GEOTECHNICAL ENGINEERING CHALLENGES TO MEET CURRENT AND EMERGING NEEDS OF SOCIETY

'Geotechnical Engineering Challenges to Meet Current and Emerging Needs of Society' includes the papers presented at the XVIII European Conference on Soil Mechanics and Geotechnical Engineering (Lisbon, Portugal, August 26 to 30th, 2024). The papers aim to contribute to a better understanding of problems and solutions of geotechnical nature, as well as to a more adequate management of natural resources. Case studies are included to better disseminate the success and failure of Geotechnical Engineering practice. The peer-reviewed articles of these proceedings address the six main topics:

- New developments on structural design
- Geohazards
- Risk analysis and safety evaluation
- Current and new construction methods
- Environment, water, and energy
- Future city world vision

With contributions from academic researchers and industry practitioners from Europe and abroad, this collection of conference articles features an interesting and wide-ranging combination of innovation, emerging technologies and case histories, and will be of interest to academics and professionals in Soil Mechanics and Geotechnical Engineering.

PROCEEDINGS OF THE XVIII EUROPEAN CONFERENCE ON SOIL MECHANICS AND GEOTECHNICAL ENGINEERING, 26–30 AUGUST 2024, LISBON, PORTUGAL

Articles

A - New developments on structural design
A - Nouveaux développements en matière de conception structurelle

Incorporating site variability into LRFD design of piles 273
M.Y. Abu-Farsakh & M. H. Rahman

Evaluation of design methods for geosynthetic-reinforced pile-supported embankments based on case studies 278
M.Y. Abu-Farsakh & M. Izadifar

Development of CPT-V_s correlations for soft quaternary clays of Szeged city Hungary 282
A. Al-Azazmeh & A. Mahler

Method for determining soil mechanical parameters from in-situ test data on the base of real nonlinear soil deformation 286
A.A. Alekhin, A.Zh. Zhussupbekov & G.A. Zhairbaeva

An experimental study of failure mechanisms developed in rock masses under circular footing 291
A. Alencar, C. Sánchez-Barberán, R. Galindo, M. Muñiz-Menéndez & A. Viana da Fonseca

A comparative discussion on soil arching evolution in CPS and GRPS embankments 295
M. Almasraf, A. Salimnezhad, B.E. Kelek, O. Cinininoglu & S. F. Cinicioglu

A modified Rowe cell with bender elements for dynamic testing of soils and interfaces 301
A. Almukashfi, R. Castellanza, A. Gomes Correia, M. Arroyo, C. Zuretti, D. Bendea & I.D. Moldovan

Renforcement par inclusions rigides: évaluation du transfert de charge au sein d'une plateforme granulaire renforcée ou non par des géosynthétiques 305
A.M. Alzate, B. Simon, C. Terqueux, L. Briançon & P. Villard

Prediction of uplift and compression bearing capacity of screw piles in saturated sand 311
D.K. Andreasen, A.K. Koteras & L. B. Ibsen

Evaluating the reliability of existing methods for predicting installation torque of screw piles in saturated sand: A comparative study 315
D.K. Andreasen, L.B. Ibsen & A. K. Koteras

1-D intrinsic compression curves for settlement analysis of soft clays 320
C. Athanasiu, A.B. Tsegaye, E.R. Sørlie & K.E.L. Johnsen

Numerical modelling of rigid inclusion reinforced road platform, under surface loading and mobile loading 326
T. Badinier, N. Ouechten, T. Dubreucq & L. Thorel

Centrifuge modelling of tapered wall jacked into dense sand 330
L. Bałachowski, W.F. Kabeta, L. Thorel, M. Blanc & T. Dubreucq

Effects of non-linear response of shallow foundations on transmission tower serviceability 334
P. Barbieri, T. Newson, M.Y. Xiao & H. P. Hong

Automating stability analysis using BIM-FEA-Integration 338
J. Beck, H. Jürgens & S. Henke

Micropile bearing capacity analysis using fiber optic technology 342
R. Bednarek & A. Jaroszek

Cross analysis between different evaluation methods of small strain moduli in clays and marls of Parisian subsoil 346
N. Berthoz, N. Dufour, A. Rallu, Y. Aslan & D. Branque

Settlement analysis for a nuclear plant design 352
M. Blanckaert, B. Pelletier, S. Depinois & M. T. Hoang

A critical review of field testing of helical steel piles 356
P.J. Bourne-Webb, T.M. Bodas Freitas, P. Marques & E. Godinho

Modelling the interaction of an underground structure with the soil in a megalopolis 361
I. Boyko, V. Nosenko & O. Lytvyn

Machine learning to improve the ground model for road settlement prediction 365
M. Brček, J. Panuška & M. Kopecký

Automatic parameter calibration of advanced constitutive soil models and application to a boundary value problem 369
F. Brosz, J. Machaček & H. Zachert

Mechanical features of stabilized soils with low cement content 375
M.A. Castaneda-Lopez, T. Lenoir, L. Thorel & J.-P. Sanfratello

Application of optimization algorithms in geotechnical engineering as decision-making support tool 380
K. Cerek, E. Hadjiloo & J. Grabe

Performance-based interaction domains for pile groups 384
R. Cesaro, R. Di Laora, C. Iodice & A. Mandolini

Rheological study of soil-cement-GGBFS mixture 390
S. Choudhary, P.K. Meena, A. Kumawat & L. Borana

Influence of volumetric boundary conditions on the water-retention behaviour of reconstituted and intact clay shales 395
F. Christ & A.A. Lavasan

Definition and analysis of ground surface vibration curves induced by railway traffic 400
A. Colaço, R. Gomes & E. Fortunato

Integrating cluster-based knowledge for local undrained shear strength prediction 404
S. Collico, G. Spagnoli, A. Fraccica & E. Romero

Back-analysis of deep excavations supported by strutted retaining walls 410
V.I. Cordoni, L. Gelonch, B. Solà, C. de Santos & A. Ledesma

Correlations between SPT and DPSH results based in energy measurements 414
N. Cruz, J. Cruz, C. Rodrigues, L. Fagundes & C. Chaquisse

Hydric and mechanical properties assessment of basalts from Madeira island, Portugal 418
N. Cueto, J.F. Vieira de Sousa, J.P.S. Perneta, R. Meza & M. L. Pereira

