the building to collapse because foundation beams and pads are able to support the structure after the pile failure (with additional settlement). This unusual situation allows us to check the capacity of the soil-foundation interface to develop a nonlinear response. Figure 9 shows the Y displacement of the foundation element and the soil, showing the relative displacement between two nodes initially in contact.

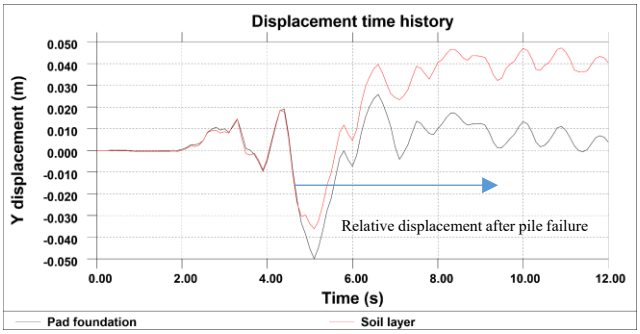

Figure 9. Sliding at the "new" shallow foundations.

3.2.2 Gapping

Another complex phenomenon known to be a potential source of energy dissipation is gapping, allowed between the soil and the foundation beams. In the same areas, concrete walls move almost as rigid blocks (sliding and rocking), deforming the soil around them. This induces high horizontal forces to soil embedding the footings and plastic deformations occur. Having defined a tensionless interface, lateral soil cannot follow the foundation movement and detachment occurs.

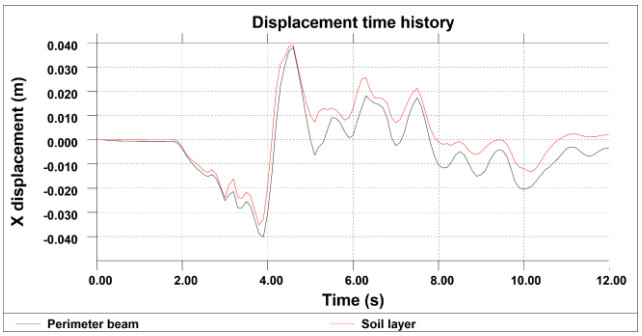

Figure 10. Gapping at perimeter foundation beam.

In addition, it is also noted how the distance between soil and foundation slightly increases over time, suggesting a progressive yielding of the embedding soil.

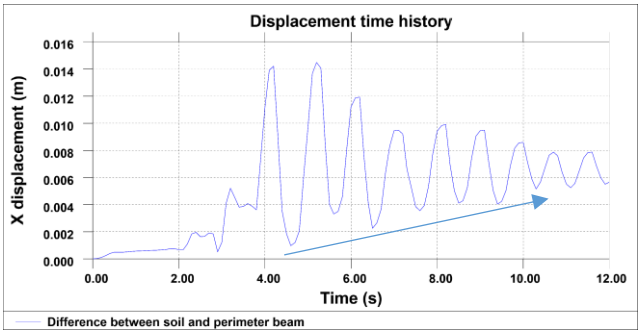

Figure 11. Differential horizontal displacement.

4 CONCLUSIONS

A case study where the nonlinear soil-structure interaction has been modeled explicitly in a global FE model is presented. Key results proving the existence of nonlinear mechanisms in the foundation-soil interface are also shown.

The paper aims to show that for a comprehensive and integrated performance-based oriented seismic design approach of rigid buildings on soft soils, in addition to the structural nonlinear behavior, we must consider that the foundation participates in the energy dissipation process during earthquake loading. This helps to achieve a more realistic seismic behavior of

this type of buildings, including explicitly in the system response the geometrical and material nonlinearities developed in the near field.

In addition to a more accurate representation of seismic response, there is mounting analytical and experimental evidence that material and geometric nonlinearities in the soil and soil-foundation interface may play a beneficial role (Gajan and Kutter, 2008, Anastasopoulos et al., 2010, Liu et al., 2013, Gazetas et al., 2014, Sakellariadis et al. 2021) boosting its inclusion in the design phases of structures. The effort in modeling these phenomena could be thus justified, for the sake of designing more cost-effective structures and enhancing resilience.

ACKNOWLEDGEMENTS

The authors would like to acknowledge colleagues at Arup who participated in the project described in this paper, especially Paolo Fici who also contributed to the preparation of Section 2. We would also like to thank our client Nationaal Coördinator Groningen (NCG) for the opportunity to work on this project.

ABSTRACT: Given the catastrophic accidents seen in the last decade at tailings storage facilities (TSF's), there is a growing consensus that a better understanding of the behaviour of these structures is needed including different approaches to analyse their stability. In that sense, the use of numerical tools allowing coupled hydromechanical stress-strain analysis has been encouraged. This paper presents the results of PLAXIS 2D® numerical analysis conducted on a simple slope where the water head was increased in the upstream boundary and a seepage flow was established. A parametric study was developed for different slope heights, water heights, and soil permeability, where the minimum time required for a steady-state seepage flow stabilization was identified. A mathematical formulation is proposed that relates the normalized water height, the soil permeability, and the steady-state time.

RÉSUMÉ: Compte tenu des accidents catastrophiques observés au cours de la dernière décennie dans les installations de stockage de résidus (TSF), il existe un consensus croissant selon lequel une meilleure compréhension du comportement de ces structures est nécessaire, notamment différentes approches pour analyser leur stabilité. En ce sens, l'utilisation d'outils numériques permettant une analyse couplée hydromécanique contrainte-déformation est nécessaire. Cet article présente les résultats de l'analyse numérique PLAXIS 2D® menée sur une pente simple où la hauteur d'eau a été augmentée dans la frontière amont et un écoulement d'infiltration a été établi. Une étude paramétrique a été développée pour différentes hauteurs de pente, hauteurs d'eau et permeabilité du sol, où le temps minimum requis pour une stabilisation à l'état stable d'un écoulement d'infiltration à travers la pente a été identifié. Une formulation mathématique est proposée qui relie la hauteur d'eau normalisée, la perméabilité du sol et le temps d'équilibre.

Keywords: Tailings; PLAXIS 2D®; liquefaction; seepage flow; permeability.

1 INTRODUCTION

Advances in mining technology allowed the exploitation of lower-quality deposits, leading to the generation of more tailings, the discarded material after ore extraction. This has created an increasing pressure on tailings storage facilities which need to be larger in a shorter time. Moreover, the rupture of these structures often involves the release of material downstream, with catastrophic consequences for populations, the environment, and the economy. The triggering causes of failure in these structures are numerous which can be summarized in the following: the existence of defects in the structure, problems in the foundation, unusual weather events, seismic events, overtopping, subsidence, and lack of maintenance during operation and after its closure.

The analysis of several case studies identified static liquefaction and cyclic liquefaction in most cases (Mánica et al., 2022). In practice, static liquefaction phenomena occur much less frequently than cyclic liquefaction phenomena, but their effects are generally much more serious.

The term liquefaction, which was originally created by Mogami and Kubo (1953), has historically been used with a variety of phenomena involving soil deformations caused by monotonic, transient, or repeated disturbances of saturated, cohesionless soils under undrained conditions. The generation of excess pore pressures under undrained loading conditions is common to all liquefaction phenomena. When cohesionless soils are saturated, however, rapid loading occurs under undrained conditions, so that the

tendency toward densification causes excess pore pressure to increase and effective stresses to decrease.

Ledesma et al. (2022) presented a procedure to assess the vulnerability of a tailings dam due to flow liquefaction. The procedure required the development of a numerical model with the complete definition of the contour boundaries of the dam under study, where the tailings had to be modeled using a constitutive model capable of capturing the onset of liquefaction and the subsequent loss of strength for complex stress values and the ability to change from drained to undrained loading or fully coupled flow deformation loading without changing material parameters.

This requires a thorough characterization of the tailing material for the proper identification of critical state and instability locus (Viana da Fonseca and Cordeiro, 2022) as well as the influence of stress induced anisotropy (Viana da Fonseca et al., 2023). Delgado et al. (2023) highlighted that this geomechanical characterization needs to be performed up to high stress levels to simulate the stress state at the bottom of large embankments. In some cases, the embankments need to be reinforced with cemented berms (Meneses et al., 2023) where more sustainable binders may be used (Caetano et al., 2023).

This paper aims to summarize the main conclusions drawn from a parametric study with hydromechanical stress-strain numerical analysis in tailings storage facilities to assess their stability with the progressive rise of water. For the analysis, the PLAXIS 2D® software and the Mohr-Coulomb constitutive model were used to evaluate which parameters influence the stability of the water flow. Subsequently, a correlation was established to determine the time necessary to promote a stable/permanent flow regime in tailings storage facilities (TSFs).

2 NUMERICAL ANALYSIS

2.1 Model geometry

In the developed study, two types of embankment sections were used. The first one consists of a 30º slope with a height of 35 m in the upstream boundary and 8 m in the downstream boundary. The second model has the same slope but twice the dimensions of the first one. A larger embankment was used to evaluate the effect of embankment dimensions on the steady-state seepage flow stabilization time. The geometry of the first model can be seen in Figure 1.

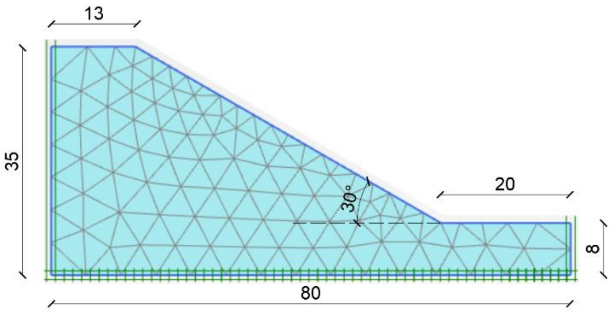

Figure 1. Geometry and dimensions of the first numerical model.

2.2 Material parameters

The constitutive model used was the linear elastic perfectly plastic Mohr-Coulomb model. The parameters for the material were determined through a significant set of monotonic compression triaxial tests, conducted in the Geotechnical Laboratory of FEUP (Table 1).

Table 1. Soil parameters (Mohr-Coulomb).

Parameter		Value	Unit
Unit weights	γ_{sat}	18.00	kN/m^3
	γ_{unsat}	20.00	kN/m^3
Initial void ratio	e	0.800	-
Young Modulus	E	44 000	kN/m^2
Poisson ratio	ν	0.30	-
Friction angle	ϕ'	33.40	º
Cohesion	c'	2	kN/m^2
Coef. earth pressure at rest	K_0	0.45	-
Permeability	k_x=k_y	10^{-5} *to* 10^{-8}	m/s

2.3 Mesh and boundary conditions

The PLAXIS® plane strain numerical model has finite elements with triangular 15-node elements. The generated mesh comprises 1493 nodes in 174 triangular elements.

In terms of mechanical boundary conditions, the bottom boundary was fixed in both directions, while the left and right boundaries were only fixed horizontally. As for hydraulic boundary conditions during the hydromechanical analysis, a constant head was imposed in the left boundary (which changes depending on the analysis), and on the right bottom border a null head was imposed to simulate downstream drainage.

The numerical analysis comprises two consecutive phases: i) an initial phase to activate the stress state (Gravity Loading); ii) a second stage where the hydraulic boundaries were activated and a hydromechanical numerical analysis (fully coupled flow-deformation analysis) was developed.

These analyses were repeated for the two model heights (H=35 m and 70 m), seven water heads on the left boundary (H_w=5m, 10m, 15m, 20m, 25m, 30m to 35m), four soil permeabilities (k=10^{-5}, 10^{-6}, 10^{-7}, and 10^{-8} m/s), and different seepage times (from a couple of months to several years). The seepage time is imposed as the time factor of the fully coupled flow-deformation analysis.

3 RESULTS

3.1 Identification of steady-state flow condition

For all the analyses where the stability of the embankment was assured, the maximum groundwater flow was recorded for each seepage time, water height, and soil permeability, as illustrated in Figure 2. Therefore, it was possible to plot the relation between water flow and seepage time. Figure 3 shows an example of such graph, where it's clear that after some time the seepage flow stabilises. The minimum time to the groundwater flow stabilization was considered the time to steady-state.

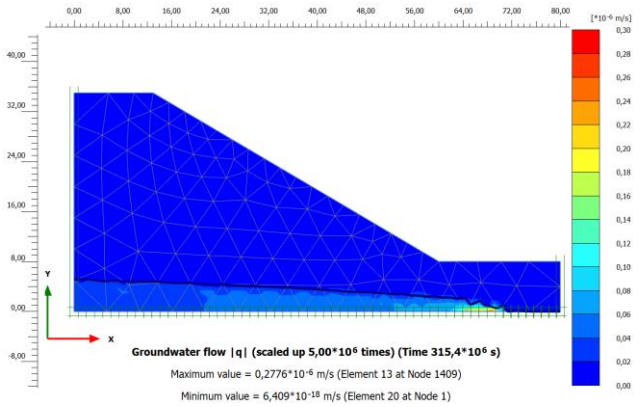

Figure 2. Groundwater flow (m/s) for the first embankment section, with Hw=5m, k=10-6 m/s and seepage time=10years.

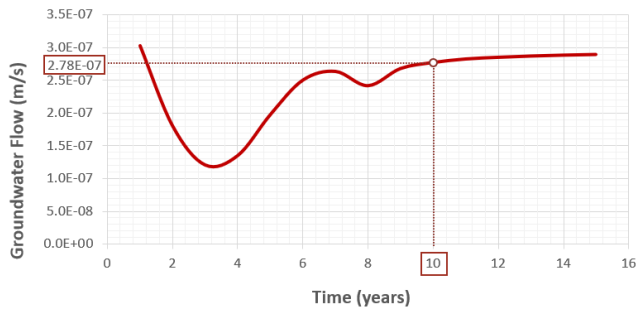

Figure 3. Groundwater flow recorded for each seepage time, and minimum flow time obtained (First embankment section with H_w=5m and k=10^{-6} m/s).

For water heights of 25m, 30m, and 35m in the first embankment section of 35 m, and for water heights of 50m, 60m, and 70m in the second model of 70 m, the slope collapsed without groundwater flow stabilization.

3.2 Results of the parametric study

To compare all the analyses performed in the two model geometries, the water weight was normalized by the slope height (H_w/H) leading to the following ratios: 0.143, 0.286, 0.429, and 0.571. Figure 4 presents the minimum flow time obtained for each height ratio (H_w/H), demonstrating that it does not change much with the height ratio but it varies significantly with soil permeability.

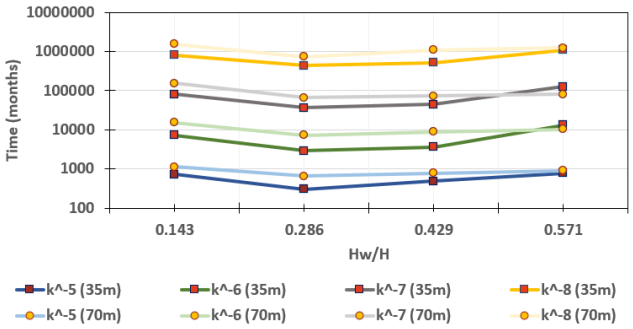

Figure 4. Minimum flow time for each height ratio (H_w/H) and soil permeability for the two model geometries.

3.3 Proposed interpretation model

Considering all the 32 data points obtained, a relation was pursued between the three variables: height ratio, soil permeability, and minimum flow time. Figure 5 shows the 3D graph obtained with the data points used for its generation. To improve the visualisation of the data, logarithms were applied to the two variables: soil permeability and minimum flow time. So, instead of a permeability of 10^{-5} m/s it only appears -5.

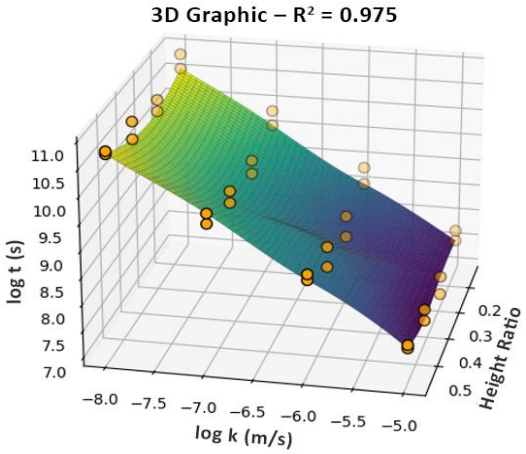

Figure 5. 3D Graphic, with the variables Time (log t (s)), Permeability (log k(m/s)), and Height Ratio.

After creating the 3D graph relating the three variables, a mathematical function that could represent that graph was formulated – equation (1)

$$t = a + b(\frac{H_w}{H}) + c(k) + d\left(\frac{H_w}{H}\right)^2 + e(k)^2 + f(\frac{H_w}{H})(k) \quad (1)$$

where t is the flow time, k is the soil permeability, H_w is the water height, H is the embankment height, and a, b, c, d, e, and f are correlation coefficients. For these later, the following values provided the best adjustment to the data points: a = 3.1639, b = -4.8535, c = -0.9772, d = 6.7779, e = 0.0038, f = -0.0116.

Including the coefficient values in equation (1) the following complete function was obtained, for which a correlation coefficient (R^2) of 0.975 was obtained:

$$t = 3.164 - 4.853(\frac{H_w}{H}) - 0.977(k) + 6.778\left(\frac{H_w}{H}\right)^2 + 0.004(k)^2 - 0{,}012(\frac{H_w}{H})(k) \quad (2)$$

4 CONCLUSIONS

A numerical study was performed to demonstrate the influence of soil permeability, embankment height, and water head on the minimum time for the stabilization of seepage flow. For this purpose, hydromechanical stress-strain numerical analysis were performed in PLAXIS 2D® with Mohr-Coulomb constitutive model. For higher water heads the slope was unstable, but for the other conditions, it was possible to identify the minimum flow time for each case. It was concluded that for a certain soil permeability (k) there is not much variation in the minimum flow time with the height ratio (ratio of water head by embankment height, H_W/H). The paper finishes with a mathematical expression to obtain the minimum flow time depending on the given variables (k and H_W/H).

Establishing the geotechnical category through analysis of difficult soils - a proposed procedure

Établissement de la catégorie géotechnique par l'analyse des sols difficiles - une procédure proposée

E. Milutinovici*, G. Dragomir, D. Mihailescu
Prospect Technical Studies, Bucharest, Romania

**emiliamilutinovici@gmail.com*

ABSTRACT: Establishing the geotechnical category for a site is an important result of the geotechnical investigation process. According to it, the design and execution characteristics are established, which directly influence the costs of a construction. The most influential factor in establishing the geotechnical category is the type of foundation ground, specifically if this is considered as difficult soil. The procedure developed in the paper involves the analysis of such difficult soils; thus, for each individual borehole, the type of difficult soils is established, based on the geotechnical properties determined by field and laboratory tests. Depending on the foundation solution, although the soils where the future construction is to be founded may be part of the category of difficult soils, it is possible that they will not negatively influence the way of execution or exploitation of the future construction. As a result, the score given to this risk factor can be reduced, thus reducing the final score for establishing the geotechnical category. This paper presents a detailed procedure to allow the standardization of setting the geotechnical category for several types of constructions and geological areas, intending to optimize the method of establishing the geotechnical category and the geotechnical risk.

RÉSUMÉ: L'établissement de la catégorie géotechnique d'un site est un résultat important du processus d'étude géotechnique. Selon lui, les caractéristiques de conception et d'exécution sont établies, ce qui influence directement les coûts d'une construction. Le facteur le plus influent dans l'établissement de la catégorie géotechnique est le type de sol de fondation, en particulier s'il est considéré comme un sol difficile. La procédure développée dans l'article implique l'analyse de ces sols difficiles; ainsi, pour chaque forage individuel, le type de sols difficiles est établi, sur la base des propriétés géotechniques déterminées par des essais sur le terrain et en laboratoire. Selon la solution de fondation, bien que les sols où la future construction doit être fondée puissent faire partie de la catégorie des sols difficiles, il est possible qu'ils n'influencent pas négativement le mode d'exécution ou d'exploitation de la future construction. En conséquence, la note attribuée à ce facteur de risque peut être réduite, réduisant ainsi la note finale pour l'établissement de la catégorie géotechnique. Cet article présente une procédure détaillée pour permettre la standardisation de la définition de la catégorie géotechnique pour plusieurs types de constructions et de zones géologiques, dans le but d'optimiser la méthode d'établissement de la catégorie géotechnique et du risque géotechnique.

Keywords: Difficult soils; geotechnical category.

1 INTRODUCTION

In recent years, Romania, with the help of the European cohesion fund, has invested heavily in road infrastructure. Thus, in order to complete and integrate into the structure of TEN-T (The Trans-European Transport Network), the competent state institutions have promoted and financed numerous road infrastructure projects: highways, express roads, road rings. For each of these projects, one of the most important steps in achieving a feasible design is the geotechnical study. In order to carry out the geotechnical study, the standards and technical norms are aligned with the European norms. However, there are typical conditioning according to the natural and engineering characteristics specific to Romania.

The main technical norm that establishes the way of carrying out geotechnical studies and interpreting the obtained data, is NP074 "Normative regarding technical documentation for constructions". In accordance with this technical norm, both geotechnical investigations and design are carried out according to the geotechnical category of the work established according to the criteria described in the norm.

2 LEGISLATIVE PROVISION

The geotechnical category is a notion that appears in geotechnical design standards and norms. In Eurocode 7, part 1, one of the principles stated is that "in order to establish minimum requirements regarding the volume and content of field research, calculations and control verifications, the complexity of each geotechnical design and the associated risks must be identified" (ASRO, 2008). The geotechnical categories in which geotechnical designs/works can fit are 3: category 1, 2 and 3.

In order to establish the geotechnical category, 5 criteria will be applied. These are: land conditions, groundwater, classification of buildings by importance, neighborhoods and seismic area. (MDLPA, 2023). For each criterion, a score is given according to its characteristics. The lower the score obtained after evaluating all the criteria, the lower the geotechnical category of the design/work, so the associated risks are fewer. Also, the higher the score awarded, the higher the geotechnical category and the associated risk is also considered major (MDRAP, 2014).

3 PRESENTATION OF METHOD

In calculating the geotechnical category, the criterion of ground conditions can have the greatest influence, due to the variation of the score from 1 point for good foundation soils to 6 points for difficult foundation soils. No other criterion is given such a high score as that given for difficult foundation soils. As a result, it becomes extremely important to classify as difficult foundation soils, to be done very carefully considering the design and financial implications.

The working method involves a detailed study of the conditions under which a ground can be considered being a difficult soil or not. As a result, the authors consider that the spliting into categories of terrain conditions must take into account both the classification of a land as an intrinsic characteristic in the category of difficult lands and the circumstantial characteristic that can make the award of the maximum score different. Thus, while for a certain constructive situation, the existence of a difficult soil within the foundation ground can be considered a difficult ground condition, for another constructive situation, the influence of the difficult soil is minimal, so the ground condition is no longer considered difficult and can be considered medium or good. The two characteristics that lead to the establishment of field conditions are, in the authors' view: a. the type of soil (foundation ground) and b. the type of interaction between foundation ground and construction (mainly type of foundation: shallow or pile foundation). It is necessary to study in parallel the both characteristics.

Road infrastructures such as motorways, expressways, bypass, ringsare mainly linear constructions, developed over long lengths and having complex objectives. Projects that are ongoing in Romania and subject to the procedure in this article can have lengths between 10 and 100 km. Such work can not only take place in areas where geology/geomorphology can change (hence the types of soil/foundation land), but also the construction characteristics of a road infrastructure can be very different.

3.1 Determining the type of difficult soil/foundation ground

In the category of difficult foundation soils / lands belong to the following types (MDLPA, 2023):
1-sandy soils, including loose silty soil. It is considered to be loose soils, those soils for which the results obtained from performing in situ investigations of the Standard Penetration Test type, have N30<9 values (ISPIF, 1988); 2-saturated sandy soils susceptible to liquefaction under seismic actions. They are considered to be liquefiable soils, those soils which constitute themselves as "extensive layers or thick lenses of loose sand, with or without silty or clayey particles, below the level of the groundwater, or where the level of the underground water is close to the surface of the land" (ASRO, 2006); 3-fine soils with consistency index CI<0.5, are those soils that fall into the category of soft plastic soils (ASRO, 2018); 4-sensitive soils (loess, loessoidic soils), are those soils whose structure and mechanical behavior change substantially and irreversibly in contact with water (MDRT, 2011); 5-soils with high swelling and contraction (expansive soils) , with high and very high activity are those clay soils active in relation to water, which have the property of significantly changing their volume as a result of moisture variation (MDRT, 2012); 6-soils with a high content of organic matter, are those soils formed relatively recently (as geological age) and which include organic matter, such as banks, silts, peatlands, gyttja and dy (ISPIF, 1988), (ASRO, 2018); 7-sloping lands with sliding potential, are those lands that have a hazard coefficient with values that show a medium or high landslide hazard, with a very high probability of landslides. (Guvernul Romaniei, 2003); 8-uncontrolled earth fillings less than 10 years old, are those lands that belong to the category of anthropogenic lands (ASRO, 2018) and which can be identified when crossing existing old roads or platforms, or crossing controlled or uncontrolled warehouses; 9-fillings from household

waste, regardless of age, belong to the category of anthropogenic lands, located near urban areas, having a controlled character, where the contours are clearly defined or uncontrolled, constituting illegal landfills, whose contours are undefined and not fully identifiable at the time of geotechnical investigations; 10-Freezing sensitive soils (difficult soil category mentioned in the 2014 version of NP074) are those soils that are sensitive to frost identified in the depth range between the land surface and the depth of freezing (ICPTT, 1990); (IRS, 1977).

The authors suggest the following methodology: a.for each geotechnical drilling performed, difficult soils are identified throughout its depth, thus classified according to the criteria mentioned above; b. based on the investigations carried out, the thickness of the identified layer is established, but also its extension in space, especially along the investigated linear structure, but also transversely, where they exist. In the case of infrastructure works carried out over long distances, most investigations are carried out axially, in longitudinal profile; c. It also identifies the depth at which difficult earth appears, as well as the depth at which it is no longer identified.

Thus, one by one, the types of soil encountered in geotechnical drilling (in each drilling performed) are analysed if they fall into the categories of difficult soils mentioned.

3.2 Establishing the type on interaction between the foundation soils/ground and the construction (foundation type)

In a very simplist way, the highways structures are divided in road structures and bridge structures. In functie de modul de realizare, road structures se impart in embankments, cuttings and mixt profiles. Depending on the foundation mode, bridge structures are direct (shallow) foundation or indirect (usually piles) foundation and the road structure are made in embankment, in cutting or in mixed profile.

In order to know the type of interaction with the foundation ground, the authors recommend dividing the studied route of the motorways into objects to be treated separately and unitarily. These can be: a. Indirect foundations structures (viaducts, bridges, overpasses); b. shallow foundations structures (viaducts, bridges, overpasses); c. Facilities, shallow foundation: administrative buildings, footbridges, lighting poles; d. directly founded road structures: highway/expressway body, parking lots, built in cutting conditions, in embankment conditions or in mixed profile conditions. Can be add as many objectifs are needed.

3.3 Concomitant analysis of the two criteria

For each type of difficult soil identified, the type of structure is also analyzed.

As an example, the situation of marlys soils can be considered a paradox. The same type of marly soil can be considered within a linear structure of highway/expressway type, as good foundation condition or difficult foundation condition.

When we consider the marlys soils as being at surface in the depth of moisture vatiation during the changing season, the marly soils are part of the category of difficult soils, because they significantly change their volume due to moisture variation. In this case the score for ground conditions is 6.

Thus, if a marly soil is identified in depth, as bedrock (almost incompressible, prequaternary) and is constituted as foundation ground for indirect foundations, the marly soils are part of the category of good or medium foundation ground conditions, the score granted being 2 points or 3 points. In the Table 1, the authors shows an example of how the dual character of marly soils as ground foundation condition can be interpreteted.

4 RESULTS

The results are expressed in tabular form, both for classification in the category of difficult lands and for establishing the geotechnical category.

Table 1. Exemplification of marly soil duality characterisation.

Criterion	**Hypothesis 1**	**Hypothesis 2**
Objective	Road structure in cutting area	bridge
Borehole no.	BH35	BH36
Depth interval (m)	3-30	3-30
Soil type	Marly clay	Marly clay
Foundation type	Direct (shallow)	Indirect (piles)
Foundation depth (m)	6.00	25.00
Soil category	3-difficult	2-medium
Soil subcategory	5	5
Score	6	3
Total score from other factors	10	10
Total score	16	13
Category of risk	high	medium

5 CONCLUSIONS

The paper aims to present a procedure for determining the land conditions for framing a design/construction in a geotechnical category and is based on practical engineering, taking into account Romanian standards and norms. It is intended to be constituted as a description of a way of practice in Romania.

In order to determine the geotechnical category, the most important criterion that influences the score awarded is ground conditions (type of soils). Although the standards and norms in force consider that ground conditions are defined only by the types of soils / foundation lands encountered (good, medium, difficult), the authors consider that besides this intrinsic feature, the circumstantial characteristic related to the interaction between the foundation earth / ground and the construction (type of foundation) must be taken into account.

The concomitant analysis of the two characteristics influences the correctness of scoring for the criterion of ground conditions, there being situations in which a foundation soil / land that can fall into the category of good or medium foundation soils, to enter the category of difficult soils, if the circumstantial characteristic is modified.

The transition from the overall study of the criterion of ground conditions to its detailed study, taking into account the type of soils but also the characteristics of the interaction between soils and construction, entails a higher precision in the classification in the geotechnical category, therefore an increase in the safety of the future construction.

ACKNOWLEDGEMENTS

The authors are grateful for possibilities to work in such a big geotechnical project with the unconditional support of Prospect Technical Studies and Search Corporation.

Numerical assessment of the ongoing settlements of the western tower of Terreiro do Paço, in Lisbon, Portugal

Évaluation numérique des affaissements en cours à la tour ouest de Terreiro do Paço, à Lisbonne, Portugal

L. Miranda*, J. Carreto
LNEC, Lisboa, Portugal

**lmiranda@lnec.pt*

ABSTRACT: The development of Terreiro do Paço Square began after the 1755 Lisbon earthquake, with the construction of the eastern side buildings. On the western side, an embankment had to be built first, in an area previously occupied by the river, overlying the existing soft soils. The western tower was constructed later, overlooking the Tagus River, and was not completed until the mid-nineteenth century. In 1941, a Portuguese historian reported that this tower had suffered a settlement of more than 0.5 m. Between 1956 and October 2019, the southeast and northeast corner's settlement increased by 0.15 m and 0.11 m, respectively. Interestingly, no damage was found on the external walls or the arched ceiling of the first storey, indicating a rigid body movement. More recently, the Lisbon Municipality sought to extend the Lisbon Museum by placing one of its modules in the newly vacant western tower. Using the finite elements approach and a three-dimensional numerical model, stress and strain studies were carried out with the purpose of analysing the effect of the rehabilitation works on its safety and functionality. Because of the period since the tower's completion and the permeability of the muddy soils in its foundation, a soft soil constitutive model with creep was used to simulate the ongoing settlements, with satisfactory results. This allowed for a more reliable prediction of future settlements caused by the tower's new usage.

RÉSUMÉ: Le développement de la place du Terreiro do Paço a commencé après le séisme de Lisbonne de 1755, avec la construction des bâtiments du côté est. Du côté ouest, il a fallu d'abord construire un remblai, dans une zone précédemment occupée par la rivière, sur les sols mous existants. La tour ouest a été construite plus tard, surplombant le Tage, et n'a été achevée qu'au milieu du XIXe siècle. En 1941, un historien portugais rapportait que cette tour avait subi un affaissement de plus de 0,5 m. Entre 1956 et octobre 2019, l'affaissement des coins sud-est et nord-est a augmenté respectivement de 0,15 m et 0,11 m. Il est intéressant de noter qu'aucun dommage a été constaté sur les murs extérieurs ou sur le plafond voûté du premier étage, ce qui indique un mouvement rigide du corps. Plus récemment, la Municipalité de Lisbonne a cherché à agrandir le musée de Lisbonne en plaçant un de ses modules dans la tour ouest nouvellement vacante. En utilisant l'approche des éléments finis et un modèle numérique tridimensionnel, des études de contraintes et de déformations ont été réalisées dans le but d'analyser l'effet des travaux de réhabilitation sur sa sécurité et sa fonctionnalité. En raison de la période écoulée depuis l'achèvement de la tour et de la perméabilité des sols boueux de ses fondations, un modèle constitutif de sol mou avec fluage a été utilisé pour simuler les affaissements en cours, avec des résultats satisfaisants. Cela a permis une prévision plus fiable des futurs affaissements provoqués par la nouvelle utilisation de la tour.

Keywords: Settlements; foundation; numerical modelling; historic building.

1 HISTORIC FRAMEWORK

The development of Terreiro do Paço Square began after the 1755 Lisbon earthquake, with the construction of the eastern side buildings. On the western side, an embankment had to be built first, in an area previously occupied by the river, overlying the existing soft soils. The western tower was constructed later, overlooking the Tagus River, and was not completed until the mid-nineteenth century. Its structure consists of exterior walls of stone masonry, a 1st floor supported by stone arcades and vaults, resting in 16 stone columns, being the remaining floors and the roof supported by the exterior walls and four steel pillars, circular and hollow, at the centre of the building. Its foundation comprises a "massive 7 m thick masonry block, resting on a wooden grid" (Castro, 1966), to which pine piles are connected.

Concerning the geological-geotechnical scenario at the tower site, the survey campaign carried out by the Rodio company, in 1965 (Castro, 1966), revealed the presence of heterogeneous landfills, with remains of ancient foundations, to depths of 5 to 10 m. Under the landfill, a layer of clayey mud appears, with increasing thickness towards the river, followed by a layer of

sand, also with a slope towards the river and a thickness varying between 5 and 10 m. Then, another mud formation follows, but with a siltier component, and a thickness (under the tower) of around 8 m, which becomes more clayey in contact with the Miocenic formation, which occurs at around 40 m depth (Figure 1). The water table was found at elevation +1.0 m.

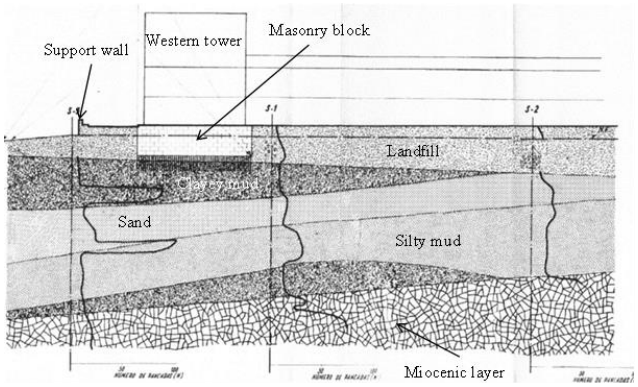

Figure 1. Geological-geotechnical profile at the zone of the western tower, adapted from Castro (1966).

In 1941, a Portuguese historian reported that this tower had suffered a settlement of more than 0.5 m. These significant settlements are explained by the high deformability of the materials in the tower's foundation and its thickness. Regarding the higher settlements of the tower when comparing with the other western wing buildings, this is explained by an increase in the thickness of the muddy soil from north to south, but also by the south area having been gained from the river through the construction of an embankment, after the 1755 earthquake, constituting an additional load on the compressible foundation.

From 1956 onwards, LNEC began measuring the vertical displacements of 8 topographic marks installed in the western wing buildings of Terreiro do Paço. The records are shown in Figures 2 and 3 (Braz, 2019). Between 1956 and 2019, the additional settlement was of 0.153 m, in the southeast corner of the tower (mark N8), and of 0.114 m, in the northeast corner (mark N7). The settlement profile (Figure 2) resembles the deformation of a cantilever beam, fixed at the north end and loaded at the south end. The greatest curvature of the settlement profile was recorded between the N4 and N6 marks, in an area where cracks were identified in the arcade and façade of the Ministry of Agriculture building.

There is an absence of readings between 1989 and 1999. The increase in settlement (66 mm, at the N8 mark) and settlement rate might have been due to an embankment construction, in 1995, as part of the Blue Line of the Lisbon Subway, located at a minimum distance of 35 m from the tower, and due to the TBM passage, from December 1997. In 2009, there was also an increase in the settlement rate, which could be attributed to the construction of a reinforced concrete pile curtain near the south and east façades of the tower. From 2010-2012, the settlement rate reduced at the N6, N7 and N8 marks, remaining practically constant until 2019.

A relevant fact, which is in line with a rigid body type movement of the tower, is the absence of cracks in the exterior walls or in the vaults supporting the 1st floor (Valente and Mesquita, 2017).

2 NUMERICAL MODELLING

2.1 Goals

Recently, the Lisbon Municipality sought to extend the Lisbon Museum by placing one of its modules in the newly vacant western tower. Using the finite elements approach and a 3D numerical model, stress and strain studies were carried out with the purpose of analysing the effect of the rehabilitation works on its safety and functionality. In this model, the evolution of the settlements since the tower's construction was simulated, considering: the mechanical and geometric properties of the masonry block foundation; the

temporary embankment, built as part of the Lisbon Subway Blue Line construction; and the distribution and magnitude of the permanent and live loads, in the current situation, and after rehabilitation of the tower, to serve the new Museum functions, including the construction of new floors and the removal of the 4 central pillars above the 1st floor.

2.2 Calculation model

2.2.1 Model geometry

The width of the model is equal to the width of the masonry block plus 50 m on each side, to minimize the borders' influence on the results. A depth of 50 m was considered in the z-direction, to reach the Miocenic formation. A support wall, at 16 m distance from the south façade of the tower, was also considered (Figure 4). The tower was assumed to be nearly square in plan, with 24.6 m sides. An extra width of 1.4 m, in the x-direction, and of 1.7 m, in the y-direction, was adopted for the masonry block, with an average depth of 7 m.

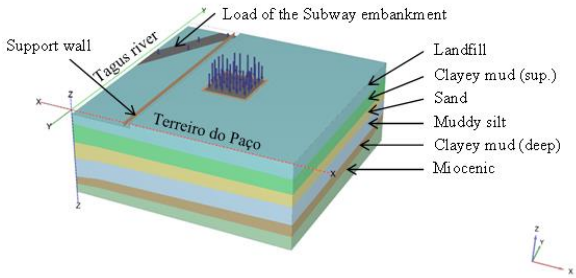

Figure 4. Geometry, geological layers, loads and axes of the calculation model.

The real arrangement of the geological layers is reproduced in Figure 5. Interfaces were introduced between the landfill and the support wall, and between the former and the masonry block, and assigned half the resistance of the adjacent soil. The finite element mesh was generated in *Plaxis 3D* and refined to have a greater density of elements around the masonry block and under the applied loads (Figure 6).

2.2.2 Modelling of the foundation loading

The simulation of the tower's structure, and of the respective permanent and live loads, was carried out through the application of distributed loads at the top of the masonry block, both in the current situation and in the situation of future use. Globally, the tower's requalification project will lead to a 6 % increase on the foundation loading and the removal of the 4 central pillars implies additional loading of the outer walls.

The Lisbon Subway embankment was simulated by a distributed load of 105 kPa, corresponding to a height of 5 m, applied in a width similar to the tunnel diameter.

2.2.3 Foundation materials characterization

A soft soil constitutive model with creep was adopted for the muddy materials, with the aim of integrating the effect of time on their behaviour. Given the period since the construction of the tower and the typical permeability of these soils, it was considered likely that the occurring settlements were due to secondary consolidation of the soil, or creep.

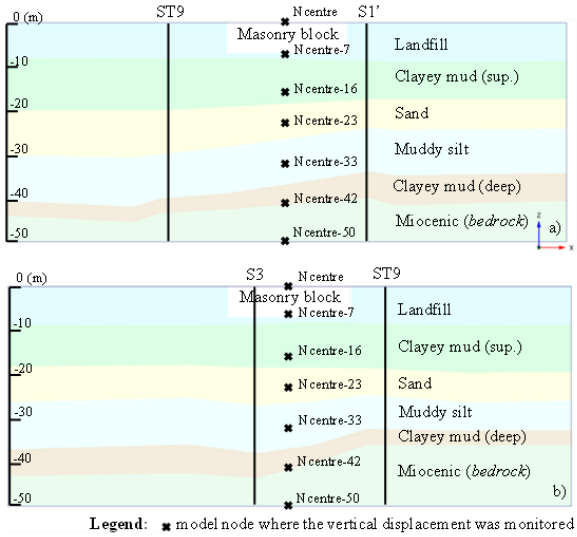

Figure 5. Cross-sections of the geological layers, passing through the centre of the tower: a) x-z and b) y-z.

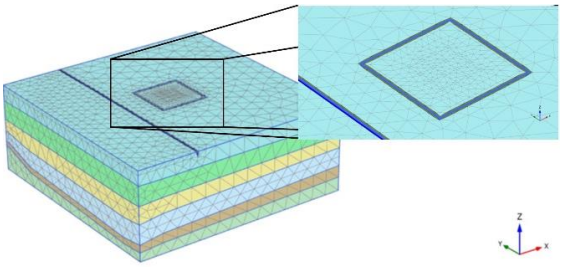

Figure 6. Finite element mesh.

For the remaining materials an elasto-plastic constitutive model with a Mohr-Coulomb failure criterion was implemented, including the muddy silt, since this material presents physical characteristics closer to a silt than to a mud. For the masonry, the linear, single-phase elastic model was adopted, as the voids between masonry blocks were filled with mortar.

In Tables 1 to 3, the parameters that simulate the physical and mechanical properties of the materials are presented. Regarding the muddy materials, the value of the initial void index (e_0) was based on the density of the solid particles, equal to 2.75, and on the water content, obtained from Castro (1966). The modified

compressibility, λ^*, and expansibility, k^*, indexes' values were based on LNEC's knowledge of the typical characteristics of these materials in the area. The value of the modified creep index, μ^*, was adjusted to obtain, in the southeast corner of the tower (N8), a similar settlement to the one obtained from 1956 to 2019 (Braz, 2019), while keeping the value in the usual range for organic soils.

The parameters for the remaining materials were defined considering the work of Castro (1966).

2.2.4 Calculation model stages

The calculation model encompassed several phases, namely:

- Initial phase, to establish the initial stresses.
- Phase 1, in which the ground on the south side of the tower was modelled, simulating a fictitious excavation near the river and the construction of the south wall. An elastoplastic analysis was performed, without consideration of consolidation. The displacements at the end of this stage were nullified, so it only influenced the "in situ" stresses.
- Phase 2, in which the masonry foundation block was built and the loads from the tower were applied almost instantly (1 day), allowing the soil to consolidate in the remaining period. This phase went from 1840, when the tower was built, to 1956, when the settlement monitoring campaign began. The calculated values of the settlements are due to the tower's construction.
- Phase 3, which ran from 1956 to 1995. At this stage, only consolidation of the foundation ground occurred.
- Phase 4, which began in 1995, the year when a temporary embankment was placed over the Blue Line tunnel of the Lisbon Subway, and ended in 2007, the year when the embankment was removed. From 1989 to 1999, no geodetic campaigns were carried out by LNEC. With the resumption of measurements, a very significant increase of the tower settlement rate was noted. Thus, this phase was introduced to evaluate the influence of the embankment construction on the behaviour of the tower.
- Phase 5, which began in 2007 and ended in 2021. In this phase, only consolidation of the ground was considered.

To perform a comparative study of the estimated settlements between 2001 and 2100, 3 distinct scenarios were considered, specifically:

- Scenario 6a, in which the current loading situation was maintained.
- Scenario 6b, in which the loading corresponded to the new structure and tower functions.
- Scenario 6c, theoretical situation in which permanent and live loads remained the same until 2100, and 1 m of the masonry block was excavated, reducing its weight and, consequently, the load on the foundation ground. This situation was simulated in the model through reducing the volumetric weight of the masonry from 24 kN/m^3 to 20.6 kN/m^3.

The reinforced concrete pile curtain, built to mitigate the effects of soil liquefaction on the tower, wasn't modelled, as its construction, in 2009, didn't have a significant effect on the settlements of the tower (Figure 3).

Table 1. Parameters adopted for muddy materials.

	Clayey mud (sup.)	**Clayey mud (deep)**
γ (kN/m^3)	17.6	19
e_0	1.24	0.96
λ^*	0.0757; 0.15	0.0757; 0.15
κ^*	0.0371	0.0371
μ^*	0.018	0.018
ϕ'(º)	20	25
c'(kPa)	0.3	0.3
k (m/day)	0.432x10^{-3}	0.0432 x10^{-3}

γ - saturated soil unit weight; ϕ' – effective friction angle; c' – effective cohesion; k – permeability coefficient.

	γ (kN/m^3)	E (MPa)	ν
Masonry	24	2000	0.2

2.3 Calculation model results

2.3.1 Model results from construction to 2021

In the model, the vertical displacements are monitored at the 4 corners of the tower (N8, N7, M8, M7) and at its centre: at the surface (Ncentre), at -7 m (Ncentre-7, base of the masonry block), at -16 m (Ncentre-16, shallow clayey mud), at -23 m (Ncentre-23, sand), at -33 m (Ncentre-33, muddy silt), at -42 m (Ncentre-42,

deep clayey mud) and at -50 m (Ncentre-50, Miocenic) (Figures 5 and 7).

Figure 7 shows the vertical displacement over time for each of the nodes mentioned above. After the immediate settlement of the layers of sand and muddy silt, there is an initial phase of relatively higher settlement rate, up to approximately 5000 days, which gradually reduces as a result of the primary consolidation of the shallow and deep clayey mud layers. It is estimated that this phase would be almost completed 65 years after the construction of the tower, giving way to the secondary consolidation (through creep) of these layers, with a lower settlement rate and a tendency of stabilization.

The largest settlement occurs in the tower's southwest corner, followed by the southeast corner, which is in accordance with the observations made by Valente and Mesquita (2017). The accumulated settlement at point N8, from 1956 until 2019, attained 153 mm. This value, and the differential settlement between nodes N8 and N7, are in accordance with the accumulated settlements recorded by Braz (2019).

Despite the foundation of the subway embankment having suffered a settlement of 1.15 m, its construction, between 1989 and 1999, seems to have an insignificant effect on the behaviour of the tower.

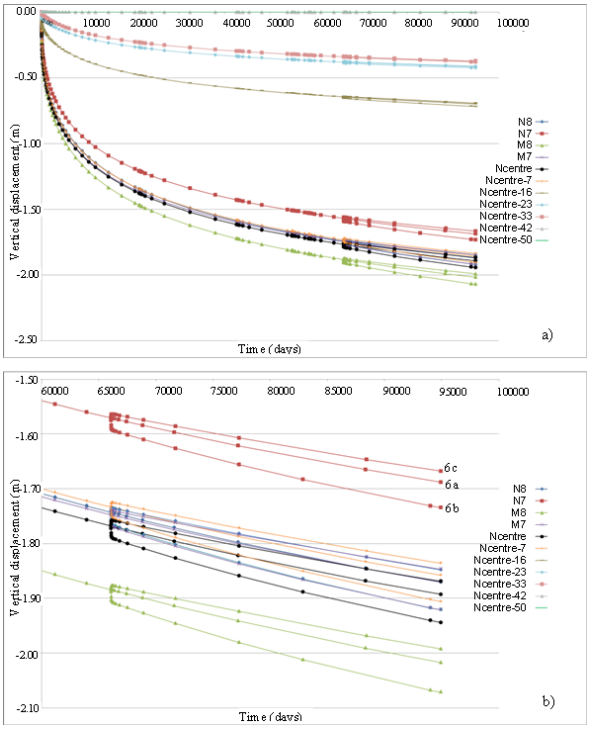

Figure 7. Evolution of the vertical displacement: a) since the beginning of the tower's construction; b) evolution of settlements in phases 6a, 6b and 6c.

Additionally, the vertical displacement at the base of the tower's foundation block (Ncentre-7) is very similar to the one at its top (Ncentre), in accordance with the high stiffness of the block. Moreover, the masonry block rotates like a rigid body, as can be seen in Figure 8.

The vertical displacement of the shallow clayey mud layer is around 33 to 40 % of the settlement of the masonry block and the layers of muddy silt and sand are responsible for around 20 to 25 % of the total settlement of the tower's foundation.

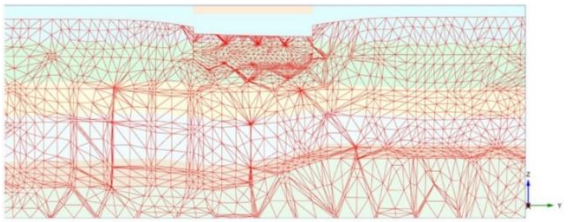

Figure 8. Displacements of the masonry block in 2021 (increased 5 times)

2.3.2 Model results after 2021

The 3 distinct scenarios, from 66078 days (2021) on, are shown in Figure 8: the settlement rate remains the same if the current situation continues (6a); it increases slightly with the increase in loading after the requalification of the tower (6b); and it decreases faintly when 1 m of the masonry block is excavated (6c), after expected bulking from load removal.

Maintaining the current loading, a settlement of 128 mm is obtained in the southeast corner of the tower (N8), between 2021 and 2100, which corresponds to an average rate of 1.6 mm/year (Table 4), a value higher than the rate measured from 2012 onwards (1 mm/year). A differential settlement between N7 and N8 of just 11 mm is calculated with the numerical model.

Table 4. Settlement and average settlement rate, between 2021 and 2100, in N7 / N8, for the current loading situation.

	$\delta_{(2021\text{-}2100)}$ (mm)	$\delta_{(2021\text{-}2100)}/\Delta t$ (mm/year)
N8	128	1.6
N7	117	1.5

$\delta_{(2021\text{-}2100)}$ – settlement; Δt – time period (79 years).

Changing the loading, after requalification of the tower, a settlement of 174 mm is obtained in the southeast corner of the tower (N8), between 2021 and 2100, which corresponds to an average rate of 2.2 mm/year (Table 5). A differential settlement between N7 and N8 of 14 mm is calculated. The increase in the average settlement rate, compared to the previous situation, results from the mud's primary consolidation, due to the increase of load on the foundation (around 6 %).

Considering a 1 m deep excavation of the masonry block, a settlement of 107 mm is obtained in the

southeast corner of the tower (N8), between 2021 and 2100, which corresponds to an average rate of 1.4 mm/year (Table 6). A differential settlement between N7 and N8 of 9 mm is estimated.

Table 5. Settlement and average settlement rate, between 2021 and 2100, in N7 / N8, for changing the loading, after requalification of the tower.

	$\delta_{(2021\text{-}2100)}$ (mm)	$\delta_{(2021\text{-}2100)}/\Delta t$ (mm/year)
N8	174	2.2
N7	160	2.0

Table 6. Settlement and average settlement rate, between 2021 and 2100, in N7 / N8, for the situation after a 1 m deep excavation of the masonry block.

	$\delta_{(2021\text{-}2100)}$ (mm)	$\delta_{(2021\text{-}2100)}/\Delta t$ (mm/year)
N8	107	1.4
N7	98	1.2

2.4 Comparative analysis of the modelled cases

Comparing the situation with increased loading, after requalification of the tower, with the current loading situation, there is a difference in the accumulated settlement in 2100, in the southeast corner of the tower (N8), of 46 mm, and, in the northeast corner of the tower (N7),of 42 mm (Table 7). In terms of differential settlement, between N7 and N8, the change in loading leads to a negligible increase of 4 mm.

Comparing the situation of 1 m deep excavation of the masonry block with the current loading situation, there is a reduction in settlement in 2100, in the southeast corner of the tower (N8), of 21 mm, and, in the northeast corner of the tower (N7), of 19 mm (Table 7). The reduction of the differential settlement, between N7 and N8, compared to the current situation, does not exceed 2 mm and is insignificant.

Table 7. Settlement difference in 2100, between scenarios.

	$\Delta\delta_{req\text{-}current\ (2100)}$ (mm)	$\Delta\delta_{exc\text{-}current\ (2100)}$ (mm)
N8	46	-21
N7	42	-19

$\Delta\delta_{req/exc\text{-}current\ (2100)}$ – settlement difference in 2100, between the current situation and after requalification / after a 1 m deep excavation of the masonry block, respectively.

In a nutshell, the excavation of the masonry block has a limited effect on reducing the settlement of the tower in 2100 and has virtually no effect on the differential settlement. This happens because the settlement of the tower, at this stage, is caused by secondary consolidation of the mud layers. The effect of the change in loading, due to requalification, on the differential settlement between N7 and N8 is also reduced, although an increase in accumulated settlement of around 40 mm is expected in 2100, in N7 and N8, in relation to the current loading settlement.

3 CONCLUSIONS

Given the settlement history of the western tower of Terreiro do Paço, and for the purpose of evaluating the consequences of the loading changes on its foundation, three-dimensional stress and strain analyses were carried out, assuming different scenarios.

If the current situation continues, it is expected that the tower will suffer an increase in settlement, in 2100, of 0.12 m in the southeast corner, while the settlement difference between the southeast and northeast corners will only increase by 0.01 m.

With requalification of the tower, load changes will result in an increase in accumulated settlement in the southeast and northeast corners of the tower of around 0.04 m in 2100, in relation to the current scenario, but without significant change in differential settlement.

The possibility of minimizing future settlements of the tower, by removing 1 m in height of the masonry block, has a limited effect, especially with regard to the differential settlements, and requires the reinforcement of the façade and columns foundation. It is, therefore, a complex and low-efficiency solution.

In view of these results, it is considered that the requalification of the tower will not significantly deteriorate its safety and functionality conditions. In fact, after its construction, the tower has already suffered an estimated settlement greater than 0.65 m, with no consequences in terms of its stability.

An energetic approach to the soil mechanical behaviour description in a zero-dimensional formulation

Une approche énergétique de la description du comportement mécanique du sol dans une formulation à dimension zéro

A. Yu. Mirnyy*
Lomonosov Moscow State University, Moscow, Russian Federation
**MirnyyAY@mail.ru*

ABSTRACT: Geotechnical risks assessment in limit state design involves the use of mathematical models to predict the stress-strain state of the soil under the external loads. Most of these models are based on continuum mechanics solutions and rely on the concepts of "moduli" as parameters of stress-strain curve. For dispersed media, these concepts are devoid of physical meaning, since the mechanism of resistance to volumetric compression, shear strain and plastic yielding are fundamentally different, and are not caused by the rigidity of the bonds between the crystal lattice elements. The proposed energy approach allows to estimate the energy spent on each process occurring in a dispersed soil under mechanical action. The change in porosity, internal friction, hardening due to dilatancy and the increase in pore pressure are expressed by separate energy parameters, each of which in turn is described by a nonlinear stress state function. User defined threshold strain levels allow to turn on and off various mechanisms. The proposed approach better corresponds to the physical meaning of the processes. The method can be easily applied to adapt the theory of plasticity solutions. The development of a mathematical model based on the proposed approach will improve the quality of forecasting the occurrence of limit states in the soil bases.

RÉSUMÉ: L'évaluation des risques géotechniques dans la conception à l'état limite implique l'utilisation de modèles mathématiques pour prédire l'état de contrainte-déformation du sol sous les charges externes. La plupart de ces modèles sont basés sur des solutions de mécanique des milieux continus et reposent sur les concepts de "modules" comme paramètres de la courbe contrainte-déformation. Pour les milieux dispersés, ces concepts sont dépourvus de signification physique, car le mécanisme de résistance à la compression volumétrique, à la déformation par cisaillement et à la déformation plastique est fondamentalement différent et n'est pas causé par la rigidité des liaisons entre les éléments du réseau cristallin. L'approche énergétique proposée permet d'estimer l'énergie dépensée pour chaque processus se produisant dans un sol dispersé sous action mécanique. Le changement de porosité, le frottement interne, le durcissement dû à la dilatance et l'augmentation de la pression interstitielle sont exprimés par des paramètres énergétiques distincts, chacun étant à son tour décrit par une fonction d'état de contrainte non linéaire. Les niveaux de contrainte seuil définis par l'utilisateur permettent d'activer et de désactiver divers mécanismes. L'approche proposée correspond mieux à la signification physique des processus. La méthode peut être facilement appliquée pour adapter la théorie des solutions de plasticité. Le développement d'un modèle mathématique basé sur l'approche proposée améliorera la qualité de la prévision de l'occurrence des états limites dans les bases du sol.

Keywords: Energy approach; triaxial compression; dispersed soil; mathematical model.

1 INTRODUCTION

Dispersed soils mechanical properties study is largely complicated by the parallel flow of various processes. During volumetric strain compaction occurs, which, in turn, leads to the formation of additional contacts, changes in shear resistance conditions. In plasticity theory this process is described by hardening – an increase in the yield strength as plastic straining occurs.

At the same time, during the shear, phenomena due to the discreteness of the structure are observed – dilatancy and contraction – which cause a change in the volume of the pore space. As a consequence, the direct determination of the stress-strain state parameters mutual dependence is difficult. Various researchers have obtained dependence data for certain values of third-party factors, for example, the degree of density, water saturation, drainage regime, etc. A comprehensive analysis of these data, in fact, has not yet been carried out: most of the laws of soil mechanics are phenomenological in nature, and do not

explain the physical nature of the processes taking place.

In addition to the multifactorial nature of the processes under study, the fundamental description of the dispersed soils mechanical behaviour laws is complicated by the limited capabilities of the test equipment. In no other field of materials science or, in a broader sense, solid mechanics, such a large number of devices of various designs are used. This is due to practical difficulties when trying to implement a homogeneous stress-strain state in the sample, but since most of the stress-strain state components are vector quantities, the resulting deviations lead to an increase in the discrepancy between the exact analytical solution and the actual experiment. Together with the change in the sample structure (and, as a consequence, the physical and mechanical properties) during the experiment, this does not allow for unambiguous interpretation of the test results.

2 THEORETICAL ANALYSIS

The solutions to the mechanics of granular media appear to be the direct method of describing dispersed soils mechanical behaviour, taking into account the discreteness of their structure (Kandaurov, 1966). Based on the characteristic particle size, a calculation scheme can be constructed that allows us to consider the equilibrium of individual particles, taking into account their mutual location. Unfortunately, as the number of particles increases, the number of equations in the solution also increases, and the introduction of different sized particles or deviations from the idealized packaging into the scheme leads to a stochastic solution, the result of which coincides in the limit with the solutions of solid mechanics.

The most well-known generalizing theory linking shear resistance parameters with physical characteristics is the critical state theory (Roscoe et. al, 1958). This theory assumes that each value of the average stress corresponds to its own value of the porosity coefficient, and the porosity coefficient, in turn, determines the amount of resistance to plastic yielding. Despite the active development of this theory in literary sources, in most implementations it is impossible to describe hardening or softening, as well as shear straining with its help.

In most cases, physical characteristics are completely excluded from the problems of soil mechanics, and the solution is carried out for an idealized solid body, the parameters of which are moduli, linking stresses and strains with linear or nonlinear laws. These parameters are obtained by laboratory tests and comparison of experimental values of stress-strain state components. At the same time, a significant number of studies have been carried out linking the values of these parameters with physical characteristics, in particular density, consistency, and granulometric composition (Goldin and Rasskazov, 2001; Kryzhanovsky et. al., 1985). The correlations obtained in these studies do not allow us to describe the causes of dependence, but only quantify it.

An alternative method of interpreting the results of laboratory tests can be the energy method, which is widely used in the mechanics of deformable solids and, in particular, in the theory of plasticity (Drucker and Prager, 1952). A change in the stress-strain state of some medium at a point is accompanied by energy transformations. On the one hand, external forces acting on this medium do the work. On the other hand, the energy expended is partially stored by elastic forces, and partially spent on overcoming internal friction and irreversible structural changes. Taking into account that in the conditions of a laboratory experiment the system can be considered as closed, the energy approach can be confidently applied as an additional method of interpreting the results.

The pioneers in the application of the energy method were specialists in the field of the plasticity theory of metals. The hypothesis of internal energy constancy during plastic yielding allowed to formulate the von Mises failure criterion. Most theories of plastic yielding (first of all, Prandtl–Reissner, Saint-Venant–Mises, Hill) take into account the work of plastic strain or its power. For example, the analysis of the work of strains allows us to describe the hardening during plastic yielding on the basis of Prandtl diagram.

In relation to soil mechanics, this approach was first adapted in the law of unassociated flow and a specialized flow condition. Also known are the works of a group of researchers in the field of critical state theory (Roscoe et. al., 1958), the main provisions of which were derived from energy prerequisites. A group of researchers considered a method for determining the transition point to plastic yielding based on the work expended (Crooks and Graham, 1976). Currently, the energy approach is used in the study of soil properties under dynamic loading, which makes it possible to assess the degree of energy absorption by comparing the work of elastic strain and the energy dissipated during one loading cycle (Ishihara, 2006). Based on the work of strain, it is proposed to evaluate the so-called "strain instability" - the strain levels at which structural changes occur in dispersed soils (Voznesensky, 2018; Usov and Voznesensky, 2016). Also, energy methods are used to determine the history of loading (re-compaction parameters), among them the methods of pre-

consolidation pressure determination (Becker, 1987; Wang and Frost, 2004).

3 RESEARCH METHODOLOGY

In this paper, we propose a method for interpreting the test results of axisymmetric triaxial compression from the standpoint of the energy and work of strain. This test method was chosen as, on the one hand, quite widespread, and on the other – allowing measurements of all stress-strain components during the experiment.

Triaxial compression tests can be carried out in various modes that determine both the initial state of the sample and the drainage conditions during the experiment. If we do not consider the unconsolidated regime as highly specialized, then at the initial moment of the experiment, filtration consolidation in the sample is considered completed (there is no excess pore pressure, the density of the skeleton is constant and can be unambiguously determined). In the case of full water saturation in the undrained mode during loading, the volume of the pore space remains constant due to the incompressibility of the liquid. This means that only shear strain will occur in the soil skeleton, and the increment of the average stress will cause an increase in pore fluid pressure instead of volumetric strain. The pore pressure change will also be caused by an additional change in the pore volume during the shearing – the pressure will fall in dilating soils and grow in contracting ones. Consequently, in the course of undrained tests, energy will be spent on elastic shear strain, plastic shear strain and pore pressure changes.

In the drained mode, the pore space is open during the experiment, therefore, the pore pressure does not change, and an increase in the average stress p will cause volumetric strain. This usually happens when using the standard stress trajectory (CTC) where an increase in the maximum main stress also causes an increment in the average stress. The processes of dilatancy and contraction proceed freely. Energy is spent on elastic and plastic shear and volumetric strain, and the plastic volume strain consists of the action of medium stress and dilatancy/contraction.

The implementation of the loading trajectory with a constant average stress (TC) leads to the fact that any volumetric strain in the experiment occurs solely due to dilatancy/contraction. Energy is spent on elastic and plastic shear strains, and volume strains are exclusively plastic and are caused by dilatation/contraction. Thus, in the presence of a series of experiments in different modes, with different loading trajectories and at different average stresses, parallel processes can be divided and the work expended on them can be compared.

The total work can be determined through the vertical force F and the movement of the rod Δh (1). The resulting value should be attributed to the volume of the sample in order to proceed to the specific work of strain.

$$\Delta W_{tot} = \Delta F \cdot \Delta h \quad (1)$$

where ΔW_{tot} (J/m^3) is the specific work of strain, ΔF (N) is the vertical force increment, Δh (m) is the rod displacement.

4 EXPERIMENTAL STUDIES

As an experimental basis, this paper considers the results of triaxial compression tests of model soils (quartz grains of 2-5 mm fraction), performed in a stabilometer with a sample diameter of 300 mm, manufactured by NPP Geotek LLC for the Moscow State University of Civil Engineering. The tests were performed at an average stress of 200, 400 and 800 kPa. All tests were performed in kinematic mode with a constant strain rate. As a result, the dependences of vertical strain on the stress deviator, as well as volumetric strain on the vertical, were obtained, taking into account all the necessary corrections due to the design of the device. The resulting data set allows you to build any dependencies for other stress-strain state components.

The simplest analysis is performed for tests along the TC trajectory. If we select the last section corresponding to the constant slope of the dependence graph $W(\gamma)$, then we can assume that only plastic strain develops in this section (Fig. 1). At the same time, both shear strains and volume strains develop due to dilatancy. Considering that the energy costs in this case are caused solely by overcoming friction, the ratio of linear approximation equations can be considered as a function of internal friction, which is confirmed by the linear dependence of this ratio on the cell pressure. This ratio corresponds in meaning to the plastic ratio λ between the increment of plastic strain and the intensity of tangential stresses in the theory of plastic flow (2):

$$d\lambda = \frac{dA_p}{2\tau^2} \quad (2)$$

Where $\Delta\lambda$ is the specific work of strain, ΔA_p (J) is the work increment, τ (Pa) is the shear stress.

It is noteworthy that these lines intersect the ordinate axis at almost the same point corresponding to the shear strain γ = 0.0108-0.0129. Such shear strain corresponds to axial strain ε = 0.007, which in absolute

terms is 4.2 mm – approximately the average particle size in the samples studied.

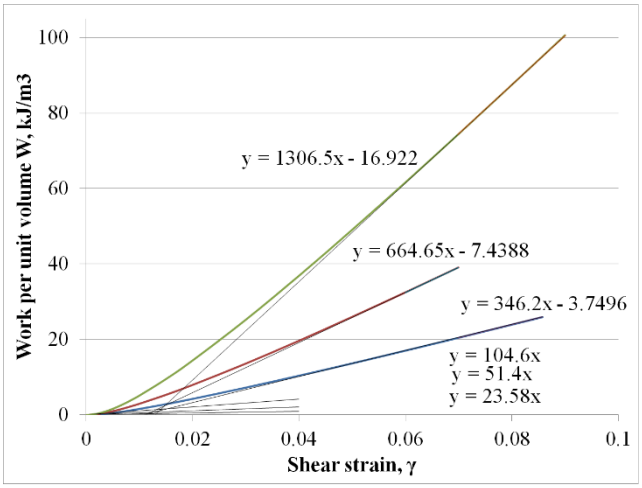

Figure 1. Dependences of the specific work of strain on the shear strain for tests at a pressure in the chamber of 200, 400 and 800 kPa with the correlation equations of the initial and final linear sections.

For tests performed at different average stresses, these ratios are obtained differently, since the resistance to plastic flow is determined mainly by internal friction. If we plot the obtained values of $d\lambda$ on a graph depending on the average stress, then these values are well approximated by a linear function (3) reflecting the dependence of the resistance to plastic flow on the average stress:

$$d\lambda(p) = 1.6p + 25 \qquad (3)$$

where $\Delta\lambda$ is the specific work of strain, p (Pa) is the mean stress.

The threshold shear strain at which the transition to plastic flow occurs is γ = 0.03-0.05 for all tests.

If we correlate the obtained rate of work change to the shear strain and the work performed by the loading device, then we can identify a discrepancy – for example, for a sample tested at a pressure in a chamber of 800 kPa, the work of shear strain is 77.1% of the total work of the loading device. The remaining 22.9% of the energy is spent on friction in the elements of the device, deformation of the membrane and – mainly – on plastic volume strain. This observation gives grounds to consider the dependence of volumetric strain on the stress deviator, and similarly to obtain the amount of energy spent on plastic volume strain. Given that the tests were carried out in kinematic mode, the resulting percentage ratio directly allows to determine the dilatancy angle (4):

$$\psi = arcsin\frac{22.9}{77.1} = 17.3°. \qquad (4)$$

Where ψ (°) is the dilatancy angle.

On the other hand, the construction of approximating lines from the origin allows us to obtain the energy consumed for elastic strain. Their slope is also proportional to the cell pressure, while these points are approximated by a power function. This correlates well with the power law of the dependence of stiffness on stress, repeatedly described for various conditions (Benz, 2007; Janbu, 1963; Schanz et. al., 1999).

In the test along the trajectory of deviatory crushing (CTC), these processes will overlap with each other, while ceasing to be linear, since during the experiment the average stress increases (which means there is an increase in stiffness and shear resistance). This means that both elastic and plastic strains with increasing stresses will require more energy. But, given that the tests are carried out on the same material, the dependencies obtained earlier will be partially valid.

5 RESULTS AND DISCUSSION

Based on the analysis of the results of the triaxial compression test with a constant average stress, the following patterns were determined:

- specific work of elastic shear strain W_e^s (5):

$$W_e^s = 0.0803p^{1.075}; \qquad (5)$$

- specific work of plastic shear strain W_p^s (6):

$$W_p^s = 1.6p + 25; \qquad (6)$$

- specific work of plastic volume strain W_p^v (7):

$$W_p^v = 0.297W_p^s; \qquad (7)$$

Taking into account that the values of threshold strainss can be determined from the end points of the linear approximation sections, using these parameters it is possible to reproduce the shape of the original experimental curve. The modelling method is quite simple – for a certain step of shear strain (for example, 0.1%), the value of the stress deviator is calculated. In this case, the specific work of strain is calculated by (4-6), depending on the average stress. When the threshold strains are reached, individual terms are turned on or off. The dependencies obtained as a result of modelling are shown in Fig. 2.

It follows from the simulation results that the proposed approach allows reproducing experimental dependencies with high accuracy. The simulation result consists of separate fairly simple mathematical patterns (4-6), each of which acts in the appropriate

range of strains: up to the level of 0.007, it is exceptionally elastic, then elastic and plastic, after 0.03 - plastic. At the same time, part of the energy consumed is spent on volumetric plastic strain.

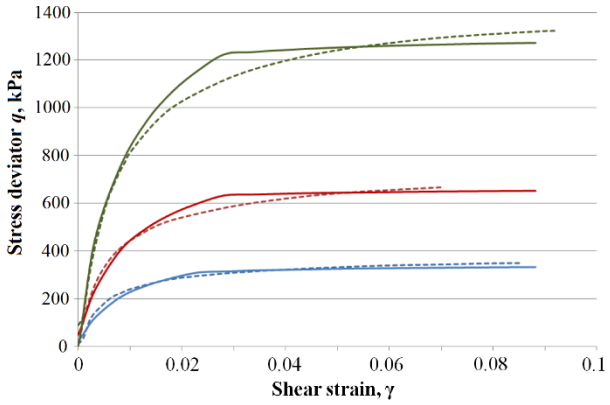

Figure 2. The result of modelling experimental curves. The dotted line shows experimental data, the solid line shows modelling.

The greatest discrepancy is observed at the transition site from elastic-plastic deformation to plastic flow. This is probably due to the smooth development of dilatancy in the real sample, which can be taken into account when processing the test results in more detail.

Based on the joint analysis of tests on two different trajectories, it is possible to separately describe all the ongoing deformation processes.

6 CONCLUSION

The method proposed in this paper for interpreting the results and modelling mechanical behaviour has a number of advantages in relation to solid mechanics.

- the theories of stresses and strains are used separately, the connection between them is established using energy parameters reflecting the physical meaning of the processes occurring during deformation;
- the resulting parameters are scalar quantities, and are represented as simple functions of the average stress;
- threshold strain values can be determined experimentally and correlated with the granulometric composition of samples.
- the proposed method of analysing the results of triaxial compression tests can be applied to other types of laboratory tests (simple shear, oedometric compression), provided that the stress-strain state is constant during the experiment.

Terrasol - Setec, Paris, France

**christian.moormann@igs.uni-stuttgart.de*

ABSTRACT: Eurocode 7 is known as the European standard for geotechnical engineering design and is widely considered as a great success story. The second generation of the standard recently being finally drafted by CEN/TC250 SC7 will be published 2024/2025 and will represent a significant step forward towards further harmonization and efficient guidance for geotechnical design. Besides other geotechnical structures this is the case also and especially for piled foundations. In comparison to the first generation the clause on piled foundations in EN 1997-3 ´Geotechnical Structures´ has been fundamentally revised and improved including new rules for pile design. For example, in the second generation pile groups and piled rafts will be covered equivalently to single piles. Detailed guidance is provided to consider actions due to ground displacements like downdrag. Revised sets of correlation, model and partial factors were specified. The design approaches for axial and lateral loaded piled foundations were harmonized. As the authors have been involved in the evolution of the revised clause on pile foundations since 2011 this paper aims to inform first-hand about the upcoming changes and to present the improvements and challenges.

RÉSUMÉ: L'Eurocode 7 en tant que norme européenne pour la conception géotechnique est largement considéré comme une grande réussite. La deuxième génération de la norme récemment rédigée par le CEN/TC250 SC7 sera publiée en 2024/2025 et constituera une avancée significative vers une harmonisation plus poussée avec des orientations efficaces pour la conception géotechnique: c'est notamment le cas des fondations sur pieux. Par rapport à la première génération, le chapitre relatif aux fondations sur pieux a été fondamentalement révisé et amélioré, avec de nouvelles règles pour la conception des pieux. Par exemple, dans la deuxième génération, les groupes de pieux et radiers dur pieux seront traités avec un niveau de détails similaire à ceux des pieux isolés. Des recommandations détaillées sont fournies pour prendre en compte les actions dues aux déplacements du sol comme le frottement négatif. Les ensembles de facteurs de corrélation, de modèle et partiels ont été révisés. Les approches de conception pour les fondations sur pieux chargés axialement et latéralement ont été harmonisées. Comme les auteurs ont été impliqués dans l'évolution de la clause révisée sur les fondations sur pieux au cours des 12 dernières années, cet article vise à présenter simplement les changements à venir ainsi que les améliorations et les défis qui se profilent.

Keywords: Eurocode 7; piled foundations; pile groups; piled rafts; partial factor; axial and transversal loading.

1 EURCODE 7, PART 3 (2025)

In its second generation the new Eurocode 7 comprises three parts as illustrated in Figure 1. The contents of the existing Eurocode 7, Part 1 ´General rules´ (EN 1997-1:2004) have been split between EN 1990 ´Basis of structural and geotechnical design´, a revised Part 1 (EN 1997-1:2024) ´General rules´; and a new Part 3 (EN 1997-3:2025) ´Geotechnical structures´.

The new Part 3 comprises text from Sections 5-9 and 11-12 of the original Part 1 together with new Clauses on reinforced fill structures, ground reinforcing elements, ground improvement and groundwater control (Bond et al. 2019). In this context the Section 7 ´Pile foundation´ of EN 1997-1:2024 formed the basis for the new Clause 6 ´Piled foundations´.

The contents of the existing Eurocode 7, Part 2 ´Ground investigation and testing´ (EN 1997-2:2007) are also being revised to focus in the new Part 2 ´Ground parameters´ (EN 1997-2:2024) on derivation of design parameters. Calculation models that currently reside in Annexes to EN 1997-2:2007, e.g. on CPT-based calculation of axial pile resistances, have been moved to the new Part 3, as illustrated in Figure 1.

Relevant for the design of piled foundations according to the second generation of Eurocodes are therefore mainly EN 1990, EN 1997-1 and EN 1997-3 whereby the relevant design aspects are illustrated in Figure 1.

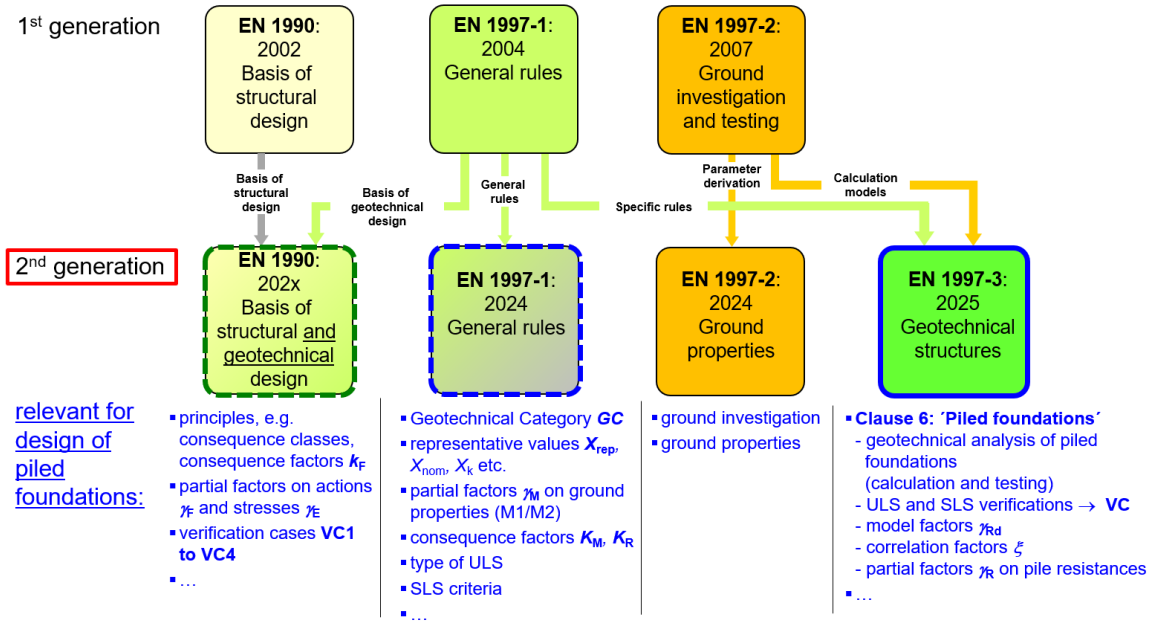

Figure 1. Division and redistribution of the 1st generation of Eurocode 0 and Eurocode 7 into the standards of the second generation; at the bottom: contents of these standards being relevant for design of piled foundations.

2 CLAUSE 6: PILED FOUNDATIONS

2.1 Introduction

Relevant for the design of piled foundations is predominantly Clause 6 'Piled foundations' of EN 1997-3:2025 which was elaborated on basis of Section 7 'Pile foundation' of EN 1997-1:2024 whereby the previous regulations were fundamentally revised, improved and supplemented including new resp. additional rules for pile design. Fundamentally, in the second generation pile groups and piled rafts will be covered equivalently to single piles whereby the regulation of the first generation focused solely on single piles. Detailed guidance is provided to consider actions on piles due to ground displacements like downdrag. Revised sets of correlation, model and partial factors were specified. The design approaches for axially and laterally loaded piled foundations were harmonized.

As each Clause of EN 1997-3 (Clauses 4 to 12) follows a common structure, also Clause 6 comprises the following sub-sections which have the same order as the Clauses in EN 1997-1:2024 and which provide structure-specific rules in addition to the general rules specified in Part 1 of Eurocode 7:

6.1 Scope
6.2 Basis of design
6.3 Materials
6.4 Groundwater
6.5 Geotechnical analysis
6.6 Ultimate limit states
6.7 Serviceability limit states
6.8 Execution
6.9 Testing
6.10 Reporting

These sections of Clause 6 provide specific regulations for the analysis and design of piled foundations. In this context the detailed information documented in Clause 6 includes for example the following aspects:

- requirements on the minimum extent of ground investigations;
- analysis of piled foundations due to structural loads and effects of ground displacements;
- design of piled foundations by testing, calculation, prescriptive measures;
- the specification of ultimate limit state (ULS) and serviceability limit state (SLS) verifications for single piles, pile groups and piled rafts including a definition of the verification cases (VC) being relevant for those verifications;
- the specification of the sets of model factors γ_{Rd}, correlation factors ξ as well as partial factors γ_R for the evaluation of the design value of pile resistances.

Besides the structure-specific regulations documented in Clause 6 of EN 1997-3, information needed for the design of piled foundations are provided also by EN 1990 and EN 1997-1 as illustrated in Figure 1.

EN 1990 specifies the principles of classification of structures according to consequences classes and the consequences factors k_F for actions as well as the principles of limit state design and of the verification by the partial factor method including specification of partial factors on actions γ_F and stresses γ_E. EN 1990

also specifies the ´Verification Cases´ VC1 to VC4 being relevant for different design situations like structural resistance, static equilibrium and geotechnical design and the related sets of partial factors. The partial factors can either be applied on material properties, i.e. the ´Material Factor Approach´ (MFA), or to resistances, i.e. the ´Resistance Factor Approach´ (RFA).

EN 1997-1 as well provides relevant specifications and regulations needed for the design of piled foundations. Besides specifications of the Geo-technical Category (GC) which should be determined by a combination of the Consequence Class (CC) of the structure and the Geotechnical Complexity Class (GCC), the evaluation of representative values X_{rep} as well as partial factors γ_{M} on ground properties and consequence factors both on ground properties k_{M} and resistances k_{R} are specified in Part 1 of Eurocode 7.
In the following some of the most relevant modifications for the design of piled foundations according to second generation of Eurocode 7 are explained in more detail.

2.2 Ground investigations

In addition to EN 1997-2:2024 which includes fundamental requirements on ground investigation and evaluation of ground properties section 6.2 of EN 1997-3 provides additional specific regulations, e.g. specifications on the minimum depth d_{min} of field investigation on piled foundations (Table 1).

Table 1. Minimum depth of ground investigation for piled foundations.

Application	Minimum depth
Single piled foundation	d_{min} = max (5 m; 3·$B_{\mathrm{n,eq}}$)
Pile groups or piled rafts in soils and in very weak and weak rock masses	d_{min} = max (5 m; 3·$B_{\mathrm{n,eq}}$; p_{group})
Pile groups or piled rafts in strong rock masses	d_{min} = max (3 m; 3·$B_{\mathrm{n,eq}}$)

d_{min} is the minimum investigation depth beneath pile base level.

$B_{\mathrm{n,eq}}$ is the equivalent size of the pile base, equal to B_{b} (for square piles), D_{b} (for circular piles), or p_{b}/π (for other piles);

B_{b} is the base width of the pile with the largest base (for square piles);

D_{b} is the base diameter of the pile with the largest base (for circular piles);

P_{group} is the smaller dimension of a rectangle circumscribing the group of piles forming the foundation, limited to the depth of the zone of influence.

2.3 Verification of axial resistance of single piles (ULS)

For axially loaded single piles the axial (compression) resistance shall be verified using:

$$F_{cd} \leq R_{cd} \tag{1}$$

Thereby, the verification for axial loaded piles (single piles, pile groups and piled rafts) could be harmonized as solely the Resistance Factor Approach (RFA), where the partial factors are applied on the pile resistance, shall be used in combination with Verification Case VC1, where the partial factors are applied on the actions. Thus, the design value of actions is defined as follows:

$$F_{cd} = 1.35G_{rep} + 1.5Q_{rep} \tag{2}$$

with Q_{rep} as caractersitic value, combination value, frequent value or quasi-permanent value.

The design value of the axial pile resistance is defined as follows:

$$R_{\mathrm{cd}} = \frac{R_{\mathrm{c,rep}}}{\gamma_{\mathrm{Rc}} \cdot \gamma_{\mathrm{Rd}}} \; or \; \left(\frac{R_{\mathrm{b,rep}}}{\gamma_{\mathrm{Rb}} \cdot \gamma_{\mathrm{Rd}}} + \frac{R_{\mathrm{s,rep}}}{\gamma_{\mathrm{Rs}} \cdot \gamma_{\mathrm{Rd}}}\right) \tag{3}$$

where γ_{Rc}, γ_{Rb}, γ_{Rs} are partial factors for pile resistrances and γ_{Rd} is a model factor.

The representative values of the pile resistance in axial compression $R_{\mathrm{c,rep}}$ resp. of the base and shaft resistance $R_{\mathrm{b,rep}}$ and $R_{\mathrm{s,rep}}$ can be obtained by testing, by calculation or by prescriptive rules. The use of prescriptive rules is very rare for piles. For the determination of the axial resistances of single piles by calculation either the ´Ground Model Method´ or the ´Model Pile Method´ can be applied. In case of the Ground Model Method the axial resistance of a single pile is calculated based on ground properties determined from both field and laboratory tests, accounting for horizontal variability of the ground in the piled area. The Model Pile Method is a calculation method to determine the axial resistance of a single pile based on individual pile resistance profiles determined from correlations with field test results or ground properties from field or laboratory tests. Methods of calculating base and shaft resistance are included in Annex C of EN 1997-3 for ground parameters as well as for cone penetration methods and for pressuremeter methods. Figure 2 provides an overview about these calculation methods.

The axial resistance of a single pile at ultimate and serviceability limit state may be also determined from the results of static load tests. Dynamic impact and rapid load tests may be used to determine the ultimate limit state of a single pile in compression.

Pile resistance based on ground parameters

$q_{s,rep}$ with $\alpha \cdot c_u$ or $\beta \cdot \sigma'_v$

$q_{b,rep}$ with N_c or N_q

Pile resistance based on CPT or PMT data

$q_{s,rep}$ = f (soil type, pile type, q_c or p^*_{LM})

$q_{b,rep}$ = f (soil type, pile type, q_c or p^*_{LM})

pile resistance based on CPT profiles:

$q_{s,rep}$ with $c_s \cdot q_c$

$q_{b,rep}$ with $c_b \cdot k_{shape} \cdot q_c$

pile resistance from PMT profiles:

$q_{s,rep}$ with $\alpha_{pile\text{-}ground} \cdot f(p^*_{LM})$

$q_{b,rep}$ with $k_{b,PMT} \cdot p^*_{LM}$

Pile resistance based on empirical tables

Example: Representative values of unit shaft resistance $q_{s,rep}$ for bored piles in soils

Fine soils		Coarse soils	
Undrained shear strength c_u (kPa)	**$q_{s,rep}$ (kPa)[a, b]**	**Mean cone resistance q (MPa)**	**$q_{s,rep}$ (kPa)[a,b]**
60	30-40	7,5	55-80
150	50-65	15	105-140
≥ 250	65-85	≥ 25	130-170

[a] The lower value represents the 10 % quantile and the upper value the 50 % quantile

[b] Intermediate values can be obtained by linear interpolation

Figure 2. Available calculation methods for evaluation of axial pile resistances.

Table 2 specifies the evaluation of representative values of axial pile resistances from calculated or measured values.

Table 2. Evaluation of representative axial resistances of single piles based on calculation or testing.

Ground Model Method: R_{calc} from ground parameters (c_u, φ′ and c′, p_{LM}*, q_c, N_{SPT}, etc.)	$R_{rep} = R_{calc}$
Model Pile Method: R_{calc} from N field test profiles (N CPTs, N PMTs, N SPTs, etc.)	$R_{rep} = \min\left\{\frac{R_{calc,mean}}{\xi_{mean}}; \frac{R_{calc,min}}{\xi_{min}}\right\}$
Pile tests: R_{test} from static, dynamic impact or rapid load tests	$R_{rep} = \min\left\{\frac{R_{test,mean}}{\xi_{mean}}; \frac{R_{test,mean}}{\xi_{min}}\right\}$

Figure 3 visualizes the possible procedures to evaluate design values of axial pile resistances from testing and calculation. Tables 3 and 4 document the model factors γ_{Rd} for verification of axial pile resistance assisted by testing and calculations.

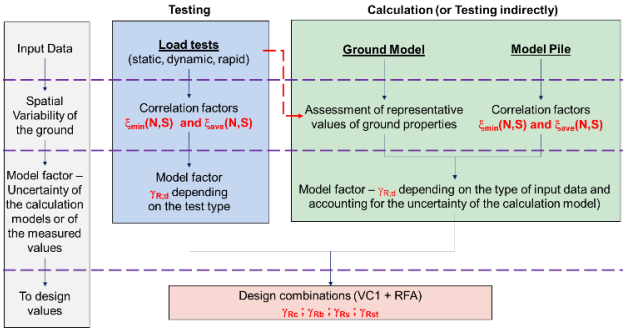

Figure 3. Calculation procedures for piles.

Correlation factors ξ allows to consider the spatial variability of the ground alternatively to the selection of the representative values of the ground parameters which is always related to subjective interpretation. Correlation factors ξ as documented in section 6.2.4 of EN 1997-3 continues to be dependent form number of executed pile tests or ground profiles. The correlation factors given reflect an average uncertainty corresponding to a coefficient of variation of about 12%; other approaches are therefore acceptable if spatial variation is lower or higher.

The correlation factors for the Model Pile Method can be adjusted according to the density of the field test profiles (CPTs, PMTs, etc.) considering the ratio of the average horizontal spacing d_{avg} between the N

Table 3. Model factors γ_{Rd} for verification of axial pile resistance assisted by testing.

Verification by		**Model factor γ_{Rd}**		
		Fine soils	Coarse soils	Rock mass
Static load tests		1.0	1.0	1.0
Rapid load tests (multiple load cycles)		1.4	1.1	1.2
Rapid load tests (single load cycle)		1.4	1.1	1.2
Dynamic impact tests (signal matching)	Shaft bearing	1.5	1.1	1.2
	End bearing	1.4	1.25	1.25
Dynamic impact tests (multiple blow)	Shaft bearing	1.5	1.1	1.2
	End bearing	1.4	1.2	1.2
Dynamic impact tests (closed form solutions)	Shaft bearing	Not permitted	Not permitted	Not permitted
	End bearing	Not permitted	1.3	1.3
Wave equation analysis		Not permitted	1.6	1.5
Pile driving formulae		Not permitted	1.8	1.7

Table 4. Model factors γ_{Rd} for verification of axial pile resistance by calculation.

Verification by	**Based on**	**Model factor γ_{Rd}**	
Ground Model Method	Ultimate pile tests	1.15	
	Extensive comparable experience without site-specific control tests	1.3	
	Serviceability pile tests	1.35	
	No pile load tests and limited comparable experience	1.55	
		Compressive resistance	Tensile resistance
Model Pile Method	Pressuremeter test	1.15	1.4
	Cone penetration test	1.1	1.1
	Profiles of ground properties based on field or laboratory tests	1.2	1.2

tests profiles located in the area S to a reference distance d_{ref} = 30 m:

$$\xi_{mean}(S) = 1 + \frac{d_{avg}}{d_{ref}}(\xi_{mean} - 1) \quad (4)$$

$$\xi_{min}(S) = 1 + \frac{d_{avg}}{d_{ref}}(\xi_{min} - 1) \quad (5)$$

2.4 Verification of axial resistance of pile groups and piled rafts (ULS)

As already mentioned Clause 6 of EN 1997-3:2025 covers not only single piles but equally also pile groups and piled rafts.

Pile group design shall consider that the resistance and load-displacement behaviour of single piles in a group might show significant variation compared to the behaviour of single piles due to pile-pile interaction. Calculation of pile group effects should consider the potential changes in stress and density of the ground resulting from pile installation together with the effects of group behaviour due to the structural loads taking the stiffness of the pile cap and the structure into account. The ultimate vertical resistance of a pile group R_{group} with n piles should be determined from:

$$R_{group} = \min\{\sum_i^n R_i ; R_{block}\} \quad (6)$$

where R_i is the ultimate axial resistance of the i-th pile in the pile group, taking full account of the effects of pile interaction, and where R_{block} is the ultimate vertical resistance of the block of ground bounded by the perimeter of the pile group. The design resistance of a pile group $R_{d,group}$ shall be verified using

$$F_d \leq R_{d,group} \quad (7)$$

with

$$R_{d,group} = \frac{R_{rep,group}}{\gamma_{R,group} \cdot \gamma_{Rd,group}} \quad (8)$$

where $\gamma_{R,group}$ is a resistance factor and $\gamma_{Rd,group}$ is a model factor for the pile group.

The design of piled rafts shall consider beside the pile-pile interaction the pile-raft interaction (Figure 4). Considering the compatibility of the displacements of the piles and the raft, the ultimate compressive resistance $R_{piled\text{-}raft}$ of a piled raft should be determined as

$$R_{piled-raft} = \left(\sum_i^n R_{c,i} + R_{raft}\right) \quad (9)$$

where R_{raft} is the additional bearing resistance from the raft. The design resistance of a piled raft $R_{d,piled\text{-}raft}$ shall be verified using

$$F_d \leq R_{d,piled-raft} \quad (10)$$

with

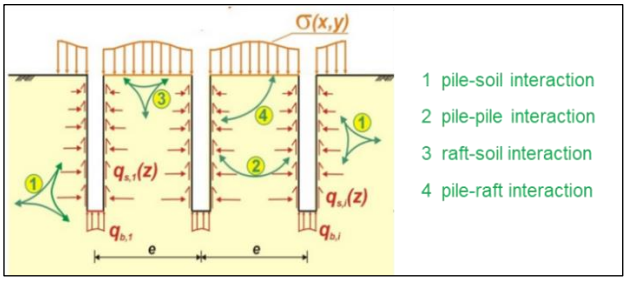

Figure 4. Interaction effects to be considered for the verification of piled rafts according to EN 1997-3, 6.5.6.

$$R_{d,piled-raft} = \frac{R_{rep,piled-raft}}{\gamma_{R,piled-raft} \cdot \gamma_{Rd,piled-raft}} \quad (11)$$

where $\gamma_{R,piled\text{-}raft}$ is a resistance factor and $\gamma_{Rd,piled\text{-}raft}$ is a model factor for the piled raft.

For the ULS-verification of axially loaded pile groups and piled rafts EN 1997-3 pretends the application of verification case VC1 in combination with RFA and partial factors of $\gamma_{R,group}$ = 1.4 resp. $\gamma_{R,piled\text{-}raft}$ = 1.4 leading to a comparable equivalent gloabal safety level as for spread foundations or single piles. For combined axial and transversal loaded pile groups and piled rafts both approaches, MFA or RFA, might be used for ULS-verficiations.

Verification of limit states for pile groups and piled rafts may be carried out by analytical or empirical, but preferential by numerical calculation methods.

2.5 Pile settlements and SLS verifications

Verification of the serviceability limit state for piled foundations should be based on modelling that accounts for non-linear stiffness of the ground, flexural stiffness of the structure, and interaction between the ground, structures, and piles. The non-linearity of the load-displacement curves of axially loaded piles should be considered for the verification of both geotechnical and structural limit states.

The settlement of a single pile may be determined from load tests or calculated using empirical or analytical methods or numerical modelling.

2.6 Downdrag (negative skin friction)

The adverse effects of a drag force caused by moving ground shall be included in the verification of serviceability *and* ultimate limit states of piled foundations when relevant. Thereby the drag force caused by downdrag should be classified as a permanent action. The effects of the downdrag should be modelled by carrying out a ground-pile interaction

analysis, to determine the depth of the neutral point L_{dd} corresponding to the point where the pile settlement s_{Pile} equals the ground settlement s_{ground}. This neutral point is different for SLS or ULS conditions as shown in Figure 5 which also illustrates the approach recommended to be used to calculate the neutral point and the dragforce owing to potential downdrag.

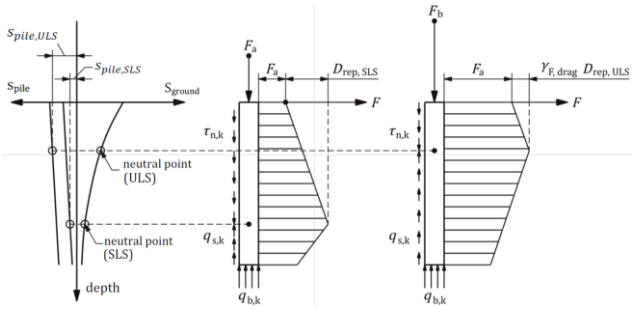

Figure 5. Force distribution for assessment of drag force on a pile subject to downdrag according to EN 1997-3, C.9.

The representative drag force D_{rep} should then be determined from

$$D_{rep} = p \int_0^{L_{dd}} \tau_s \cdot dz \qquad (12)$$

where p is the perimeter of the pile and τ_s is the (negative) unit shaft friction causing downdrag at depth z. EN 1997-3 provides in its Annex C a simplified approach for calculating the drag force by adopting a depth to the neutral plane L_{dd} that results in an upper value of the drag force.

2.7 Transversal loading

Clause 6 of EN 1997-3 provides also guidance on the verification of single piles, pile groups and piled rafts due to lateral loading. In Annex C.12 calculation models, mainly based on *p-y* curves from undrained and drained soil properties, are provided to calculate the behaviour of transversely loaded single piles. For the verification of the transverse resistance either the MFA or the RFA can be applied.

2.8 Buckling

The buckling resistance of a slender pile under compression and embedded in soil should be determined by a validated model, either analytic or numerical, according to second order theory considering the support of the soil and initial transverse deflection due to production imperfections, installation etc. EN 1997-3 provides detailed guidance to evaluate the buckling resistance by analytical methods even though other approaches, e.g. by numerical methods can be applied.

2.9 Cyclic effects

Cyclic and dynamic actions can result in reduced ground strength and stiffness leading to additional pile displacements and loss of resistance. Therefore, EN 1997-3 requests to consider the adverse effects of cyclic and dynamic actions on the long-term axial and transverse resistance of piled foundations. In Annex C.14 of EN 1997-3 the concept of ´stability diagram´ based on Poulos (1988) is provided to determine in a simple way whether the axial cyclic loads applied at the pile head can induce any degradation effects to reduce the axial pile resistance.

2.10 Further aspects

Clause 6 of EN 1997-3 provides guidance to many further aspects being relevant for piled foundations including further calculation and design issues but also execution, testing and reporting. Even aspects of sustainability are addressed as the thermal, geo-technical and structural design aspects of thermo-activated deep foundations are mentioned.

ACKNOWLEDGEMENTS

The authors have been involved at various stages in the development of the second generation of Eurocode 7, serving on a range of evolution and working groups or project teams. They are grateful to their colleagues for their contributions to the development of EN 1997-3.

Evaluation of seismic-induced crest settlement of earth dams

Évaluation du tassement de la crête des barrages en terre induit par les séismes

A. Nardo*, G. Biondi, E. Cascone
University of Messina, Contrada di Dio, Messina, Italy
**andrea.nardo@studenti.unime.it*

ABSTRACT: In this paper an original empirical formula for the prediction of the permanent crest settlement of earth dams is proposed starting from the results of a large set of 2D dynamic finite element analyses carried out with reference to an Italian zoned earth dam. Various seismic parameters, representative of the input motion, have been considered as possible predictive variables, individually or in combinations, and an original seismic parameter is introduced to reliably describe the variation of the crest settlement with the characteristics of the input motion in terms of amplitude, energy and frequency content. The proposed empirical formula has been checked using data available in the literature with reference to two other Italian earth dams, for which specific predictive formulas have been also derived. Finally, the use of the proposed seismic parameter to check the possible occurrence of earthquake-induced limit states in earth-dam is also explored.

RÉSUMÉ: Dans cet article, une formule empirique originale pour la prédiction du tassement permanent des barrages en terre est proposée à partir des résultats d'un grand ensemble d'analyses dynamiques 2D par éléments finis effectuées en référence à un barrage en terre zoné italien. Différents paramètres sismiques, représentatifs du mouvement d'entrée, ont été considérés comme des variables prédictives possibles, individuellement ou en combinaison, et un paramètre sismique original est introduit pour décrire de manière fiable la variation du tassement de la crête avec les caractéristiques du mouvement d'entrée en termes d'amplitude, d'énergie et de contenu fréquentiel. La formule empirique proposée a été vérifiée à l'aide des données disponibles dans la littérature en référence à deux autres barrages en terre italiens, pour lesquels des formules prédictives spécifiques ont également été dérivées. Enfin, l'utilisation du paramètre sismique proposé pour vérifier l'occurrence possible d'états limites induits par les tremblements de terre dans les barrages terrestres est également explorée.

Keywords: Earth dams; seismic performance; damage index; predictive correlations; dam crest settlements.

1 INTRODUCTION

The seismic performance of an earth dam and the possibly expected damage (freeboard loss, slope instability, cracking and erosion of water tightness elements, soil liquefaction) depend on several factors, such as the type of dam, the construction materials, the geometry, the foundation soils, the past loading history and the characteristics of the seismic-induced ground motion (e.g. USCOLD 1992, Adamo et al. 2020).

It is widely recognised (e.g. Swaisgood 2003, Aliberti et al. 2019, Nardo et al. 2024a) that the permanent crest settlement of earth dams represents a suitable index of their seismic performance and of the earthquake-induced level of damage.

Seismic-induced crest settlements can be evaluated by performing numerical dynamic analyses that allow simulating complex geometries, as well as reproducing the non-linear soil behaviour through advanced constitutive models; however, the simulation of other stages necessary to reproduce the pre-earthquake effective stress state can significantly increase the computational effort.

Swaisgood (2003) investigated the factors that influence crest settlement using 69 case histories of performance of dams during strong and weak earthquakes and proposed a relationship between crest settlements and the peak horizontal ground acceleration at the site of the dam. Although this approach is promising, it does not consider the mechanical characteristics of different dams. Therefore, relationship calibrated on individual dams may be more reliable.

As an alternative, some authors recently proposed original empirical formulas valid for a single dam giving the crest settlement as a function of an intensity measure representative of the characteristics of the input motion (e.g. Zefa et al 2022, Khalid et al. 2023, Nardo et al. 2023).

In this paper, 2D dynamic finite element analyses have been performed with reference to an Italian zoned earth dam for which an accurate geotechnical

characterization is available. Specifically, the seismic response of the San Pietro dam was investigated using to 58 rock outcropping earthquake records. In the analyses the soil behaviour has been simulated using an isotropic hardening elasto-plastic hysteretic model.

Several seismic parameters, representative of the amplitude, energy, frequency and duration of the input motion (Zefa et al., 2022) have been considered (individually or in combinations) to detect the proper variable for an accurate prediction of the permanent crest settlements of the dam.

As a result, an original intensity measure and a predictive formula (the latter valid for the San Pietro dam) has been proposed. Results available in the literature for two other Italian dams have been used to check the effectiveness of the predictive formula relating the proposed seismic parameter to the crest settlements.

Finally, the proposed intensity measure and the predictive formula developed for the San Pietro dam have been used to assess the occurrence of possible limit states induced by the ground motion and hence predict the seismic-induced level of damage expected at the dam.

2 DAMS EXAMINED IN THE ANALYSES

The dynamic analyses presented in the paper refer to the San Pietro dam. The results of dynamic analyses relative to two other earth dams have been also collected and analysed: namely, the Marana Capacciotti dam, examined by Elia and Rouainia (2013), and the Camastra dam, studied by Sica and Pagano (2009). Figure 1 schematically shows the main sections of these three dams.

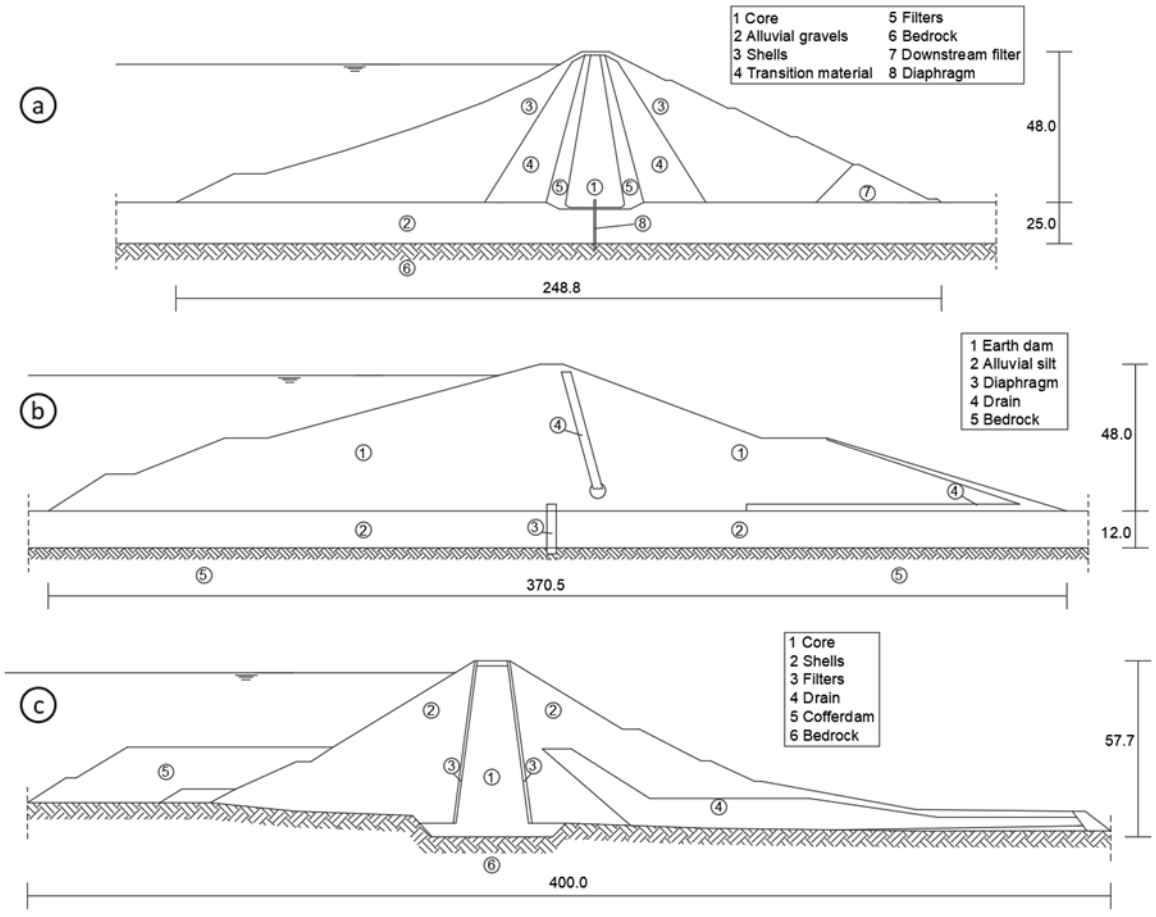

Figure 1. Object dams: a) San Pietro dam, b) Marana Capacciotti dam and c) Camastra dam.

2.1 San Pietro dam

The San Pietro dam is a zoned earth dam placed along the Osento river in Campania, in an area of high seismicity. It has a height of about 48 m (Figure 1a).

The geotechnical characterization of the dam embankment and of the foundation soils is based on the results of the investigations described by Calabresi et al. (2004). Data on the geotechnical soil properties and on the seismic hazard of the dam site can be found in Biondi et al. (2021) and Cascone et al. (2021).

The dam has been modelled using a finite element code, simulating the non-linear soil behaviour through the HSsmall model, an isotropic hardening elasto-plastic hysteretic model, available in the code library. The calibration of the constitutive model for the soils of the dam and of the foundation is described by Casablanca et al. (2022) and Nardo et al. (2024b).

The values of the small strain shear modulus G_0 adopted in the analyses have been evaluated starting from the small strain shear modulus profiles obtained interpreting the results of available cross-hole tests.

The model parameters have been calibrated on the results of oedometer tests, resonant column tests, drained and undrained triaxial compression tests carried out on undisturbed soil samples. The values of model parameters are summarized in Table 1.

The numerical analyses have been performed in plane strain conditions, discretizing the dam and the foundation soils in a finite element mesh of about 5000 triangular 15-noded elements. The FE numerical models used in the static and dynamic analyses are depicted in Figure 2.

To reproduce the pre-earthquake stress-strain state of the dam and foundation soils, under the static conditions, the staged construction of the dam and the subsequent impoundment of the reservoir have been preliminarily simulated.

In dynamic analyses the coarse-grained soils of the dam flanks below the phreatic line have been considered in undrained conditions, according to the Undrained A procedure implemented in the computer code Plaxis. The portion of the flank above the phreatic line is considered drained, neglecting the effect of suction on the shear strength of the flank. The previous assumption of a fully undrained flank was preliminarily checked according to the relationship provided by Zienkiewicz et al. (1980). Furthermore, several fully coupled dynamic analyses have been performed to verify the correctness of the fully undrained assumption for the saturated flanks. The results in terms of the excess pore water pressures and crest settlements are practically comparable, so, the assumption of fully drained behaviour of the saturated flank seems to be reasonable.

Two sets of acceleration records have been used for the dynamic analyses of the San Pietro dam:

- a set of 58 earthquake records, recorded on rock outcropping sites, encompassing wide ranges of amplitudes, energy and frequency contents with the aim of exploring the seismic behaviour of the dam at several intensity levels;
- a *validation set* of 7 earthquake records, recorded on rock outcropping sites, compatible with the seismicity of the dam site (Biondi et al. 2021, Nardo et al. 2024b).

The first set of accelerograms has been used as a *calibration set* for the development of a suitable formula to predict the crest settlement of the San Pietro dam. For this *calibration set*, the peak ground acceleration ($PGA = 0.096$ - $0.673g$) and the Arias Intensity ($I_A = 0.01$ - 2.01 m/s) vary within large intervals (Nardo et al. 2024b), thus representing a broad set of seismic motions, suitable to adequately explore the dam response in a wide range of strain levels. These intervals of PGA and I_A also comprise the values of the seismic parameters of the *validation set* of 7 earthquake records which was used to validate the proposed predictive formula.

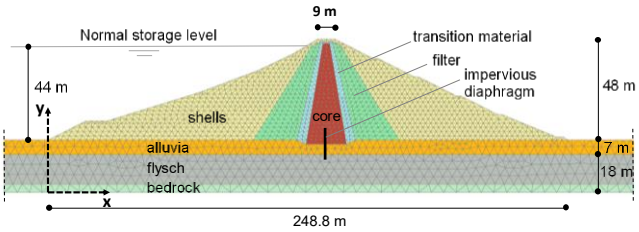

Figure 2. FEM adopted in the numerical analyses.

Table 1. Model parameters of the San Pietro dam.

Parameters	Core	Shell	Alluvia	Flysch
$E_{50\ ref}$ (MPa)	30	30	440	440
$E_{oed\ ref}$ (MPa)	30	17.5	440	440

R_f	0.9	0.85	0.9	0.9

2.2 Marana Capacciotti dam

The Marana Capacciotti dam is a homogeneous earth dam located in southern Italy and built between 1970 and 1975. Its height is about 57 m (Figure 1b).

Elia and Rouainia (2013) calibrated an advanced kinematic hardening model (RMW model) to describe the non-linear behaviour of the dam and foundation soils in both static and cyclic loading conditions.

The FE analyses of the dam have been undertaken assuming plane strain free draining conditions. To minimize the lateral boundary effects, the mesh has been horizontally extended approximately to three times the width of the base of the embankment, and vertically down to 42 m from the ground surface, where a bedrock formation can be identified. Standard boundary conditions along the vertical and bottom sides of the mesh have been used during the static analyses.

The initial static stress state and the corresponding model internal variables have been obtained following the approach described by Elia et al. (2011). After the simulation of the embankment construction, in four layers, the subsequent reservoir impounding to the maximum serviceability conditions has been numerically reproduced through a coupled seepage analysis.

The initial shear modulus profile along the dam axis has been obtained as a result of the static analyses. Once the static stress state has been initialized, the dynamic simulations have been performed applying the input motions to the solid nodes at the base of the mesh as prescribed horizontal displacement time histories, with fixed vertical displacement. To avoid spurious wave reflections at the boundaries of the foundation layer, tied-nodes boundary conditions have been adopted along the lateral sides of the mesh.

The first natural frequency of the dam embankment is 1.28 Hz corresponding to a fundamental period of 0.78 s (Elia and Rouainia 2013).

The selection of the input motions was based on the seismic hazard study relative to the dam site. Specifically, 5 earthquake records were selected and scaled to two different *PGA* values, namely 0.127*g* and 0.425*g*, thus obtaining 10 input motions having Arias Intensity in the range I_A = 0.06 - 2.47 m/s.

2.3 Camastra dam

The Camastra Dam, built between 1963 and 1964, is a zoned earth dam located in Southern Italy, in a seismic prone area. It is characterized by a height of about 57 m (Figure 1c).

The constitutive model adopted to simulate the soil behaviour is the Hujeux model, characterized by both isotropic and kinematic hardening.

The determination of the hardening parameters was carried out by estimating a suitable G/G_0-γ curve for the soils at hand and then by back-analysing this trend through the Hujeux model. The shear modulus at small strains G_0 was obtained from the shear wave velocity measurements of the DH test and conventionally referred to a value of shear strain equal to 10^{-5} %. The model parameters have been set also considering the results of triaxial and oedometer tests, carried out on the core and shell materials during the design and the construction stage.

The first natural frequency of the dam embankment in the transversal direction is 3 Hz and was obtained by interpreting several weak motion events recorded by the Camastra Dam seismic network (Sica et al., 2008).

The seismic response was investigated by Sica and Pagano (2009) using 7 acceleration records as input motion, selected through a seismological study of the dam site. The values of *PGA* and I_A of the selected accelerograms vary in the intervals *PGA*=0.168-0.528*g* and I_A=0.02 – 4.44 m/s.

3 ANALYSIS OF RESULTS

The results presented in this paper have been obtained through dynamic analyses of the San Pietro dam, carried out under plane strain condition using the computer code *Plaxis*. Through the best-fit of the numerical results, a predictive formula has been calibrated to estimate the crest settlements of the dam as a function of a suitable set of seismic parameters. Specifically, screening analyses pointed out that the intensity measure $I_D = I_A \cdot T_m / PGV^{0.5}$, defined by Nardo et al. (2024b) as a suitable combination of the Arias intensity I_A, mean period T_m and peak ground velocity *PGV*, represents a proper predictive parameter to assess the dam crest settlement.

Using an integral definition of the mean period and the Parseval's theorem, the product of $I_A \cdot T_m$, can be expressed in the following form:

$$I_A \cdot T_m = \frac{\pi}{g} \int_0^{\omega_N} \omega^{-1} C^2(\omega) d\omega \quad (1)$$

where ω_N is the Nyquist frequency, $C(\omega)$ is the Fourier amplitude spectrum of the acceleration time-history, ω is the circular frequency and *g* is gravity acceleration. This form represents the area of the acceleration amplitude Fourier spectrum weighted with respect to the inverse of circular frequencies, thus implying that lower frequencies have a larger weight.

PGV describes the motion amplitude at the intermediate frequencies, providing a more accurate indication of damage potential than peak ground acceleration (Kramer 1996). Also, according to Trifunac and Brady (1975) and Housner and Jennings (1982), *PGV* can be correlated to the earthquake intensity since it is directly associated with the energy demand.

Thus, the use of the proposed intensity measure I_D allows accounting for the energy demand at both low and intermediate frequencies which are generally more relevant for geotechnical systems such as dams and embankments.

Figure 3 shows the results of the analyses carried out using the *calibration set* of accelerograms and the linear best-fit described by eq. 2. In the figure the results obtained using the *validation set* of accelerograms are also plotted, showing a good agreement with the proposed predictive formula.

Using results of dynamic analyses relative to the Marana Capacciotti (Elia and Rouainia 2013) and the Camastra (Sica and Pagano, 2009) dams, it has been confirmed that I_D is well related to the earthquake-induced crest settlement and two specific different predictive formulas, namely Eqs. 3 and 4, have also been derived.

The empirical predictive formulas proposed for the San Pietro (Eq. 2), Marana Capacciotti (Eq. 3) and Camastra (Eq. 4) are plotted in Figure 4 together with the values of the permanent crest settlements adopted in their derivation:

$$w_c = 2,67 \cdot I_D \quad (2)$$

$$w_c = 2,05 \cdot I_D \quad (3)$$

$$w_c = 0,92 \cdot I_D \quad (4)$$

Equations (2)-(4) provides w_c in cm as a function of the proposed intensity measure I_D given in $(cm \cdot s)^{0.5}$. As described by Nardo et al. (2024b), differences in the regression coefficients of the proposed formulas, representin the gradients of the linear best-fits plotted in Figure 4, can be ascribed to the factors affecting the dynamic response of the dam.

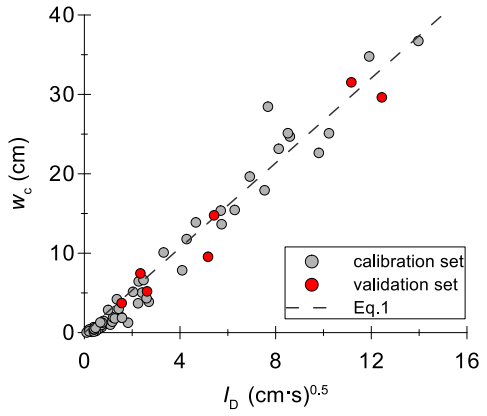

Figure 3. Crest settlements computed for the San Pietro Dam and predictive formula (eq.1).

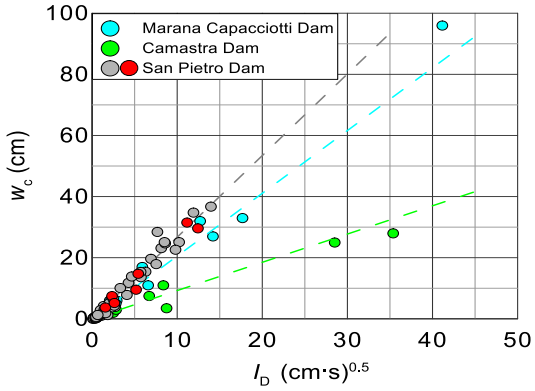

Figure 4. Crest settlements computed for three earth dams and relative linear best fits.

Recently, Nardo et al. (2024a) and Aliberti et al. (2019) proposed threshold values $w_{c,y}/H$ of the normalized crest settlement (i.e. the crest settlement normalized with respect to the total height H of the dam-foundation system) to check the possible occurrence of serviceability (*Operative limit states* OLS, *Damage limit states* DLS) or ultimate (*Life Safety limit states* LLS and *Collapse limit states* CLS) limit states. These threshold values were derived using a large set of well-documented case-histories and update those previously proposed by Swaisgood (2003).

According to Nardo et al. (2024b), the combined use of I_D and of the threshold values of the normalized permanent crest settlement allows a reliable evaluation of the earthquake-induced level of damage in earth dams. An example of this combined use is presented in Figure 5 with reference to the San Pietro, Marana Capacciotti and Camastra dams.

For the San Pietro dam it is apparent that accelerograms characterized by $I_D < 3$ do not induce any damage since it is $w_c/H < 0.1$; values of I_D in the range 3÷11 correspond to normalized crest settlements for which the OLS and DLS could be achieved; finally, the *Damage limit state* could be attained for $I_D > 12$.

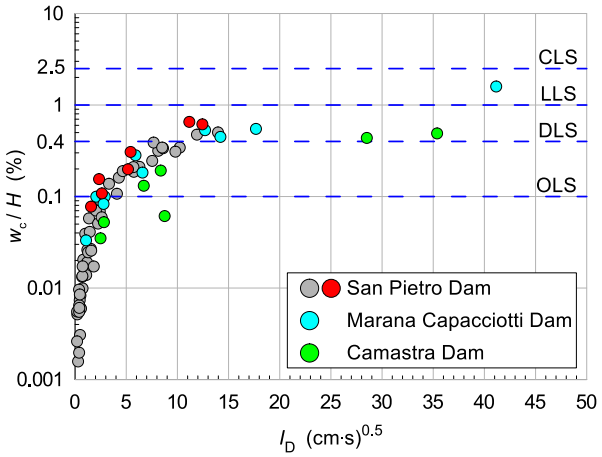

Figure 5. Evaluation of the expected level of damage for three earth dams.

Similar conclusions can be drawn for the Marana Capacciotti and the Camastra dams. It can be observed that, in the examined cases, the threshold value $w_c/H = 1\%$ is never reached (with only one exception relative to the Marana Capacciotti dam) implying that for the input motions considered herein these three dams can only suffer moderate damage.

4 CONCLUSIONS

The seismic performance of the San Pietro dam has been studied through a finite element analysis using

two set of input motions and the obtained results have been used to develop and verify a predictive formula for the assessment of the crest settlement.

Analysing data available in the literature, it has been verified that the proposed seismic intensity measure is well correlated to the crest settlements, also for other two Italian dams. Using a suitable combination of the intensity measure I_D and threshold values of the normalized crest settlement recently proposed by Nardo et al. (2024a) and Aliberti et al. (2019), a simplified evaluation of the expected level of earthquake-induced damage in the examined earth dams has been proposed.

ABSTRACT: Rainfall-triggered slope failures are a well-known cause of disasters. To increase the stability of slopes a retaining wall is often proposed. However, associated earthworks could bring the great danger of a landslide during the construction process, if not properly managed. The paper aims to investigate the collapse cause of residential buildings located at the edge of the slope in the northwest part of Vietnam, where engineering works were performed to prevent failure due to undercutting soil erosion. During the retaining wall construction works, significant vibrations and additional dynamic loads could have affected the building foundations' bearing capacity, leading to structural failure. Another cause is associated with heavy precipitation recorded at the site just after the excavation works down the slope. The paper consists of analyses allowing simulation of possible scenarios, including the effect of changing saturation conditions using the metrological data. The analyses concerned slope stability improvement to secure the remaining infrastructure.

RÉSUMÉ: Les glissements de terrain déclenchés par les précipitations sont une cause bien connue de catastrophes liées aux structures. Pour accroître la stabilité, la construction d'un mur de soutènement est souvent proposée. Cependant, de tels travaux peuvent également entraîner un danger élevé de glissement de terrain pendant la construction s'ils ne sont pas gérés correctement. L'objectif de l'article est d'investiguer la cause de l'effondrement des bâtiments résidentiels situés en bordure du talus dans le nord-ouest du Vietnam, où des travaux d'ingénierie ont été effectués pour prévenir les défaillances dues à l'érosion des sols causée par le sous-excavation. Pendant les travaux de construction du mur de soutènement, des vibrations importantes et des charges dynamiques supplémentaires auraient pu affecter la capacité portante des fondations des bâtiments, entraînant une défaillance structurelle. Une autre cause est liée aux fortes précipitations enregistrées sur le site juste avant le début des travaux d'excavation en descente du talus. L'article comprend des analyses permettant de simuler des scénarios possibles, y compris l'effet des conditions de saturation changeantes à l'aide des données météorologiques. Les analyses ont porté sur l'amélioration de la stabilité du talus afin de sécuriser les infrastructures restantes.

Keywords: Slope stability; rainstorm event; infrastructure failure; retaining wall.

1 INTRODUCTION

Slope stability issues are a common safety concern when it comes to development plans in urban areas. Landslides can occur due to natural processes and poor management of developing sites. The natural process like changing climate conditions, are very challenging to control. When it comes to human factor-triggered landslides most of the failures could be easily avoided by fully understanding the danger caused by the construction works and management of developing sites. The present study analyses triggering factors of the collapse of buildings located by the edge of the natural slope. The collapse is recognised to be associated with extreme precipitation events recorded at the site and poor drainage conditions after the retaining wall construction works.

Retaining walls are primarily designed to improve the structure stability but can also eliminate the soil erosion effect on the river banks or slopes located by the waterways, undercutting the slope at its toe. When considering the construction of the retaining wall in areas of high-risk failure due to the presence of associated infrastructure, the method of reinforcement

installation is crucial (Look, 2022). There are a number of case studies researching rainfall-triggered landslides (Lacroix et al, 2020; Maturidi et al, 2021) or slope failures due to poor execution of earthworks during the installation of reinforcements. Engineering practice shows that one of the most common causes of slope failures is the decrease of soil shear strength due to the development of groundwater pressure at the potential slip surfaces (Filho and Fernandes, 2019). Long-lasting precipitation is affecting dipper parts of a slope profile resulting in severe collapses (Patuti et al, 2017; Alsubal et al, 2019). The present paper aims to investigate the real cause of slope failure in the northwest part of Vietnam. The sequence of events recorded at the site, both natural and manmade, resulted in severe damage to the surrounding infrastructure, forcing the residents to evacuate. The authors tried to reconstruct the process by collecting available data and investigating mechanisms that could have caused the failure of the slope and the infrastructure.

2 STUDY SITE DESCRIPTION

The case study site is located in a mountainous district in the centre of Dien Bien province, in the northwest part of Vietnam (Figure 1). It is divided into two landform zones where the terrain elevation ranges from 350-1000 m a.s.l. The terrain is morphologically complex with a number of valleys and rivers crossing the entire region, where during the wet season the meandering streams are cutting the mountain toes. What is important for the case study is the presentation of the local climate condition that has a major effect on the working conditions of the infrastructure and causes of natural hazards. The conditions are typical for tropical monsoon climate. The annual rainfall ranges from 1,600 to 2,400 mm.

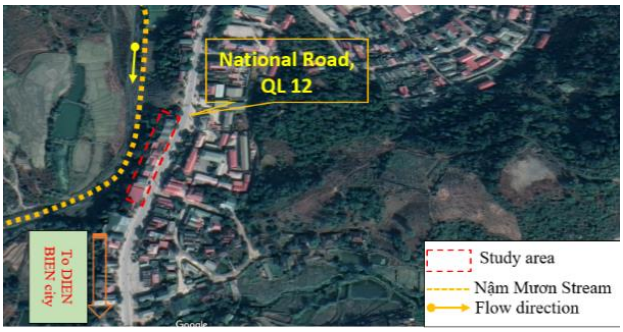

Figure 1. Location of study area.

The case study concerns a natural slope with extensive infrastructure developed at the top edge. The infrastructure development started with the construction of a local road near the edge and the design of the drainage system redirecting the runoff down the 25m high slope. Following the road construction number of storey buildings were constructed in the section between the road and the slope's edge. At the toe of the slope, there is a natural stream passing with the flow changing depending on the rainfall volume. In recent years, the local community's major awareness has been focused on the erosion effect due to the stream continuously cutting the toe of the slope. Thus, a retaining wall was constructed to control the water erosion and improve the slope's stability. After the works were accomplished significant rainfall events took place. The finger pipe drainage was installed at the back of the wall. A few weeks later the residents reported the first building cracking, which continued to develop until the next severe rainfall event that was followed by the slope failure and a collapse of buildings located at the study site. Figure 2 presents graphically the sequence of events leading to a final slope failure. The authors of the present paper aim to investigate events and the processes contributing to the failure occurrence. Based on the data collected from the site investigation report, meteorological report and the information gathered during the site visits, the analytical study was performed to reflect the in-situ conditions.

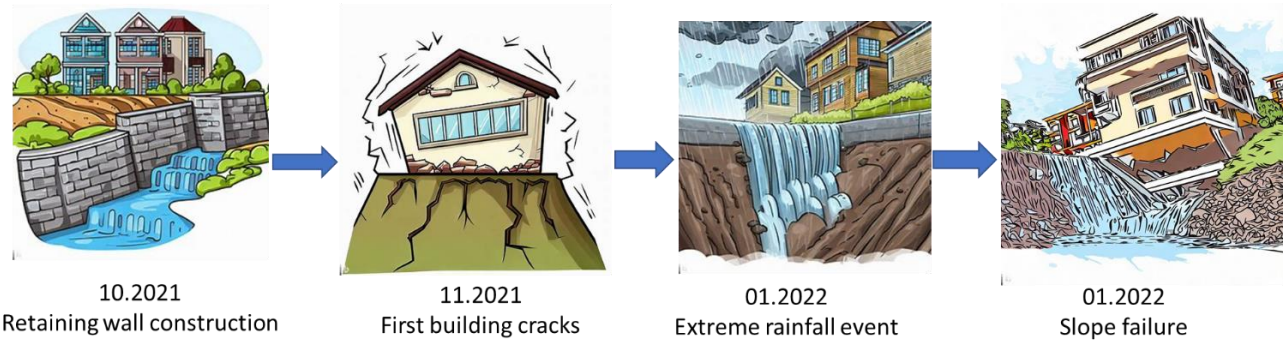

Figure 2. Graphical presentation of the sequence of events leading to a structural failure of residential buildings.

3 GEOTECHNICAL CONDITION

For analyses of the conditions at the study site, a geotechnical investigation was performed. During the site investigation, 11 core samples were collected and transported to the laboratory where physical and mechanical parameters were determined using triaxial tests. There were 4 main geotechnical layers determined, with the groundwater table investigated at 2,5m depth. The experimental results of physico-mechanical parameters are presented in Table 1.

Table 1. Physico-mechanical properties of soil layers.

Parameter	Soil type			
	Fill	Shale *	Shale **	Sandstone **
w (%)	23.9	28.2		
γ (g/cm^3)	1.96	1.90	2.2	2.50
e (%)	0.69	0.8		
Ip (%)	16.2	15.7		
c‘ (MPa)	0.0167	0.174	0.09	0.18
φ‘ (°)	17	20	32	46

*highly weathered; **moderately weathered

Since the rainfall events in the study were concerned with having a major effect on the failure, the precipitation data were also analysed. To allow further understanding of the failure cause the rainfall data was collected from the nearby monitoring station. Important for the study is the accumulative rainfall of 2000 mm recorded on 10.2021. Another crucial note for the study is that the finger pie drainage behind the retaining wall was found to be clogged during the site investigation.

4 RESULTS AND DISCUSSION

The authors attempted first to reflect the sequence of events by analysing all the circumstances at the site starting with matching the recorded rainfall data with the time of constructing the retaining wall, through observed cracks on the buildings and the time of the final failure of the slope. The graph presented in Figure 3, shows the chronologic sequence of events to give a better understanding of all the possible causes of the final failure of the slope, which eventually resulted in severe damage to the residential buildings. In late 2021, due to the alarming technical condition of the slope, the local authorities decided to support the toe by constructing the retaining wall, in the form of a concrete gravity wall, preventing potential failure. The excavation works that took place on 7-20.10.2021 caused heavy ground vibrations that were reported by the local citizens occupying the buildings located at the top of the slope. Soon after the retaining wall works were completed a significant rainfall event was recorded, reaching 30 mm on 22.10.2021. It is worth noting that the accumulation rainfall recorded for October is 2000 mm. A week later, the first cracks developing in the buildings were observed. It was only 2 months later, on 16.01.2022 when more damages to the building were reported and the slope failed after the rainfall event that reached nearly 45 mm in a single day. Through the analytical approach and detailed investigation of events, it is assumed that two major factors triggering the slope failure were the retaining wall earthworks and poor drainage conditions during the torrential precipitation.

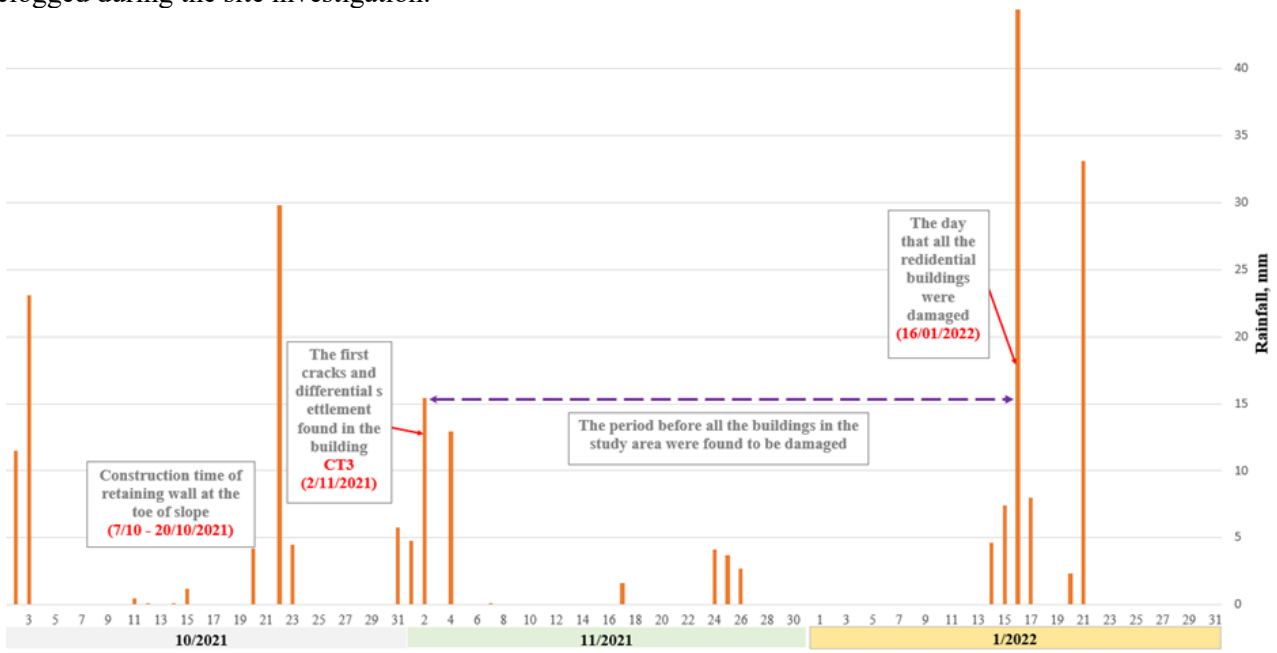

Figure 3. The sequence of events leading to a final failure with referencing rainfall data recorded in the study area.

During the earthworks, the dynamic loads loosened the soil material at the building foundation. The following rainfall could then easily penetrate the soil profile causing the decrease of the soil's mechanical parameters due to build-up of effective stress, also caused by poor drainage conditions. Based on geotechnical investigation data and rainfall volume the computations of geotechnical safety were performed to determine the failure mechanism and to reflect the sequence of the events. Based on the analyses the restoration works and computations of geotechnical safety were performed. The slope stability analyses were performed using the finite element method for the parameters obtained from the site investigation. The geotechnical model used for further analyses was based on the Mohr-Coulomb soil model, and the factor of safety was computed based on the shear strength reduction method. There were different scenarios for the analyses applied, depending on the changing groundwater level due to rainfall and infiltration. To ensure safety the entire slope was re-engineered and reinforcement such as MSE and gabion wall was proposed. The system allowed for minimising the excavation and earthworks' impact on the remaining infrastructure so as not to cause any more damage. Finding the optimum solution, the deformations and the factor of safety were computed as presented in Figure 4. The obtained factor of safety was 1.34 > [FS]=1.25 and maximum horizontal displacement did not exceed 4.25 cm < [δ]=H/200 = 7.5 cm, where H is the total height of the wall.

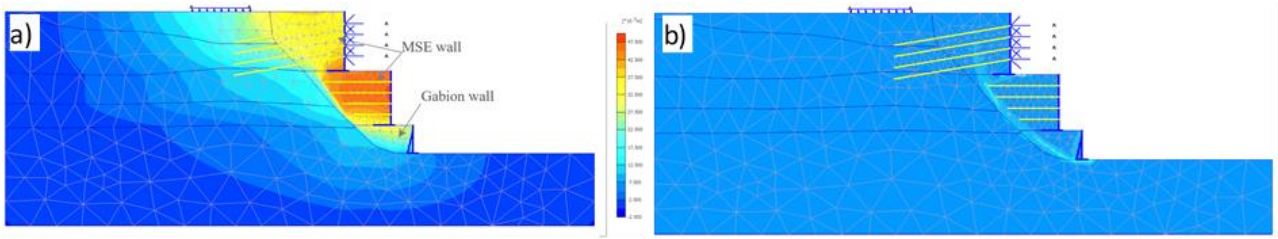

Figure 4. Computations of geotechnical safety a) displacements, b)FS and slip surface determination.

5 CONCLUSIONS

The study's objective was to investigate the on-site conditions and imitate the events that may have led to the residential building damage and eventually the slope failure. The site investigation data, meteorological monitoring reports, drainage conditions and the examination of earthworks during the construction of the retaining wall allowed comprehensive examinations of events that contributed to the slope's failure. Based on all the gathered information a reclamation plan was implemented and solutions for improving the geotechnical safety were proposed, by computing the factor of safety and total deformations of failed and then newly engineered slopes. The lesson learned from the case study is that the earthwork aiming at improving safety, in particular circumstances, when dealing with severe weather events could have the opposite, even damaging effect.

Effect of variability parameters on 3D probabilistic slope stability prediction

Impact des paramètres de variabilité sur la prédiction probabiliste de stabilité des pentes en 3D

E.A. Oguz*, T.M.H. Le
Norwegian Geotechnical Institute, Department of Geotechnics and Natural Hazards, Trondheim, Norway
**emir.ahmet.oguz@ngi.no*

ABSTRACT: Uncertainties in landslide assessment arise substantially from spatial variability of geotechnical and hydrological parameters. Spatially variable model parameters are often represented by a probability density function with a mean and a standard deviation, and a covariance function with a spatial correlation length. The variability parameters are frequently selected based on values in literature due to a lack of real data, thus not necessarily representing the true spatial variability characteristics of a given problem. Such a selection might lead to overestimated or underestimated safety levels. Therefore, there is a need to quantify how the choice of variability parameters affects the safety levels. This study addresses this need by studying the effect of variability parameters on the landslide slope stability predictions in terms of factor of safety using the 3-Dimensional Probabilistic Landslide Susceptibility model (3DPLS) on a simplified 2 m-thick inclined slope. Different sizes of an ellipsoidal sliding surface were analysed for a range of variability parameters over varying extent of problem domains. The results indicate that variability parameters significantly affect the safety levels depending on the extent of the problem domain and the size of the sliding surface. In addition, the critical spatial correlation length leading to the lowest safety level is found to have strong correlation with the size of the sliding surface.

RÉSUMÉ: Les incertitudes en évaluation des glissements de terrain résultent de la variabilité spatiale des paramètres géotechniques et hydrologiques. Ces paramètres modélisés, variables spatialement, s'appuient souvent sur des données littéraires, ne reflétant pas totalement la réalité spatiale par manque de données réelles. Cette sélection pourrait conduire à des niveaux de sécurité surestimés ou sous-estimés. Il est donc crucial d'évaluer son impact. Cette étude examine comment les paramètres de variabilité affectent les prédictions de stabilité des pentes de glissement à l'aide du 3DPLS sur une pente inclinée de 2 mètres d'épaisseur. Diverses tailles de surface de glissement ellipsoïdales ont été analysées sur différents domaines, montrant une forte influence des paramètres de variabilité sur les niveaux de sécurité, en fonction de l'étendue du domaine et de la taille de la surface de glissement. De plus, il est constaté une forte corrélation entre la longueur de corrélation spatiale critique, associée au niveau de sécurité le plus bas, et la taille de la surface de glissement.

Keywords: Probability; landslide; spatial variability; 3D slope stability.

1 INTRODUCTION

Slope stability predictions are subjected to a variety of sources of variability, including aleatory and epistemic uncertainties associated with the geotechnical and hydrological parameters, the uncertainty in input data, and the limitations of prediction models. One of the sources contributing substantially to the uncertainties of model predictions is natural spatial variability of the soil parameters. Geotechnical and hydrological parameters can vary significantly over short distances. This can lead to significant changes of parameters between adjacent areas, and results in different levels of slope stability (Fenton & Griffiths, 2008).

Spatially variable model parameters can be modelled by using a probability density function with a mean and a standard deviation, and a covariance function with a spatial correlation length representing the spatial dependence of the parameters. In the literature, many studies addressed the need for accounting for variability and showed the impact on stability predictions (e.g., Hu et al., 2022; Kasama & Whittle, 2016; Tabarroki et al., 2013; Zhu et al., 2019). The findings of these studies revealed that deterministic models or traditional probabilistic models without spatial variability might lead to unconservative estimates of failure probability.

The essentiality of accounting for the spatial variability in slope stability prediction over large areas was addressed in the literature (Arnone et al., 2016; Mergili et al., 2014; Oguz et al., 2022). Oguz et al. (2022) developed the 3-Dimensional Probabilistic Landslide Susceptibility, 3DPLS, model to account for spatial variability over large areas. 3DPLS model

utilizes random field approach for spatially variable soil parameters and performs 3D slope stability analyses over a landslide susceptible zone in a probabilistic framework. Using the 3DPLS model, Oguz et al. (2022) showed the significant impact of spatially variable soil parameters on landslide stability predictions.

In practice, variability parameters are primarily chosen based on the literature values due to insufficient data from the area susceptible to landslides. The selection of variability parameters can impact stability predictions, and the extent of this effect needs to be addressed. This study addresses this need by conducting a parametric study on a shallow, 2 m thick inclined slope. The current study expands the investigation on the impact of variability level and degree of spatial variability in Oguz et al. (2022) by further exploring the impact of varying dimensions of sliding surface and problem extents in a probabilistic framework.

2 THE 3DPLS MODEL

The 3DPLS model (Oguz et al., 2022) was developed to address the spatial variable model parameters in rainfall-induced landslide susceptibility assessment. The model couples a hydrological model relying on Iverson's solution of the Richards equation assuming tension saturation (Iverson, 2000) and a slope stability model employing the extension of Bishop's method of slope stability to 3D (Hungr, 1987). Spatial variable model parameters are modelled with 2D Gaussian and lognormal random fields (Fenton & Griffiths, 2008). Uncertainties in model parameters are propagated to the model output through Monte Carlo simulations, in each of which a new random field is generated for the spatial variable model parameters.

The 3DPLS model generates ellipsoidal sliding surfaces over a landslide-susceptible area discretized into grid units, i.e., cells. An ellipsoidal sliding surface characterized by the lengths of principal semi-axes $a_e - b_e - c_e$, and inclination and aspect of motion, respectively β and α. β and α are calculated by the 3DPLS model using the input data. While a_e is defined along the principal semi-axis in the direction of the steepest slope, b_e is the length along the semi-axis perpendicular to the steepest slope. c_e is the depth of the sliding surface defined perpendicular to the other two semi-axes (Oguz et al. 2022).

In the 3DPLS model, the spatial variability in the horizontal dimensions is modelled with 2D Gaussian and lognormal random fields. The spatial variability along the soil thickness/depth is not modelled for simplicity. The model, through Monte Carlo simulations, provides FS maps for each simulation, mean FS maps, and the probability of failure, P_f, map.

In this study, a global factor of safety, F_S^g, is defined for each simulation as the most critical sliding surface over the problem domain such that $F_S^g = \min[F_{Si}: i = 1, \dots, n]$ where n is the number of cells over the problem domain. Following Monte Carlo simulations, F_S^g values are averaged to calculate the mean global factor of safety, μ_g, such that $\mu_g = 1/N_S \sum(F_S^g)$ where N_S is the number of simulations. The effect of variability parameters on 3D probabilistic slope stability prediction was investigated considering the μ_g values for different problem domain extents, sliding surface dimensions, and varying variability levels. Current study utilized the up-to-date version, 3DPLS v1.0, (2022). The details of the model can be seen in Oguz et al. (2022).

3 PARAMETRIC STUDY

In this study, a simplified problem geometry has been examined where the soil layer has a thickness of 2 m with a 25° inclination over a varying size of the problem domain: 200 m x 200 m, and 50 m x 50 m. The ground water table is assumed at the ground surface with a surface parallel flow through the inclination. The problem domain was discretized into 2 m cell size. Different sizes of an ellipsoidal sliding surface were utilized assuming equal horizontal semi-axes, i.e., $a_e = b_e = \{10, 20, 40\}$ m, with a constant semi-axis along the depth, i.e., $c_e = 2$ m. β is calculated same as the inclination of the problem domain. A parametric study was conducted for drained case, i.e., effective stress based, with the unit weight of the soil and water being 20 and 10 kN/m^3, respectively. A frictional material is utilized with cohesion, c', and friction angle, ϕ', treated as spatially variable parameters (see Table 1). Varying spatial correlation lengths, l, from zero, i.e., no spatial dependence, to 1000 m where soil parameters are highly correlated over the problem domain were examined. Same correlation lengths in horizontal directions were assumed.

Table 1. Variability of parameters.

	c' (kPa)	ϕ' (°)
Mean value	6 (lognormal dist.)	40 (normal dist.)
*CoV	0.10, 0.20,0.30	0.05,0.10,0.15
l (m)	0,10,40,80,200,1000	

*Coefficient of variation for low, moderate, high levels

Deterministic model simulations were performed to have an idea of the safety level for different ellipsoidal sliding surfaces. The deterministic F_S^g for 10-10-2, 20-

20-2, and 40-40-2 m size ellipsoidal sliding surfaces are 1.57, 1.48, 1.45, respectively. Further increasing the size to infinity, i.e., infinite slope stability condition, leads to a F_S^g of 1.29. This study performed 3D probabilistic slope stability analyses for each combination of variability level and spatial correlation length with 1000 random field realizations and the results are presented in the following section.

4 RESULTS

4.1 Effects of parameter variability

Figure 1 presents how variability parameters, including variability levels and degree of spatial dependence, influence the 3D probabilistic slope stability predictions over 200 m x 200 m problem domain. The results show that the values of μ_g are lower than the corresponding values of the deterministic F_S^g regardless of variability levels. As the variability level increases at any correlation length, the values of μ_g decrease for each ellipsoidal sliding surface dimension.

For a given ellipsoidal sliding surface dimension, μ_g is significantly affected by correlation length. No spatial dependence, i.e., 0 m correlation length, leads to higher μ_g compared to the other values of the correlation length. This was attributed to the fact that cells with lower values of strength parameters are most likely to be adjacent to cells with high values. These low values of strength parameters are compensated by the high values in stability calculation, and higher μ_g is obtained.

The results reveal that an increase in correlation length at low range (approximately <80-100 m) resulted in a decrease in μ_g, but further increase beyond a threshold value leads to a subsequent rise in μ_g. A more substantial reduction was observed for larger variability levels. As the correlation length increases, the random field tends to smooth out the spatial variations over the field, and the spatial dependence between neighboring cells becomes stronger. The adjacent cells are more likely to have similar parameter values. Consequently, the probability of encountering a weak zone within the sliding surface would decrease. Therefore, further increasing the correlation length results in higher values of μ_g. Similar observations were made for 2D single slopes in the literature (e.g., Kasama and Whittle 2016; Tabarroki et al. 2013).

4.2 Critical correlation length and effect of problem domain extent

This study revealed that a particular correlation length leads to the lowest value of μ_g and will hereafter be referred to as the 'critical correlation length'. This study examined the critical correlation length for different sizes of the ellipsoidal sliding surface, extents of problem domain, and all variability levels. The results showed strong correlation between critical correlation length and length of the sliding surface in the direction of motion, i.e., $L = 2a_e$. The correlation coefficient was found to be in the range of 0.62-0.76 for 200x200, and 50x50 m extent of the problem domain, with an overall correlation of 0.59 for all analyses. Besides, linear regression revealed that the critical correlation length is approximately 1.8 times the length of the sliding surface in the direction of motion.

Figure 2 presents the effects of the extent of problem domain on the probabilistic slope stability predictions in terms of the μ_g for 10-10-2 m sliding surface and high variability level. It is observed that the μ_g decreases as the extent of the problem domain increases regardless of the ellipsoidal sliding surface dimension and correlation length. A larger problem extent results in increased parameter fluctuation across the domain, leading to a wider confidence interval by remaining nearly consistent mean value.

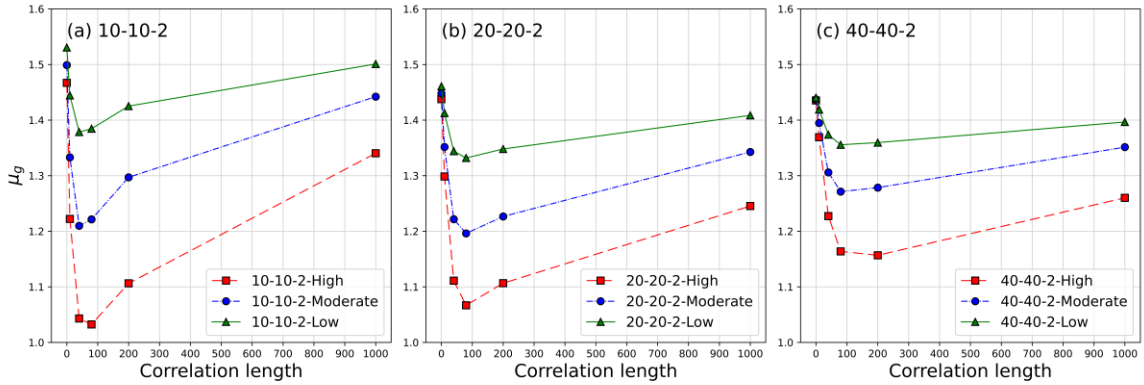

Figure 1. Effects of variability level and degree of spatial dependence on the values of μ_g for different sizes of sliding surface.

Wider confidence interval amplifies the influence of weak zones on F_S^g, consequently resulting in a progressive reduction of μ_g obtained through Monte Carlo simulations, see Figure 2.

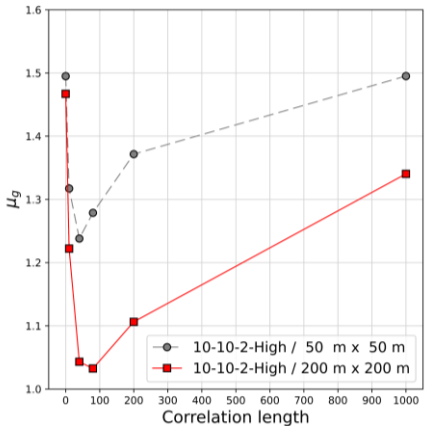

Figure 2. Effects of the problem domain extent for 10-10-2 m sliding surface and high variability level.

5 CONCLUSION

The current study investigated the impact of variability parameters on the 3D probabilistic slope stability prediction using the 3DPLSmodel. A simplified 2 m-thick 25° inclined slope was studied with spatial variable geotechnical strength parameter. Sliding surfaces of varying dimensions were used over varying extents of problem domain.

The results showed that 3D probabilistic slope stability predictions are substantially affected by the variability level and degree of spatial dependence. Accounting for variability in the analysis leads to lower safety levels compared to deterministic approach, regardless of problem domain extent or sliding surface dimension. The decrease in μ_g was found to be greater at a higher variability level. The degree of spatial dependence substantially affects the predictions. Significantly lower values of μ_g can be obtained depending on the correlation length. Additionally, a larger problem domain extent was found to be leading to lower values of μ_g for a given sliding surface dimension.

A critical value of correlation length resulting in the lowest μ_g was identified. A strong correlation between the critical correlation length and the sliding surface dimension was observed with an average correlation coefficient of 0.59. The critical correlation length was found to be approximately 1.8 times the length of the sliding surface. The relationship between critical correlation length and length of the sliding surface is of high importance in the absence of substantial information on the variability characteristics of the soil parameters, particularly in the context of design of critical infrastructures with slope stability.

ABSTRACT: Safer and more sustainable mining implies a better assessment of the mechanical behaviour of ore tailings under different realistic testing conditions. This paper addresses the issue of reconstituting samples for element testing of ore tailings from the Panasqueira mine, an important Portuguesa tungsten mine with suitable mining waste management. The paper discusses the capabilities of a slurry-base reconstitution method using ore tailings from this mine. To this end, the undrained triaxial behaviour of the reconstituted samples and the effects of the reconstitution method on the characteristics of samples with unusual geometries, such as those used in the Hollow Cylinder Apparatus, are discussed.

RÉSUMÉ: Une exploitation minière plus sûre et plus durable implique une meilleure évaluation du comportement mécanique des résidus de minerai dans différentes conditions d'essai réalistes. Cet article aborde la question de la reconstitution d'échantillons pour des essais élémentaires de résidus de minerai de la mine de Panasqueira, une importante mine de wolframite portugaise dont la gestion des déchets miniers est appropriée. Il examine les capacités d'une méthode de reconstitution à base de mise en moule en utilisant les résidus de minerai de cette mine. En vue de cela, le comportement triaxial non drainé des échantillons reconstitués et les effets de la méthode de reconstitution sur les caractéristiques des échantillons à géométrie inhabituelle, tels que ceux utilisés dans l'appareil à cylindre creux, sont examinés.

Keywords: Element testing; wolframite ore tailings; slurry-based reconstitution method, undrained triaxial compression.

1 INTRODUCTION

The last century has seen an increase in the volume of tailings produced, caused by the demand for minerals and metals. The behaviour of these unconventional geomaterials under different loading paths is still poorly understood, which may justify some of the serious disasters that have occurred all over the world (Wang et al. 2014). However, for laboratory testing to be successful, it is necessary to obtain intact samples or, when these are not available, to prepare suitable reconstituted samples. This article discusses the characteristics of reconstituted samples and the effects resulting from the preparation of reconstituted samples, with different sizes and shapes, of tungsten ore tailings using the slurry deposition method (Carraro & Prezzi, 2008, Tastan & Carraro, 2013). Reconstituted samples were prepared with different water contents to assess the effect on the sample's void ratio. Possible segregation problems in the preparation of each type of sample were also evaluated. Finally, some results of undrained triaxial compression tests are presented and compared in order to verify the repeatability of the sample preparation method.

2 SLURRY-BASED EXPERIMENTAL PROCEDURE TO PREPARATE RECONSTITUED SAMPLES

2.1 Studied Material

The tungsten ore tailings used in this study were collected at the Panasqueira´s mine in Portugal. Although there are no records of past accidents nor evidences of possible risks, these tailings were selected for the geotechnical investigation presented in this paper.

The basic physical and identification properties of the tungsten ore tailings were firstly determined. The liquid and plastic limits were measured as 23 and 15%, respectively, the density of the solid particles being 3.15. The void ratio of the intact samples taken were also determined, ranging from 0.62 to 0.75. Tungsten ore tailings, as well as other mining by-products, generally consist of irregular particles originating from the crushing and grinding of mined rock. Panasqueria´s tailings are composed of 16% clay-like, 73% of silt-like and 11% of sand-like, according to their sizes.

2.2 Reconstitution method at UC/ISEC

Based on the technique proposed by Carraro and Prezzi et al. (2008), an equipment was developed to mechanically mix the tailings with water and obtain a truly homogeneous mixture of the slurry. Operation consists in introducing the mine tailings and water into the metal mixing vat and running it for around 2 minutes, using a specially designed blade to deeply mix the mixture. After this time, the mixer is switched off and the tap located at the bottom of the metal vat is opened to pour the paste by gravity into the mould of the sample to be tested. This equipment facilitates the reconstitution of samples of different sizes and shapes, including cylindrical triaxial samples and hollow samples for the Hollow Cylinder Apparatus (HCA).

Once the slurry paste has been deposited in the mould, it is noticeable that the suspended particles tend to settle under the effect of gravity. The paste becomes denser and expels the water out of the tailing voids towards the surface. As the water dissipates, the soil particles tend to move closer together and the voids tend to shrink, as demonstrated in the tests carried out by Qin et al. (2021). To assess the settling time of the slurry paste after deposition, two 1000 ml graduated test tubes were used. Approximately 700 ml of slurry paste with a water content of 27% was placed in the test tubes. The water content defined to prepare the paste took into account two aspects: the liquidity limit (23%) and the warranty of a continuous deposition of the slurry. Approximately 2kg of tailings were placed in the mixer along with 540g of water. It should be noted that it is important that the weight remaining in the metal vat is sufficient to allow constant deposition rate of the paste. As deposition is gravitationally-driven, reducing the weight of the material in the container leads to changes in deposition speed and, as a result, variability throughout the sample, particularly in larger samples such as HCA ones. Once the deposition of the slurry is complete, readings were taken at 5-minute intervals until the end of the first 30 minutes and at 10-minute intervals until 60 minutes. Analysing Figure 1, which shows the settlement results over time, it can be seen that there is a more pronounced increase in settlement up to 30 minutes, which, then, tend to stabilise over time.

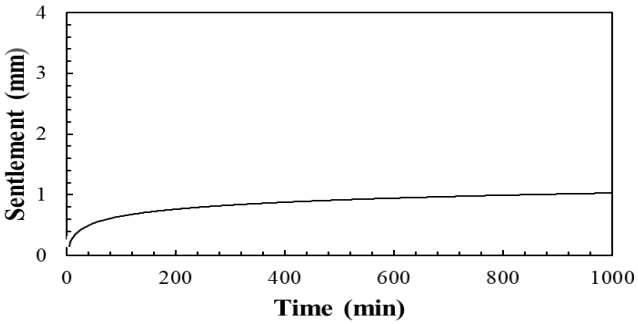

Figure 1. Settling of the surface of the paste over time.

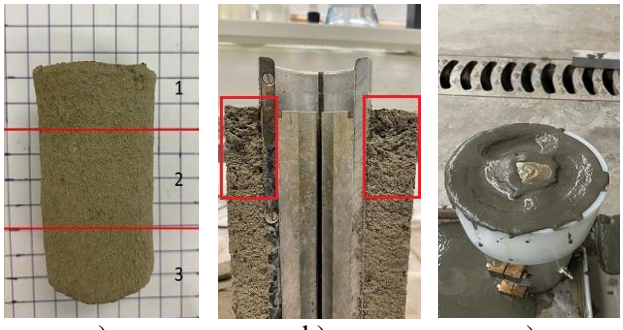
2.3 Full section cylindrical triaxial samples

In order to study the settlement of the paste in full-section samples that could be used in triaxial tests, as well as possible segregation effects, three samples were prepared in metal moulds with a diameter of 50 mm and an average height of 70 mm with the same water content (27%) (Figure 2a). The height of the samples varies slightly due to the uncontrolled fitting of the impermeable base. Table 1 summarises the results obtained.

Table 1. Settlement the full section samples.

Sample	Settlement (mm)	DH/H (%)
A1	3,73	4,99
A2	4,25	5,44
A3	3,85	5,27

It should be noted that the sample preparation method developed shows very similar settlement values.



a) b) c)

Figure 2. Reconstituted samples: a) Sample division zones in the full section; b) Zone 1 sample hollow section.; c) Depositing the slurry with the collar.

This settlement should be taken into account when preparing samples in the triaxial equipment, by adding a surplus of slurry to compensate the variation in height (Qin et al. 2021). The results obtained for the full-section moulds indicated settlement values of around 4mm. for an initial average height of 70mm. It should be noted that all the moulds were left to rest for 30 minutes and then placed in an oven. The value of 4 mm is in line with that obtained in Figure 1 for the settlement after 30 minutes.

To assess possible particle segregation effects, the samples were removed from the mould after a drying process and divided in three parts, as shown in Figure 2a. Visual inspection did not detect any obvious particle segregation in any of the sample zones. This conclusion is corroborated by the determination of particle size curves for each of the three zones of the three samples produced. Similar grain size distribution curves were obtained, being also identical to those of the tailings before deposition, as it can be seen in Figure 3. However, it was possible to observe that for particles smaller than 0.06, zone 1 of the three samples analysed showed slightly higher percentages of finer particles when compared to the initial particle size curve. The analysis of the density of solid particles provides identical conclusions, with values ranging between 3.15 and 3.17.

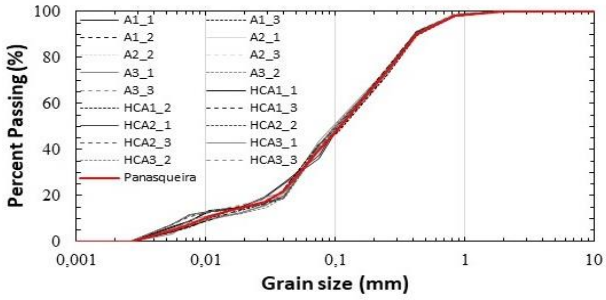


Figure 3. Particle size distribution curves of Panasqueira tailings and different zones of reconstituted samples.

In order to study the effect of different water contents used to prepare the slurry, particularly its influence in terms of void ratio (e), 5 samples were prepared using the same mould used previously, with water contents varying between 26 and 34 %. The values chosen were based on the liquidity limit and the homogeneous deposition of the sample, as well as the maximum limit for visible segregation in the sample. Figure 4 illustrates the results, showing the "theoretical" variation of e based on equation 1, which assumes an obviously invalid hypothesis that the soil is fully saturated and that no water is expelled from the voids after deposition:

$$e = G\ x\ w = 3{,}15\ .\ (w) \qquad (1)$$

where e is the void ratio and w the desired water content, both values deriving from the experiments. There is a clear difference, for each water content used, between the "theoretical" and the resulting values of void ratio, the latter being smaller due to the observed particle settlement. Still, the void ratio increases for more liquid slurries, but never as markedly as if the particles had not settled. It should be noted that all the samples had an equal deposition time of 30 minutes.

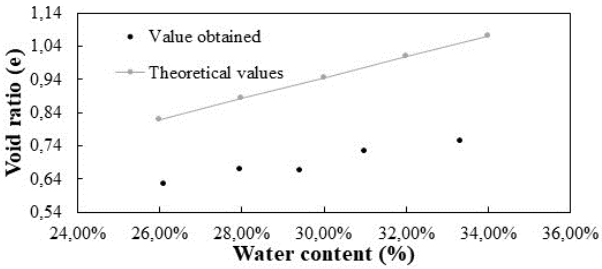

Figure 4. Variation of the void ratio (e) as a function of the water content of the slurry used in the reconstitution.

2.4 Hollow Section Samples for the HCA

Hollow cylindrical samples, with 60ID:100OD:200H mm (inner diameter:outer diameter:height) have also been prepared, aiming for future tests to be carried out in a HCA. Due to the hollow section, the slurry is deposited by means of circular movements along the circular crown of the sample.

Three samples have been prepared: i) HCA1: no collar (extension above the mould), no surplus soil in the vat; ii) HCA: no collar, with surplus soil in the vat; iii) HCA3 with collar, with surplus soil in the vat. For the HCA1 sample, it is visible that in zone 1, represented as an example in Figure 2b, there was some lack of material, showing a visibly porous surface. It was possible to determine a settlement of around 12 mm below the surface of the mould, corresponding to a relative settlement of 6.1%. By analysing the particle size curves, zone 1 of the HCA1 test shows a slightly higher percentage of fines compared to the other zones and the original particle size curve. The use of surplus soil (HCA2) makes it possible to achieve a completely filled surface in zone 1, while maintaining the settlement of 12 mm in relation to the top of the mould. Finally, with the use of a collar (HCA3) in addition to the soil surplus in the vat while preparing the mixture (Figure 2c), the entire mould is filled, with no settlement being observed, since the same occurs in the collar, and no variability being visually detected in the three zones. It should be noted that, due to the process of mounting the sample in a HCA, and unlike in a triaxial equipment, it is mandatory for the top of the sample to be flush with the top of the outer mould.

3 LABORATORY REPEATABILITY OF SLURRY SAMPLES

In order to assess the uniformity of the samples reconstituted using the sludge deposition method described above, 6 undrained triaxial compression tests were carried out with three different consolidation stresses (200, 800 and 1500 kPa). All the samples were prepared using the method described in Section 3.2 for full-section samples, with a water content of 27%. The tests were carried out under the same conditions and the results are illustrated in Figure 5. Independently of the initial consolidation stresses, all the samples show an initial contracting behaviour followed by a dilating behaviour for higher strains. Comparing the pairs of tests, similar behaviour can be identified, even if TX1_800 sample shows a slightly more rigid behaviour in comparison to TX2_800 test. Despite this difference, acceptable in laboratory testing, the results suggest that the technique used to reconstitute the samples shows good repeatability, although future improvements may be achieved.

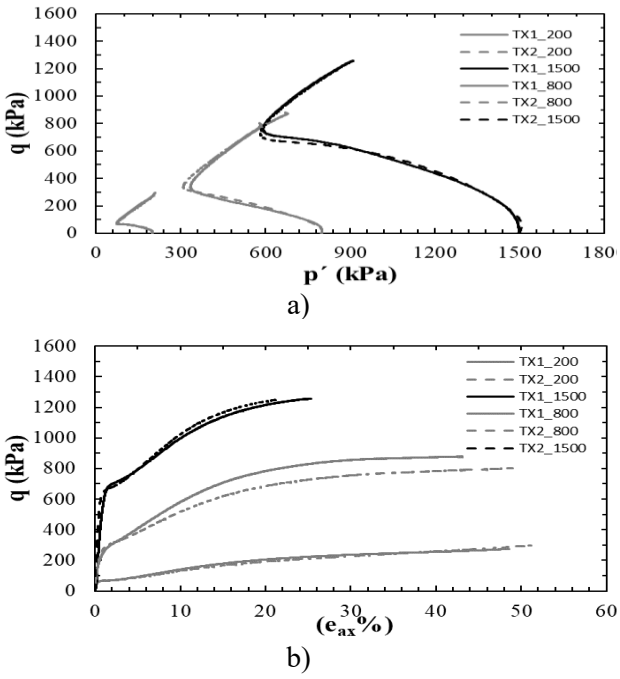

Figure 5. Undrained triaxial compression tests: a) Stress path in p´-q space; b stress-strain behaviour.

4 CONCLUSIONS

This paper discusses the preparation of reconstituted samples through the deposition of slurry paste, using samples of different sizes and geometries. The following aspects can be highlighted:

- The slurry-based sample preparation method proposed produces a homogeneous mixture with no obvious visual segregation effects.
- Sedimentation of the tailing's particles from the Panasqueira´s mine occurs initially in the first 30 minutes, showing a tendency to stabilise
- The samples top layers had a slightly higher percentage of fines compared to the other layers.
- The settlement process, after slurry deposition, causes a significant decrease in the void ratio.
- The increase in the slurry water content causes a less significant increase of the void ratio than expected from an ideal no-settlement condition.
- The preparation of reconstituted hollow-section samples for HCA requires a collar so that the paste settlement does not affect the next steps.
- The triaxial tests carried out show a good potential for repeatability of the samples produced by the technique presented.

ABSTRACT: Riverside alluvium areas are prone to consolidation settlements that can induce serviceability and/or structural damage to construction. Several in-situ measurements can be used to monitor soil and structural displacement. However, the use of Synthetic Aperture Radar (SAR) images has been proven to be an accurate monitoring tool for ground and structural displacements, allowing regular displacement monitoring over wide areas, with approaches such as Interferometric SAR (InSAR). The applicability of SAR images in consolidation settlement monitoring is analysed in the case study of an industrial area in the northern part of Lisbon city (Portugal). The site has been used since de 1980s and several storehouses have been built ever since. The goal of this work is to compare the in-situ measurements with long-term InSAR time series acquired by Sentinel-1 between 2018 and 2022. From 2006 and 2014, a maximum vertical displacement of ~1 m was measured with *in situ* techniques. The Sentinel-1 data (2018-2022) measured displacement rates between 6 and 8 mm/year. This work presents the use of the European Ground Motion Service (EGMS) time series to complement *in situ* measurements of the industrial area. The evolution of SAR satellites is also analysed though the comparison of the image characteristics and their influence on consolidation subsidence monitoring.

RÉSUMÉ: Les zones d'alluvions riveraines sont sujettes à des tassements de consolidation qui peuvent entraîner des dommages de service et/ou structurels à la construction. Plusieurs mesures in situ peuvent être utilisées pour surveiller les déplacements du sol et des structures. Cependant, l'utilisation d'images de *Synthetic Aperture Radar* (SAR) s'est avérée être un outil de surveillance précis pour les déplacements du sol et des structures, permettant une surveillance régulière des déplacements sur de vastes zones, avec des approches telles que l'interférométrie SAR (InSAR). L'applicabilité des images SAR dans la surveillance des tassements de consolidation est analysée dans l'étude de cas d'une zone industrielle située dans la partie nord de la ville de Lisbonne (Portugal). Le site est utilisé depuis les années 1980 et plusieurs entrepôts ont été construits depuis. L'objectif de ce travail est de comparer les mesures in situ avec les séries temporelles InSAR à long terme acquises par Sentinel-1 entre 2018 et 2022. Entre 2006 et 2014, un déplacement vertical maximal de ~1 m a été mesuré avec des techniques in situ. Les données de Sentinel-1 (2018-2022) ont mesuré des taux de déplacement entre 5 et 8 mm/an. Ce travail présente l'utilisation de la série temporelle de le *European Ground Motion Service* (EGMS) pour compléter les mesures in situ de la zone industrielle. L'évolution des satellites SAR est également analysée à travers la comparaison des caractéristiques de l'image et leur influence sur la surveillance de l'affaissement de la consolidation.

Keywords: Settlement; ground movement monitoring; InSAR; EGMS.

1 INTRODUCTION

The Tagus river alluviums present several challenges for the construction and serviceability of structures, requiring the need for soil reinforcement (Falcão et al., 2000; Pinto et al., 2011, 2016; Sêco e Pinto et al., 2020). The Póvoa de Santa Iria industrial area ground was reinforced in 2002 using stone columns, allowing the growth of the industrial site. Nevertheless, in 2012, one of the storehouses started to show signs ground displacement.

In fact, displacements reaching 1.00 m were measured between 2006 and 2015 using topographical monitoring. Displacements were also captured using the remote sensing technique, Interferometric Synthetic Aperture Radar (InSAR). Between 2015 and 2022 displacements of ranging from 3.00 mm/year to 8.50 mm/year were captured in the European Ground Motion Service (EGMS) (Copernicus, 2023; Costantini et al., 2021).

The goal of this work is to combine *in situ* and remote sensing monitoring techniques to monitor and evaluate the ground displacement of the Santa Iria industrial area.

2 SITE DESCRIPTION

The Póvoa de Santa Iria industrial site is located north of Lisbon, near the Tagus river (Figure 1).

The site is built on top of the Tagus river alluviums, composed by sludge and sand and can reach depths up to 60 m. The alluviums are followed by "Areolas de Cabo Ruivo", a Mycenaean formation composed of clayey sands and sandstones with a thickness of about 21 m (LNEG, 2011). From the geotechnical survey conducted in 2015, the lithology observed is presented in Table 1.

Table 1. Lithology of the site.

Depth (m)	Description
2.00 – 3.00	**Landfill** Crushed aggregate limestone
18.80 – 27.00	**Alluvium** Sludge and sands
> 24.00	**"Areolas de Cabo Ruivo"** Silty clays

The area has been used as an industrial site since before 2002, when the soil was reinforced with stone columns. In fact, through the analysis of historical optical imagery (Google Earth Pro, 2023), a history of the construction could be established since 1985.

Prior to March 2002, only one storehouse is present on the site, closer to the river (Figure 2). This first storehouse was then demolished between 2004 and 2005, and replaced with the storehouse that we see today (Figure 1).

Figure 1. Póvoa de Santa Iria industrial site in April 2023 (adapted from Google Earth Pro, 2023).

Figure 2. Póvoa de Santa Iria industrial site in March 2002 (adapted from Google Earth Pro, 2023).

The construction evolution of the industrial site is presented in Figure 3. After the soil reinforcement in 2002, the industrial site grew exponentially, especially between 2002 and 2012.

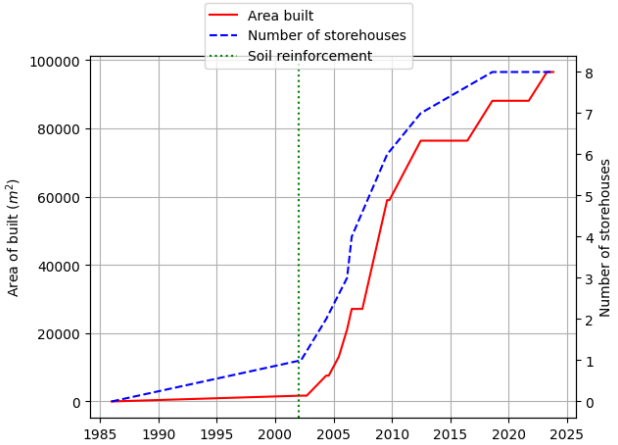

Figure 3. Construction evolution of the industrial site.

In 2012, one of the storehouses (SH1) built in 2006 showed signs of large ground displacement with cracks on the building. In 2014 another storehouse (SH2) also started to show signs of displacement on the ground surrounding the building.

The displacements of the storehouse were monitored between 2014 and 2015, and in 2023 using topography. These measurements were then complemented with the data from the EGMS between 2015 and 2022.

3 TOPOGRAPHICAL MONITORING

In 2014 six topographic targets were placed in SH1 (Figure 4), A1 to A3 in the North façade of the building, and A4 to A6 in the South façade. The targets were monitored between 2014 and 2015, and in 2023.

From the construction of SH1 in 2006 until 2014, the building registered a maximum displacement of 1.03 m in A5. It can be observed that the North and the South façades of SH1 behave differently. In fact, between 2006 and 2014, the North façade settled ~0.45 m, whereas the South façade settled ~0.98 m (Figure 5). The South façade settled the double of the North façade, this differential displacement is probably the reason cracks appears on the building.

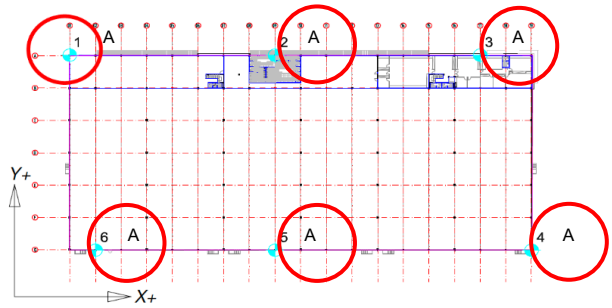

Figure 4. Location of the topographic targets.

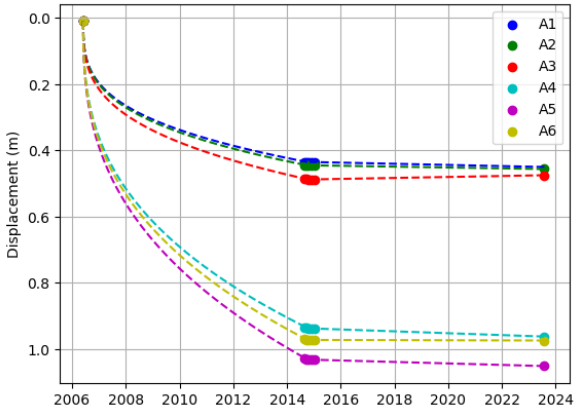

Figure 5. Displacement observed in SH1 with topographical monitoring.

In Figure 5, two types of displacement are distinguished. It is between 2006 and 2014 that the major displacements are observed, where a load settlement curve can be fitted. However, between 2014 and 2023, the movements seem to be linear, with rates ranging from 3.50 mm/year to 7.80 mm/year.

4 INSAR MONITORING

To complement the topographic monitoring, InSAR was used. InSAR is a technique that allows the analysis of long-term temporal series of displacements in the Earth's surface though the comparison of several SAR images (ASF, 2019; Bamler & Hartl, 1998; Crosetto et al., 2016; Earth Science Data Systems, 2020; Ferretti et al., 2007; Massonnet & Feigl, 1998).