Analysis of the feasibility of applying reinforcement for laying direct foundations 424
M.C.C.S. da Silva & P.C. de A. Maia

Rate-dependent confined crushing in granular media 428
S.K. Das

Slog: an open geotechnical software 433
J. de Sauvage

A semi-analytical model for axial soil-pile interaction in generalized inhomogeneous soils 438
A. Della Corte, O. Orakci, A. Tsikas, S. François & G. Anoyatis

Integrating MT-InSAR and conventional monitoring with numerical analysis for tunnel excavations: A case study 444
G. Della Ragione, E. Bilotta, Di Mariano & A. Gens

A t-z approach for the design of axially loaded piles in consolidating soil 448
A.E. Detlefsen, A. Franza & K.K. Sørensen

Port silo foundations on piles under vertical cyclic stresses 452
P. Dogaru & R. Ciortan

Effect of strain-softening and strength anisotropy on the undrained resistance of deeply embedded pile/pipe section 456
Y.P. Dong

Improvement of tubular piles by effective closure 462
M. Doubrovsky & V. Dubravina

Mechanical characterization of a saturated marine clay for pavement design and performance 468
J.H.C. Everton & S. Erlingsson

Integrating local data into geotechnical design through a predictive probabilistic approach 474
A. Finiasz, J. Hassaoui, C. Jacquard & E. de Rocquigny

Impact of the testing methods on physical properties of high plastic clay 478
J. Frankovská, M. Brček & J. Brčeková

Reinforced soil technique for temporary slope stabilisation in loose saturated ground 482
G.R. French & S.D. Thomas

Creative approaches for enhancing excavation shoring efficiency through diaphragm wall prestressing techniques 488
M.C. Frydrych

Limit equilibrium solution for lateral pile capacity in cohesive soil 492
T. Gans-Or & S. Pinkert

Effect of microplastics on swelling behaviour of geosynthetic clay liners (GCLs) 497
Y. Gao, R.K. Rowe & A. El-Zein

The behaviour of piles in unsaturated expansive clays under cyclic lateral loading 503
T.A.V. Gaspar, R.A. Murison, S.W. Jacobsz, G. Heymann & A.S. Osman

Undrained triaxial test stress path shape as an indicator of sample quality 507
V. Gjelsvik & K. Kahrs

Cohesive soil behavior under cyclic loading in undrained conditions 511
A. Głuchowski & W. Sas

Numerical simulation of pore water pressure evolution beneath a raft foundation during a river flooding 515
E.P. Graterol, J.G. Gutiérrez-Ch, L. Mediero & S. Senent

Evaluation train induced ground vibration boom with Vibtrain 520
A. Håård, J.A.T. Johansson, K. Viking & S. Larsson

On the thermal failure of sand-clay mixture 524
A. Hamidi, A. Shirasb & S. Tourchi

Soil-structure interaction of two different configurations of a cut and cover tunnel 528
A.M. Hasan, B.J. Shwan & O.Q. Aziz

Dynamic pull-out tests to characterize the earthquake behavior of soil-nailed walls 532

The impact of small strain stiffness parameters on geotechnical numerical modelling - a case study in Budapest, Hungary 939
Á. Wolf, K. Ficzek & Zs. Szilvágyi

Numerical study of ground movements induced by traditional foundation underpinning 945
J. Woodcock, A. Fasano & A. Nikolic

Comparison of Markov Chain Monte Carlo and Sequential Monte Carlo inference techniques for calibrating soil parameters in a braced excavation 949
N. Yang, T. Le & L.T. Nguyen

Simulation of sand-fines mixtures behaviour based on bounding surface plasticity and equivalent void ratio 955
F.H. Yeh, L.F. Prada-Sarmiento, M. Tafili, D. Sarkar, T. Wichtmann & L. Ge

Load bearing mechanism of screw piles under compressive loading in clayey soil 961
P. Zahedi & D. Igoe

Simplified finite element modeling of TBM tunneling 967
H. Zaiter, H. Mroueh & E. Bourgeois

Determining the modulus of subgrade reaction for piled raft foundations by numerical modelling 971
B. Zarazvand & J. Frankovska

Examining the behavior of laterally loaded large-diameter monopiles using coupled FDM-DEM simulations 975
Z. Zhang, Z.-T. Zhang, X.-D. Zhang, W. Wang, G.-M. Yu & Z.-Q. Zhang

Research on macro-meso relationship of geological materials based on Discrete Element Method: Review and prospect 979
M. Zhou, Q. Zhang & R. Ding

Numerical simulations of soil tests emulating ground behaviour beneath super-tall building foundations 983
Y. Zhou & T. Kiriyama

Challenges in characterisation of natural sands with fines 989
H. Zhou & S. Sharma

Smart foundations for undermined and seismically affected territories 995
A. Zhussupbekov, B. Bazarov, A. Sarsembayeva, A. Omarov, S. Mussakhanova & D. Mukhanov

Method for triaxial experiments for unconventional strain paths and back-calculation using Neohypoplasticity 1001
J. Zürn, L. Mugele & H.H. Stutz

Creep of organic soils due to small load increments 1005
C. Zwanenburg, B. Wittekoek & M. Konstadinou

B - Geohazards
B - Géorisques

Discharge flow rate under sheet piles, a prediction model 1013
A. Ahangar Asr, A. Johari & A. A. Javadi

Contract for the stabilization of the north cliff in Azenhas do Mar 1017
S. Almeida & M. Pereira

Overcoming geotechnical challenges to maximise re-use of an existing brownfield site for use as a rail test track 1023
P. Anning, J.K. Thillainadarajah & A. Kushwaha

Ravines in collapsible soils of Luanda, Angola: forms of erosion – state of the art 1027
F.M. António, F.A.B. Bonito & A.A.R.C.A. Benta

Reliability analysis of a Po River embankment affected by underseepage 1033
I. Bertolini, M. Marchi, L. Tonni & G. Gottardi

Concept for sustainable lab and in-situ research on earthquake induced geohazards 1038
J. Bojadjieva, V. Sheshov, K. Edip, T. Kitanovski, D. Ivanovski, I. Gjorgjeska & A. Bogdanovic

Seabed and sub-seabed boulders as an engineering hazard in the marine environment; a risk mitigation strategy for subsea cables 1042
L.J. Burley, E. Tataki, H.M. Taylor, V. Terente & N. Dyer