SAR is an active imaging system that uses microwaves and records the backscattered signal. This system allows for all-day, all-nigth and all-weather measurements since the microwaves can penetrate clouds.

The InSAR technique can measure displacements through the difference of the phase registered in different images, called the interferometric phase, $\Delta\phi$. Considering ϕ_1 and ϕ_2 two phases registered at a given point by image 1 and image 2, respectively, the interferometric phase is given by the following equation:

$$\Delta\phi = \phi_2 - \phi_1 \quad (1)$$

The interferometric phase, $\Delta\phi$ is affected by displacement, topography, atmosphere, satellite orbit and noise. The interferometric phase is then given by:

$$\Delta\phi = \Delta\phi_{displacement} + \Delta\phi_{topography} + \Delta\phi_{atmosphere} + \Delta\phi_{orbit} + \Delta\phi_{noise} \quad (2)$$

The measurements points were obtained through the EMGS, that is a service that provides InSAR displacement time-series across Europe with the Sentinel-1 satellite (Copernicus, 2023; Costantini et al., 2021). Today the time series available are from 2018 to 2022 and provide measurements every 6 to 12 days. Two points were obtained in SH1, one on the North façade and another one on the South façade with displacement rates of 5.60 mm/year and 7.50 mm/year, respectively (Figure 6).

5 RESULTS AND DISCUSSION

The InSAR measurements confirmed the linear pattern of displacement observed with topography from 2014 onwards. In fact, similar movement rates are captured with both techniques, with displacement ranging from 3.50 mm/year to 7.80 mm/year and from 5.60 mm/year to 7.50 mm/year with topography and InSAR, respectively.

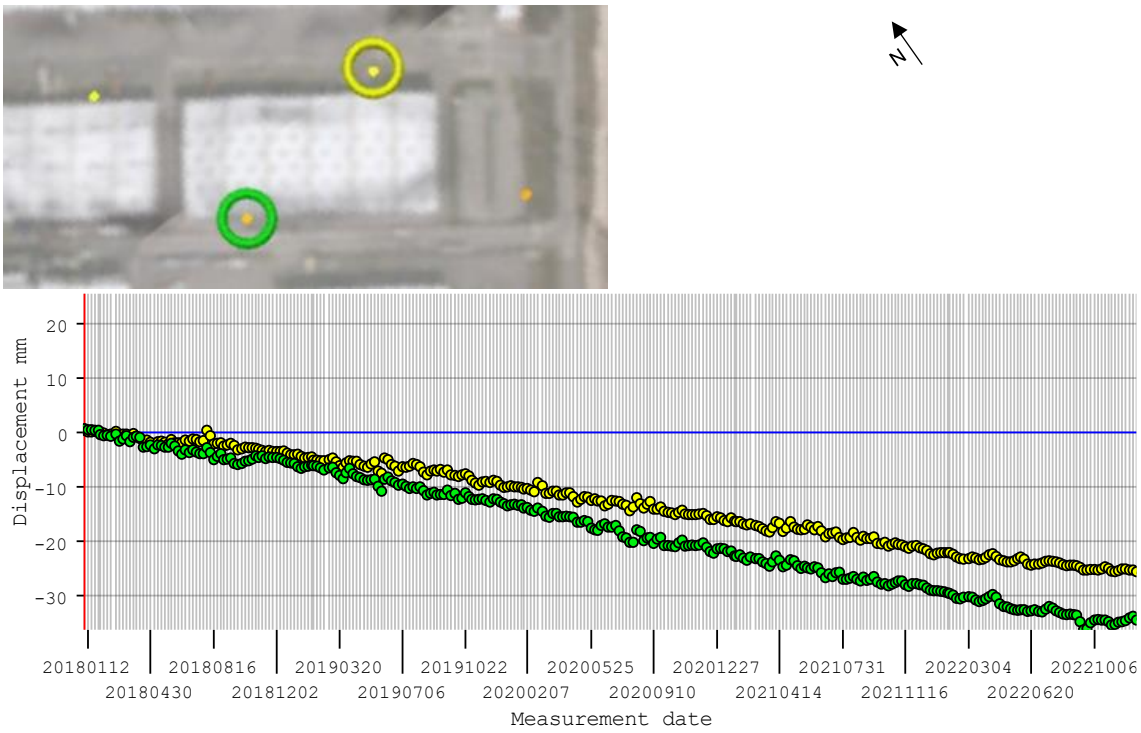

Figure 6. Vertical displacement of SH1 from 2018 to 2022 (adapted from Copernicus, 2023).

From 2014 onwards the settlement of SH1 seems to have stabilized and presents now a linear movement of a couple of millimetres per year. This behaviour is present not only in SH1 but in the whole industrial area, that presents linear movements, with larger displacements when approaching the Tagus River (South).

This study shows that InSAR can be a useful and reliable technique when monitoring displacement of structures. However, InSAR has its limitations, first the fact that measurement points limited to the backscatter registered, which makes man made structed good measuring points (Massonnet & Feigl, 1998) but not planar fields for example. Then, the measuring points are limited to the resolution of images, for Sentinel-1 the maximum resolution is 5 x 5 m. Lastly, the maximum displacement that can be measured with InSAR techniques is half the wavelength between image acquisition (Massonnet & Feigl, 1998), which in the case of Sentinel-1 is 27 mm every 6 to 12 days (ESA, 2023), i.e. ~1.60 m/year to ~0.80 m/year.

6 CONCLUSIONS AND FUTURE DEVELOPMENT

The Póvoa de Santa Iria industrial area presented settlements over time that seem to have reduced and is moving now at a rate of few millimeters per year.

In this case the EGMS, and InSAR, have proven to be effective tools to retrieve displacement time series over the last decade and the displacement trends over large areas.

Future developments of this analysis include the use of other SAR images to measure displacement over the Póvoa de Santa Iria industrial area to:

- Have better resolution results, i.e. more measuring points, with for example images of TerraSAR-X that has a 1 x 1 m resolution.
- Characterise the displacements that occurred between 2006 and 2014 with images of satellites that were flying during this time period. For example, ENVISAT (2002 – 2011) or ALOS-2 (2006 – 2013).

ABSTRACT: The overpass of Ch. 18.978 of the new highway Fier-Vlore in the West South of Albania less than one year after the opening to the traffic was closed due to excessive settlements of the abutments. This paper illustrates the work for analysing the causes of the problem and the design for the rehabilitation of the structure of the overpass. The abutments are constructed as an embankment of 8m on top of which was placed a RC raft with 4 piles 16m deep. From the geological re-study, it was seen that the geological layers, contrary to what was predicted, were a mixture of silty-clays and organic clays with very weak properties. To analyse the problem, consolidation analysis was carried out and for rehabilitation interventions of soil reinforcement by stone columns with vibro-compaction techniques and foundation reinforcement with additional piles were evaluated. Based on the detailed geotechnical analysis, it was estimated that the consolidation time for the soil-structure system was nearing its end. These analyses were verified by the monitoring in site and was decided for an intervention only to reposition the superstructure of the overpass and the replacement of the damaged supports and bearings. The article indicate the importance of a pre-consolidation process, the proper calculation of time of consolidation and monitoring influence to the performance of the overpass structure.

RÉSUMÉ: Le viaduc du Ch. 19.978 de la nouvelle autoroute Fier-Vlore dans l'ouest-sud de l'Albanie, moins d'un an après l'ouverture à la circulation, a été fermée en raison de tassements excessifs des culées. Cet article illustre les travaux d'analyse des causes du problème et la conception de la réhabilitation de la structure du viaduc. Les culées sont construites comme un remblai de 8 m au-dessus duquel a été placé un radier RC à 4 pieux de 16 m de profondeur. De la réétude géologique, il a été constaté que les couches géologiques, contrairement à ce qui était prévu, étaient un mélange d'argiles limoneuses et d'argiles organiques aux propriétés très faibles. Pour analyser le problème, une analyse de consolidation a été réalisée et, pour la réhabilitation, des interventions de renforcement du sol par des colonnes de pierre avec des techniques de vibro-compactage et de renforcement des fondations avec des pieux supplémentaires ont été évaluées. Sur la base de l'analyse géotechnique détaillée, il a été estimé que le temps de consolidation du système sol-structure touchait à sa fin. Ces analyses ont été vérifiées par le suivi sur site et il a été décidé une intervention uniquement pour repositionner la superstructure du viaduc et le remplacement des supports et appareils d'appui endommagés. L'article indique l'importance d'un processus de pré-consolidation, du calcul approprié du temps de consolidation et de l'influence de la surveillance sur la performance de la structure du viaduc.

Keywords: Consolidation; overpass structure rehabilitation.

1 INTRODUCTION

The overpass of Ch. 18.978 of the new highway Fier-Vlore in the west-south of Albania was closed less than one year after the opening to the traffic due to excessive settlements of the abutments. This paper illustrates the work for analysing the causes of the problem and the design for the rehabilitation of the structure of the overpass. The abutments are constructed as an embankment of 8m on top of which a RC raft with 4, 16m deep piles was placed. From the geological re-study, it was seen that the geological layers, contrary to what was predicted, were a mixture of silty-clays and organic clays with very weak properties. To analyse the problem, consolidation analysis was carried out and, for the overpass rehabilitation interventions solutions involving soil reinforcement by stone columns with vibro-

compaction techniques and foundation reinforcement with additional piles were evaluated. Based on a detailed geotechnical analysis, it was estimated that the consolidation time for the soil-structure system was nearing its end. These analyses were verified by monitoring in site and an intervention only to reposition the superstructure of the overpass and the replacement of the damaged supports and bearings was decided. The article indicates the importance of proper calculation of time of consolidation and monitoring on the performance of the overpass structure.

2 PROBLEMS IN THE VIADUCT

2.1 Description of the existing design

The viaduct at km 18.978 consists of two spans bridge structure facilitating passage across the service road (secondary) of the 'By-Pass Fier' highway. The Figure 1 gives the cross section of the overpass.

The structure is composed of 4 girder precast post-tensioned beams (20.75m) every 1.62m connected by a 20cm reinforced concrete slab and supported by elastomeric bearings at the abutments and at the cap-beam of the central pier. The width of the superstructure is 5m +2*0.6m=6.2m.

Abutments A and B consist of a plate supported on 4 piles (6+14m, D=80cm) with a 6m above-ground part to achieve the overpass level filled with granular material. The granular material substitute also the first 4m of the natural soil under the abutments.

The pier is a 4.8x1.2m reinforced concrete wall supported on 1.5m thick foundation plate with 6 piles (D=80cm).

The levelling of the super-structure with the filling of the abutments is done by means of a 10 cm expansion joint.

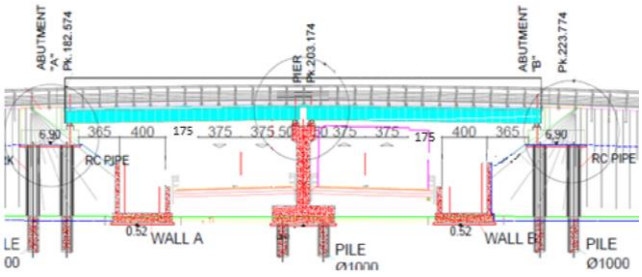

Figure 1. View of the viaduct structure.

2.2 Observed settlements

Approximately 10 months after opening to traffic, significant openings and unevenness were detected at the expansion joints. These deformations indicated settlements of the abutments. After this finding, the viaduct was closed for operation and benchmarks were placed in the abutments and in the central pier for periodic measurement of settlements. The first measurements have shown 35-40cm settlements.

Monitoring of settlements was carried out throughout the analysis, design and implementation of rehabilitative interventions.

2.3 Structural damages

Besides settlements, the structure exhibited cracks in the reinforced concrete walls of the abutments, accompanied by lateral deformations and initial signs of rubber cracks in the elastomeric bearings. The Figures 2 and 3 illustrate some of the damages.

Figure 2. View of elastomeric bearing damage.

Figure 3. View of RC abutment wall damage.

3 ANALYSIS OF THE EXISTING CONDITIONS

3.1 General for existing condition

In response to the investor's request, a comprehensive analysis was conducted to comprehend the issues and determine measures to restore the viaduct's functionality. The design geological study wasn't performed for the exact position of the viaduct, so a new detailed geological study was done.

3.2 Geological study

The recent study revealed exceedingly soft soils, particularly at depths of 9-12-24m, characterized by organic soil and extremely soft clays. The bedrock was at a depth of 44m. One of the borehole logs is given in the Figure 4.

#	Name	Thickness	Top Elevation	Bottom Elevation
1	Fill	1	0	-1
2	Clay 2	7	-1	-8

Figure 5. View of layers geotechnical parameters.

3.3 Analysis

Two types of analysis were performed: finite difference and finite element numerical analyses (Software Settle 3D and Plaxis 2D).

Figures 6 to 8 depict the mentioned models. In each model after the generation of the natural stress field are simulated the stages of construction by

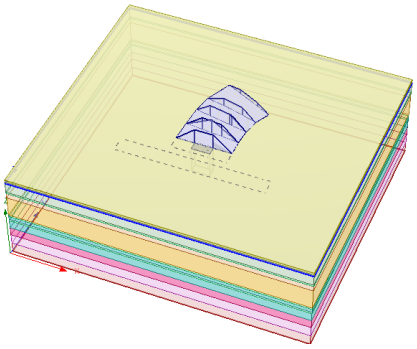

Figure 6. View of finite difference (FD) model. (Settle 3D).

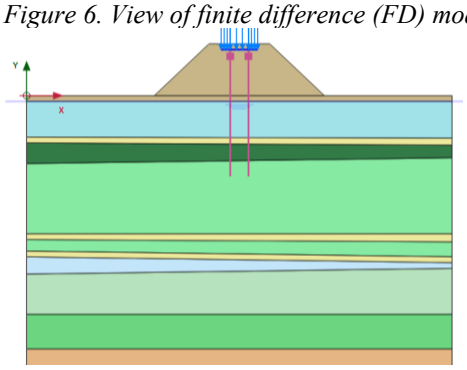

Figure 7. View of numerical FE cross section model. (Plaxis 2D).

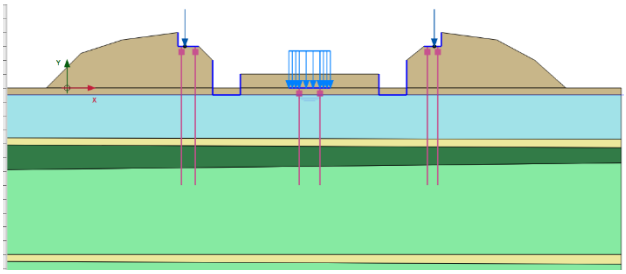

Figure 8. View of numerical FE longitudinal section model.

3.4 Results and conclusions for existing condition

Figures 9 to 11 show some results of the deformation analysis.

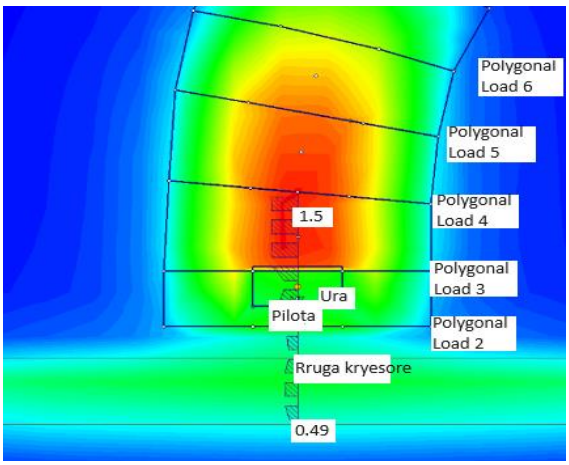

Figure 9. Settlement for the FD model.

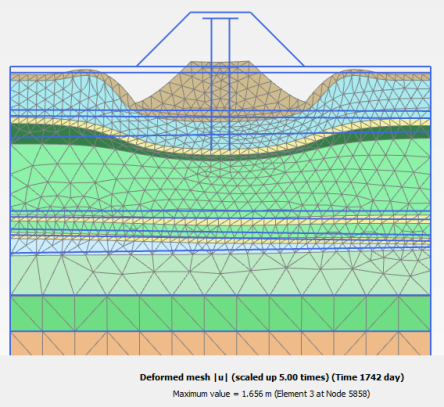

Figure 10. Deformed numerical cross section numerical model.

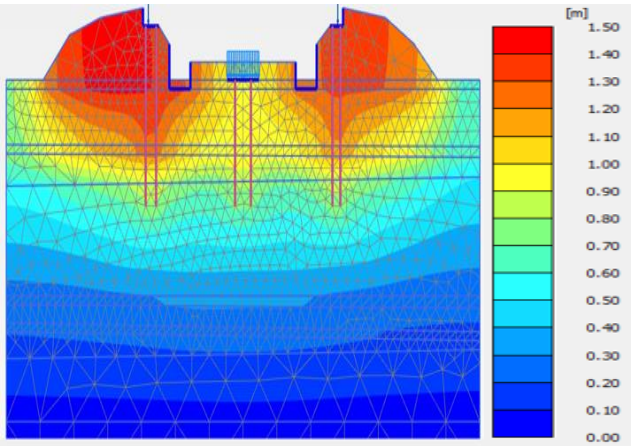

Figure 11. Settlement for the numerical longitudinal model.

The essential conclusions of the performed analyses may be summarized as follows.
The total settlements (immediate and consolidation) for the analytical model are 150cm. The time of 90% of consolidation is 5 years and 98% correspond to 50years.

The total settlements (immediate and consolidation) for the numerical model are 165/144cm. The time of 90% of consolidation is 1.8 years and 98% correspond to 4.9 years.

The values of settlements in both types of models are similar and only the time of consolidation differs indicating that the coefficients of compression given in the geological study were not calibrated.

This conclusion is proved also by the manual simplified calculations.

4 ANALYSIS OF INTERVENTION SCENARIOS

4.1 Identification of intervention scenarios

Based on the analysis results it's seen that the problems results from insufficient capacity of the viaduct foundations. So, structural and soil reinforcement methodologies have been identified for rehabilitaion intervention scenarios.

4.1.1 First Scenario of Interventions (I)

Scenario "I" consists in the following interventions.
1. Soil reinforcement and consolidation
This intervention consists in the execution of vertical drains (stone columns and wick drains) in a uniform manner and the system of removal of drained waters. The duration of the drainage is expected to be about 1 year until the majority of the consolidation is achieved, Then the overpass structure can be rehabilitated (repositioning of bearings and beams).
2. Widening of abutment A and B.
3. Repositioning of bearings and beams by jack or crane lifts.

4.1.2 Second Scenario of Interventions (II)

Scenario "II" consists in the following interventions.
1. Soil and structural foundation reinforcement.
This intervention consists in the execution of RC drilled piles connected with a widening foundation of the abutments and central pier.
2. Widening of abutment A and B and central Pier foundation.
3. Repositioning of bearings and beams by jack or crane lifts.

4.1.3 Third Scenario of Interventions (III)

Scenario "III" consists in the control of settlements and the following interventions.
1. Extension/elevation of abutment A and B by RC blocks that support the bearings.
2. Replacement of beam bearings by lifting with a jack or crane and placing new bearings.
3. Separation of the continuous slab in the middle pier.
4. Widening of the support of the beams in the middle pier.
5. Continuous monitoring and adjustment/restoration of the support of the abutments and pier every 6-9 months to adapt to the uniformity of the soil settlements. (The duration of this process is expected to be up to 3 years).

The adjustment and re-elevation of the support blocks will be done in case of deformations that cannot be accommodated by the connecting joints on the surface.

The jack-up of the superstructure will be carried out as in point 2.

4.2 Results for each scenario

Figures 12 to 16 give the main results of analyses.

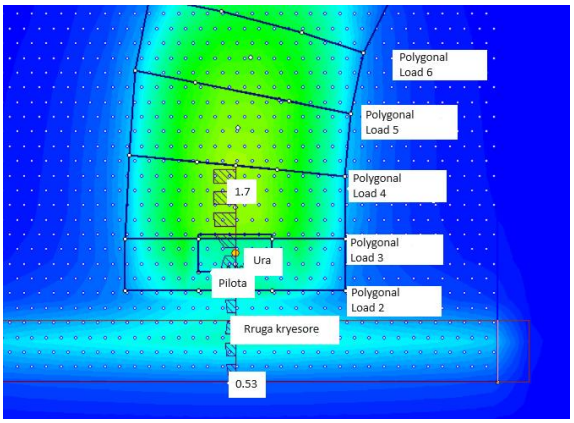

Figure 12. Settlements of abutment A for SC soil reinforcement. (u_{max}= 1.7m), Scenario I.

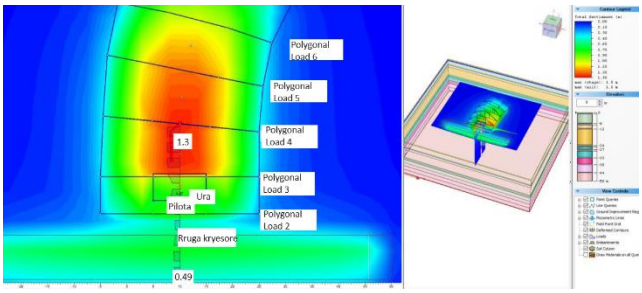

Figure 13. Settlements of abutment A for RC piles reinforcement. (u_{max}= 1.5m), Scenario II.

Settlements of Pier foundation for RC piles reinforcement has resulted u_{max}= 0.83m, Scenario II.

Scenario III will ensure the sequential stability of the overpass - soil system, but after the abutments we will again have settlements that will be uniform and reduced in time for a period of up to 3 years. Settlements can cause difficulties in circulation and must be considered during operation and maintenance. The settlements that the reinforced structure will suffer result from the difference between the current settlements and those at the time of the end of the consolidation.

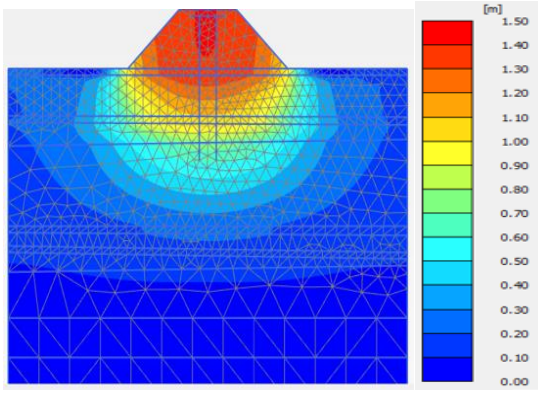

Figure 14. Settlements of abutment A for consolidation time 300 days. Plaxis 2D.

The total settlements in the model with detailed numerical analysis for a time 300 days are given in Figure 14. The max settlements are u_{max}=140cm.

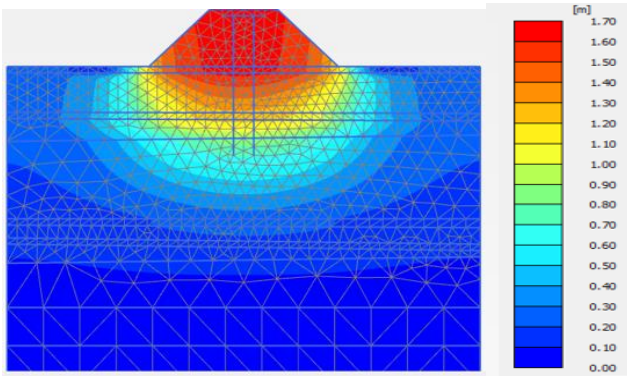

Figure 15. Settlements of abutment A for consolidation time 675 days.

Total settlements in the model with detailed numerical analysis for a time 675 days are given in figure 15. The max settlements are u_{max}=165.1cm.

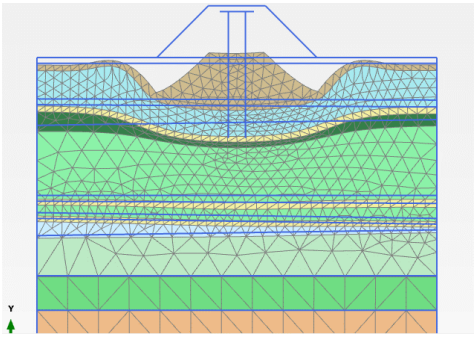

Figure 16. Settlements of abutment A for consolidation time 1742 days.

Total settlements in the model with detailed numerical analysis for a time 1742 days are given in Figure 16. The max settlements are u_{max}=165.6cm.

The differences in the settlements are about 25cm. So an increase/continuation of settlements of 25cm is expected for a period of 675-180= 495 days (1.35 years). In order to cope with these settlements, the project of changes to the structure of the abutments and the replacement of elastomeric bearings supports was made.

4.2.1 Analysis of the bridge structure

The calculation model for the bridge remains almost the same during the intervention phase and completely the same during the exploitation phase, therefore the intervention does not affect the bearing capacity of the superstructure for vertical loads and traffic loads.

Even for seismic loads, the intervention will not have effect during the exploitation phase of the work.

The capacity of the bridge for design loads remains unchanged as per the original project.

We have built a model given in Figure 17, to analyze the impact of the settlements and then to take the

forces in the supports and choose the suitable elastomeric bearings for the support of the superstructure and the accommodation of the continuation of the settlements.

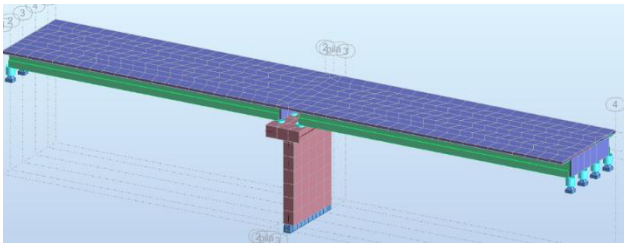

Figure 17. View of bridge structure model.

From the result, it is seen that the continuous slab in the middle support will be destroyed (0.017+0.008 rad – 4.5° for slab section above pier), and the bearings will suffer large residual transverse deformations, much larger than the deformations allowed during a calculated seismic event.

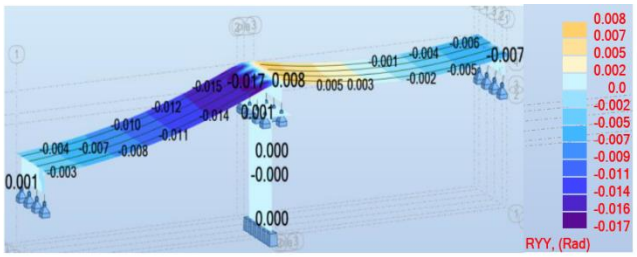

Figure 18. Rotations (Rad) in the slab bridge structure model for design seismic load.

For the internal forces from the result of the undamaged structure, new elastomeric bearings have been chosen and the support block of the bearings and the transversal diaphragm of the beams have been reinforced. The Figure 18 presents details of the strengthening intervention in the abutments.

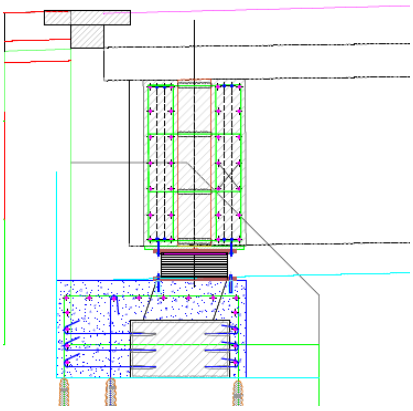

Figure 19. View of the interventions in the abutments.

The continuous slab on the pier has been replaced with a joint that will allow large deformations.

5 CONCLUSIONS

After ascertaining the problem from the Investor, a rehabilitative intervention was requested. Three possible interventions to perform structure rehabilitation of the bridge have been identified: (I) stone columns + structural rehabilitation, (II) RC piles + foundation and structural rehabilitation, (III) Evaluation of time of consolidation + structural bearings re-habilitation.

After detailed analyses and continous monitoring of settlements, it was seen that the settlements has reached about 80% of the total settlement and only 15-20cm are predicted to occur after bearings rehabilitations. Moreover, the differential settlements between abutments and the central pile are about 2-5cm.

So it was decided to rehabilitate only the structure and no intervention was foreseen for the foundations and abutment fillings. The results of continous monitoring up to now (+2cm for a period of one year) show the good judgement for the choice of analyses and intervention.

ABSTRACT: The Centro de Estudios y Experimentación de Obras Públicas (CEDEX) is an autonomous body organically attached to the Ministry of Transport, Mobility and Urban Agenda of Spain, being the Laboratorio de Geotecnia one of its units. Although traditionally the activity of this Laboratory has been mainly aimed at the field of transport infrastructures, hydraulic works, and environmental geotechnics, throughout its history it has also carried out different works related to geotechnical pathologies of historical-artistic monuments and urban ensembles. Frequently, the cause of the pathology in these historical buildings or urban ensembles is the existence of an adjacent natural slope with special geological or geotechnical conditions. In these cases, the scope of the intervention of the Laboratorio de Geotecnia has been variable, from site investigation works, diagnosis, and proposal of corrective solutions to the accompaniment of the execution of repair work. Interesting examples are the following: a) works carried out to characterize the geotechnical problems of the "hanging houses" of the town of Frías (Burgos), declared a Historic-Artistic Site; b) studies carried out in the monumental complex of the Alhambra, in Granada; c) site investigation and reinforcement works at the historical building of the Parador Nacional de Turismo of Carmona, in Seville province. The objective of this communication is to offer an overview of some of these cases, not previously, or only poorly, published, in which the Laboratorio de Geotecnia has intervened in the past.

RÉSUMÉ: Le Centro de Estudios y Experimentación de Obras Públicas (CEDEX) est un organisme autonome organiquement rattaché au ministère des Transports, de la Mobilité et de l'Agenda urbain d'Espagne, étant l'une de ses unités. Bien que traditionnellement l'activité de ce laboratoire ait été principalement orientée vers le domaine des infrastructures de transport, des travaux hydrauliques et de la géotechnique environnementale, tout au long de son histoire, il a également réalisé différents travaux liés aux pathologies géotechniques des monuments historiques et artistiques et des ensembles urbains. Fréquemment, la cause de la pathologie dans ces bâtiments historiques ou ensembles urbains est l'existence d'une pente naturelle adjacente avec des conditions géologiques ou géotechniques particulières. Dans ces cas, la portée de l'intervention du Laboratorio de Geotecnia a été variable, des travaux d'étude de site, de diagnostic et de proposition de solutions correctives à l'accompagnement de l'exécution des travaux de réparation. Des exemples intéressants sont les suivants : a) travaux réalisés pour caractériser les problèmes géotechniques des « maisons suspendues » de la ville de Frías (Burgos), déclarée site historique et artistique; b) études réalisées dans le complexe monumental de l'Alhambra, à Grenade; c) étude du site et travaux de renforcement du bâtiment historique du Parador Nacional de Turismo de Carmona, dans la province de Séville. L'objectif de la présente communication est d'offrir une vue d'ensemble de certaines de ces affaires, non publiées ou pauvrement publiées auparavant, dans lesquelles le Laboratorio de Geotecnia est intervenu dans le passé.

Keywords: Historical building; geotechnical pathology; natural slope; site investigation.

1 RELEVANT STUDIES CARRIED OUT BY CEDEX

Numerous historic buildings in Spain are located in topographically elevated areas, next to the crest of slopes or cliffs, mainly because of defensive reasons. These slopes are made up of geological formations of different nature, and, in any case, are exposed to phenomena of degradation by erosion and instabilities that develop with greater or lesser speed depending on the type of material, geological structure, inclination and other factors. The result is the appearance of geotechnical pathologies that affect these buildings, and it is necessary to study and correct. Table 1 shows, in chronological order, some relevant cases in which the Laboratory of Geotechnics of CEDEX has intervened in relation to this kind of geotechnical problems in the past three decades, approximately. It is not intended to include all interventions of this type, but the most significant, due to the importance of the

building, the scope of the intervention or the uniqueness of the study. Two of them are summarized in subsequent sections: the case of Frías and that of the Parador de Carmona. The scope of the works has been variable, from soil investigation, diagnosis, and proposal of corrective solutions to the control of remedial works for the geotechnical pathologies detected.

Table 1. Most significant monuments and historical-artistic urban complexes adjacent to natural slopes with geotechnical problems in which the CEDEX Geotechnical Laboratory has intervened.

Building or urban complex	Pathology or cause of intervention	Date of intervention	Type of action
Monumental complex of Alhambra, Granada *(Santos et al., 1994) (Cuéllar et al. 1995)*	Stability of slopes, fall of rocks and stones. Differential movements in buildings, degradation of foundation support. Collapse of walls.	1989-1995	Inspections and mapping of cracks in buildings. Geological and geotechnical investigation. Auscultation of movements and deformations. Definition of foundation conditions. Boreholes, in situ and laboratory geotechnical tests and geophysical tests. Stability analysis. Study of structural elements. Seismic behavior.
"Hanging houses" of Frías, Burgos	Erosion processes at travertine rocky promontory cliffs adjacent to the "hanging houses" and other buildings of the old town.	1993	Study of slope degradation processes and their impact on buildings; proposals for solution and minimization of collapse and rock falls risks.
Citadel of Ibiza, Baleares *(Martínez et al., 2001)*	Deterioration of the cliff under the wall of the Citadel of Ibiza.	1996	Geological-geotechnical study of the cliff, and proposal of measures for wall underpinning.
Parador of Carmona, Sevilla	Detachment of a large block of calcarenite, created by a crack originated in the 1504´s earthquake, on which the south wing of the building rests.	1997-1998	Soil investigation, identification of the origin of the damage, design and control of the proposed underpinning works.
Hermitage of Bethlehem of Carrión de los Condes, Palencia	Stability problems of the slope adjacent to the hermitage, undermined at its foot by the Carrión river.	2009-2014	Study of the stability and control of execution of slope stabilization works at the left bank of the Carrión River.
Hermitage of San Tirso and San Bernabé in Ojo Guareña, Burgos *(González et al., 2019)*	Subsidence of the esplanade of access to the hermitage, excavated in karstic limestone. The esplanade is located on a slope 60 m above the Guareña river sinkhole.	2016	Geotechnical investigation, determination of the causes of the pathologies, related to plugging of the sinkhole and saturation of the colluvial.
Mudéjar tower of Coca, Segovia *(Pardo et al., 2021)*	Stability problems, due to fluvial erosion, of the natural slope next to whose crest the tower is located.	2018	Geotechnical study of the stability of the slope and proposals for reinforcement to protect the tower area.

Due to the importance of the monumental complex and the relevance of the work carried out, it is worth highlighting the actions carried out in the monumental complex of Alhambra and Generalife (Granada), where the geotechnical characterization of the foundation conditions of a series of buildings was performed for several years, as well as stability studies of the slopes surrounding the area (Santos et al., 1994). The triggers of these studies were the visible cracks in the buildings and the signals of instability that appeared on some of the slopes by the walls and towers of the complex. A long-range work plan was established aimed at the design of geotechnical actions for correction or reinforcement of slopes and foundations and the definition of a surveillance network for the monitoring of movements in the buildings to control their evolution.

Within this group of studies relating to the Alhambra palace, it is worth highlighting the work of characterizing the dynamic properties of the ground, foundations, and walls of the tower of Comares (Cuéllar et al., 1995). G_{max} values of the different materials were determined by seismic refraction, P waves transmission tomography and cross-hole and down-hole tests. Using data obtained from dynamic surface wave tests and static plate load tests carried out in two trenches dug in the vicinity of the palace, it was possible to determine the variation of the secant module G of the ground with the level of shear strain for the stress levels expected from earthquakes. In the rest of the materials this variation was determined using the data obtained from samples tested in the laboratory. The analysis of the response of the structure to earthquakes of magnitude M = 5, such as

those that had recently been recorded at the top and bottom of the tower, allowed to verify the goodness of the estimated dynamic parameters.

Another study was carried out for the General Directorate of Coasts in 1996, consisting of the geological-geotechnical characterization of the natural cliff located under the wall of the citadel of Ibiza. The conditions of the cliff and the wall were analysed using terrestrial photogrammetry (from a boat in this case) and corrective measures were proposed for the undermined areas of the wall (Martínez et al., 2001).

A frequent type of instability of historic building is the one that occurs when the building is situated at the crest of a slope whose foot is affected by river erosion. The cases of Ermita de Belén de Carrión de los Condes (Palencia) and the Mudejar Tower of Coca (Segovia) belong to this type of instability (see Table 1). The case of the Hermitage of San Tirso and San Bernabé de Ojo Guareña (Burgos), constructed in a cave in karst limestone, refers to subsidence of the platform of access to the hermitage due to saturation of colluvial soils when the sinkhole of the Guareña River, located at the same slope 60 m below the hermitage is blocked with detritus (see Table 1).

2 CLIFF EROSION PROCESSES BELOW MEDIEVAL TOWN OF FRÍAS

In 1993 CEDEX carried out a study of the geotechnical-geological problems that affected the old town of Frías, located on top of a carbonated rocky massif, of travertine origin, below which, especially on the southern slope, the rest of the town stretches out on loamy and clayey materials. The vertical cliffs surrounding the promontory have a height of between 15 and 20 m, being the area of the castle the highest point with a height of 30 m (Figure 1). A piedmont of 60 to 100 m in length and slope of 20º to 30º extends at the bottom of the cliffs. On the crest of the promontory, especially at the southern and southeastern sides, a line of houses, known as "hanging houses", are located. The promontory sides presented a certain state of deterioration due to erosion of the cliff materials. Given the irregular and chaotic growth that travertine had in its formation, a multitude of cracks and fractures appeared throughout the escarpment of the promontory. The geological-geotechnical risks were inscribed in the processes of alteration and geomechanical degradation and possible detachments of blocks of different sizes, risks supported by the large number of events over the centuries recorded in different bibliographic citations. When the study was carried out, three areas were considered the most dangerous: the castle, in relation to blocks located at the top of the rock; several areas of the southern cliff where the "hanging houses" are located; and the north side of the promontory below the main church of the town.

The study carried out by the CEDEX for the Junta de Castilla y León was based on two basic lines of work: on the one hand, the geological-geotechnical characterization of the rocky massif that forms the cliffs, and on the other, the determination of the general topographic and geometric characteristics of the site and affected buildings. It was considered of special importance to determine the state and structure of the rock, and in particular, the geometric definition of the sets of blocks and the mapping of the preferred directions of lithoclases of the tuffaceous formation, by means of both direct observation and photographs of different scales (Figure 2). This work was completed with the determination of the topography of the cliffs, by means of terrestrial photogrammetry, based on a general stereographic principle, in the vertical plane, whose restitution allowed to obtain the geometry and the contour lines of the cliff without optical deformation. Thus, a "topographical" plan of the vertical plane and the corresponding cross sections of the cliff were obtained (Figure 3). Besides, a planimetric and altimetric survey of the surroundings of the cliff at the nearby streets, at its crest and foot, as well as a detailed mapping of the plants and elevations of the affected houses was carried out. Likewise, the cracks observed in these buildings were mapped.

Once the pathology was described, the study proposed a series of stabilization actions (Figure 4), discarding those that, due to their volume or impact, could represent a substantial change in the existing heritage environment, and resorting to specific or local application systems that were, as far as possible, immersed inside the massif or masked their visual effects in the exposed areas. It was based on two basic principles: on the one hand, the safety conditions linked to the buildings next to the cliff should be completely guaranteed, and, on the other, the systems of stabilization assets (bolts, buttresses, etc.) were restricted to those large sizes of block, slabs, or stones, which due to their volume and weight could imply significant risks. In addition, the installation of a dynamic barrier to stop the fall of minor blocks at the foot of the slope was proposed. From these basic ideas, the conditions presented by the rocky massif and cliff were analysed, together with the adjoining buildings, establishing a differentiation by zones according to the specific typology of the existing problem in each case (unstable blocks, cantilevered cornice, etc.).

.

Figure 1. View of the southern cliff of the promontory of Frías with the "hanging houses", and detail of the castle.

Figure 2. Geotechnical zoning of the cliff (Frías).

Figure 3. Photogrammetric vertical contour map of the cliff (Frías).

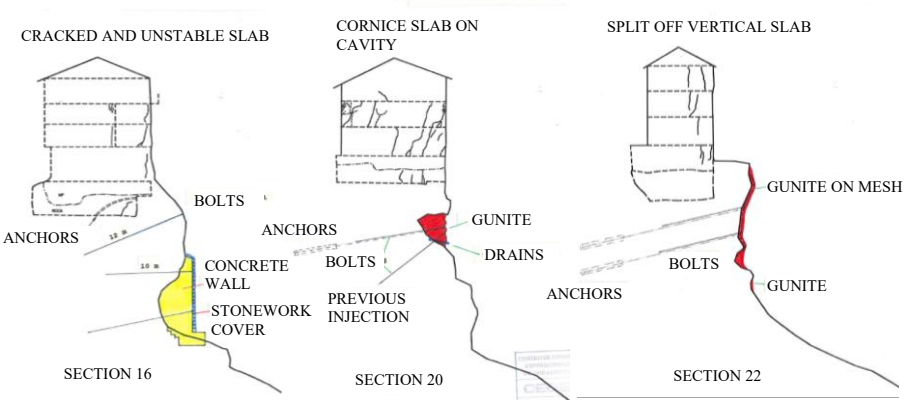

Figure 4. Photogrammetric profiles, crack mapping in party walls of the houses and proposed reinforcement actions (Frías).

Recommended treatments included bolting, preferably injected, of unstable wedges and blocks; selective sealing and protection with coloured gunite of soft rock levels; underpinning of blocks with gunite; filling of cavities with concrete or gunite with a shade closure face for camouflage and provision of drainage pipes; gunite on mesh, accompanied by anchors or bolts; and in some areas the execution of a concrete wall covered with masonry for landscape integration.

3 SLOPE INSTABILITY AFFECTING HISTORICAL BUILDING IN CARMONA

The Parador Nacional de Turismo de Carmona, built in 1970, on what had been the Parade Ground of the Alcázar of King Pedro the 1st of Castille, in the Sevillian town of Carmona, is located at the crest of a hillside, next to the meeting of two slopes of erosion, south and east. The stratigraphic profile of the terrain corresponds to a superficial platform of calcarenites lying on *albero* sandstone and underlying grey intercalations of sands, clays, and marly clays. The area of implantation of the south wing of the Parador was located on a large block of the calcarenite platform separated by a crack from the rest of it. This crack, with origin in the 1504's earthquake, caused horizontal and vertical displacements of the detached block greater than one meter. After an initial treatment of the platform under the Parador with injections in 1970 and two successive underpinnings: one with soil nailing in 1981 and the other with anchors in 1987, movements continued, forcing the closure of the south wing. Under these conditions, the Geotechnical Laboratory of CEDEX carried out a study of the ground to establish corrective measures.

Once the available data and the observed pathologies had been analysed, 10 triple-tub rotation boreholes were proposed, as a complement to those from previous campaigns, which made it possible to get a set of geological profiles of the foundation ground. Tests carried out on samples from the boreholes served to identify the natural state and evaluate the mechanical behaviour of the materials. The presence of horizontal movements in the Parador was clearly conditioned by the tilting of the calcarenite block whose movement was linked, on the one hand, to the progressive erosion of the materials underlying the calcarenite, and on the other, to the effect of the water infiltrated through the "crack" that broke off the block in the lower sandy levels. On the other hand, it was necessary to consider two basic mechanisms of instability of the slope: the first, with predominance of horizontal movements and possible emergence on the slope with mobilization of relatively small superficial sliding masses supported on soft soils. The second corresponded to deep landslides in very deformable areas of the lower loamy clays.

As a proposal to reinforce the south wing of the Parador, a stabilization of the movement of the broken calcarenite block was proposed through a treatment of armed injections. In the Parador de Carmona this treatment consisted mainly of the nailing and massing of the area of the crack that affected the south wing, in addition to the stabilization of the supporting levels located under the calcarenite block until reaching the relative elevation of -44 m, in relation to the level of entrance to the Parador (elevation ±0.00 m). The treatment was designed based on a series of buttresses, with separation of about 5 m, which were drilled and treated alternately, from the south and north areas of the south wing, by means of steel tube fans equipped with sleeve valves. The adoption of the buttress configuration in the treated ground was intended to prevent the formation of a barrier to groundwater seepage. The depth of the treatment up to 44 m, and its location on both sides of the crack allowed to also ensure stabilization for the differe mechanisms outlined. The previous treatment was completed with the execution of a drainage system of the hillside in three levels. For the execution of the work, a technical specification was established in which, among other aspects, the requirements of the injection mixtures and the operating procedure to be followed during the treatment were specified. Under the technical direction of CEDEX a Spanish company specialized in injections proceeded to execute the underpinning works, permanently controlling, during the four months that the works lasted (January to May of 1997) the vertical movements of the Parador with levels of precision and electro-levels and the horizontal movements with convergence tapes, extensometers, and crack gauges. In total, 33 armed injection fans were performed, with a total of 297 drills. In the cases in which the movements observed by the auscultation advised it, especially during the month of April, in which, due to the intensification of the injection works, a raising of the building began to be detected, the volumes and rate of injection were reduced, considerably decreasing these uplift movements. The injection was carried out by three pumps with two lines each, continuously recording pressure, flow rate and volume injected per sleeve.

About the drainage of the hillside, once the injection works were completed, a total of 43 horizontal drains were executed, with lengths of 20, 30, 40 and 44 m. The drains were completed with the execution of three perimeter ditches, placed at the supposed foot of the landslide.

Throughout the work, the state of the building was continuously monitored by means of auscultation,

with the aim of knowing the effect of the underpinning works and other factors (climatological) on it and be able to adopt appropriate corrective measures at any time. For the control of horizontal movements, 23 convergence sections were established distributed over two floors to alleviate, as much as possible, thermal conditions. Likewise, three instrumented sections with a large base extensometer were arranged. For the control of vertical movements, 90 m of electrolevels and a conventional precision levelling system were used, for which a fixed point was installed in the parade ground, anchored at elevation -41 m. In total, 34 INVAR levelling strips were placed, which were controlled with an accuracy of 0.2 mm. The analysis of the evolution of the vertical movements recorded by means of the levelling strips, from their installation in the Parador in mid-January until the end of June, allowed to verify how since the beginning of May the movements of all the points stabilized.

The subsequent monitoring of the behaviour of the ground on which the Parador lays, particularly in periods of heavy rain, indicated a correct functioning of the reinforcement executed, without any evidence of evolution of old damage or appearance of new damages that could question its validity.

4 CONCLUSIONS

An overview of some cases of geotechnical pathologies of Spanish historical monuments adjacent to natural slopes, in which the Laboratorio de Geotecnia of CEDEX has intervened in the past, has been presented. Two not previously published interesting case histories have been described in more detail.

Slope instability risk assessment along the Almada municipality coastline, Portugal

Évaluation des risques d´instabilité des pentes le long du littoral de la municipalité d´Almada, Portugal

F. Paulino*, E. Fernandes, A. Dinis
Geovia, S.A., Lisbon, Portugal

A. Aires, A. Godinho
Câmara Municipal de Almada, Almada, Portugal

**fpaulino@geovia.pt*

ABSTRACT: The Portuguese continental coastline extends for 987 km, centralizing around 75% of the national population in just 25% of the territory, generating 85% of the gross domestic product (GDP). Approximately 30% of the coastline is considered a protected area and included in the National Network of Protected Areas, with around 50% including areas belonging to the Rede Natura 2000. The exponential growth that has occurred in recent decades, resulting in increased demographic pressure on the coastal strip, has been promoting the occupation of dangerous zones subject to possible landslides. It is known that the adulteration of the physical landscape, in the name of development, has reached alarming proportions. The loss of territory and damage to coastal infrastructure are visible consequences of human intervention on the coast. As a result, it is crucial to investigate the mass movements of cliffs. This type of movement is difficult to predict due to its lack of warning signs and displacement speeds that occur in seconds. Once the movement begins, it is impossible to contain it, making it necessary to identify potential weaknesses in cliffs and minimize inherent risks by understanding rupture mechanisms. With this communication it is intended to present the geomechanical study of the stability of several cliffs of the municipality of Almada.

RÉSUMÉ: Le littoral portugais s´étend sur 987 km, centralisant environ 75% de la population nationale sur seulement 25% du territoire, générant 85% du produit intérieur brut (PIB). Environ 30% du littoral est considéré comme une zone protégée et inclus dans le réseau national des zones protégées, avec environ 50% comprenant des zones appartenant au Rede Natura 2000. La croissance exponentielle survenue au cours des dernières décennies, entraînant une pression démographique accrue sur la bande côtière, a favorisé l´occupation de zones dangereuses sujettes à d´éventuels glissements de terrain. On sait que la falsification du paysage physique, au nom du développement, a atteint des proportions alarmantes. Les conséquences de l´intervention humaine sur le littoral sont visibles, à savoir la perte de territoire et les dommages aux infrastructures de protection côtière. Cependant, les mouvements de masse sur les falaises doivent être considérés comme l´un des principaux axes d´étude en raison de leur irrégularité temporelle. Ce type de mouvement se caractérise par des vitesses de déplacement de l'ordre de la seconde, pas toujours précédées de signes avant-coureurs et, de ce fait, considérées comme difficiles à prévoir. Une fois de mouvement amorcé, il devient impossible de le contenir, ce qui nécessite de comprendre les mécanismes de rupture pour identifier les signes de faiblesse potentielle des falaises et minimiser le risque inhérent. Avec cette communication, il est prévu de présenter l'étude géomécanique de la stabilité des différentes falaises de la municipalité d´Almada.

Keywords: Risk assessment; rock cliffs; slope stability.

1 INTRODUCTION

The incorporation of stability studies of Portugal's coastline zones in land planning and urbanism policies is a recent development that started in the 90s. This change in mentality demonstrates an awareness of the potential risk to people and property caused by cliff movements. This is due to an increase of the Portuguese coast occupation rate.

Ten study locations were selected along the Almada municipality coastline for risk assessment, using information provided by the Almada municipality, namely:

- Olho-de-Boi (Poente)
- Banática
- Pica Galo
- Abas da Raposeira
- Foz do Rego

- Porto Brandão
- Arriba Fóssil da Costa de Caparica
- Arriba Fóssil do Bairro do Fóni
- Arriba Fóssil – Via Panorâmica Pablo Neruda
- Quinta da Arealva.

2 METHODOLOGY

Initially, the applied methodology consisted of a semi-quantitative risk assessment to promote a simple and quick prioritization of risks identified. This was achieved by determining the Risk Index (RI), using the following equation:

Risk Index (RI) = Probability of Occurrence (PO) x Magnitude (M) x Potential Damage (PD)/Response Capacity (RC) (1)

where (PO x M) defines the dangerousness (D) and (PD/RC) represents the vulnerability (V).

This methodology is adapted from Costa et al. (2009). Each term in the equation was categorized on a scale of 1 to 5 (respectively: not significant, reduced, average, high and very high). Equation (1) calculates the risk values associated with the hazard in question. The matrix used to calculate RI values for all possible scenarios was recalculated for the interval [0;1], instead of [0.2;1], for better perception of the obtained values. The calculated values were divided into 5 classes of equal amplitude.

The danger calculated by this methodology must be understood as an apparent danger, differing from the concept proposed by Varnes (1984). This is because it is not based on the probability of an occurrence, but rather on a weighted calculation that relies on available information and on the expert assessment of geological-geotechnical factors that affect cliff stability (refer to Figure 1). Even though this assessment has some degree of subjectivity, when well-founded, it is generally more valuable than mere numerical calculations, namely in Geotechnics (Schubert, 2004). Furthermore, an expedited initial assessment allows the concentration of more detailed studies in places that require priority intervention.

In the second phase, the behaviour was measured through geomechanical analysis of the cliffs wherever RI≥0.80 was obtained, based on the geotechnical characterization of the rock mass and on identifying rupture mechanisms (Brissos, 2013; Brissos et al., 2014).

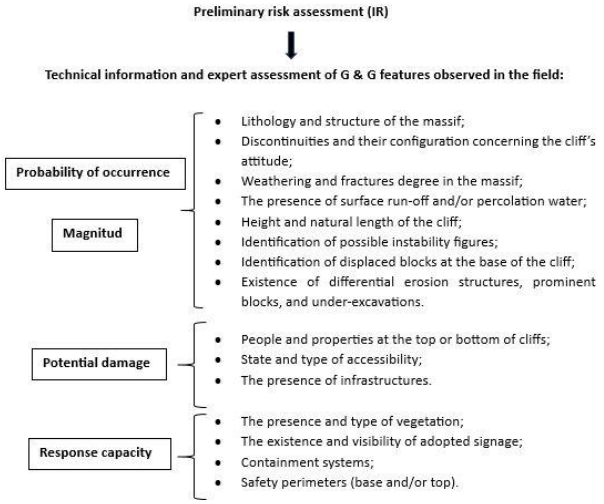

Figure 1. Schematization of the preliminary risk assessment methodology.

3 RESULTS

3.1 Preliminary risk assessment (1st phase)

Table 1 presents the values attributed to the different variables of equation (1), as well as the calculation of the Risk Index (RI) associated with the problem under analysis.

The cliffs in the Almada municipality represent a risk due to the lithological and weathering characteristics of the rock mass. These conditions can lead to frequent instabilities caused by differential erosion of the existing rock masses. Figure 2 shows the panoramic view of the fossil cliff in Bairro do Fóni, with houses adjacent to the cliff's crest, figure 3 shows a fallen limestone block from Banática cliff near two parked cars, figure 4 represents a panoramic view of the fossil cliff in Olho de Boi, with Almada Cemetery behind, and figure 5 shows the panoramic view of the cliff in Porto Brandão, with houses adjacent to the base of the cliff.

Table 1. Calculation of hazard, vulnerability and risk values for the identified locations.

Locals	Stations	Dangerousness			Vulnerability			Risk Index	
		PO	M	Final Value	PD	RC	Final Value	Preliminar RI	Classification
Olho de Boi	1	5	5	25	5	1	5	1,00	Very high
	2	5	4	20	3	3	9	0,16	Insignificant

Figure 2. Panoramic view of the fossil cliff in Bairro do Fóni with houses adjacent to the cliff's crest (June, 2023).

Figure 3. Limestone block from Banática Cliff near parked cars (June, 2023).

Figure 4. Panoramic view of the fossil cliff in Olho de Boi with Almada Cemetery behind (June, 2023).

Table 1 shows that certain locations have a higher risk index due to the greater height of the cliffs, the history of incidents and the possibility of large blocks being mobilised from these locations (as shown in Figure 3).

This higher risk index, in specific cases like Olho-de-Boi, Banática, Porto Brandão and Bairro do Fóni, is associated with poor conditions caused by their close proximity to urban areas with constructed infrastructure both at the top and at the base of the cliffs.

Figure 5. Panoramic view of the cliff in Porto Brandão with houses adjacent to its base (June, 2023).

For example, the landslides and rock fall events observed at the Olho-de-Boi cliff occurred at the base of the slope, leading to an overhang at the top. This indicates that the layers with the least resistance are located at the bottom of the cliff, while the ones with the most resistance are at the top. It is obseved that the most weathered and the less weathered layers are divided by tension cracks parallel to the cliff and subvertical fractures visible at the top of the cliff.

In Banática, the houses are located near the slope (between 2.0m and 10.0m) and there is no protection against slope movements. This is a scenario of maximum damage potential and no response capacity.

In Porto Brandão, there are several residential and commercial buildings occupying the foot of the cliff with no safety distance. This represents a very high vulnerability, as there is minimum response capacity and maximum potential damage.

In Bairro do Fóni, there is a very sharp cliff retreat with evidence of significant ravines. There are buildings located on the top of the cliff, with emphasis to an overhanging reinforced concrete structure at risk of structural failure.

Considering the above, it became evident that stability studies must be conducted in these areas. This is necessary not only because of the geomechanical conditions that favour instability phenomena, but also due to the high vulnerability associated with human occupation at both the base and the top of these cliffs.

3.2 Reassessment of risk and proposal mitigation measures mitigation (2nd phase)

The preliminary risk evaluation in this study was reassessed based on the geological-geotechnical characterization of each cliff and the geotechnical zoning. The estimated retreat rates and the simulation of the trajectories of falling blocks from the studied cliffs also contributed to the reassessment of the preliminary risk.

The risk reassessment also considered the current and future of the areas of influence (crest and base), with the results presented in Table 2.

It appears that in general the values remained the same in practically all locations. The exception occurred at a station 38 on fossil cliff in Bairro do Fóni.

After the risk reassessment, the Risk Index (RI) is maintained based on the occurrence of falling blocks in the past, the number of people using the access paths to the top or base of the cliffs, and the annual retreat rate of the cliffs.

Table 2. Risk reassessment and comparison with the preliminary risk evaluation.

Locals	Stations	Dangerousness			Vulnerability			Risk Index		
		PO	M	Final Value	PD	RC	Final Value	Final RI	Preliminar RI	Classification
Olho de Boi	1	5	5	25	5	1	5	1,00	1,00	Very high
	4	5	5	25	5	1	5	1,00	1,00	Very high
Banática	7	5	4	20	5	1	5	0,80	0,80	Very high
	8	5	5	25	5	1	5	1,00	1,00	Very high
Porto Brandão	11	5	5	25	5	1	5	1,00	1,00	Very high
Arriba Bairro do Fóni	38	5	4	20	4	1	4	0,64	0,80	High
	39	5	4	20	5	1	5	0,80	0,80	Very high
	41	5	5	25	4	1	4	0,80	0,80	Very high
	44	5	4	20	5	1	5	0,80	0,80	Very high

Based on this reassessment, a proposal for a short-term risk mitigation plan was presented (Table 3). The adopted approach focuses on reducing long-term vulnerability by reinforcing appropriate signage and placing physical fences to prevent access to the top of the cliff.

The dismantling of some larger, potentially unstable blocks, must be considered using appropriate dismantling methodologies, as well as, the fixing of metal nets to control blocks that may detach from the cliff face.

Subsequently, nailing should be carried out, possibly associated with cables and steel mesh, pulled and anchored to the massif, to fix the larger volume consoles. The use of shotcrete, always accompanied by the execution of drainage holes, could be an alternative. The installation of ridge ditches allows the collection of runoff water, making infiltration and washing of fractures more difficult. The effective implementation of a monitoring plan is still considered necessary for long-term prevention perspective.

Table 3. Risk mitigation plan proposed for the case study.

Risk Mitigation				
Structural				
Stabilization measures		Protection measures	Drainage	Non-structural
Correction	Reinforcement			
Dismantling of rock blocks; Cliff re-profiling	Nails; Metal mesh associated with steel cables / shotcrete	Nailed/anchored metal mesh	Cliff crest ditch	Implementation of appropriate danger signs in clearly visible locations (foothills and crests); Restriction and prohibition lanes with respective signs and fences, at the base and on the crest and foothills; New Jersey-type barriers in areas that require protection against blocks that could roll from the top of the cliff to homes

4 CONCLUSIONS

The methodology used for instability risk assessment of the studied cliffs relies heavily on subjective methods, rather than quantitative analysis. However, this methodology demonstrates higher reliability in establishing a preliminary risk zoning. This allows to hierarchise the most critical cliffs, which are in need of detailed stability studies, implementation of risk stabilization and mitigation measures, and their respective monitoring.

Strength resistance of sea dikes to increased wave overtopping due to the rise in sea levels

Résistance des digues à l'augmentation du déferlement des vagues due à l'élévation du niveau de la mer

ABSTRACT: The predicted rise in sea levels due to climate change results in the requirement to increase the height of coastal dikes in order to maintain current safety levels. The extraction of suitable natural clay material for dike coverings is significantly restricted. Therefore, this study will consider dredged material as an alternative and if higher wave overtopping rates can be tolerated. Field tests with simulated water infiltration rates similar to those of a storm surge event at existing dikes were conducted. Soil samples were subsequently taken and examined in the laboratory, e.g. by triaxial tests. The results showed, that dredged material with a certain clay content is as suitable for dike coverings as glacial till and soft marsh soil, which are commonly used for dike coverings in estuaries resp. the Baltic Sea region. Measurements by vane tests directly after a storm surge event revealed different soil strengths across the dike, whereby the future highest hydraulicly loaded areas showed the lowest but still sufficient strength resistances. In an explicit numerical simulation model all field and laboratory test results were merged. For simulating the non-static wave overtopping at the dike crest, shear forces were applied at distinct dike surface areas. By defining a failure criterion for a progressing erosion process and high overtopping rates, a dike failure similar to observed ones in the past could be simulated.

RÉSUMÉ: L'élévation prévue du niveau de la mer en raison du changement climatique impose d'augmenter la hauteur des digues côtières afin de maintenir les niveaux de sécurité actuels. L'extraction de matériaux argileux naturels appropriés pour les revêtements de digues est considérablement limitée. Par conséquent, cette étude examinera les matériaux de dragage comme alternative et déterminera si des taux de débordement des vagues plus élevés peuvent être tolérés. Des essais sur le terrain ont été réalisés avec des taux d'infiltration d'eau simulés similaires à ceux d'une onde de tempête sur les digues existantes. Des échantillons de sol ont ensuite été prélevés et examinés en laboratoire. Les résultats ont montré que les matériaux de dragage ayant une certaine teneur en argile conviennent aussi bien aux revêtements de digues que le till glaciaire et le sol mou des marais, qui sont couramment utilisés pour les revêtements de digues dans les estuaires et dans la région de la mer Baltique. Les mesures effectuées à l'aide d'essais à la girouette directement après une onde de tempête ont révélé des résistances du sol différentes d'un bout à l'autre de la digue, les futures zones les plus chargées sur le plan hydraulique présentant les résistances les plus faibles, mais néanmoins suffisantes. Dans un modèle de simulation numérique explicite, tous les résultats des essais sur le terrain et en laboratoire ont été fusionnés. Pour simuler le débordement non statique des vagues sur la crête de la digue, des forces de cisaillement ont été appliquées à des zones distinctes de la surface de la digue.

Keywords: Sea dike; wave overtopping; dredged material; failure, soil mechanics.

1 MOTIVATION

Dikes in Germany and other countries consist in most cases of a sand core which is covered with a cohesive dike covering and a grass revetment. The purpose of the dike covering and the grass revetment is to resist the hydraulic loads by waves and currents and prevent erosion.

Due to the predicted sea level rise, the height of coastal dikes has to be increased in order to maintain current safety levels. One aspect hereby is the allowed overtopping rate at the dike crest and the landward slope.

Examinations by (Van Hoven et al, 2010) have shown, that higher overtopping rates, than actually allowed, do not damage the dike, if the grass revetment has a good quality and no singularities in the dike exist.

For a better understanding of these processes and the suitability-check of alternative cohesive materials, physical tests, i.e. field and laboratory tests in

conjunction with numerical simulations were conducted.

2 FIELD TESTS

2.1 Infiltration tests

The infiltration tests were performed to simulate a storm surge or heavy rainfall. The question to be answered is: how does the water content and thus the corresponding shear strength change over the depth of the dike covering in dependence of the infiltration time? This is of particular importance for the stability of the dike covering and thus its resistance against failure.

Therefore, tests at dike coverings consisting of glacial till, soft marsh soil and dredged material were conducted. The infiltration times were up to 38 hours, which is in good accordance with one of the heaviest storm surges at the Baltic Sea on 21/10/2023. After the distinct infiltration times, undisturbed soil samples were taken with a drilling rig (Figure 1).

Figure 1. Field test set up.

A direct test-result is the permeability of the examined dike section. Regarding the aging of a dike it can be concluded, that the permeability of a new constructed dike is lower than that of an older dike. This is due to cracks and fissures, which develop over time; initiated by weathering processes (drying out – wetting) and by burrowing animals. The permeability of an older dike can be taken to $5x10^{-5}$m/s. This is in good accordance with (TAW, 1996; Achmus et al, 2019) for soft marsh soil dikes and applies, thus also for glacial till and dredged material dikes.

2.2 Vane tests after storm surge

Vane tests at a section of a soft marsh soil dike near Wedel were executed immediately after the heavy storm surge event "Xaver" did occur. Due to the limited data, the findings are mere qualitatively.

The results (Table 1) are: at the seaside slope below driftline (i.e. level, where material was deposited by the storm surge) and at the dike crest, the strength tends to be higher than at the seaside slope above driftline and the landside slope. This might be explained by the maintenance and usage of the dike: vehicles move below the driftline to remove the deposited material and pedestrians walk on the dike crest. Both events lead to a recurring compaction. It has to be mentioned, that the inclination of the landside slope is 1:3 and at the seaside 1:6 to 1:10. Above the driftline more signs for burrowing animals were encountered. No overtopping did occur during Xaver.

At the landside slope the strength is the lowest, but still sufficient according to (EAK, 2002). But this also means, that in the area where wave overtopping occurs the resistance and strength of the dike is the lowest.

Table 1. Mean undrained shear strength cu [kPa].

Depth [cm]	Seaside below driftline	Seaside above driftline	Dike crest	Land-side
10	67	53	72	39
40	104	53	80	43
70	123	78	78	42

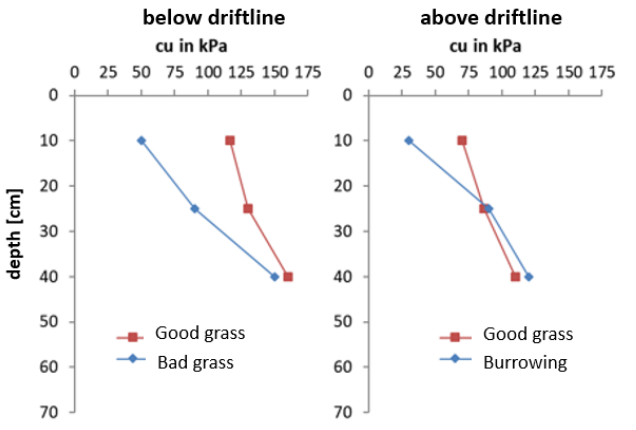

Figure 2. Influence of grass quality and burrowing.

Figure 2 illustrates that in sections with poor grass quality or evidence of burrowing activities, the strength is lower, reaching values comparable to a well-established grass quality revetment at a depth of approximately 30 cm. This implies that the resistance against near-surface slope sliding (Achmus et al, 2019) is evidently affected.

3 LABORATORY TESTS

3.1 Water contents

The undisturbed samples were analysed regarding the classifying properties. Additionally, the water content as caused by the infiltration tests were determined. No safe correlation between infiltration times, depths and water contents or levels of saturation is possible for all examined materials and dike sections (of different ages). The corresponding undrained shear strength values cu vary likewise between 30 (no infiltration) and 400 kPa (24h infiltration).

The results reflect the heterogeneity of the dike material in itself over a dike section and the locally different permeability due to cracks. Hence, the water applied by the infiltration tests does not infiltrate perfectly vertically but follows in the direction of cracks.

3.2 Soil mechanical tests

Soil mechanical tests: triaxial tests and compression tests were executed for determining the strength and the stress-strain-behaviour of the dike covering for the numerical model.

The stress-strain-curves varied quite widely. No safe correlation to the aspects mentioned above as well as classifying properties was possible. Hence, the stress-strain-curves were grouped and reference curves were developed therefrom.

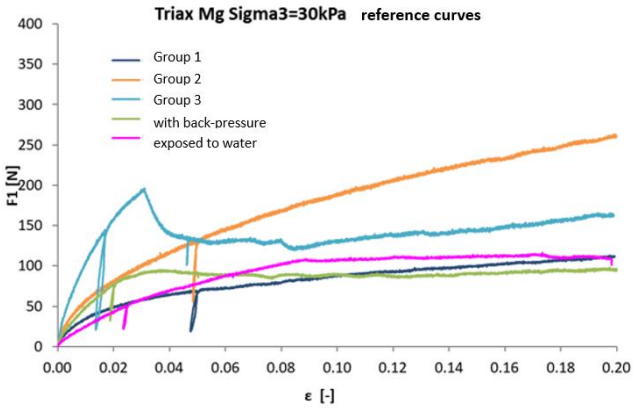

Figure 3. Stress-strain-curves of refence tests.

Figure 3 shows the reference stress-strain-curves for glacial till, which could be differentiated in 3 groups. The tests were performed with the water content of the soil samples as taken in situ. Additional test-series were done with samples which were exposed to water at the base and the top, and samples with back-pressure, i.e. full saturation.

The samples with back-pressure have a higher initial strength than the samples of group1 and water-exposed, but align at larger strains quite well. Therefore, and for an unequivocal handling at the numerical simulation, the results of the samples with back-pressure were used in the following.

4 NUMERICAL MODEL

4.1 Model and parameters

The software FLAC3D, Vers. 7.0 (Itasca, 2019) with the hardening soil model was used for the simulation of a dike section at a storm surge event. The finite difference method was chosen due to the expectable large deformations.

The derived model parameters for the examined dike materials are given in Table 2.

Table 2. Model parameters.

	Glacial till	**Soft marsh soil**	**Dredged material**
ρ_d [g/cm³]	1,83	1,54	1,35
φ' [°]	33,2	33,1	36,9
c'[kPa]	8,2	7,3	11,1
ψ [°]	5	3	3
ν [-]	0,3	0,3	0,3
p_{ref} [kPa]	25	25	25
E_{50ref} [kPa]	5445	4480	4720
E_{oedref} [kPa]	5025	2105	1290
E_{urref} [MPa]	30,3	24,55	18,55
m [-]	0,56	0,13	0,62

The comparison of the shear-strength highlights, that the difference of the 3 examined materials are quite similar. Regarding the compression it is noted, that the soft marsh soil and dredged material are softer than the glacial till.

4.2 Simulation of stability and erosion process due to wave overtopping

The results of the field and laboratory tests were implemented in a numerical model dike in which the material at the seaside above driftline and the landward slope were set to be 50% weaker than at the dike crest and the seaside below driftline (Table 1). At these conditions, the dike is stable, with a factor of safety of about 2.

For simulating the storm surge event, shear stresses due to overtopping according to (Weissmann, 2003) and the criteria for erosion according to (Hoffmans, 2009) were used. I.e. that at a deformation of 10 cm erosion occurs.

The shear stresses were applied at the seaside above driftline, dike crest and landward slope in a strip of 1m width. The limited strip reflects the investigations by (Van Hoven et al, 2010) with the overtopping

simulator, where the first damages occurred locally at weak zones of limited expansion.

At each grid point in the numerical model, the deformation velocities were measured. The critical value of 10 cm was at $5x10^{-6}$ m/s. At an overtopping rate of 100 l/(s m), i.e. shear stresses of 960 N/m², the dike started to fail. Therefore, it was assumed, that the surrounding soil of an eroded area softens to 20% of the initial strength, due to the consequent water infiltration. In this way a progressive dike failure developed (Figure 4). The numerically simulated dike-failure and a documented one (Achmus et al, 2019) fit quite well. The dashed lines indicate the initial dike geometry.

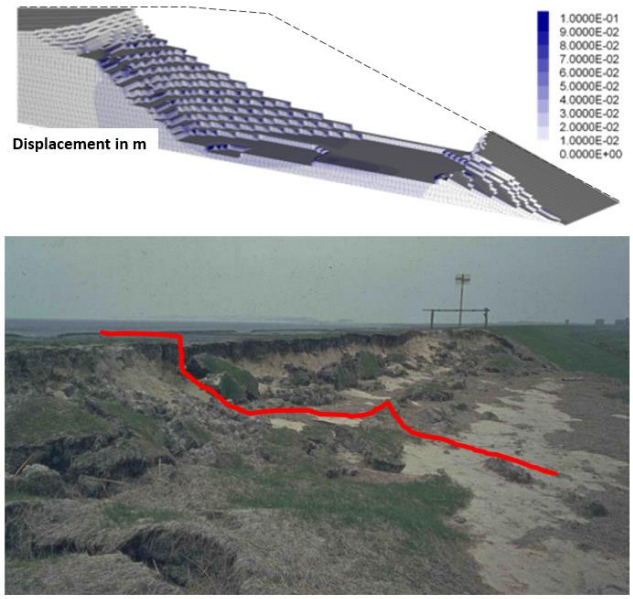

Figure 4. Numerical results and physical dike failure.

5 CONCLUSIONS

From the examinations and simulations the following conclusions can be drawn: The permeability of the examined cohesive dike coverings are about $5x10^{-5}$ m/s. For soil mechanical tests, a soil sample with back-pressure reflects the worst in-situ situations quite well. The seaside slope above drift line and the landward slope, which are exposed to wave overtopping are weaker than the other areas of a dike. A good grass quality and dike management are crucial for a high dike resistance. Dredged material is equivalent to commonly used materials, especially soft marsh soil. A realistic dike failure at high overtopping rates could be simulated.

Although higher overtopping rates as accepted could be applied in the numerical model, the authors want to emphasise, that the climate change leads to cracks and bad grass revetments due to droughts. Thus, the dike-resistance will be decreased, if not adequate actions will be taken.

ACKNOWLEDGEMENTS

The authors are grateful for the support by the state authorities of Schleswig-Holstein, Hamburg, Bremen and Mecklenburg–Western Pomerania at conducting the field tests and the waterways and shipping authority of Stralsund for the first fruitful discussions.

ABSTRACT: Many flood protection dams in Europe were built more than 100 years ago. These dams often do not meet current flood protection requirements due to increased level of safety requirements, higher damage potential in the valley plains and due to higher peak discharges or water levels expected with changing climatic conditions. A first series of centrifuge tests on an idealized cross-section of a flood protection dam has been carried out in the geotechnical centrifuge at TU Delft in order to study the seepage behaviour of a horizontally layered dam consisting of layers with coarse and fine-grained material. Main aspects of the testing equipment such as a specially manufactured test box which allows to simulate certain flood events of different durations and intensities are presented. Furthermore, measured values of the pore pressure during the investigated flood event, are presented and discussed in comparison to the results of finite element modelling of the dam. Finally, the influence of the hydraulic boundary conditions on the seepage behaviour in the physical and numerical modelling is critically discussed.

RÉSUMÉ: De nombreux digues de rivière en Europe ont été construites il y a plus de 100 ans. Souvent, ces digues en terre ne répondent plus aux exigences récentes en matière de protection contre les crues, en raison des besoins accrues en matière de sécurité, du potentiel de dommages plus élevé et de l'augmentation des niveaux d'eau attendus due au changement climatique. Une première série d'essais en centrifugeuse sur une coupe idéalisée d'une digue de terre a été réalisée dans la centrifugeuse géotechnique de l'Université technique de Delft afin d'étudier le comportement d'infiltration d'une digue stratifiée composée de couches de sol grossier et de sol fin. Les principaux aspects de l'équipement d'essai, tels qu'une boîte d'essai spécialement fabriquée qui permet de simuler certains événements de crue de durées et d'intensités différentes, sont présentés. En outre, les valeurs mesurées de la pression interstitielle pendant la crue étudiée sont présentées et discutées en comparaison avec les résultats de la modélisation par la méthode des éléments finis. Enfin, l'influence des conditions limites hydrauliques sur le comportement de l'infiltration dans la modélisation physique et numérique fait l'objet d'une discussion critique.

Keywords: Centrifuge modelling; seepage; flood protection dam; numerical modelling.

1 INTRODUCTION

Many flood protection dams no longer meet today's safety requirements, especially in the context of climate change. Higher water levels must be expected nowadays. This is illustrated by the example of the flood protection dams along the Alpine Rhine, which are currently being restored in sections. The original straightening and damming of the Rhine started in the 19th century (*Schweizerische Bauzeitung*, 1927) and no longer fulfils flood protection requirements.

A conservative engineering design approach assumes steady-state seepage flow through the dam and is often considered when investigating dam stability or developing measures against stability problems (CIRIA, 2013). However, it seems reasonable to consider transient seepage conditions, as flood events in alpine regions often only have a duration of 12 to 48 h. This could offer a potential for cost minimisation in project planning of remediation measures. Research results on a model river-embankment consisting of silty-sandy material in a geotechnical centrifuge by Giretti et al. (2022) show that the saturation front in the dam reaches the air side of the dam only after a long flood period. Mayor (2013) reports similar results in his large-scale tests at

the river Rhône dam, whereas it should be considered that the time until the saturation front reaches the air side depends directly on its permeability and its degree of saturation at the beginning of the flood.

However, if transient flow conditions are to be considered in the design, a more detailed understanding of the evolution of pore water pressure in the dam body is required to ensure safe design. Physical modelling under transient flow conditions can provide valuable data for better interpretation and potentially validation of numerical calculation methods.

A model-dam is used because the construction of a 1:1 scale model dam is complex and costly (Mayor, 2013; Toromanovic et al., 2020). A geotechnical centrifuge is used to increase the acceleration field and thus the effective stresses in the model to ensure comparable results of the model tests with the prototype (Madabhushi, 2014). A geometrically *n*-times smaller dam is subjected to an *n*-times larger *g*-level as the effective stresses are generally accepted to be linearly correlated with depth (Wood, 2004; Askarinejad et al., 2015).

2 METHOD

The focus of the herein described investigation on the flow behaviour and permeability within a layered flood dam lies on the physical centrifuge modelling. Subsequently, a numerical model was created – as would typically be the case in current engineering practise – in order to supplement the experimental results in the sense of a comparative investigation.

2.1 Centrifuge modelling

The experiments were conducted at 100 *g* in the geotechnical centrifuge at TU Delft which has a radius of 1.22 m and a basket size of 400x500x500 mm (Allersma, 1994; Zhang and Askarinejad, 2021). A testing strongbox was created for this purpose. A flood wave could be generated inflight with the help of a water tank and servo coupled valves. In addition, an overflow was placed on the air side of the dam to maintain a constant water level. The model box has outer dimensions of LxHxW = 615x200x120 mm, with 15 mm thick aluminium panels and a transparent front made of 15 mm thick acrylic glass. Figure 1 shows a model dam installed in the test box in the centrifuge basket. The water tank for the flood wave (1.6 litres) is situated on top of the test box. The model dam was constructed according to the prototype of a typical cross-section of the river Rhine dam. On top of the permeable Rhine gravel lies a less permeable layer of flood deposits on which the gravelly dams were built.

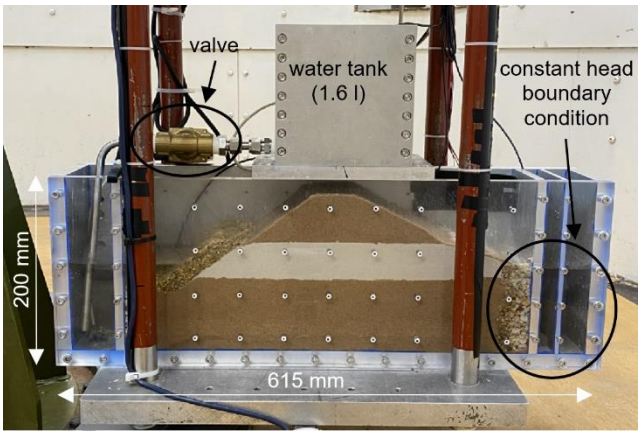

Figure 1. Modell Dam inside the strongbox.

The model dam was constructed at a scale of 1:100 as shown in Figure 2. The crest of the dam is 80 mm higher than the air side terrain and has a base width of approximately 350 mm. It is important that the underlying permeable Rhine gravel is modelled as well since it may influence the seepage behaviour. Geotechnical properties of the materials used in the model are summarised in Table 1. In prototype, the Rhine gravel and the Rhine dam have a similar permeability, so both materials are modelled with Baskarp B25 sand (Pol et al., 2021). For the less permeable layer of flood deposits a mixture of Geba Sand (Maghsoudloo et al., 2021) with 5% Kaolin Clay was used (Figure 2). The permeabilities were determined with constant head tests (Head & Epps, 2011). The values determined in the tests correspond to the vertical permeability k_v.

Table 1. Geotechnical properties of the dam materials used in the centrifuge test.

Soil type	$e^{1)}$	k_v [m/s]	φ'_{cv} [°]
Baskarp B25 Sand	0.69	$6 \cdot 10^{-5}$	32 - 34
Geba Sand with 5% Kaolin Clay	0.64	$2 \cdot 10^{-6}$	~ 31[2)]

[1)] voids ratio after compaction at w = 10%
[2)] value applies for Geba Sand without clay

The soil materials were placed in the model box in layers with a water content of 10% and compacted uniformly. After the entire box was filled, the dam was shaped by removing the excess material. At the same time, samples were taken to check the layer density.

Three Porewater-Pressure-Transducers (PPT) were installed at the bottom of the model (Figure 2) in order to record the propagation of pore water pressure in the dam. In order to check the boundary conditions, two PPTs were installed in the left inlet tank and in the right outlet tank, respectively. Figure 3 shows the planned flood characteristics in the prototype scale for the tests. The water levels refer to the heights from the

base of the strongbox (Figure 2). The riverbed accordingly lies at a height of 7.4 m. The goal was to model a flood wave consisting of a pre-wave (13 m), peak (15.4 m) and post-wave (12.3 m) by opening and closing the valves, starting from an initial river level at 9.4 m (steady state with 2 m high river, see Figure 2). Water was used as the fluid for the centrifuge experiments. The model time for seepage processes is therefore reduced by a factor of 1:100[2] (Garnier et al., 2007; Wood, 2004) since the model was tested at 100 *g*. This means that the entire flood event with a duration of 60 h at prototype scale translates to 21.6 s in the centrifuge experiment. The experiments were recorded through the acrylic glass using a digital camera.

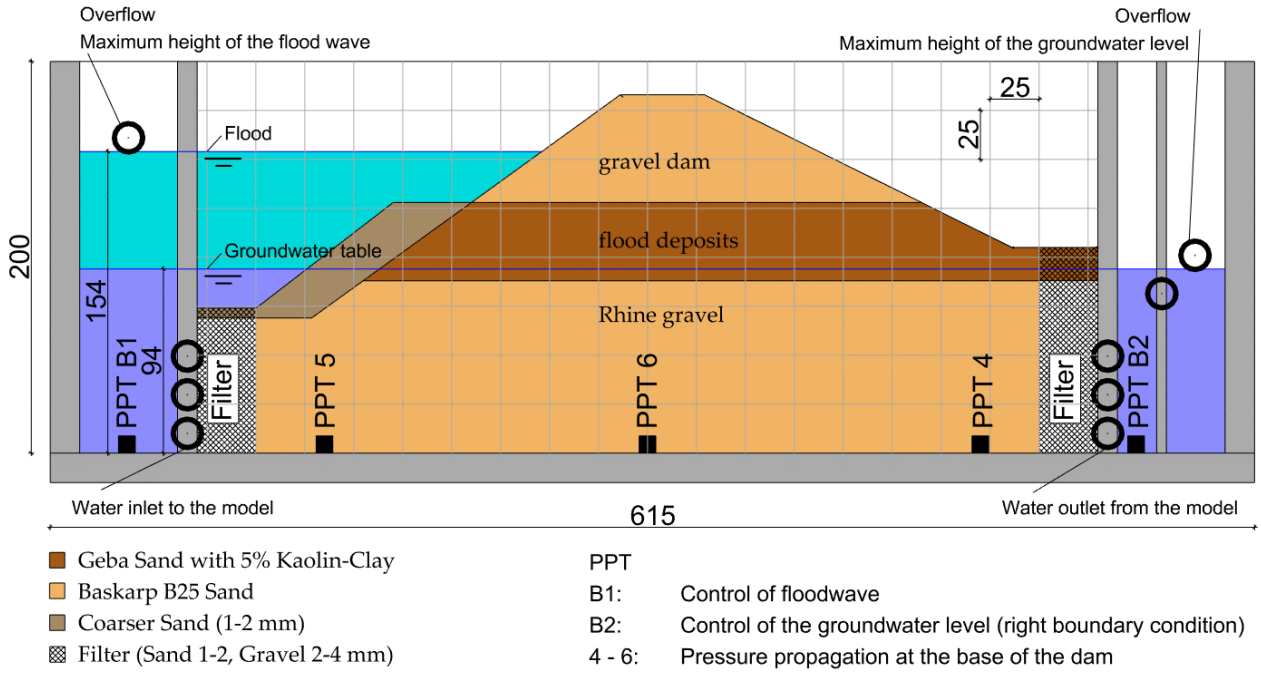

Figure 2. Geometry of the dam built into the test box including positions of PPTs. Dimensions in [mm].

The test procedure is described hereafter with the corresponding prototype time steps, model time is given in parentheses: After the centrifuge reaches 100 *g* (t = 0), the initial water level of 9.4 m (94 mm) is kept constant for 14 d (2 min) to allow stationary conditions to be established. Subsequently, the flood wave is applied stepwise within 60 h (21.6 s) as shown in Figure 3. Finally, the model is kept under 100 *g* for another 35 d (5 min) to restore initial conditions.

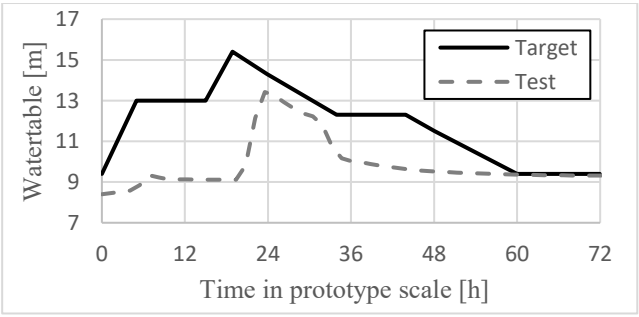

Figure 3. Target hydrograph of the flood wave in prototype scale compared to the actual flood wave achieved during the test (measurement of PPT B1, riverbed is located at 7.4 m).

After the centrifuge test, the model is checked for any signs of erosion, piping processes or stability problems. The initial water table is restored before starting the next test series. However, the desired flood wave could not be achieved because some of the valves could not be opened or closed properly at 100 *g* (Figure 3). Thus, it was difficult to maintain a constant water level with the water available in the tank due to the loss of water through seepage.

2.2 Comparative numerical model

A comparative numerical model of the dam is set at prototype scale in the program PlaxFlow2D from Plaxis with the same boundary conditions as given in the experiment. Special attention was paid to the following points:

- The flood wave is modelled according to the data measured in the centrifuge test (‘Test’ hydrograph in Figure 3).
- The permeable berm on the water side made of coarse sand is not modelled to minimise the computational effort. It is assumed that due to the higher permeability, it does not significantly influence the seepage behaviour.

- A constant head boundary condition is set on the air side as given in the centrifuge model test.
- The FEM model with the corresponding boundary conditions and the mesh is shown in Figure 4.

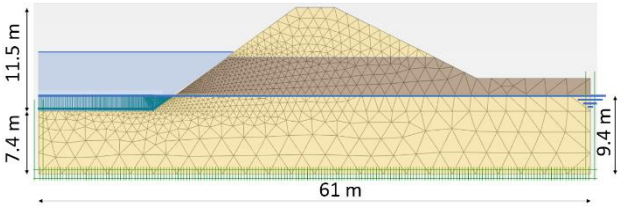

Figure 4. FEM model geometry with mesh and boundary conditions for the PlaxFlow calculation: The initial water level of the river is indicated with blue arrows and corresponds to the height of the constant head boundary condition on the right edge of the model (initially no hydraulic gradient). The variable water level is indicated in blue on the left.