The Tonbridge to Hastings undrained earthwork and modernisation programme and engineering research (THUMPER) 1048
D. Butcher, S. Fielder, S Holt & T. Hunt

Centrifuge tests on the uplift and deformation patterns of clay cover layers in deltas 1052
C. Cengiz, M.A. Cabrera, B. Wittekoek, M. Fransen, L. Wopereis & C. Zwanenburg

UAS thermal imagers for monitoring and analysing landslide in a mudstone area 1056
H.-W. Chen, C.Y. Chen & Y.Y. Liu

Evaluating the interface shear strength of geocomposite drain and HDPE geomembrane layers in landfill cover systems 1062
F. Chihi & G. Varga

A simplified procedure for FE analysis of an earth dam under seismic loading 1066
A. Choudhury, P. Ghosh & S.K. Mishra

Change of soil permeability during and after soil liquefaction 1072
M.-C. Chu, C.-C. Tsai, Y.-C. Kao, Y.-X. Liu & C.-Y. Jou

Strength and rainfall-induced erosion resistance of bio-cemented soil slopes 1076
R. Devrani, P. Vangla & S. Sharma

Evaluating undrained shear strength and sensitivity in soft sensitive clay using piezocone and field vane tests 1080
B. Di Buò, P.W. Mayne, P. Paniagua & S.S. Agaiby

Numerical analysis of an unstable slope 1086
A. Di Mariano, J. Serna-Garcia, Y.F. Vargas-Alzate & A. Gens

Monitoring the hydro-mechanical effects of vegetation cover on shallow landslide triggering: Preliminary results from a case study in western Norway 1090
A. DiBiagio, V. Capobianco, A. Oen & L.M. Tallaksen

Slope stabilization at Régua-Ferrão section of the Douro railway line 1094
C.M. Dinis & A.M. Pereira

Resonant column round-robin testing 1100
N. Dufour, H. Calissano, L. Batilliot, I. Rogoff, C. Simon, A. Disantantonio, T. Lando & E. Bourguignon

Experimental investigation of influence of soil plasticity on compression characteristics and creep behaviour of clayey soils 1104
M.N. Duy & J. Jerman

Nonlinear finite element analyses of earthquake effects in slopes 1109
A. Eikebrokk & A.M. Kaynia

Appraisal of various measures for liquefaction flowslide mitigation in a mild sloping ground 1113
M.H. Fansuri, M. Chang, R.R. Rayhansyah, H.J. Lin, T.C. Upomo & R. Kusumawardani

Coastal cliff stabilization and access stair reconstruction at Peneco beach, Algarve, Portugal 1119
C. Fartaria, A. Pinto, J. Dinis, P. Nunes & M. Silva

A design procedure for high energy rockfall barriers 1123
D. García, L.Molano, G. Torres & D. Freitas

Calibration of soil water retention parameters based on field measurements 1127
T.A.V. Gaspar, S. Pradhan, A.S. Osman & D.G. Toll

Use of Bayesian Kriging to develop new soil property maps for Quito, Ecuador 1131
C.E.L. Gilder, M.M. Othman, C. Zapata, E.A. Holcombe, R. De Risi, F. De Luca & P.J. Vardanega

Liquefaction resistance of carbonate sands from cone penetration tests 1136
D. Giretti & V. Fioravante

2D Seismic response analyses from 3rd Level Seismic Microzonation in the Southern Italy: Approaches and applications 1142
S. Grasso, M.R. Massimino & M.S.V. Sammito

Slope stability modelling of urbanisation scenarios for communities in north Quito, Ecuador 1146
R. Hen-Jones, C. Zapata, E. Jiménez, E.A. Holcombe & P.J. Vardanega

Forensic investigation of quick clay landslide released by construction work at Asak, Norway 1150
H. Heyerdahl, Å.M.W. Amdal, R. Frauenfelder, K. Sverdrup-Thygeson & A.O.K. Lysdahl

Vulnerability assessment of buildings to landslides: application to Swiss case studies 1154
E.P. Howald, L. Francone & D. Martinelli

Fire-induced changes in the geotechnical properties of a volcanic soil 1160
L. Iervolino, D. Peduto & V. Foresta

Remote sensing techniques for soil-structure interaction health monitoring 1166
D. Infante, S. Moretti, M. Zimbardo & A. Scotto di Santolo

Slope failures risk acceptance in the construction of roads on the clayey mine spoil dump, Czech Republic 1170
J. Jurko & N. Droniuc

Local site response analyses based on field measurements compared to vs30 site-condition and geologic and topographic constraints 1174
O. Kegyes-Brassai, G. Kovacs, T. Toth, B. Labar & A. Wolf

A geotechnical and geophysical characterization of the influence of seasonal variation on railway embankments 1179
Q. Khan, S. Donohue, A. Trafford, B. Dashwood & J.E. Chambers

Laboratory assessment of shear strength parameters in sandy soil by lime permeation method and sensitivity analysis from Doi Chang case study 1183
A. Koirala & S. Soralump

Numerical and experimental evidence of the impact of soil nonlinearity on the response of an SSI system 1188
M. Koronides, S. Kontoe, L. Zdravković, D.M. Potts, A. Vratsikidis, D. Pitilakis & A. Anastasiadis

Particle size distribution induced fabric effects on the onset and post liquefaction behaviours of soils 1194
J. Leak & D. Barreto

On the liquefaction induced pore water pressure ratio underneath existing buildings 1199
S. Lirer, F. Valtucci, P. Bonassisa, L. Mele & A. Flora

Disintegration of natural granite residual soil and the geohazard implication 1205
X.Y. Liu, Y. Miao, X.W. Zhang, G. Wang & H.D. Gao

Endangered historic sites: The case study of Santa Croce in Ravenna (Italy) 1209
M. Marchi, I. Bertolini & G. Gottardi

Coastal erosion process at Calhetas parish, São Miguel island, Azores 1214
F. Marques, A.M. Malheiro, P. Amaral, A. Santos & L. Cunha

Prediction program for slow moving landslides 1218
R. Marte & H. Ramoser

Mapping and monitoring tailings storage facilities with muography 1224
M.A. McLean, F. Scutti, R. Seikel, S. Krishnan, C. Webster, S. Collins, S. Palanisamy, P.H. Panchal, J. Donovan, A.R. Duffy, C. Goss & A.N. Christensen

Liquefaction resistance of TP-Lisbon sand: A comparison between cyclic triaxial and cyclic direct simple shear tests 1228
F. Molina-Gómez, A. Viana da Fonseca, C. Ferreira & B. Caicedo

Geotechnical interventions to mitigate the geomorphological risk of the access road to Ribeira Quente parish - Azores archipelago 1232
L. Moniz, P. Amaral, A.M. Malheiro, F. Marques & A. Santos

Effect of bentonite permeation on the fabric and strength of Ottawa Sand 1236
D. Mourtada & G.A. Jaoude

Mapping the 3D effect for slope stability analyses of quick clay slopes 1241
S.S. Nagula, L. Rødvand, H.P. Jostad & S. Degago

Analysis of rock slope failures. Case studies on Romanian mountain roads 1245
A.-Cs Nagy, C. Bruchental, D.M. Paşca, V.-S. Fărcaş, D.-V. Moldovan & L.-E. Moldovan

Geotechnical seismic site characterization of deep alluvial sand sites in the South Iceland Lowland 1249
E.A. Olafsdottir, S. Erlingsson & B. Bessason

Numerical modelling of the seismic site effects in Lisbon: role of buried and surficial morphology 1255
L. Oliveira, R.C. Gomes, S. Amoroso, A. Pagliaroli & P. Teves-Costa

Expansive and collapsible soil behaviour under the Revised Soil Classification System 1259
R. Ortiz-Hernández & E. Rojas-González

Rockburst conditions prediction based on a decision tree algorithm 1265
D. Owusu-Ansah, J. Tinoco, J. Matos & F. Lohrasb

Combining slope satellite image analysis and artificial intelligence algorithms for highway service level assessment 1269
D. Owusu-Ansah, J. Tinoco, J. Matos & R. Cabral

Stabilization of excavation slopes between km 0+000 and km 2+000 of the EN337, in the municipality of Vouzela 1273
F. Paulino, E. Fernandes & A. Dinis

ReSist - A municipal policy to increase awareness on seismic risk 1277
C. Pinto, M.A. Ferreira, C. Almeida, M. Inácio, P. Pacheco, C. Pousada, C.S. Ferreira & A. Ferreira

The Citizens Observatories as a tool to manage geohazards. Lisbon Multihazards CO case study 1283
C. Pinto, A. Frias, P. Leonardo, C.S. Oliveira, M. Inácio, R. Carrilho Gomes & M. Ferreira

An early warning procedure based on coupling short-time weather forecasting and numerical slope analysis 1287
M. Pirone, G. Forte, A. Santo, G. Urciuoli & L. Picarelli

Ground investigation methods used in high-speed railway for mitigation of dissolution features risk in chalk 1291
S. Pryce, M. Black, H. Saroglou, G. Katsigiannis & S. Muniyasamy

Sensitivity analysis of the effects of liquefiable soil deposits on differential settlement of buildings by numerical modelling 1297
J. Quintero, M. Millen & A. Viana da Fonseca

A new, durable micropile for the foundation of rockfall protection structures 1301
M.J. Rebhan, H.-P. Daxer, R. Marte, M. Schuch & S.L. Burtscher

Landslide susceptibility map of the southern slope of the municipality of Odivelas using the AHP method 1305
A.J. Roque & M.J. Coelho

Numerical and theoretical investigation on the triggering mechanisms of rainfall-induced landslides 1311
G.M. Rotisciani, A. Desideri & A. Amorosi

Innovations in liquefaction mitigation: Modelling the mechanical cyclic behavior of biocemented soils 1315
Z.N. Sahlab, D. Terzis & L. Laloui

Performance design of shallow foundations interacting with liquefiable soils 1319
I. Sarao Mannelli, V. Minardi, G. Canetta & B. Becci

Effects of temperature, pore fluid composition and rate of shearing on the residual shear strength of soils 1325
G. Scaringi, O.P. Dhakal & M. Loche

Sand stabilization with colloidal silica for protection from liquefaction caused by dynamic loads 1330
R.F. Sharafutdinov, D.P. Kuznetsova, V.S. Morozov & Y.I. Stolyarov

Landslide monitoring: comparative analysis of long-term automated systems in Brazil and the UK 1335
A. Silva, C. Levesque, B. Norberto, S. Holloway & D. Fornelli

Assessment of geotechnical properties using optimisation methods 1341
M. Stãnciucu & I. Mircea

Comparative assessment of liquefaction susceptibility of unconsolidated deposits 1346
M. Stãnciucu & I. Dogaru

Liquefaction risk assessment of airport infrastructure using geological data and remote sensing techniques 1350
M. Taftsoglou, S. Valkaniotis, G. Papathanassiou & S. Argyroudis

Sand boil observations and geotechnical characterization of river embankments for the development of a backward erosion piping database 1356
L. Tonni, M. Marchi, I. Bertolini, A. Bassi & A. Rosso

Thermo-hydro-mechanical analysis of soil strata suffered from desiccation cracking 1362
S. Tourchi, M. Jabbarzadeh & H. Sadeghi

Prediction of water content under climatic actions. A method based on spectral analysis and soil transfer functions 1368
Y.F. Vargas-Alzate, J. Vaunat, A.M. Zapata-Franco & A. Di Mariano

Managing uncertainties in the geotechnical design of climate change resilient infrastructures 1373
P. Vitale & Z.Q. Liu

Shear strength of sand under different range of confining stresses using various shearing devices 1377
M. Vivoda Prodan, J. Peranić, V. Jagodnik, D. Marušić, D. Štiberc, N. Kamenar & Ž. Arbanas

Simulation of responses of a Tender Net Foundation on silty ground subjected to consecutive earthquakes 1383
H. Vo-Cong, K. Takeuchi, Y. Tomono & T. Matsumoto

Enhancing landslide anomaly detection in aerial imagery through pre-processing and GANomaly deployment 1389
C.H. Wang, K.C. Lo, C.Y. Hu & P.H. Wang

Development and experimental calibrations of a multifunction slope monitoring device - Smart Pole 1394
C.H. Wang, S.Y. Jeng, B.J. Hou & Y.T. Hu

The A83 Loch Shira landslide, Scotland 1398
M.G. Winter, T. Waaser & G. Fiddes

Back analysis of flexible barrier response following an open hillslope landslide impact at Pa Mei, Hong Kong 1402
E.K.L. Wong, J.W.C. Lau, J.-W. He, Z.-H. Zhou & S.L. Chan