The pressure conditions are compared at points that are always saturated (PPTs in Figure 2). However, it must be assumed that the modelling of the unsaturated dam area above has an influence on the results. For a comparative model, the unsaturated zones of the dam and their behaviour are described using the Van Genuchten (1980) model implemented in the software. Thus, with the help of the dimensionless water content Θ, the relative hydraulic permeability K_r of partially saturated soils can be described:

$$\Theta = \frac{(\theta - \theta_r)}{(\theta_s - \theta_r)} \quad (1)$$

$$K_r(\Theta) = \Theta^{\frac{1}{2}}\left[1 - \left(1 - \Theta^{\frac{1}{m}}\right)^{m}\right]^2 \quad (2)$$

In equation 1, θ describes the actual volumetric water content, θ_r is the residual and θ_s is the saturated volumetric water content. The parameter m is linked to the soil-water retention curve given in Equation 3 as m = 1-1/n:

$$\theta = \theta_r + \frac{(\theta_s - \theta_r)}{[1+(\alpha \cdot h)^n]^{(m)}} \quad (3)$$

In equation 3, α, n and m are model parameters describing the curvature of the water retention curve after Van Genuchten (1980) and h is the pressure head (suction is positive). However, no soil-water retention curves were available for the materials used. To be able to carry out an approximate calculation and compare it to the centrifuge tests, parameter sets stored in Plaxis were used, see Table 2. The parameter sets were selected on the basis of the particle size distribution in such a way that the numerical calculation models produced the best possible comparison to the centrifuge test results. Due to the chosen procedure, some general points must be emphasised:

- The calculations represent an initial estimate. The actual water retention curves and the associated parameters α and n may differ from those used in the present model.
- A difference between drying and wetting curves can be observed in reality (Benson et al., 2014). This is not taken into account in the numerical model.
- As there is no information on the ratio of saturated horizontal permeability k_h to vertical permeability k_v and a reliable estimate is difficult, no distinction was made.

Table 2. Input parameters for the transient seepage analysis.

	Geba Sand with 5% Kaolin Clay	**Baskarp B25 Sand**
$k_h = k_v$ [m/s]	$2.3 \cdot 10^{-6}$	$5.0 \cdot 10^{-5}$
e_{init}	0.64	0.69
θ_r	0.01	0.1
θ_s	0.34	0.32
α [1/m]	1.7	5.21
n	1.717	2.374

3 COMPARISON OF RESULTS

The dam did not exhibit any stability problems during the centrifuge tests. Furthermore, it became evident that the entire model (i.e. the centrifuge basket) tilts slightly during the experiments, which results in a water level that is inclined relative to the model box. This phenomenon occurs when the centre of gravity is not in the axis of the centrifuge basket's hinge. However, due to the flood wave and the seepage, the centre of gravity is constantly changing - which explains the phenomenon (the model was installed perpendicular to the flight direction to avoid curvature of the water surface). Thus, at the beginning of the test, the water table at PPT B1 was lower at about 8.4 m than at the end of the test at about 9.3 m (Figure 3). Nevertheless, the propagation of the flood wave through the dam during the centrifuge experiments could be analysed with the help of the PPT measurements, see Figure 5. It is noticeable that there is a significant damping of the flood wave upon entering the dam (see PPT5) and the propagation of the flood wave within the dam is significantly slower on the water side than towards the air side. This becomes clear by comparing the shifting of the pressure peaks over time. The delay between the flood wave and PPT5 is about 5.6 hours, whereas it is only about 3.3 hours between PPT6 and PPT4.

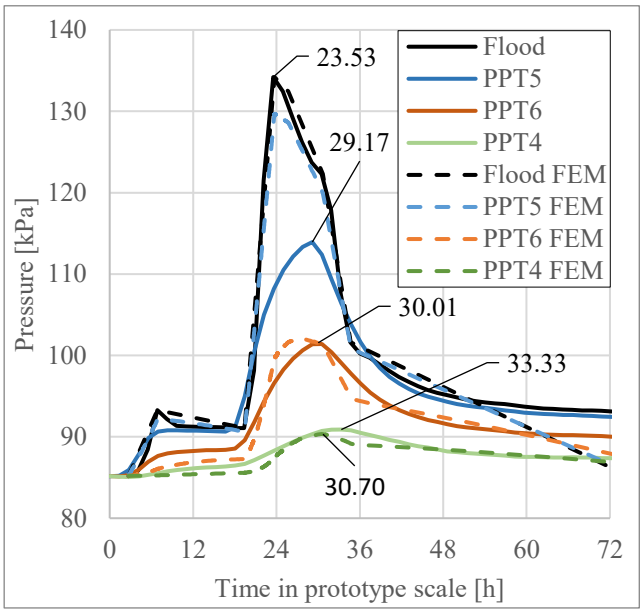

Figure 5. Results of the PPT measurement during the centrifuge tests and comparison with the FEM-simulation. The timestamps of the pressure peaks are indicated in the diagram.

By comparing the pressure changes from the centrifuge test with those from the comparative numerical model (FEM in Figure 5), the following observations can be made: The infiltration behaviour of the numerical model differs significantly from the physical model (PPT5 shows almost no damping in the numerical model compared to the data from the centrifuge test). Nonetheless, PPT6 and PPT4 show relatively good agreement at least in the damping of the pressure magnitude. In the centrifuge test it took about 10 hours to reach the maximum pore pressure at the air side of the dam (peak of PPT4 compared to peak of 'Flood'), whereas in the numerical model there are only about 7 hours in between.

4 CONCLUSION

A difference in time of rise and magnitude of the pore water pressure due to high water levels was observed between the physical model test and the comparative FEM simulation (Figure 5). The difficulties in predicting the pore water pressure distribution and the development of the saturation front in dams were already pointed out by Vaughan (1994) in his Rankine lecture, since most models do not take stress dependent permeability in terms of overburden pressure and heterogeneity of the material into account. In addition, there are considerable uncertainties in soil permeability measurements (anisotropy etc.). The largest deviations between the numerical model and the centrifuge test are found on the water side of the dam. The numerical model overestimates the speed at which the flood wave infiltrates the dam and underestimates the damping of the pore water pressures on the water side.

A further topic to be addressed is the influence of the hydraulic boundary conditions, as it is reasonable to assume, that the type of the air side boundary condition not only has an influence on the dam stability, but also on the overall seepage behaviour. This is particularly relevant as the centrifuge tests are intended to represent the conditions within the prototype dam in order to more realistically portray the behaviour under flood conditions. The tests presented in this paper are based on hydraulic boundary conditions on the air side of the dam corresponding to a constant hydrostatic water pressure (Figure 6 a).

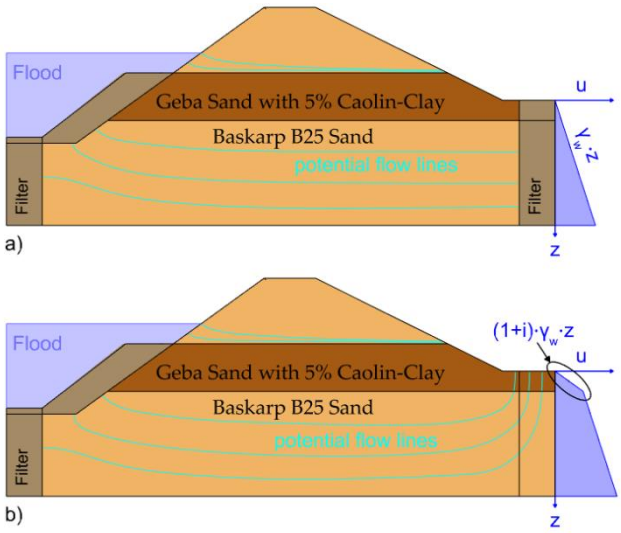

Figure 6. Variation of the boundary conditions on the air side of the dam and their potential influence: a) constant head boundary as modelled in the first test series; b) impermeable boundary – excess pore water pressure assumed below the interlayer as a result.

If the dam was constructed on a widespread fine-grained layer, as it is the situation in parts of the Alpine Rhine, some excess pore water pressures may develop beneath the bottom of the dam on the air side during a flood. As an extreme case, there could be a vertical impermeable boundary such as a construction pit closure in the dam footing area, see Figure 6 b. The pore water pressure distribution beneath the bottom of the dam on the air side therefore depends directly on the permeability and the distance of the air-side boundary condition (this applies to models as well as to prototypes) and must be carefully chosen.

The following observations may be considered to improve the results from further experiments:

- More PPTs should be installed on the water side of the dam to better quantify the flood wave propagation into the dam close to the riverbed. This is where the largest differences between

centrifuge tests and numerical simulation have been observed.

- The initial degree of saturation of the dam above the seepage line is unknown - but this significantly influences the infiltration time (Mayor, 2013). The installation of tensiometers to measure suction could therefore be advantageous.
- The intended flood wave, which is inspired by real flood events, could not be achieved due to the complexity of the test control. If the flood wave characteristics are to be simplified for further tests, possible saturation changes of the dam before the flood should be considered.
- It should be considered whether the test may be carried out with viscous fluid instead of water to reduce the time scaling factor (Wood, 2004). This could help to simplify the experimental control and data collection.

ACKNOWLEDGEMENTS

The authors would like to thank the Agency for Civil Protection (ABS) of the Principality of Liechtenstein, on whose behalf the centrifuge model tests could be carried out. The assistance of the technicians from TU Delft, Karel Heller, Kees van Beek, Roland Klassen and Ronald van Leeuwen greatly contributed to the successful execution of the tests.

ABSTRACT: Internal erosion in gap-graded soils is a major risk faced by earth dams and levees. However, the understanding of internal erosion mechanisms, especially at the particle scale, is still limited. This research couples the Discrete Element Method (DEM) with Computational Fluid Dynamics (CFD) to simulate the internal erosion (suffusion) process in gap-graded soil samples and further train Artificial Intelligence (AI)/Deep Learning (DL) algorithms to identify subtle patterns and anomalies related to internal erosion initiation. A time-lapse micro-structure visualisation approach is introduced using 3D voxelization of soil elements under internal erosion. Particle-scale parameters such as particle and flow velocity, number of contacts, contact forces etc are extracted from the CFD-DEM simulations throughout the internal erosion process forming time-series tensors used to train the AI models. The Autoencoder models with 3D Convolutional Neural Network (CNN) layers as encoder and decoder are developed to investigate the micro-scale patterns within the particle-fluid assembly together with the variations and anomalies throughout the erosion process. Using Sequential Training framework, anomalies within the data are detected by Convolutional Autoencoder models to identify the locus and time of internal erosion initiation. In addition, the micro-mechanisms during the initiation of internal erosion such as fine particle migration and contact loss are investigated. The 3D voxelization approach for internal erosion micro-mechanism visualisation can be integrated with advanced imaging techniques (e.g., micro-computed tomography) for early detection of internal erosion in future.

RÉSUMÉ: L'érosion interne dans les sols à granulométrie écartée représente un risque majeur pour les barrages en terre et les digues. Cependant, la compréhension des mécanismes d'érosion interne, en particulier à l'échelle des particules, reste limitée. Cette recherche couple la Méthode des Éléments Discrets (DEM) avec la Dynamique des Fluides Computationnelle (CFD) pour simuler le processus d'érosion interne (suffusion) dans des échantillons de sol à granulométrie écartée et pour entraîner davantage les algorithmes d'Intelligence Artificielle (IA)/Apprentissage Profond (AP) afin d'identifier des modèles subtils et des anomalies liées à l'initiation de l'érosion interne. Une approche de visualisation micro-structurale en accéléré est introduite en utilisant la voxelisation 3D des éléments de sol sous érosion interne. Des paramètres à l'échelle des particules tels que la vitesse des particules et du flux, le nombre de contacts, les forces de contact, etc., sont extraits des simulations CFD-DEM tout au long du processus d'érosion interne pour former des tenseurs en série temporelle utilisés pour entraîner les modèles d'IA. Des modèles d'Autoencodeurs avec des couches de Réseau Neuronal Convolutif (CNN) 3D comme encodeur et décodeur sont développés pour étudier les modèles microscopiques au sein de l'assemblage particule-fluide ainsi que les variations et anomalies tout au long du processus d'érosion. En utilisant le cadre de Formation Séquentielle, les anomalies dans les données sont détectées par des modèles d'Autoencodeur Convolutif pour identifier le lieu et le moment de l'initiation de l'érosion interne. De plus, les micro-mécanismes lors de l'initiation de l'érosion interne tels que la migration des particules fines et la perte de contact sont étudiés. L'approche de voxelisation 3D pour la visualisation des micro-mécanismes d'érosion interne peut être intégrée avec des techniques d'imagerie avancées (par exemple, la micro-tomographie informatisée) pour la détection précoce de l'érosion interne à l'avenir.

1 INTRODUCTION

Internal erosion is a typical issue faced by earth dams and levees, posing a significant risk to public safety and the economy. This phenomenon frequently occurs in gap-graded soils subjected to certain hydraulic and mechanical conditions. The initiation and development of internal erosion are mainly influenced by three factors: (a) particle gradation, (b) hydraulic condition, and (c) mechanical state (Brown & Bridle, 2009). In this context, the internal erosion has been studied through field monitoring (Cai et al., 2020; Chen et al., 2018), laboratory tests (Planès et al., 2016), numerical simulations (Tran et al., 2017), and data-driven analysis (Fisher et al., 2016; Yousefpour & Fazel Mojtahedi, 2023). Internal erosion usually initiates from imperceptible transport of fine particles at the pore scale with no evident signs and gradually develops into catastrophic dam breaches, which highlights the necessity of insight into the particle scale behaviours and their link to the macro-scale/field observations.

This study couples the Discrete Element Method (DEM) with Computational Fluid Dynamics (CFD) to simulate the internal erosion process in gap-graded soils, simulating the suffusion mechanism (Qi et al., 2022). 3D voxelization of the gap-graded soil was conducted with associated particle-scale parameters stored in the voxels as the input for the DL model. The Autoencoder models with 3D Convolutional Neural Network (CNN) layers as encoder and decoder are developed to investigate the micro-structure patterns within the particle-fluid assembly. A Sequential Training framework is introduced for Dl models to detect anomalies within the time-series of 3D particle-scale tensors for an assessment of locus and time of internal erosion initiation.

2 METHODOLOGY

2.1 CFD-DEM simulation

The coupled CFD-DEM simulations are performed to assess the internal erosion initiation process in gap-graded soil driven by a range of hydraulic gradients. A gap-graded sand sample with a Fine Content (FC) of 25% is selected for the simulation. The sample gradation and mass fractions for the grain sizes are provided in Table 1.

Table 1. Soil sample gradation and mass fractions.

Particle Group	Diameter	Finer %	Mass %
D1	3.43	62.5%	37.5%
D2	2.36	25.5%	37.5%
D3	0.36	12.5%	12.5%
D4	0.30	0	12.5%

The 3D CFD-DEM model of the gap-graded sand is created within a cylindrical shell (D=15mm, H=25mm). The time step of DEM is set to be 5e-7s for the stability of the calculation. For the first step, the particles are randomly generated at the top of the cylinder with predefined mass fractions and then settled to the bottom under gravity as shown in Figure 1. The generated dry samples are then compacted by a top plate to achieve a target sample density before saturation.

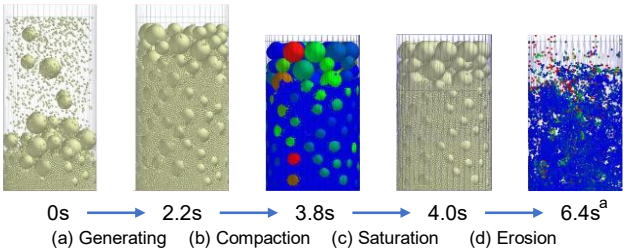

Figure 1. CFD-DEM model (a) Sample generating, (b) sample compaction to target porosity, (c) saturation and stabilization of compacted sample, (d) internal erosion.
[a] Coarse particles are hidden at t=6.0s for better visualization.

The compacted dry sample is then coupled with CFD under static hydraulic pressure for saturation. Both the DEM and CFD simulations continue to reach equilibrium during the saturation process. For the erosion stage, the plate on the top is replaced by a mesh that is only permeable to the fine particles. The hydraulic pressure of the outlet is set to 0, while that of the inlet is fixed to a value that applies a hydraulic gradient to the whole sample. The hydraulic pressure is linearly increased from 0kPa at t=4.0s to 100kPa at t=5.5s, during which fine particles are gradually eroded from the pore space between coarse particles. The eroded particles are deleted when they exit the top mesh.

2.2 Particle-scale data and 3D microstructure representation

The CFD-DEM simulation outputs are extracted in a high temporal resolution of 0.01s, which produces abundant particle-scale data. This data includes time-lapse tensor of particle velocity, contact force, contact number etc, which can reflect the subtle changes in interaction and migration of particles during internal erosion. However, this data could not require pre-processing before using as an input for DL models.

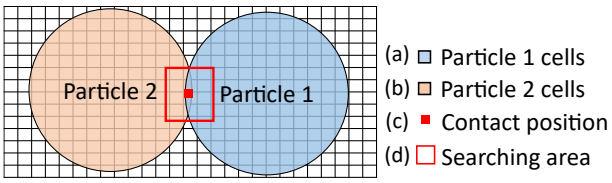

Figure 2. Particle data representation (a)&(b) cells with information from particle 1 &2, (c) contact position of two particles, (d) area to search for the contact cells.

To facilitate such purpose, a voxelization algorithm is developed to convert the particle-scale data into 3D matrix (tensor) representations. Voxels are defined using grids within the particle-fluid assembly domain. Each voxel is occupied by particles and fluid. The relevant particle-scale data are assigned to the respective DEM voxels, including particle velocity, contact force, contact number etc (Figure 2). As coarse particles are intact during suffusion, only fine particle parameters are considered in this process.

The voxels for storing the contact information are detected within a domain centred at the contact position by comparing the voxel-particle distance and the particle radius. With the particle information stored in the voxels, the constructed 3D matrices serve as the input for the subsequent Machine Learning models.

2.3 Deep learning approach

Convolutional Neural Networks (CNN) have been proven powerful in capturing/extracting features from image data (Tang et al., 2022). Also, Autoencoders have been successfully used for unsupervised anomaly detection for problems where normal (true) versus anomaly (fake) data is not known apriori (Yousefpour & Fazel Mojtahedi, 2023). Considering the 3D particle-scale data structure from CFD-DEM, a 3D Convolutional Autoencoder (CAE) architecture is deemed as a viable architecture to extract spatial-temporal patterns and anomalies related to subtle microstructure changes in the soil sample around the initiation of erosion. In this problem, the sample 3D microstructure is visualised by the generated particle-scale tensors. These time-series tensors are treated as image data for the CAE algorithm. The encoder compresses the input data into latent representations while the decoder reconstructs the input from the latent space. The encoder and decoder are constructed from 3D Convolutional layers and the necessary max pooling or deconvolutional layers as depicted in Figure 3. The CAE model learns the reconstruction error distribution over the training dataset and then detects anomalies within the test dataset using a set error threshold. A data point is recognised as an anomaly if its reconstruction error is larger than this threshold.

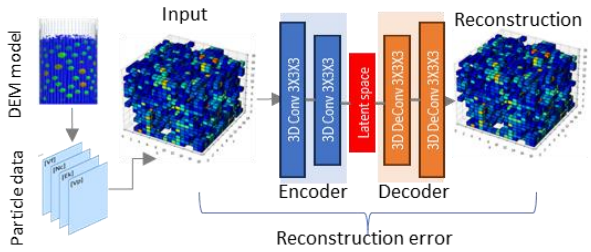

Figure 3. 3D CNN Autoencoder architecture.

2.4 Data division and sequential training

CFD-DEM outputs are extracted at a time step of 0.01sec, from 4.0sec to 6.4sec, generating a time-series of 240 tensors. Sequential Training is a systematic approach of Machine Learning (ML) training in consecutive steps, where the training database size grows linearly at each step, rather than using the entire dataset at once (Yousefpour & Fazel Mojtahedi, 2023). This approach has proven effective in detecting the initiation of internal erosion based on the evolution of the number and trend of anomalies. In this study, Sequential Training was conducted over eight stages. During each step, a distinct segment of the data was used for training followed by a non-overlapping segment for validation (see Figure 5).

3 RESULTS

3.1 Fine particle migration

To better capture the internal erosion process, only a fraction of the whole CFD-DEM located at the top of the sample where the most intensive migration of fine particles happened is incorporated to train the CAE model. The particle velocity tensors are converted to a binary scale, such that voxels with particle velocity are represented as 1. Visualizing two slices of the binary tensors at t=4.1s, shown in Figure 4(a) and t=6.2s, shown in Figure 4(b) reveals the patterns of fine particles migration. It's also observed that the scatter within the selected region gets denser as the fine particles gradually migrate from lower positions to the top. In particular, potential preferential erosion paths that fine particles take through the pore space between coarse particles are captured.

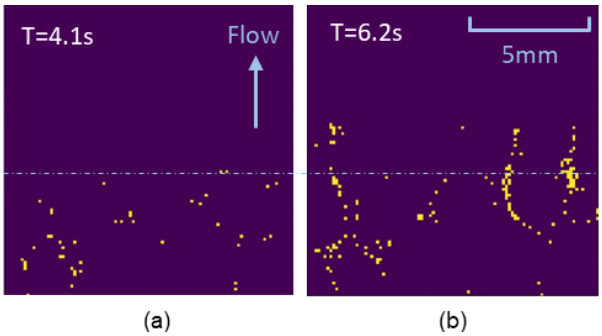

Figure 4. Binary particle velocity slices (a) before suffusion (T=4.1s) (b)after suffusion (T=6.2s).

3.2 Anomaly detection

The Convolutional Autoencoder model is trained using the binary particle velocity tensors prior to obvious internal erosion initiation in the sample (mass loss). The reconstruction errors are calculated for tensors within the test dataset after each training step. The number of detected anomalies from the testing data is recorded as the internal erosion evolves after the application of hydraulic gradient at t=4.0s as shown in Figure 5. The number of anomalies stays constant at the initial steps (from 4.0s to 5.2s) with all the test data being recognised as anomalies, meaning the fine particle velocity patterns during this stage are largely different from the test dataset and internal erosion did not happen at this stage. After t = 5.2s, the number of anomalies decreases abruptly, which can indicate a sudden pattern change of the fine particles. Between 5.2s and 5.6s, the number of anomalies starts to converge to a constant value. This trend shows that the training dataset is more representative of the test dataset patterns (therefore fewer anomalies are identified) and be an indicative of the approximate time of internal erosion initiation. Based on the above observations, it can be inferred that internal erosion initiated between 5.2s and 5.4s.

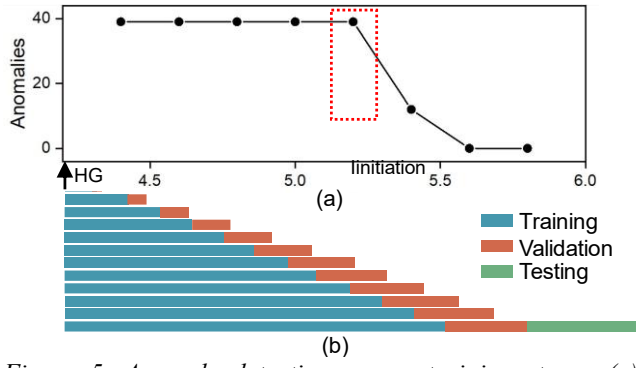

Figure 5. Anomaly detection across training stages (a) Number of anomalies detected from different training stages (b) sequential training stages.

4 CONCLUSIONS

This research investigates the initiation of internal erosion in gap-graded soils through a Convolutional Autoencoder deep learning algorithm trained using CFD-DEM simulations data.

Fine particle velocity data are visualized using a 3D voxelization method and converted to time-lapse binary tensors to assess the internal erosion patterns during the initiation phase. The subtle changes in the microstructure of the soil element and migration patterns of the fine particles are captured using this approach.

The CAE model trained with the time-series of particle-scale tensors based on the sequential training framework shows a sudden drop followed by the convergence trend close to the initiation of internal erosion. This shows that the 3D voxelisation approach for internal erosion micro-mechanism visualisation can be potentially integrated with advanced imaging techniques (e.g. micro-CT) for early detection of internal erosion in future studies.

ABSTRACT: The construction of the highway E-80 has begun in Serbia, which will represent the traffic hub of the Western Balkans and will be part of the main regional transport network of Southeast Europe. Its total length through Serbia is 77 km, and one part of the route is designed through a typical plain terrain, while a larger part of the route passes through hilly terrain. The construction of the tunnel "Debelo brdo" is planned partly in an open cut excavation with a length of 240 m, and partly with an underground excavation with a length of 190 m. The geotechnical conditions of tunnel construction in open cut excavation, and especially the geotechnical conditions of tunnel excavation, will be presented in the paper.

RÉSUMÉ: La construction de l'autoroute E-80 a commencé en Serbie, qui constituera la plaque tournante du trafic des Balkans occidentaux et fera partie du principal réseau de transport régional de l'Europe du Sud-Est. Sa longueur totale à travers la Serbie est de 77 km, et une partie de l'itinéraire est conçue sur un terrain plat typique, tandis qu'une plus grande partie de l'itinéraire traverse un terrain vallonné. La construction du tunnel „Debelo brdo" est prévue en partie avec une excavation à ciel ouvert d'une longueur de 240 m et en partie avec une excavation souterraine d'une longueur de 190 m. Les conditions géotechniques de construction de tunnels en fouille à ciel ouvert, et notamment les conditions géotechniques de creusement de tunnels, seront présentées dans l'ouvrage.

Keywords: „Debelo brdo" tunnel; temporary slopes; open cut excavation; tunnel excavation; piles.

1 INTRODUCTION

The construction of the E-80 Nis-Merdare-Pristina highway is of special economic and social interest for the Republic of Serbia. It represents the traffic hub of the Western Balkans and will be part of the main regional transport network of Southeast Europe (that's why it was called the "Peace Highway"). The total length of the highway is 77 km. The "Debelo Brdo" tunnel is located on the first 36.3 km long highway section. The construction of one tunnel tube with an approximate cross-section of about 85 m^2 is planned by the project. The height of the open part of the tunnel in relation to the pavement is about 8.3 m, while the structural height ranges from 10.9 - 11.9 m, not counting the protective support structure.

2 GENERAL GEOTECHNICAL CHARACTERISTICS OF THE TERRAIN

The geological structure at the location of the "Debelo brdo" tunnel consists of younger Neogene hilly terrains. The complex corresponds to the upper Miocene and lower Pliocene, so it is separated as a Mio-Pliocene complex of heterogeneous lithological composition. In the surface part, marly clays of the weathered zone dominate (in the tunnel zone, the thickness of the weathering crust is over 10 m), and the base consists of marls with rare layers of silt and fine-grained sand, while thinner layers of sandstone also occur occasionally. In the zone of the entrance portal of the tunnel, the occurrences of active sliding as well as conditionally unstable terrains, whose relief forms are characteristic of calmed landslides,

have been determined, so that inadequate cutting could cause new instabilities (Rakic et al., 2019).

Along the route of the tunnel with a total length of 430 m, two geotechnical quasi-homogeneous zones were separated: GTZ-1 and GTZ-2. The first geotechnical zone (GTZ-1) represents the weathering crust of marls and sandstones dominated by silty marly clays. This area is in the overburden area above the tunnel, with a thickness of 10-13 m, and its border approximately follows the surface of the terrain. It is a material of hard-plastic to semi-hard consistent state with extremely high plasticity. When it is exposed to atmospheric influence for a long time, it easily disintegrates, crushes and crumbles. Within this geotechnical zone, the tunnel excavation will be carried out in an open cut excavation. The second geotechnical zone (GTZ-2) is built of clayey marl, locally silty-sandy, and represents the basic rock mass in which the complete underground excavation for the tunnel will be carried out.

Piezometer constructions were installed in two exploration boreholes, in which regular observations were made. The piezometric level ranged from 5.5 to 13.5 m, which indicates that water filtration is carried out down the slope, and as the morphology of the terrain is variable, the GWL ranges from 300 to 307 m. At the time of field investigation works, the groundwater level was approximately at the level of the tunnel or just below it.

Geotechnical longitudinal section of the terrain, with separated geotechnical zones, conditionally stable slope, forecast groundwater level, position of tunnel level and proposed method of excavation, is shown in Figure 1.

3 DEFINING PHYSICAL-MECHANICAL PARAMETERS

Laboratory tests have shown that the Mio-Pliocene clay-marly complex is extremely plastic material with a yield strength of over 110% in some samples.

These are materials with I_c>1.0, so the uniaxial compressive strength is usually q_u>250 kPa. However, occasional occurrences of sandstone laminae and thinner marl laminae (thickness 10-20 cm), as well as zones of slightly weathered marl, had a significant impact on the increase in uniaxial compressive strength. The tests were performed in accordance with the appropriate standard (SRPS EN 1926), but a non-standard method was also applied, which involved several cycles of unloading and reloading at lower values of axial pressure. For these reasons, a significantly wider interval of q_u values was determined, which ranged from q_u= 243–774 kPa (Figure 2).

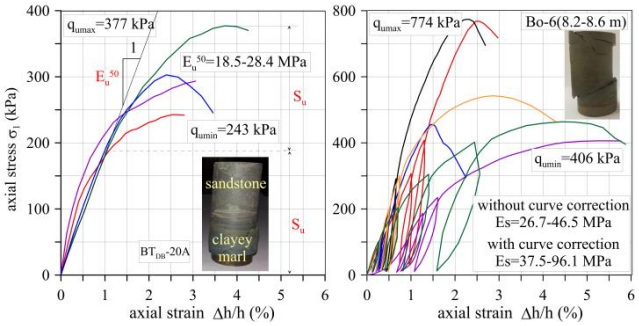

Figure 2. Characteristic diagrams for standard and non-standard uniaxial tests.

Due to significant heterogeneity of the environment, the value of undrained modulus of elasticity ranged in a very wide interval from E_s=26.7-95 MPa. In addition, the values of the undrained modulus of elasticity were also obtained based on correlations with the undrained shear strength (s_u) using the appropriate dependence and amounted to E_s=33.0-89.0MPa (Duncan and Buchignani,1976).

It should be noted that geophysical investigations were also carried out at the location of the tunnel, and that the values of the modulus of elasticity were obtained in the interval of E_s=35-82MPa.

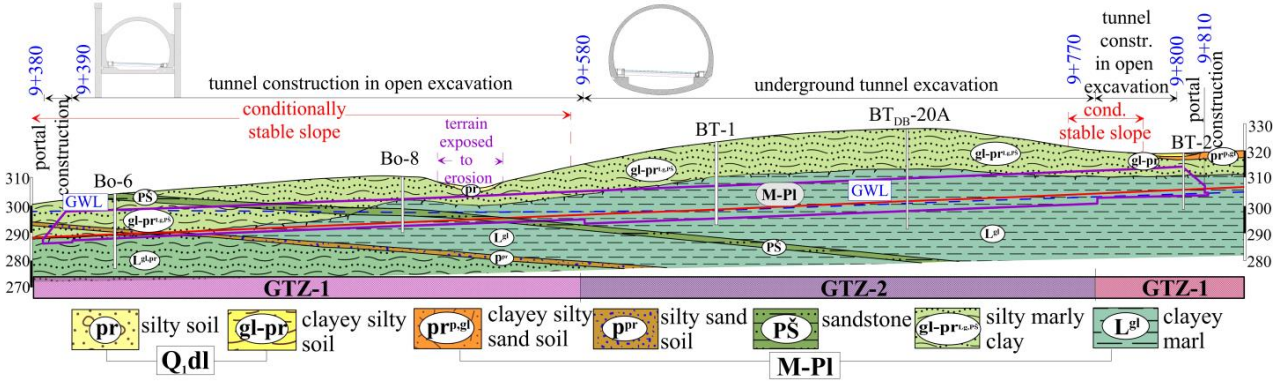

Figure 1. Geotechnical longitudinal section along „Debelo brdo“ tunnel.

When it comes to shear strength parameters, geotechnical characteristics have shown that it is necessary to propose parameters for two different excavation systems. The first one refers to the case that underground works and protection of slopes with supporting structures are carried out quickly in a short time interval after excavation. In that case, it is proposed to use "critical" shear strength parameters, which are defined at the appropriate displacement value. In the case that the construction of the tunnel cannot be carried out in a short period of time, the use of residual shear strength parameters is proposed, due to the fact that an active landslide has been identified in the immediate zone of the tunnel.

It is characteristic that on the basis of oedometer tests, all samples showed swelling potential, regardless of the soil from which they were taken (silty marly clays-gl-pr^{Lg} or locally silty clayey marls-L^{gl,pr}). In some samples, the swelling stress was higher of σ_{sw}>300 kPa.

Based on the observation of the field conditions and the summary analysis of all laboratory tests, the proper values of the physical-mechanical parameters, which were used during the geotechnical analysis, were adopted (Table 1).

Table 1. Proper values of physical-mechanical parameters.

GT layer	Physical-mechanical parameters						
	γ kN/m^3	c' kPa	φ' (°)	c_r kPa	φ_r (°)	E_s MPa	E_r MPa
(gl-pr^{Lg})	18.5	28	18	12	10	20	60
(L^{gl,pr})	19	40	20	12	11	25	75

4 GEOTECHNICAL CONDITIONS OF TUNNEL CONSTRUCTION

4.1 Tunnel construction on open excavation part

For the construction of tunnels in an open excavation, securing with piles is provided. Geotechnical analyses were conducted in two phases. In the first phase of the excavation, the top parts of the slope were covered, while in the second phase, the excavation for the construction of the tunnel structure was analysed.

The first phase involves the formation of a temporary slope and a working plateau for the installation of piles. As it is a conditionally stable slope, the analysis was first performed using the residual shear strength parameters, for the designed slope inclination of 1:2, and on that occasion the safety factor Fs<1.0 was obtained. Therefore, it was suggested that the excavation be carried out with one berm 4 m wide at a height of about 5 m in relation to the elevation of the working plateau. However, in the case that earthworks and slope protection with a supporting structure are carried out in a short period of time without the influence of atmospheric changes, the analysis was also performed with "critical" parameters of shear strength, so that a significantly higher factor of safety was obtained (Fs=1.747). Within the second phase of excavation, protective piles will be carried out secured by the brace beam.

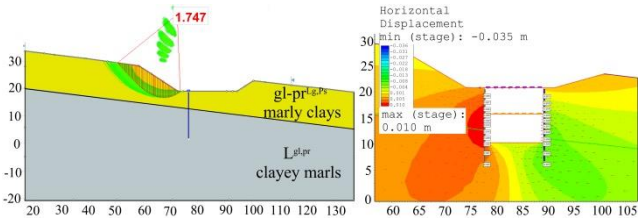

Figure 3. Geotechnical stability analyses (stability of temporal slope and horizontal displacement of piles).

4.2 Tunnel construction on underground excavation part

The underground excavation of the tunnel will be carried out according to the principles of NATM (New Austrian Tunnelling Method). Excavation is planned with phased development of the profile: calotte, abutments, and then the inverted arch. For the protection of the calotte excavation, a primary support is provided: pipe-roof shield, ribs, reinforcement mesh and layers of shotcrete. To prevent excessive settlements, an elephant foot, installation of micro piles and anchors, and construction of a temporary inverted arch are provided. To secure the excavation in the area of abutments and inverted arch, a construction made of ribs, reinforcement mesh, layers of shotcrete and anchors is planned. Also, at the level of the abutments, the construction of the second elephant foot, the installation of the second row of micro piles and the second temporary inverted arch is planned.

For the stress-strain analysis in different phases of construction in the tunnel support and the surrounding rock mass, tunnel stability calculations were performed using a 2D model with the indirect introduction of 3D effects. Simulating tunnel excavation and supporting was carried out in nine steps. By adopting certain assumptions about the properties, condition and behaviour of the rock masses (Coulomb-Moore failure criterion, different values of the modulus of elasticity for loading E_s and unloading E_r, the pipe shield is simulated with a material with equivalent properties, relaxation stress in the excavation phase by λ=0.3, was simulated by progressive softening of the rock, after installing the pipe shield, the stresses in the rock mass were relaxed to λ=0.7), geotechnical

analyses were conducted and the values of certain parameters were obtained, which are shown in Table 2.

Table 2. Values of parameters used during the simulation of the impact on the tunnel face excavation.

N_s	λ_{cr}	r_p	λ_0	r_{p0}	K_o
9.8	0.41	24.7	0.7	10.1	0.65

r_p-radius of the plasticization zone for the case of unsupported excavation

r_{p0}-radius of plasticization zone for the case of relaxation $\lambda_o = 0.7$

Verification of the tunnel support was performed using the software package *Phase2*. The phases of model creation followed the usual construction practice (excavation and application of security measures). The calculation results indicate that the excavation will cause significant displacements of the rock mass in the zone of the tunnel excavation, and certain displacements will be manifested on the surface of the terrain as well (Figure 4). Also, the plasticization zone of the rock mass occurs up to the surface of the terrain. The biggest stress-strain changes occur in the stage of the calotte excavation, under the pipe shield, in the area of the elephant feet. For these reasons, the possible effects of lowering the pipe shield to the floor of the calotte were considered on a modified model, without the elephant foot and micropiles at the level of the calotte. Calculation models with calculation results, which indicate the effects achieved by modifying the design solution, are shown in Figure 4.

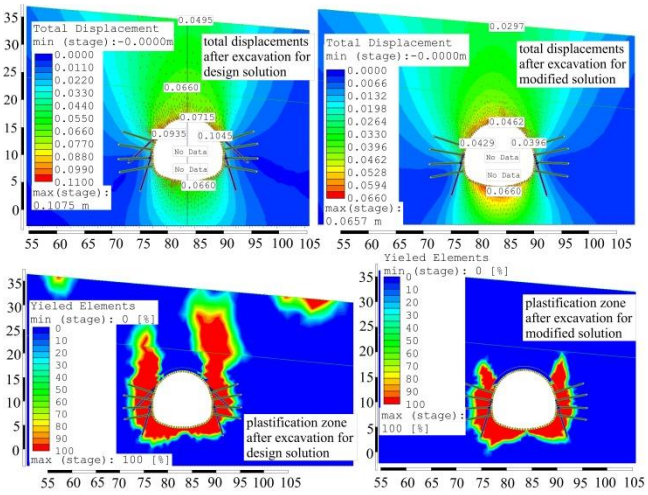

Figure 4. Stress-strain analyses for design and modified solution.

It is proposed that the excavation of the calotte be carried out by phase development of the face side, with the formation of a supporting body.

Summary of all displacements for the proposed design solution, as well as the solution with the proposed modification is shown in Figure 5.

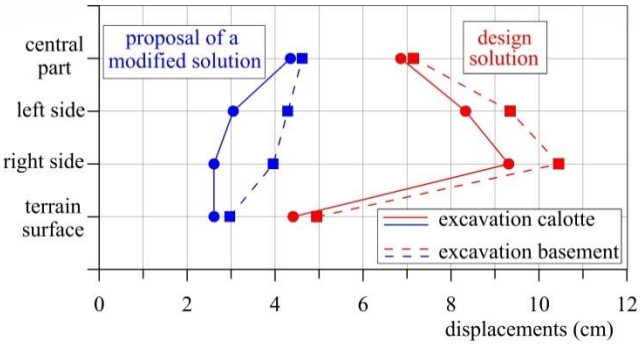

Figure 5. Summary of displacements of calotte and invert arch for design and modified solution.

5 CONCLUSIONS

For the construction of the "Debelo brdo" tunnel, the geotechnical conditions related to the excavation of the tunnel in the open excavation, and in the part of the underground excavation, were analysed separately.

For the construction of the tunnel in the open excavation, it is planned to secure the excavation by installing piles. Geotechnical analyses have shown that temporary slopes, above the level of the working plateau, can be performed with the proposed slope inclination of 1:2, but with a 4 m wide berm at a height of 5 m above the working plateau.

When it comes to the underground excavation, for the proposed design solution, geotechnical analyses obtained significant displacements of the rock mass, which are also manifested on the surface of the terrain. For these reasons, the analysis was also performed for a partially modified solution with an extended pipe shield, but without the application of the elephant foot and micropiles at the calotte level. With this variant, significantly smaller deformations around the tunnel excavation and negligible deformations on the terrain surface were obtained.

Geotechnical structures stability: ULS calculations using the finite element method

Stabilité des ouvrages géotechniques: calculs aux ELU par la méthode des eléments finis

ABSTRACT: The new version of Eurocode 7 deals explicitly with the use of the finite element method for the design of geotechnical structures. The relevance of this method is widely recognized for Service Limit States (SLS) i.e. to assess the deformations of the structures (soil settlements, displacements induced by the progress of the work or even interactions with the neighbouring works). For Ultimate Limit State (ULS) verifications, so far in most cases the finite element method is used to performed two types of computations: search for a limit load (verification of a bearing capacity for example) or reduction of resistance properties of the ground, called "phi-c reduction". The new requirements elaborated in the future EC7 gives the opportunity to discuss more precisely how finite elements can be used for geotechnical stability analyses. The article presents the current possibilities of the CESAR software, and discusses additional functionalities that can be introduced to facilitate the verifications required by the new normative framework.

RÉSUMÉ: La nouvelle version de l'Eurocode 7 traite explicitement de l'utilisation de la méthode des éléments finis pour le dimensionnement des ouvrages géotechniques. La pertinence de cette méthode est largement reconnue pour les Etats Limites de Service (ELS) c'est-à-dire pour évaluer les déformations des ouvrages (tassements de la surface du sol, déplacements liés à l'avancement des travaux ou encore interactions avec les ouvrages voisins). Pour les vérifications aux Etats Limites Ultimes (ELU), jusqu'à présent dans la plupart des cas la méthode des éléments finis est utilisée pour effectuer deux types de calculs: recherche d'une charge limite (vérification d'une capacité portante par exemple) ou réduction des propriétés de résistance du sol («c-phi réduction»). Les nouvelles exigences du futur EC7 donnent l'opportunité de discuter plus précisément de la manière dont les éléments finis peuvent être utilisés pour les états limites ultimes. L'article présente les possibilités actuelles du logiciel CESAR, et discute des fonctionnalités supplémentaires qui peuvent être introduites pour faciliter les vérifications requises par le nouveau cadre normatif.

Keywords: ULS; stability; finite element method; phi-c reduction.

1 INTRODUCTION: EVOLUTIONS OF EUROCODE 7

The second generation of Eurocode 7, which should be finalized in a near future, introduces significant evolutions as regards the use of numerical methods for geotechnical design. Numerical modelling is recognized as an efficient tool for service limit states (SLS) provided that suitable constitutive models are used. For Ultimate Limit States (ULS), the future rules define more precisely how numerical tools can be used. They distinguish several factoring approaches: RFA (Resistance Factoring Approach), MFA (Material Factoring Approach) and EFA (Effect factoring approach). RFA is not generally applicable to numerical methods because the mode of failure and thus the available resistance is not known in advance; EFA consists in factoring outputs of the calculation and can be seen as a specific post-treatment of numerical results; last, MFA consists in factoring input data and can in most cases be treated using the familiar “phi-c reduction” procedures (Brinkgreve and Bakker, 1991, Griffiths and Lane, 1999).

One of the major evolutions lies in the fact that design approaches (DA) have been replaced by the notion of verification cases (VC), and that the verification of ULS by numerical methods is now explicitly twofold: it combines a geotechnical verification based of MFA, and a structural verification based on EFA.

This contribution discusses in what respect the usual numerical tools are fit to match the requirements of the rules, and how they should be adapted.

2 PRINCIPLES OF FINITE ELEMENT ASSESSMENT OF ULS

The principle of the so-called phi-c reduction procedures consists in initializing the stresses in a geotechnical structure, using a preliminary calculation that has led to a state of equilibrium. Then, the program reduces the strength properties of the soil (c and tan φ are divided by a given value F), and searches for the largest value of F for which the calculations conclude that stability is reached. Various softwares may adopt (very) different strategies to reach the final result, but they have in common the fact that the strength reduction results in a correction of the stress state, which is converted into out-of-balance nodal forces. It must be kept in mind that the computed displacements should be interpreted cautiously. Nevertheless, this type of procedure has been extensively discussed and is now widely accepted.

3 SOFTWARE ADAPTATIONS RELATED TO EVOLUTIONS OF DESIGN RULES

3.1 Construction stages

The construction of a geotechnical structure generally comprises several construction stages. From a numerical point of view, data are transmitted from one stage to the following. In the CESAR code, the user can define explicitly a "staged construction" model, which contains the successive construction stages.

The verification requires an MFA analysis is conducted for each construction stage. The sequence of *computation stages* is therefore no longer linear and parallel to the *construction stages*, but includes verification stages. This requires that suitable modifications be brought to the user interface. In the recent version of the software CESAR, the user is given the possibility to define sub-phases to answer this specific need (Figure 1).

3.2 Checking stability for a given reduction factor

For some structures, the safety factor is large and the phi-c reduction produces, often at high computational cost, a safety factor much larger than 1. Another perspective, which might be adopted in the future Eurocode 7, is to verify that the safety factor is larger than 1.25, in other words, that the structure is stable for strength properties reduced by a factor 1.25. It can be expected that this type of verification will be much faster in many cases. In practice, this should require only minor (if any) modification to the existing finite element codes implementing a phi-c reduction procedure; but this specific type of verification should be clearly identified in the interface of the software, because the result is no longer the value of the safety factor, but rather the fact that the structure is stable for a given value of the strength reduction factor. It can be expected that the final version of EC7 will define a clear terminology to describe the type of verification that is to be performed.

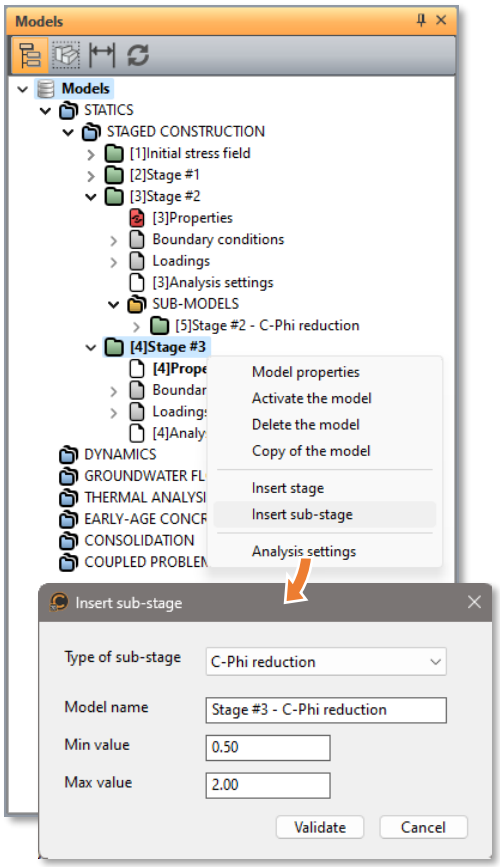

Figure 1. View of the stage sequence in the „Models "tree, and insertion of a sub-stage.

3.3 Accounting for the role of structural elements

Eurocode 7 requires to perform also EFA verifications to check the resistance of structural elements. Two possibilities can be considered:

- perform simulations in which structural elements have a linear elastic constitutive model and check if the computed forces and bending moments are compatible with the structure resistance characteristics,

- perform simulations with non-linear models (e.g. perfect plasticity) that include the possibility of failure.

The second solution corresponds to a higher level of complexity, and may resort to a wide variety of models, which means that the interpretation of the results may not be straightforward. This is why, even if the second approach may seem more complete, it is not necessarily preferable in the current state of ULS verifications.

3.4 Role of groundwater level

Groundwater level in the design is an important factor, yet difficult to determine and/or monitor. The Eurocode 7 makes the choice to use representative values, which means that no factoring is applied on the effects of water. Conversely, there is no need for specific evolutions of the software currently in use.

3.5 Interface shear strength

It is worth noting that shear strength of interfaces (between ground and structures) should be factored, which is not necessarily automatically supported in all FEA software. It is expected that the user understands how the software is implementing the material factoring approach, but it is preferable that the choices made regarding soil-structure interfaces be clear.

3.6 Limiting the area subjected to strength reduction

Some authors (for instance Magnan and Meyer, 2018) point out that in some situations, it can be advisable to reduce the strength properties only in certain parts of the ground. In the case of embedded walls for instance, reducing the strength properties on both sides of the wall leads to increase the active pressure on the wall, in a manner that is not necessarily realistic.

To this end, the user interface of the finite element code CESAR offers the possibility to exclude some areas of the mesh (bodies) from the strength reduction procedure.

4 EXAMPLES

4.1 Strength reduction method for MFA

In the scope of the MFA analysis, a robust phi-c reduction procedure is required. The one programmed in CESAR has been duly validated by comparison to analytical methods such a Bishop. In the scope of the Finite Element method, the German Soil Mechanics society has gathered results of several software answering to a benchmark problem (DGGT, 2019). The originality of the problem lies in the fact that the soil mass is made up of two different layers (sand and marls) and in the presence of the wall, assumed to be linear elastic. Soil-structure interfaces with friction behaviour are taken into account in the modelling and their resistance is factored (Figure 2).

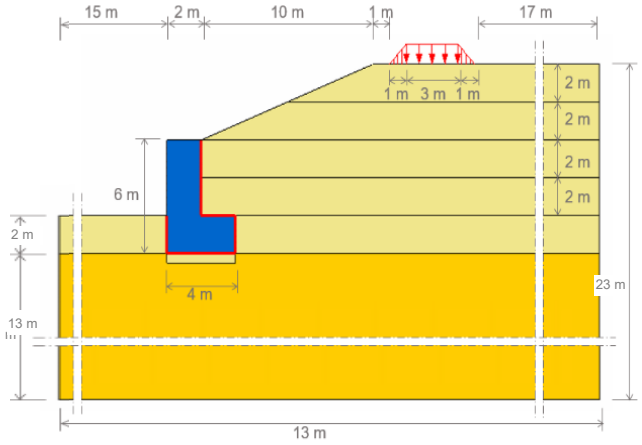

Figure 2. Scheme of the benchmark problem.

The Table 1 gives the safety factors reached by CESAR software, in both 2D and 3D. They show a very good agreement with the values of the benchmark. More, the mechanism of the failure is very well represented with the display of shear strains (Figure 3).

Table 1. Comparison of results.

	Sand	**Sand & Marls**	**Marls**
CESAR 2D	1.81	1.58	1.39
CESAR 3D	1.76	1.62	1.39
Benchmark	[1.74; 1.83]	[1.56; 1.63]	[1.36; 1.41]

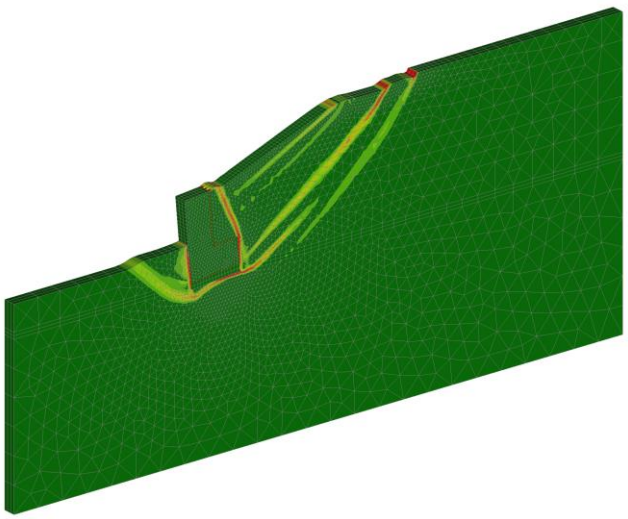

Figure 3. Example of failure mechanism (deformed mesh).

4.2 Strength reduction method with excluded areas

As an illustration of the influence of the restriction of the strength reduction to some areas in the ground, and more precisely of excluding the ground behind an embedded wall, a staged construction of an experimental sheet pile wall in Hochstetten has been modelled. This project has often been used as the support of a benchmark exercise and is therefore well documented (Von Wolffersdorff, 1994a, 1994b). To give only a general description, the final excavation depth was 5 m and the distance between the two walls was 4 m. The wall was built in sand. The construction comprises four excavation stages and a level of props; a load is applied at the ground surface behind the right wall.

Once the final state is reached, a phi-c reduction computation is performed either by reducing the strength in all the mesh (Figure 4), or by reducing the strength only in the ground located between both walls (Figure 5); the idea is to compare the active pressure on the wall with the available resistance. We do not discuss here the conditions in which this approach is relevant, but just show that numerical results give different failure mechanisms and factors of safety. The position of the shear band is a little modified and the factor of safety increases from 1.13 to 1.43.

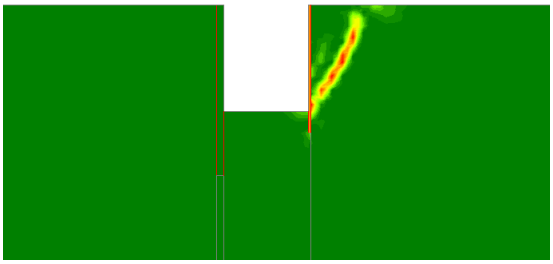

Figure 4. Failure mechanism for a homogeneous strength reduction (FOS = 1.13).

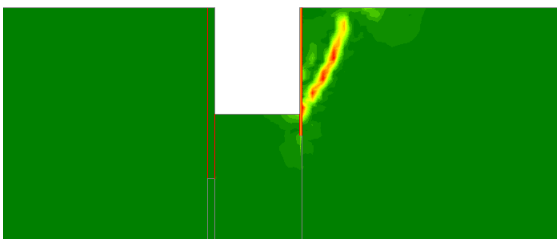

Figure 5. Failure mechanism for a strength reduction applied only to the ground between the walls (FOS = 1.43).

5 CONCLUSION

The preparation of the next version of Eurocode 7, has taken into account from the beginning the question of the use of numerical methods for the verification of geotechnical structures. This makes it necessary to rethink the ergonomics of the software used by engineering companies, in order to make verifications easier to perform – and numerical results easier to check. This communication is an attempt to identify the counterpart of the evolutions of the normative framework in terms of development of new procedures (or adaptation of existing procedures) in the existing computing software.

ABSTRACT: It is estimated that Brazil has around 570 Mt of iron ore stored in dams without a national reuse plan. This case study focuses on the Carajás Mine tailing dam, a reservoir with a volume of 100 Mm³ and iron ore content of 63%, located in the state of Pará. Regarding the geotechnical risk during excavations to remove the tailing, the present work identifies in depth the fine and coarse tailing through laboratory and field tests. Analyzes will be conducted to verify if the ruptures can represent a trigger that leads the tailing to liquefaction. The seismic piezocone tests (SCPTu) were reinterpreted considering perched water table, saturated specific weight equal to 30.1 kN/m³, cone factor (Nkt) equal to 15. Field seismic data were compared to laboratory seismic tests to determine the void ratio and shear modulus (G0) along the entire tailing profile, analyzing possible layers with liquefaction potential.

RÉSUMÉ: On estime que le Brésil possède environ 570 Mt de mineral de fer stocké dans des barrages sans plan national de réutilisation. Cette étude de cas concerne de la Carajás Mine résidus, un réservoir d'un volume de 100 Mm³ et d'une teneur en mineral de fer de 63%, situé dans l'État du Pará. Concernant le risque géotechnique lors des excavations pour éliminer les résidus, le présent travail identifie en profondeur les résidus fins et grossiers à travers des essais en laboratoire et sur le terrain. Des analyses seront menées pour vérifier si les ruptures peuvent représenter un déclencheur menant à la liquéfaction des résidus. Les essais sismiques au piézocône ont été (SCPTu) réinterprétés en considérant: nappe phréatique perchée, poids spécifique saturé égal à 30,1 kN/m³, facteur de cône (Nkt) égal à 15. Les données sismiques de terrain ont été comparées aux essais sismiques de laboratoire pour déterminer l'indice de vide et le module de cisaillement (G0) sur tout le profil du résidu, analyser les couches possibles ayant un potentiel de liquéfaction.

Keywords: Perched water table; iron ore tailings; seismic piezocone; bender element.

1 INTRODUCTION

In 2021, Brazil's National Mining Agency (ANM) issued Resolution No. 85, promoting and facilitating the reuse of tailings and waste generated from mining activities through innovative mineral processing techniques. The reuse of iron tailings, particularly from legacy deposits, contributes to reducing risks for society by eliminating materials with high liquefaction potential.

The best technique for recovering tailings deposited in reservoirs or dams made of this material depends on the characteristics of the deposit, composition, storage condition, transportation possibilities, handling and final use of the tailings (ENGELS et al, 2004).

Souza (2020) apud Muir et al. (2005) incorporate that topography and watercourses are preponderant in the analysis of technical and economic viability in mining and reusing the mineral asset present in the tailings. There are three primary methods for reclaiming materials from natural resources: hydraulic re-mining using high-pressure water monitor guns, mechanical reclamation, and dredging.

According to Souza (2020), it is necessary to guarantee geotechnical safety in tailings removal operations for the entrepreneur and other parties involved. In this sense, it is crucial to identify the heterogeneity of the tailings released into the reservoir, analyzing the history of disposal, resistance, deformation and pore pressures.

Becker (2022) et al, reassessing the work of Whittle et al. (2022) in dam B1 (Brumadinho), considers the presence of extensive horizontal layers of fine, clayey, plastic tailings, with a low density coefficient, which

led to the formation of several perched water tables. Stability analyzes using the limit equilibrium method proved to be satisfactory and consistent with failure, provided that adequate resistance, type of sliding surface, stratigraphy and pore pressure are used.

The identification of thin soils (plastic) through piezocone tests is well debated by Aguiar (2022), identifying normalized undrained resistance (Su/σ'v) in the order of 0.11, much lower than the value of 0.22 proposed by Mesri (1975) for soft clays.

In the case of the Fundão sandy tailings, the shear speed in the laboratory to obtain the undrained condition was estimated at 0.011 mm/min according to Coelho (2018). This makes it clear that ruptures in fine materials can be a trigger for liquefaction in thick materials, since the rupture speed in plastic materials can be greater than the dissipation time of non-plastic tailings.

Therefore, this work focuses on the importance of back-analyzing data from seismic piezocone tests in correctly determining the geotechnical profile, identifying tailings with liquefaction potential and how a good interpretation can help in decision-making when planning the removal of tailings in a dam reservoir, combining geotechnical and operational safety.

2 METHOD

2.1 Materials and testing

The tailings have iron contents of about 63%. Table 1 shows the performed geotechnical laboratory (physical characterization and bender element tests) and field studies (standart penetration, SPT, and seismic piezocone, SCPTu, tests) for the characterization and determination of geotechnical parameters of those tailings.

Table 1. Data survey.

Date	Survey	Quant	Test
2001	SPT	141	Granulometry; chemical characterization
2010	SPT	214	Granulometry; chemical characterization
2022	SCPTu	4	Physical characterization; bender element

2.2 Perched water table

Figure 1 shows layers of fine material influencing the position of the water table, generating a suspended water table (ICOLD, 2001). The term perched sheet is used in places where the pore pressures measured by tests and instruments differ from the hydrostatic pressures, this occurs when there are layers of low permeability materials and the water above this layer creates groundwater and below it may even be dry or governed by horizontal and vertical flows.

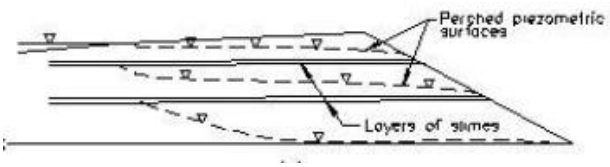

Figure 1. Perched water table around the slimes layers (ICOLD, 2001).

2.3 The problem of surface and subsurface flow

The permeability of tailings is influenced by two mechanisms during hydraulic disposal: segregation during discharge and consolidation. In this reservoir, the high rainfall in the region leads to particle transport by erosion and suspension. Submerged flow, which is complex, can initially transport coarse particles to areas occupied by fine particles. Figure 2 aims to illustrate these flow characteristics of the Carajás Mine tailings dam.

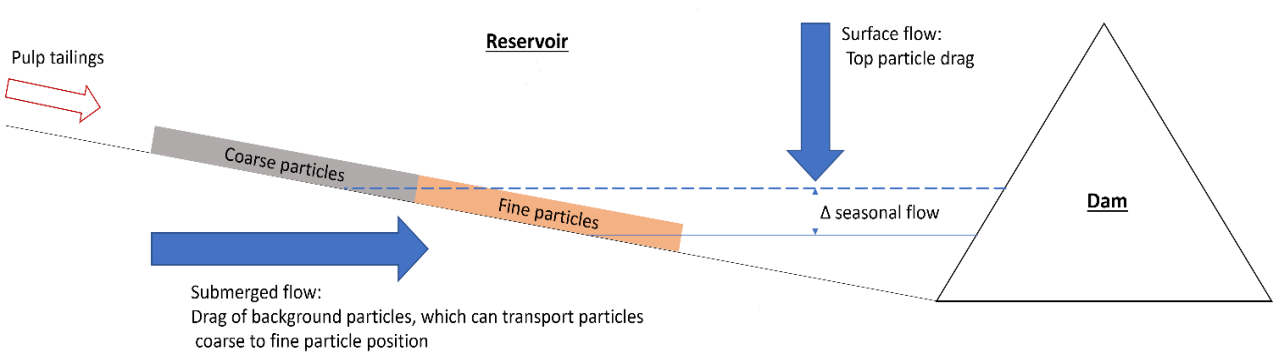

Figure 2. Hydraulic segregation of tailing over time of tailings of the Carajás Mine dam.

2.4 Criteria fine and coarse tailings

To determine the layers of fine (plastic) and sandy (non-plastic) tailings, data from the geotechnical investigation campaign and an analysis of the reservoir's history may be conducted, as follows:

- Analysis of the percussion survey campaign to identify the thickness of the tailings packages deposited in the reservoir;
- Understanding the history of tailings release based on the hydrocyclone and its underflow (sandy) and overflow (fine) discharge;
- Analysis of the SCPTu campaign and determination of the Ic behavior index (Jefferies and Been, 2006), suspended water table, vertical flow and dissipation of pore pressures;
- Analysis of the shear modulus (G_0) using the Bender element and seismic cone tests.

2.5 Criteria for evaluation of liquefaction potential in sandy tailings

The state parameter (ψ) can be obtained through correlation with the normalized cone resistance (Q_{tn}). According to Jefferies and Been (2016) ψ values below -0.05 tend to exhibit strain softening (contractile) behavior under undrained shear and indicate that the tailings may be prone to liquefaction.

Triaxial tests conducted on the Fundão dam in the fine tailings did not indicate liquefaction potential (Morgenstern, 2016).

Based on a large database of historical liquefaction cases suggested a correction factor to correct the normalized cone strength in silty sands to an equivalent value of clean sand (Qtn,cs). After the accident at the B1 dam in Brumadinho, Robertson (2021) updated Eq. 5.

$$Q_{tn} = \left[\frac{q_t - \sigma_v}{p_a}\right](p_a/\sigma'_{v0})^n \quad (1)$$

$$n = 0{,}381\left[I_{c(R\&W)}\right] + 0{,}05\left(\frac{\sigma'_{v0}}{p_a}\right) - 0{,}15 \quad (2)$$

$$Q_{tn,cs} = K_c\, Q_{tn} \quad (3)$$

$$K_c = 1{,}0 \qquad \text{if } I_c < 1{,}7 \quad (4)$$

$$K_c \approx 15 - \frac{14}{1+\left(\frac{I_c}{2{,}95}\right)^{11}} \qquad \text{if } I_c < 3{,}0 \quad (5)$$

$$\psi = 0{,}56 - 0{,}33\, log Q_{tn,cs} \quad (6)$$

where q_t is the corrected cone resistance, I_c is the soil behaviour type, K_c is the correction factor, p_a is the atmospheric pressure.

Schnaid and Yu (2007) propose the incorporation of the shear modulus (G0) to interpret the mechanical properties of sandy soils. The state parameter can be obtained through correlation (Eq. 7).

$$\psi = \alpha\left(\frac{\sigma'_{v0}}{p_a}\right)^{\beta} + \chi \ln\left(\frac{G_0}{q_c}\right) \quad (7)$$

where $\alpha = -0{,}520$, β =-0,07 and χ=0,18 average values obtained by calibration suggested by the authors.

3 RESULTS

3.1 Field investigation

Location of the piezocone tests is shown in figure 3 and results obtained from piezocone data of SCPTu-01 conducted at Carajás Mine tailing dam are presented in Figures 4 and 5. Analyses results indicated that, from the 4.5m to 12m depth, there is a layer of fine grained material, with plastic behavior.

This conclusion is based on both the direct and indirect results of the piezocone test, and is in line with historical information about the discharge of tailings into this reservoir. The SCPTu-01 piezocone is the most representative of the four tests carried out in the dam reservoir, which contains predominantly fine tailings combined with coarse tailings.

In Figure 5, the stiffness of fine soils is assessed using the rigidity index (Ir), defined as the ratio of the shear modulus (G_0) to the undrained soil strength (Su). This index is a relevant parameter for estimating the consolidation coefficient (ch) using the piezocone.

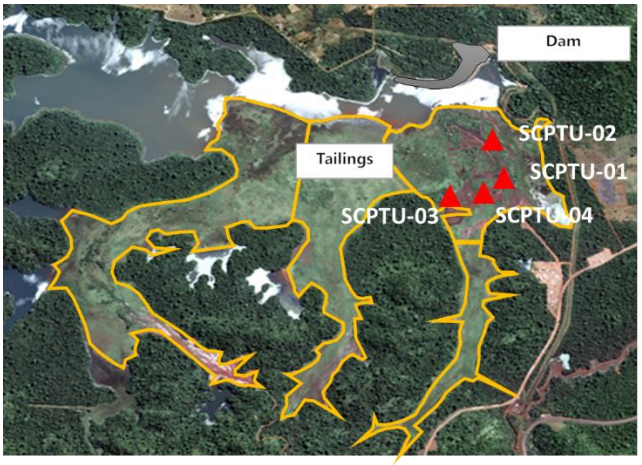

Figure 3. Site of reclamation iron tailings. Piezocone location SCPTu-01,02,03 and 4.

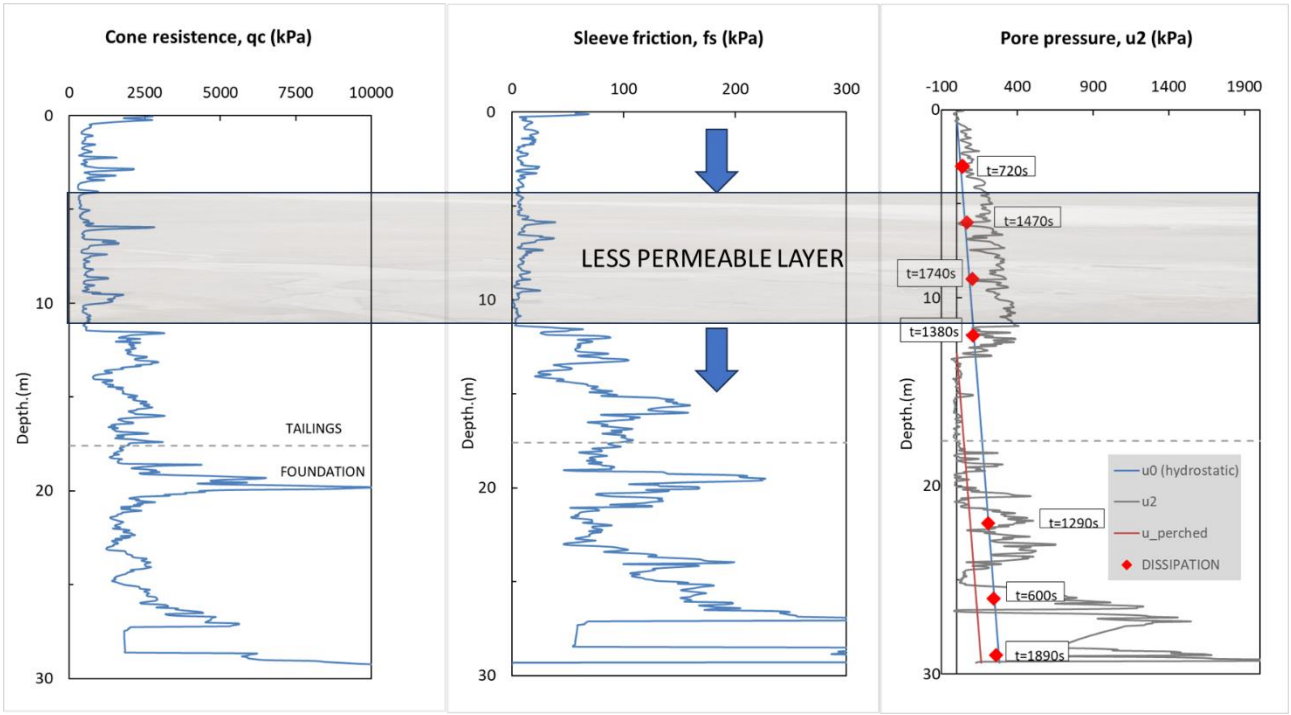

Figure 4. Direct piezocone data of SCPTu-01.

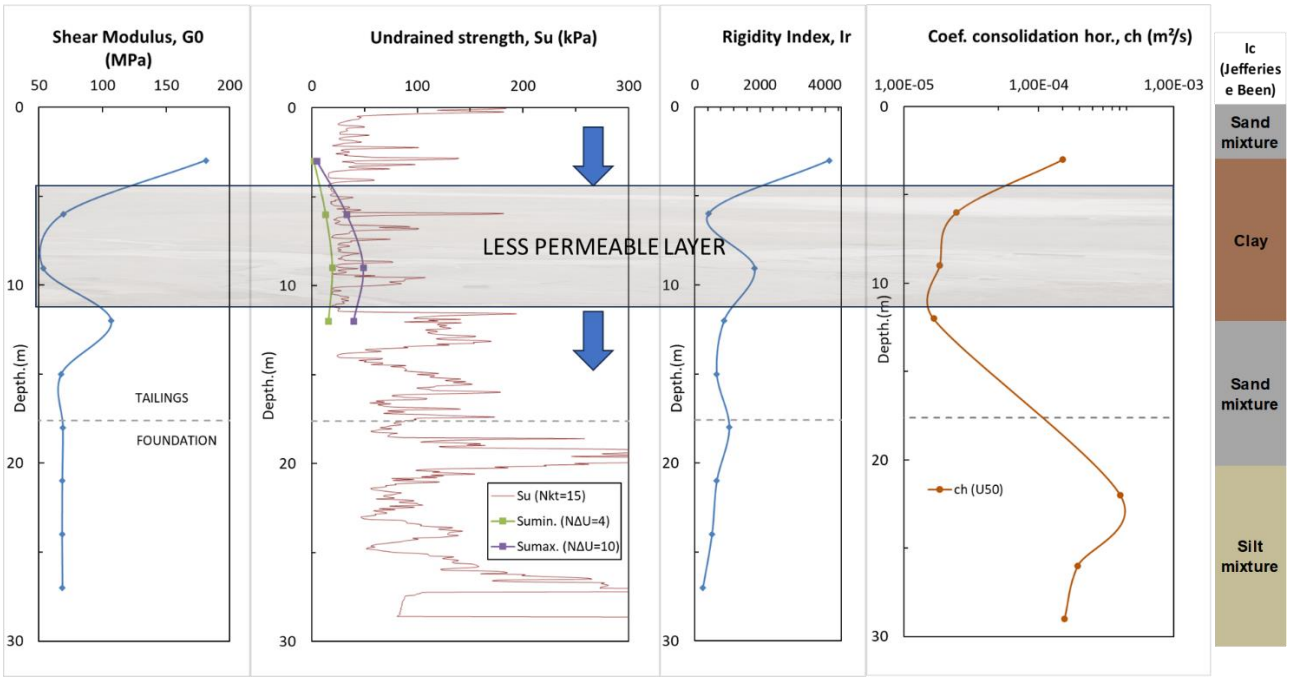

Figure 5. Indirect piezocone data of SCPTu-01.

3.2 Laboratory studies

3.2.1 Index properties

Table 2 present results of laboratory test for physical characterization of tailings from the Carajás Mine tailing dam. Figure 6 shows comparison of grain size distribution of the tailings from the Carajás Mine dam with the determined values for another iron tailings.

These laboratory tests results confirmed the geotechnical profile determined using the piezocone test, showing sandy grain size interspersed with a fine grain layer. The granulometry of the dredged tailings in the present study has a higher fines content in relation to the tailing samples from Brumadinho B1 (Viana, 2022) and Vargem Grande VG (Souza, 2020). It is essential to highlight that the percentage of iron varies depending on the granulometry of the tailings, being more concentrated in the fine grained material.

Table 2. Average values of physical characterization of the tailings from the Carajás Mine dam.

Test	Value
Moisture content (w)	17%
Particle density	4.80 g/cm³
Void ratio	0.83
Saturated density	3.03 g/cm³

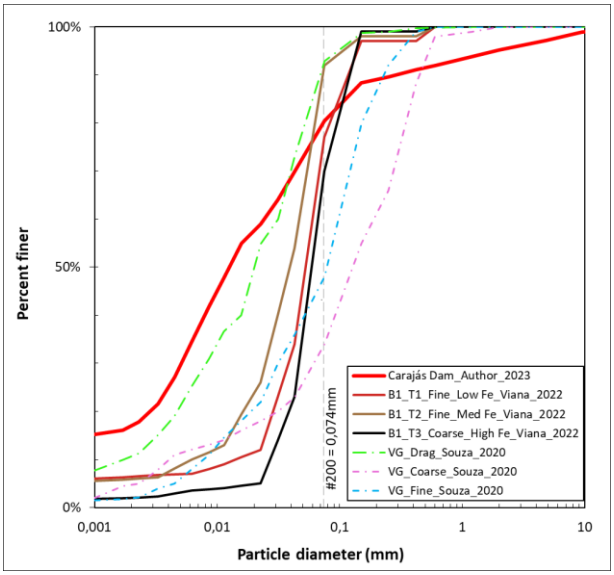

Figure 6. Comparison of grain size distribution of the tailings from the Carajás Mine dam with another iron tailings.

3.2.2 Bender element

For the Bender Element test, samples of the tailings of Carajás Mine dam was collected at 6 m depth from the top. In the laboratory, this sample was conditioned in a triaxial chamber, connected to end-to-end electrodes to measure the speed of the S wave (V_s) at each variation in effective stress consolidation (Fig. 7). The tests were conducted on the same sample, which initially had a relative density of 30%, and was subsequently tested at 50% and 75%. The samples were isotropically consolided for effective stresses of 25 kPa, 50 kPa, 100 kPa, 200 kPa, 400 kPa and 600 kPa. The shear modulus (G_0) can be obtained through correlation (Eq. 8).

$$G_0 = \rho . V_s^2 \qquad (8)$$

where ρ is a specific gravity (kg/m³)

Figure 8 show results of correlation between the shear modulus (G_0) and S wave velocity in the Bender Element test. With the results obtained in the field (V_s), it is possible to obtain the depth profile of the shear modulus (G_0). Notice that Silva (2022) carried out Bender element tests on fine and sandy tailings and the results were similar to the present work.

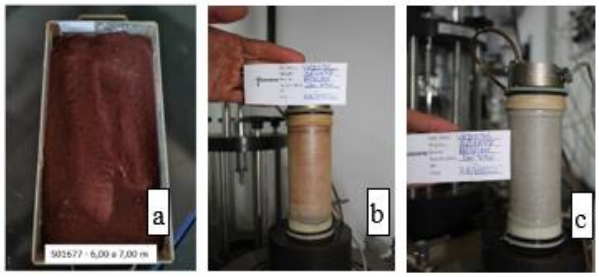

Figure 7. a) Sample; b) Bender element initial condition; c) Final condition.

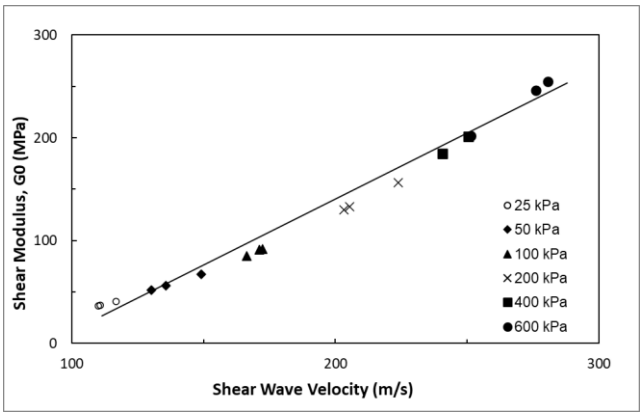

Figure 8. Correlation of shear modulus (G_0) and S wave velocity in the Bender Element test.

3.2.3 Comparison of determined results from Bender element and seismic piezocone tests

Figure 9 presents a comparison of the shear modulus of tailings from the Carajás Mine dam, determined using results from the Bender Element and seismic piezocone tests. These results validate the findings obtained from laboratory tests.

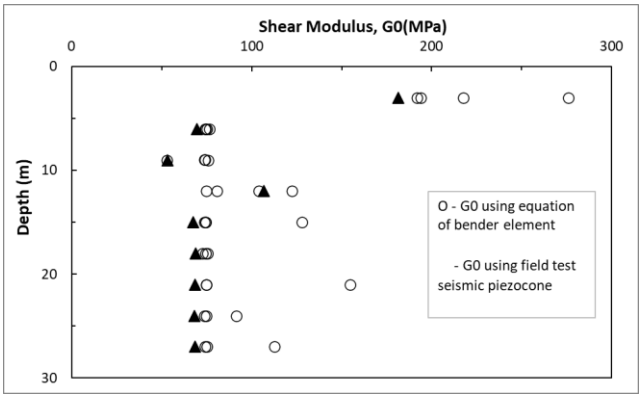

Figure 9. Comparison of results of shear modulus profile (G_0) with depth determined from the Bender Element and seismic piezocone tests.

3.2.4 Potential liquefaction

Figure 10 shows the profile of the state parameter obtained by the methodology of Robertson (2010/2021) and Schnaid and Yu (2007). Notice that the procedure for evaluation of the state parameter by

Schnaid and Yu (2007) is valid for sands and the determine values for the fine tailings using this methodology may not be representative. The results suggest that the sandy tailings near the surface do not exhibit liquefaction potential. However, the sandy tailings situated beyond the fine tailings show liquefaction potential, as indicated by positive state parameter values (ψ). According to Jefferies and Been (2016), materials exhibit contractive behavior when ψ exceeds -0.05.

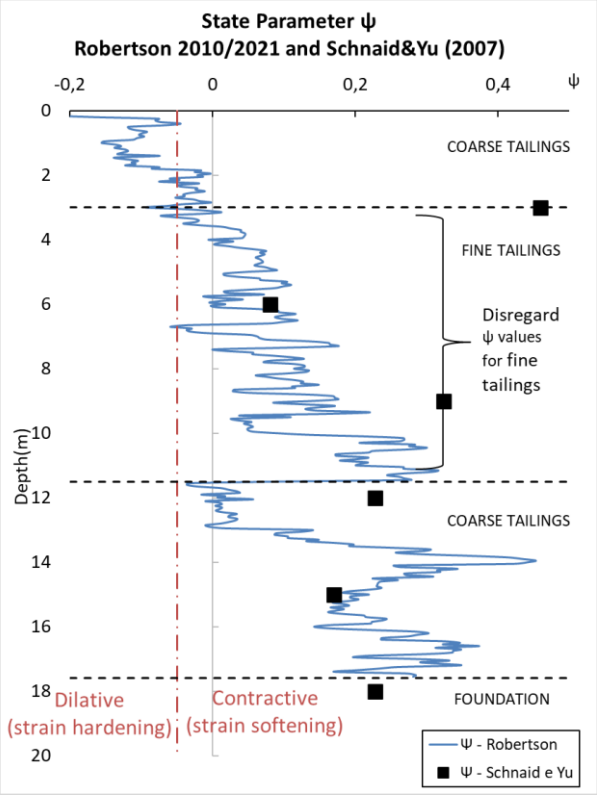

Figure 10. Profile of the state parameter obtained by the methodology of Robertson (2010/2021) and Schnaid and Yu (2007).

4 CONCLUSIONS

The performed geotechnical study indicate that certain tailings from the Carajás Mine dam may have liquefaction potential. It is noteworthy that the excavation process and potential ruptures in the fine tailings could trigger liquefaction. Based on these findings, both submerged and surface excavations were planned to commence from upstream to downstream of the dam reservoir. This approach aims to minimize the liquefied volume in the event of temporary instabilities, ensuring that it remains small enough to prevent overtopping of the structure. As coarse and fine tailings may undergo changes over time due to surface and subsurface flow, it is crucial to conduct investigation campaigns regularly to support stability analyses and potential geometry revisions for stabilizing the tailings. This is particularly important in regions with liquefaction potential.

ACKNOWLEDGEMENTS

The work presented in this paper is part of the main author's dissertation at COPPE/UFRJ.

The authors are grateful to Vale for providing data for this study.

ABSTRACT: This article presents a comprehensive comparison of the predictive accuracy of 5 Machine Learning algorithms – Support Vector Machine, Decision Tree, Random Forest, Extreme Gradient Boosting (XGBoost) and Back-propagation Neural Network – in forecasting maximum settlements induced by earth pressure balance tunnel boring machines. The study evaluates those algorithms' performance using a dataset of 2,590 settlement measurements associated with soil parameters and shield operational parameters, collected from 13 km of the Grand Paris Express Project (line 15 South West and line 14 South). The analysis reveals that, for the small dataset used in this study, ensemble methods, specifically XGBoost and Random Forest, outperform artificial neural networks in predicting settlements. These methods remain reliable even with only 30% of the dataset used for training. The article further explores the regularization and optimization of hyperparameters for Random Forest and XGBoost, shedding light on their enhanced predictive capabilities. Furthermore, variations in the data split between training and testing sets are explored, highlighting the effectiveness of these Machine Learning algorithms in achieving accurate predictions with limited datasets.

RÉSUMÉ: Cet article présente une comparaison approfondie de la fiabilité de 5 algorithmes d'apprentissage automatique: Support Vector Machine, Decision Tree, Random Forest, Extreme Gradient Boosting (XGBoost) et Back-propagation Neural Network - dans la prévision des tassements maximaux induits par le creusement des tunnels au tunnelier, spécifiquement au tunnelier à pression de terre. L'étude évalue les performances des algorithmes en utilisant un ensemble de données de 2 590 mesures de tassements associées à des paramètres de sol et à des paramètres de pilotage du tunnelier, collectées auprès de 13 km du projet du Grand Paris Express (ligne 15 Sud-Ouest et ligne 14 Sud). L'analyse révèle que, pour le petit ensemble de données utilisées dans le cadre de cette étude, les méthodes ensemblistes, spécifiquement XGBoost et Random Forest, surpassent les réseaux neuronaux artificiels dans la prédiction des tassements. Ces méthodes restent fiables même avec seulement 30% de l'ensemble de données utilisé pour l'entraînement. L'article explore également la régularisation et l'optimisation des hyperparamètres pour Random Forest et XGBoost, mettant en lumière leurs capacités prédictives améliorées. De plus, des variations dans la répartition des données entre les ensembles d'entraînement et de test sont explorées, soulignant l'efficacité de ces algorithmes d'apprentissage automatique dans l'obtention de prédictions précises avec des ensembles de données limités.

Keywords: TBM; artificial intelligence; data analysis; optimization; surface settlements.

1 INTRODUCTION & SCOPE OF WORK

Tunnelling in dense urban areas and complex geologies generates significant risks, particularly in the form of surface settlements accompanying the tunnelling progress. Established techniques, including empirical formulas and numerical modelling, have traditionally served to predict these settlements. However, with the growing advancements in Machine Learning (ML), researchers are increasingly exploring its application for the prediction of tunnelling-induced

settlements (Kim et al., 2022; P. Zhang et al., 2020; W. Zhang et al., 2021; Zhou et al., 2023).

One pivotal consideration emerges: the quantity of data required to harness the full potential of ML methodologies, while avoiding the pitfalls of overfitting—a common challenge in adapting complex models to limited datasets. In this article, the authors address this critical question by proposing a methodology to determine the volume of data required for achieving acceptable predictive performance depending on the specificities of each project.

2 METHODOLOGY

The methodology employed in this study is designed to rigorously evaluate the performance of five selected Machine Learning (ML) algorithms in forecasting tunnelling-induced soil settlements.

2.1 Dataset description

The data used in this study originates from 2 metro lines of the Grand Paris Express (GPE), which is considered as the largest tunnelling project in Europe to date. The dataset contains parameters related to Tunnel Boring Machine (TBM) operations, as well as combined soil parameters following (Chen et al., 2019) and maximum settlement observed on top of the tunnel axis s_{max}. Soil parameters include layer thickness and location relatively to the tunnel section, and soil mechanical properties.

Ensuring the quality of the data is of utmost importance, requiring a meticulous preprocessing phase (Richa, 2023; Richa et al., 2022). This includes tasks such as handling missing values, managing outliers, and incorporating feature engineering among others. Through these measures, the dataset undergoes optimization, ensuring it is well-suited for the effective training of ML models.

The resulting dataset comprises 2,590 observations, providing a robust foundation for the subsequent analyses. Selected key variables include tunnel geometry, TBM operating parameters, and geological conditions. These variables are cover depth (D[m]), advance rate (R_A[mm/min]), torque of the cutting wheel (T_o[kN.m]), front pressure (P_f[bar]), thrust (T_h[kN]), pressure (P_g[bar]) and volume (V_g[m^3]) of grout, soil density (γ[kN/m^3]), pressuremeter modulus (E_M[MPa]) and soil rheological coefficient alpha (α[-]), earth pressure coefficient (K_0[-]), soil cohesion (c[kPa]), and soil friction angle (φ[°]).

To ensure data robustness, a statistical analysis is conducted on the selected variables, serving a dual purpose: validating data quality and enhancing comprehension. The results are presented in

Table 1.

2.2 Machine learning

2.2.1 Algorithms

This study relies on the utilization of five distinct ML algorithms: Support Vector Machine (SVM), Back-propagation Neural Network (BPNN), Extreme Gradient Boosting (XGBoost), Random Forest (RF) and Decision Trees (DT).

The choice was based on the findings of previous studies, such as Su et al., (2022), which compared the performance of SVM, BPNN and XGBoost using a dataset of 533 observations. The study concluded that XGBoost exhibits superior accuracy and interpretability compared to BPNN and SVM. Consequently, the primary focus of this study is on XGBoost, complemented by another ensemble method based on Trees: RF. DT algorithm is used to highlight the improvements achieved by RF and XGBoost.

It's crucial to note that each of these models comes with its own set of hyperparameters, which are key configurations influencing the model's behavior. As an example, one vital hyperparameter in XGBoost is "n_estimators", representing the number of trees in the ensemble. Optimizing these hyperparameters is a key aspect of the model training process.

Table 1. Statistical Description of selected features.

Unit	s_{max} *mm*	R_A *mm/min*	T_o *kN.m*	P_f *bar*	T_h *kN*	P_g *bar*	V_g *m^3*	D *m*	γ *kN/m^3*	E_M *MPa*	α	K_0	c *kPa*	φ °
Mean	-3.5	33	4687	1.2	20599	2.7	10	29.5	12	66.6	0.4	0.3	41.4	20

2.2.2 Model training and evaluation

The model training process involves a division of the dataset into training, validation, and testing sets. This partitioning ensures the assessment of model performance on distinct subsets of data, providing insights into generalization capabilities. To enhance robustness, cross-validation techniques are applied, mitigating the risk of model overfitting and ensuring a more reliable estimation of performance metrics.

Error metrics, including Root Mean Squared Error (RMSE) and R-squared (R^2), are employed to quantify the models' predictive accuracy. Lower RMSE values indicate better accuracy, and R^2 values closer to 1 means that the model effectively explains the variance in the data.

Learning curves offer an additional layer of insight, depicting how model performance evolves concerning the training size. These curves aid in identifying not only how much data is enough data to obtain a sufficient training score but also highlight potential issues related to overfitting.

2.2.3 Regularisation and optimisation

To enhance the predictive performance of the obtained models, two crucial techniques – regularization and optimization – are employed.

Regularization techniques control the complexity of models by adjusting hyperparameter values. This process helps strike a balance between bias and variance, preventing overfitting, where the model becomes too tailored to the training data, thereby improving its generalization to new, unseen data.

Optimization of Machine Learning algorithms aims to systematically adjust the model's hyperparameters for optimal performance. In this study, the Random Search technique is employed to explore different hyperparameter combinations, contributing to an iterative refinement process. The objective is to enhance the model's capacity to capture underlying patterns in the data.

Table 2. Model results for 5 ML algorithms using 80% of data for training.

	R^2		RMSE	
	Train	***Test***	***Train***	***Test***
SVM	0.91	0.84	0.73	0.86
BPNN	0.95	0.89	0.53	0.71
DT	1	0.82	0	1
RF	0.99	0.91	0.24	0.68
XGBoost	1	0.93	0.02	0.64

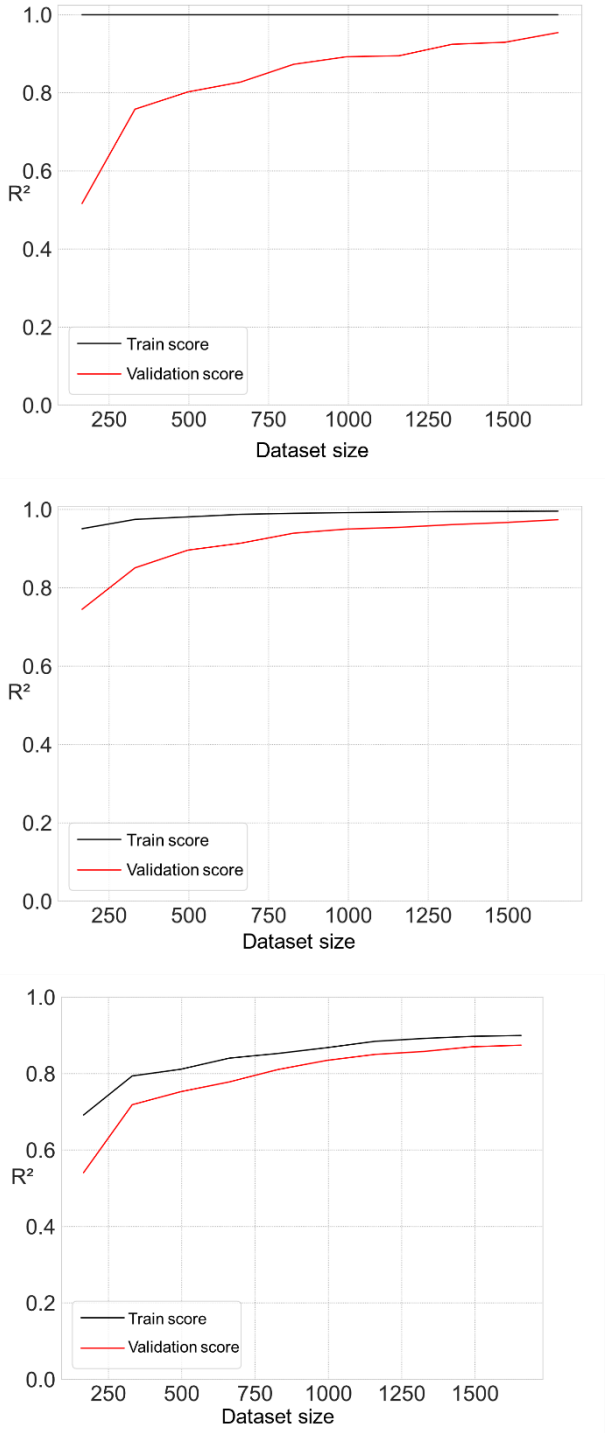

Figure 1. Learning curves of DT (top), RF (middle) and SVM (bottom).

3 RESULTS

3.1 Comparative assessment of algorithms

In the initial phase, the model is subjected to training and cross-validation using 80% of the dataset, with the remaining 20% reserved for testing. The findings, presented in Table 2., offer valuable insights.

Firstly, both RF and XGBoost showed superior predictive performance with higher R^2 and lower RMSE during testing. However, a notable observation unfolded regarding models based on tree structures, including DT, XGBoost, and RF. These models exhibit signs of overfitting, reaching maximal scores on the training datasets.

Moreover, analyzing the learning curves (Figure 1) showed that XGBoost and RF have exceptional performance with a relatively limited dataset size, approximately 600 observations, which represents 30% of the dataset.

3.2 Training with limited data

Building upon the earlier findings, the authors opted for a training set comprising 30% of the dataset, reserving the remaining 70% for testing. The outcomes affirm that 777 observations seem to provide enough data for the effective training of RF and XGBoost. Notably, the R^2 scores on the test set are impressive, standing at 0.91 and 0.93 for RF and XGBoost, respectively.

Despite their strong predictive performance, it's evident that both models show signs of overfitting. The R^2 score on the training set remains at the maximum value of 1, underscoring a tight fit to the training data. Consequently, the next crucial steps involve regularization techniques, followed by the optimization of hyperparameters for these models. These measures aim to enhance their generalization capabilities and fine-tune their predictive accuracy.

3.3 Dealing with overfitting

Addressing overfitting in these algorithms involves a strategic approach to regularization. For instance, this involves constraining the depth of the trees in the ensemble because excessively deep trees tightly adhere to the training data, resulting in overfitting. Various hyperparameters undergo regularization in this study, including the number of trees (n_estimators) in the ensemble, the maximum number of features considered for leaf division in RF, or for XGBoost, gamma, which acts as a regularization parameter.

Determining the optimal values requires a delicate balance between bias and variance, considering the range of values that minimizes both errors (Figure 2). To pinpoint the optimum value within this range, a Random Search is conducted. This method efficiently explores the parameter space, identifying the value that yields optimal results without succumbing to overfitting or underfitting.

Results show that, even after undergoing regularisation and optimisation, both algorithms continue to give remarkable performance in testing. XGBoost reaches an R^2 close to 0.9, while RF achieves 0.92, with the R^2 for the training set never reaching the maximum value of 1 (Figure 3).

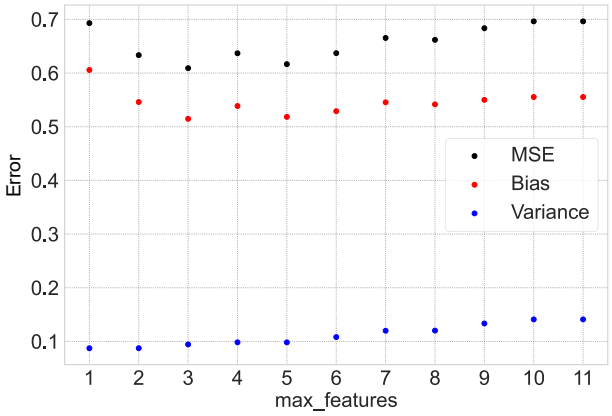

Figure 2. Example of bias and variance calculations for max_features hyperparameter in RF.

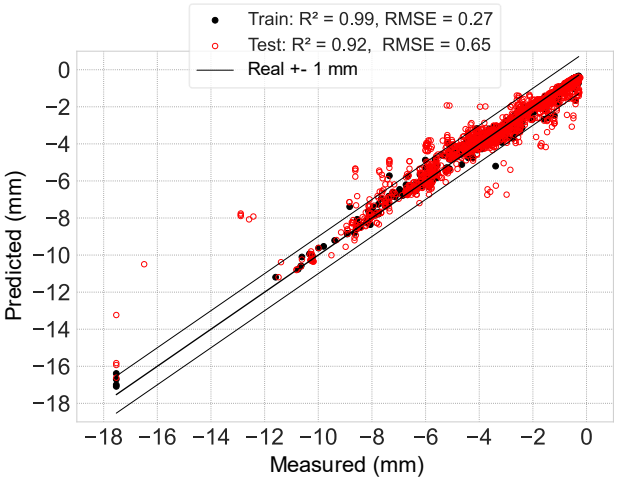

Figure 3. Results of RF after regularisation and optimisation.

4 CONCLUSIONS

This study compared 5 machine learning algorithms – Support Vector Machine, Decision Tree, Random Forest, Extreme Gradient Boosting, and Back-propagation Neural Network – giving valuable insights into their predictive accuracy for forecasting maximum settlements induced by earth pressure balance tunnel boring machines. Leveraging a dataset comprising 2,590 settlement measurements from the Grand Paris Express Project, the analysis uncovered the superior performance of ensemble methods, specifically XGBoost and Random Forest. These algorithms remain reliable even with only 30% of the dataset used for training. Furthermore, the investigation delved into the regularization and optimization of hyperparameters for Random Forest

and XGBoost, shedding light on their enhanced predictive capabilities. The exploration extended to variations in the data split between training and testing sets, emphasizing the effectiveness of these machine learning algorithms in achieving accurate predictions despite limited datasets.

Centrifuge model tests to evaluate the stability of embankments in hydrodynamic conditions

Modélisation en centrifugeuse pour évaluer la stabilité de remblais dans conditions hydrodynamiques

ABSTRACT: Embankments associated with mine tailings storage facilities, levees, and earth dams have fine granular soils susceptible to liquefaction when their state is on the wet side of the critical state line. During periods of heavy rain or drainage system issues, a partially saturated material can become saturated after infiltration during rainfall. For low degrees of compaction, the response can be contractive, particularly at medium to high confining pressures. Therefore, centrifuge model tests were performed at Deltares, Netherlands, to assess the stability of a slope made of a silty fine sand subjected to seepage flow. An upstream water level was installed inside the slope, allowing a steady-state seepage flow through the model, while water was recovered on the downstream border where the water level was kept at a much lower level. This paper presents the centrifuge test results in terms of pore pressure evolution, which was then compared with numerical analysis performed in PLAXIS 2D®.

RÉSUMÉ: Les remblais associés aux installations de stockage de rejets miniers, aux digues, et aux barrages en terre sont composés de sols granulaires sensibles aux phénomènes de liquéfaction lorsque leur état se situe du côté humide de la ligne d'état critique. Lors des périodes de fortes pluies ou problèmes dans le système de drainage, un matériau partiellement saturé peut le devenir après infiltration. Pour de faibles niveaux de compactage la réponse peut être contractante, en particulier sous contraintes effectives moyennes à élevées. Par conséquent, des essais sur modèles en centrifugeuse ont été réalisés à Deltares, aux Pays-Bas, pour évaluer la stabilité d'une pente constituée d'un sable fin limoneux soumis à un écoulement d'infiltration. Un niveau d'eau est installé à l'intérieur de la pente permettant un débit d'infiltration stable à travers du modèle, tandis que l'eau est récupérée sur la bordure en aval où le niveau d'eau est maintenu à un niveau beaucoup plus bas. L'article présente les résultats des essais en centrifugeuse, notamment l'évolution de la pression interstitielle, qui est comparé aux résultats de l'analyse numérique réalisée dans PLAXIS 2D®.

Keywords: Seepage flow; liquefaction; slope stability; numerical analysis.

1 INTRODUCTION

There are different types of embankments, such as mine tailings storage facilities, levees, and earth dams, facing potential risks under adverse hydrodynamic conditions. These geotechnical structures often contain fine granular soils that can be sensitive to liquefaction when their state is on the wet side of critical state line. If liquefaction is not contained and propagates throughout the deposit, a flow slide results.

For instance, dry stacks are massive embankments of compacted filtered tailings. To construct these massive embankments, the tailings slurry obtained in the mining process passes through a filtering system to reduce its water content. However, the term "dry" stack can be misleading, as the state of the material forming the stack is not entirely dry. Davies (2011) suggests that it is a partially saturated material with a degree of saturation around 70-85%, but this depends on several factors (filtration process, type of material, transportation mode, climate conditions…).

Under inadequate draining conditions, a filtered dry stack in a partially saturated state can become fully saturated through infiltration during rainfall. When the degree of compaction is high (typically over than 95% of standard Proctor), filtered tailings show dilatant response under various confining stresses. Lower degrees of compaction result in a contractive response, particularly under medium to high confining pressures. Additionally, when the material is less compacted and/or on the wet of optimum, it may

become saturated under high effective stresses induced by embankment rise. Depending on the material's permeability, mineralogy, and loading rate (due to subsequent lifts), excess pore pressures may develop in the embankment. This can mobilize low undrained strength ratios far from critical state conditions eventually dropping to post-peak residual values, displaying non-Newtonian behaviour (Gens, 2019). In a climate change scenario, the increased frequency of heavy rain and storms poses additional challenges.

For these reasons, design must account for the fact that material strength depends on various factors, including the type of material, degree of saturation and compaction, drainage conditions, effective stresses due to loading, and/or excess pore pressure generation. Driven by the recognition of the brittle nature of liquefaction failure (Morgenstern et al., 2015; Jefferies et al., 2019, Arroyo and Gens, 2021), stress-deformation hydromechanical analyses of tailings dams are replacing the limit equilibrium methods that, until recently, were considered the best available practice for stability analyses (Garbarino et al., 2018, Mánica et al., 2022).

Nevertheless, it is recognised that effective use of these numerical models requires adequate calibration. Without this calibration, any attempt to simulate ground improvement technologies or more stable geometries will be seriously hampered. In a recent European Project, H2020-GEOLAB-SAFETY, simple slope models were tested in a geotechnical centrifuge. This paper presents some of the results obtained, together with hydromechanical numerical analyses.

2 CENTRIFUGE TESTS

The GeoCentrifuge at Deltares is a beam centrifuge with a 260 g-tonne capacity and a platform radius of 5.0 m. The experiment presented here comprises a homogeneous profile of a silty sand obtained with the mixture of two silica based natural soils: 56% of Geba sand and 44% of a fine fraction of Baskarp sand. This mixture allowed the simulation of the grain size distribution curve of an iron tailing material for which dry stacking is being studied. The obtained silty sand has the following physical properties: 47% of fines content, curvature coefficient Cc=0.74, uniformity coefficient Cu=2.94, mean effective diameter D_{50}=0.086 mm, maximum void ratio = 1.03, and minimum void ratio = 0.63. The model is initially prepared with unsaturated loose material by moist tamping (Figure 1), being placed in the centrifuge for an acceleration of 100g. The g-level is applied at the base of the model container corresponding to the base bottom layer of soil. After a permanent steady-state water flow is established, the hydraulic gradient is gradually increased by raising the water head on the left boundary while keeping a low water head at the right boundary. The model is instrumented with 10 pore pressure transducers (PPTs) from MEAS France (EPB-PW-7BS/Z0/PC0.5/L5M) with measuring range between -50 and 700kPa and accuracy of 0.5%FS.

Figure 1. Physical model inside the strongbox.

3 NUMERICAL MODELING

3.1 Geometry and scale factors

Numerical analysis using PLAXIS 2D® simulated the centrifuge experiment at prototype scale. Table 1 summarises the scale factors to convert the physical model results into prototype scale, so that they could be compared to the numerical data. The imposed acceleration was 100 g, although the conversion to the prototype scale used *N* values corresponding to the measured *g* level at each instance. The prototype geometry consists of a 30º slope with a height of 39 m in the upstream boundary and 8 m in the downstream boundary. There's a blanket drain at the bottom right corner of the model, extending 17.2 m from the right boundary (Figure 2).

Table 1. Scaling laws for centrifuge tests at Ng (Taylor, 1995).

Parameter	Scale (Model/Prototype)
Linear dimension (m)	1/N
Stress (kPa)	1
Time for water flow (s)	$1/N^2$

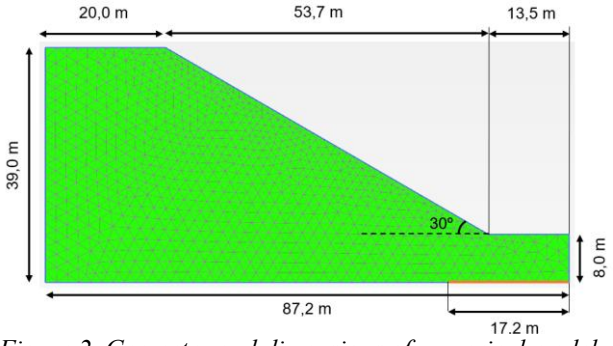

Figure 2. Geometry and dimensions of numerical model.

3.2 Material parameters

The constitutive model used was the linear elastic perfectly plastic Mohr-Coulomb model. The parameters for the material were determined through monotonic compression triaxial tests, conducted in the Geotechnical Laboratory of FEUP. To accurately simulate the unsaturated conditions above the water table, the van Genuchten parameters associated with the soil water retention curve were introduced in the groundwater parameters (Table 2).

Table 2. Soil parameters (Mohr-Coulomb).

Parameter		Value	Unit
Unit weights	γ_{sat}	18.10	kN/m^3
	γ_{unsat}	15.00	kN/m^3
Young Modulus	E	50 000	kPa
Poisson ratio	ν	0.31	-
Friction angle	ϕ'	33.32	º
Initial void ratio	e	0.800	-
Cohesion	c'	0	kPa
Coef. earth pressure at rest	K_0	0.4507	-
Permeability	k_x=k_y	$1x10^{-5}$	m/s
Van Genuchten parameters	S_r	0.00	-
	S_{sat}	1.00	-
	g_n	2.26	-
	g_a	1.82	-
	g_l	-0.66	-

3.3 Mesh and boundary conditions

The PLAXIS® numerical model has plane strain finite elements with triangular 15-node elements. The mesh created for this case is considered "very fine", comprising 13741 nodes in 1680 triangular elements. The bottom boundary was fixed in both directions, while the left and right boundaries were only fixed horizontally.

The numerical analysis comprises two phases: i) an initial phase to activate the stress state (Gravity Loading); ii) a hydromechanical numerical analysis (fully coupled flow-deformation analysis) where the head in the left boundary, and in the drain region were raised gradually, following the head evolutions measured in centrifuge test and shown in Figure 3.

So, the hydraulic boundary conditions during the hydromechanical analysis, comprise a null flux imposed in the bottom boundary, except for the drain region, where a head evolution (head function 1) was applied. In the left boundary, the other head evolution was applied, as indicated in Figure 3 (head function 2). These functions were created to represent the water table conditions observed in the centrifuge test.

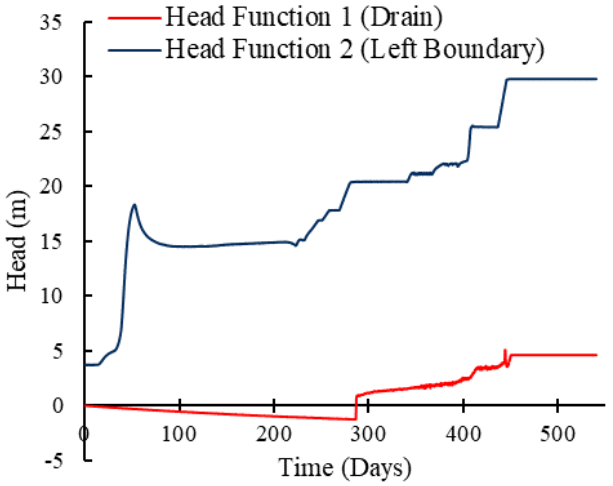

Figure 3. Water table elevation: head evolutions on the left boundary and in the drain region measured in the centrifuge test.

4 RESULTS

The physical and numerical model results are compared in terms of the pore pressures obtained in nine points of the model.

Figure 4 presents the pore pressures at the last phase of the numerical analysis, where a failure happened. The figure also shows the position of the PPTs as well as the position of the water table.

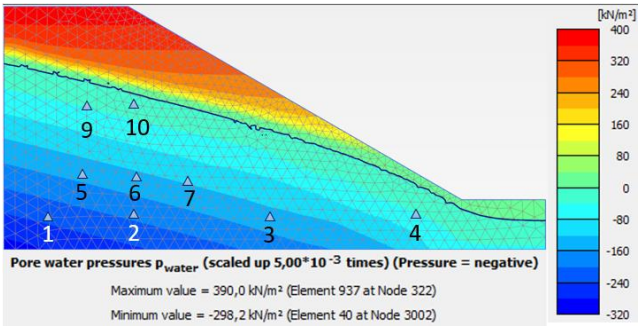

Figure 4. Pore pressure distribution and water table at the last phase of the numerical analysis, as well as the position of selected PPTs.

Figures 5 and 6 show the pore pressure evolution with time in six PPTs. Figure 5 shows that the measured values of the PPTs located close to the left boundary match the calculations well. However, Figure 6 shows that the values differ for the PPTs further away from the left boundary. This indicates that the slope failed faster in the centrifuge test than in the numerical model. This difference may be related to a small erosion at the slope toe that was noticed in the centrifuge test which may have resulted in a faster collapse of the slope than in the calculations.

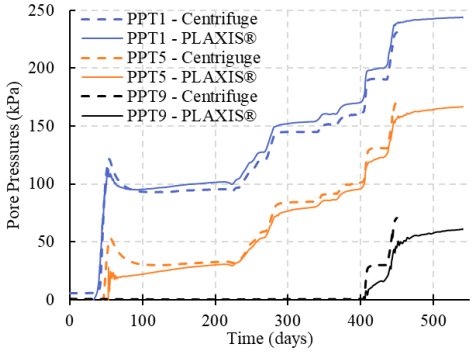

Figure 5. Pore pressures over time (PPTs 1, 5 and 9).

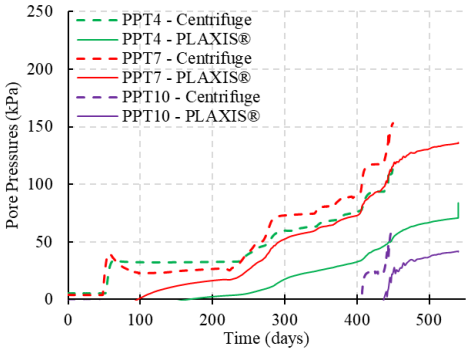

,

Figure 6. Pore pressures over time (PPTs 4, 7 and 10).

Indeed, the slope collapses at 540 days in the numerical model and at 450 days in the centrifuge experiment. This is shown by the sharp increase in pore pressure in all considered points at the failure moment. Be aware that the additional 90 days (540-450) corresponds to 13 min in the centrifuge test (model scale). Further studies are being performed on this data, namely to analyse post-mortem results obtained with a mini-CPT and with a laser scan of model surface.

5 CONCLUSIONS

A comparison of the pore pressures registered in the centrifuge test and calculated with the numerical model shows that their values match well for the points closer to the left boundary, showing that the numerical model is well-simulating the water percolation. Furthermore, a similar type of failure was observed in the experiment and the centrifuge test. Slope failure came earlier in the centrifuge test than in the numerical calculations, probably due to the relatively fast erosion of the slope in the centrifuge test. Future developments include the use of advanced numerical analyses capable of simulating soil liquefaction.

ABSTRACT: A frequently adopted method to improve engineering properties of soft soils is the dry deep mixing method, where dry binders like lime and cement are mixed with the soil using a rotating mixing tool. To date, the properties of improved soil are predominantly measured using destructive methods and based on locally constrained methods. Latest sensing technologies such as distributed fibre optic sensing (DFOS) are promising tools to map temporal and spatial changes of geotechnical structures. However, the use of DFOS for stabilised soil has received scant attention. There is a lack of detailed investigations on monitoring curing temperature and detecting weakness zones in stabilised soil using distributed temperature sensing (DTS) and on the strain transfer mechanism between a fibre optical cable and the stabilised soil. This paper experimentally examines DFOS to quantify the integrity and the stress-strain relation of stabilised soil. Samples with layers of stabilised and remoulded clay were instrumented with a loose tube fibre optical cable to monitor changes in the curing temperature. The results indicate that untreated soil layers with a thickness of a few centimetres can effectively be identified when installing a fibre optical cable during the first hours after soil improvement. To address the strain transfer mechanism, composite fibre optical strain cables were directly embedded into stabilised soil samples and tested in unconfined compression tests. The obtained data show that the stiffness differences between the stabilised soil and the fibre optical cable resulted in a complicated strain transfer, which requires further investigation. The findings from this research suggest that DFOS can provide a means of evaluating the engineering performance and safety of stabilised soil.

RÉSUMÉ: Une méthode fréquemment adoptée pour améliorer les propriétés techniques des sols mous est la méthode du mélange sec en profondeur, où des liants secs comme la chaux et le ciment sont mélangés au sol à l'aide d'un outil de mélange rotatif. À ce jour, les propriétés des sols améliorés sont principalement mesurées à l'aide de méthodes destructives et basées sur des méthodes localement contraignantes. Les dernières technologies de détection, telles que la détection par fibre optique distribuée (DFOS), sont des outils prometteurs pour cartographier les changements temporels et spatiaux des structures géotechniques. Cependant, l'utilisation de la DFOS pour les sols stabilisés n'a reçu que peu d'attention. On manque d'études détaillées sur la surveillance de la température de durcissement et la détection des zones de faiblesse dans les sols stabilisés à l'aide de la détection de température distribuée (DTS) et sur le mécanisme de transfert de contrainte entre un câble à fibre optique et le sol stabilisé. Cet article examine expérimentalement la DTS pour quantifier l'intégrité et la relation contrainte-déformation du sol stabilisé. Des échantillons avec des couches d'argile stabilisée et remoulée ont été instrumentés avec un câble à fibre optique à tube lâche pour surveiller les changements de la température de durcissement. Les résultats indiquent que les couches de sol non traitées d'une épaisseur de quelques centimètres peuvent être efficacement identifiées lors de l'installation d'un câble à fibre optique au cours des premières heures suivant l'amélioration du sol. Pour étudier le mécanisme de transfert de contrainte, des câbles composites à fibres optiques ont été directement intégrés dans des échantillons de sol stabilisé et soumis à des essais de compression non confinée. Les données obtenues montrent que les différences de rigidité entre le sol stabilisé et le câble à fibres optiques ont entraîné un transfert de contrainte compliqué, qui nécessite une étude plus approfondie. Les résultats de cette recherche suggèrent que le DFOS peut fournir un moyen d'évaluer la performance technique et la sécurité des sols stabilisés.

Keywords: Distributed fibre optic sensing; ground improvement; deep dry mixing; observational method.

1 INTRODUCTION

The dry deep mixing (DDM) method has been widely employed in countries including Finland, Japan, Norway and Sweden. Traditionally, dry binders such as lime and cement have been mixed with soft soil to obtain stabilised soil columns with improved strength and deformability properties.

Current design procedures weigh the area of the improved and unimproved soil to obtain average strength estimates for the total soil volume (Norsk Geoteknisk Forening, 2012) and to evaluate settlements during loading (e.g., Broms, 1991; Alen et al., 2005; Baker, 2000). In this approach, the spatial variability of both the stabilised and virgin soil is neglected. Likewise, any interaction between the DDM columns and the surrounding clay is ignored. These limitations introduce considerable uncertainties in the design of DDM and often result in conservative estimates.

Field testing and full-scale trials have frequently been employed to improve adopted design solutions. However, traditional field-testing techniques such as sampling of the stabilised soil columns and penetration tests are destructive and often provide only locally constrained data at a specific time after the soil mixing. Reliable data about potential weakness zones in the stabilised soil is often lacking. Monitoring of full-scale field trials typically results in cumulative settlements or settlement data at specific depths. Spatially distributed data about the stress-strain response of stabilised soil remains missing.

A potential technique to obtain high resolution data about the field performance of DDM improved soil is distributed fibre optic sensing (DFOS). Recent research showed the successful application of DFOS in geotechnical engineering (Soga and Luo, 2018). For example, distributed temperature sensing (DTS) was used to quantify the integrity of a cast-in-place concrete pile (Rui et al., 2017). Another study showed that distributed strain sensing (DSS) can provide the full strain profiles of bored concrete piles (Pelecanos et al., 2018). So far, the application of DFOS to DDM has however received scant attention.

The hypothesis of this research is that DFOS can unlock the real performance of DDM improved soil. The specific research objectives were to experimentally investigate if DTS can detect weakness zones in stabilised soil, and if DSS can quantify the stress-strain response of stabilised soil.

2 METHODOLOGY

Two types of laboratory tests were carried out: so-called temperature and strain tests. For each test type, the used soil was a very sensitive clay from Tiller-Flotten, Norway. L'Heureux et al. (2019) provided a detailed description of this clay. The following sections discuss both test types in more detail.

2.1 Temperature tests

The DTS cable was a single-mode optical fibre (PureBandTM-PLUS from SUMITOMO ELECTRIC) within a hydraulic oil (Shell Tellus S3 M 46) filled plastic tube with an internal and external diameter of 2 and 3 mm. The cable was placed at the centre of an isolation box (Figure 1a), which replicated semi-adiabatic conditions (Bache et al., 2022). Two specimens with a diameter of 100 mm and a height of 200 mm with equal parts of stabilised and remoulded clay were prepared.

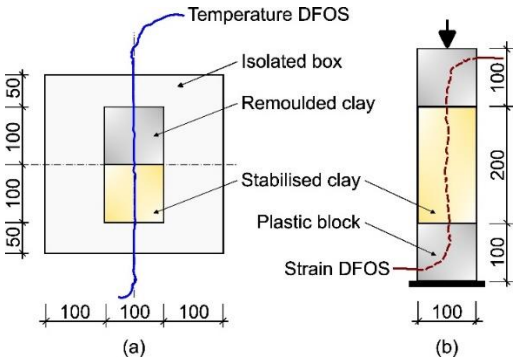

Figure 1. Experimental setups: (a) vertical cross-section of the temperature tests and (b) view of the strain tests. Dimensions in mm.

First, the Tiller-Flotten clay was manually remoulded. Then 50 kg/m^3 of dry burnt lime was added to half of the remoulded clay and mixed. The lime-clay mixture was then added to the isolation box and moulded using a tamping rod. This work was carried out with caution to avoid damage of the DTS cable while minimising the air content of the stabilised clay. The remoulded clay was then poured into the top half of the specimen to replicate a weakness zone in the stabilised soil.

An OBR4600 fibre optic interrogator from Luna Innovations and a spatial resolution of 1 cm was used. A reference measurement was carried out immediately after the sample preparation was finalised. Subsequently, measurements were taken about every 5 minutes until almost 40 hours.

2.2 Strain tests

Three stabilised soil specimens with a diameter of 100 mm and a height of 200 mm were prepared. Similar to the temperature tests, the Tiller-Flotten clay was first remoulded and then mixed with 50 kg/m^3 of dry burnt lime and 50 kg/m^3 of ordinary Portland

cement (CEM I 52.5 R). Then, the lime-cement-clay mixture was moulded in a plastic cylinder, in which an EpsilonSensor composite fibre optical core (Nerve-Sensors, 2023) was centrally placed. The EpsilonSensor had a diameter of 3 mm, an elastic modulus of 3 GPa and a strain measurement range of ±4%. The specimens were then wrapped in plastic and cured at room temperature (around 21°C).

After 19 to 27 days the specimens were tested in unconfined compression (UC) tests. Figure 1b shows the experimental setup including purpose-built slotted, rigid plastic blocks to guide the cable from the stabilised soil specimen. This setup ensured that the uniaxial load was only applied to the stabilised soil and not to the fibre optical cable. The UC tests were carried out with displacement rates between 0.2 to 0.4 mm/min and displacement increments between 0.1 to 0.4 mm. Fibre optic strain measurements were obtained before the loading started and after every displacement increment. Again, the OBR4600 with a spatial resolution of 1 cm was used.

3 RESULTS

3.1 Temperature tests

Figure 2 shows the DTS data during the first eight hours of the tests. In the stabilised clay section of the specimens, the measured temperature decreased with the experimental time. This is a result of the reference reading, which was conducted after the peak of the temperature increase had been reached. Consequently, all subsequent readings indicated a temperature reduction compared to the reference reading. By contrast, the temperature transferred to the untreated clay section and caused a temperature increase.

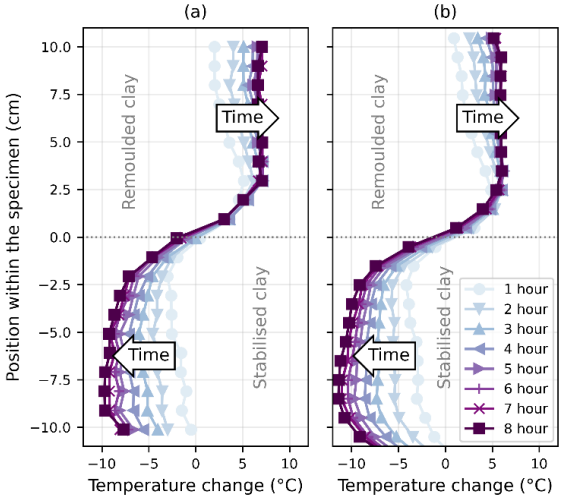

Figure 2. Distributed temperature sensing profiles within the first eight hours of the temperature tests: (a) first specimen and (b) second specimen.

The DTS data exhibited a signature temperature profile at the transition zone between the stabilised and untreated soil, see Figure 2. This suggests that zones with lower binder content in DDM can be detected using DTS. The data further indicate that notable temperature changes were obtained for the first five hours. This suggests that in the field a DTS cable should be installed directly after a DDM column is installed and immediate measurements should be taken.

3.2 Strain results

The three strain tests resulted in UC strength and stiffness values between 524 to 674 kPa and 27 to 54 MPa, respectively. These values agree with typical strength and stiffness values of laboratory improved soils (e.g., Hov and Larsson, 2023).

Figure 3 shows strain profiles obtained for the three different tests. Each strain profile relates to a specific axial strain, ε_{UC}, applied on the stabilised soil specimen. Interestingly, the strain data show a maximum strain value in the centre region of the specimens which differs from the theoretical axial strain profile of UC tests. The disagreement may be due to stiffness differences between the DSS cable and the stabilised soil affecting the associated strain transfer mechanism. Similar observations about complex strain transfer were reported when embedding DSS cables in both granular (Zhang et al., 2020) and cementitious material (Zhang et al., 2022).

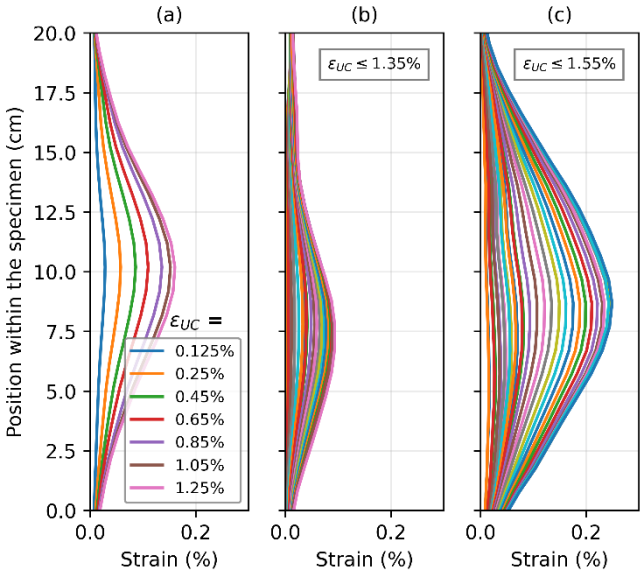

Figure 3. Distributed strain sensing profiles for the three tested specimens before the fibre optical cable noticeably slipped. For test (a), the applied axial strain in the unconfined compression test, ε_{UC}, are indicated. For tests (b) and (c), each strain profile corresponds to ε_{UC} increments of 0.05%.

In addition to the different strain profiles, the magnitude of the strains measured by the DFOS was considerably lower than the applied strain (compare measured strains with applied ε_{UC} in Figure 3). This observation indicates that the entire strain could not be transferred from the stabilised soil to the DSS cable. Again, this inconsistency may be due to the notable stiffness differences between the stabilised clay and the DSS cable and partial slippage. In addition, the length of the DSS cable was most likely too short to transfer the entire applied strain to the DSS cable.

The differences between the three strain tests are likely a result of how well the stabilised soil could be compacted in the vicinity of the DSS cable. Although great care was taken while preparing these specimens, good bond between the DSS and cable and the stabilised soil was difficult to achieve. This is especially true for the top of test (b) as can be seen from Figure 3b.

4 CONCLUSIONS

The objectives of this research were to examine if DTS can reveal anomalies in stabilised soil, and if DSS can quantify the stress-strain response of stabilised soil. This study can draw the following conclusions:

- During the first hours after mixing clay with lime, DTS exhibited a signature temperature profile at the interface between the stabilised and untreated soil. This implies that DTS may locate weakness zones with lower binder content of only a few centimetres in stabilised soil.
- DSS data resulted in notably different strain magnitudes and profiles compared to the axial strains in UC tests. The obtained disagreement could be attributed to stiffness differences between the stabilised clay and the fibre optical cable and the small length of the DSS cable in the stabilised soil specimen causing a complex strain transfer mechanism. This finding indicates that caution must be applied when interpreting the strain data from a DSS cable embedded in stabilised soil.

The obtained results support the hypothesis that DFOS can provide novel insight into the properties and performance of DDM improved soil. However, future studies are required to explore the interface behaviour between DSS cables and stabilised soil to better understand the associated strain transfer. In addition, full-scale tests are needed to study the installation of fibre optical cables in stabilised soil.

ACKNOWLEDGEMENTS

The authors are indebted to MSc Eiwind Solum Rørvik for his valuable contribution to this research while working on his MSc thesis (Solumn, 2023). The support of the staff of the NGI rock and soil mechanics laboratory of this experimental work is greatly appreciated. We also thank the Research Council of Norway (grant number 328767 "GOAL – Green soil stabilisation") for the financial support.

ABSTRACT: The recent accidents involving tailings dams in Brazil have promoted significant changes in the current legislation and, consequently, have made the criteria and assumptions in projects related to mining tailings dams more restrictive. The short deadlines set by the inspection agents, the unavailability of areas, constructive restrictions and, mainly, the need for systematic operational controls during construction to eliminate possible triggers for the liquefaction process to which such structures are susceptible, made the application of steel pile walls as a reinforcement/containment element in dams to become technically feasible in comparison with conventional alternatives. The pile driving method associates the pressing method (Press in) to the rotation technique (Gyropress) and presents, among other advantages, low vibration levels, low noise levels, easy driving in different types of foundations and minimization of downstream damage. This paper presents the results of the application of the pile driving using the press in method to reinforcement as part of the process that dam decharacterization projects developed in Brazil by the applications of criteria and premises established by the International Press-in Association (IPA, 2019).

RÉSUMÉ: Les récents accidents impliquant des digues à stériles au Brésil ont entraîné des changements significatifs dans la législation actuelle et, par conséquent, ont rendu plus restrictifs les critères et les hypothèses dans les projets liés aux digues à stériles minières. Les délais courts fixés par les agents d'inspection, l'indisponibilité des zones, les restrictions constructives et, principalement, la nécessité de contrôles opérationnels systématiques pendant la construction afin d'éliminer les déclencheurs possibles du processus de liquéfaction auquel ces structures sont sensibles, ont fait que l'application de murs de pieux en acier en tant qu'élément de renforcement/confinement dans les barrages est devenue techniquement réalisable par rapport aux solutions de rechange conventionnelles. La méthode de battage des pieux associe la méthode de pressage (Press in) à la technique de rotation (Gyropress) et présente, entre autres avantages, de faibles niveaux de vibration et de bruit, un battage facile dans différents types de fondations et une minimisation des dommages en aval. Cet article présente les résultats de l'application du battage de pieux à l'aide de la méthode de pressage pour le renforcement dans le cadre du processus des projets de décaractérisation des barrages développés au Brésil par l'application des critères et des prémisses établis par l'Association internationale de pressage (IPA, 2019).

Keywords: Steel piles; dam, tailings, decharacterization.

1 INTRODUCTION

The last decade was marked by two accidents involving mining dam collapses in Brazil, which prompted significant changes in state and federal legislation, as well as in techniques for disposing of mining tailings. In this context, at the federal level, the National Mining Agency (ANM) published Resolution No. 95 of 2022, which covers the entire country and establishes precautionary regulatory measures to ensure the stability of mining dams.

In response to the new guidelines and criteria, the entrepreneurs had to update their geological-geotechnical information bases and gain a better understanding of the boundary conditions that control the geotechnical and hydraulic behavior of the structures, in operation or not. As part of this process, new field investigations and susceptibility studies of the materials that make up the dams (embankment, tailings, and foundation) were initiated, to evaluate of the undrained behavior of these materials. As a result, several structures were declared unstable, with safety factors below the requirements, resulting in the need to reinforce the structures.

The short deadlines established in the legislation for reinforcing the structures, as well as factors such as the unavailability of areas and construction restrictions, such as the generation of vibration and

noise that could be triggers for the process of liquefaction and cause instability dams, required the search for new alternatives to implement the reinforcements.

As a technically feasible alternative, studies using steel piles as a construction element and reinforcement have shown advantages over conventional solutions. Among the different technologies for driving piles, the press-in method stands out. This method is widely used in the construction of walls to protect against tsunamis in Japan, and in slope stabilization works in urban areas, mainly in Japan and Europe, according Dobrisan (2018). The Press in method consists of using hydraulic jacks attached to the pile installation equipment to press the piles into the ground. When compared to the other driving techniques used, the press in method stands out due to its fast execution and low noise and vibrations. This technique also determines the load capacity of the piles, since this driving is like a static load test (Tehrani et al., 2016). Installation by pressing uses static loading for its execution. Its design is based on using the tensile strength of piles previously installed in the ground to obtain the reaction force to press, with a static load, the new piles that will be driven into the ground. Depending on the resistance penetration of the foundation soil, it may be necessary to combine the Press in method with the Gyropress technique. In this case, the Gyropress method combines driving by pressing with the rotational movement of the pile, which results in the cutting of the ground by means of a cutting tool (drill) welded to the tip of the pile. Therefore, this combination allows them to be driven piles into resistant materials such as rocks or concrete structures (Ishihara, 2018) (Randolph, 2021).

According to Viel (2022), the advantages of this method are related to:

- low vibration levels, making possible the application in restricted areas like dams at risk or near homes,
- low noise levels;
- ease of driving in almost any type of terrain;
- minimizing damage downstream;
- reduced construction time
- facility with transportation and handling of construction materials;
- the possibility to vary the pile lengths;
- high resistance to compression, bending and cutting;
- high quality control during the construction stages.

In the case of a project using tubular piles installed by the press-in method, it is recommended to adopt the premises and criteria consolidated by the International Press-in Association (IPA), in the document Press-in retaining structures: a handbook (IPA, 2019).

In view of the advantages of using steel piles and the pressing method, the aim of this work is to present a technical feasibility analysis of the use of tubular steel piles to reinforce dams, enabling stabilization and reinforcement processes prior to the dam decommissioning process. A methodological proposal for sizing this type of structure in Brazil will be presented, addressing the particularities and adaptations required, and finally the application of the sizing of a fictitious reinforcement structure, designed according to the proposed methodology.

In order to design these reinforcements, some items deserve special attention, including the calculation of the forces on the pile, the moments and displacements acting on the piles, as well as the evaluation of the behavior of the foundation materials in the face of the demands imposed, and it is also important to note that the behavior of the groundwater after the piles are installed must be analyzed.

2 METHODOLOGY

The design of the steel piles will be based on the calculation methodology presented in the document Press-in retaining structures: a handbook prepared by the International Press-in Association (IPA). The stability of the retaining structure will be checked using the computer software Slide 2® and RS2®.

According to Santos and Futai (2021), for a structure in which one of the dimensions extends indefinitely in relation to the others the assumption of plane state of deformation of the reinforced soil is realistic. The beam element developed in the Timoshenko methodology, as pointed out in the work by Cheng et. al. (1997), adequately correlates principles of stress distribution in beams according to the mechanics of deformable solids and displacement behavior associated with shear forces, using geometric and deformability parameters of the retaining wall and boundary elements of the soil medium itself.

Considering the guidelines contained in the IPA manual, the analysis of tubular piles to be adopted in this study will consider equation (1) to define the tension yield stress adopted for the material:

$$\sigma_e = \frac{M_{max}}{Z} \qquad (1)$$

where Mmax is the maximum moment in the pile (kNm) and Z is the resistant moment area (m³).

It is important to note that the IPA recommends that σ_max should be lower than the steel's admissible

stress, so a safety factor of 1.50 will be used over the yield strength.

Equations (2) and (3) show the calculations developed to measure the area resistant moment, and there is a correction for the resistant moment per meter, dividing it by the diameter of the pipe plus the spacing between them:

$$Z_i = \frac{\pi \left({R_{ext}}^4 - {R_{int}}^4\right)}{4 * R_{ext}} \quad (2)$$

$$Z = \frac{Zi}{Dext + e} \quad (3)$$

For the maximum shear force developed in the pile, referring to the Plane State of Deformation, the Tresca failure criterion will be used in which, in the direction of the shear stress. Equations (4) and (5) express the equations evaluated:

$$\tau_{xy} = \frac{\sigma_e}{2} \quad (4)$$

$$F_{máx} = \tau_{xy} * A \quad (5)$$

where σ_e= tension yield stress adopted for the material (MPa); τ_xy= yield shear stress (MPa); A= effective area of the section (m²).

Although studies in Brazil take into account the determination of reference Safety Factors (SF) for stability studies, in this study, due to the use of the Press-in method, in addition to the SF, the criteria defined in Japan will be used, which prioritize the limit state of use according to the guidelines of the Japan Road Association (2009). Therefore, the maximum horizontal pile displacement is used as a design criterion:

- Less than 1% of the length the pile in the case of normal works;
- Less than 3% of the length the pile in the case of temporary works;

In addition to the displacement criterion presented, the pile's resistance to bending and shearing forces will also be checked. To do this, the maximum bending moment found in the piles in the simulations performed must be less than an allowable moment calculated for each pile or set of piles.

The piles are first inserted into the model embedded in competent material, and then the number of pile rows and embedment length are adjusted to meet the criteria for relative displacement, bending stresses, and safety factors. First, the maximum bending moment in the pile is observed to determine which pile configuration (number of rows, type of steel, and pile thickness) has a higher allowable moment and is closest to the maximum achieved. The analysis is then conducted for the most suitable configuration from the point of view of bending stresses. If necessary, the pile length is adjusted by increasing the embedment to reduce the relative displacement at the top of the pile until the relative displacement criterion is met, and then the pile length is adjusted if it is necessary to embed more than required to reduce the relative displacement at the top of the pile until the relative displacement criterion is met in the most optimized way. This length adjustment will be reflected in the bending moments generated, so it should be re-evaluated with respect to the allowable moments of the proposed pile configuration. It should be noted that this process can be repeated several times until the most optimized result is obtained, with relative displacements and maximum moments below and closer to the allowable ones.

In addition to the bending stresses and relative displacements, the yielding of the foundation materials and the shear deformations associated with yielding will also be observed, looking for the formation of a failure mechanism that could lead to the pile collapse. After this stage, the solution is validated using the safety factors obtained by limit equilibrium, according to Brazilian and international standards, demonstrating the effectiveness of the solution.

3 RESULTS

3.1 Definition of the boundary conditions for the design of the structure

This stage of the project consists of defining the position and alignment of the pile rows and checking the conditions of the containment structure's foundation.

The location of the containment must take into account the conditions of the subsoil and the geomorphology of the terrain. In order to better understand the subsoil, a campaign of geotechnical investigations should be carried out, including field and laboratory tests that will help validate the geotechnical parameters of the area, define the stratigraphic profile of the subsoil and identify the water level. In order to define the specifications for the necessary driving system, it is important to check the resistance parameters. For this study, a geotechnical profile of a fictitious foundation was proposed.The geotechnical parameters for the foundation and materials were defined using values from the literature and are shown in Table 1.

3.2 Taling Dam without reinforcement

Based on the resistance and deformability parameters established above, the structure was checked for the current condition, without the implementation of reinforcement. In this condition, it was found that the dam does not present favorable safety conditions for the liquefied (Figure 1) and pseudo-static (Figure 2), scenarios, thus justifying the implementation of reinforcement works for these conditions.

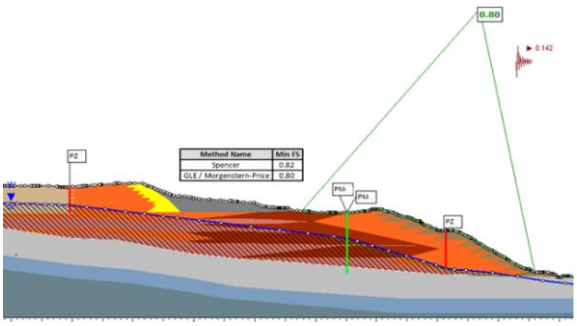

Figure 2. Stability analysis for the dam's base scenario - pseudo-static scenario.

3.3 Tailing dam with reinforcement

Bearing in mind that the project is presented as a definitive solution, the evaluation criterion for relative displacements is that they must be less than or equal to 1% of the total length of the pile. In this context, the section meets the established criterion with the greatest displacement occurring in axis 5 of the solution, at 0.94%. (Figure 3). As for the bending stresses, in the configuration defined for this section, in axes 1, 2 and 3, there is a solution with a 1200 mm pile, 21 mm thick and grade 50 steel, in which the maximum bending moment of 1926.8 kNm was verified in axis 2, which is lower than the 3516 kNm admissible for this configuration. For axes 4, 5 and 6, the solution is a 1500 mm pile, 25 mm thick and grade 50 steel, in which the maximum bending moment of 2171.9 kNm was verified. (Figure 4) in axis 6, which was lower than the 5446 kNm admissible for this configuration. Finally, as for the other evaluations, yielding and shear deformation, the section behaved satisfactorily and within expectations during the scenarios evaluated, undergoing yielding in some regions of the tailings. (Figure 5), with a maximum shear deformation of less than 5% near the piles (Figure 6), indicating that these regions where yielding occurs are not representative of a rupture wedge that could lead to the collapse of the structure. The results of the stress-strain study and the behavior of the piles in terms of permissible and acting moments are shown in Table 2. This fact was proven in the limit equilibrium analyses, which in the liquefied scenario the solution presents FS of 1.24 (Figure 7 higher than FS>1.1 and FS of 1.23 (Figure 8) for the pseudo-static scenario, higher than FS>1.1, both stipulated by the CDA (2019).

4 CONCLUSIONS

As presented, there are technologies available that can promote the geotechnical improvement of upstream dams, to increase the safety conditions of the structure and carry out its de-characterization process. The innovative nature of using the press-in method to reinforce these structures susceptible to liquefaction stands out. In this application context, this methodology becomes viable due to the low levels of vibrations during driving, which, through full-time control and monitoring, can avoid triggering liquefaction during the construction of the reinforcement. Therefore, given the relevance and risk levels associated with such geotechnical structures, to conduct the reinforcement, a monitoring plan must be implemented with the installation of quick response piezometers associated with geophones. It is worth mentioning that control levels must be previously defined through the execution of tested areas.

ACKNOWLEDGEMENTS

The authors are grateful to Fonntes Geotécnica for having provided an environment that supports us in overcoming challenges, with the opportunity and incentive to develop innovative projects to serve our clients and to disseminate the results in scientific circles to promote knowledge in the geotechnical community.

ABSTRACT: Estimating the characteristic value of strength parameters for design is an important matter in geotechnical practice. In this study, Latin Hypercube Sampling (LHS) is used to generate statistical meshes with the spatial variability of the friction angle and the true effective cohesion of the soil. For this, typical values of the coefficient of variation and of the horizontal and vertical scales of fluctuation of the friction angle and of the effective cohesion are adopted. Soil characterization is simulated in each of these statistical meshes. The characteristic values of the friction angle and effective cohesion are estimated following two procedures regarding the assumed knowledge of the soil properties. With these characteristic values, unsupported cuts are designed using the Load and Resistance Factor Design (LRFD) method. Slope stability analyses are performed with the software *mechpy*, using the Random Finite Element Limit Analysis (RFELA) and considering the above-mentioned meshes. Then, the probability of failure of the designed unsupported cuts is estimated using direct reliability analysis. The results show that adopting this procedure using simulation of site characterization has a substantial effect on the probability of failure.

RÉSUMÉ: L'estimation de la valeur caractéristique des paramètres de résistance pour le projet est une question importante pour la pratique géotechnique. Dans cette étude, l'échantillonnage hypercube latin (LHS) est utilisée pour générer des mailles statistiques avec la variabilité spatiale de l'angle de frottement et de la cohésion effective réelle du sol. Des valeurs typiques du coefficient de variation et des échelles horizontale et verticale de fluctuation sont adoptées pour caractériser le sol. Les valeurs caractéristiques de l'angle de frottement et de la cohésion effective sont estimés en suivant deux procédures en fonction de la connaissance supposée des propriétés du sol. Les talus d'excavation sont dimensionnés en utilisant la méthode *Load and Resistance Factor Design* (LRFD). Les analyses de stabilité des talus sont réalisées en utilisant le logiciel mechpy et le *Random Finite Element Limit Analysis* (RFELA) en prenant en compte les maillages statistiques. Enfin, la probabilité de rupture des talus d'excavation non soutenus est estimée à l'aide d'une analyse de fiabilité directe. Les résultats montrent que l'adoption de cette procédure utilisant la simulation de la caractérisation du site a un effet substantiel sur la probabilité de rupture.

Keywords: Characteristic value; simulated characterization; unsupported cut; probabilistic analysis; numerical limit analysis.

1 INTRODUCTION

The load and resistance factor design (LRFD) method uses representative values that can be taken as characteristic values, determined from the available data of soil characterization using statistical methods. When performing probabilistic analyses, it is important to take into account the spatial variability of soil properties to properly account for the inherent uncertainties, as it was shown in several studies that spatial variability has a significant effect on the probability of failure (Cho, 2007; Griffiths et al., 2009; Ji et al., 2012; Chok et al., 2015; Yang et al., 2022). The main objective of this study is to assess the influence of the procedure used for determining

the characteristic values of the effective cohesion, c', and the friction angle, ϕ', of soil on the probabilistic analysis of unsupported cuts under drained conditions, considering the effect of spatial variability. An adaptation of the Random Finite Element Method (RFEM) (Fenton & Griffiths, 2008), the Random Finite Element Limit Analysis (RFELA) is used for this purpose. A similar procedure can be applied to undrained conditions.

Latin Hypercube Sampling (LHS) is used to generate statistical meshes with the spatial variability of c', and ϕ' of soil in drained conditions, adopting typical values of the coefficient of variation, COV, and of the scales of fluctuation in the horizontal and vertical directions, θ_x, and θ_y (Phoon & Kulhawy, 1999; Cami et al., 2020; ISSMGE-TC304, 2021).

The characteristic values of the strength parameters are estimated through two scenarios regarding the knowledge of the soil properties. One where there's no prior knowledge of the mean value and COV of the soil properties, and the other where there's prior knowledge of these soil parameters. The first scenario is based on a site characterization simulated on the statistical meshes. Then, the characteristic value for each statistical mesh is estimated from the mean value and COV of c' and ϕ' therein obtained. In the second scenario, the characteristic value is estimated using the input parameters, the mean value, and the COV of c' and ϕ' used to generate the statistical meshes. The properties' design values are defined according to the principles of the Eurocode 7. The unsupported cuts are designed using deterministic stability analyses with Finite Element Limit Analysis (FELA). These stability analyses aim to evaluate the maximum unit weight γ_{EC7} for which the unsupported cuts with height h and inclination β verify safety.

The stability analyses of the designed unsupported cuts are then evaluated with RFELA. The probability of failure is estimated through the direct integration of the Probability Density Function (PDF) on the failure side of the limit state function (Huang & Griffiths, 2011). The limit state function is defined by the margin of safety, computed by the difference between the resistance and the loading (Baecher & Christian, 2003; Christian, 2004).

The generation of the statistical meshes, the simulation of site investigation, and the stability analyses of unsupported cuts are performed using the software *mechpy* (Vicente da Silva & Antão, 2013), developed at the Department of Civil Engineering of NOVA School of Science and Technology. This is a FELA software, where the kinematic and static theorems of limit analysis are implemented within a finite element analysis framework (Vicente da Silva et al., 2020). It has been applied by the authors to reliability analyses (Simões et al., 2014, 2020). The software uses a remesh procedure based on Martin's (2011) work. In this approach, the analyses are performed in 4 steps, in which the finite element meshes are progressively refined in the zones of higher plastic distortion.

2 DESCRIPTION OF THE PROBLEM

This paper considers a problem of an unsupported cut with h = 15 m, l = 12 m, L = 35 m, L_1 = 50 m, D = 22 m, and β = 45º, modelled in plane strain state, with the boundary conditions presented in Figure 1.

The shear strength parameters c' and $\tan\phi'$ (here regarded as uncorrelated random variables) with the mean values of 10 kPa and 27º, and COV of 0.2 and 0.08, respectively, are assumed to follow the lognormal distribution, with the scales of fluctuation θ_x (30, 50, 80, and ∞) and θ_y (1, 3, 80, and ∞), measured in meters. Hence, four cases are assessed, three of which with spatial variability [case 1 (θ_x = 30 m; θ_y = 1 m); case 2 (θ_x = 50 m; θ_y = 3 m); case 3 (θ_x = 80 m, θ_y = 80 m)], and one without spatial variability [case 4 ($\theta \to \infty$)].

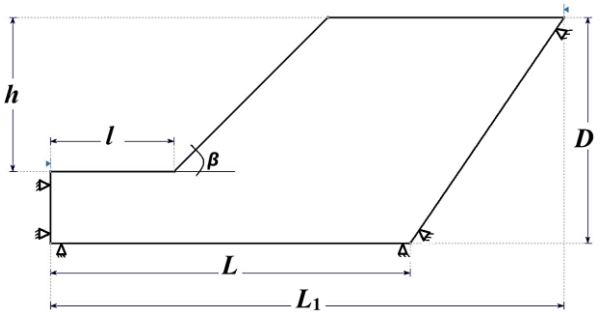

Figure 1. Geometry and boundary conditions of the numerical model.

The same values of scales of fluctuation are adopted for both c' and ϕ'. Cases 1 and 2 correspond to realistic situations, whereas case 3 is used for control and comparison with case 4. For cases 3 and 4, only the second scenario is considered.

3 GENERATION OF STATISTICAL MESHES

The generation of the random fields is achieved with LHS, a more efficient sampling technique than standard Monte Carlo (McKay et al., 1979;

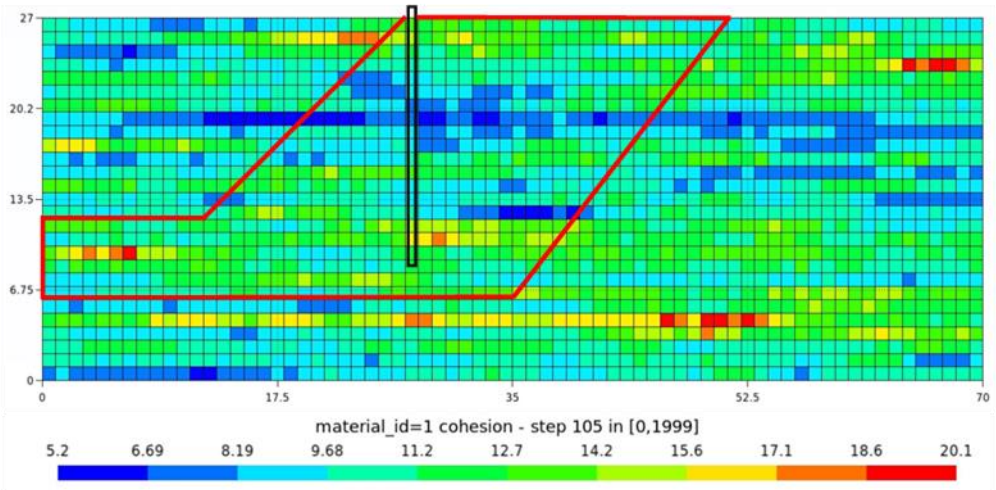

Figure 2. Example of a statistical mesh sample, of c' distribution, superposed with the geometry considered in finite element calculations.

Olsson et al., 2003). A two-dimensional ellipsoidal correlation function is used to describe the autocorrelation of the random variables (Fenton & Griffiths, 2008), from element to element, for a horizontal distance, Δ_x, and a vertical distance, Δ_y, from the centre of mass for the elements of the statistical mesh:

$$\rho(\Delta x, \Delta y) = \exp\left[-2\sqrt{\left(\frac{\Delta_x}{\theta_x}\right)^2 + \left(\frac{\Delta_y}{\theta_y}\right)^2}\right] \qquad (1)$$

in which ρ is the coefficient of correlation. An example of a statistical mesh is presented in Figure 2, with 70 m width and 27 m height, containing square statistical elements of 1x1 m^2 dimension. For this study, 2000 statistical meshes were generated for each of the cases 1 to 3 described in section 2.

4 SITE CHARACTERIZATION

The site characterization is simulated on both c' and ϕ' statistical meshes and provides the "exact" value of these spatially distributed random properties, although, in practice, measurement errors are inevitable (Yang et al., 2022). This simulation of site investigation is executed at the crest of the unsupported cut as shown in Figure 2 obtaining the values of c' and ϕ', from the top boundary down to $1.2h$. In this procedure, these values are collected at points situated 1 m from each other, assuming that such values could be obtained from site characterization, for each statistical mesh. The values of c' and ϕ' obtained in this way are used for determining the characteristic values of the parameters, for each sample, for the 1st scenario described in Section 1. In this scenario, 2000 characteristic values are calculated for each case, while in the 2nd scenario, only one characteristic value is computed for each case.

5 DESIGN

The characteristic value is defined from the values of the parameters of the statistical meshes using the following equation:

$$X_k = \exp[Y_m(1 - k_n.COV_{\ln X})] \qquad (2)$$

where Y_m is the mean value of the logarithms of individual parameters, and k_n is the statistical coefficient related to the type of distribution, confidence limit, and number of test values n. For the first scenario, k_n is calculated using the expression:

$$k_n = t_{n-1}^{0.95}\sqrt{1/n} \qquad (3)$$

in which $t_{n-1}^{0.95}$ is the student's t-value for n-1 degrees of freedom at a confidence level of 95% (Bond & Harris, 2006; Frank et al., 2004). In this scenario, n = 19, which corresponds to the number of values of c' and ϕ' collected in each characterization simulated.

As for the second scenario, k_n is estimated by:

$$k_n = N_{95}\sqrt{1/n} \qquad (4)$$

where N_{95} represents the Normal distribution, evaluated for a 95% confidence level and infinite degrees of freedom. For this scenario, k_n is computed by assuming n = 30.

The design value of the ground properties X_d is derived from the characteristic value by applying the Design Approach 1, Combination 2 (DA1 – C2) of the Eurocode 7 (EN 1997-1, 2004),

$$X_d = x_k/\gamma_M \quad (5)$$

in which γ_M is the partial factor of safety considered equal to 1.25 for c' and $\tan\phi'$.

6 STABILITY ANALYSIS

This process starts by mapping the values of c' and ϕ' from the statistical meshes into the finite element mesh with the geometry of the unsupported cut (Figure 2), as presented in the example in Figure 3 a). Subsequently, the stability analyses are performed, applying the kinematic and static theorems of limit analysis. The approximation of the unit weight that causes the collapse of the unsupported cut is obtained from both analyses and the average of the two, $\gamma_{RFELA,i}$, is determined for each statistical mesh sample. The failure mechanisms can be inferred from the mesh deformation and the maximum distortion (Figure 3 b)) in the case of the kinematic theorem calculations.

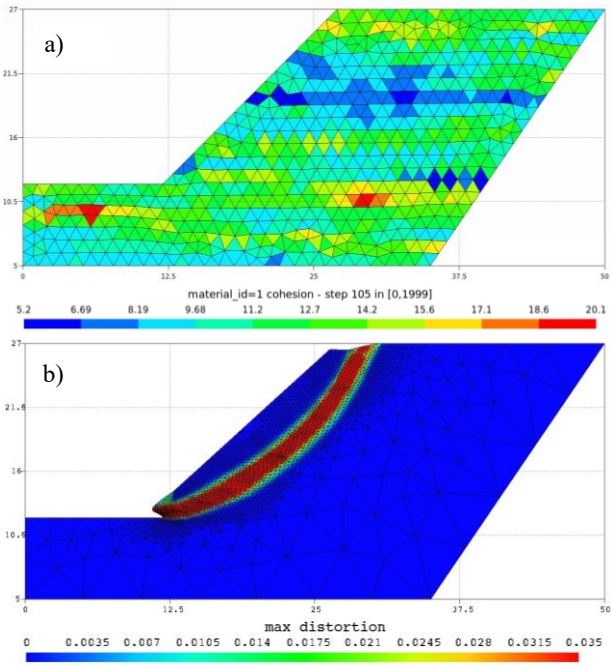

Figure 3. Example of a result of: a) mapping RFELA mesh values of c', and b) a deformed mesh with maximum distortion, determined from kinematic theorem calculations.

7 PROBABILITY OF FAILURE

For performing the direct reliability analysis, in this study, the margin of safety is computed as:

$$M = \gamma_{RFELA} - \gamma_{EC7}.(1 + COV.\Delta) \quad (6)$$

in which Δ is either zero or a random "noise" that follows the normal standard distribution, with a mean of 0 and a standard deviation of 1, assuming that COV is equal to 0.10. The implementation of the random "noise" seeks to simulate the effect of variability in the action.

The purpose is to find the probability of $M \leq 0$, and it is estimated using the cumulative distribution function of either the Normal or the Log-normal distribution.

For cases 1 and 2 it was found that the Normal distribution gave the best approximation to the data, and for cases 3 and 4 it was the Log-normal.

Figure 4 presents an example of the CDF of the margin of safety, for comparison of a situation with the random "noise" ($\mathbf{M\Delta} \rightarrow \Delta \neq 0$) and another without it ($\mathbf{M} \rightarrow \Delta = 0$). It is also possible to observe that the random "noise" has a significant effect on the probability of failure.

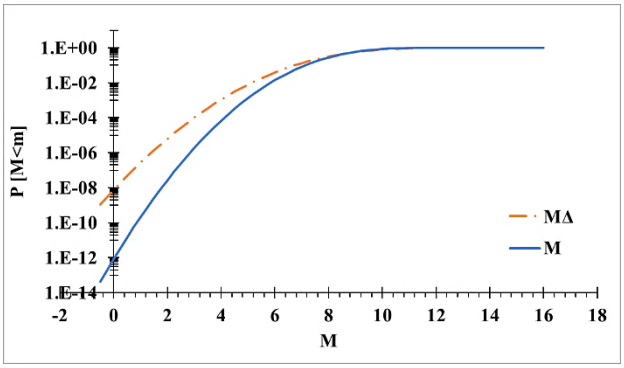

Figure 4. Cumulative distribution function of the margin of safety for case 1, with site characterization simulation.

Table 1 lists the results of the cases considered in this study. It shows that the probability of failure increases with the scale of fluctuation. There are clear differences in the results of the first (***1st sc.***) and the second (***2nd sc.***) scenarios considered. The probability of failure is substantially lower in the first scenario in both cases 1 and 2. The difference between the two scenarios is much greater when no random "noise" is considered.

Figure 5 presents the comparison between the curves of the cumulative relative frequency of cases 1 and 2, for $\Delta = 0$, 1st scenario. It shows how in the first case the values remain closer to the overall mean value of M, therefore with a lower probability of failure. This suggests that, with greater spatial variability (smaller θ), the mean values of ground properties along the slip surface in the generated statistical meshes are closer to its overall mean value. As the scale of fluctuation increases, the spatial distribution of ground properties approximates a

homogeneous state ($\theta \rightarrow \infty$). Therefore, the mean values of the properties in the statistical meshes along the slip surface exhibit a growing divergence from the overall mean value. When the spatial variability of shear strength properties is not considered in probabilistic analysis, the probability of failure is considerably higher (case 4).

Table 1. Results of the probabilistic analyses.

Case	θ_x	θ_y	p_f			
			$\Delta = 0^1$		$\Delta \neq 0^2$	
	(m)	(m)	*1st sc.*[3]	*2nd sc.*[4]	*1st sc.*[3]	*2nd sc.*[4]
1[5]	30	1	8.4×10^{-13}	2.2×10^{-9}	8.3×10^{-9}	3.8×10^{-7}
2[5]	50	3	5.8×10^{-8}	3.4×10^{-5}	2.0×10^{-6}	1.2×10^{-4}
3[5]	80	80	--	3.0×10^{-3}	--	4.6×10^{-3}
4[6]	∞	∞	--	2.7×10^{-3}	--	4.5×10^{-3}

[1]without random noise; [2]with random noise; [3]first scenario; [4]second scenario; [5]RFELA analysis; [6]FELA analysis.

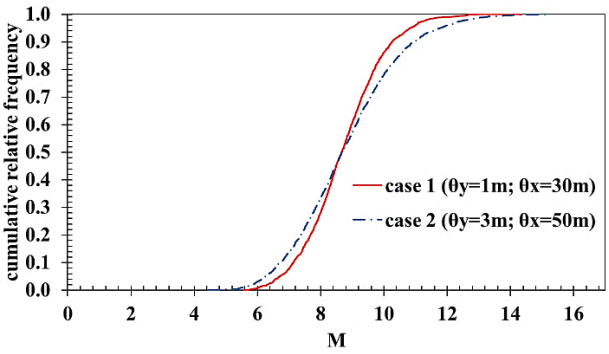

Figure 5. Example of the cumulative distribution function of the margin of safety, cases 1 and 2 (1st scenario; Δ=0).

When the scale of fluctuation is very high, $\theta = 80$ m (case 3), the probability of failure is of the same order of magnitude as the analysis with $\theta \rightarrow \infty$ (case 4). This is a consequence of the homogenization of the mesh caused by the low spatial variability.

These results demonstrate that when performing probabilistic analyses of unsupported cuts, it is important to consider the spatial variability of soil properties. It also shows the clear benefits of performing site characterization, for determining the characteristic value, rather than assuming complete knowledge of the grounds' properties, even in this case, where that knowledge was used to generate the samples themselves.

8 CONCLUSIONS

The degree of knowledge of a site's properties plays an important role in reliability analyses due to the influence of uncertainty on the probability of failure. The results show that the simulations of site characterization have a substantial effect on the probability of failure; in every case studied it decreased the value obtained. The use of the characteristic values obtained from the simulated site characterization has emphasized its importance in the probabilistic analysis of unsupported cuts, even when there is prior knowledge of the ground properties.

Uncertainty in the actions has a major impact on the probability of failure, as its effect resulted in a clear reduction of its value for both scenarios.

Spatial variability of ground properties, within a realistic range, has a considerable influence on the probability of failure. Neglecting it can lead to an overestimation of the probability of failure.

The significance of the correlation between c' and ϕ' in probabilistic analyses of unsupported cuts on spatially variable soils is an important aspect to ponder, and its effect is the subject of further study.

ABSTRACT: In this paper, a summary of the study on the accuracy of routine soil mechanics laboratory tests and their implications for engineering geologists is presented. The shear strength and physical properties of soils, all material parameters, which should yield consistent results across different laboratories for a given soil were examined. The accuracy of laboratory test results can be influenced by various factors, including the thoroughness of reconstituted slurry preparation, the choice of the apparatus or test method, or discrepancies in the processing of tests by the laboratory itself. To investigate this issue, several samples of fine-grained soils were submitted to 3 different soil mechanics laboratories. The findings revealed significant discrepancies in the results obtained. For instance, the determination of the clay fraction through grain size distribution exhibited differences of up to 43% between two laboratories (22% versus 65%). Similarly, significant variations were observed in the determination of shear strength parameters, where the critical friction angle differed by 8° on a single soil (20.5° versus 28.5°). These discrepancies have practical implications, particularly when considering numerical modelling of slope stability what can lead to unrealistic conclusions. This was demonstrated through a parametric study of a model landslide, which yields varying results for the factor of safety between 1 to almost 3. Overall, this study emphasizes the importance of accurate and consistent laboratory test results in soil mechanics across different laboratories. By addressing the factors influencing accuracy increases the reliability and practical implications of soil mechanics testing. Furthermore, given the inconsistencies in the results, the utility of correlation equations as a valuable tool for estimating shear strength of soils is demonstrated.

RÉSUMÉ: Dans cet article, un résumé de l'étude sur la précision des tests de mécanique des sols réalisés en laboratoire et leurs implications pour les géologues du génie est présenté. La résistance au cisaillement et les propriétés physiques des sols, tous des paramètres matériels qui devraient fournir des résultats cohérents dans différents laboratoires pour un sol donné, ont été examinés. La précision des résultats des tests de laboratoire peut être influencée par divers facteurs, notamment l'exhaustivité de la préparation des suspensions reconstituées, le choix de l'appareil ou de la méthode d'essai, ou les écarts dans le traitement des tests par le laboratoire lui-même. Pour étudier cette question, plusieurs échantillons de sols fins ont été soumis à 3 laboratoires de mécanique des sols différents. Les résultats ont révélé des écarts significatifs dans les résultats obtenus. Par exemple, la détermination de la fraction argileuse par la distribution granulométrique présentait des différences allant jusqu'à 43 % entre deux laboratoires (22 % contre 65 %). De même, des variations significatives ont été observées dans la détermination des paramètres de résistance au cisaillement, où l'angle de frottement critique différait de 8° sur un seul sol (20.5° contre 28.5°). Ces écarts ont des implications pratiques, notamment lors de la modélisation numérique de la stabilité des pentes, ce qui peut conduire à des conclusions irréalistes. Cela a été démontré à travers une étude paramétrique d'un glissement de terrain modèle, qui donne des résultats variant entre un facteur de sécurité de 1 à presque 3. Dans l'ensemble, cette étude souligne l'importance de résultats précis et cohérents des tests de laboratoire en mécanique des sols dans différents laboratoires. En abordant les facteurs influençant la précision, on augmente la fiabilité et les implications pratiques des tests de mécanique des sols. De plus, étant donné les incohérences des résultats, l'utilité des équations de corrélation comme outil précieux pour estimer la résistance au cisaillement des sols est démontrée.

Keywords: Laboratory testing; soil mechanics; shear strength, estimation of friction angle.

1 INTRODUCTION

Shear strength parameters and physical index properties are key soil conditions for reliable stability analyses. This study is mainly focused on the accuracy of the results of basic soil mechanics tests in the everyday practice of commercial laboratories in Czech Republic. Specific cases that involve possibly different results obtained from testing the same soil samples in three different soil mechanics laboratories are discussed. The aim is to quantify the sources of

differences, which may be attributed to various factors such as the type of testing equipment used, the correctness and precision of the laboratory tests procedure, and/or the laboratory's ability to correctly process the data obtained from the tests. The determination of shear strength parameters in the laboratory is the preferred method, but in this case it's possible to estimate them or/and check their correctness based on the correlation equations with some of the soil index properties. Numerous correlations have been established to estimate shear strength of cohesive soil based on liquid limit w_L (e.g. Stark and Eid, 1994), on the plasticity index I_P (Kenney, 1959, Equation (1); Kanji, 1974, Equation (3); Wood, 1990, Equation (2)), or on the clay fraction percentage c.f. (Skempton, 1964). Rohac et al. (2020) concluded that the best predictor for estimating of both shear parameters is I_P and preliminary evaluation by empirical correlations can be useful in the engineering practice. The shear strength parameters results differences' impact is demonstrated through a parametric study of slope stability using the geotechnical software Geo 5 considering the limit values of shear strength parameters for the same sample from the shear zone.

2 MATERIAL AND METHODS

2.1 Laboratories

To assess the accuracy of the results 6 soil samples were sent to 3 selected soil mechanics laboratories in the Czech Republic. All these laboratories are widely used for commercial purposes, in this study labelled as lab A, B and C. Shear strength laboratory tests were also performed by the authors of the study for comparison and are labelled as *This study*.

2.2 Soil samples

The soil samples consisted of 2 natural clays and refined kaolin and bentonite. The natural samples (labelled 1002 and 1009) were taken from the landslide-prone area of Prackovice in the Czech Republic during borehole investigation. The goal was to study not only the variation in results between different laboratories but also the differences within the same laboratory. Therefore, we sent both natural clay samples in two forms as thoroughly homogenized reconstituted slurry labelled as sample M and the same soil as dried core pieces from the borehole labelled as sample S (see Figure 1). In the case of the dried core, each laboratory had to prepare the reconstituted samples themselves, while reconstituted slurry samples (M) were prepared by the authors according to Burland (1990). This way, any potential influence of sample preparation on the results of laboratory tests can be monitored. The second group of samples included refined kaolin from Kaolin Malaysia Sdn Bhd labelled as KAOL and refined bentonite from the Černý vrch locality from Keramost, a.s., Czech Republic, labelled as BENT. These soils were chosen based on their different and in literature well studied physical properties (e.g. Sun et al., 2019; Duque et al., 2022). These samples were sent to the laboratories as dry powder.

Figure 1. Natural clay samples, both in two forms: slurry (M) and dried core (S).

2.3 Properties and parameters

In the laboratories, the physical properties of soils were determined, such as the liquid limit (w_L, determined by Casagrande cup in lab A and B, by cone penetration test in lab C), plastic limit (w_P), from which the plasticity index ($I_P = w_L - w_P$) was derived. Additionally, the grain size curve and the percentage of clay fraction (c.f.), defined as particles <0.002 mm were analysed. The shear strength parameters were also determined by different apparatuses depending on laboratory. Authors and lab A determined φ'_{cr} by triaxial CIUP test, while lab A, B and C used direct shear test. In the case of φ'_r, the authors and laboratory A determined it by ring shear test, laboratories A and B by direct shear box test.

The values of I_P from laboratories were used for estimation and/or verification of critical friction angle and residual friction angles based on following correlation equations from literature:

$$\varphi'_{cr} = 0.81 - 0.223 \log I_p \quad (1)$$

$$\sin \varphi'_{cr} = 0.35 - 0.1 \ln(I_p/100) \quad (2)$$

$$\varphi'_r = 46.6 I_P^{-0.446} \quad (3)$$

where φ'_{cr} and φ'_r are the critical and residual friction angles and I_P (%) is the plasticity index. These corelations were selected because of their widespread use and large dataset over which they were calibrated. Results of these estimations are compared with results obtained thru determination in the laboratories.

2.4 Slope stability

The most controversial shear strength results obtained from the laboratories were used in stability analysis of the well-studied landslide that disrupted the D8 highway in the Czech Republic in 2013 (Roháč et al., 2020). The factor of safety (FS) was analysed with the Geo 5 Software (Fine Ltd.) using the Morgenstern-Price method. The landslide condition corresponds to post-collapse, with FS≈1, where the φ'_r was used (Skempton, 1964, Palladino and Peck, 1972). The mechanical and geological setting of the soil from the slip surface was analogous to soil samples used in this study (Valečka, 1989).

3 RESULTS

3.1 Properties and parameters

All laboratory results are shown in Figure 2. The results of c.f. within a single sample (1009-S) reached a difference of up to 41% (22 vs. 63%). A systematic error is evident in the values: Lab A consistently (5 out of 6 cases) determined the lowest c.f. value, while lab B consistently reported the highest c.f. value for the same sample. Similar discrepancies were also shown in the determination of w_L, where lab A always determined higher values than lab B, both using the Casagrande cup method, lab C uses the cone penetration test. These differences were also reflected in the results of the plasticity index.

Furthermore, variations were noted in the results even within the same laboratory for samples S and M. Samples S consistently yielded lower c.f. values, likely due to incomplete soil mixing in the given laboratory. Significant differences were also observed in the results related to soil shear strength. For example, φ'_{cr} for sample 1002 ranged from 20.5°to 28.5°. It was observed that the direct shear test provided the result of shear strength higher by up to 8° compared to the triaxial device. The tendency depending on the shear apparatus used is consistent with Kostkanová and Herle (2012).

In the case of φ'_r , it was observed that the ring shear test provided the lowest value for the residual friction angle (lower by up to 6° compared to the direct shear test, 8.7 vs. 14.7°), consistently with literature (e.g. Vithana et al., 2012).

In the case of strength determination in lab B, parameters with a non-zero cohesion were obtained for both, residual and critical state shear strength (e.g., for sample 1002-S: $\varphi'_r = 3.5°$, $c_r = 44$ kPa). Consequently, these erroneous results were re-evaluated by the authors of this study in all cases using the dataset from the laboratory test protocols (e.g., for sample 1002-S: $\varphi'_r = 11.6°$).

The results of I_P were used for estimating of φ'_{cr} and φ'_r. Figure 2 also shows these estimations and compares them with the laboratory-determined results. The shear strength estimates for φ'_{cr} closely aligned with the results of triaxial tests for both sets of samples. The estimates of φ'_r in both cases overestimated values obtained from ring shear tests. This can be explained by the fact that the used eq. (3) was calibrated on the data from direct shear tests only (Kanji, 1973).

3.2 Slope stability

Table 1 illustrates the impact of different φ'_r results on FS of the analyzed slope.

Table 1. Differences in factor of safety FS.

Lab. test	φ'_r (kPa)	c_r (kPa)	FS
Ring shear	8.3	0	1.08
Direct shear	11.6	0	1.46
Direct shear	3.5	44	2.84
Equation (3)	9.5	0	1.22

Since the landslide condition corresponds to post-collapse, with an approximate FS of 1, the FS value is taken as a basis for evaluating the accuracy of the laboratory results and estimates of φ'_r. The most reliable result is determined by ring shear apparatus (FS=1.08). Conversely, an erroneously evaluated direct shear test with non-zero cohesion offered an unusually high FS value (FS=2.84), confirming its unsuitability for application in slope stability analysis. Interestingly, upon re-evaluating the data from this same test in accordance with the theory of soil mechanics, a more meaningful result was obtained (FS=1.46). As expected, the direct shear test reached higher φ'_r compared to the result obtained from the ring shear test. Lastly, the use of correlation equations for strength estimation proved to be very beneficial in this case, resulting in an FS value of 1.22.

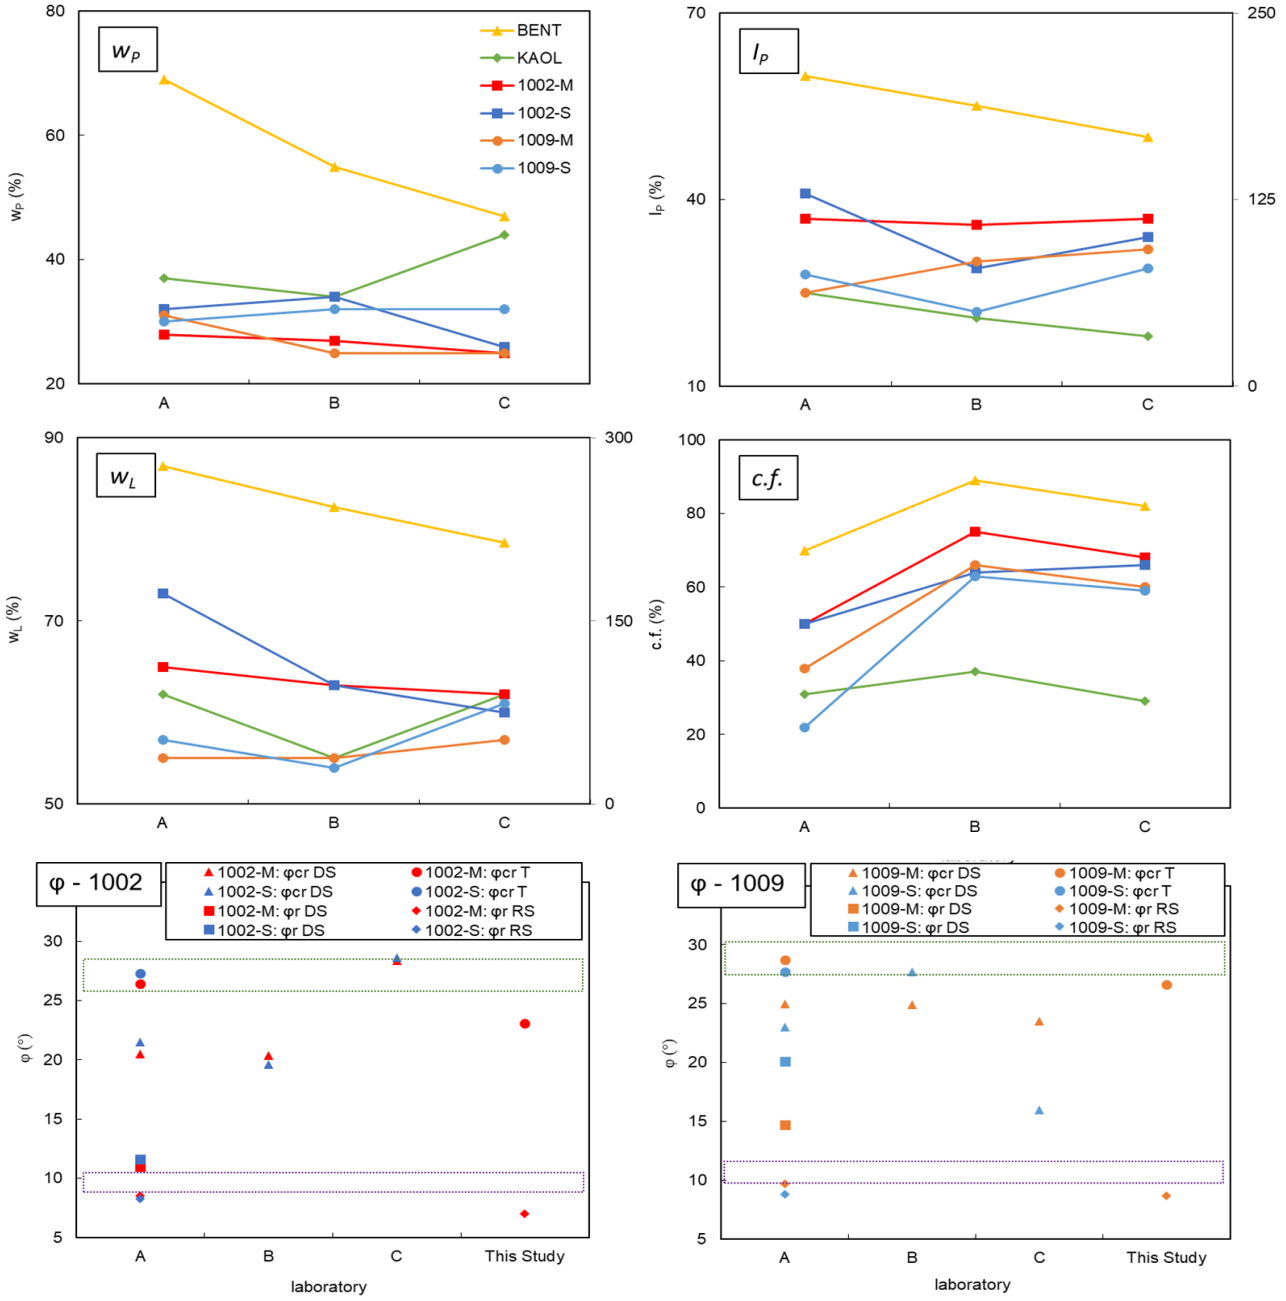

Figure 2. Results of all properties and parameters corresponding to the source laboratory (A, B, C) or This study; in graph for I_P and w_L – sample BENT (yellow) corresponds to the axis on the right side of the given graph; in graph for φ-1002 and φ-1009, results of Direct Shear tests (DS), Ring Shear tests (RS) and Triaxial CIUP tests (T); estimations of φ'_{cr} by combination of Equation (1) and Equation (2) labelled with green area, estimations of φ'_r by Equation (3) labelled with purple area.