Technical aspects and remediation work for hazardous landslides: Tskneti example, Georgia 1408
T. Yildiz, D. Kuparadze & D. Pataridze

Towards improved earthquake preparedness: Site effects considering multiple seismic zones 1412
A.M. Zapata-Franco, Y.F. Vargas-Alzate, J. Vaunat & A. Di Mariano

C - Risk analysis and safety evaluation

Spatial vulnerability of levees to cascading hazards 1448
M. Bačić, N. Rossi, L. Librić & M.S. Kovačević

Insights from the implementation of levelAMS, a geotechnical asset management software, on Brisa's network 1452
J. Barros, M. Pinheiro, M. Cruz, I. Gonzalez & T. Miranda

Distributed strain, settlement and temperature sensing in geotechnical earth embankments 1457
Ł. Bednarski, T. Howiacki, R. Sieńko & K. Zuziak

Effect of suction and preparation method on the compressibility of Stava silty tailings 1463
G. Bella, D. Czerski, S. Ghezzi, M. Giani, M. Lüscher & C. Ambrosi

Extension of the Lisbon subway between Santos station and the Terminal of the Cais do Sodré station - assessment of excavation induced damage in buildings 1469
F. Bernardo, S. Ferreira, R. Pistone, R. Pina & A. Tavares

Eurocode 7 – Second Generation: Retaining structures – Looking beyond the partial factors for safety in design 1475
W. Bogusz

Excavation and tunnelling impact on existing structures in the context of the second generation Eurocodes 1481
W. Bogusz

Pile response to the effect of basement construction in soft clay 1485
T. Boonyarak, A.Y. Aung & Z.Z. Aye

Assessment of displacements and deformation mechanisms in a rockfill dam: case study of Cerro da Mina reservoir 1491
L. Bottaro, G. Tavares, M. Oliveira & A. Rodrigues

Eurocode 7 – second generation reinforced fill structures 1497
G. Bräu & N. Denies

The implications of poor leadership on geotechnical risk 1503
C.A. Bridges

Designing a pre-load embankment for the construction of a stage over a sanitary landfill founded in soft soils 1507
A. Brito & J. Carreto

Eurocode 7 – second generation - numerical methods 1513
S. Burlon, H. Walter & C.C. Smith

Tensile strength of rocks: Comparison of different testing methods 1517
J. Castro, J. Justo, M.H. Olson & M. Miranda

Probability-based hybrid landslide assessment system integrating landslide susceptibility and numerical modeling 1521
Y.-H. Chen & K.-W. Liao

Large-scale soil investigations for greenfield railways using airborne geoscanning: A case study from Mato Grosso, Brazil 1527
C.W. Christensen, B.R. Bloss, A.A. Silva, E.J. Harrison, M.S. Gomes & R.W.M. Ferraz

The use of dynamic load tests for execution control of driven precast piles in logistic warehouses 1531
J. Costa, J.M. Díaz & J.C. Sanchez

Review of SPT-undrained shear strength correlation for UK soil deposits 1535
J.J. Crispin, C.E.L. Gilder & P.J. Vardanega

Why geotechnical engineering isn't ready yet for machine learning? 1539
T. Daktera & L. Janodet

Geotechnical parameters estimation in iron ore tailings piles via Bayesian models 1543
B.M. de Lacerda, R. Chammas, T.C.O. Fonseca & T.B. dos Santos

Interactive three-dimensional management of data from technological control of stacks and dams – case study 1547
B.M. de Lacerda, S.C. Chammas, W. Silva & V. Rezende

A method for the prediction of greenfield 3D settlement troughs around deep excavations 1551
M. De Luca, G. Russo, M.V. Nicotera & I. Esposito

Monitoring of soil deformations induced by deep mixing using an FME-based data analysis tool 1555
F. Deckner, V. Enbom, A. Kriege, K. Borgström & T. Forsberg

Calibration of a numerical model for the investigation of piled rafts under dynamic loading 1560
Y. Degu, O. Reul, A. Worku & F. Tschuchnigg

Eurocode 7 – Second generation. Design of ground improvement works 1566
N. Denies, C. Bohn, P. Pandrea, M. Topolnicki, C. Plomteux & K. Trybocka

Estimation of permeability coefficient using machine learning algorithms on the example of AdaBoost and Artificial Neural Network algorithms 1572
J. Dzięcioł & W. Sas

Probabilistic stability assessment of deforested steep slopes using 3D finite element method 1578
A. Ebener & K. Lesny

Development of database of monitoring results for retaining walls of deep excavations 1584
A. Ene, I. Ciocaniu, D. Marcu & H. Popa

Eurocode 7 – Second generation: determination of representative values 1588
J. Estaire, J. Sorgatz & T. Orr

Behaviour of stabilizing piles arranged with different layouts 1594
L. Fantera, S. Lirer, A. Desideri & S. Rampello

Safety assessment of a gravity dam using a hydromechanical model: fracture propagation at the dam/foundation interface 1600
M.L.B. Farinha, N.M. Azevedo & S. Oliveira

Analysis of subsidence problems on a highway section in Valencia (Spain) with the help of satellite radar interferometry 1606
A. Fernández Eusebio, J. Moreno Robles, F. Pardo de Santayana, D. Mora Cejudo, A. Parrilla Alcaide, D. Carrasco Díaz, A. Mendizabal, J. Duro, D. Monells & R. Iglesias

Characterization of a highway reinforced earth wall pathology with the help of a terrestrial laser scanner model, analyses of the causes and proposal of remediation measures 1612
A. Fernández Eusebio, J. Moreno Robles, F. Pardo de Santayana, D. Mora Cejudo & A. Parrilla Alcaide

Comparison between biocementation and a traditional cover solution to avoid ravines in slopes caused by water flow 1618
R. Fernández Rodríguez & R. Cardoso

Risk analysis of decommissioning design of tailings dams 1622
J.S. Figueira, C. Mata, G. Tavares, A. Brito, J. Marcelino & L. Caldeira

Comparison of floating and end-bearing pile wall barriers for tunnelling in layered soil 1626
A. Franza

A holistic risk sensitivity analytical approach for assessing flood protection infrastructure 1630
H.K. Fung & V. Nyambayo

Eurocode 7 – second generation - ground model 1636
H. Garin, M. Baldwin, P. Reiffsteck, K-J. van der Made & R. Wudtke

Influence of lateral stress on soil-structure interface tests in a hollow cylinder apparatus 1640

ECSMGE 24
XVIII EUROPEAN CONFERENCE
ON SOIL MECHANICS AND
GEOTECHNICAL ENGINEERING

Preface

The ISSMGE European Region and the Portuguese Geotechnical Society (SPG) are pleased to welcome you to the XVIII European Conference on Soil Mechanics and Geotechnical Engineering in Lisbon, Portugal, on the 26th to the 30th of August 2024.