4 CONCLUSIONS

- The slurry preparation process, specifically the level of thoroughness in mixing, significantly impacted the results obtained through subsequent research methods.
- A systematic error of laboratories in measurements was identified, particularly noticeable during the determination of clay fraction percentages and liquid limits.
- The selection of the shear test device type had a notable impact on the results of the internal friction angle.
- The inaccuracies in determining the internal friction angle had a significant impact on the factor of safety values for a landslide slope, potentially resulting in misleading conclusions in engineering geological surveys.

- Correlation equations can be a useful tool for verifying the results of the shear strength laboratory tests.

Assessment of seismic ground amplification at the Chieti courthouse site

Évaluation de l'amplification sismique du sol au palais de justice de Chieti

ABSTRACT: During the 2009 L'Aquila earthquake (M_W = 6.1), the Chieti courthouse was partially damaged by the ground shaking. To better understand the reasons why the damage affected essentially the southern portion of the structure, a study on local seismic response effects was carried out. The historical center of Chieti is located on the top of a hill (330 m a.s.l.), in the Periadriatic sector of Central Apennines, consisting of Pleistocene clays to sands and conglomerates deposits of the Mutignano formation (FMT), carved by Pescara and Alento rivers. The courthouse area is located above landfill deposits rich in historical artifacts, up to 10 m thick, covering sub-horizontal sandy-conglomerate deposits, about 30 m thick, which in turn overlay mostly pelitic lithofacies of the FMT several hundred meters thick. In this study, we reconstruct a geotechnical model of the Chieti hill mainly through *in-situ* (boreholes, SPT, DMT and SDMT) tests. Moreover, we performed a 2D FEM site response analysis to evaluate the ground motion spatial pattern in the courthouse site in terms of main ground motion parameters. An input motion representative of the 2009 L'Aquila earthquake was derived through a deconvolution of the 2009 recordings at the RAN accelerometric station of Chieti Scalo and applied at the seismic bedrock. Physical phenomena responsible for site effects are discussed by comparing 1D and 2D site response analyses at selected points.

RÉSUMÉ: Lors du séisme de 2009 à L'Aquila (M_W = 6.1), le palais de justice de Chieti a été partiellement endommagé par les secousses du sol. Pour mieux comprendre les raisons pour lesquelles les dommages ont affecté essentiellement la partie sud de la structure, une étude sur les effets de la réponse sismique locale a été réalisée. Le centre historique de Chieti est situé au sommet d'une colline (330 m d'altitude), composé d'argiles aux sables et aux dépôts de conglomérats, sculptés par les rivières Pescara et Alento. La zone du palais de justice est située au-dessus de dépôts d'enfouissement riches en artefacts historiques, jusqu'à 10 m d'épaisseur, couvrant des dépôts sub-horizontaux de conglomérat sableux, d'environ 30 m d'épaisseur, qui recouvrent à leur tour les lithofacies principalement pélitiques. Dans cette étude, nous avons procédé à une reconstruction du modèle géotechnique du col de Chieti obtenu par des essais in situ. De plus, nous avons effectué une analyse 2D FEM de la réponse du site pour évaluer le modèle spatial du mouvement du sol sur le site du palais de justice en termes de paramètres principaux du mouvement du sol. Un mouvement d'entrée représentatif du tremblement de terre de L'Aquila en 2009 a été obtenu par déconvolution des enregistrements de 2009 à la station accélérométrique RAN de Chieti Scalo et appliqué au socle rocheux sismique. Les phénomènes physiques responsables des effets sur le site sont abordés en comparant les analyses de réponse 1D et 2D du site à des points sélectionnés.

Keywords: 2009 L'Aquila earthquake; site response analysis; in-situ tests; numerical modelling.

1 INTRODUCTION

In 2009 a M_W 6.1 earthquake affected the area of L'Aquila, Central Italy, causing 309 victims and extensive damage to buildings and infrastructure. During this event, the courthouse of Chieti, an L-shaped masonry 3-storeys building, approximately 70 km far from the epicenter, was partially damaged. In this respect, a detailed site investigation of seismic dilatometer (SDMT) tests, foundation boreholes and cyclic laboratory tests were performed in 2011 on Chieti hill to restore this historical building. According to Amoroso et al. (2013), the geotechnical campaign allowed to detect weak zones in the Southern part of the building when compared to the Northern part of the structure in terms of constrained modulus and horizontal stress index in the upper 8 m of depth. This information resulted in agreement with the earthquake observations since the structure appeared to be considerably fissured in its Southern part, while approximately intact in the Northern area.

In this study, we reconstruct a geotechnical model of the Chieti hill mainly through the available in-situ (boreholes, SPT, DMT and SDMT) tests. Moreover,

we performed a 2D FEM site response analysis to evaluate the ground motion spatial pattern in the courthouse site. An input motion representative of the 2009 L'Aquila earthquake was derived through a deconvolution of the 2009 recordings at the RAN accelerometric station of Chieti Scalo and applied at the seismic bedrock. Physical phenomena responsible for site effects are discussed by comparing 1D and 2D site response analyses at selected points.

2 GEOLOGICAL SETTING

The historical center of Chieti is located on the top of a hill (330 m a.s.l.), in the Periadriatic sector of Central Apennines, consisting of Pleistocene clays to sands and conglomerates deposits of the Mutignano formation (FMT), carved by Pescara and Alento rivers. The courthouse area is located above landfill deposits rich in historical artifacts, up to 10 m thick, covering sub-horizontal sandy-conglomerate deposits, about 30 m thick, which in turn overlay pelitic-sandy (mostly grey clay) lithofacies of the FMT (Fig. 1a).

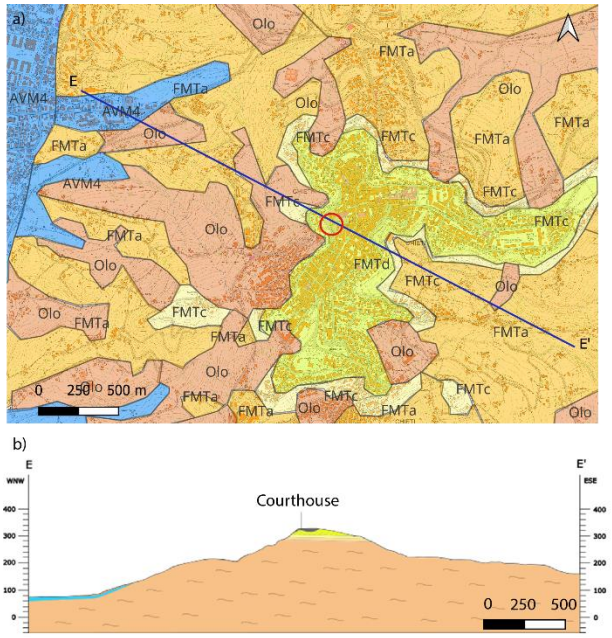

Figure 1. Geological map of Chieti (modified from CARG 361 Chieti https://www.isprambiente.gov.it/Media/carg/361_CHIETI/Foglio.html); FMT is Mutignano formation, when d is the sandy-conglomerate lithofacies, c is the sandy-pelitic lithofacies, and a is the pelitic-sandy lithofacies; the blue line depicted the EE' cross section; the red circle identifies the courthouse area (a). Cross section EE'; landfill deposits are represented only in the courthouse area and their position and thickness derived from available in-situ tests (b).

The geological cross section (Fig. 1b) shows a simplified version of the stratigraphic setting of Chieti hill. Landfill and Holocene slope deposits are only reported in the area of the Courthouse, due to the availability of data from boreholes, SDMT, DMT and SPT performing in previous studies. The seismic response is therefore analyzed in detail in the following only in this area.

3 SUBSOIL MODEL

The soil characterization for site response analyses was essentially based on the results of six seismic dilatometer (SDMT) tests, in virgin soil and in boreholes filled with sand, reaching a depth up to 50 m from ground level, carried out around the Courthouse (Amoroso et al., 2013). Average values for each lithotype were defined (Table 1); the Poisson ratio was assumed as 0.35 for all material with the exception of grey clay (0.43). Nonlinear normalized shear modulus (G/G_0) and damping (D) curves from literature were employed (Table 1). Cyclic simple shear tests were available for grey clays; however, given the high stiffness, a visco-elastic linear behaviour has been assumed for these materials. As matter of fact, the grey clays are characterised by shear wave velocity (V_S) values equal to 450-500 m/s in the upper part increasing with depth to 600 m/s as reported by down-hole (DH) tests available in the area of Chieti campus of the University of Chieti-Pescara (Italy) at the toe of the hill. No information is available on deep Vs profile in the FMTa. For this reason, the grey clays were characterized with an average value of 600 m/s and assumed as seismic bedrock in the deconvolution and direct site response analyses reported in the following.

Table 1. Reference subsoil model for Chieti hill with related mechanical parameters for each lithotype used in the analyses.

	Lithotype	γ (kN/m³)	Vs (m/s)	Nonlinear curves

4 SEISMIC RESPONSE AT THE CHIETI COURTHOUSE

4.1 Definition of input motion

For the definition of the seismic input, reference was made to the L'Aquila earthquake recordings of April 6, 2009 earthquake at the CHT permanent station located at the Chieti campus of the University of Chieti-Pescara. The subsoil model at the station (Table 2) has been defined using existing borehole logs and DH tests in the area as well as multichannel analysis of surface waves (MASW) and single station noise measurements carried out at CHT in the framework of the present study.

Table 2. Subsoil model at CHT for deconvolution analyses (h: thickness of soil layers).

Lithotype	h (m)	γ (kN/m³)	Vs (m/s)	Nonlinear curves
cover	2	17.1	160	Rollins et al. 1998 avg.
Alluvial soils (sands and silts)	10	18.5	280	Seed e Idriss 1970 upper b.
	8	18.5	310	Seed e Idriss 1970 upper b.
Alluvial soils (gravels)	6	20.0	460	Rollins et al. 1998 avg
Grey clays	-	20.5	600	-

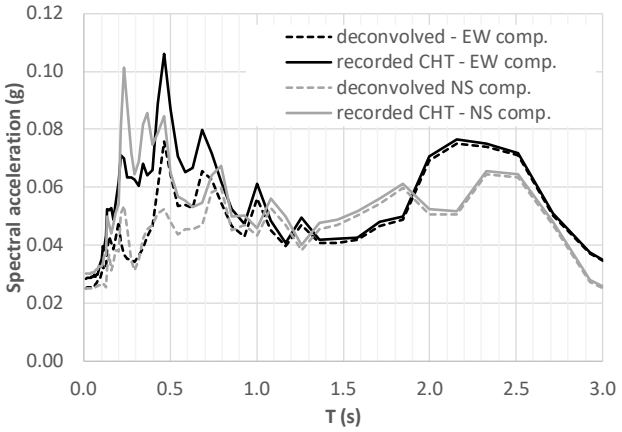

Figure 2. Recorded vs deconvoluted response spectra for April 6, 2009 earthquake.

Deconvolution analyses were therefore executed to derive the motion at seismic bedrock outcropping starting from the CHT recorded surface time history accelerations. Deconvolution analyses were executed with the 1D equivalent linear STRATA code (Kottke and Rathje, 2008) working in the frequency domain. It must be observed that the position of the real seismic bedrock (i.e. a material characterized by V_S equal or higher than 800 m/s) is unknown and the FMTa formation (mostly grey clays) at the bottom of the alluvial cover (V_S=600 m/s) were assumed as bedrock. Recorded and deconvolved response spectra are reported in Figure 2: as the amplification function is characterized by peaks at 2-4 Hz and 10-15 Hz, great reduction in spectral amplitude at outcropping bedrock is observed in the medium-to-low period range (i.e. below 0.5s).

4.2 2D seismic response analysis

Bidimensional site response analyses were carried out on the EE' cross-section (Fig. 1b) using the 2D finite element equivalent linear LSR2D code (https://www.stacec.com/). The computer code is extensively used in Italy especially for Seismic Microzonation purposes and it has been validated using other well-known 2D FEM codes like QUAD4M (Pagliaroli et al., 2020). The bedrock is constituted by the grey clays (V_S=600 m/s) and therefore the deconvolved motion has been assumed as input motion of the analyses. The physical and mechanical properties of the materials are reported in Table 1. Three control points were selected for output motions: A and B at eastern and western sides of the Courthouse, respectively and C at the location where maximum thickness of landfills is reached (Figure 3a). At these points, additional 1D STRATA analyses were also executed in order to assess the influence of morphological and topographic features on the ground motion through the 2D/1D comparison.

The comparison between 1D and 2D response is shown for node A in Figure 3; similar considerations can be made for the other nodes. The 2D analyses predicts higher spectral acceleration with respect the 1D model in the whole period range. The effects of the landfills is evident at low periods (0.1-0.2 s) where the coupling between stratigraphic and morphological effects leads to higher values in 2D analyses. At longer periods the response is essentially driven by 2D effects: in particular the amplification at 2-3s can be related to the 2D resonance of the upper part of the Chieti hill according to the model by Paolucci (2002). Other complex 2D effects take place at 0.4-0.6s.

The comparison of the 2D response in the three selected nodes (Figure 3) highlights the role of the landfills: nodes C, characterized by the higher fills thickness (around 12m) is characterized by major spectral accelerations exceeding 0.1 g in 0.15-0.25s range. Slightly higher amplitudes can be found at node B with respect to A in the same range showing ground motion variation in the Courthouse area. The spectral amplitude at 2-3s is the same in all the nodes thus confirming the 2D resonance of the hill as driving phenomena. The 2D effects at 0.4-0.6s (showing differences between A-B and C) are probably related

to topographic effects at the hill edge (A-B are closer to hill border than C) or to the buried morphology of the contact between landfill and the underlying sands.

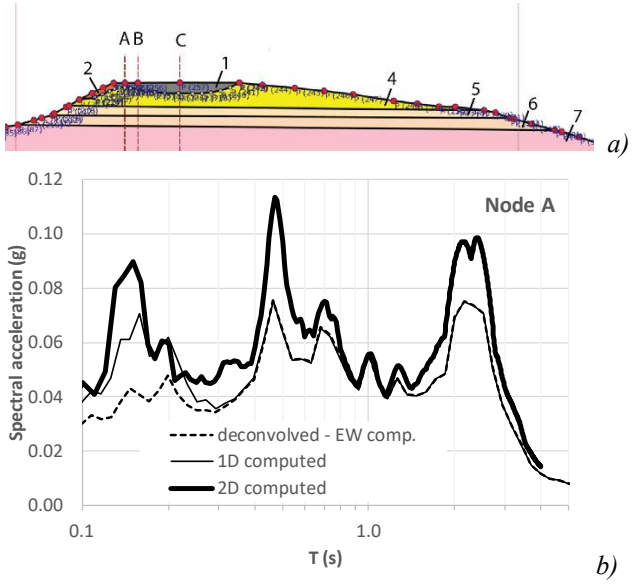

Figure 3. Stratigraphy of the courthouse area with the position of control points and lithotypes numbered as in Table 1 (a), 1D and 2D computed response spectra compared with input motion for EW component (b).

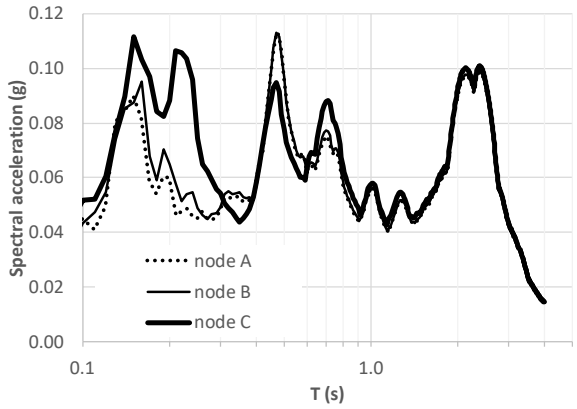

Figure 4. Response spectra computed with 2D analyses at node A-B-C for EW component.

5 CONCLUSIONS

The paper reports the results of the seismic response of Chieti hill during the April 6, 2009 earthquake which induced damage to the Courthouse historical building. The signal recorded by the CHT station at the toe of the hill was deconvoluted by means of 1D equivalent linear analyses to the outcropping of grey clays assumed as seismic bedrock of the area. *Ad hoc* MASW and single station microtremor tests were carried out for the geotechnical characterization of CHT site. The subsoil model of the Chieti hill has been reconstructed using several existing seismic dilatometer (SDMT) tests performed in the area of the Courthouse. The CHT deconvoluted signal was used as seismic input for 2D finite element modelling of the Chieti hill. The output results were processed in terms of acceleration response spectra with particular reference to the Court area where additional 1D modelling were executed, in order to highlight the 2D effects related to the buried and surficial morphology.

The comparison between 1D and 2D modelling highlighted amplification of ground motion related to stratigraphic effects of the landfill cover around 0.1s where spectral accelerations as high as 0.1g are reached. Additional 2D effects were found around 0.4-0.6s, including the fundamental period of the Courthouse, probably related to topographic effects at the hill edge and to the buried morphology. Finally, 2D resonance effects of the upper part of the hill is responsible for further amplification around 2-3 s.

The amplifications linked to the variations in thickness of landfills are relevant for the historical buildings of few floors located on the top of the Chieti hill. More efforts should be devoted to reconstruct the landfills distribution along the Chieti hill for a comprehensive seismic risk assessment of the building stock and cultural heritage of city centre.

ABSTRACT: In the CEN/TC250 Programming Mandate M/515, the lack of compatibility between Eurocode 7 and Eurocode 8 was clearly addressed when directions for development of the new generation of EN 1997 and EN 1998 were outlined. In the present paper the most relevant modifications of the new Codes are illustrated outlining the inputs required by Eurocode 8, parts 1 and 5, for site categorisation and seismic geotechnical design, followed by the illustration of the new items introduced in Eurocode 7 to ensure that ground investigation and the resulting ground model properly consider seismicity between their objectives.

RÉSUMÉ: Dans le mandat de programmation M/515 du CEN/TC250, le manque de compatibilité entre l'Eurocode 7 et l'Eurocode 8 a été clairement abordé lorsque les orientations pour le développement de la nouvelle génération des EN 1997 et EN 1998 ont été définies. Dans le document, les modifications les plus pertinentes des nouveaux codes sont illustrées en présentant d'abord les entrées requises par l'Eurocode 8, parties 1 et 5, pour la catégorisation des sites et la conception géotechnique sismique, puis par l'examen des nouveaux éléments introduits dans l'Eurocode 7 pour garantir que l'investigation du sol et le modèle de sol qui en résulte prennent correctement en compte la sismicité entre leurs objectifs respectifs.

Keywords: Ground model; seismic geotechnical design; Eurocode 7; Eurocode 8; ground investigation.

1 INTRODUCTION

In the CEN/TC250 Programming Mandate M/515, the lack of compatibility between Eurocode 7 (EN 1997-1: 2004) and Eurocode 8 (EN 1998-5: 2004) was specifically addressed when directives for development of the new generation of EN 1997 and EN 1998 were given. To fulfil the Mandate, an Evolution Group 6 (EG6) was established by SC7 from which the following principles and line of actions were suggested: a) the design of a geotechnical structure is a unique process that needs to be accomplished by considering all possible boundary (e.g., loading) and environmental (e.g., seismicity) conditions since the very beginning of the design process; b) recommended design procedures must ensure a smooth transition between static and seismic design: transfer of seismic action effects to the ground should consider the possibility of permanent displacements of foundations and retaining structures and energy dissipation mechanisms in the ground; c) more emphasis is needed in both EN 1997 and EN 1998 for the assessment of seismic-dynamic properties of the ground: ground investigation covered in EN 1997-2 must include appropriate tests for seismic design (e.g.: geophysical methods for site investigation, cyclic and dynamic laboratory testing); d) verification of the seismic performance of a geotechnical structure should be possible with both approaches adopted in EN 1997, that is, Material factor approach (MFA) and Resistance factor approach (RFA).

Limiting to some relevant aspects only, the purpose of the paper is to illustrate and discuss from the specific perspective of Eurocode 7 how the Mandate

requirements have been implemented and the practical consequences for geotechnical design within the new generation of Eurocodes.

2 THE CONTRIBUTE OF EUROCODE 7 TO SEISMIC DESIGN

Reading through Part 1 and Part 5 of FprEN 1998, it is clear that prEN1997-2023, hereafter indicated as EN 1997 for simplicity, has been conceived considering also the geotechnical inputs for seismic design. Most relevant information is in fact included among the objectives of the Ground Model, that is a tool conceived to represent all basic properties of a site, specifically those not dependent from the programmed construction. The content of the Ground Model includes, but is not limited to, the following items:

- Bedrock & structural geology
- Geology & geomorphology
- Seismicity
- Hydrogeological conditions
- Geotechnical conditions

The Ground Model should be developed from the very beginning of design and progressively developed and updated with information from ground investigation (desk studies; field and laboratory investigations; information obtained with monitoring).

In FprEN 1998-1-1:2024, hereafter indicated simply as EN 1998-1, site conditions must be assessed before any quantitative evaluation of the seismic action expected at the site. With this aim, knowledge of the site geology and seismicity from regional seismic risk maps is needed; potentially active faults or other causes of permanent ground deformation and settlements, such as the presence of unstable slopes affecting the area or of potentially liquefiable soil deposits under the considered seismic action, should be identified. According to the above list, all these items are in fact the specific ingredients of the Ground Model to be progressively addressed from the beginning of the design process (JRC 2024).

In EN 1998-1, site conditions are discussed in Clause 5 for the evaluation of the seismic action. In this clause a site categorisation is proposed for simplified assessment of stratigraphic amplification. Categories are preferentially established on the basis of the profile of the shear wave velocity v_s in the ground and of the depth of the conventional seismic bedrock H_{800} (i.e., the depth at which v_s is larger than 800 m/s). According to EN 1998-1, the site may fall in one of six different categories, ranging between A and F, as described in Table 1, where $v_{s,H}$ is the equivalent shear wave velocity computed over the depth H_{800}.

Table 1. Site categorisation based on bedrock depth H_{800} and the equivalent shear wave velocity value $v_{s,H}$. (reproduced from FprEN 1998-1-1:2024).

	Ground class	**Stiff**	**Medium stiffness**	**Soft**
Depth class	$v_{s,H}$ range / H_{800} range	400 m/s ≤ $v_{s,H}$ < 800 m/s	250 m/s ≤ $v_{s,H}$ < 400 m/s	150 m/s ≤ $v_{s,H}$ < 250 m/s
very shallow	$H_{800} \leq 5$m	A	A	E
shallow	5m < $H_{800} \leq$ 30m	B	E	E
intermediate	30m < $H_{800} \leq$ 100m	B	C	D
deep	$H_{800} \geq 100$m	B	F	F

When the full set of information is not available, the normative Annex B of EN 1998-1 gives a simplified procedure to assign the site category. Such procedure relies upon a combination of qualitative and quantitative parameters, the former describing the predominant soil type and the latter its consistency, through an estimate of its stiffness range. Two more options are given by EN 1998-1 when information for site classification is incomplete: when direct measurements of v_s are not available, it is possible to estimate the v_s profile from well-established empirical correlations between v_s and geotechnical parameters or field test results; when the bedrock depth H_{800} is not known the soil category may be assigned from the equivalent value of the shear wave velocity $v_{s,H}$ and the fundamental frequency of the soil deposit f_0. Finally, the identification of the bedrock may also be obtained from geological, geophysical, or geotechnical

information, including microzonation maps. Whatever the procedure to characterise the ground is, standard or simplified, a field investigation is always needed to quantify ground properties. Such investigation shall include the identification of the soil constituting the deposit and some intrusive in situ testing (e.g. static or dynamic penetration tests, vane and pressuremeter tests or laboratory testing). With the 2nd generation of Eurocodes the geotechnical designer must keep well in mind that geotechnical seismic design needs to be supported with data collected with the ground investigation and that such data must be included in the Ground Model. This is not the case for the present version of Eurocodes, where the ground investigation for the seismic design is not explicitly included in the ground investigation for geotechnical design, resulting in a very weak link between EN 1998-5:2004 and EN 1997-2:2007 for the evaluation of ground properties.

A clear separation between the two Eurocodes can also be found in the approaches for verification of limit states. Significant steps have then been taken to implement compatibility between static and seismic geotechnical design. According to FprEN 1998-5:2024, hereafter shorted as EN 1998-5, both the Material Factor Approach (MFA) and the Resistance Factor Approach (RFA) may be used to verify that the design resistance R_d is greater or equal to the design value of the effects of actions E_d. This is not the case for the present version of EN 1998-5, that allows only verifications with MFA. Moreover, a very close link between EN 1998-5 and EN 1997-2 (2nd generation) emerges from Clause 6 of the seismic Code on ground properties. According to 6.1(2), derived and representative ground properties are explicitly considered for seismic design and their values are those indicated by the Ground Model and the Geotechnical design model respectively. Note that in the present version of EN 1998-5, a distinction between derived and characteristic values of ground properties was not considered, and design values did not appear explicitly in the code. On the contrary, with the 2nd generation of EN 1998-5, many requirements on the ground investigation are given. Among these: suggestion for measurement of the v_s profile with geophysical methods or alternatively the use of empirical correlations with standard penetration and/or static cone penetration tests. Finally, specific reference to cyclic and dynamic laboratory tests is made for a direct derivation of geotechnical properties, such as strain dependent stiffness and damping ratio. In turn, many clauses of its parts 1 and 2 provide indications on how implement the Ground model considering specific inputs for seismic design.

Criteria to design the ground investigation are given in EN 1997-2. In the preliminary investigation seismic hazard has to be addressed and determined. Moreover, within the scopes of the design investigation, seismic properties of ground are explicitly indicated in Clause 3. Criteria given for the planning of investigations in Clause 5.4.1 (4) prescribe that the extent of investigation shall cover the depth for calculation of the seismic ground response as specified in EN 1998-1 Clause 5 and EN 1998-5 Clause 6. A note to the same clause states that the Zone of Influence under cyclic, dynamic and seismic actions can be different from the one under static loading; consequently, the extent and the objectives of ground investigations must be revised accordingly. Although never actually stated in the Code, the above criteria must be reflected by the Ground Model whose extent should match the Zone of Influence that has been identified for the project and that must fully cover the volume of investigation.

The determination of ground properties for cyclic, dynamic and seismic design is addressed by EN 1997-2 Clause 10. Ground investigations should provide relevant information on:

- stress-strain response to cyclic actions, including small strain stiffness,
- energy dissipation properties,
- development of excess pore water pressures under cyclic actions,
- shear strength under cyclic action,
- post cyclic behaviour in terms of post-cyclic shear strength,
- dissipation of cyclic-induced pore water pressure, and other associated deformations,
- cyclic undrained shear strength for liquefaction assessment (see EN 1998-5).

The direct determination of the shear and compressional wave velocities is addressed by Table 10.2 of EN 1997-2 with a comprehensive list of geophysical tests followed by recommendations on their selection. Consistently with the cases considered by EN 1998-1 a list of tests to be used for indirect determination of the shear wave velocity profile is also given, with indication of the appropriate test standard to follow and of the requirements for interpretation of results. Particularly relevant to implement the seismic site categorisation of EN 1998-1 is the subclause 10.7, addressing the determination of the position of the bedrock and of the fundamental frequency f_0 of the soil deposits. Depth of the seismic bedrock may be obtained from geophysical tests or by indirect methods

if accompanied by direct inspection of samples retrieved from the bedrock layer. The fundamental frequency of soil deposits may be estimated from records of ambient vibrations at the ground surface transformed in the horizontal-to-vertical spectral ratio (HVSR). Laboratory tests for measuring response to cyclic and dynamic actions are listed in Table 10.1 of Clause 10, reproduced below as Table 2, with indications of the strain level for which each testing method is appropriate. A specific subclause considers laboratory testing to obtain information on the variation of the secant shear modulus and damping ratio against shear strain. These data are particularly relevant for numerical modelling of geotechnical structures subjected to seismic loading. When results from laboratory testing are not available, EN 1997-2 presents in Annex G methods to obtain seismic properties indirectly from empirical correlations with soil physical properties or with results of field testing.

Table 2. Laboratory tests for measuring response to cyclic and dynamic actions. (reproduced from prEN 1997-2).

	Laboratory test (and associated test standards)					
Test	**Cyclic torsional shear**	**Cyclic direct simple shear**	**Cyclic triaxial**	**Resonant column**	**Bender elements**	**Cyclic triaxial for rock**

Medium (10^{-2} -10^{-1})	-	(full)	full	-	-	-

- = not applicable; 'one' = one conventional value; 'full' = full curve; () = partially applicable

3 CONCLUSIVE REMARKS

The 2nd generation of Eurocode 7 has been conceived with the formalization of a new concept, that is the Ground Model defined as a site-specific collection of data about geometry and properties of the ground and groundwater, based on results from field investigation and other available data. This definition implies that also the seismic properties of the ground must be included in the Ground Model, and this has important consequences on the design of Ground Investigation and on Reporting. EN 1998-Parts 1 and 5 and EN 1997 Parts 1 and 2 have been considerably influenced by the assumptions that the Ground Investigation is a comprehensive activity, programmed to fulfil all the needs for geotechnical design including those motivated by seismic actions. The Ground Model is the tool to share among all the actors involved in design a comprehensive representation of the site. It contains all the features to ensure safety and serviceability for any possible design situations, including the seismic one. A specific Guideline on the implementation of the Ground Model will be made available by TC250/SC7, together with similar guidelines on the most innovative aspects of the 2nd generation of Eurocode 7.

Influence of pore fluid composition on shear strength of reconstituted normally consolidated kaolinite

Influence de la composition du fluide interstitiel sur la résistance au cisaillement de la kaolinite reconstituée et normalement consolidée

M. Schröder*, J. Grabe
Hamburg University of Technology, Hamburg, Germany
**Maximilian.schroeder.gbt@tuhh.de*

ABSTRACT: Kaolinite is a prominent proxy material in geotechnical engineering that is regularly used in small- and large-scale geotechnical modelling and testing. The material is usually mixed with demineralised water and reconstituted subsequently. This contribution investigates the influence of pore fluid composition on the angle of shearing resistance of very pure kaolinite through CIU triaxial tests. Potassium, sodium and calcium chloride are tested in different concentrations. The results show that adding salt increases the shearing resistance angle. However, other influential factors like pH, valence and atomic radius also play significant roles. Future investigations will expand towards illite and a broader range of studied salt concentrations.

RÉSUMÉ: La kaolinite est un matériau de substitution important dans l'ingénierie géotechnique, régulièrement utilisé dans la modélisation et les essais géotechniques à petite et grande échelle. Le matériau est généralement mélangé à de l'eau déminéralisée et reconstitué par la suite. Cette contribution étudie l'influence de la composition du fluide interstitiel sur l'angle de frottement de la kaolinite très pure au moyen d'essais triaxiaux CIU. Les chlorures de potassium, de sodium et de calcium sont testés à différentes concentrations. Les résultats montrent que l'ajout de sel augmente l'angle de frottement. Cependant, d'autres facteurs influents tels que le pH, la valence et le rayon atomique jouent également un rôle significatif. Les recherches futures s'étendront à l'illite et à une gamme plus large de concentrations de sel étudiées.

Keywords: Clay; shear strength; salt; kaolinite.

1 INTRODUCTION

Using reconstituted proxy materials for fine-grained soils is common in geotechnical engineering, the most prominent material being kaolin. Applications reach from triaxial testing for constitutive model development and application (Wichtmann and Triantafyllidis, 2018; Dao et al., 2023) to centrifuge modelling (Gaudin et al., 2011). In most cases, the industrial dry clay powder is mixed with demineralised or de-ionized water to prepare a slurry, which is consolidated afterwards.

This paper investigates the influence of the pore water composition on the shear strength of kaolinite as representative of the 1:1 clay mineral. For this purpose, slurries are mixed with different salt concentrations and types. A total of five CIU triaxial tests were performed. The results from tests with salt are compared to the use of demineralised water, representing the established approach from the literature.

2 FINDINGS FROM THE LITERATURE

Lambe (1958) elaborates that shear strength is reduced if

- salt concentration is lowered,
- pH increases or
- the valency of the compound (salt type) is lowered (e.g. from Ca^{++} to Na^{+}).

All the above-stated phenomena expand the double layer of the clay particles and reduce their attraction.

Warkentin and Yong (1962) explain that the shear strength of kaolinite strongly depends on the fabric and identify three different structure types with decreasing associated strength. They attribute the highest shear strength to an edge-to-face flocculated structure, which Lambe (1958) calls non-salt flocculation. This structure is created at low pH (Osipov, 1975). The strength is further reduced if the clay is dispersed or deflocculated (higher pH). The lowest shear strength is attributed to face-to-face flocculation. Lambe (1958) names this salt flocculation. It occurs at high salt concentrations when the diffuse double layer reduces,

and the repulsive forces of the negatively charged faces are reduced.

According to Warkentin and Yong (1962), the shear strength depends on the amount of contact per unit volume and the strength of the interparticle forces of each contact. This means that a flocculated fabric can lead to either high or low shear strength depending on the strength of the interparticle forces present.

3 MATERIALS

3.1 Pore fluids

A total of five different pore fluids, which are labelled according to Table 1, are studied. Pore fluid 1 represents demineralised water. The pore fluids 2 and 3 are a 0.01 molar calcium chloride ($CaCl_2$) and a one molar potassium chloride (KCl) solution as used in the GLOSOLAN-SOP-06 standard for soil pH determination (Global Soil Laboratory Network, 2021). The study then expanded towards using sodium chloride (NaCl) and calcium chloride solution at the same concentration in grams per litre at high salt content to provoke a strong influence of salt type. Table 2 shows the determined conductivity and pH values of the used fluids.

Table 1. Studied pore fluids – composition.

Salt type	Concentration [g/l]	Concentration [M]
demineralised	-	-
$CaCl_2$	1.11	0.01
KCl	74.55	1.00
NaCl	74.55	1.28
$CaCl_2$	74.55	0.67

Table 2. Studied pore fluids – conductivity and pH.

Pore fluid	Conductivity [mS]	pH [-]
demineralised	≈ 0	6.9
0.01M $CaCl_2$	2.35	8.0
1M KCl	108.4	7.5
1.28 M NaCl	109.4	6.7
0.67 M $CaCl_2$	103.6	10.1

3.2 Clay

3.2.1 General properties

An industrially available clay powder is studied in this work. The material is similar to the one in Martinez and Stutz (2019). The mineralogical composition of the materials and selected properties are given in Tables 3 and 4. The particle size distribution of the material is depicted in Figure 1.

Table 3. Studied kaolinite–selected properties.

Property	Value
Specific surface [m²/g]	14.8
D_{50}-value [µm]	0.7
Particle specific gravity [g/cm³]	2.675

Table 4. Studied clay – Mineralogical composition determined by high-quality XRD analysis.

Mineral	Mass per cent [%]
Quartz	1.1
Illite	3.2
Kaolinite	95.7
Clay (total)	98.9

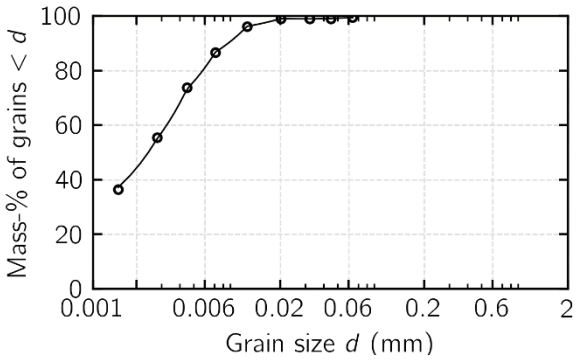

Figure 1. Particle size distribution of studied clay.

3.2.2 Atterberg limits and plasticity

Liquid limits, as determined by the Casagrande method, and plastic limits and indices are shown in Table 5. The results show the values determined from three tests. Dry powder and fluid were mixed at a mass ratio 1:2, left for four days to equilibrate and tested from wet to dry state, meaning that the slurry is dried further throughout the test.

Sodium chloride in such a high concentration affects kaolinite powder in such a way that the validity of classic Atterberg testing procedures should be questioned. The material does not behave like soil when remoulded. Most likely, this is due to the large atomic radius of sodium chloride. This reduces particle contact.

Table 5. Atterberg limits.

Pore fluid	Liquid limit [%]	Plastic limit [%]	Plasticity index [%]
demineralised	56.7	31.7	25.0
0.01M $CaCl_2$	59.1	34.5	24.5
1 M KCl	59.6	35.9	23.7
1.28 M NaCl	41.9	32.0	9.9
0.67 M $CaCl_2$	51.3	28.0	23.3

4 TESTING

4.1 Sample preparation

The dry industrial clay powder is pre-mixed with the solutions under atmospheric conditions, while the dry powder is mixed into the total liquid, not vice-versa. In the second stage, the pre-mixed slurry is homogenised by vacuum mixing for one hour. Finally, the slurry is carefully poured into consolidation columns and initially consolidated by applying a pressure of 300 kPa. The water content of the slurries is different for each pore fluid chosen, assuring good mixability while maintaining a high content of solids. All slurries are mixed at a minimum of 1.5 times the liquid limit but differ from the ratio used to determine Atterberg limits. All three samples for one test are cut out of the same batch using metal cylinders. Final consolidation takes place in the triaxial device.

4.2 Testing procedure

Tests are performed on normally consolidated samples with dimensions of 36 mm diameter and a sample height of 90 mm. The initial void ratios of the specimens are given in Table 6. The shearing velocity is set to 0.02 mm/min at 18 degrees Celsius. The back pressure is set to 400 kPa. Tests are performed with 400, 600 and 800 kPa effective confining pressure.

Table 6. Initial void ratios before consolidation (-) of the triaxial specimens.

Pore fluid	Sample 1 (400 kPa)	Sample 2 (600 kPa)	Sample 3 (800 kPa)
demineralised	1.429	1.465	1.471
0.01M $CaCl_2$	1.471	1.487	1.461
1 M KCl	1.822	1.790	1.796
1.28 M NaCl	1.365	1.334	1.370
0.67 M $CaCl_2$	1.391	1.385	1.423

4.3 Results

The slope of the Mohr-Coulomb failure envelope and the axis intercept are given below in Table 7. Regression analyses were performed in the t-s stress field, with the maximum stress ratio being set as the failure criterion. Membrane and filter paper corrections were not performed. Figure 2 shows the stress paths in the t-s field for the samples using demineralised water exemplarily. As expected, the samples behave normally consolidated.

Table 7. M-C failure envelope parameters for kaolinite.

Pure fluid	The slope of the curve φ [°]	Axis intercept c [kPa]
demineralised	20.16	23.81
0.01M $CaCl_2$	25.12	0.00
1 M KCl	32.23	0.00
1.28 M NaCl	24.15	1.78
0.67 M $CaCl_2$	23.24	1.09

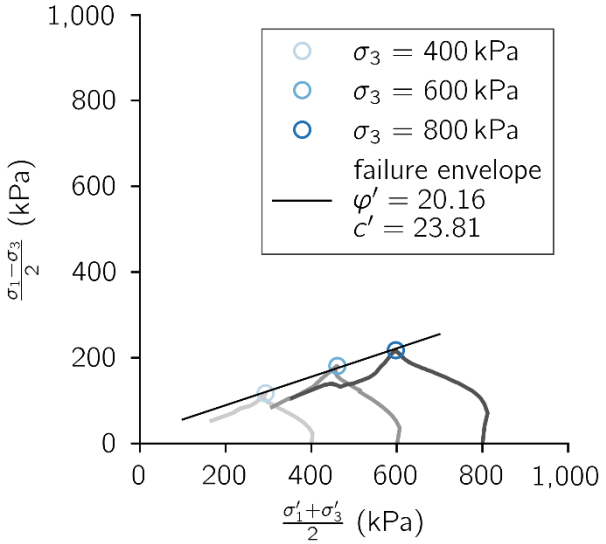

Figure 2. The stress paths of the samples made from kaolinite and demineralised water.

Figure 3 depicts the relationship between the angle of shearing resistance and plasticity index as taken from Table 5. A trend of declining angle of shearing resistance with increasing plasticity index (Lambe and Whitman, 1969) is not visible. Potassium and sodium chloride yield remarkable results. As mentioned before, kaolinite mixed with sodium chloride solution yields unusual results. The substantial increase in the angle of shearing resistance for potassium chloride is remarkable as the plasticity index is unaffected.

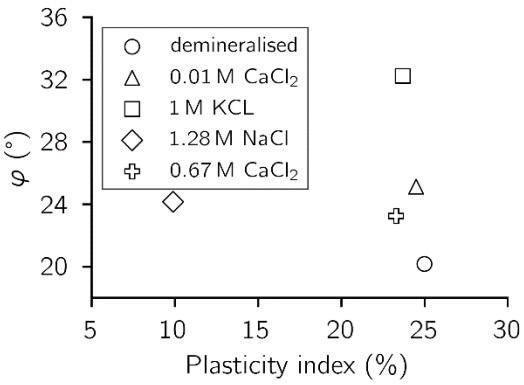

Figure 3. The determined angle of shearing resistance plotted over the plasticity index.

The determined angle of shearing resistance is plotted over pH in Figure 4. The trend for pH dependency is not clear. Generally, adding salt (increasing conductivity) to the pore fluid increases the angle of shearing resistance. A very high concentration of calcium chloride leads to a similar angle of shearing resistance compared to a low concentration. Adding about one gram per litre of calcium chloride strongly increases the angle of shearing resistance and pH. A high sodium chloride concentration increases the shearing resistance angle with a slight pH decrease. In contrast, a high potassium chloride concentration yields the highest angle of shearing resistance increase only with a moderate increase in pH.

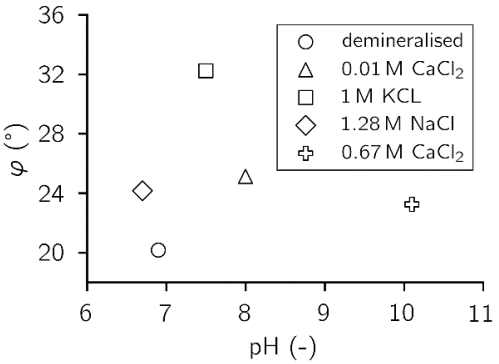

Figure 4. The determined angle of shearing resistances plotted over the pH value.

5 DISCUSSION

The angle of shearing resistance increases when salt is added to the pore fluid compared to demineralised water. This holds for each salt type and concentration presented in this study. Salt cancels out the potential repulsion forces between particles. It decreases the thickness of the diffuse double layer. However, the salt type and the concentration greatly influence the behaviour. The pH value, although significantly changed compared to demineralised water, does not seem to influence the angle of shearing resistance as much. The significant gain of shear strength with potassium chloride might be attributed to the small valence radius of K^+ ions that strongly bond the out-orientated tetrahedral oxygens of kaolinite particles.

6 CONCLUSIONS

The results show that the factors influencing the angle of shearing resistance and fabric in kaolinite are complex and interacting. Applying general textbook concepts proves to be complicated. Analysis of conductivity or salt concentration alone does not allow the prediction of the angle of shearing resistance development. pH, valence and atomic radius of salt types need to be considered. The study will be expanded towards lower concentrations of all three salt types and illite as representative of the 2:1 clay mineral group. It will be combined with sedimentation testing to identify fabric types.

ACKNOWLEDGEMENTS

The authors acknowledge Julia Patterson's support in conducting the tests and Mercedes Molina Gamez's valuable input. This work is funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) – project number 51685914. This support is gratefully acknowledged.

Groundwater statistics in the second-generation Eurocode 7

Statistiques des eaux souterraines dans l'Eurocode 7 de deuxième génération

T. Schweckendiek*
Deltares & Delft University of Technology, Delft, Netherlands

CEDEX, Madrid, Spain

A.J. Bond
Geocentrix, Banstead, United Kingdom

**Timo.Schweckendiek@deltares.nl*

ABSTRACT: The second-generation Eurocodes, in particular EN 1990 and EN 1997, will rely more heavily on reliability and probability approaches for design (and verification) of geotechnical structures and for treating available data. The determination of groundwater levels will be based on concepts like annual probability of exceedance or fraction of time exceeded. When groundwater time series are available, the required groundwater levels can be determined using statistical analysis. In this paper we illustrate assessing the various groundwater levels values using extreme value statistics for real life data sets, highlighting pitfalls and providing practical recommendations for geotechnical practitioners. To that end, we address the selection of probability distributions, processing of the data to obtain annual extreme values and sanity checks of the results.

RÉSUMÉ: Les Eurocodes de deuxième génération, en particulier les EN 1990 et EN 1997, s'appuieront davantage sur des approches de fiabilité et de probabilité pour la conception (et l'évaluation) des structures géotechniques et également lors du traitement des données disponibles. L'évaluation des niveaux des eaux souterraines sera basée sur des concepts tels que la probabilité annuelle de dépassement ou la fraction de temps dépassée. Lorsque des séries chronologiques sur les eaux souterraines sont disponibles, les niveaux d'eau souterraines requis peuvent être déterminés à l'aide d'une analyse statistique. Dans cet article, nous illustrons l'évaluation des différentes valeurs des niveaux d'eau souterraine à l'aide de statistiques de valeurs extrêmes pour des ensembles de données réelles, en soulignant les pièges et en fournissant des recommandations pratiques aux praticiens géotechniques. À cette fin, nous abordons la sélection des distributions de probabilité, le traitement des données pour obtenir des valeurs extrêmes annuelles et les contrôles de cohérence des résultats.

Keywords: Groundwater; statistics; uncertainty; extreme values; design values.

1 INTRODUCTION

1.1 Second generation Eurocodes for geotechnical design

The second-generation Eurocodes will be published during the period 2023 to 2027 and will fully replace the current codes by 2028, when the first-generation Eurocodes are withdrawn. In the 2nd-Gen Eurocodes, the design of geotechnical structures is spread across four standards: EN 1990 for the *basis* of geotechnical design and three parts of EN 1997 for specific aspects of geotechnical design.

The scope of the 2nd-Gen EN 1990 (published in 2023) has been extended to include geotechnics (as reflected in its revised title *Basis of structural and geotechnical design*), which necessitated generalization of the core principles of EN 1990, particularly with respect to the verification of ultimate limit states (Bond et al., 2019).

The 2nd-Gen EN 1997 has been split into three parts, with general principles and rules in *Eurocode 7 – Geotechnical design* – Part 1: *General rules*; provisions for determining ground properties from ground investigation in Part 2: *Ground properties*; and specific rules for design and verification of common geotechnical structures in Part 3: *Geotechnical structures*.

1.2 Objectives and outline

According to a survey after the introduction of the first-generation Eurocodes, one of the main improvements that geotechnical engineers wanted to see in the 2nd-Gen Eurocode 7 was improved guidance on selection of water pressures (Bond, 2011). This has

been addressed both in the 2nd-Gen EN 1997-1 and in EN 1990:2023.

The objective of this paper is to show how to determine various groundwater level values using a real data set.

The concepts related to groundwater in the 2nd-Gen Eurocodes are explained before presentation of the example. Data is fitted with different distribution functions to obtain the various groundwater levels that are required for geotechnical design.

2 WATER ACTION VALUES

2.1 Classification of water actions

In the same way as other actions are handled, the characterization of water actions in EN 1990:2023 depends on whether they are classified as permanent, variable, or accidental.

When the variation in magnitude of the water action is small or monotonic throughout the design service life, it should be classified as permanent. Its representative value (denoted $F_{w,rep}$ or $G_{w,rep}$) is then given by one of three possible values:

- a single characteristic value G_{wk} equal to the mean value of G_w (= $G_{wk,mean}$)
- either the upper or lower characteristic value, $G_{wk,sup}$ or $G_{wk,inf}$, whichever is more onerous
- a nominal value $G_{w,nom}$

These choices are illustrated in the top part of Figure 1. A nominal value is often used in geotechnical design when there is sparse information about groundwater levels (and hence pressures). This paper, however, concentrates on the case where there is sufficient data available to determine characteristic values of water levels and pressures.

Alternatively, when the variation in magnitude of the water action is neither negligible nor monotonic, it should be classified as a variable action whose representative value $F_{w,rep}$ is made up of two components:

- a permanent component $G_{w,rep}$ taken as the mean value of G_w ($G_{wk,mean}$), i.e. the first option above
- a variable component $Q_{w,rep}$ that represents the variation in water action from the mean

These choices are illustrated in the middle part of Figure 1. The magnitude of the variable component $Q_{w,rep}$ depends on which combination of actions is appropriate for the design situation being considered and can be any of the alternatives given in Table 1.

Finally, when the water action is of significant magnitude and typically of short duration but unlikely to occur during the design service life, it should be classified as an accidental action whose representative value $F_{w,rep}$ (denoted $A_{w,wep}$) is as specified in bottom part of Table 1.

Table 1. Specification of water actions according to EN 1990:2023.

Variable or accidental water action	**Symbol**	**Probability of exceedance**
Characteristic	Q_{wk}	2% per annum (return period 50 years)
Combination	$Q_{w,comb}$	10% per annum (return period 10 years)
Frequent	$Q_{w,freq}$	Fraction of time exceeded = 1%
Quasi-permanent	$Q_{w,qper}$	Fraction of time exceeded = 50%
Accidental	$A_{w,rep}$	0.1% per annum (return period 1000 years)

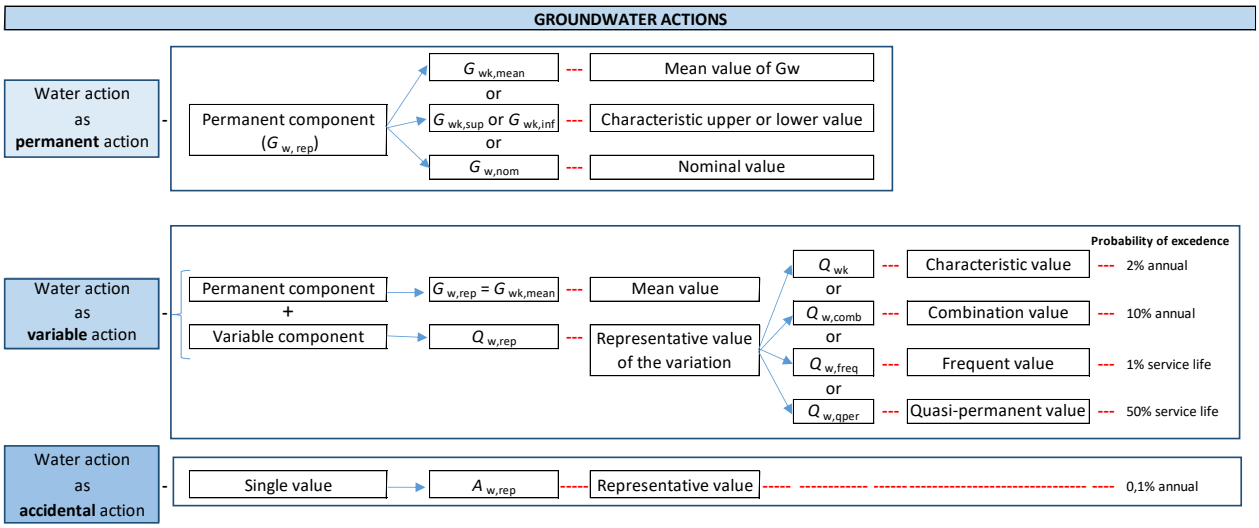

Figure 1. Determination of the representative value of water actions.

2.2 Statistical analysis

For basic theory, we refer the reader to standard textbooks on the topic; here we provide pointers to the approaches relevant to the determination of water action values.

For the quasi-permanent and frequent values, we simply assess the 50% quantile (median) and the 1% quantile of the entire data set (time series in Figure 2), respectively. This determination requires the data to be equally spaced in time, otherwise the data points have to be weighted according to the time period they represent.

The combination, characteristic and accidental values are defined with annual probabilities of exceedance. To obtain these values, the most straightforward option is to determine a probability distribution for the annual maxima (or minima), and then assess the respective quantiles according to Table 1. Since we deal with maxima or minima, the most common extreme value distributions to be considered for this task are:

- Generalized Extreme Value (GEV)
- Weibull
- Gumbel (e.g. Gumbel, 2013)

An alternative to analysing annual maximum or minimum values directly, which we illustrate in the example below, is the 'peaks-over-threshold' method (Lechner et al., 1993).

3 EXAMPLE

To illustrate the application of extreme value statistics for the various values of groundwater action as described above, we analyse a real-life data set and discuss the findings, possibilities and pitfalls.

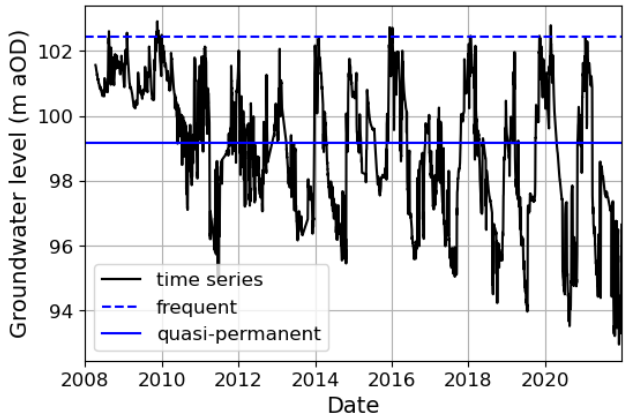

Figure 2. Groundwater level time series including quasi-permanent and frequent values.

3.1 Data set

The data set (from Dunshaughlin in Ireland) contains daily readings of groundwater levels between April 2008 and December 2021, so almost 14 years of data. Figure 2 also shows the quasi-permanent and frequent values, which were obtained from the data as explained in 2.2.

For our particular geotechnical design example, we are looking for exceedance of high groundwater levels. For simplicity in this example, we assume that low groundwater levels do not cause a limit state to be exceeded. We will use the annual maxima to assess the extreme value statistics. The data set exhibits an apparent downward trend in the low water levels, which we ignore here because the high groundwater levels, particularly the annual maxima, do not show such a trend.

3.2 Fitting extreme value distributions

Fitting the distributions mentioned in 2.2 using the maximum likelihood approach leads to the visual fit compared to the empirical cumulative distribution function (ECDF) in Figure 3. Visual comparison does not give a conclusive answer as to which distribution fits the data best, even though the Weibull distribution approximates the right tail (high values) best, as highlighted in Figure 3.

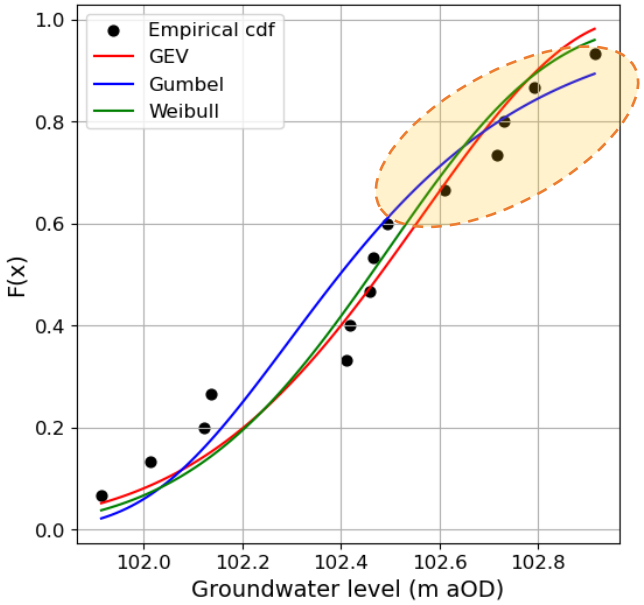

Figure 3. Extreme value distributions compared to Empirical Cumulative Distribution Function (ECDF).

Using the fitted extreme value distributions and the other definitions of water action values discussed in 2.2, the results are presented visually in Figure 4 and numerically in Table 2.

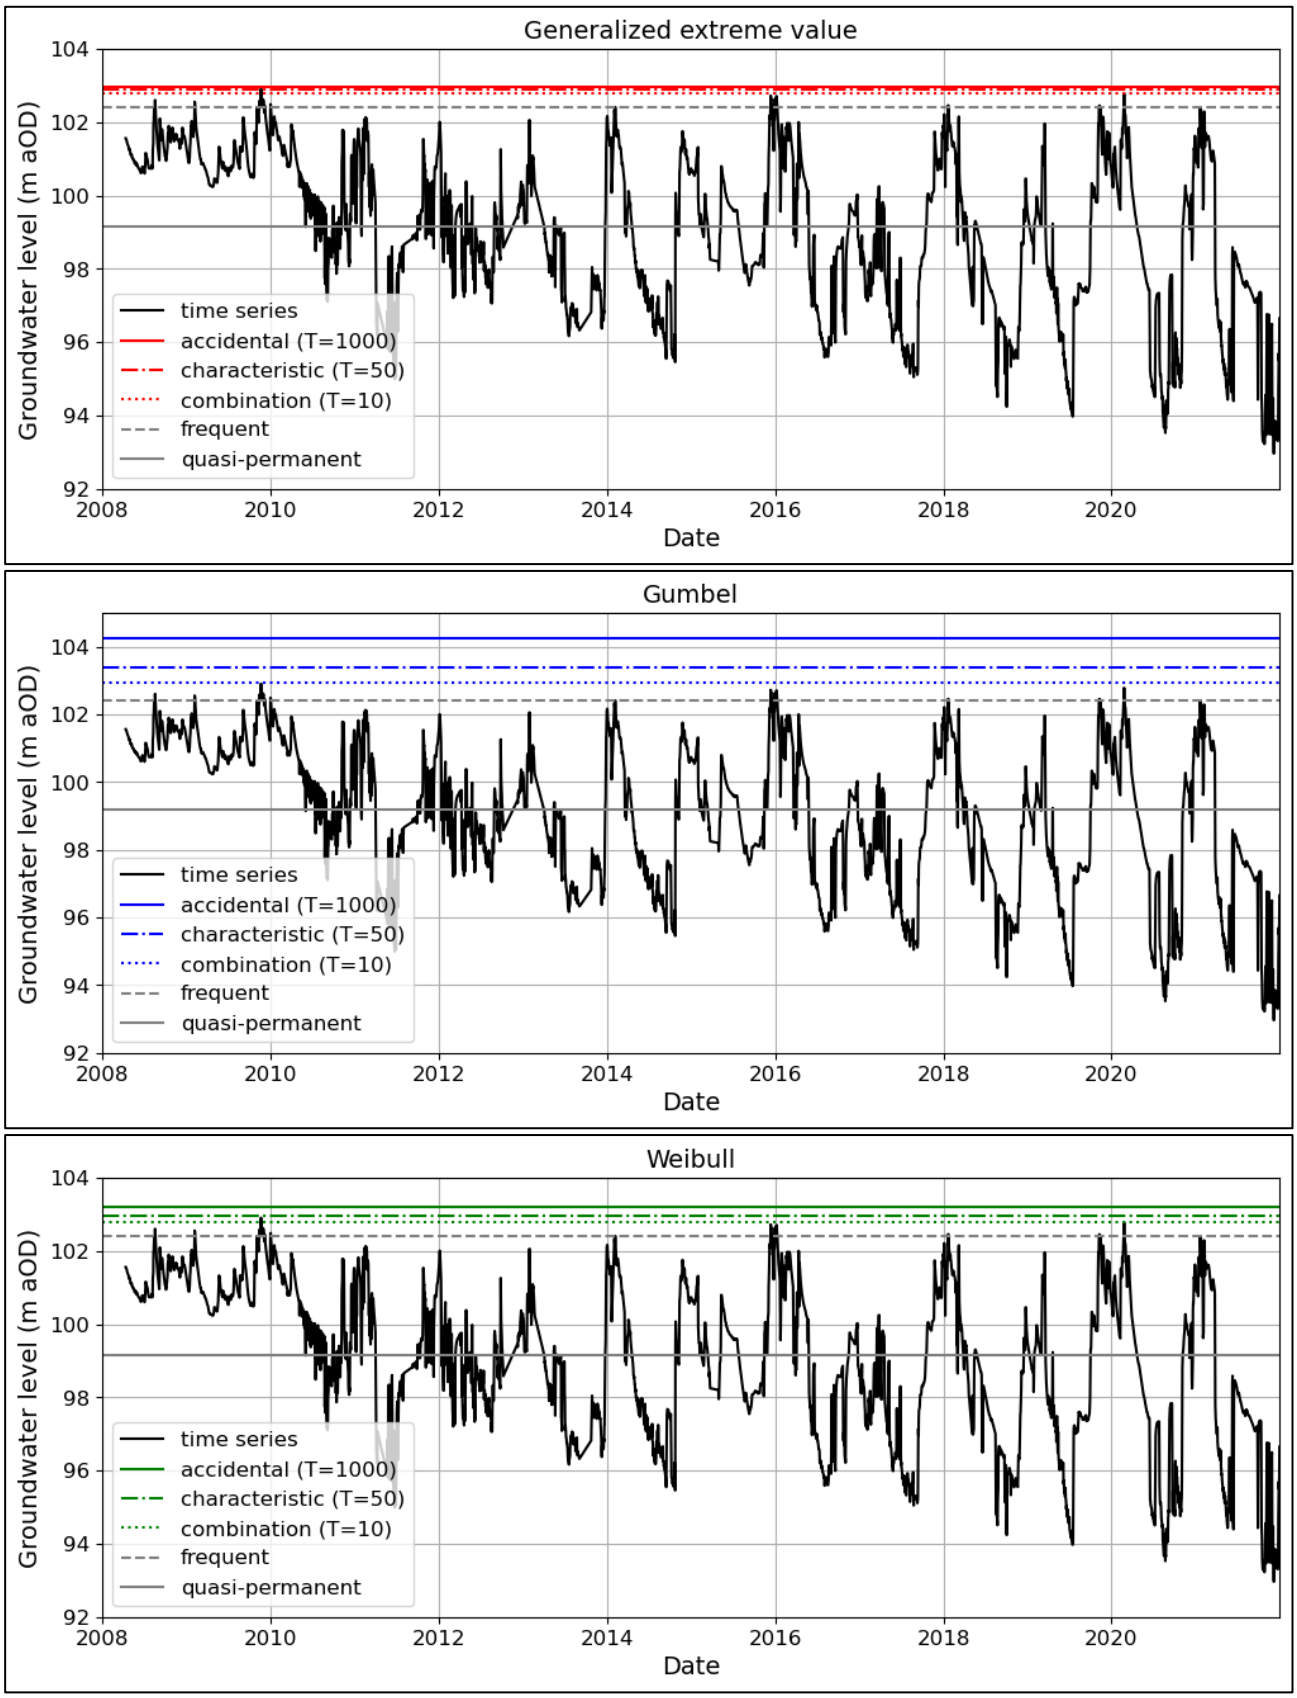

Figure 3. Comparison of extreme value distributions fitted to annual maxima of the time series (top: GEV; middle: Gumbel; bottom: Weibull).

Table 2. Groundwater levels, according to EN 1990 definitions, per distribution fit (in m aOD).

Value	Data set	Gumbel	GEV	Weibull
Characteristic	Annual maxima	103.40	102.91	102.98
Combination		102.93	102.80	102.80
Frequent	Time series	102.43 (independent)		
Quasi-permanent		99.18 (independent)		
Accidental	Annual maxima	104.26	102.98	103.20

3.3 Discussion

To begin with, we observe that the time series exhibits a considerable seasonal variation of roughly 7 to 8 m, while the variation in the extremes (maxima) falls within a relatively small bandwidth of approximately 1 m.

Furthermore, we observe that the quasi-permanent and frequent values are equal and independent of the choice of distribution (by definition), while the characteristic, combination and accidental values differ. Below we discuss observations and sanity checks of the fits to make the most appropriate choice.

Firstly, the combination values from the different distributions are practically identical, so we do not need to select a preferred distribution. For the characteristic and accidental values, we see bigger differences (around 0,5 m as maximum) between the distributions.

The GEV produces very similar values for the combination, characteristic and accidental cases, which is not credible. Therefore, we make a visual check by inspecting the probability density and cumulative distribution functions (PDF and CDF), as depicted in Figure 4.

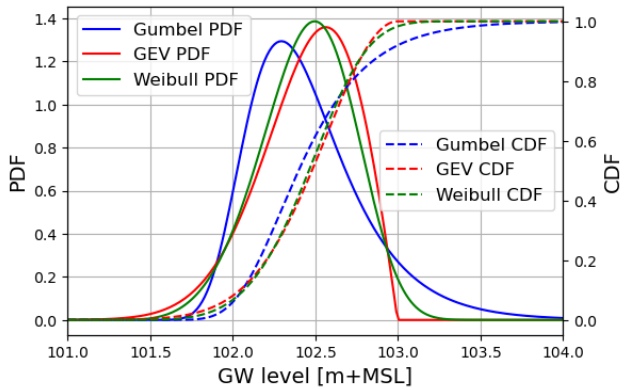

Figure 4. Extreme value distributions (PDF and CDF) fitted to the annual maxima using maximum likelihood.

We immediately observe that fitting the GEV distribution has actually led to a distribution of minima with a fat tail to the left. The sharp bend in the right tail, resulting in a right tail with zero thickness, is the reasonfor the little to no difference between the combination, characteristic and accidental values. Hence, the GEV is not suited to this case. The Gumbel distribution has the fattest right tail, while the Weibull distribution has a less fat right tail. As observed earlier from Figure 3, these latter distributions give a reasonable match to the data.

The Gumbel distribution produces values far higher than the observed range, with the highest value observed in 14 years still somewhat below the combination value (return period: 10 years).

The Weibull distribution exhibits clear separation of the combination, characteristic and accidental values. The combination value is exceeded exactly once in 14 years, while the maximum observed is still somewhat below the characteristic value.

Additionally, we may consider goodness-of-fit measures like chi-square or Kolmogorov-Smirnov tests. However, with such small data sets of 14 annual maxima, these have limited value and instead we prefer to decide on the distribution to use based on visual inspection. The conservative choice in this case is the Gumbel distribution with the associated values in Table 2, while choosing the Weibull distribution leads to more favourable but equally defendable values considering the information that is available. Of course, if more information (for example regarding a physical upper limit to the data) was available, this should be taken into account in the decision.

A final remark on the use of annual maxima is that maxima may stem from the same ‘event’, depending on the year limit used. Also, the peak-over-threshold method is prone to multiple peaks in the same event and not necessarily a remedy for this issue. The issue can be solved mostly, though, by choosing the year limit in summer, if high values are attained in autumn/winter.

4 CONCLUSIONS

In the 2nd-Generation Eurocodes (specifically EN 1990:2023), characteristic values of water actions are defined in terms of probability and frequency, requring statistical analysis. The alternative is to assess nominal values using judgment and experience.

Statistical analysis is rather straightforward and requires just a couple of lines of code (e.g. using SciPy in Python or R). Of course, reasonable data sets of sufficient length in time need to be available for statistical analysis to be beneficial.

As demonstrated in the example, there is no unique solution and judgment is also required for assumptions and choices in the statistical analysis, such as the type of (extreme value) probability distribution. Sometimes

also outliers have to be removed. At the same time, we have shown that reasonable choices can be made based on relatively simple sanity checks and visual inspection of the results. In that sense, the current exercise is no different to other experience-based assumptions in geotechnical engineering.

We recommend providing further guidance to practitioners for assessing water action values, also covering issues not addressed in this paper, such as dealing with very short time series of measurements or scaling extreme value distributions to different reference periods.

ABSTRACT: As a consequence of the growing population in urban areas even high-rise buildings have to be planned near existing sensitive infrastructures. In the east of Frankfurt am Main, Germany, a new high-rise building is planned. This new building is located directly between the river Main and the eastern inner harbour. The high-rise building will have a height of about 75 m and will be founded on a Combined Pile-Raft Foundation (CPRF) in the tertiary, soft marl. The new structure will be constructed next to important, sensitive traffic infrastructure. The foundation of the new high-rise building adjoins directly existing historic quay structures, which are more than 100 years old. For analysis of the stability and the serviceability of the heavily eccentric loaded foundation of the new high-rise building and the existing structures and for the investigation of the soil-structure interaction complex three-dimensional, non-linear numerical simulations have been carried out. The paper introduces into a very complex construction project in which the realistic consideration of the soil-structure interaction is very important for the serviceability of the foundation of the planned high-rise building as well as for the surrounding infrastructure.

RÉSUMÉ: En raison de la croissance démographique dans les zones urbaines, même les immeubles de grande hauteur doivent être planifiés à proximité des infrastructures sensibles existantes. À l'est de Francfort-sur-le-Main, en Allemagne, un nouveau bâtiment de grande hauteur est prévu. Ce nouveau bâtiment est situé directement entre la rivière Main et l'arrière-port est. Le bâtiment de grande hauteur aura une hauteur d'environ 75 m et sera fondé sur une fondation combinée sur pieux et radeaux (CPRF) dans la marne tertiaire molle. La nouvelle structure sera construite à côté d'infrastructures de circulation importantes et sensibles. Les fondations du nouveau bâtiment de grande hauteur jouxtent directement les structures de quai historiques existantes, vieilles de plus de 100 ans. Pour l'analyse de la stabilité et de l'aptitude au service des fondations chargées fortement excentriquement du nouveau bâtiment de grande hauteur et des structures existantes et pour l'étude de l'interaction sol-structure, des simulations numériques complexe tridimensionnelles et non linéaires ont été réalisées. L'article introduit un projet de construction très complexe dans lequel la prise en compte réaliste de l'interaction sol-structure est très importante pour la fonctionnalité des fondations du bâtiment de grande hauteur prévu ainsi que pour l'infrastructure environnante.

Keywords: Numerical analysis; deep foundation; CPRF; high-rise building; soil-structure interaction.

1 INTRODUCTION

A new high-rise building is planned in the east of Frankfurt am Main, Germany. The new building is located directly between the river Main and the eastern harbour. At the moment a filling covers the construction site, shown on Figure 1. The high-rise building will be a 75 m high hotel with 22 floors (Fig. 2). The hotel will be constructed directly by the roundabout intersection. Under the roundabout intersection two levels will be constructed for building equipment and appliances, for the entrance and for parking. The vehicle access will be facilitated under the southern bridge along the river Main by a ramp.

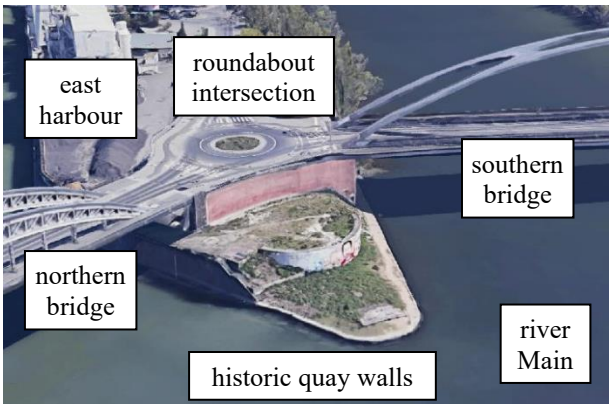

Figure 1. Construction site (google earth).

Figure 2. Visualisation of the planned high-rise building (B&L Group, Hamburg, Germany).

The high-rise building will be founded on a Combined Pile-Raft Foundation (CPRF). The 2 m thick foundation raft has a near to triangular shape and an area of 815 m². The load of the superstructure will be transferred into the CPRF through walls and columns also through a large single column at the tip of the triangular raft. The loads on the foundation raft are given in Table 1. The total load of the high-rise building including the foundation raft is estimated to be about $F_{tot,k} = G_{tot,k} + Q_{tot,k} = 507$ MN. The load has a non-symmetric distribution and is viewed as eccentric.

The foundation of the two levels under the roundabout intersection is a raft founded on micro piles. The micro piles are necessary to resist the uplifting at high water levels of the river Main. According to the regulations the whole project is classified into the Geotechnical Category GC 3, which is the category of the most complex construction projects (CEN 2004).

Table 1. Loads on the foundation raft.

Structural element	Type of load (characteristic)	Load magnitude
Walls and columns	Dead load	325 MN
	Live load	60 MN
Highly loaded single column	Dead load	65 MN
	Live load	15 MN

On the construction site and in the direct neighbourhood the following structures exist:

- Roundabout intersection (centre of Fig. 1)
- Historic quay walls
- Southern abutment of the northern bridge (left in Fig. 1)
- Northern abutment of the southern bridge (right in Fig. 1)

The roundabout intersection is founded on a classic pile foundation. The space under the roundabout intersection is partly filled. This filling has to be removed for the construction of the two levels which will be used for the high-rise building also in order to place the micro piles. The structure of the roundabout intersection includes abutments of the northern and the southern bridge.

The construction site is surrounded by quay walls. The quay walls consist of unreinforced concrete walls and of sheet pile walls. The concrete walls are more than 100 years old.

The southern abutment of the northern bridge is a huge block of concrete. The northern abutment of the southern bridge was founded on classic pile foundation. Both abutments are integrated into the structure of the roundabout intersection.

2 SUBSOIL CONDITIONS

Mainly by two core drillings the subsoil was investigated with the following results:

- artificial filling (0.7 m to 16 m thick)
- quaternary alluvial clay
- quaternary sand and gravel } 0.6 m to 3.1 m thick
- tertiary marl (minimum 80 m thick)

In addition to the core drillings a comprehensive programme of in-situ tests and laboratory tests has been carried out to detect the soil mechanical parameters. Several environmental laboratory tests on soil samples were carried out to classify the effort for disposal this excavation material.

The groundwater level on the construction site is equal to that of the river Main. At high water levels the construction site would be partly submerged under water.

3 FOUNDATION OF HIGH-RISE BUILDING

The foundation of the high-rise building is planned as a CPRF. A CPRF is a hybrid deep foundation system which combines the bearing capacity of a foundation raft and load transferring of the piles or barrettes. The CPRF is a technical and economical optimized

foundation system. The CPRF can be used for the foundation of classic high-rise buildings as well as for engineering constructions like bridges and towers. For the CPRF, the same technical regulations as for classic deep foundations can be applied. To complete the design and safety concept the international Combined Pile-Raft Foundation Guideline has to be considered (ISSMGE 2013). Due to the interaction between the foundation elements and the subsoil CPRFs have a very complex bearing and deformation behaviour. Hence CPRFs have to be classified into the Geotechnical Category GC3 according to EC 7 (CEN 2004). The advantages of a CPRF compared to a conventional spread foundation and to a classic pile foundation are the reduction of:

- settlements and differential settlements
- the bending moments of the foundation raft
- pile materials (30 % to 50 %)

and the increasing of the bearing capacity of spread foundations. More explanations about CPRF and several examples from engineering practice are given in Katzenbach et al. (2016).

The comprehensive numerical analysis using the Finite-Element-Method (FEM) led to the optimized geometry of the CPRF with a thickness of 2 m for the raft and 34 piles with a diameter of 1.5 m and length of 40 m and 45 m. Figure 3 shows the FE-model of the CPRF.

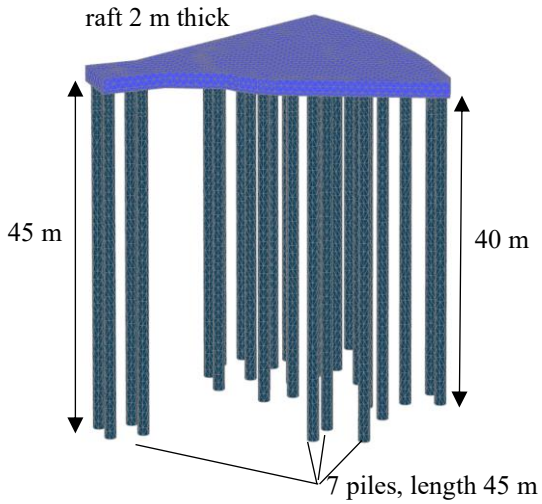

Figure 3. FE-model of the CPRF.

4 NUMERICAL MODEL OF THE PROJECT

The 3-dimensional FE-model (cutout) of the project is shown in Figure 4. The complete model consists of about 772,000 tetrahedral 10-node elements with about 1,170,000 nodes. The modelled subsoil has a base area of 200 m x 200 m and a depth of 105 m. For executing the numerical analysis, the FE-software PLAXIS 3D was used. Figure 5 shows all single structures in the whole construction site.

All construction phases on the project area which have taken place over the years are simulated in a sequence of single steps:

- initial situation
- construction of the quay walls
- construction of the abutment of the northern bridge
- construction of the piles of the roundabout intersection
- construction of the superstructure of the roundabout intersection
- construction of the abutment of the southern bridge
- removal of the filling on the construction site and under the roundabout intersection
- construction of the bored piles of the CPRF and of the micro piles below the roundabout intersection
- construction of the foundation raft of the CPRF and of the roundabout intersection
- hardening of the foundation rafts
- activation of dead loads and traffic loads of the superstructures

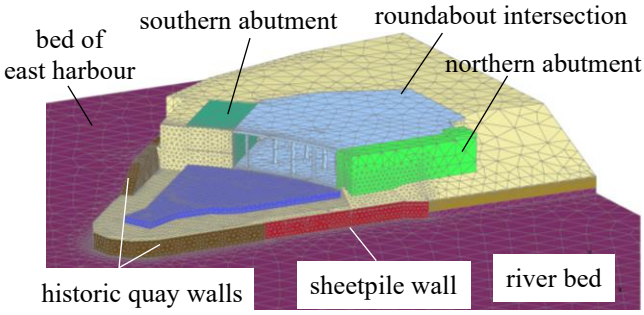

Figure 4. FE-model of the project (cutout).

These phases take into considerations the changes of stresses in the subsoil during all previous unloading and reloading of soil and stress cycles. It leads to a more realistic approach and estimation for the computed deformations as a result of constructing the new hotel building.

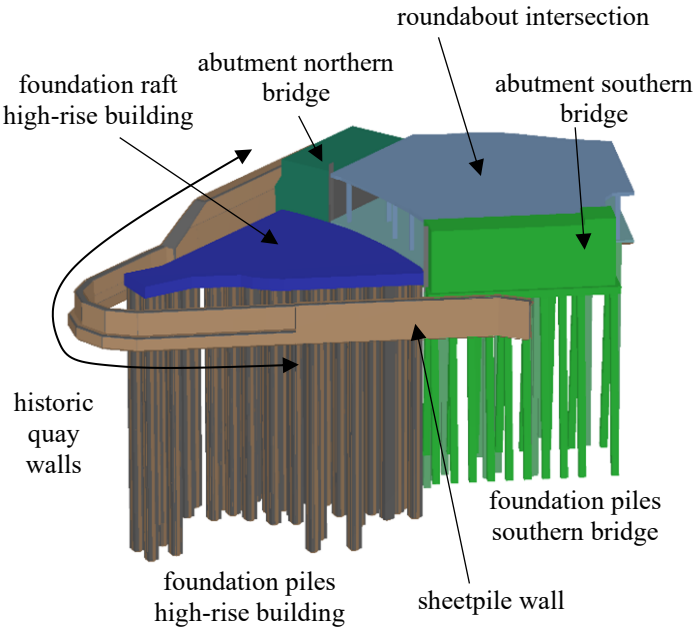

Figure 5. Structural model.

Different constitutive material laws for the different material behaviour of the soil and the structures were implemented. For the material behaviour of the artificial fillings a linear elastic-ideal plastic constitutive material law was used including the failure criterion of Mohr-Coulomb (MC). For this constitutive material law the relation between the Young´s modulus E and the stiffness E_s is defined by the Poisson ratio ν. In PLAXIS the modulus of stiffness E_s is named as E_{oed} according to the oedometer tests.

For the material behavior of the other soil layers the elasto-plastic constitutive material law "Hardening-Soil" (HS) was used. With this constitutive modelling the deformation behavior is described by a non-linear, hyperbolic, stress-dependent function, which enables the definition of different stiffness values depending on the stresses. Furthermore, effects of hardening after shear strain can be defined. The soil mechanical parameters used in the numerical simulation are shown in the Tables 2 and 3.

For the material behavior of the construction elements consisting of concrete respectively reinforced concrete (piles, rafts, walls etc.) and the sheet pile wall consisting of steel a linear elastic constitutive material law was used. In this constitutive material for the concrete resp. rein-forced concrete the Young´s modulus is E = 30.000 MN/m² and the Poisson ratio is υ = 0.2. For the steel the Young´s modulus is E = 210.000 MN/m² and the Poisson ration is υ = 0.3.

Table 2. Soil mechanical parameters.

5 SPRING STIFFNESS AND SUBGRADE REACTION MODULUS OF THE HIGH-RISE BUILDING

For the structural analysis and dimensioning of the superstructure of the high-rise building the spring stiffness of the piles and the distribution of the subgrade reaction modulus of the raft are to be estimated and calculated. For the determination of the stiffnesses and the subgrade reaction modulus a FE-calculation was carried out with the sum of the full characteristic dead load $G_{tot,k}$ and the full characteristic traffic load $Q_{tot,k}$. The spring stiffness of the piles is defined by the relation of the load on the piles to the settlements of the pile head. The subgrade reaction modulus is defined by the relation of the stresses under the raft to the settlements of the raft. The calculated

settlements of the foundation are shown in Figure 6. The resulting spring stiffnesses and the subgrade reaction modulus for the calculation of the superstructure are shown in Figure 7.

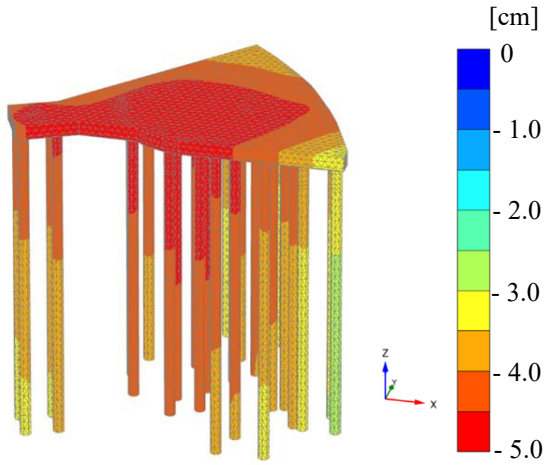

Figure 6. Calculated settlements of the CPRF for ($F_{tot,k} = G_{tot,k} + Q_{tot,k}$).

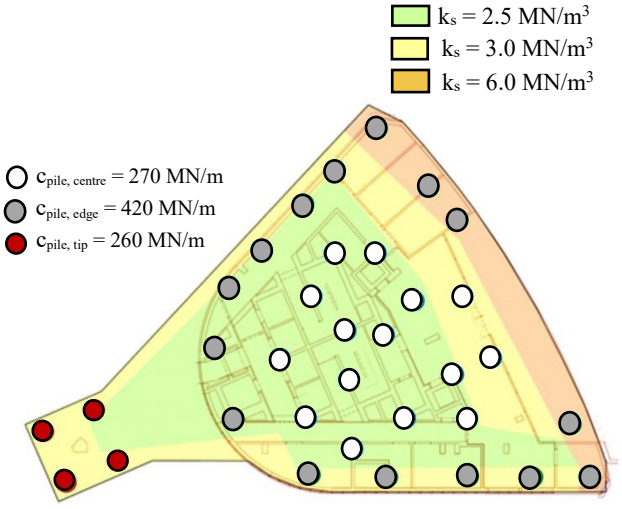

Figure 7. Spring stiffness and subgrade reaction modulus for calculation of the superstructure.

6 BEARING BEHAVIOUR OF THE CPRF

The bearing behaviour of the CPRF can be specified by the CPRF coefficient α_{CPRF}. The coefficient declares the relation between the resistance of the piles ($R_{pile,k}$=450 MN) and the total resistance ($R_{tot,k} = F_{tot,k}$) of the whole CPRF (507 MN), as shown in Equation (1). The CPRF coefficient of $\alpha_{CPRF} = 0$ means that the whole load $F_{tot,k}$ is carried by the foundation raft. A CPRF coefficient of $\alpha_{CPRF} = 1.0$ means that the whole load $F_{tot,k}$ is carried by the foundation piles as a classic pile foundation.

$$\alpha_{CPRF} = \frac{\sum R_{pile,k,i}(s)}{R_{tot,k}(s)} = \frac{450\ MN}{507\ MN} = 0.89 \qquad (1)$$

7 DISPLACEMENTS OF EXISTING STRUCTURES

For the investigation of the displacements of the existing structures as a result of the construction of the new high-rise building further FE-simulations were carried out. To estimate realistic displacements the simulations considered the full characteristic dead load $G_{tot,k}$ and 33 % of the characteristic traffic load $Q_{tot,k}$. As a so-called settlement active load F_{sett} the calculated settlements of the whole project area shown in Figure 8.

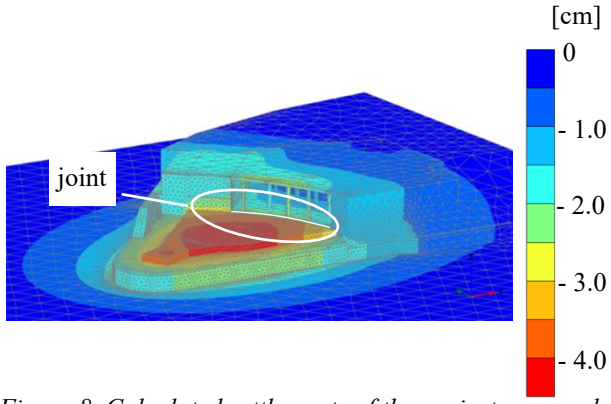

Figure 8. Calculated settlements of the project area and adjacent buildings for [$F_{sett} = G_{tot,k} + (1/3 \cdot Q_{tot,k})$].

The predicted settlements of the high-rise build-ing are estimated to be 2.5 cm and 4.5 cm. The predicted settlements of the existing bridge abutments and the structure of the roundabout intersection are between 0 cm and 2.5 cm, which in this case will not lead to any damage to these structures. The construction detail of the joint between the new high-rise building and the sublevels in the roundabout intersection (see Fig. 8) is very important for the serviceability of the new structure. The calculation forecasts differential settlements of about 0.5 cm and 2.0 cm. For these differential settlements the joint has to be designed to guarantee a watertight and plane passage.

The existing historic quay walls are very sensitive structures. The FE-simulation shows that the hori-zontal displacements in x-direction (Fig. 9 top) and in y-direction (Fig. 9 bottom) will be between 0 cm and ±0.5 cm. This will not lead to any major or considerable damage for these structures.

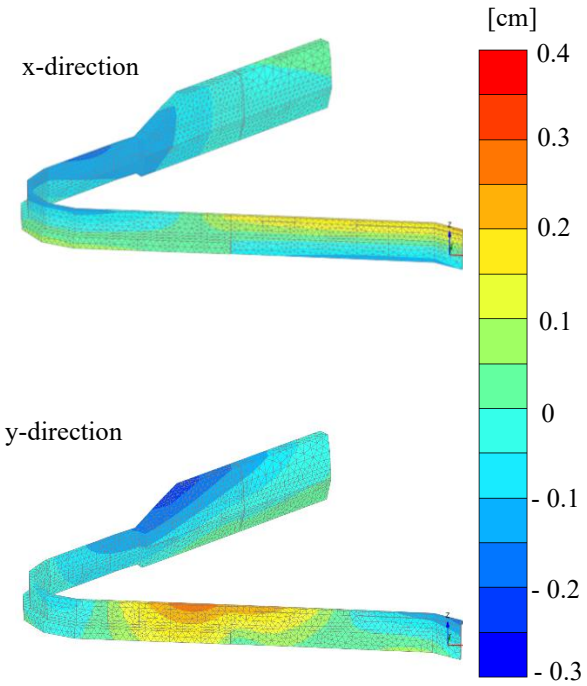

Figure 9. Calculated horizontal displacements of the quay walls for [$F_{sett} = G_{tot,k} + (1/3 \cdot Q_{tot,k})$].

Regarding the settlements of the historic quay walls the prediction is between 1 cm and 3 cm as shown in Figure 10. For the evaluation of the stability and the serviceability the criterion of maximum angular rotation ψ will be applied. For the prevention of any fissures in any structure the criterion is $\psi \leq 1/500$ (GGS 1993). The predicted maximum angular rotation of the historic quay walls is $\psi = 1/1{,}000$. Hence there will be no danger of damage for the historic walls.

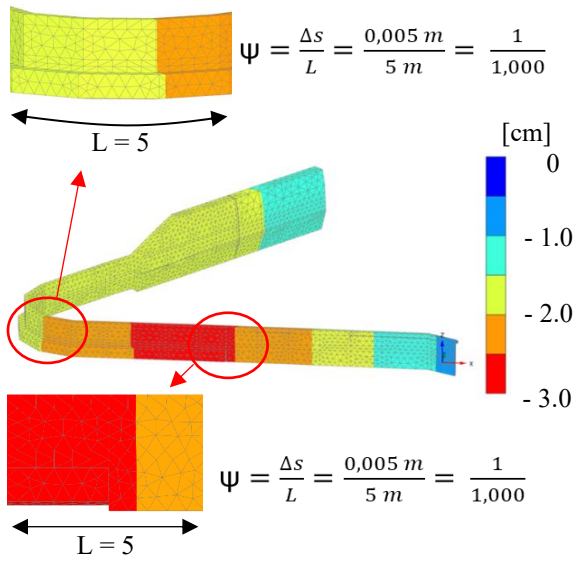

Figure 10. Calculated settlements of quay walls for [$F_{sett} = G_{tot,k} + (1/3 \cdot Q_{tot,k})$].

8 CONCLUSIONS

For analysis of the stability and the serviceability of the heavily eccentric loaded foundation of the new high-rise building and the existing structures and for the investigation of the soil-structure interaction complex three-dimensional, non-linear numerical simulations are very important. These numerical simulations have to take into account all geometric and material specific boundary conditions, including the history of the construction of the whole area.

The numerical simulations delivered the spring stiffness and the subgrade reaction modulus, which are needed for the analysis and the design of the superstructure.

The hybrid foundation system CPRF transfers the building load into the subsoil by the piles and by the raft. This leads to an optimized construction with a minimized impact on the environment.

Regarding the horizontal and vertical displacements of the existing structures due to the new high-rise building the numerical simulations show, that there will be no considerable risk.

Performance of state parameter for undrained shear behaviour

Performance du paramètre d'état pour le comportement en cisaillement non drainé

AECOM, Virginia, U.S.A

**uzair.shah@tum.de*

ABSTRACT: In literature, the concept of state parameter, which is a difference between the current void ratio and the steady-state void ratio at the current stress level, is presented to be a useful state index for the comparison of shear behaviour under drained conditions. This is due to the nature of state parameter to simultaneously take into account the effects from void ratio and pressure as both control the volume change potential and hence, the shear behaviour. However, the analysis on undrained shear behaviour of some laboratory-standard sands shows that relationships between the state parameter and stress ratio at initial peak strength (which mobilizes upon the onset of strength reduction or softening leading to liquefaction) are influenced by the level of consolidation pressure. For some samples, at the same state parameter, the increase in consolidation pressure showed the increase in stress ratio mobilized at the instability state which means that the effect of densification (cause of dilative potential) overpowers the effect of pressure increase (cause of contractive potential). Whereas, other samples showed the decrease in stress ratio mobilized at the instability state with the increase in consolidation pressure against the same state parameter. This represents bias in the behavioural comparisons just on the basis of initial states which is also influenced by the curved geometry of the steady state line on e-log(p') plane. These equivocal effects on the basis of state parameter also hinder the applicability of such correlations in judging the influence of material properties on the instability state.

RÉSUMÉ: Dans la littérature, le concept de paramètre d'état, qui est une différence entre le rapport de vide actuel et le rapport de vide à l'état d'équilibre au niveau de contrainte actuel, est présenté comme un indice d'état utile pour la comparaison du comportement de cisaillement dans des conditions drainées. Ceci est dû à la nature du paramètre d'état qui prend simultanément en compte les effets du taux de vide et de la pression, car tous deux contrôlent le potentiel de changement de volume et, par conséquent, le comportement en cisaillement. Cependant, l'analyse du comportement en cisaillement non drainé de certains sables standard de laboratoire montre que les relations entre le paramètre d'état et le rapport de contrainte à la résistance maximale initiale (qui se mobilise au début de la réduction de la résistance ou de l'adoucissement conduisant à la liquéfaction) sont influencées par le niveau de la pression de consolidation. Pour certains échantillons au même paramètre d'état, l'augmentation de la pression de consolidation a montré l'augmentation du rapport de contrainte mobilisé à l'état d'instabilité, ce qui signifie que l'effet de la densification (cause du potentiel de dilatation) l'emporte sur l'effet de l'augmentation de la pression (cause du potentiel de contraction). En revanche, d'autres échantillons ont montré une diminution du ratio de contrainte mobilisé à l'état d'instabilité avec l'augmentation de la pression de consolidation par rapport au même paramètre d'état. Cela représente un biais dans les comparaisons comportementales sur la base des états initiaux, qui est également influencé par la géométrie incurvée de la ligne d'état stable sur le plan e-log(p'). Ces effets équivoques sur la base du paramètre d'état entravent également l'applicabilité de ces corrélations pour juger de l'influence des propriétés des matériaux sur l'état d'instabilité.

Keywords: State parameter; shear behaviour; liquefaction; steady state; instability state.

1 INTRODUCTION

Liquefaction is a significant reduction or loss of strength in saturated, loose and cohesionless sands upon the undrained shearing. Literature shows abundant laboratory tests on the loose sand samples undergoing high strength reduction followed by large strains. This loss of strength is induced by the increase of porewater pressure, and consequently, the reduction in effective stresses due to the contractive potential of loose samples. The liquefaction of granular soils,

particularly sands, has been systematically studied within the framework of steady state (or interchangeably, the critical state), which is defined as the ultimate state at which a mass of particles deforms with constant stress and constant volume (Poulos, 1981). In addition to the steady state (SS), the quasi-steady state (or QSS) which is a state of local minimum resistance mobilized during the undrained shearing has also been reported (Been et al., 1991; Ishihara, 1993; Yamamuro and Lade, 1998). Occurrence of QSS follows the mobilization of instability (IS) state which marks the local or initial peak in strength at which softening or even collapse of a loose grain skeleton triggers. The instability state is instantaneous in its occurrence, whereas, the QSS is a transitional state of temporary standstill in strength which persists during a certain range of strains (depending upon the sample state) and is followed by re-hardening towards the SS. The typical undrained behavior of sand sample showing the instability state and quasi-steady state is schematically presented in Figure 1(a). Used stress invariants are $q = \sigma'_{zz} - \sigma'_{xx}$ and $p' = (\sigma'_{zz} + 2\sigma'_{xx})/3$. Where, σ'_{zz} and σ'_{xx} are the vertical and radial normal stresses, which are also the major and minor principal stresses, respectively. $\sigma'_{xx} = \sigma'_{yy}$ due to the considered axisymmetry. Initial state parameter, $\Psi_{o(ss)}$, is the difference between void ratio (e) and e on the SS line at p'_c. As the contractive samples shows overshooting of state path across the steady state line towards the QSS on $e - p'$ plane, the reference state for instability state and post-instability softening should be the QSS at which the contractive potential exhausts (Figure 1-b). Therefore, $\Psi_{o(qss)}$ as the difference between void ratio and $e_{(qss)}$ corresponding to p'_c can also be examined. Moreover, the laboratory tests show that the initial states plotting underneath the SS line also show the instability and softening. Hence, the binary classification of shear behaviour on the basis of initial state with reference to the SS line in order to separate contractive/liquefiable states from the dilative/safe states can be misleading. Stress ratio mobilized at the instability state is lower than that mobilized at the quasi-steady state and steady state and shows high state dependencies as compared to that at the latter two states (Ishihara, 1993; Yamamuro and Lade, 1998; Murthy et al., 2007). Strength reduction following the instability state can lead to catastrophic failure in loose deposits, which suggests to consider it as a yield state. However, It is challenging to understand the influence of state on the stress ratio at instability from the literature due to high scatter in the correlations (Olson and Stark, 2003; Murthy et al, 2007; Rabbi, 2019) which hinders their field applicability.

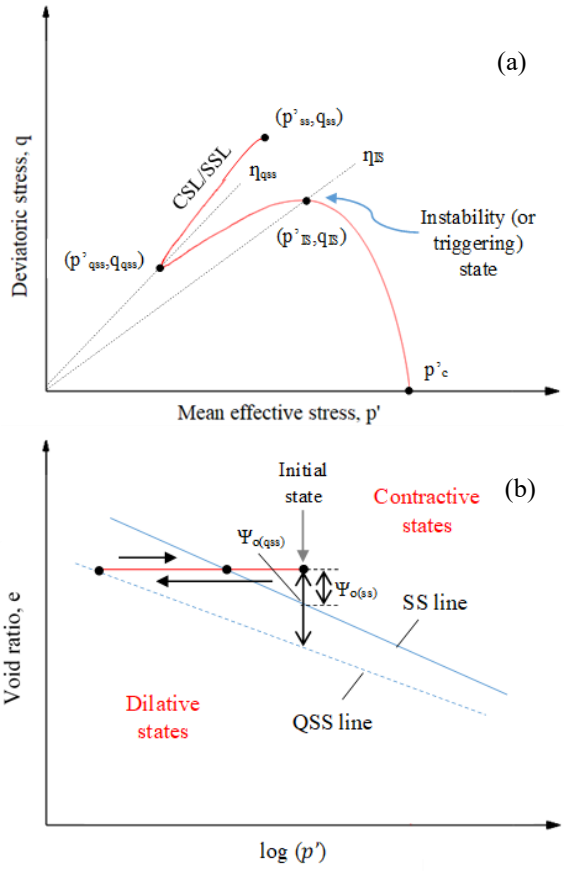

Figure 1. Schematic undrained behaviour showing temporary liquefaction or Quasi-steady state (a) effective stress path; (b) state path and loci on e-p' plane.

2 ANALYSIS ON LABORATORY TESTS

Analysis of the undrained triaxial test data from the literature was involved in order to understand the dependencies of strength behavior on state and material properties. Table 1 summarizes some index properties of sands for which the test behavior will be analyzed and discussed.

Table 1. Index properties of analysed sands.

Sand	D_{50} (mm)	C_u	Grain shape
Toyoura sand (TS)[1]	0.22	1.4	Angular
Fujian sand (FS)[1]	0.4	1.53	Angular to sub-rounded
Ottawa sand (OS)[2]	0.4	1.43	Rounded
TS finer[3]	0.17	1.7	Sub-angular

Sources: [1] from Yang and Wei (2012), [2] from Murthy et al. 2007 & [3] from Verdugo (1992)

Approximated steady state lines (SSLs) from the triaxial tests conducted on these materials are shown in Figure 2. Comparison of the two gradations of Toyoura sand shows the steady state lines of both to be parallel but translating downwards with the widening of gradation. A comparison can also be drawn between the steady state behavior of Fujian sand (FS) and Ottawa sand (OS) on the basis of their equal mean grain diameter (D_{50}). The steady state line of FS plots above the OS which can be attributed to its more angular grains despite the relatively wider gradation. A comparison can also be drawn between the Ottawa and Toyoura sand on the basis of their same C_u. The relatively upwards plotting of steady state line for TS can be due to its finer gradation (or smaller D_{50}) which can be linked with the corresponding higher settlement void ratios but owing to it angular grains, the steady state line of Toyoura sand is also relatively steeper.

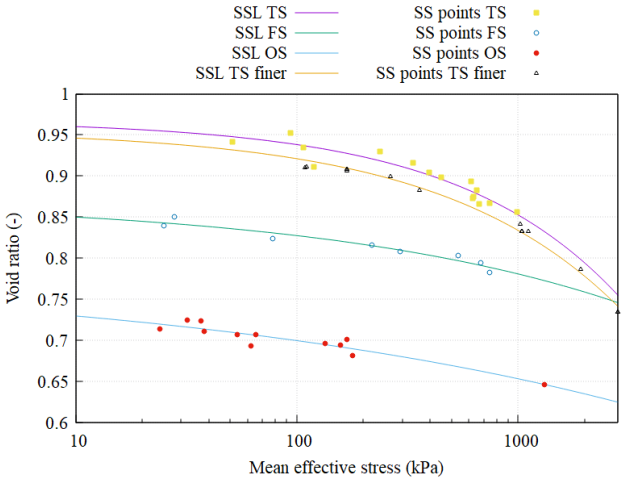

Figure 2. Steady state lines for analysed sands.

For behavioral comparison of instability stress ratio against the initial state parameter with reference from the SSL ($\Psi_{o(ss)}$), and QSSL ($\Psi_{o(qss)}$) are provided in Figure 3. Generally, the q_{IS}/p'_{IS} increases with the decrease in Ψ_o, which shows the proximity of sample state with the SSL. As the influence of consolidation pressure is present despite the normalized q_{IS}/p'_{IS} ratio (because the values of p'_{IS} hold the influence of p'_c), the bifurcation is performed here with respect to the p'_c. The analyzed tests on Fujian and Toyoura sand opted either the $p'_c = 100\ kPa$ or $p'_c = 500\ kPa$ which helped to understand the mechanics influenced only by the change in void ratio. The q_{IS}/p'_{IS} ratio is increasing with the increase in void ratio due to the decreasing availability of pore spaces for sand grains to rearrange into and showing higher grain interlocking and geometrical interference. The $q_{IS}/p'_{IS} - \Psi_o$ relations are fitted with straight lines.

For the case of finer TS, a higher scatter can be seen which is due to a wide range of consolidation pressures in this category, i.e. 1 MPa $\leq p'_c \leq$ 3 MP. For Toyoura, Fujian and Ottawa sands, the $q_{IS}/p'_{IS} - \Psi_o$ relation moves slightly downwards with the increase in p'_c. This shows that for samples at the same $\Psi_{o(ss)}$ or $\Psi_{o(qss)}$, effects from the increase in consolidation pressure (favoring contractive potential) overpower the densification (or reduction in the void ratio favoring dilative potential). Whereas, In the case of finer Toyoura sand, the $q_{IS}/p'_{IS} - \Psi_o$ relation for the higher p'_c values plots above the one for the lower consolidation pressure. At the same $\Psi_{o(ss)}$, gradual strengthening of the samples of finer TS with the increase in p'_c is seen from the test results by Verdugo (1992). This ratcheting in the $q_{IS}/p'_{IS} - \Psi_o$ relations due to the increase in p'_c limits their utilization.

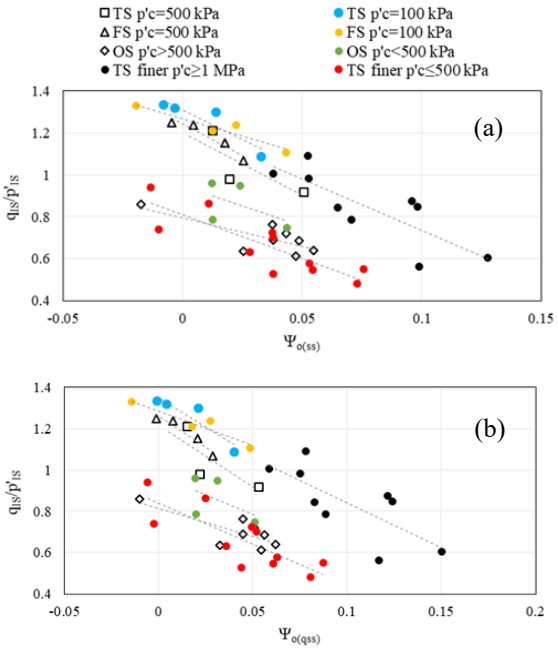

Figure 3. Instability stress ratio against initial state parameter with reference to (a) Steady state; (b) Quasi-steady state.

The instability or the post-peak softening mechanisms is present around $\Psi_{o(ss)} \leq 0$. This means that the samples with initial states lying under the approximated steady state line also showed the instability (or post-peak strength) behavior. To compare between the TS and TS finer, the TS finer has relatively wider composition with relatively less angular grains. The lower Cu, higher D50 and relatively angular grain shape of the TS suggest the higher interlocking in its sample. Therefore, the $q_{IS}/p'_{IS} - \Psi_o$ relation for the TS is plotting above than that of the finer TS. Behavior of FS and OS is

compared together due to their equal D_{50} but different particle shapes (OS being relatively more round grained) even though the gradation of the FS is relatively wider. Resultantly, the $q_{IS}/p'_{IS} - \Psi_{o(ss)}$ relations for the angular FS are plotting above that from the OS. These inferences on the basis of material properties are limited as the relations are simultaneous influenced by the consolidation pressure. Due to the diminishing of the contractive volumetric strain potential (or $\delta p' < 0$) coincides with the quasi-steady state which terminates the post-instability softening. With this expectation, relations between q_{IS}/p'_{IS} and $\Psi_{o(qss)}$ were presented but they also shows the similar dependencies.

3 CONCLUSIONS

Mobilization of the instability state triggers strength reduction which is expected to cause catastrophic failure in loose deposits. In the literature, it was attempted to draw relationships between the stress ratio at instability and the state parameter but the practical utilization of such relationships demands to study their unreasonably large scatters and dependencies. Stress ratio at instability cannot be defined as a function of state parameter due to its other state dependencies. The increase in consolidation pressure causes reverse effects (i.e. either strengthening or weakening) on such relations for different sands. Moreover, simultaneous and resembling effects from consolidation pressure and material properties make it challenging to judge their isolated influences on relationships between the instability stress ratio and state parameter which is schematically shown in **Error! Reference source not found.**. Practical utilization of instability state as yield condition demands to address the bias caused by initial state and points towards examining the performance of other state indices as well.

ABSTRACT: The kinematic exterior approach, in the framework of the yield design theory, is widely utilised for assessing foundation bearing capacity. This study aims at extending this approach to shallow foundations on reinforced soil by rigid inclusions. The interaction diagram in the (V, H, M) space is obtained by combining the interaction curves derived from different failure mechanisms. The resisting forces provided by the rigid inclusions are evaluated using a multicriterion approach and are considered at the intersection of the inclusions with the failure surface. Furthermore, the soil inertia due to the horizontal seismic excitation is also considered in the analysis. The results reveal that the bearing capacity under seismic load is unaffected in the zone of interest for foundations with a sufficient safety factor under static loading.

RÉSUMÉ: L'approche cinématique par l'extérieur, dans le cadre de la théorie de calcul à la rupture, est largement utilisée pour évaluer la capacité portante des fondations. Cette étude vise à étendre cette approche aux fondations renforcées par inclusions rigides. Pour ce faire, le diagramme d'interaction dans l'espace (H, V, M) est obtenu en combinant les diagrammes d'interaction issus de différents mécanismes de rupture. L'effet de renforcement apporté par les inclusions rigides est pris en compte au moyen des forces résistantes développées à l'intersection de l'inclusion avec la surface de rupture, et sont évaluées à l'aide d'un multicritère. De plus, cette étude prend en compte les effets d'inertie du. Les résultats révèlent que la capacité portante sous charge sismique n'est pas impactée dans la zone d'intérêt pour les fondations présentant un facteur de sécurité suffisant sous charge statique.

Keywords: Yield design; bearing capacity; rigid inclusion-reinforced foundation; ASIRI+.

1 INTRODUCTION

The reinforcement technique using rigid inclusions (RI), represents an alternative foundation solution that offers significant technical and economic advantages in comparison to conventional pile foundations. This technique has been used successfully in numerous projects involving complicated geotechnical contexts.

This foundation concept consists of a shallow foundation on a reinforced soil with vertical rigid elements, known as rigid inclusions, which reduce the foundation settlement while enhancing its vertical bearing capacity. There is no direct connection between the shallow foundation and the RIs. Instead, a gravel layer is introduced as a load transfer platform (LTP) as depicted in Figure 1.

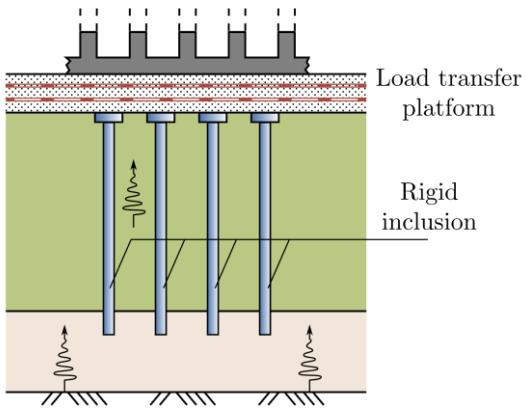

Figure 1. Shallow foundation on soil reinforced by rigid inclusions under seismic loading.

Recent studies have focussed on the dynamic response of such foundations (Shen et al., 2022a, b,

2023). However, the question of the bearing capacity under static and seismic loading has not yet been studied in detail and no practical methodology is available. Consequently, this study focuses on addressing the seismic bearing capacity problem of RI-reinforced foundations using the kinematic exterior approach.

2 KINEMATIC EXTERIOR APPROACH

2.1 Theoretical framework

Within the context of the yield design theory, the kinematic exterior approach operates as an upper-bound analysis method. This approach involves evaluating a kinematically admissible virtual velocity field $\underline{\hat{U}}$ and verifying whether the virtual power of external loads applied to the system, denoted as P_e, is less than or equal to the maximum resisting power of the soil, denoted as P_{rm}.

An upper-bound K encompasses the space delineated by:

$$K \subset \{P_{rm}(\underline{\hat{U}}) \geq P_e(\underline{\hat{U}})\} \quad (1)$$

The maximum resisting power P_{rm} is equal to:

$$P_{rm}(\underline{U}) = \int_\Omega \pi\left(\underline{\hat{d}}\right) d\Omega + \int_\Sigma \pi(\llbracket \underline{\hat{U}} \rrbracket)\, d\Sigma \quad (2)$$

where $\pi(.)$ represents the density of virtual power due to the strain rate $\underline{\hat{d}}$ within the volume Ω and to the virtual velocity $\llbracket \underline{\hat{U}} \rrbracket$ at the velocity discontinuity surface Σ. These quantities are derived from the strength criteria. The explicit formulation of the function $\pi(.)$ for various criteria, applicable to both continuous materials and interfaces, can be found in the work of Salençon (1983, 2002).

The virtual power of all external forces P_e applied to the system encompasses the power of the loads exerted on the foundation, in terms of forces and moments, as well as the body forces originating from soil inertia.

In the case of a foundation reinforced by RIs, the formulation of P_e remains unchanged when compared to the case without reinforcement. Nonetheless, the contribution of reinforcement by RIs, represented by P_{RIs}, should be added into the resisting power part, as outlined in:

$$K \subset \{P_{rm}(\underline{\hat{U}}) + P_{RIs}(\underline{\hat{U}}) \geq P_e(\underline{\hat{U}})\} \quad (3)$$

2.2 Application to the study of geotechnical structures

The kinematic exterior approach has been employed in previous work to investigate the bearing capacity of strip foundations resting on homogeneous cohesive and cohesionless soils subjected to static and seismic loads (Salençon and Pecker, 1995a, 1995b; Paolucci and Pecker, 1997; Soubra, 1999).

It can be also found that the kinematic exterior approach has already been used to study the stability problem of reinforced geotechnical structures, such as nailed slopes.

De Buhan et al. (1992) investigated the stability of nailed slopes using the kinematic exterior approach. The study comprised kinematic mechanisms based on triangular blocks and logarithmic spiral failure surfaces. Several slope stability softwares, including TALREN (Terrasol, 2023), PROSPER (De Sauvage and Rajot, 2018), and STARS (Antoine, 1990), also employ failure surfaces in the form of logarithmic spirals. The contribution of nail reinforcements is introduced by employing a multicriterion approach based on various failure modes associated with the nails.

Very few applications of the kinematic exterior approach to study RI-reinforced foundations have been conducted so far. This is partly due to the inherent complexity introduced by the presence of the three distinct components: the soft soil, the granular LTP, and the RIs, which makes it difficult to determine kinematically admissible virtual velocity fields $\underline{\hat{U}}$.

Pecker et al. (1998) evaluated the seismic bearing capacity of a shallow foundation on cohesive soil reinforced by RIs, using the kinematic exterior approach. The findings were compared with the results of five centrifuge tests carried out for the Rio-Antirrio bridge project. Figure 2 presents a kinematic mechanism considered in that study, which closely resembles the failure mechanism observed in the centrifuge tests.

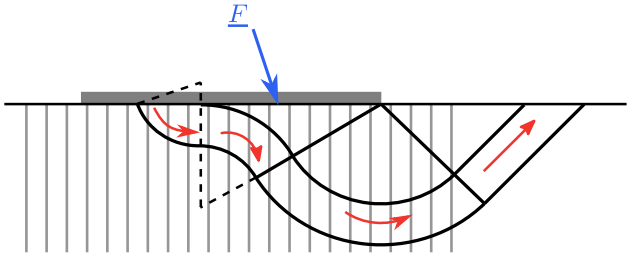

Figure 2. Virtual velocity field considered in the bearing capacity estimation of the Rio-Antirrio bridge foundation.

In this mechanism, the contribution of the RIs was considered by the intrinsic material resistance and their skin friction. Additionally, a failure criterion

representing the slide failure between the LTP and the foundation was introduced and superimposed onto the results obtained through the kinematic exterior approach.

3 BEARING CAPACITY OF A STRIP FOOTING ON REINFORCED SOIL

3.1 Description of the problem

This study focuses on the seismic bearing capacity of a strip foundation on reinforced soil by RIs. A strip foundation of width B is placed on a half-space consisting of a LTP of thickness h_{LTP} and purely cohesionless behaviour (friction angle φ), over a cohesive soft soil layer with a cohesion c and no tensile strength. The soft soil layer is reinforced with RIs, as illustrated in Figure 3.

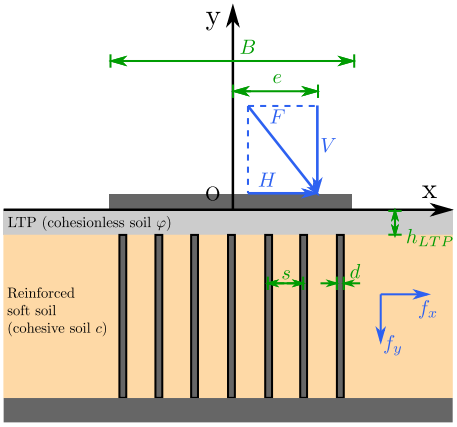

Figure 3. Studied configuration: strip foundation on reinforced soil by Ris.

The RI rows are modelled by embedded beams. They are assumed to be regularly spaced under the foundation with a spacing s and are embedded in the compact soil layer.

The force transmitted to the footing is denoted as $\underline{F}$, and the moment $\underline{M}$ is calculated by multiplying the vertical force by the eccentricity e.

Additionally, the soil inertia effects are considered through body forces due to seismic and gravity loading, denoted as $f_x = \rho a_x$ and $f_y = \rho(g \pm a_y)$, respectively. The horizontal

3.2 Simplified sub-systems

The presence of reinforcements and the LTP layer in RI-reinforced foundations introduces additional complexity to the failure mechanisms when compared to non-reinforced configurations. To address this, three simplified sub-systems (or cases), illustrated in Figure 5, are proposed, corresponding to the different potential failure mechanisms are investigated:

- Case I: This sub-system considers a homogeneous frictional soil, where the failure mechanism is primarily concentrated in the LTP, resulting in a failure depth lower than h_{LTP};
- Case II: This sub-system deals with the potential sliding and uplift at the interface between the LTP and the reinforced soft soil;
- Case III: Involves a homogeneous cohesive soil reinforced by RIs. The failure mechanism depth in this case exceeds h_{LTP} and intersects the RIs, that contribute thus to the resistance. It should be noted that the contribution of the soil and the RIs are calculated separately, as depicted in Figure 6.

The upper-bound solutions for the three cases are denoted $K^{up,I}$, $K^{up,II}$, and $K^{up,III}$. They are combined to determine the stability domain K^{up} of a foundation reinforced by RIs, as described in :

$$K^{up} = K^{up,I} \cap K^{up,II} \cap K^{up,III} \quad (4)$$

3.3 Failure analysis of a rigid inclusion

The RIs are considered by accounting for their action at the intersection with the failure surface. The RI is divided into two parts by the intersection: interior part with a length L_{int} and exterior part with length L_{ext}, as depicted in Figure 4 (a). The forces at this intersection are decomposed into an axial force T_n, a shear force T_c, and a bending moment M_c, as shown in Figure 4 (b). Their maximum value are limited by several criteria:

- Material intrinsic strength;
- Vertical interaction resistance;
- Lateral interaction resistance: plastification of the soil;
- Lateral interaction resistance: plastification of the RI.

3.3.1 Material intrinsic strength resistance

The combination of T_n, T_c, and M_c that occurs at the intersection of the RIs with the velocity discontinuity surface can be represented by:

$$\left(\frac{T_n}{R_n}\right)^2 + \left(\frac{T_c}{R_c}\right)^2 + \left|\frac{M_c}{R_m}\right| - 1 \leq 0 \quad (5)$$

where R_n, R_c, and R_m are the axial, shear, and flexural capacities of a rigid inclusion related to the material intrinsic strength and the inclusion's section. In the case with the presence of the steel reinforcement in the concrete inclusions, the reinforcement should be considered.

3.3.2 Axial soil-inclusion interaction resistance

The maximum axial force T_{nl} that a RI of diameter d can provide is also governed by parameters such as the skin friction, the forces at the head and the tip of the RI, and the internal "pullout" failure mechanism. This can be described by:

$$T_{nl} = min\,(F_0 + q_s L_{int}\pi d, F_L + q_s L_{ext}\pi d) \quad (6)$$

where F_0 represents the maximum force controlled by a Prandtl failure mechanism in the LTP, F_L represents the maximum force at the inclusion tip, which is typically of significant magnitude. Additionally, q_s denotes the characteristic value of the inclusion shaft friction.

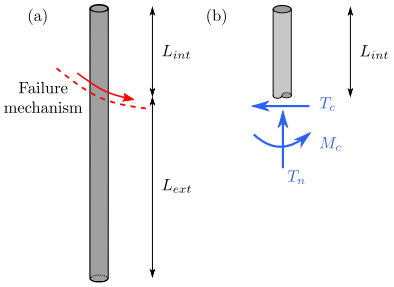

Figure 4. Scheme of a RI intersected by a failure mechanism: (a) interior length L_{int} and exterior length L_{ext} and (b) RI forces at the intersection.

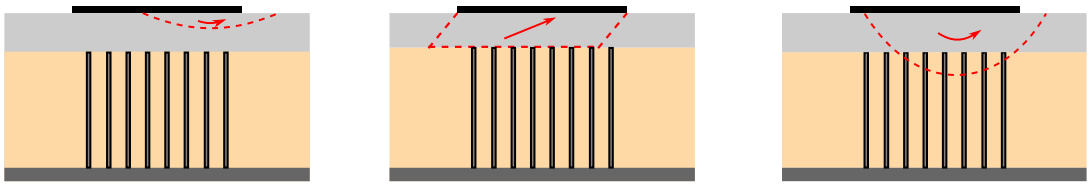

Figure 5. Simplified sub-systems for a foundation reinforced by Ris.

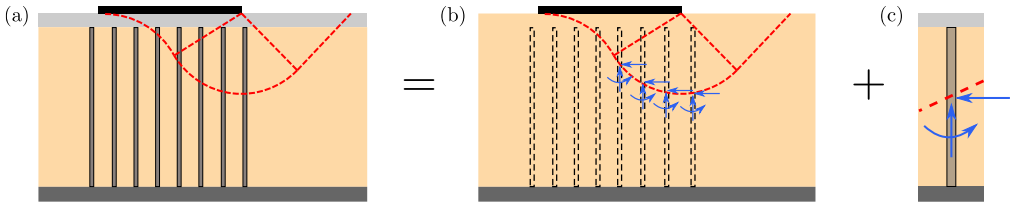

Figure 6. Detailed description for Case III: (a) multi-block failure mechanism, (b) simplified configuration, and (c) forces at the intersection of RI with failure interaction.

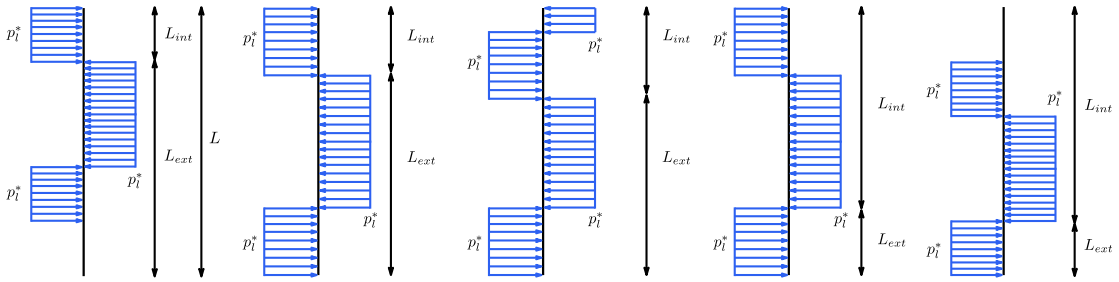

(a) $L_{int} < L/4$ (b) $L_{int} = L/4$ (c) $L/4 < L_{int} < 3L/4$ (d) $L_{int} = 3L/4$ (e) $L_{int} > 3L/4$

Figure 7. Distribution of lateral pressure for limit equilibrium model.

3.3.3 Lateral soil-inclusion interaction resistance

This criterion corresponds to the mobilised resistance due to lateral soil-inclusion interaction. The pressure within the interior length L_{int} or the exterior length L_{ext} of the RI is restricted by the limit pressure p_l^* in the soil.

The lateral interaction of the RI is analysed through a limit equilibrium model, as depicted in Figure 7. Several lateral pressure distributions for various lengths L_{int} and L_{ext} are considered.

The corresponding shear force T_{cl1} and bending moment M_{cl} at the intersection and the maximum bending moment M_{max} within the RI generated by the lateral pressure can be expressed with respect to the ratio L_{int}/L, as shown in Figure 8.

3.3.4 Formulation of the RI multicriterion

The combination of the four criteria in the T_n-T_c plane defines a useful stability domain, known as the RI multicriterion and illustrated in Figure 9. This domain

establishes the limits on the potential resisting forces provided by the RIs.

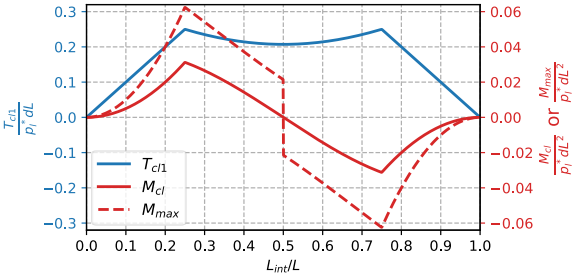

Figure 8. Evaluation of T_{cl1}, M_{cl}, and M_{max} due to soil-inclusion lateral interaction for different values of the ratio L_{int}/L.

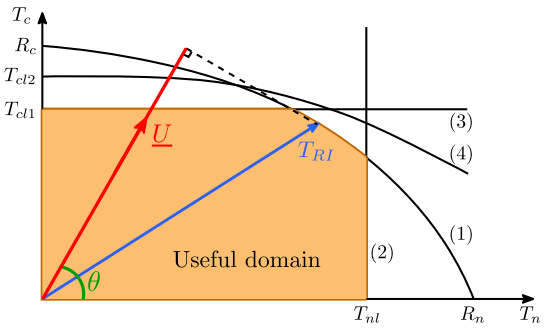

Figure 9. RI multicriterion in the T_n-T_c plane.

When failure occurs, the resisting forces developed by the RI must lie on the boundary of this useful domain, and its position is determined by the principle of maximum work. This principle indicates that the forces on the boundary are chosen in a way that maximises the resisting power provided by rigid inclusions within a given failure mechanism. Once the virtual velocity at the intersection of the inclusion with the failure surface is specified, the virtual power of the inclusion can be calculated.

3.4 Practical application

A typical foundation configuration is considered. It consists of a 10 m wide strip foundation, resting on a 0.5 m thick LTP layer with a friction angle of 38°. The soft soil is considered as cohesive, characterised by an undrained shear strength c of 25 kPa, a q_s = 25 kPa and p_l^* = 200 kPa. The soft soil is reinforced by rows of RI with a diameter of 0.4 m and a length of 10 m. The axis-to-axis spacing is 1.5 m, resulting in a coverage area ratio of 5.6 %. The head of the RI corresponds to the base of the LTP.

The bearing capacity of the foundation is studied using the approach presented in the previous sections. The interaction diagram is normalised by the product of the cohesion c and the width of the foundation B, as depicted in Figure 10.

For small vertical forces, the V-H interaction diagram is predominantly controlled by Case I (blue curve), corresponding to failure within the LTP layer. As the vertical force increases, a sliding mechanism between the LTP and the soft soil becomes apparent (green curve). Finally, for greater vertical forces, the interaction diagram is primarily controlled by Case III (red curve), which represents a failure mechanism in the reinforced soil.

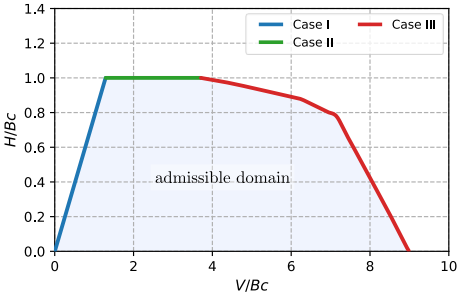

Figure 10. Bearing capacity of a strip foundation on reinforced soil by RI in the normalised V-H plane.

4 SOIL INERTIA EFFECT ON THE BEARING CAPACITY

4.1 Interaction diagram under various soil inertia values

The adverse impact of soil inertia forces on the bearing capacity of non-reinforced foundations can be significant, particularly for foundations designed with a low safety factor under a vertical centred load. This impact for RI-reinforced foundations is studied in this section.

The V-H interaction curves for several acceleration values in the soil ranging from 0 to 0.4 g are displayed in Figure 11.

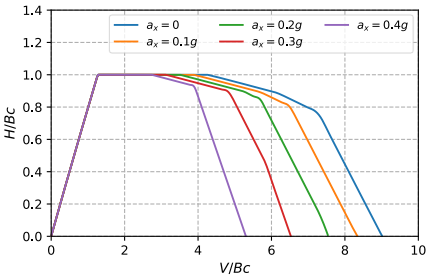

Figure 11. Normalised V-H interaction curves for different ground accelerations.

It is observed that the shape of the V-H interaction curves is not affected by soil inertia effects, and only the amplitude of their right-hand side (Case III), which is controlled by the failure mechanism traversing the reinforced soil, is influenced by the soil inertia.

4.2 Bearing capacity under different soil inertia values

The bearing capacity, denoted V_{max}, represents the maximum vertical centred force that a foundation can carry. Figure 12 explores the bearing capacity values with different soil inertia values due to the horizontal seismic excitation. The soil inertia values are represented by the dimensionless soil inertia forces $\bar{F} = \rho a_x B/c$. Comparing the non-reinforced configuration (orange curve) to the reinforced configurations (blue curves for different coverage area ratios α), it can be observed that the rigid inclusion improvement enhances the foundation bearing capacity V_{max} to withstand the soil inertia.

For example, at a dimensionless soil inertia force of $\bar{F} = 2$, corresponding to a situation with $a_x = 0.33$ g, $\rho = 1.8\ t/m^3$, $B = 10\ m$, and $c = 25\ kPa$, the non-reinforced foundation exhibits a 50 % reduction in its bearing capacity due to soil inertia effect. In contrast, the reinforced configuration with the same soil inertia still retains approximately 80 % of its bearing capacity.

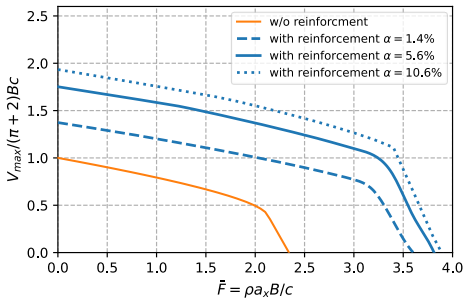

Figure 12. Evolution of the bearing capacity V_{max} of the foundation with respect to different soil inertia values.

5 CONCLUSIONS

This work extends the application of the kinematic exterior approach to rigid inclusion-reinforced foundations. To accurately estimate the contribution of the inclusions to the resistance of the system.

The bearing capacity under the soil inertia is studied for reinforced configurations with different coverage area ratios, revealing that the bearing capacity consistently increases as the coverage area ratio does. The interaction diagrams reveal that the bearing capacity under seismic load is unaffected in the zone of interest for foundations with a sufficient safety factor under static loading.

Influence of spatial variability of strength on bearing capacity for unsaturated soil

Influence de la variabilité spatiale de la résistance sur la capacité portante des sols non saturés

ABSTRACT: Soil, even within a homogeneous layer, exhibits spatial variation in cohesion. Additionally, experimental tests have confirmed that spatial variability in cohesion can occur from changes in soil fabric under unsaturated conditions. Its significant effects on slope stability have been studied comprehensively, but limited to bearing capacity problems. This paper addresses, therefore, an analytical approach that utilises limit state analysis to investigate the influence of spatial variability in cohesion on the bearing capacity of a rigid surface strip footing. The analytical study considered various scenarios, accounting for different suction profiles that addressed the spatial variability in cohesion beneath and alongside the footing. The numerical results demonstrated a 18.5% increase in the ultimate bearing capacity, attributed to the effects of spatial variability in cohesion (changes in soil fabric). Inspection of the obtained failure mechanisms for the modelled scenarios revealed deeper and wider failure patterns when a higher multiplier/increase was applied to a greater cohesion value.

RÉSUMÉ: Le sol, même au sein d'une couche homogène, présente une variation spatiale de cohésion. De plus, des tests expérimentaux ont confirmé qu'une variabilité spatiale de la cohésion peut résulter de modifications du tissu du sol dans des conditions non saturées. Ses effets significatifs sur la stabilité des pentes ont été étudiés de manière approfondie, mais limités aux problèmes de capacité portante. Cet article aborde donc une approche analytique qui utilise l'analyse à l'état limite pour étudier l'influence de la variabilité spatiale de la cohésion sur la capacité portante d'une semelle filante à surface rigide. L'étude analytique a examiné divers scénarios, tenant compte de différents profils de succion qui traitaient de la variabilité spatiale de la cohésion sous et le long de la semelle. Les résultats numériques ont démontré une augmentation de 18,5% de la capacité portante ultime, attribuée aux effets de variabilité spatiale de la cohésion (changements dans la structure du sol). L'inspection des mécanismes de défaillance obtenus pour les scénarios modélisés a révélé des schémas de défaillance plus profonds et plus larges lorsqu'un multiplicateur/augmentation plus élevé était appliqué à une valeur de cohésion plus élevée.

Keywords: Soil fabrics; spatial variability; unsaturated soil; numerical analysis; bearing capacity.

1 INTRODUCTION

Soil, even within a homogeneous layer, exhibits spatial variation in strength. Additionally, spatial variability can arise from changes in soil fabrics under unsaturated conditions or due to the drying and wetting phenomenon. Understanding the characteristics of spatial variability is essential for assessing the reliability of geotechnical engineering problems. Researchers have studied the spatial variability in soils, emphasizing its significance in introducing uncertainties within the field of geotechnical engineering (see Tan et al., 2020).

Cho (2010) conducted a numerical study, extended the traditional limit equilibrium method of slices for the purpose of analysing the probabilistic stability of slopes, into the variations in soil strength parameters and their associated uncertainties. The results showed that the proposed method adequately addressed the causes of failure that arise from differences in soil characteristics. Jiang et al. (2018) used conditional random fields to analyse slope reliability and modelled the spatial variation in undrained shear strength of soil for a slope stability problem. The method successfully incorporated the data, from site investigation to model the differences, in soil properties using conditional random fields.

The preceding studies have indicated a significant effect of spatial variability on slope stability, but their focus was restricted to addressing bearing capacity problems. Changes in soil fabric can significantly affect shear strength (cohesion) (see Toll and Ong, 2003, Shwan and Smith, 2015 and Shwan, 2015). This paper addresses the effects of spatial variability (referring to variations in cohesion resulting from fabric changes due to suction) on the bearing capacity

of a rigid surface footing under different suction profiles, using an upper-bound theorem approach.

2 PROBLEM GEOMETRY AND MATERIALS

The schematic diagram of a rigid surface strip footing (1 m width) is depicted in Figure 1a with the obtained failure mechanics, not restricted to the boundaries. While, Figure 1b shows the soil water retention curve (SWRC) for a simulated soil, plotted using an SWRC equation proposed by Shwan and Smith (2014):

$$S_r = e^{-\kappa(s-AEV)} \quad (1)$$

where S_r is the degree of saturation, κ is a fitting parameter (kPa^{-1}) accounts for soil types (see Shwan, 2023a, 2023b, and 2023c), s is the suction (kPa) and AEV is the air entry suction. Equation 1 was validated against experimental data and fitted to the Fredlund and Xing (1994) model, (see Shwan, 2015, and 2017).

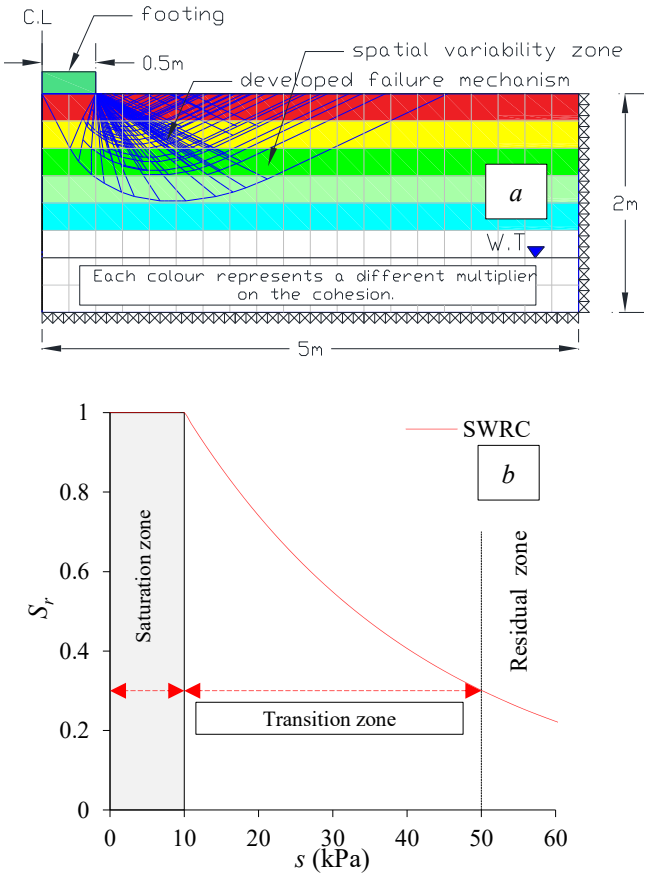

Figure 1. (a) Schematic diagram of the modelled footing, and (b) Simulated Soil-Water Retention Curve (SWRC).

The modelled suction range, applied by changing the water table level, ranged from 0 to 60 kPa.

The required parameters for the analysis were κ = 0.03 kPa^{-1} and AEV = 10 kPa, obtained through the SWRC in Figure 1b. The angle of shearing resistance (ϕ) and cohesion (c) values of 40° and 5 kPa, respectively, were used. In addition, dry, unsaturated and saturated unit weights were 14, 16 and 18 kN/m^3, respectively.

3 MODELLING SPATIAL VARABILITY

Soils exhibit different increases in effective stress under unsaturated conditions, (Bishop and Blight, 1963) attributed to different suction levels and soil structure, enhancing soil fabrics. Spatial variability in strength was, therefore, modelled in the UNSAT-DLO approach, a robust upper bound theorem approach modified by the author to account for the effects of unsaturated conditions on strength, using various scenarios. Spatial variability was attained by applying different multipliers (**M**) to cohesion (**M**× c), attributed to fabric changes, in each grid beneath the footing using different cases, see Figure 1a.

The suggested cases were categorised into two groups: Category 1 (C1), Figure 2, and Category 2 (C2), Figure 3. The case where cohesion exhibits no spatial variability (no changes in soil fabric, such as in fully dry and saturated conditions) was also simulated for comparison. Each category comprised three scenarios: SCE1, SCE2, and SCE3. Each colour in Figures 2 and 3 represents a spatial variability zone in cohesion where a different **M** value was utilised (i.e. **M**× c). The values of **M** used in the analysis are depicted in the legends of Figures 2 and 3, located in the last column of the colored grid. For the soil (grid) beneath the footing, a higher **M** value was applied, attributed to a higher applied suction which caused a higher enhancement in cohesion. As the soil was closer to the water table level (resulting in a lower suction value), a smaller **M** value was utilised. In C2, higher **M** values were applied compared to C1, as shown in Figure 3. SEC3 in Figure 3c represented the case in which the increase in cohesion due to suction was doubled (c = 10 kPa) with **M** = 2. As stated above, the fully saturated and fully dry cases (**M**=1, indicating no changes in soil fabric) were also considered, represented by the white colour in Figures 2 and 3.

4 NUMERICAL RESULTS

The failure mechanisms results obtained for C1 and C2 are shown in Figures 2 and 3, respectively. The case with no spatial variability (**M**=1), denoted as NS in the figure's legend, was superimposed with the modelled categories, denoted as SP. In Figure 2 (C1), similar

failure mechanisms were observed for both NS and SP cases, with the SP case exhibiting a higher ultimate bearing capacity ($\mathbf{Q_{ult}}$), discussed later. However, Figure 3 (C2) depicted wider and deeper failure mechanisms for cases with **M**=2 compared to C1. Clearly, the higher c value and **M**, the wider and deeper failure mechanism was obtained, see Figure 3c. The implications of the obtained failure mechanisms are significant, as strength mobilisation is a possible scenario attributed to changes in fabric,therefore, spatial variability in cohesion.

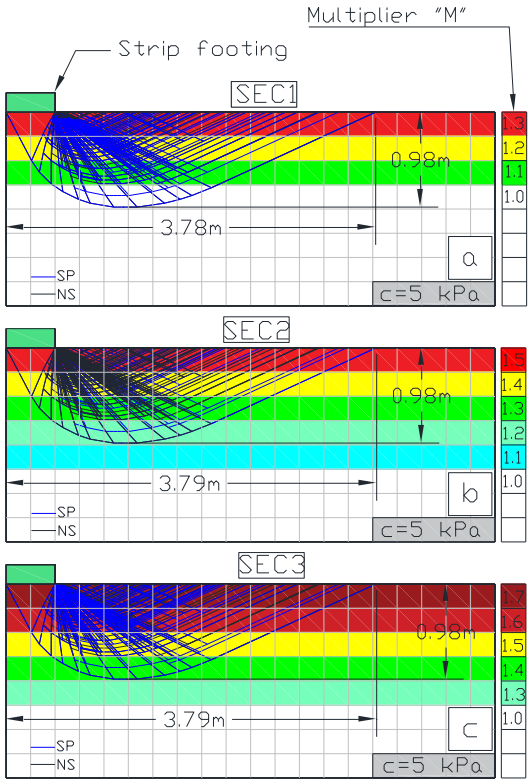

*Figure 2. Results of failure mechanisms for various scenarios with different values of **M** applied to cohesion in category 1 for (a) SEC1, (b) SEC2, and (c) SEC3.*

Figure 4 a and b shows the numerical results of the modelled scenarios previously presented in Figures 2 and 3. The x and y axes represent normalised suction and utlimate bearing capacity, respectively.

It is evident that the effect of unsaturated condition was significant compared to both the fully saturated condition (s=0 kPa) and dry case (plotted as a horizontal dashed line). For example, a 3.8-fold increase in normalised $\mathbf{Q_{ult}}$ was obtained at s/AEV = 4 for the NS case when compared with s = 0 kPa (S_r =1). Experimental studies in the literature have reported significantly higher increases in $\mathbf{Q_{ult}}$ (Mohamed and Vanapalli, (2006) (≈ 6 fold) and Shwan and Smith (2014) (≈ 10 fold). The ultimate bearing capacity was seen then to decrease, attributed to desaturation-induced strength reduction.

On the other hand, the effect of spatial variability in cohesion on the normalized $\mathbf{Q_{ult}}$ was significant. A 2.1% increase in $\mathbf{Q_{ult}}$ was obtained when comparing the C1-SEC1 with the NS cases (Figure 4a), even though almost identical failure mechanisms were obtained in Figure 2a as stated previously.

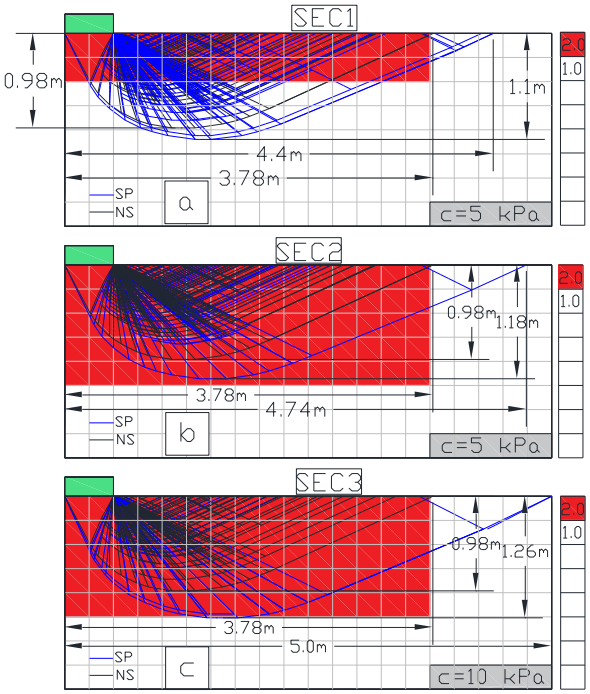

*Figure 3. Results of failure mechanisms for various scenarios with different values of **M** applied to cohesion in category 2 for (a) SEC1, (b) SEC2, and (c) SEC3.*

Figures 4a and b also exhibit other percentage increases in $\mathbf{Q_{ult}}$, when comparing SP cases with their respective NS cases. The case C2-SEC3 exhibited the highest increase in $\mathbf{Q_{ult}}$ (Figure 4b) as higher c=10 kPa and **M** =2 were used. The value **M**=2 represented the scenario where c increased by a factor of 2 due to suction effects. Experimentally, a 4.1-fold increase in c for unsaturated samples, attributed to fabric changes, was reported (Reis et al., 2011).

5 CONCLUSIONS

Even within a homogeneous deposit, soils may exhibit spatial variation in cohesion. This paper addressed a numerical study into the effects of spatial variability in cohesion for a simulated soil, attributed to fabric changes, on the ultimate bearing capacity ($\mathbf{Q_{ult}}$) for a rigid surface strip footing using an upper bound theorem, UNSAT-DLO approach. The approach, considers the effect of suction on strength, was utilised to model two different categories. Each category comprised three different scenarios. The scenarios accounted for spatial variability by applying different

multipliers (**M**) to cohesion (**M**×*c*), representing various improvements in soil fabric resulting from the application of different suction levels.

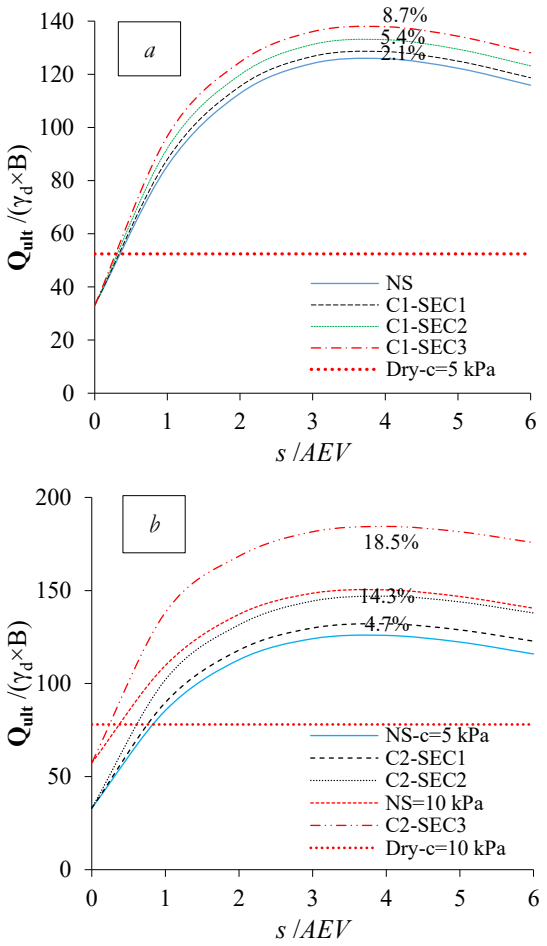

Figure 4. Normalised ***Q****ult versus normalised suction for various scenarios of the Category (a) C1 and (b) C2.*

The numerical results demonstrated a significant effect of spatial variability in cohesion on **Q**ult. Up to 8.7% and 18.5% increase in **Q**ult were obtained for various applied **M** values. Finally, different failure mechanism patterns were observed in the modelled scenarios. A wider and deeper failure mechanism was obtained when a higher **M** value was applied to a higher cohesion value case.

Prediction of load transfer curves in pile groups executed in profiles of granular soils from field test measurements

Prédiction des courbes de transfert de charge dans des groupes de pieux exécutés dans des profils de sols granulaires à partir de mesures d'essais sur le terrain

D.F. Silva*, A.S. Moura
Federal University of Ceará, Ceará, Brazil
**dantonfranca@alu.ufc.br*

ABSTRACT: Load transfer methods are relevant tools for predicting the load-settlement curve in single piles and pile groups. Several experimental studies use instrumentation data to evaluate the load transfer mechanism from the pile to the foundation soil. For pile groups, the load transfer t-z and q-z curves can be approximated to hyperbolic functions for each individual pile, adding the effect of interaction between piles through analytical formulations. Through the collection of data from 13 instrumented grouped piles (driven and bored) executed in granular soils and subjected to static loading tests, this study made predictions of the parameters that describe the hyperbolic t-z and q-z curves from correlations with field test measurements, standard penetration test (SPT) and cone penetration test (CPT), pile geometry, and initial geostatic stresses. The present research found that the parameters that describe the initial stiffness of the t-z and q-z curves have no correlation with field test measurements, unlike the parameters that describe the ultimate resistances. Therefore, in terms of load-settlement curve, the proposals were validated for a group of non-instrumented piles. The validation showed convergence of the load-settlement curve mainly for lower loads. Finally, predictions made from CPT test measurements showed more convergence to the experimental curve.

RÉSUMÉ: Les méthodes de transfert de charge sont des outils pertinents pour prédire la courbe de charge- déplacement des pieux simples et des groupes de pieux. Plusieurs études expérimentales utilisent des données d'instrumentation pour évaluer le mécanisme de transfert de charge du pieu au sol de fondation. Pour les groupes de pieux, les courbes de transfert de charge t-z et q-z peuvent être approximées par des fonctions hyperboliques pour chaque pieu individuel, en ajoutant l'effet de l'interaction entre les pieux au moyen de formulations analytiques. En recueillant des données sur 13 pieux de groupe instrumentés (enfoncés et excavés) enfoncés dans des sols granulaires et soumis à des essais de charge statique, cette étude a fait des prédictions sur les paramètres décrivant les courbes hyperboliques t-z et q-z sur la base de corrélations avec les mesures provenant d'essais sur le terrain, d'essais de percussion (SPT) et d'essais de pénétration par cône (CPT), de la géométrie des pieux et des contraintes géostatiques initiales. Cette recherche a montré que les paramètres décrivant la rigidité initiale des courbes t-z et q-z ne sont pas en corrélation avec les mesures des essais sur le terrain, contrairement aux paramètres décrivant les résistances dernières. Ainsi, les propositions ont été validées en termes de courbe charge-choc pour un groupe de pieux non instrumentés. La validation a montré une convergence de la courbe charge- déplacement, en particulier pour les charges les plus faibles. Enfin, les prédictions basées sur les mesures des essais CPT étaient plus conformes à la courbe expérimentale.

Keywords: Load transfer curves; pile group; load-settlement curve; hyperbolic functions.

1 INTRODUCTION

Load transfer methods are methodologies used to predict the distribution of the load applied to the pile into the soil. This is achieved by discretizing the pile into segments supported by nonlinear springs. The behavior of the nonlinear springs is defined based on load transfer curves, also known as t-z and q-z curves. These t-z and q-z curves are associated with the mobilization of lateral friction and end-bearing resistance, respectively, in relation to the corresponding displacement.

In this context, for grouped piles, various authors such as Gomes Filho and Moura (2021), Pan *et al.* (2017), and Zhang *et al.* (2016) propose that the t-z and q-z curves can be defined using a hyperbolic function that describes the behavior of an individual pile, as described by Fleming (1992), adding the group effect through analytical formulations, while considering the interaction between each pair of adjacent piles.

More recently, Silva and Moura (2023) proposed that the t-z and q-z curves in pile groups can be represented by hyperbolic functions. Silva and Moura (2023) also obtained the values of parameters *a* and *b* for hyperbolic t-z and q-z curves from the collected experimental studies. These parameters are associated with initial stiffness and maximum mobilized resistance, respectively, as shown in Figure 1 for the t-z curve.

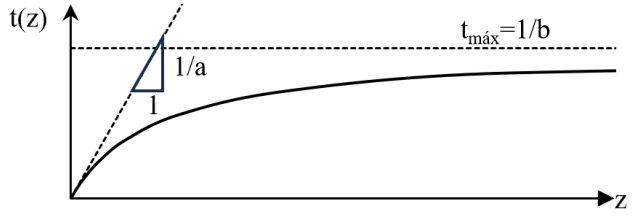

Figure 1. Hyperbolic function parameters: (a) t-z curve; (b) normalized t-z curve.

In this context, the objective of this study is to evaluate the possibility of predicting load-settlement curves in grouped piles and within granular soil profiles through correlations of hyperbolic t-z and q-z curve parameters with field test measurements. Specifically, the study focuses on measurements from cone penetration tests (CPT), including the tip resistance (q_c, in MPa) and the side friction resistance (f_s, in kPa), as well as measurements from the standard penetration test (SPT), which involves the penetration resistance index (N_{SPT}, in blow counts).

2 MATERIALS AND METHODS

Initially, the collected experimental studies were presented, as well as the characterization of the data collected about the geometry of the pile, the field tests conducted and the results of instrumented load tests.

Considering the adjustment and determination of parameters *a* and *b* for the hyperbolic t-z and q-z curves for each instrumented pile group, as well as the defined values of parameter M for pile groups as presented by Silva and Moura (2023), and the collection of field test measurements, N_{SPT}, q_c, and f_s, predictions were made for the parameters *a* and *b*. The parameter M can be defined as the initial stiffness of the load transfer curves normalized by the ultimate resistance (1/b) and pile diameter (D), and described by Equation 1. Consequently, predictions were made for the t-z and q-z curves, as well as load-settlement curves. These correlations were validated in terms of load-settlement curves for a group of non-instrumented piles.

$$M = \frac{1}{b}\frac{a}{D} \quad (1)$$

2.1 Collected field study locations

The research was developed based on the collection of field test results from instrumented, grouped piles subjected to static load tests (SLT) in granular soil profiles. To achieve this, five experimental studies were selected, totaling 10 instrumented pile groups, with 2 of them consisting of more than one instrumented pile in the group. Table 1 provides a description of the selected experimental study locations and the number of PCEs conducted.

Table 1. Locations of selected experimental studies.

Site (SLTs)	Area	Authors
1 (1)	Califórnia, USA	Briaud *et al.* (1989)
2 (3)	Ontário, Canadá	Abdlrahem and El Naggar (2020)
3 (1)	Kuwait City, Kuwait	Ismael (2001)
4 (3)	Gråbo, Suécia	Long (1993)
5 (2)	Lituânia	Norkus and Martinkus (2019)

2.2 Characterization of collected data

The characterization of the selected grouped piles from the experimental studies is presented in Table 2. The table provides identification of the used piles and their respective sites, the installation method (IM), pile diameter (D), embedded pile length (L), the maximum total load obtained in the pile group from the SLT, the quantity (N) of piles in the group, the spacing-to-diameter ratio (s/D) between the pile centers, and the maximum displacement values ($w_{máx}$).

Table 2. Characterization of selected instrumented piles.

Site	Pile Code	IM[a]	D (L) [mm]	LS[b]	Q_t [kN]	N (s/D)	$w_{máx}$ [mm]
1	1-2A	d	0.273	s	2,000	5 (3)	18.0
	1-2B		(9.15)				
	1-2C						
2	2-3A	b	0.172	r	1,975	4 (4.4)	8.8

	5-3A		(1.445)		700	4 (2)	22.5

[a] Installation method: driven (d) or bored (b);
[b] Loading speed of SLT: slow (s) or rapid (r).

In general, most of the instrumented grouped piles are driven, with diameters ranging from 0.10 to

0.273 m and lengths between 1.445 and 9.15 m. The groups consist of 4 or 5 piles and are spaced 2 to 8 times the pile diameter.

As for the load tests, the maximum load applied to the group varied from 26.4 to 2000 kN. The values of the maximum mobilized shaft resistance ($t_{máx}$) and end resistance ($q_{máx}$) ranged ranged from 6.1 to 278.4 kPa, and from 583 to 5115 kPa, respectively.

Regarding the field investigations conducted before the load tests, only the group related to site 3 lacks a CPT test, and sites 4 and 5 do not have associated SPT tests. The N_{SPT} values ranged from 17 to 40 blows, and the q_c and f_s values varied from 0.8 to 19.5 MPa and 10 to 174 kPa, respectively.

3 PREDICTION OF LOAD TRANSFER CURVES

To predict hyperbolic t-z and q-z curves in grouped piles subjected to axial compressive loads in sandy soil profiles, the parameters of the hyperbolic curve *a* and *b* obtained by Silva and Moura (2023) were used. For this purpose, it is defined that the parameters $a_{g,t}$ and $a_{g,q}$ correspond to the parameters *a* in grouped piles for the t-z and q-z curves, respectively. Similarly, the parameters $b_{g,t}$ and $b_{g,q}$ correspond to the parameters *b* of the hyperbolic curve for the t-z and q-z curves.

Thus, the aim is to make predictions for the parameters describing the hyperbolic t-z and q-z curves, $a_{g,t}$, $a_{g,q}$, $b_{g,t}$, and $b_{g,q}$. The correlations for the parameters *a* and *b* are carried out based on measurements from SPT and CPT tests, N_{SPT}, q_c, or f_s, as well as the pile diameter (D), initial geostatic stresses (σ'_{v0}), and the logarithm of the sum of relative distances between piles (ln $[\sum(r_{ij}/D)]$), where r_{ij} is the center-to-center distance between piles i and j.

Hence, correlations were established by combining one or more of these variables and adjusting their exponents to obtain curves that fit the experimental results of the instrumented piles. This was based on the coefficient of determination (R^2) of the fitting curve and the uniform distribution of experimental data points.

Figure 2 illustrates the correlation obtained for the parameter $a_{g,t}$. Equations 2 to 7 present the equations defining the correlations obtained for the parameters $a_{g,t}$, $a_{g,q}$, $b_{g,t}$, and $b_{g,q}$, with correlations for the latter two parameters derived from SPT and CPT test measurements separately: N_{SPT}, f_s e q_c. It is worth noting that the correlations for $a_{g,t}$ and $a_{g,q}$ did not converge with field test measurements and may be better described using other variables.

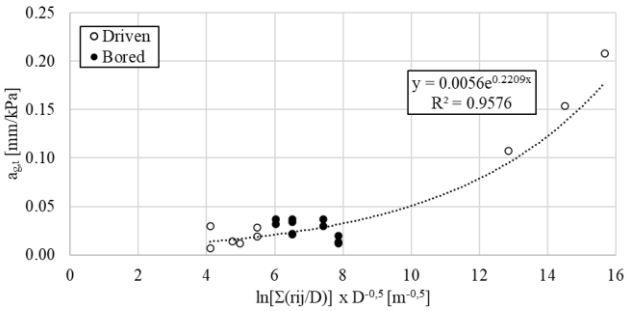

Figure 2. Correlation of the parameter $a_{g,t}$.

$$a_{g,t} = 0.0056 * e^{0,2209*\ln\left[\sum\left(\frac{r_{ij}}{D}\right)\right]*D^{-0.5}} \quad (2)$$

$$a_{g,q} = 0.0007 * e^{3.2725*\sigma'^{\,0.5}_{v0}*\ln^{-2}\left[\sum\left(\frac{r_{ij}}{D}\right)\right]*D} \quad (3)$$

$$b_{g,t} = 0.0015 * e^{0,3541*N_{SPT}^{-1}*\sigma'_{v0}} \quad (4)$$

$$b_{g,t} = 0.0014 * e^{7.0058*f_s^{-0.5}*\ln^{0.5}\left[\sum\left(\frac{r_{ij}}{D}\right)\right]} \quad (5)$$

$$b_{g,q} = 0.0014 * \left(N_{SPT}^{-0.5} * \ln\left[\sum\left(\frac{r_{ij}}{D}\right)\right] * D\right) + 2 * 10^{-5} \quad (6)$$

$$b_{g,q} = 9 * 10^{-5} * e^{0,8284*q_c^{-1}*\ln\left[\sum\left(\frac{r_{ij}}{D}\right)\right]} \quad (7)$$

In general, the fitted curves of the correlations showed high R^2, exceeding 0.93, except for the correlation of the parameter $a_{g,q}$ (R^2=0.89) and the parameter $b_{g,q}$ in relation to N_{SPT} (R^2=0.82).

It is worth noting that the method of installation of the piles did not influence the correlation results, as unique trends were observed in the correlations. Additionally, this study does not take into account the influence of various technologies for driven and bored pile installation.

To validate the correlations, the non-instrumented pile group from site 2, denominated as MPG1, was used. Two predictions were made (Figure 3), one based on N_{SPT} and the other based on f_s and q_c.

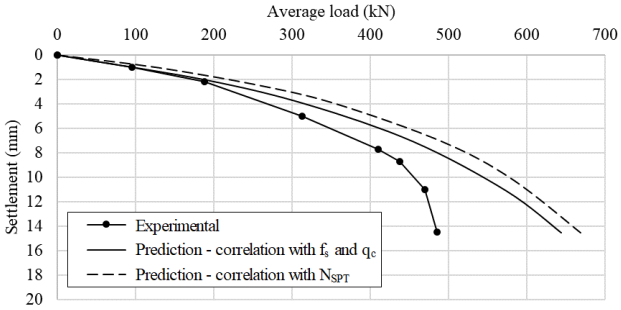

Figure 3. Comparison between the experimental and predicted load-settlement curves - MPG1 group.

From the figure, it can be observed that the predicted curves converged to the experimental curve, and the predictions based on correlations with f_s and q_c (CPT test) showed greater convergence compared to the curve obtained from correlations with N_{SPT}.

4 CONCLUSIONS

For the correlations of the parameters of the hyperbolic t-z and q-z curves in grouped piles, it was observed that both driven and bored piles showed a unique trend, allowing for predicting the parameter values from the same fitting curve.

Regarding the parameters $a_{g,t}$ and $a_{g,q}$, they are not correlated with field test measurements and converge when correlated with the diameter (D) of the pile, the spacing-to-diameter ratio of the pile (ln [$\Sigma(r_{ij}/D)$]), and the initial stress state ((σ'_{v0}), with R^2 equal to 0.96 and 0.89, respectively. It is noteworthy that this result was unexpected, considering that the formulations developed by Zhang *et al.* (2016) and Gomes Filho and Moura (2021) assume that the group effect is associated with the shear modulus (G) of the material under in situ conditions.

As for the parameters $b_{g,t}$ and $b_{g,q}$, they were estimated from field test measurements, showing convergence to the correlations with R^2 greater than 0.93, except in the correlation of the parameter $b_{g,q}$ from N_{SPT}. Furthermore, it can be observed that an increase in the value of field test measurements leads to a reduction in the parameter *b* and, consequently, an increase in mobilized resistance.

The validation in terms of load-settlement curves indicated adherence of the predicted curves to the experimental ones, especially through correlations with CPT measurements. Furthermore, it can be noticed that, for displacements up to 2 mm, the prediction through correlations with f_s and q_c surpasses the experimental curve. This suggests a greater convergence in the parameters describing the initial stiffness of the load transfer curves, $a_{g,t}$ and $a_{g,q}$.

ACKNOWLEDGEMENTS

The authors would like to thank the Department of Hydraulic and Environmental Engineering (DEHA) of the Federal University of Ceará (UFC) for supporting this research, and to the Brazilian Federal Agency for Postgraduate Education (CAPES) and the Brazilian National Council for Scientific and Technological Development (CNPq) for the financial support.

ABSTRACT: Geotechnical and structural instrumentation and monitoring have developed significantly in recent years, with the emergence of new technologies, such as medium and long-range wireless transmission equipment, that allow faster and more efficient data collection and transmission. The article proposes the performance analysis of a retention wall structure defined for an urban excavation in Lisbon using an automated geotechnical monitoring plan. It discusses the benefits and potential improvements in implementing geotechnical monitoring solutions in national projects. The monitoring plan defined uses different instruments, including vibrating wire piezometers, MEMS load cells, Shapearray automated inclinometers and biaxial tiltmeters, which provide several daily readings available in a remote and online acquisition system. The objective is to ensure the best conditions of the solution's safety, efficiency, and cost, reducing the uncertainties inherent to geological-geotechnical conditions through the Observational Method.

RÉSUMÉ: L'instrumentation et la surveillance géotechniques et structurelles se sont considérablement développées au cours des dernières années, avec l'émergence de nouvelles technologies, telles que les équipements de transmission sans fil à moyenne et longue portée, qui permettent une collecte et une transmission plus rapides et plus efficaces des données. L'article propose l'analyse des performances d'une structure de mur de soutènement définie pour une excavation urbaine à Lisbonne à l'aide d'un plan de surveillance géotechnique automatisé et discute des avantages et des améliorations potentielles dans la mise en œuvre de solutions de surveillance géotechnique dans les projets nationaux. Le plan de surveillance défini utilise différents instruments, notamment des piézomètres à corde vibrante, des capteurs de pesage MEMS, des inclinomètres automatisés Shapearray et des inclinomètres biaxiaux, qui fournissent plusieurs relevés quotidiens disponibles dans un système d'acquisition à distance et en ligne. L'objectif est d'assurer les meilleures conditions de sécurité, d'efficacité et de coût de la solution, en réduisant les incertitudes inhérentes aux conditions géologiques et géotechniques grâce à la méthode d'observation.

Keywords: Geotechnical monitoring; instrumentation; observational method; inclinometers; piezometers.

1 PROJECT DESCRIPTION

The "Phoenix Building" project comprises the constructing a building with seven upper floors, one ground floor and three underground floors in a densely urbanized region of Lisbon, Portugal, with roads, railways and other buildings and infrastructures in its surroundings. The ground floor will be subdivided into three levels to connect with the surrounding streets. The earth retaining solution adopted consists of reinforced concrete diaphragm walls with a thickness of 50cm.

Prior to the start of construction, preliminary work was carried out, including removing soil and forming temporary slopes. The diaphragm walls were excavated mainly with a hydraulic grab, although in certain situations, vertical holes were drilled with a short auger and a Kelly rod.

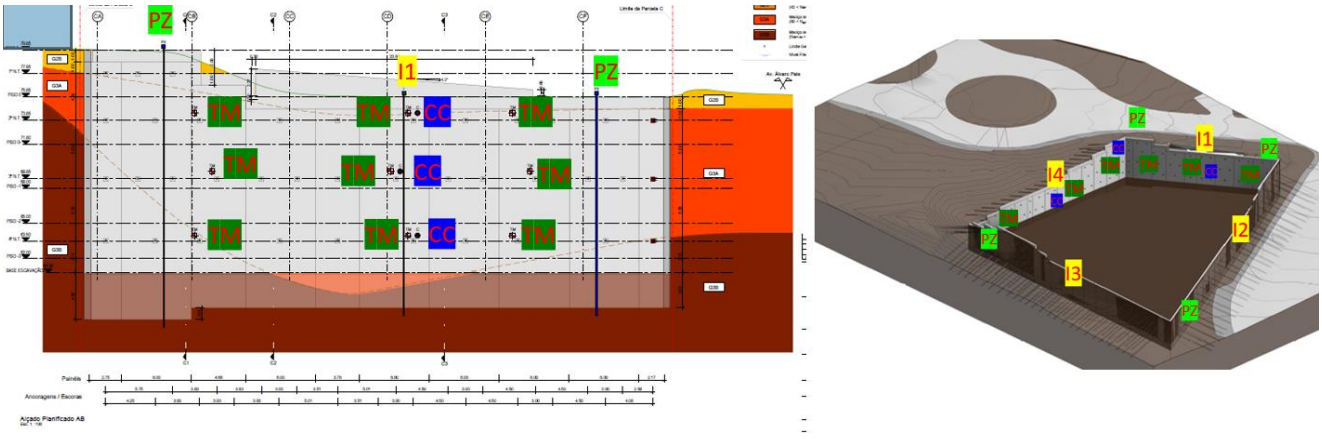

Figure 1. (Right)Instruments location in one of project cross-sections and (left)overview of a BIM 3D projection. I-inclinometer (ShapeArray); TM- Tiltmeter, CC-Load Cell, PZ-Piezometer.

During the provisional phase, the stability of the retaining wall was ensured through the application of prestressed anchors (2, 3 and 4 levels) and the installation of metal corner struts arranged at different levels.

In the final phase of construction, the integrity of the retaining wall was maintained by the structure of the building in relation to the pressures exerted by the ground and road loads. The support systems, including anchors and struts, will be decommissioned after the main structure is completed.

Summarizing, the "Phoenix Building" project encompasses the construction of a building in highly dense urban area with particular attention to retaining wall, excavation and interlocking, with the deactivation of the temporary systems after the completion of the main structure.

2 INSTRUMENTATION PLAN

The Instrumentation Plan aims to ensure safety and economy in the excavation and retaining wall of buried floors and to analyze the behaviour of structures and infrastructures during execution. The plan includes the measurement of horizontal displacements of the retaining wall, wall rotations, water level, load on the anchors and vertical displacements of the surrounding roads, using devices such as automated inclinometers (ShapeArrays), tiltmeters, piezometers, load cells and topographic marks. The plan was developed to analyze the main risks associated with executing stages.

The instruments were distributed across the four design elevations, as illustrated in the figure 1, where the instrumentation locations and 3D perspective are demonstrated. The load cells were placed in reference alignments, for which a calculation model was made, and these sections also have an inclinometer. On the other hand, 9 topographic marks were placed in total, 3 along the streets Sousa Lopes, 3 along Av. Álvaro Pais and 3 along the IP (Portugal Infrastructures) railway lines.

Table 1. Summary table of the instruments and monitored variables.

Quantities (un)	Instrument	Measured variables
4	Automated Inclinometers (ShapeArrays)	Horizontal displacements of the retaining wall
30	Tiltmeters	Retaining wall rotations
4	Vibrating wire Piezometers	Water level
16	Load Cells	Load on anchors
9	Topographic Prisms	Settlements of the surrounding structures

2.1 Collection Frequency

Given the characteristics of the project, it was recommended that the installed devices be read daily (every 6 hours) during the execution of excavation, retaining wall and superstructure work (and could be adjusted if necessary). The periodicity of reading of the topographic marks was monthly; these were the only non-automated instruments. The results were presented in online numerical tables and graphic plots and interpreted by the geotechnical consultant in collaboration with the site and supervision technicians.

2.2 Alarm Criteria

Based on the type and solution proposed for the containment executed, as well as the geology of the intervention site, it was possible to estimate the following criteria for the containment structure:

a) Alarm criterion: maximum displacements of 25mm in the horizontal direction and 10mm in the vertical direction.
b) Alarm criterion: maximum displacements of 35 mm in the horizontal direction and about 15 mm in the vertical direction.

2.3 Monitoring and Visualization System Automation

Automating geotechnical instrumentation using dataloggers and gateways is a technique increasingly used in construction and maintenance projects of geotechnical structures. This technique allows instrumentation data to be automatically collected by the data loggers and transmitted to a gateway, which sends the data to an online visualization platform.

The online platform (Level-GAM) for data visualization is a digital tool that allows the reading and interpretation of data collected by sensors installed in geotechnical structures in real-time. The platform can be accessed from anywhere, storing data in a secure and organized way, having been a valuable tool for long-term analysis of the behaviour of structures.

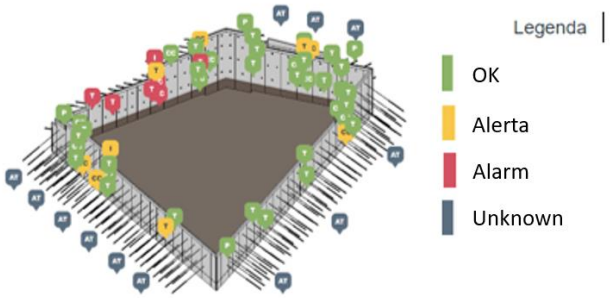

Figure 2. Level GAM online platform: Overview of the excavation, installed instruments and their status to date.

3 ANALYSIS AND INTERPRETATION

Subsequently, this paper will present and analyze the outcomes obtained from automated inclinometers strategically placed within the diaphragm walls. A comprehensive comparison will be drawn between the anticipated behaviour by numerical modelling and the actual observations made in the field.

These automated inclinometers played a pivotal role in the real-time monitoring of diaphragm wall stability, and they provided valuable correlations with other instrumentation systems such as load cells, tiltmeters, and piezometers.

The FEM models employed in this study utilize project-specific cross-sections as a reference. These models were instrumental in predicting the expected displacements within the structure. They consider geological and hydrogeological data, anchor characteristics (length, inclination, and load), and diaphragm wall parameters (thickness and sheet type). These models entail intricate mathematical calculations that factor in the geotechnical conditions of the site and the complex interactions with structural elements.

When conducting a comparative analysis between the numerical predictions and on-site results, several critical considerations must be taken into account. These include variations in geological and hydrogeological profiles, anchor quantity and load, and the distinct construction phases undertaken. It is essential to remember that numerical models are inherently predictive tools, and real-site conditions may deviate from these predictions. As such, monitoring remains an indispensable tool for substantiating these discrepancies and accurately assessing the actual field conditions

An integral facet of the analysis revolves around the pace at which excavation and anchor tensioning occurred. To shed further light on this aspect, the following figure will present the maximum cumulative displacements during the excavation phase, focusing on inclinometer I4, which exhibited the most substantial cumulative displacement.

Additionally, the figure 3 will depict the key milestones, including the testing dates of the closest anchors (N1, N2), the conclusion of the excavation phase in May 2022, a transitional period spanning from the completion of excavation to the initiation of the structural phase. Moreover, a specific emphasis will be placed on a notable period characterized by particularly intense rainfall between November and December 2022.

These temporal markers are crucial for a comprehensive understanding of the interplay between excavation and anchor tensioning and their influence on the behaviour of the diaphragm wall, especially in the context of external environmental factors such as heavy rainfall.

Table 2. Comparison table between expected and actual horizontal displacements.

ShapeArray	Estimated displacement (mm)	Actual displacement in May/2022 (mm)	Actual displacement in January/2023 (mm)	Alert Criterion (mm)	Alarm Criterion (mm)
I1	11,25	8,5	13,9	25,0	35,0
I2	11,25	5,4	8,5	25,0	35,0
I3	6,5	16,3	29,1	25,0	35,0
I4	6,5	15	38,5	25,0	35,0

Figure 3. Cumulative displacement plot with emphasis on the installation's stages of the anchors (N1, N2), end of excavation (F.E), period of heavy rains (Nov/Dec 22) and last reading made available (May/23), after reinforcement of the panel with complementary anchor.