The geotechnical challenges that the world faces are getting increasingly complex and interrelated. To develop a renewed commitment with the engineering core values and ethics in this time of rapid and defying changes, the theme of the Conference is: "Geotechnical Engineering challenges to meet current and emerging needs of society". Considering this framework, the topics of the conference are:

A - New developments on structural design.

B – Geohazards.

C - Risk analysis and safety evaluation.

D - Current and new construction methods.

E - Environment, water and energy.

F - Future city world vision.

After the pandemic period, the aim of the conference is to share in person knowledge and experience with our colleagues and strengthen the relationship between members of the geotechnical community, emphasizing the important contribution of the geotechnical engineering to solve the current and emerging society needs.

We hope that this conference exceeds your expectations with very interesting lectures, papers, posters, exhibitions and technical visits.

We gratefully thank all the speakers, authors, reviewers, supporting committees, members of ISSMGE technical committees, chairs of sessions, exhibitors, institutional partners, as well as all other participants making this conference outstanding.

We hope you have a pleasant stay in Portugal and look forward to seeing you again.

Lisbon, August 2024

Lyesse Laloui,
ISSMGE Vice-President for Europe

Alexandre Pinto,
Chairman of the Organizing Committee of the XVIII ECSMGE 2024

Acknowledgements

The Portuguese Geotechnical Society (SPG) gratefully acknowledges the important support to the XVIII ECSMGE, Lisbon, 2024, from all the Conference Partner companies.

The Portuguese Geotechnical Society also acknowledges the enthusiasm and support of the members of the Advisory Committee, the Scientific Committee and the Organizing Committee of the XVIII ECSMGE, as well as the strong participation of the Board of Reviewers that contributed to the high scientific quality of the proceedings.

The Portuguese Geotechnical Society acknowledges the important role of the authors, keynote lecturers, SOA, Forum and HTC lecturers, chairpersons, and all the persons and entities that contributed to the success of the XVIII ECSMGE.

The editors thank Mr. Manuel Carvalho and Miss Maria João Carvalho for their meticulous and comprehensive efforts in proofreading and formatting the text. Their dedication has contributed to the high quality and readiness for publication of these proceedings.

The editors extend their appreciation to Leading and in particular to Maria Brito, for her expertise in crafting the captivating graphical design of the book cover.

Editor Biographies

Nuno Guerra is Associate Professor at NOVA School of Science and Technology, where he lectures undergraduate, master and postgraduate courses in the fields of Soil Mechanics and Geotechnical Engineering, in the Civil Engineering Department. His research interests are the study of the collapse of geotechnical structures, geotechnical design considering the variability of soil properties, soil-structure interaction and the performance of retaining structures. He was Vice-President of the Portuguese Geotechnical Society (2012-2016), member of several Organizing and Scientific Committees of national conferences and Geotechnical Engineer and Consultant. He was (2004-2008) and is now (from 2016) member of the Board of the journal "Geotecnia" published by SPG, ABMS and SEMSIG. He is author of 75 papers published in national and international journals and in the proceedings of national and international conferences.

Manuel Matos Fernandes is Professor of Soil Mechanics and Geotechnical Engineering at the Faculty of Engineering of the University of Porto. His main research areas concern numerical modelling of geotechnical works, deep urban excavations and the history of Construction. He was editor of the journals Geotecnia (2000-04) and Soils & Rocks (2012-16) and President of the Portuguese Geotechnical Society (2016-20). He is author of textbooks on Soil Mechanics and Geotechnical Engineering published in Portugal and internationally. From 1991 to 2012, he co-organized the series International Workshops on Applications of Computational Mechanics in Geotechnical Engineering and co-edited its proceedings (6). In 2013 he was awarded with the Prize in Pedagogic Excellency at his university.

Cristiana Ferreira is Assistant Professor in the Department of Civil Engineering at the Faculty of Engineering of the University of Porto and an integrated member of CONSTRUCT (Institute of R&D in Structures and Construction). Her research is mainly focused on laboratory and field soil characterisation, wave-based non-destructive testing, seismic and static liquefaction characterisation and mitigation, and the mechanics of non-textbook geomaterials. She has 3 published books as editor, 32 papers in peer-reviewed scientific journals and more than 50 papers in conference proceedings.

António Gomes Correia is professor and researcher at the Institute for Sustainability and Innovation in Structural Engineering (ISISE) of University of Minho. His activities involve research, teaching and consulting in the general field of geotechnical and transportation engineering for 44 years. He has been a keynote speaker and member of the organising/technical committees for many well established international conferences. He is a co-founder of the International Society for Intelligent Construction (ISIC) as well as has founded the conference series on Transportation Geotechnics. He is also one of founding editors for the international journal "Transportation Geotechnics" (from 2014), as well as for "Transportation Engineering" (from 2020), both published by Elsevier. He is also editor of the journal "Geotecnia" (from 2016) published by SPG, ABMS and SEMSIG. He is an author/coauthor of 190 scholarly publication indexed in SCOPUS.

Alexandre Pinto is founder and technical manager of JETsj Geotecnia Lda. and invited Professor at Instituto Superior Técnico (IST) of Technical University of Lisbon. His activities involve consulting and teaching in the general field of geotechnical engineering for 30 years. He is an author/coauthor of 120 technical papers. He has been a keynote speaker and member of the organising/technical committees for several conferences. He was Vice President of Portuguese Geotechnical Society from 2016 to 2020 and is President from 2020 to 2024.

Pedro Sêco e Pinto was a Full Professor of Geotechnical Engineering at Coimbra University. He is a member of European Union Academy of Sciences, a Fellow of Portuguese Institute of Engineers and a former Director of Research of National Laboratory of Civil Engineer (LNEC). He was ISSMGE Board Member, Immediate Past President, ISSMGE President and ISSMGE Vice President. He was Chairman of ISSMGE TC "Earthquake Geotechnical Engineering". He presented 350 State-of-the Art Lectures in 80 countries. He was an Editorial in Chief of 2 International Journals and he is member of 7 Editorial Boards. He has been a member of Advisory Committee of 100 International Conferences. He worked as World Bank Consulting and United Nations Consulting. He worked on 450 major projects in Dams, Power plants, Bridges, Special Foundations, Tunnels, Highways, Landslides, Dykes, Airports and Quay Walls, in 23 countries. He is author or co-author of 500 Technical and Scientific Reports and 180 papers for Conferences and Journals and contributed for 13 Books. He received more than 50 International Awards.

ECSMGE 24
XVIII EUROPEAN CONFERENCE ON SOIL MECHANICS AND GEOTECHNICAL ENGINEERING

Keynote Lecture

On the interdependency between geotechnical and structural design

Sur l'interdépendance entre le dimensionnement géotechnique et le dimensionnement structurelle

M. Topolnicki*
Keller Polska Sp. z o.o., Gdańsk, Poland
**michal.topolnicki@keller.com*

ABSTRACT: Civil engineering structures are designed with consideration for the interaction between the structure and the ground. This interaction can be complex and is taken into account to varying degrees in the geotechnical and structural designs, which are interdependent. Demanding projects increasingly require the integration of geotechnical and structural design. However, current practice typically separates these two areas and assigns them to different design teams. Effective collaboration between geotechnical and structural engineers is therefore essential to optimise structural and geotechnical designs. A well-designed geotechnical solution, carefully selected to utilise a better foundation technique or alternative ground improvement system, can provide significant benefits. These benefits may include lower construction costs, shorter construction times, reduced CO_2 emissions, or the elimination of specific technical risks. Appropriate modifications to the structural design can also enable the implementation of a new geotechnical solution that may not have been feasible otherwise. This can result in similar advantages. The process of collaboration and arriving at final combined solutions using advanced design tools, as well as the benefits achieved, are illustrated and discussed through completed project examples. The selection of projects was based on the distinct responsibilities of geotechnical and structural engineers in developing the implemented foundation solution. Improved understanding between geotechnical and structural designers can be achieved through a better knowledge of each other's discipline.

RÉSUMÉ: Les ouvrages de génie civil sont conçus en tenant compte de l'interaction entre la structure et le sol. Cette interaction peut être complexe et est prise en compte à des degrés divers dans les conceptions géotechniques et structurelles, qui sont interdépendantes. Les projets exigeants nécessitent de plus en plus l'intégration de la conception géotechnique et structurelle. Cependant, la pratique actuelle sépare généralement ces deux domaines et les confie à des équipes de conception différentes. Une collaboration efficace entre les ingénieurs géotechniques et structurels est donc essentielle pour optimiser ces deux aspects. Une solution géotechnique bien conçue, soigneusement choisie pour utiliser une meilleure technique de fondation ou un système alternatif d'amélioration du sol, peut apporter des avantages significatifs. Il peut s'agir de coûts de construction moins élevés, de délais de construction plus courts, d'une réduction des émissions de CO_2 ou de l'élimination de risques techniques spécifiques. Des modifications appropriées de la conception structurelle peuvent également permettre la mise en œuvre d'une nouvelle solution géotechnique qui n'aurait pas été possible autrement, et des avantages similaires peuvent en résulter. Le processus de collaboration et l'élaboration de solutions combinées finales à l'aide d'outils de conception avancés, ainsi que les avantages obtenus, sont illustrés et discutés à l'aide d'exemples de projets réalisés. La sélection des projets a été basée sur les responsabilités distinctes des ingénieurs en géotechnique et en structure dans le développement de la solution de fondation mise en œuvre. Une meilleure compréhension entre les concepteurs géotechniques et structurels peut être obtenue grâce à une meilleure connaissance de la discipline de l'autre.

Keywords: Geotechnical design; structural design; foundation; optimisation; collaboration.

1 INTRODUCTION

From the perspective of 50 years, which happens to correspond to my professional career, I have witnessed the growing role of geotechnics in civil engineering. Although the foundations of structures have always been important, there have been and continue to be major changes in foundation engineering, triggered by new trends in construction and developments in geotechnics. We are building in ever more challenging conditions, for example in densely built-up areas, on very weak or degraded soils, and next to or even under

existing buildings. Structures are becoming more sophisticated and more daring and need to be built faster. New foundation techniques have been introduced, and those already in use have been significantly improved, opening up new possibilities that were not available before.

These changes have had a significant impact on structural and geotechnical design and have led to an increase in specialisation. In addition, the rapid development of engineering methods and the availability of advanced computational software have placed analyses, that not long ago required the work of large design teams, within the reach of small but professional practices.

My eminent teacher at university used to say that "civil engineering structures are not built in the air" to emphasise the point that structural design should not be carried out in isolation from geotechnical design. At present, the interdependence between structural and geotechnical design seems self-evident and the need for effective collaboration between engineers of both disciplines needs no justification. However, in day-to-day engineering practice, different situations arise which impact upon this ideal. The reality depends on the size and importance of the project, the risks involved, the staffing and capabilities of the smaller or larger design offices, and the applicable legal regime governing the whole construction process, the way investments are made, tenders and contracts are managed, works are insured and so on, which can vary even within the European Union. For these reasons, many readers of this paper will undoubtedly have their own experiences and opinions as to what this cooperation looks like in reality and whether it delivers the expected results. Such a broad picture would also be more objective than my limited experience. Nevertheless, this paper can be seen as an introduction to a broader discussion on this important topic.

The following sections present experiences and results of practical design collaboration between geotechnical engineers and structural engineers on challenging structures where the original foundation system had to be modified to meet the expectations of the clients and the general contractors responsible for the structural works. The selection of projects was based on the distinct responsibilities of geotechnical and structural engineers in developing the implemented foundation solution. The five selected examples include the following:

Case 1 – design of a modern sustainable office building, illustrating the involvement of a geotechnical engineer to optimise the foundation design in terms of construction cost and reduction of CO_2 emissions, subject to demanding verification and approval by the structural engineer;

Case 2 – geotechnical design for a large silo, developed in collaboration between geotechnical and structural engineers to find a better solution that reduced settlement and mitigated risk compared to the original foundation design, without increasing construction costs;

Case 3 – foundation design of a road bridge in very difficult conditions due to the presence of soft soils and groundwater under high artesian pressure, leading to the use of spread foundations on improved ground, which became possible after the bridge structure was modified by the structural engineer;

Case 4 – design of retaining systems for long and deep excavations for access ramps to an under-river tunnel, involving a major change in construction method, illustrating the geotechnical contractor's assumption of a leading role and design responsibility for these works and the tunnel designer's support in this regard;

Case 5 – design and execution of ground improvement works for the foundation of a football stadium by a geotechnical contractor in a situation where the structural design had not been completed, including the impact of late client led changes in relation to the stadium structure.