4 DATA DISCUSSION

As depicted in Table 2, the behaviour of inclinometers I1 and I2 closely aligned with the predictions from the numerical models. These inclinometers also exhibited noticeable consistency between the excavation phases and the tensioning of anchors. Conversely, inclinometers I3 and I4 displayed deviations from the anticipated values generated by the numerical models, ultimately triggering alert and alarm criteria, respectively. It's worth noting that these inclinometers experienced a certain time lag between the excavation and tensioning phases, potentially attributable to their placement within a transitional zone spanning levels 2 and 3 of anchors. Particularly, inclinometer I3 exhibited the most pronounced deviation, possibly influenced by variations in the geological and geotechnical conditions.

Regarding the inclinometer behaviour, it's essential to mention that excavation reached its maximum depth in May 2022 and has since been halted. During this period, an unexpected upward trend in displacements was observed, deviating from the expected stabilization observed in I1 and I2. Moreover, this trend intensified notably between November and December.

In response to these deviations, especially with the attainment of alert and alarm criteria, on-site investigations were conducted to identify the root causes of the inconsistent behaviour in I3 and I4 compared to the initial expectations. It was determined that the malfunctioning of wedges within several anchors was the primary issue, preventing the proper locking of tensioned strands and, consequently, the stabilization of the walls. This issue was prevalent in various areas and was addressed at the end of December through corrective measures, including additional anchorages. Although the impact on inclinometers I3 and I4 was more pronounced, it resulted in the overall stabilization of the retaining wall behaviour, as illustrated in Figure 3. Notably, sections I3 and I4 were equipped with only two anchors levels, certainly limiting their capacity for redistribution.

Finally, the displacements acceleration between November and December was attributed to heavy rainfall during that period. It's important to highlight that the inclinometer instrument panels for I3 and I4 were installed on excavation slopes. The heavy rain, combined with the observed impermeability of the soil layers, likely led to increased loads from the back of the containment structure due to soil saturation on the slope. This, in turn, contributed to the observed displacements.

It's crucial to emphasize the Observation Method application benefits and also the remaining instrumentation, including tiltmeters and load cells, corroborated the observations made through the inclinometers. This underscores the significance of redundancy in instrumentation systems for validation and comprehensive structural behaviour monitoring.

5 CONCLUSIONS

The project's framework required the development of safe and cost-effective solutions that align with various constraints, including geological, geotechnical, and hydrogeological factors, as well as considerations for architectural preservation and the integrity of nearby structures and infrastructures.

In this context, the Instrumentation and Observation Plan played a crucial role in managing the performance of the retaining wall structure and adjacent infrastructures. It highlighted its essential role in an urban setting, reflecting the characteristics of the current project.

Moreover, the importance of employing an automated instrumentation system was emphasized. This system not only proved its value in detecting deviations from expected behavior during periods of reduced oversight but also showcased its ongoing usefulness in monitoring and evaluating the effectiveness of implemented corrective measures.

Comparison of collapse loads obtained in 2D and 3D slope stability limit analysis

Comparaison des charges d'effondrement obtenues lors de l'analyse des limites de stabilité de pente 2D et 3D

ABSTRACT: The basis for the typical geotechnical designs of slopes and excavations are limit analysis calculations that assume 2D plane strain. The assumption is typically rather conservative, thus such design may require unnecessary additional construction material, as well as increase the construction time and environmental costs. In this paper, we present limit analyses of an embankment near a slope, typical for a temporary dead-end road in a mine or on a construction site. We modelled this problem in 2 and 3 dimensions, using Optum G2 and Optum G3 software, respectively. The results show that the 3D analysis provides collapse loads significantly higher than the 2D analysis. The shapes of the sliding surfaces also differ, as the 3D analysis allows us to determine the shape of the sliding surface in places where a 2D cross-section must be taken overly conservative. It, therefore, allows a better understanding of the mechanical behaviour of the studied structure. The collapse loads differ significantly between 2D and 3D analyses, potentially justifying the extra effort required for 3D calculations.

RÉSUMÉ: La base des conceptions géotechniques typiques des talus et des excavations repose sur des calculs d'analyse limite qui supposent une déformation plane 2D. L'hypothèse est généralement plutôt conservatrice, de sorte qu'une telle conception peut nécessiter des matériaux de construction supplémentaires inutiles, ainsi qu'augmenter le temps de construction et les coûts environnementaux. Dans cet article, nous présentons des analyses limites d'un remblai à proximité d'une pente, typique d'une impasse temporaire dans une mine ou sur un chantier de construction. Nous avons modélisé ce problème en 2 et 3 dimensions, en utilisant respectivement les logiciels Optum G2 et Optum G3. Les résultats montrent que l'analyse 3D fournit des charges d'effondrement nettement supérieures à l'analyse 2D. Les formes des surfaces de glissement diffèrent également, car l'analyse 3D nous permet de déterminer la forme de la surface de glissement aux endroits où une section 2D doit être prise de manière trop conservatrice. Cela permet donc de mieux comprendre le comportement mécanique de la structure étudiée. Les charges d'effondrement diffèrent considérablement entre les analyses 2D et 3D, justifiant potentiellement l'effort supplémentaire requis pour les calculs 3D.

Keywords: Limit analysis; 3D calculations; slope stability.

1 INTRODUCTION

Design of slopes in daily engineering practice typically uses 2D Limit Analysis or 2D Finite Element Method. Often, the Limit Analysis implementation is still one of the methods of slices, in which extra assumptions are necessary as, otherwise, the number of equations is insufficient to obtain the solution. The extra assumptions are typically conservative, yet in rare cases, they are not. This is because the method of slices ultimately calculates the upper limit load. The obtained value guarantees that the failure happens at the selected load, under assumptions taken. Yet, a not-analysed, different sliding surface with a lower bearing capacity may exist. In some cases, 3D analysis (still based on the method of slices that become prisms in 3D) may lead to a lower limit load (see e.g. Firincioglu and Ercanoglu, 2021), as the assumptions used for generating the extra equations for 3D analysis are slightly different. This should not be confused with an overall lack of safety when the method of slices is used. As shown in Krahn (2003), the collapse loads obtained from the Finite Element Method are often higher, as the extra assumptions used in the method of slices are typically conservative.

However, nowadays there are commercial software packages that allow for arbitrary accurate limit analysis, with no need for extra assumptions required for the method of slices, see for example Sloan (2011) and Krabbenhoft and Lyamin (2015). Such software gives upper and lower bounds for the

solution, hence the accuracy is governed by the limit analysis assumptions, created model, and the accuracy of the parameters used for the soil. The calculation error may be minimised to as low a value as deemed necessary by the designer. Alternatively, one can use Finite Element Analysis, where more advanced constitutive models for soil may be used, leading to a more accurate estimation of the collapse load. However, the numerical error is uncertain in such analysis as no upper and lower bound for the solution is given. Advanced Finite Element Method analyses are not considered in this paper, as the choice of extra parameters for the advanced constitutive model (e.g. related to softening of the material in line with the amount of shear strain) may lead to results that are far from the limit analysis results. On the other hand, results obtained with the Finite Element Method and Mohr-Coulomb model, under similar assumptions to those in limit analysis typically lead to collapse load in between the lower and upper bound computed with limit analysis. That is because the method giving the lower bound collapse load is similar to the Finite Element Method coupled with a special type of element.

In engineering practice, rarely the collapse load is computed in 3D. That may be due to the software package limitations or the extra effort to obtain the solution is considered not worth the savings. This paper shows that in some cases where the 2D cross-section must be taken as very conservative, the difference between 2D and 3D solutions can be very significant, potentially doubling the allowed load, and hence the use of 3D analysis for design may lead to substantial savings.

2 METHODS

Upper and lower bound limit analysis simulations were performed using Optum G2 and Optum G3 software. The problem studied represents a dead-end embankment placed next to a conical excavation, a situation often encountered in mines. We compute the upper and lower limit load based on a safely assumed 2D cross-section and then we perform the full 3D analysis.

The simulations assume undrained shearing, with soil described by a Tresca model, while the loads are transmitted to the ground through rigid plates. The choice of plates over layers of flexible pavement structure is made for simplicity. The plates are rigid as the limit analysis only handles rigid perfectly plastic materials.

The 2D and 3D geometry is given in Figure 1 and Figure 2, respectively. The total length of the domain in the horizontal direction is 78m. The embankment has a height of 2m and measures 36m at the bottom and 16m at the top, with the loaded plates taking the middle 8m. Below the embankment, there is a 1m deep dry crust soil layer. The hole has a 20m radius and a depth of 7m, reaching the end of the domain. The modelled depth of the soft clay layer below the dry crust is 18m. The 3D domain spreads additionally in the z direction for 40m, the diameter of the hole. The embankment slope spreads similarly 10m in the direction parallel to the embankment. All boundary conditions are standard, allowing for the movement of the material in the vertical direction at the sides and no movement at the bottom.

The embankment material is approximated with the Mohr-Coulomb model, with friction angle being 32 degrees and cohesion of 1 kPa, while its unit weight is 18 kN/m^3. The dry crust and soft clay layers are modelled as undrained Tresca materials. The dry crust layer has a constant undrained shear strength of 20 kPa and a unit weight of 18 kN/m^3. The clay layer has an undrained shear strength of 10 kPa, increasing by 1.7 kPa with each meter of depth and unit weight equal to 15 kN/m^3. The initial horizontal-to-vertical stress ratio K_0 in all the material is taken as 0.5. All the materials are assumed to have no tensile shear strength, with a vertical cut-off of the yield surfaces at zero mean effective stress. The forces are transmitted to the soil through rigid weightless plates.

3 RESULTS

The 2D analysis, made with approximately 50000 elements, resulted in collapse at the load between 30.5 kPa (lower bound) and 30.8 kPa (upper bound). Due to limitations in computer memory (32 GB), 3D analysis was also made with approximately 50000 elements and gave the failure load between 71 kPa (lower bound) and 79 kPa (upper bound), see Table 1 for a summary. The use of a larger number of elements would reduce the gap between the upper and lower bounds, though as the collapse load is guaranteed to be at least equal to the lower bound, the results show at least a 130% increase in the collapse load when 3D is taken into account. The shape of failure surfaces is given in Figure 3 for 2D calculations and in Figure 4 for the 3D case.

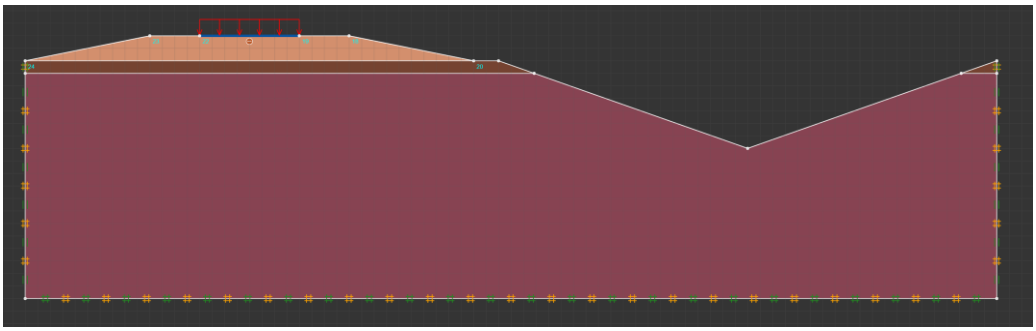

Figure 1. 2D geometry of the problem.

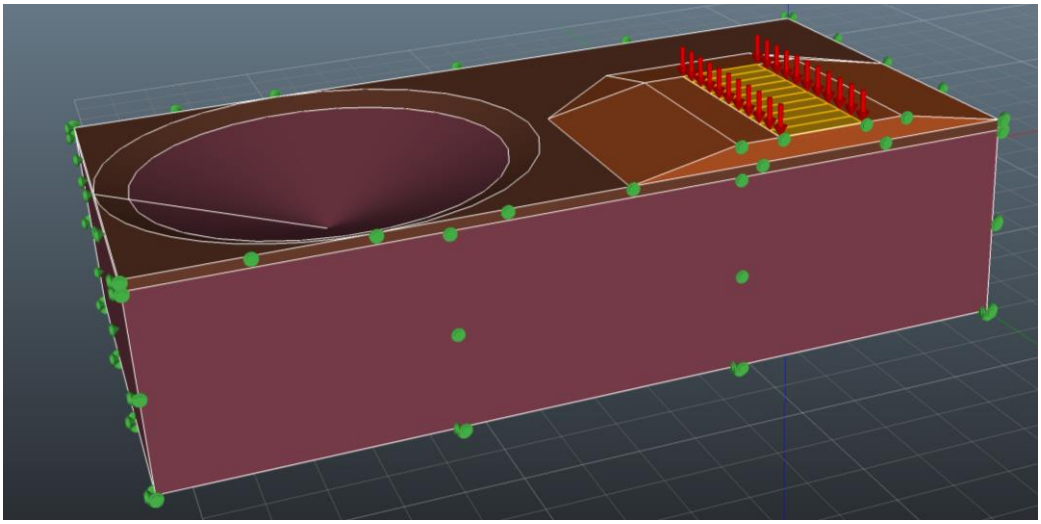

Figure 2. 3D geometry of the problem.

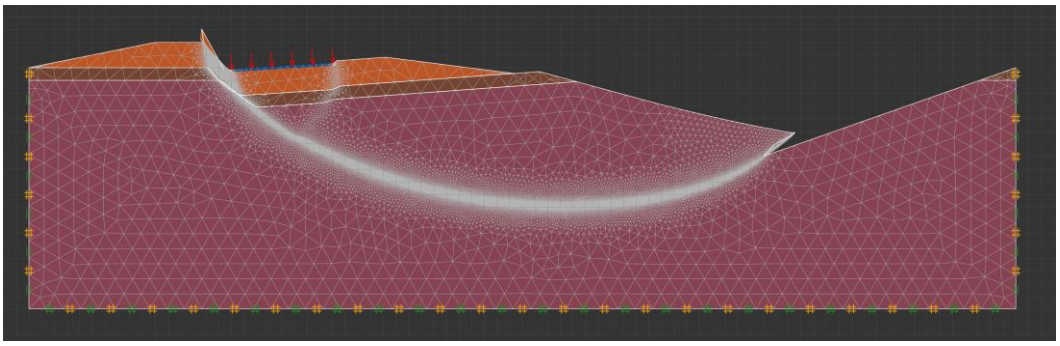

Figure 3. 2D failure surface.

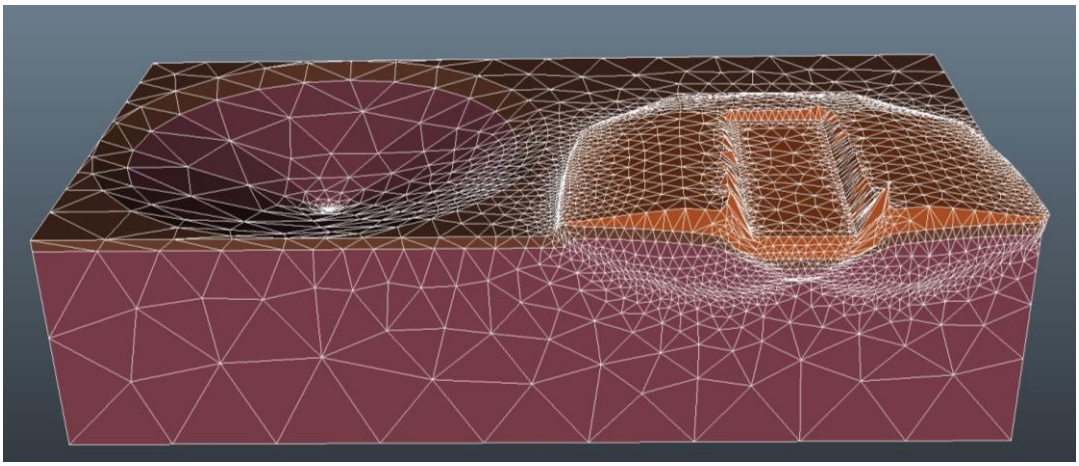

Figure 4. 3D failure surface.

Table 1. Obtained limit loads.

Analysis	Lower bound	Upper bound
2 Dimensional	30,5 kPa	30,8 kPa
3 Dimensional	71	79

4 DISCUSSION

The obtained results are very accurate for 2D analysis, with the difference between the lower and upper bound being around 1%. The difference grows to 10% in the case of 3D analysis. Nonetheless, as the lower bound load is guaranteed to be safe, the 3D analysis gives at least 2,3 times higher collapse load. This huge difference is due to a very conservative selection of the 2D cross-section, leading to different failure mechanisms in 2D and 3D, see Figures 3 and 4. This difference is large enough to have a real economic impact. Design based on 3D analyses can save money, materials and construction time.

However, 3D analysis requires a much larger amount of work as well as an investment in software and training. The 2D case can be easily computed in a day, a 3D case perhaps requires at least two or three days of work. The results indicate that the additional work can be justified by savings made. However, 3D design is something that can only be profitable for a company when the investors aim for lower cost of construction work, instead of lower cost of design and when the investors are willing to allow for additional time, likely required both for extra soil investigations, needed due to lower safety overall and longer design period.

Moreover, the 3D design, being unusual is relatively unexplored and the 3D analysis software is still under active development, unlike the relatively stagnant state of 2D analysis software. In 3D analyses, it is more difficult to check the results and be certain about the correctness of the defined problem. The accuracy of the results is lower unless much more time is spent on computation. Complex geometries are even more tricky, as it is very easy to make a mistake.

Finally, one has to sound a word of caution. The collapse load obtained with 3D limit analysis may be computationally correct but is still inaccurate due to the assumptions made. Limit analysis does not allow for altering of soil strength depending on the amount of shear strain. In reality, it is well established that the shear strength of clays and other fine materials depends on the amount of shear strain, with initial strain caused e.g. by settlements. In limit analysis, the rigid-perfectly plastic analysis will not capture such effects. Similarly, the approximation of the strength for dense granular materials, as well as variation of the strength in complex stress states, and effects of water flow and pore pressures may not be fully accounted for in such analyses. In short, limit analysis is still a relatively crude tool. For even more accuracy, one would need to perform 3D Finite Element analysis with a complex soil model that would capture those more advanced aspects of soil behaviour.

5 CONCLUSIONS

The paper shows that the 3D calculations may result in vastly different collapse loads when compared to the 2D calculations. In the analysed problem, the collapse load in the 3D case was at least 71 kPa, which is at least 2,3 times higher than the highest possible collapse load from 2D analysis (30,8 kPa).

This result indicates that we may have reserves in our 2D designs, and relying on 3D calculations can lead to a reduction in costs. Yet, both designers and construction companies are often aware of those reserves. Hidden high factors of safety are convenient in design, as they allow for design based on more uncertain soil parameters without worry. Similarly, construction companies are likely to slim down the designs on the construction site, especially when the work is temporary. Hence, the more accurate design methods resulting in an overall lower factor of safety would also require a change of practices both during design and construction. For a successful move to designs based on 3D analyses, designers would need much more accurately established soil properties. On the other hand, construction companies would need to construct the earth structures more carefully, likely instrumenting and monitoring the site more closely.

Optimal pavement design using the failure probability

Conception optimale de la chaussée à l'aide de la probabilité de défaillance

ABSTRACT: In this paper, an optimal pavement design with and without geosynthetic reinforcement is discussed and evaluated. The probability of failure is calculated for these two optimal designs and the costs of the structures are compared. For this purpose, an analysis with three main steps was performed. The first step is to develop a deterministic model that includes a computational model of the response variables of interest for a given set of input parameters such as subgrade conditions and live load. In the second step, an uncertainty model was developed in which the California Bearing Ratio of the subgrade, the total number of axle load passes, and the depth of frost penetration were treated as random variables and their values were simulated using Monte Carlo simulation. In the final step, the response variables of the deterministic model were calculated according to the uncertain parameters defined in the uncertainty model. The results of the failure probability analysis allow us to evaluate important elements of the pavement structure that should be changed in order to reduce the probability of failure.

RÉSUMÉ: Dans cet article, une conception optimale de la chaussée avec et sans renforcement géosynthétique est discutée et évaluée. La probabilité de défaillance est calculée pour ces deux conceptions optimales afin de montrer la différence que fait le renforcement. Pour ce faire, une analyse en trois étapes principales a été réalisée. La première étape consiste à développer un modèle déterministe qui comprend un modèle de calcul des variables de réponse d'intérêt pour un ensemble donné de paramètres d'entrée tels que les conditions du sol et la charge réelle. Dans la deuxième étape, un modèle d'incertitude a été développé dans lequel le coefficient de portance californien du sol, le nombre total de passages de la charge à l'essieu et la profondeur de la pénétration du gel ont été traités comme des variables aléatoires et leurs valeurs ont été simulées à l'aide d'une simulation de Monte Carlo. Dans la dernière étape, les variables de réponse du modèle déterministe ont été calculées en fonction des paramètres incertains définis dans le modèle d'incertitude. Les résultats de l'analyse de la probabilité de défaillance nous permettent d'évaluer les éléments importants de la structure de la chaussée qui devraient être modifiés afin de réduire la probabilité de défaillance.

Keywords: Reliability based design; optimization; optimal pavement structure; geosynthetics.

1 INTRODUCTION

Efficient pavement design plays a critical role in the sustainable development and longevity of transportation infrastructure. As the world's population continues to grow and urbanization escalates, the demand for resilient and cost-effective pavements becomes increasingly urgent. In particular, the complexity of today's traffic volumes, environmental pressures and evolving material technologies require a paradigm shift towards the development of optimized pavements that can withstand a wide range of loads while minimizing environmental impact. In recent decades, great progress has been made in the field of pavement construction. These include several innovative methods and materials that promise longer life and lower maintenance costs. Several authors have been working on optimizing the pavement structure designs with and without the use of geosynthetics, with geosynthetics proving to be more favorable at lower CBR values of the subgrade (Jelušič, Varga, et al., 2023; Mamlouk et al., 2000; Nicholls, 1991; Santos & Ferreira, 2012). As mentioned before by new materials, researchers are also testing waste materials such as glass, car tire waste, lignin, and nylon bags to improve the California Bearing Ratio - CBR values of the unbound sub-base course and asphalt binder course (Abukhettala & Fall, 2021; Fatemi & Imaninasab, 2016; Huang et al., 2007; Jelušič, Gücek, et al., 2023; You et al., 2022). The studies all came to the same conclusion that using waste as a building material significantly reduces maintenance costs, construction costs, and reduces CO2 emissions. The studies also showed that asphalt is the main source of CO2 emissions during production, transportation, and installation in the structure. In second place are the unbound sub-base and the unbound base course, as the

use of waste material can reduce the thickness of the required layer. To further expand the optimization process and the use of materials, the reliability-based design approach should be considered as it takes a different perspective on the matter and can be critical to understanding the failure mechanisms. In contrast to its prevalent application in various geotechnical constructions, the utilization of reliability-based design optimization remains relatively limited in the context of pavement engineering. Nonetheless, several studies have underscored the significance of failure mechanisms derived from reliability-based design, emphasizing the pivotal role they play in offering critical insights and precise information regarding the operational lifespan of pavements. (Dilip et al., 2013; Jelušič & Žlender, 2022; Sanchez-Silva et al., 2005; Saride et al., 2019). By promoting a deeper understanding of the interplay between uncertain material properties, traffic loads, structural configurations, and environmental factors, this study will pave the way for the implementation of optimal pavement design based on reliability-based design and use of geosynthetics that can meet the diverse needs of modern transportation networks.

2 OPTIMIZATION MODEL

The deterministic optimization model (*PVT-OPT*) for the targeted pavement structure (see Figure 1) consists of several elements, including a comprehensive set of input data, an objective function (*COST*) that determines the properties of the pavement structure as determined by the geotechnical analysis and design constraints, and a set of variables is also included. In particular, the inclusion of the Monte Carlo simulation method in the reliability-based design serves to effectively account for and address the inherent uncertainties contained in these variables as we expand the deterministic model into an uncertainty model. To effectively use an evolutionary algorithm to perform the optimization the problem was translated into a mixed integer problem. Firstly, an optimal design based on the AASHTO and local technical specifications - TSC for roads (AASHTO, 1993; Nicholls, 1991; TSC 06.520:2009, 2009) was obtained and further evaluated using the expanded reliability-based design method. The probability of failure was calculated and determined for the proposed optimal designs. The expanded deterministic model was then also used to provide a graphical comparison between different soil conditions, ranging from $CBR_{subgrade}$ 1 % to $CBR_{subgrade}$ 8 % and effects of the geosynthetics and reliability on the price and longevity of the pavement structure. The parameters of interest are the thickness of asphalt surface course d_{as} (m), thickness of asphalt base course d_{ab} (m), thickness of unbound base course d_b (m) thickness of unbound sub-base course and pavement construction costs *COST* (€/m^2). Also, while optimizing using the reliability-based design the failure probability *Pf* (%). To obtain the optimal values for these parameters, six distinct conditions (see, Table 1) were established according to the AASHTO guides and local technical specifications (TSC).

2.1 Constrains in the optimization model

As already mentioned, Table 1 consists of the cost objective function and the necessary conditions for the optimization model (*PVT-OPT*). The cost objective function includes the individual costs (c_i - unit price) of the different soil and construction works for the construction of a pavement structure. The costs are listed in Table 2. The material properties (Young's modulus) per AASHTO are 320 MPa for granular base, 125 MPa for granular sub-base and depending on the CBR value the subgrade stiffness differs. The six conditions, based on the AASHTO and local TSC specifications, represent the basic design constraints. It should be noted that the denotation *mod* is used to describe the modified CBR value. For example, if the CBR value of the subgrade is on the lower side, unbound sub-base is used to increase this value for the safety and durability of the pavement structure.

Condition 1 states that the thickness index of the pavement structure (D_{total}) must be greater than the required thickness index of the structure (D_{req}). The equations consist of the equivalency factors a_i specified by the AASHTO and the thickness of the asphalt surface course d_{as}, the asphalt base course d_{ab} and the sub-base course d_b.

Condition 2 limits the required asphalt thickness to account for the number of vehicles (ESAL), as per TSC specifications ESAL is the only variable that determines the thickness of the asphalt course.

Condition 3 describes the required thickness of the unbound base course to ensure the load-bearing capacity of the pavement structure, as the quality and thickness is vital in providing a sufficient load bearing capacity when calculating the required thickness index of the pavement structure. The quality of the unbound base course is translated into the equivalent factor a_i as specified by AASHTO and TSC.

Condition 4 specifies the required total thickness of the pavement structure to combat the effect of frost penetration - h_{req}, which consists of h_m which is obtained based on the geographical location and is specified in the TSC and the factor f_{fr} that considers the soil conditions on the construction site based on laboratory tests.

Condition 5 specifies the minimum thickness of the unbound sub-base course to achieve a certain *CBR* value, also known as CBR_{mod}, which following TSC should be at least 15 %. This is done to artificially create better conditions for unbound base course, as the price of unbound sub-base course is cheaper and therefore ideal to increase the *CBR* value of the subgrade. The thickness required to obtain a given CBR_{mod} value is also reduced by the factor $\gamma_{geo,sb}$ when geosynthetic reinforcement is used. The value of the mentioned factor has been determined by laboratory and field tests and is considered to be 2.0 when geosynthetics are used.

Condition 6 sets minimum asphalt thickness requirements necessary for machine-based road construction.

Condition 7 is applied when designing based on probability of failure and considers all the above conditions. With the use of Monte Carlo simulation, 100,000 random numbers of the random variables reported in table 3 were created and the 100,000 random samples were than analyzed using condition 7 to estimate the failure probability of a pavement structure.

2.2 Results of the optimization model PVT-OPT

The evolutionary algorithm is used to optimize the design, effectively using the six previously mentioned conditions. Later the deterministic model is expanded with another condition, condition 7 (see Table 1) that includes the failure probability of the pavement structure. The previously obtained results were than analyzed and a probability of failure for a pavement structure with no reinforcement and with geosynthetic reinforcement was determined (see Table 3). The findings exhibit a mutual failure probability of 19.5 % of which 15.7 % is provided by the pavement thickness index (Condition 1) and 3.8 % is due to inadequate frost resistance thickness (Condition 4), as those are also the main conditions that are checked for failure. The input data for the reliability-based design analysis and optimization can be found in Table 4. Notably, it is imperative to highlight that pavement structure with no reinforcement is thicker for 29.5 % which also translates into a cost difference of 7.37 €/m^2 which for a standard road with a width of 7 m and a length of 1,000 m (the cost calculations therefore refer to 1 km of a given pavement) add to over 51.590 € in total costs (see, Table 3). Evidently, these observations show that a pavement structure with geosynthetic reinforcement is favorable in such conditions ($CBR_{subgrade}$ = 3.5 %, h_m = 80 m, f_{fr} = 0.7 and $N = 2.5 \cdot 10^6$). Further the study calculates the relationship between cost and failure probability of the pavement structure for different soil properties to showcase the usefulness of geosynthetic reinforcement in providing an economically and sustainable pavement design (see, Figure 2).

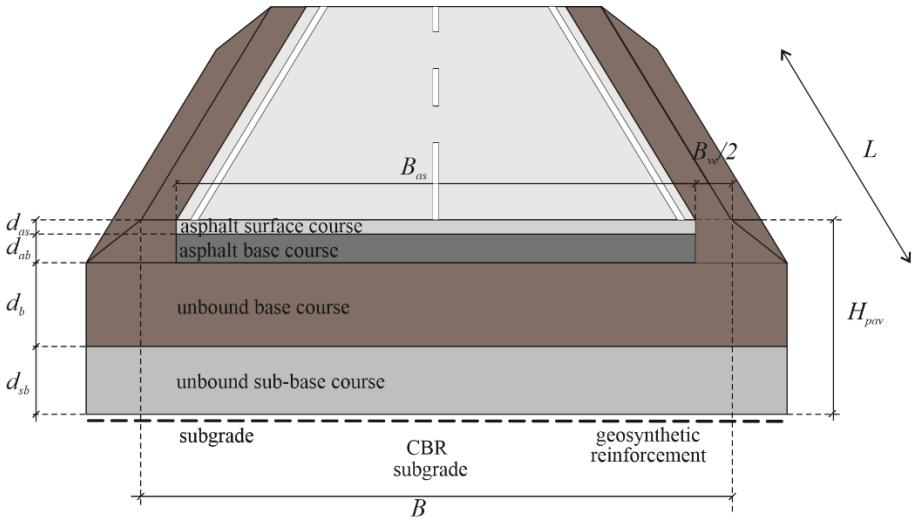

Figure 1. Cross section of the pavement design with the geometrical parameters shown.

Table 1. Optimization model PVT-OPT with all the required conditions.

Cost objective function for the PVT-OPT model	
$COST = C_{exc,re} + C_{gc} + C_{fill,b} + C_{as,subs} + C_{fill,sb} + C_{as} + C_{ab} + C_{geo}$	
$C_{exc,re} = c_{exc,re} \cdot h_{total} \cdot (B_{ve} + B_{as})$	$C_{gc} = c_{gc} \cdot (B_{ve} + B_{as})$
$C_{fill,b} = c_{fill,b} \cdot (B_{ve} + B_{as}) \cdot d_b$	$C_{as,subs} = c_{as,subs} \cdot B_{as}$
$C_{fill,sb} = c_{fill,sb} \cdot (B_{ve} + B_{as}) \cdot d_{sb}$	$C_{as} = c_{as} \cdot B_{as} \cdot d_{as}$
$C_{ab} = c_{ab} \cdot B_{as} \cdot d_{ab}$	$C_{geo} = c_{geo} \cdot (B_{ve} + B_{as})$
$C_{asb} = c_{asb} \cdot B_{as} \cdot d_{asb}$	
Condition 1	
$D_{total} \geq D_{req}$	
$D_{total} = d_{as} \cdot a_{i,as} + d_{ab} \cdot a_{i,ab} + d_b \cdot a_{i,b}$	$d_{b,CBR_{mod}} = ((c_1 - c_2 \cdot CBR) \cdot \ln(T_n) - c_3 + e^{(c_4 \cdot CBR) \cdot c_5})/\gamma_{geo,b}$ $note: \gamma_{geo,b} = 2$
$d_{asb,0} = a_1 \cdot {T_n}^{a_2}$	$d_{asb,0} = d_{as} + d_{ab}$ $note: d_{as} = 4\ cm$
$D_{req} = d_{asb,0} \cdot 0.38 + d_{b,CBR_{mod}} \cdot 0.14$	
Condition 2	
$d_{prov} \geq d_{asb,0}$	$d_{prov} = d_{as} + d_{ab}$
Condition 3	
$d_b \geq d_{b,req}$	$d_{b,req} = d_{b,CBR_{mod}}$
note: denotation *mod* stands for modified CBR value which is set to 15 %.	
Condition 4	
$h_{total} \geq h_{req}$	$h_{req} = h_m \cdot f_{fr}$
$h_{total} = d_{as} + d_{ab} + d_b + d_{sb}$	
Condition 5	
$d_{sb} \geq d_{sb,CBR_{mod}}$	$d_{sb,CBR_{mod}} = (b_1 \cdot (\frac{b_2 \cdot (CBR_{mod} - CBR)}{b_3 - CBR} + b_4))/\gamma_{geo,sb}$
Condition 6	
$d_{as} \geq d_{as,min}$	$d_{ab} \geq d_{ab,min}$
Condition 7	
$Pf = \frac{\sum_1^n A(n)}{n}$	
$If\ \frac{{D_{total}}^n}{{D_{req}}^n} \geq 1\ or\ \frac{{h_{total}}^n}{{h_{req}}^n} \geq 1\ ; than\ A\ (n) = 1; else\ \ A\ (n) = 0$	

Table 2. Unit price and material characteristics for pavement construction.

Symbol	**Meaning**	**Cost per unit**
$c_{exc,re}$	Ground excavation	9.0 €/m^3
c_{gc}	Ground compaction	2.5 €/m^2
$c_{as,subs}$	Asphalt substrate	1.5 €/m^2
c_{as}	Asphalt surface course	300.0 €/m^3
$c_{fill,b}$	Base-course fill	36.0 €/m^3
$c_{fill,sb}$	Sub-base fill	24.0 €/m^3
c_{ab}	Asphalt base course	200.0 €/m^3
c_{asb}	Single asphalt course	250.0 €/m^3
c_{geo}	Geosynthetic install.	4.5 €/m^2

Table 3. Optimal results obtained based on the deterministic model and the corresponding failure probability (Pf).

Type	d_{as} (m)	d_{ab} (m)	d_b (m)	d_{sb} (m)	COST (€/m^2)	*Pf* (%)
Reinforced:	4	12	27	31	67.42	19.5
Not reinforced:	4	12	27	62	74.06	19.5

Random variables	Mean min.	Mean max.	CoV [%]	Standard deviation min.	Standard deviation max.
N (-)	$2 \cdot 10^6$	$2.5 \cdot 10^6$	2-10	$2 \cdot 10^5$	$5 \cdot 10^5$
CBR (%)	1/3/5	3/5/8	10-15	0.1/0.3/0.5	0.45/0.75/1.2
h_m	0.7	0.8	10-20	0.07	0.16

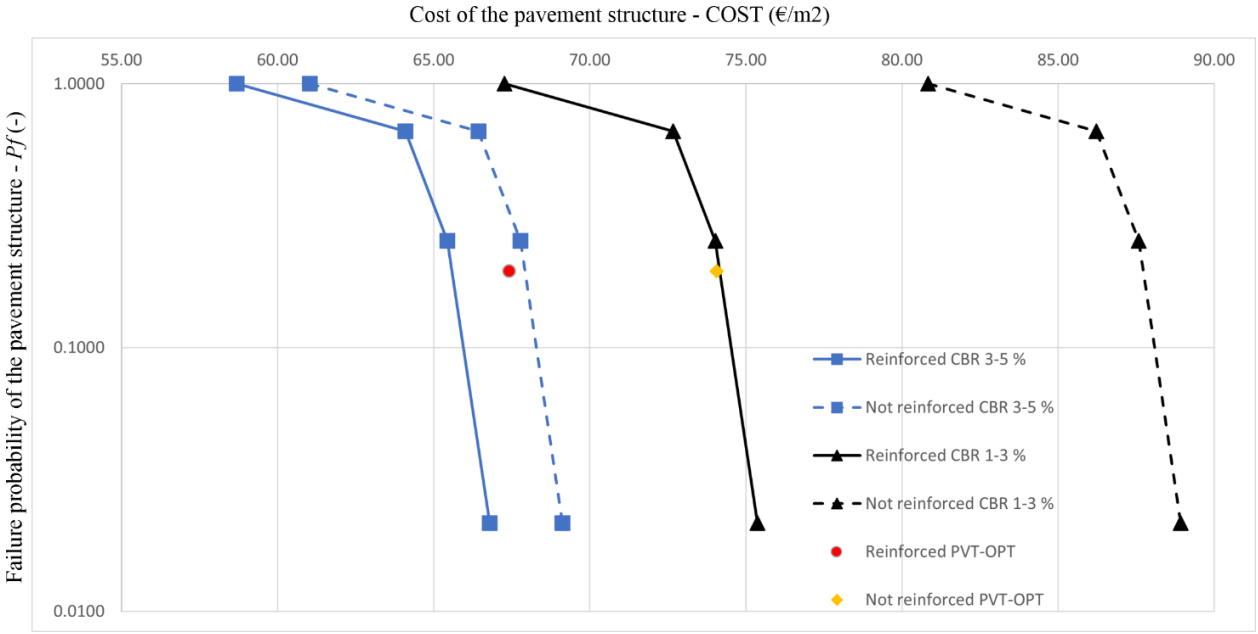

Figure 2. Relationship between COST and failure probability Pf for the optimal pavement designs.

3 CONCLUSIONS

The results of this study highlight the critical role of the thickness of the unbound base course in determining the longevity of an optimal pavement structure. Insufficient thickness of the unbound base course will result in its inability to withstand the combined effects of traffic loads and environmental stresses over a 20-year period with a probability of 15.7 %. In particular, the effects of frost depth on pavement structures with unbound sub-base courses are mitigated because these sub-base courses contribute an additional thickness to the overall structure. In addition, Figure 2 shows the correlation between the probability of failure and the cost of reinforced and unreinforced pavement structures and highlights the favorable performance of structures with geosynthetic reinforcement. Especially for soils with low modulus of elasticity and the resulting CBR values, the cost difference between traditional construction methods and those using geosynthetics is significant. Therefore, the use of geosynthetics is recommended to improve cost efficiency and environmental performance due to the reduced thickness required. Ultimately, this approach contributes to a lower probability of structural failure, highlighting its economic, environmental and performance benefits in pavement design and construction.

RÉSUMÉ: La cathédrale Saint-Pierre de Beauvais est la plus haute de voûte jamais construite au Moyen Age. Elle connut deux accidents structurels célèbres, dans le chœur en 1284 puis à la croisée du transept en 1573. En 2023 coexistent encore plusieurs types d'explications pour donner une origine à ces accidents, avec des causes structurelles, naturelles ou géotechniques. On montre que l'origine géotechnique n'est très vraisemblablement pas à retenir pour 1284. Elle peut être invoquée pour 1573, mais à titre secondaire. Le texte qui suit est la première partie de l'article.

ABSTRACT: Saint Peter's cathedral in Beauvais (France) has the highest vaults ever built during the Middle Ages. It was affected by two famous structural accidents, in the choir in 1284, and later at the transept crossing, in 1573. In 2023, there are still several explanations to account for what happened then, structural or natural causes, or geotechnical ones. We here show that nothing appears to justify a geotechnical origin in the 1284 collapse. It may be considered in 1573, nevertheless as a secondary cause. The following text is the first part of the article.

Keywords: Géotechnique et patrimoine; architecture gothique; fondations superficielles.

1 INTRODUCTION

La cathédrale Saint-Pierre de Beauvais (Figure 1) est la plus haute église gothique du monde. Elle marque l'apogée de ce style architectural qui a vu le jour en France dans les années 1140. Eugène Viollet-le-Duc, connu pour son œuvre de restauration de Notre-Dame de Paris au XIXe siècle, qualifia la cathédrale beauvaisienne de « Parthénon de l'architecture française » (Viollet-le-Duc, 1858-1868, T1, p. 71).

Cependant elle apparaît aujourd'hui comme un monument à la fois composite et inachevé. Cent soixante ans séparent la fin des travaux du chœur et le commencement du transept et sa nef gothique n'a jamais été construite (Murray, 2000). L'interruption des travaux comme leur inachèvement trouvent leur explication dans deux accidents structurels graves. Leur origine fait, encore à notre époque, l'objet de discussions qui incorporent parfois un mécanisme géotechnique (Renault, 2021).

Figure 1. Vue de la cathédrale Saint-Pierre de Beauvais depuis le sud-est, février 2014 (ph. J-D Vernhes).

La cathédrale de Beauvais a bénéficié depuis les années 1980 d'une surveillance car des fissures étaient apparues dans certaines voûtes.

L'objectif de cet article en deux parties n'est néanmoins pas de statuer sur son état actuel mais de tirer parti des données récemment collectées, à la faveur des diagnostics, pour étudier rétroactivement le rôle du système de fondations de l'édifice dans les deux accidents. Cette première partie de l'article porte sur les éléments de contexte utile à la compréhension du problème. Dans la deuxième partie de l'article (Vernhes et al., 2024b) sont exposés l'analyse géotechnique et une proposition de réponses argumentées aux questions posées. Les deux parties ainsi décrites forment un tout considéré comme indissociable.

2 DONNÉES GÉNÉRALES

2.1 Brève histoire des travaux

Dans cette partie, les sources suivantes sont exploitées pour les données générales : Viollet-le-Duc (1858-1868), Leblond (1926), Murray (2000), Bonnet-Laborderie (2006) et Meunier et Bonnet-Laborderie (2006).

2.1.1 Avant 1225: les premières cathédrales

Le centre épiscopal de Beauvais fut occupé dès le Haut Moyen Age par des églises cathédrales. Autour de l'An Mil celle qui existait fut reconstruite en style pré-roman, avec des pastoureaux calcaires (lutétiens) de remploi du rempart gallo-romain. Son transept (?) et son chœur furent agrandis au XIIe siècle mais disparurent par la suite.

En 1225, un incendie endommageait le chœur roman. L'évêque Milon de Nanteuil décida alors de le reconstruire en s'inspirant des plus grandes réalisations de son époque, dans le style *français* (gothique, alors *rayonnant*), tout en conservant provisoirement la nef et le transept romans pour le culte. L'ensemble des trois travées de la nef qui reste aujourd'hui est appelé Basse Œuvre (Figure 2).

2.1.2 1225-1340: nouveau chœur et accident

Les premiers travaux portèrent sur des éléments orientaux du transept, dont l'emprise au sol présentait un intérêt pour stabiliser au mieux l'extrémité ouest des futures parties hautes. La craie dure à silex (coniacienne à campanienne) de la carrière Saint-Pierre près de Frocourt et Bongenoult, à proximité de Beauvais, fut exploitée.

Le système de fondations utilisé n'est pas connu avec précision mais de grands terrassements préparatoires furent nécessaire pour atteindre le « niveau de bon sol » et y construire des puits à base élargie, pratique la plus courantes pour les constructions géantes du Moyen Age, selon Viollet-le-Duc. Le même affirme que les maîtres d'œuvre « (…) *ne manquaient jamais de relier entre eux tous les murs et massifs en fondation ; c'est-à-dire que, sous un édifice composé de murs et de piles isolées, par exemple, ils formaient un gril de maçonnerie sous le sol, afin de rendre toutes les parties des fondements solidaires.* » (op. cit., T5, p. 525).

Dans l'emprise des futurs chœur et partie est du transept, le remblai de comblement de l'excavation fut élevé environ deux mètres au-dessus du niveau de la rue au XIIIe siècle de telle sorte que leur dallage allait reposer sur un terre-plein.

Dans les années 1250, les deux premiers niveaux de construction étant achevés (grandes arcades et triforium), l'évêque Guillaume de Grès décida apparemment pour le troisième et dernier étage de l'édifice de sortir des proportions prévues originellement en ajoutant quelques mètres (de l'ordre de cinq) aux fenêtres hautes et donc aux voûtes. En 1272, le nouveau chœur put être occupé par le clergé, ce qui permit le lancement d'une phase préparatoire à la poursuite des travaux : sans doute le démantèlement du transept roman après fermeture et étaiement provisoire de l'ouest de la Haute Œuvre.

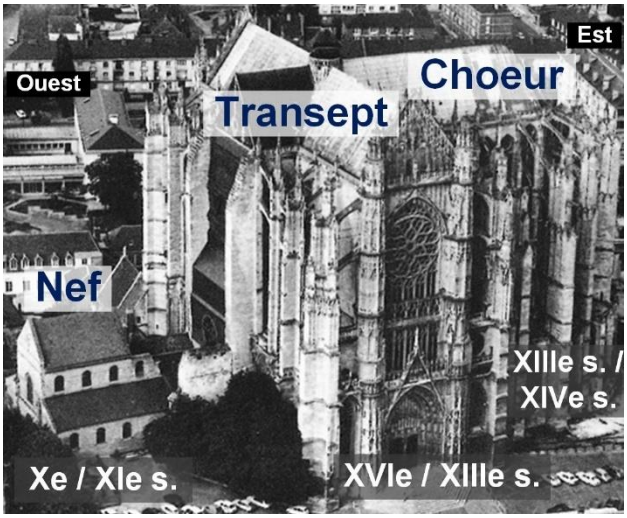

Figure 2. Vue aérienne de la cathédrale, fin des années 1970 (ph. : n. c. ; in : Bonnet-Laborderie, 2006), habillée.

Le 29 novembre 1284, durant cette nouvelle phase de chantier, des voûtains des travées droites du chœur, les plus vulnérables, s'effondrèrent (Figure 3), marquant pour tout l'Occident « *la dernière limite à laquelle la construction des grandes églises du XIIIe s. ait pu arriver* » (*op. cit.*, T1, p. 71). Le diagnostic nécessaire à la reprise des parties concernées et le chantier qui s'en suivi s'acheva en 1340. « *On mit donc plus de temps à réparer le chœur qu'à le construire* » (Murray, 2000).

2.1.3 1499-1605: nouveau transept et accident

1340 coïncide en France avec le début d'une période de crise militaire, sanitaire et économique qui eut pour effet d'interrompre presque totalement les grands chantiers en cours, ce qui advint à Beauvais.

L'embellie de la deuxième moitié du XVe siècle remit à l'ordre du jour, dès les années 1480, la poursuite des travaux par la construction des deux vaisseaux manquants du transept, dont le seul en place était resté mal étayé à l'ouest.

En septembre 1499, pendant 23 jours, furent réalisés des sondages derrière le chœur à la considérable profondeur de 10 toises (19 m) et un autre de 32 pieds (10 m) à l'emplacement du futur bras sud du transept ; les premiers pour s'assurer de la fermeté du terrain, le dernier pour obtenir des informations sur les fondations posées au XIIIe siècle (Meunier et Bonnet-Laborderie, 2006).

Le grand architecte Martin Chambiges fut chargé en 1500 de la délicate conception d'une « greffe » en style gothique *flamboyant*, compatible stylistiquement et mécaniquement avec le haut édifice en place, puis de la conduite des travaux pendant les 32 années qui suivirent, jusqu'à sa mort.

Pour les nouvelles fondations, dont les caractéristiques furent sans doute analogues aux précédentes, il choisit non la craie mais la pierre calcaire (lutétienne) des carrières de Mérard, Mouy et Mello, une trentaine de kilomètres à l'aval hydrographique de Beauvais. Le reste de l'œuvre fut réalisée avec les mêmes approvisionnements de craie qu'au XIIIe s. (*op. cit.,* 2006).

La construction du transept fut achevée après la mort de l'architecte, entre 1537 (bras nord) et 1550 (bras sud). C'est dans cette période que survint le projet de coiffer la croisée du transept d'une tour lanterne à trois niveaux surmontés d'une flèche (Figure 4a), et non d'une simple flèche en bois comme Chambiges avait dû le prévoir (*op. cit.*). La base du transept déjà construite était alors considérée comme capable d'en soutenir le poids, et l'ensemble devait tenir moyennant des modifications des parties hautes qui pouvaient encore être prises en compte.

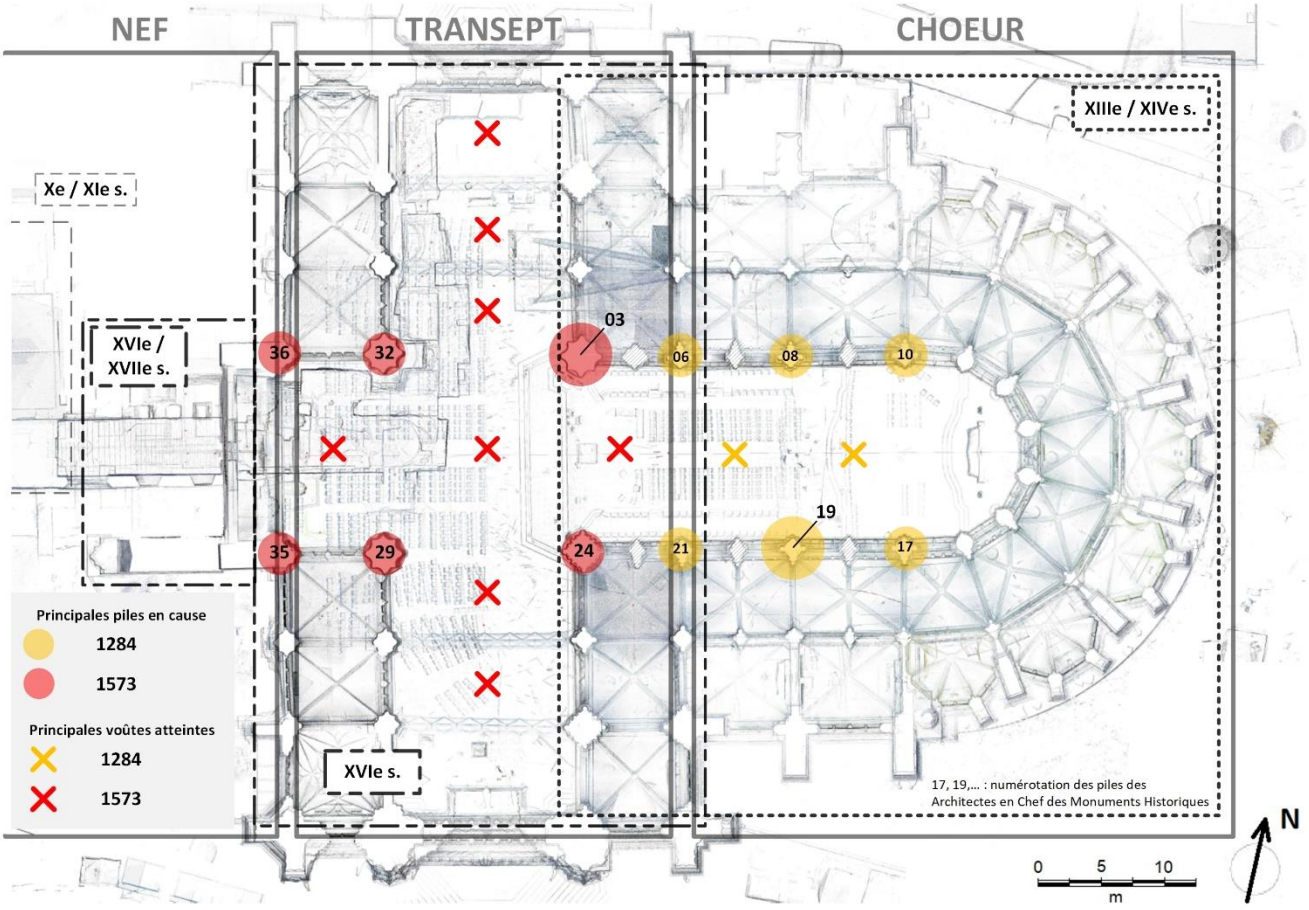

Figure 3. Localisation d'éléments liés aux accidents de 1284 et 1573 (fond de plan Lidar : Martin, 2021 ; habillé).

Ce nouveau projet, dont les pierres furent prélevées dans la carrière de calcaire lutétien de Saint-Leu-d'Esserent (à une quarantaine de kilomètres de Beauvais) dès 1558, et dont la réalisation s'étendit de 1563 à 1569, reporta la construction des deux premières travées centrales de la nef ainsi que le

démantèlement de nouvelles travées de la Basse Œuvre à 1572 (Lamboley, 1993, p. 1 ; Poncelet, 2002).

Après de nombreux signes avant-coureurs, un support de la tour lanterne s'effondra le jour de l'Ascension 1573, un 30 avril, le lendemain de chutes de fragments de pierre. C'est seulement le 16 août qui suivi que les trois supports restants cédèrent (op. cit., 1993), entraînant avec eux la lanterne, démolissant dans sa chute ou du fait de l'ébranlement toutes les voûtes des travées qui l'entouraient, y compris une du XIIIe siècle, ainsi que la pile n° 3 (Figure 3).

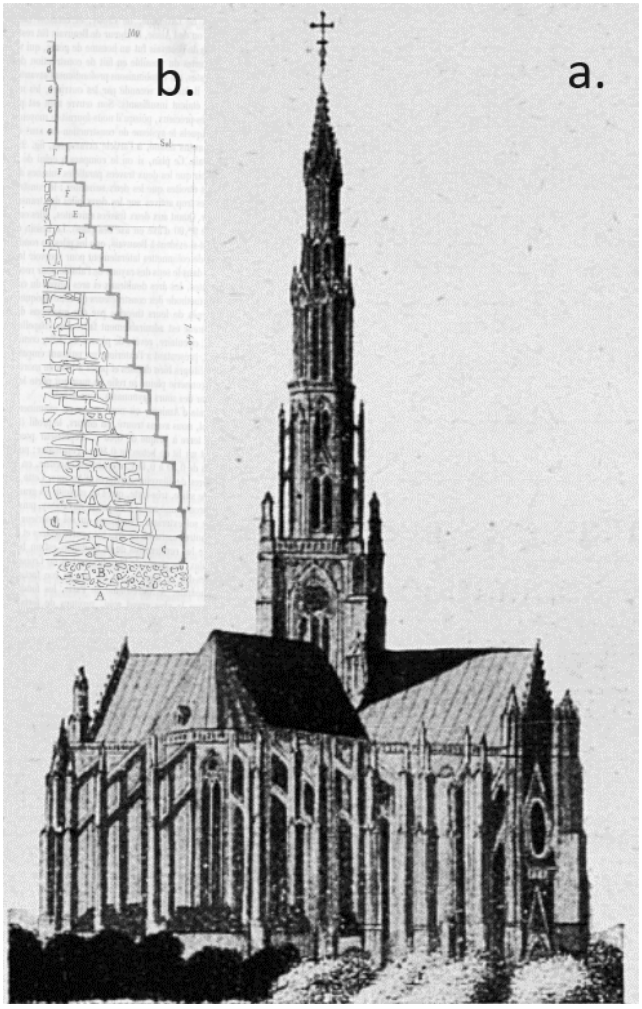

Figure 4. (a.) Vue cavalière de la cathédrale surmontée d'une tour de croisée avec flèche sommitale, en élévation de 1569 à 1573 (in Leblond, 1926, p. 27) ; (b.) En incrustation, coupe verticale d'un puits de fondation maçonné, observé par E.-E. Viollet-le-Duc à la cathédrale d'Amiens (op. cit., T4, p. 176).

Les travaux de réparation, restituant finalement le projet de Chambiges, un peu amoindri, s'étendirent jusqu'en 1605, sans qu'il ne reste assez de moyens pour construire la nef. Le contrebutement que la nef et les tours du massif occidental non construits auraient dû exercer sur le carré du transept pour en bloquer les poussées au vide, fut assuré de façon provisoire (jusqu'à nos jours) par des murs boutants, à l'emplacement des premières colonnes du vaisseau central de la nef (Figure 3, zone XVIe / XVIIe s.).

2.2 Géologie du centre historique de Beauvais

Située 60 km au nord de Paris, Beauvais est construite dans une vallée alluviale au socle crayeux. De ces deux données naturelles découleront un ensemble de caractéristiques géotechniques concernant la cathédrale Saint-Pierre.

2.2.1 Topographie et hydrographie

Le centre-ville historique de Beauvais, très plat, se situe à des altitudes situées dans la fourchette 65 à 70 m NGF (Nivellement Général de la France), avec 68/69 m NGF autour de la cathédrale.

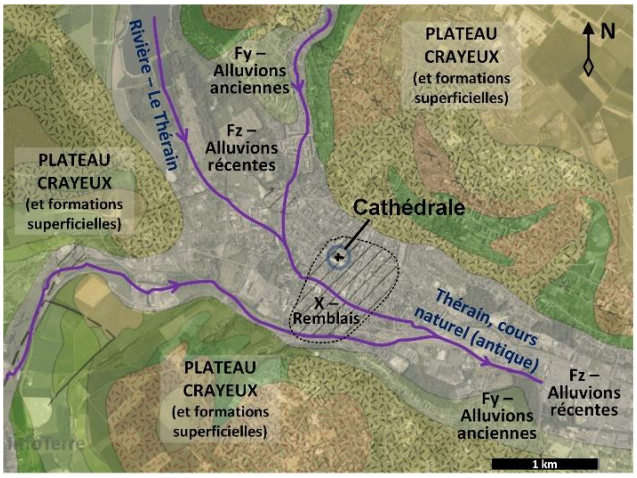

Figure 5. Extrait habillé de la carte géologique vecteur harmonisée (Blondeau et al., 1974), en transparence sur photo aérienne IGN, via Infoterre (BRGM, 2023).

Beauvais est située dans la vallée alluviale d'un affluent de l'Oise, le Thérain (Figure 5), très canalisé depuis l'Antiquité et dont le cours le moins artificiel passerait aujourd'hui au sud du centre-ville, en moyenne vers 63 m NGF.

2.2.2 Stratigraphie

L'altitude dans le quartier cathédrale devait être à peine à 65 m NGF avant les aménagements de l'époque gallo-romaine. La ville connut alors une surélévation artificielle par remblaiement de craie damée, le processus continuant avec l'accumulation de débris d'occupation urbaine au Moyen Age, des remblais anthropiques globalement notés X sur la carte géologique (Figure 5).

Au-dessous de ces remblais se trouvent les dépôts du Thérain en deux ensembles bien contrastés, Fz et Fy selon la terminologie du BRGM. Ce sont les alluvions récentes et anciennes, respectivement fines

(argile, limon et éventuellement tourbe), et grossières (sables et graviers de silex). Cette succession corrélant fortement âge et granularité s'explique par le dernier épisode d'eustatisme et ses conséquences en termes de régime hydraulique des rivières et donc de transportabilité des matériaux d'érosion, phénomène gouverné par le changement climatique entre pléistocène et holocène (Lebret *et al.*, 1991). Ces dépôts sont donc en principe relativement homogènes et leur interface assez franche.

Sous les alluvions se trouve la craie, roche tendre et gélive, datée du campanien. En fond de vallée, où est située la cathédrale, la craie a subi un rabotage de l'ordre de 50 m de hauteur, correspondant au dénivelé moyen avec le plateau picard. Ce processus, accentué par la gélifraction des âges glaciaires, a dégradé, dans ses premiers mètres supérieurs, la craie en place.

2.2.3 Hydrogéologie

Il existe deux nappes intéressant le fond de la vallée du Thérain à Beauvais, la nappe alluviale bien sûr, mais également celle de l'aquifère de la craie qui y trouve un exutoire continu.

Ces deux nappes sont en continuité hydraulique car les deux aquifères (craie à fissuration ouverte et alluvions anciennes) ne sont pas séparées par un niveau imperméable.

2.3 Reconnaissances *in situ*

Entre septembre 1499 et juin 2001, il ne semble pas qu'il y ait eu dans la cathédrale ou à ses abords immédiats de reconnaissances de sol, si ce n'est un sondage signalé par la BSS (BRGM, 2023), réalisé en 1967 « au pied d'un bénitier » dans le croisillon nord du transept, mais trop peu profond et surtout mal documenté pour être intéressant. Il faut cependant mentionner aussi deux bases de sismique réfraction réalisées par la Compagnie Générale de Géophysique en 1992, au nord et à l'est de la cathédrale, mais dont on a que les résultats interprétés (Lamboley, 1993).

En 2001 sont réalisés 4 sondages destructifs au pied de chaque pilier du carré du transept (BS Consultants, 2001), suivi en juin 2021 d'un sondage carotté dans le croisillon nord du transept également pour une reconnaissance de fondation de pile (Mazet et Marcie, 2021), sondages intéressants pour les questions soulevées dans cet article.

Pour étayer le modèle géotechnique global leur ont été adjointes les données de sondages localisés dans le centre-ville, cinq issus de la BSS (BRGM, 2023 ; ancienne nomenclature : 01024X0167PZ22, 01024X0093S, 01024X0111F, 01024X0124F.PAC, 01024X0095PIEU1) et une cinquantaine d'autres réalisés pour un projet immobilier (Arnassalon et Geisler, 2012).

2.3.1 Sols et eau, enseignements

Depuis la surface, l'ensemble des sondages consultés donnent des résultats convergents : la base des remblais est le plus souvent autour de 65 m NGF ; celle des alluvions modernes, variables en épaisseur, de 61 à 63 m NGF, altitudes qui sont également celle du toit des alluvions anciennes. Leur base est encore plus variable, de 55 à 59 m NGF, mais leur épaisseur ne semble jamais inférieure à trois mètres, typiquement quatre mètres sous la cathédrale.

La craie apparaît bien comme altérée dans les premiers mètres sous les alluvions anciennes, à tel point que ces dernières sont mécaniquement plus compétentes qu'elle. Vers 50 m NGF, la craie devient plus dure, c'est-à-dire à peu près 20 m sous le niveau de la cathédrale, profondeur atteinte par le sondage de 1499.

La compétence mécanique des horizons décrits est bien corrélée aux retours d'expérience : faible dans les remblais et alluvions modernes (q_c ou E_M typiques de 2 ou 3 MPa), quatre à sept fois plus élevée dans les alluvions anciennes mais seulement deux fois plus dans la craie altérée.

L'eau phréatique est une question plus délicate à traiter car son niveau moyen et ses variations actuelles peuvent difficilement être associés avec certitude à ceux de 1225 ou 1499. Mais, la nappe étant à la fois alimentée par une rivière régulée depuis l'époque gallo-romaine et bénéficiant d'un appoint constant d'approvisionnement par l'aquifère de la craie, on peut raisonnablement émettre l'hypothèse que les hauteurs piézométriques observées dans les dernières années présentent un intérêt rétroactif.

Figure 6. Photographie d'une caisse de carottes dans la zone de contact entre maçonnerie et sol support pour la pile n° 83 (Mazet et Marcie, 2021) habillée.

Il apparaît alors que le niveau d'eau dans le sol de la ville est assez stable au long de l'année, typiquement autour de 62/63 m NGF, avec un battement métrique. Cela veut dire que ce niveau est proche de l'interface entre les deux types d'alluvions, avec possible mise en

charge, modérée, des récentes, de perméabilité de l'ordre de grandeur de 10^{-6} m/s. Celle-ci contraste avec celle des alluvions anciennes et de la craie altérée, toutes deux proches de 10^{-4} m/s.

2.3.2 Fondations, enseignements

Les cinq sondages de reconnaissance de 2001 et 2021, concentrés sur le transept, ont trouvé des bases de fondation de piles à des cotes de 60,5 à 62,5 m NGF, bases reposant sur les alluvions anciennes (Figure 6), c'est-à-dire le « bon sol ».

Il est très vraisemblable que toutes les fondations de la Haute Œuvre (au XIIIe comme au XVIe siècle) ont été réalisées suivant le même principe. Ce qui reste beaucoup moins clair est la largeur d'empattement à leur base et leur caractère jointif à la base si l'empattement est important.

Taupin (1992) a considéré qu'elles étaient toutes liées à leur base, aboutissant à un cas de « radier général » du point de vue de la portance du terrain, suivant peut-être en cela (à défaut de les avoir vues) un exemple bibliographique issu des observations à la cathédrale d'Amiens, dans la même aire géographique que Beauvais et historiquement concordant (Figure 4b). Un fait est qu'avec un tel empattement, ces fondations sont très grandes à leur base, d'une largeur d'au moins cinq mètres, peut-être jusqu'à huit ou neuf.

Cela clôt la description des données nécessaires à l'analyse des accidents structurels de la cathédrale. Celle-ci se trouve dans la partie 2 du présent article.

RÉSUMÉ: La cathédrale Saint-Pierre de Beauvais est la plus haute de voûte jamais construite au Moyen Age. Elle connut deux accidents structurels célèbres, dans le chœur en 1284 puis à la croisée du transept en 1573. En 2023 coexistent encore plusieurs types d'explications pour donner une origine à ces accidents, avec des causes structurelles, naturelles ou géotechniques. On montre que l'origine géotechnique n'est très vraisemblablement pas à retenir pour 1284. Elle peut être invoquée pour 1573, mais à titre secondaire. Le texte qui suit est la seconde partie de l'article.

ABSTRACT: Saint Peter's cathedral in Beauvais (France) has the highest vaults ever built during the Middle Ages. It was affected by two famous structural accidents, in the choir in 1284, and later at the transept crossing, in 1573. In 2023, there are still several explanations to account for what happened then, structural or natural causes, or geotechnical ones. We here show that nothing appears to justify a geotechnical origin in the 1284 collapse. It may be considered in 1573, nevertheless as a secondary cause. The following text is the second part of the article.

Keywords: Géotechnique et patrimoine; architecture gothique; fondations superficielles.

1 INTRODUCTION

Cet article est la deuxième partie d'un tout indissociable. Dans la première partie (Vernhes et al., 2024a), on trouvera tous les éléments de contexte nécessaires à l'argumentation utilisée dans les lignes qui suivent: éléments historiques, architecturaux, géologiques, hydrogéologiques et géotechniques. Nous conseillons donc au lecteur d'avoir lu le premier article avant d'aborder celui-ci.

2 ACCIDENT DE 1284

2.1 Cause d'après les sources

Il existe trois types d'interprétations pour expliquer l'effondrement partiel de voûtes du chœur en 1284, deux en partie haute de l'édifice, une en fondation.

Il s'agit pour la première de la rupture de colonnettes monolithes solidaires d'une maçonnerie appareillée dont les mortiers auraient progressivement tassé, provoquant la rupture d'arcs-boutants (Viollet-le-Duc, 1858-1868, T4, pp. 177-181; Heyman 1995). La deuxième invoque la mise en résonnance du système culée/arc-boutant au même endroit, et particulièrement au niveau de la pile dite n° 19 (Figure 1) causée par un vent en rafale (Lamboley, 1993, sur la base d'un rapport CEBTP de 1987; Murray, 2000).

La troisième suggère l'existence d'un tassement différentiel lent dans les fondations (Lamboley 1993, Heyman 1995), sans localisation précise du phénomène cependant. Pour justifier cela, Lamboley s'appuie sur des constats de fissurations dans les soubassements, mais qu'il est allé chercher au transept, où se trouve une fausse crypte, et non dans le chœur. Heyman considère, lui, que la durée de stabilité de 12 ans des parties hautes ainsi qu'une analyse structurelle

théorique exonèrent l'accident de 1284 d'une cause principalement structurelle; d'où il introduit l'idée d'une consolidation du sol en fondation dont la durée typique serait d'une douzaine d'année, celle-ci produisant l'accident.

2.2 Origine géotechnique en 1284?

Tout concours à penser que l'on consacra aux fondations de la cathédrale au XIIIe siècle les moyens nécessaires pour trouver « le bon sol », à une profondeur devenue considérable du fait de la surélévation de plusieurs mètres du niveau de la ville.

Des tassements de plusieurs centimètres pour des pressions estimées au sol de l'ordre de 5 bars (0,5 MPa) se produisirent en cours de travaux, possiblement différentiels, mais compensés par la lenteur des travaux, le suivi géométrique de l'œuvre et la souplesse de toute structure maçonnée. Une fois les travaux terminés en 1272, les tassements postérieurs restèrent sans doute limités car ni les alluvions anciennes, ni la craie altérée ne se présente comme susceptible de consolidation du fait de leur perméabilité élevée.

L'accident de 1284 est bien documenté comme s'étant produit dans les parties hautes des travées droites du chœur, structurellement les plus vulnérables par rapport au chevet ou à la travée centrale de transept déjà en place. Dès lors, l'hypothèse indémontrable d'un tassement différentiel de fluage venant à bout des systèmes culée-arc-boutant de ces seules travées droites, mais pas du reste de la Haute Œuvre, est sans grand intérêt.

Qui plus est, on remarquera aussi que les modifications structurelles de 1284 à 1340 n'ont pas inclus de reprises en sous-œuvre d'après l'analyse du bâti effectuée par Murray (2000), et au contraire, ont entraîné un alourdissement de la maçonnerie qui devait bien se reporter sur les fondations existantes, donc jugées dignes de confiance.

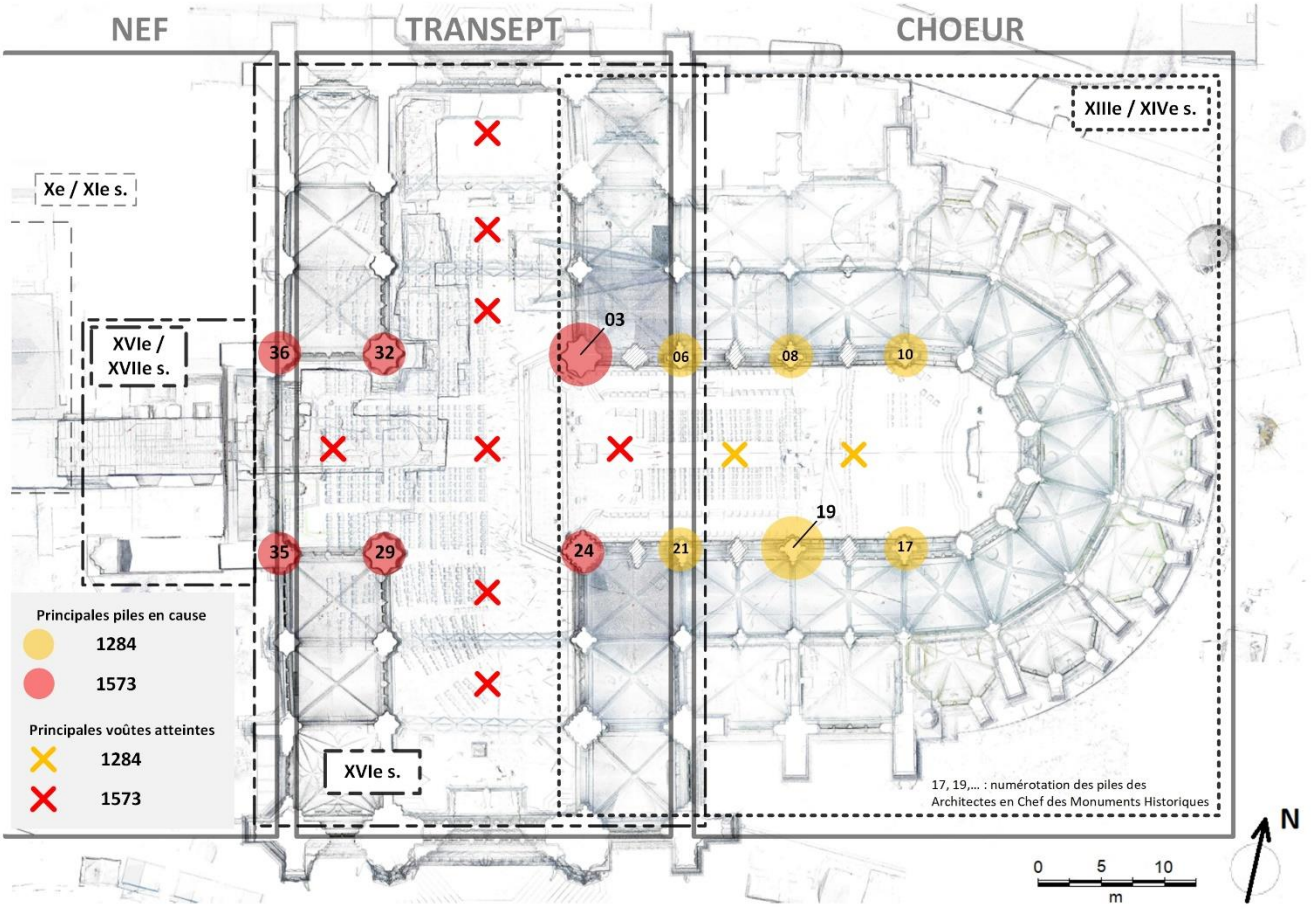

Figure 1. Localisation d'éléments liés aux accidents de 1284 et 1573 (fond de plan Lidar : Martin, 2021; habillé).

Du reste, l'explication la plus simple pour comprendre l'accident consiste à lire en creux les travaux qu'il entraîna : un raidissement généralisé des parties hautes atteintes. Elles s'étaient avérées trop souples, non pas en soi, mais en raison de la décision en cours de chantier de surélever de plusieurs mètres les voûtes de la cathédrale. Cette décision dû être prise au mépris des dimensions choisies pour les parties sous-jacentes, des proportions éprouvées, devenues inadaptées à contrer durablement le bras de levier

exercé par les nervures des voûtes quadripartites. Des déplacements somme toute très faibles mais permanents purent aboutir après quelques années à une perte de pression entre les claveaux des nervures des voûtes et ce qui s'en suivit.

Ainsi, nous ne souscrivons pas à l'hypothèse d'une origine géotechnique dans l'accident de 1284.

3 ACCIDENT DE 1573

3.1 Cause d'après les sources

La première cause de l'accident de 1573 évoquée dans les sources utilisées est celle d'un basculement de la tour-lanterne entraînée par un défaut de contrebutement à l'ouest, où la nouvelle nef n'était pas encore construite. La tour tout entière portait sur les quatre piliers élancés de la croisée du transept (Figure 1). La charge totale de la tour était de 10 000 tonnes environ, piliers porteurs compris. La charge en pied des piliers porteurs était alors environ trois fois plus importante qu'aujourd'hui. Aussi, cette absence de contrebutement entraînait une poussée au vide des niveaux voûtés et un lent déversement, tandis que la grande hauteur libre des piliers ainsi que le chargement colossal qu'elle subissaient pouvaient provoquer leur flambement.

Bien que la prise au vent de la tour lanterne et sa flèche soit non négligeable, les témoignages écrits des mois et même années précédant l'accident concordent à décrire un mécanisme de ruine lent et visible, donc indépendant du vent, assimilable par nature à une charge instantanée.

La cause première est donc une charge excessive, mais deux sources donnent explicitement un rôle aux fondations dans l'accident, Lamboley (1993) et Heyman (1995); le premier à travers l'insuffisance des fondations, se traduisant par des tassements différentiels prenant leur origine dans la craie molle rencontrée jusqu'à « 24 m de profondeur»; le deuxième évoquant un phénomène de poinçonnement des piliers du carré du transept, avec des tassements, de consolidation encore, de 20 à 30 centimètres d'amplitude, sans plus de détail sur le mécanisme et son lien avec les descriptions de l'époque.

3.2 Origine géotechnique en 1573?

Pour vérifier le rôle des fondations dans l'accident, on peut faire l'hypothèse que les déformées de la structure actuelle, héritées de l'accident et mesurables encore aujourd'hui, donnent la réponse. Or, certaines de ces mesures ont été faites en 1975, 1983 et 1985 et exploitées par l'Architecte en Chef des Monuments Historiques J.-L. Taupin en 1992 (Lamboley, 1993).

Compte-tenu de la souplesse de la structure, il aurait fallu des tassements différentiels pluri-décimétriques et postérieurs à 1569 pour provoquer le basculement évoqué, traduits par des variations de hauteurs des bases de piliers (36/32/03 et 35/29/24, Figure 1) qu'à ce jour aucune source n'atteste. En revanche, une rotation d'un pilier ou la rotation combinée de piliers dans l'axe ouest-est (Figure 2), même faibles, serait plus lourde de conséquences, d'une part parce que celle-ci entraînerait un excentrement des charges par rapport à l'axe de symétrie de leur support, avec possible divergence du phénomène, d'autre part parce que, comme en 1284, ces mouvements joueraient considérablement sur l'état mécanique des très hautes voûtes et nervures des trois tambours superposés, avec, à la première rupture, des conséquences en chaîne.

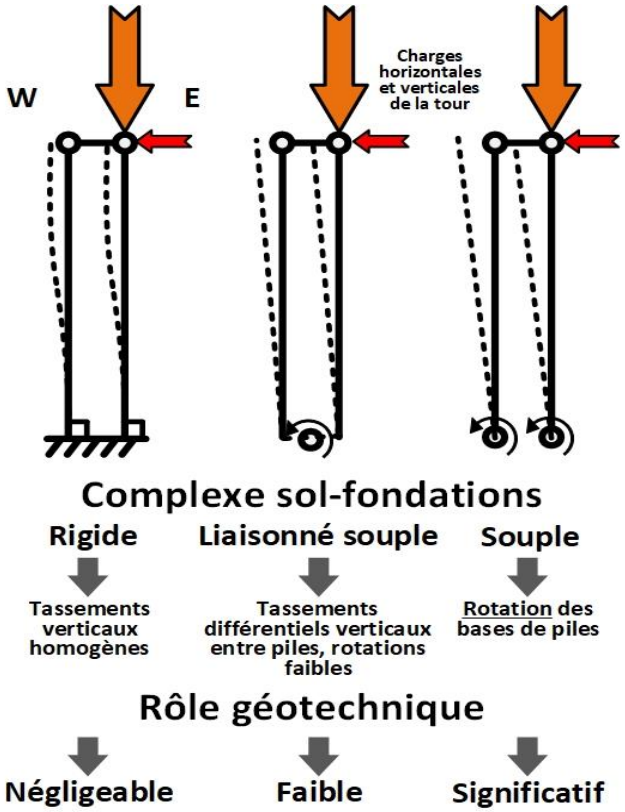

Figure 2. Situations mécaniques théoriques et simplifiées des piles de la travée centrale ouest du transept (voir localisation dans la Figure 3a, cadre en pointillés), soumises aux charges de la tour disparue.

Cela étant posé, la verticalité des bases de piliers attesterait de l'absence de rôle géotechnique dans l'accident de 1573, celui-ci se produisant par le fléchissement des piliers en section courante, singulièrement dans les parties les plus hautes.

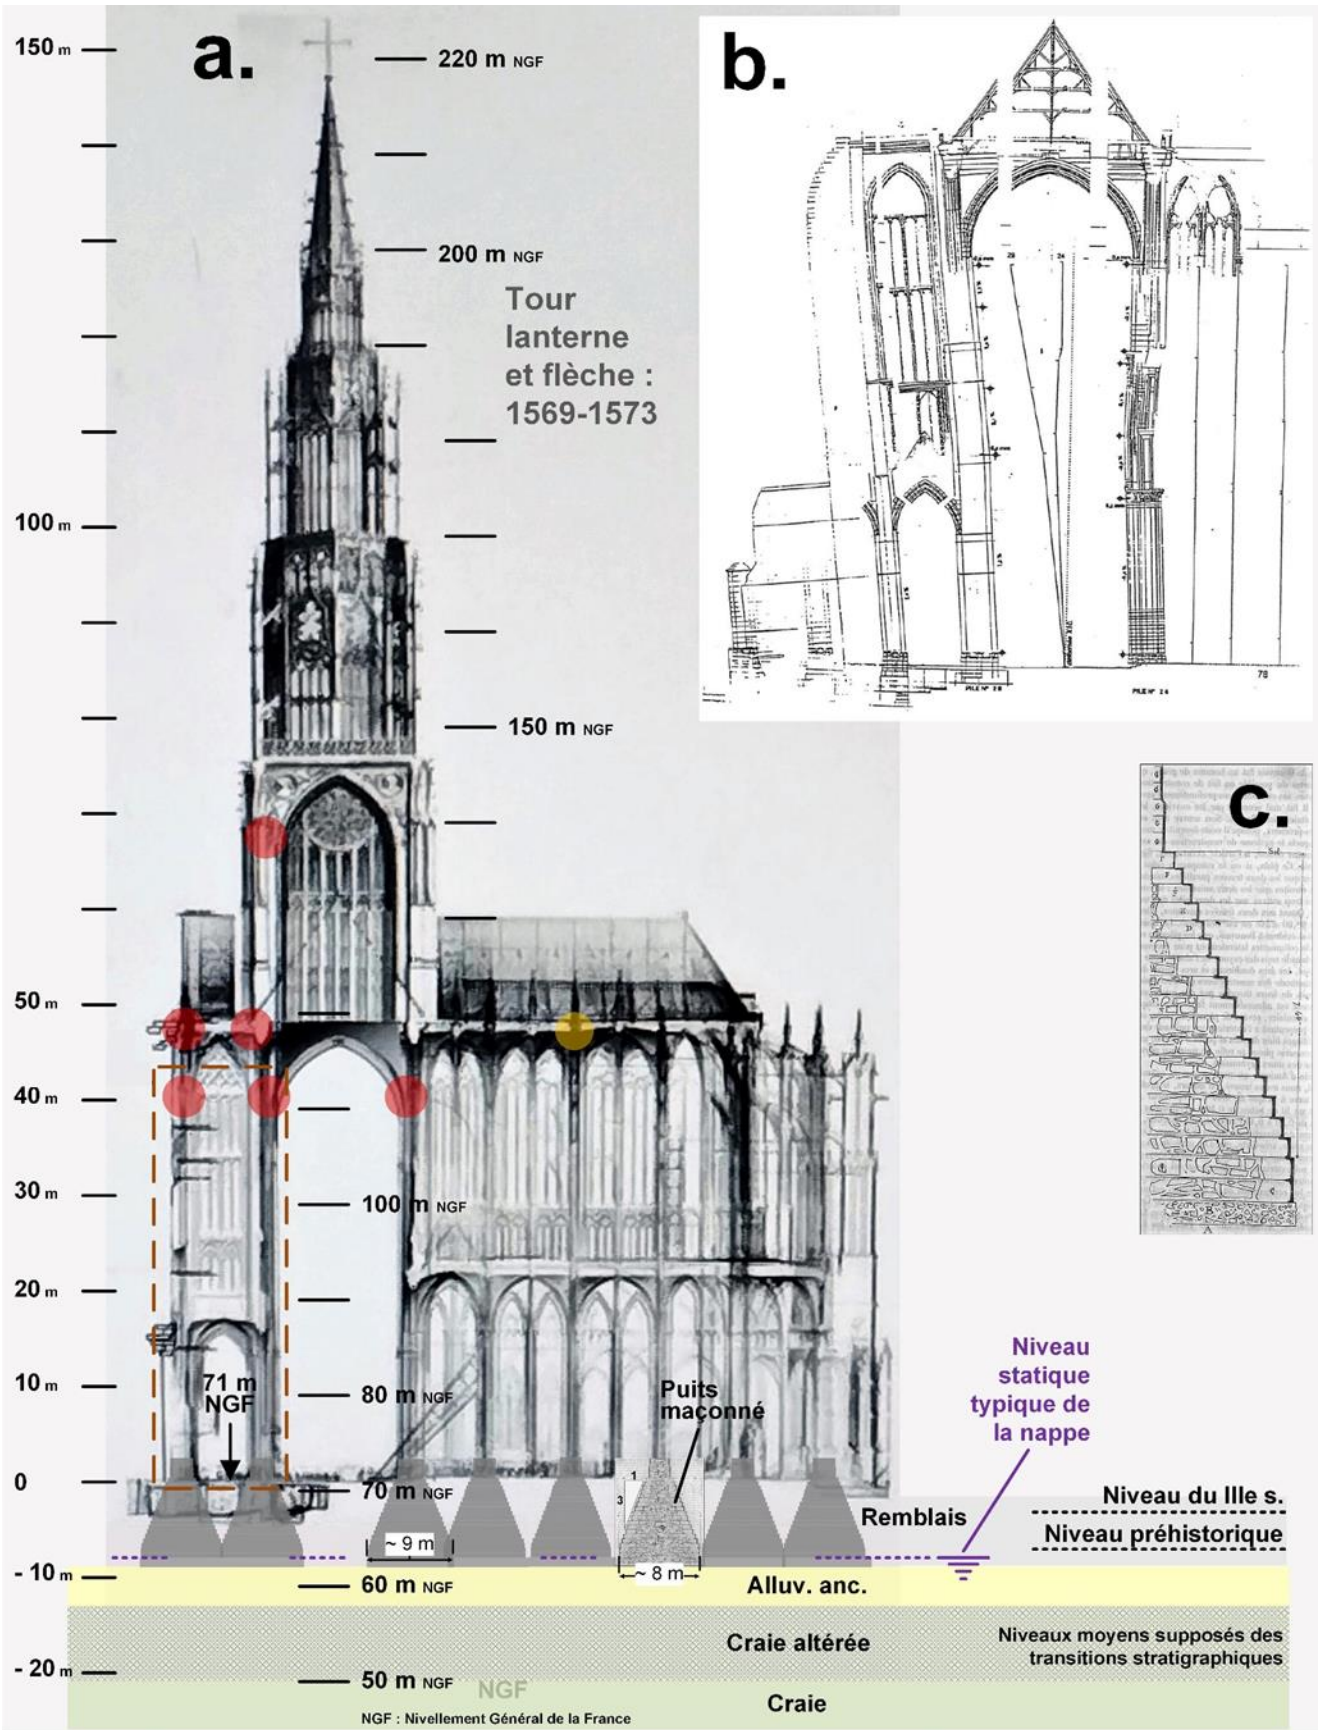

Figure 3. (a.) Coupe axiale ouest-est de la cathédrale avec évocation de sa tour lanterne et de ses fondations; habillée (fond Lidar : Martin, 2021; dessin de la tour : Woillez, E., v. 1838); (b.) Déformées restituées par Taupin, 1992, sur la hauteur des piles sud du carré du transept; (c.) coupe verticale d'un puits de fondation maçonné, observé par E.-E. Viollet-le-Duc à la cathédrale d'Amiens (op. cit., T4, p. 176).

L'extrait de la restitution avec exagération horizontale de Taupin en 1992 montre une combinaison des deux situations envisagées (Figure 3b), avec une rotation visible depuis la base des piliers occidentaux, amplifiée par des déformations des maçonneries elles-mêmes, notamment à la base du triforium. C'est jusqu'à 35 cm de déplacement à 40 m de hauteur qui ont été mesurés, soit une rotation de l'ordre de 1 %.