So, taking each case in turn.

2 CASE 1 - SUSTAINABLE OFFICE BUILDING

The building incorporates state-of-the-art technology for sustainable utility management and air quality control, including an anti-pandemic system, and has been awarded a BREEAM Excellent rating. With a height of 55m and a length of 120m, the building has a terraced layout and houses a two-storey underground car park with 218 spaces (Figure 1a).

The alternative foundation solution for this building, developed by a geotechnical contractor and ultimately adopted for construction, uses a perimeter diaphragm wall, CFA piles, and foundation slab as an integrated support system (Figure 1b). It represents a significantly optimised solution compared to the original design developed by the structural engineer, not only in terms of reducing the cost of the geotechnical works, but also in terms of reducing the carbon footprint. However, the client's agreement to implement the alternative solution was subject to the approval of the structural engineer. The structural engineer required a calculation to demonstrate that the optimised foundation system would not cause greater settlement than the original design and would meet the load bearing capacity requirements of the code.

In the subsoil, below the level of the foundation slab, the following soil layers with a slope of

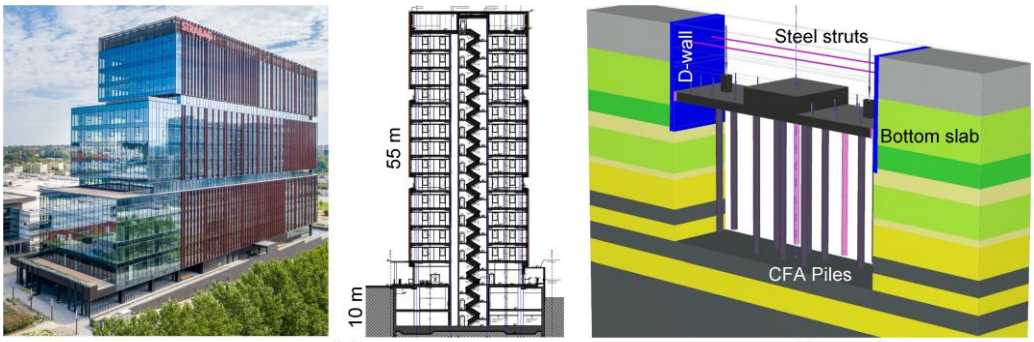

Figure 1. (a) Modern 13-storey office building (courtesy of Ghelamco); (b) The integrated foundation system consisting of perimeter diaphragm wall, CFA piles, and a bottom slab.

approximately 1:10 occur: organic silt, up to 3m thick, over a length of about 30% of the longitudinal cross-section of the building; medium sand, up to 3m thick, over a length of about 20%; sandy clay, 1 to 4m thick, over a length of about 50%; and below this, coarse sand, 4 to 7m thick, underlain by alternating layers of clay and sand. Groundwater is present at a depth of about 5m below the bottom of the excavation and poses no threat to the works. Under these ground conditions, the foundation of the heavy building required deep foundations and the support of the approximately 10m deep excavation with diaphragm walls and temporary struts.

The original foundation design included a 0.6m thick and 13 to 16.5m deep diaphragm wall around the entire 302.5m perimeter of the building, used as a shoring system to protect the excavation and as a permanent outer wall for the underground part of the building (Figure 2a). The foundation slab was supported by 186 CFA piles of 0.8m diameter and 21m average length, consisting of a 12m pile section below the bottom of the foundation slab and a 9m upper section, designed to carry 100% of the applied loading. The design assumed that the piles would be installed from ground level due to the dense pattern of cross struts in the excavation, which prevented the piling rig from working inside the pit. This required the upper part of the piles to be trimmed and the cutting debris to be removed.

The alternative solution was to combine the diaphragm wall, CFA piles, and foundation slab as bearing elements of an integrated support system. This allowed the number of piles to be reduced to 119 while increasing their length by 3 and 4m, shortening the diaphragm wall by an average of 2.5m and reducing the thickness of the foundation slab from 1.0 to 0.9m, locally, from the original 1.9 to 1.35m (Figure 2b).

It was crucial for the project that the geotechnical engineer carried out advanced calculations to confirm that the alternative solution could be implemented without compromising the design originally adopted by the structural engineer. For this task, two three-dimensional FEM models with generalised ground conditions were created in PLAXIS 3D to analyse 8.4m wide transverse sections S1 and S2 of the foundation slab (Figure 3a), which pass through heavily and moderately loaded parts of the building (Figure 2). The calculation results showed that the expected settlements of the foundation slab for the integrated support system were even lower than for the original design, which assumed that the full acting load would be carried by a relatively large number of piles, without considering the slab interaction (Figures 3b and 3c, respectively). The load-settlement curves of the CFA piles, both individually and in groups, were also carefully examined to verify the shaft and base resistances and to determine their ultimate load bearing capacity. Based on the positive results of these analyses, the alternative foundation design was subsequently approved by the structural engineer.

In order to optimise the thickness of the foundation slab and design its reinforcement, the geotechnical engineer developed a map of equivalent stiffnesses of the subsoil based on the calculated settlements and stresses under the slab in the two representative sections S1 and S2 (Figure 4a). As shown in Figure 4b, very similar settlements were obtained in the equivalent stiffness calculation, allowing the use of Autodesk ROBOT software to determine the final geometry and reinforcement of the foundation slab.

By implementing an optimised foundation solution for the building, developed by the geotechnical contractor, a significant reduction in the carbon footprint of the foundation works was also achieved. It is worth noting that the installation of the CFA piles, used an innovative solution to limit concreting to the effective length of the pile, further reducing the amount of concrete used on site. This involved the use of a bentonite slurry to ensure the stability of the borehole along the unconcreted length of the top of the pile as the auger was pulled out of the ground. A detailed summary of the carbon footprint reductions achieved is presented in Table 1.

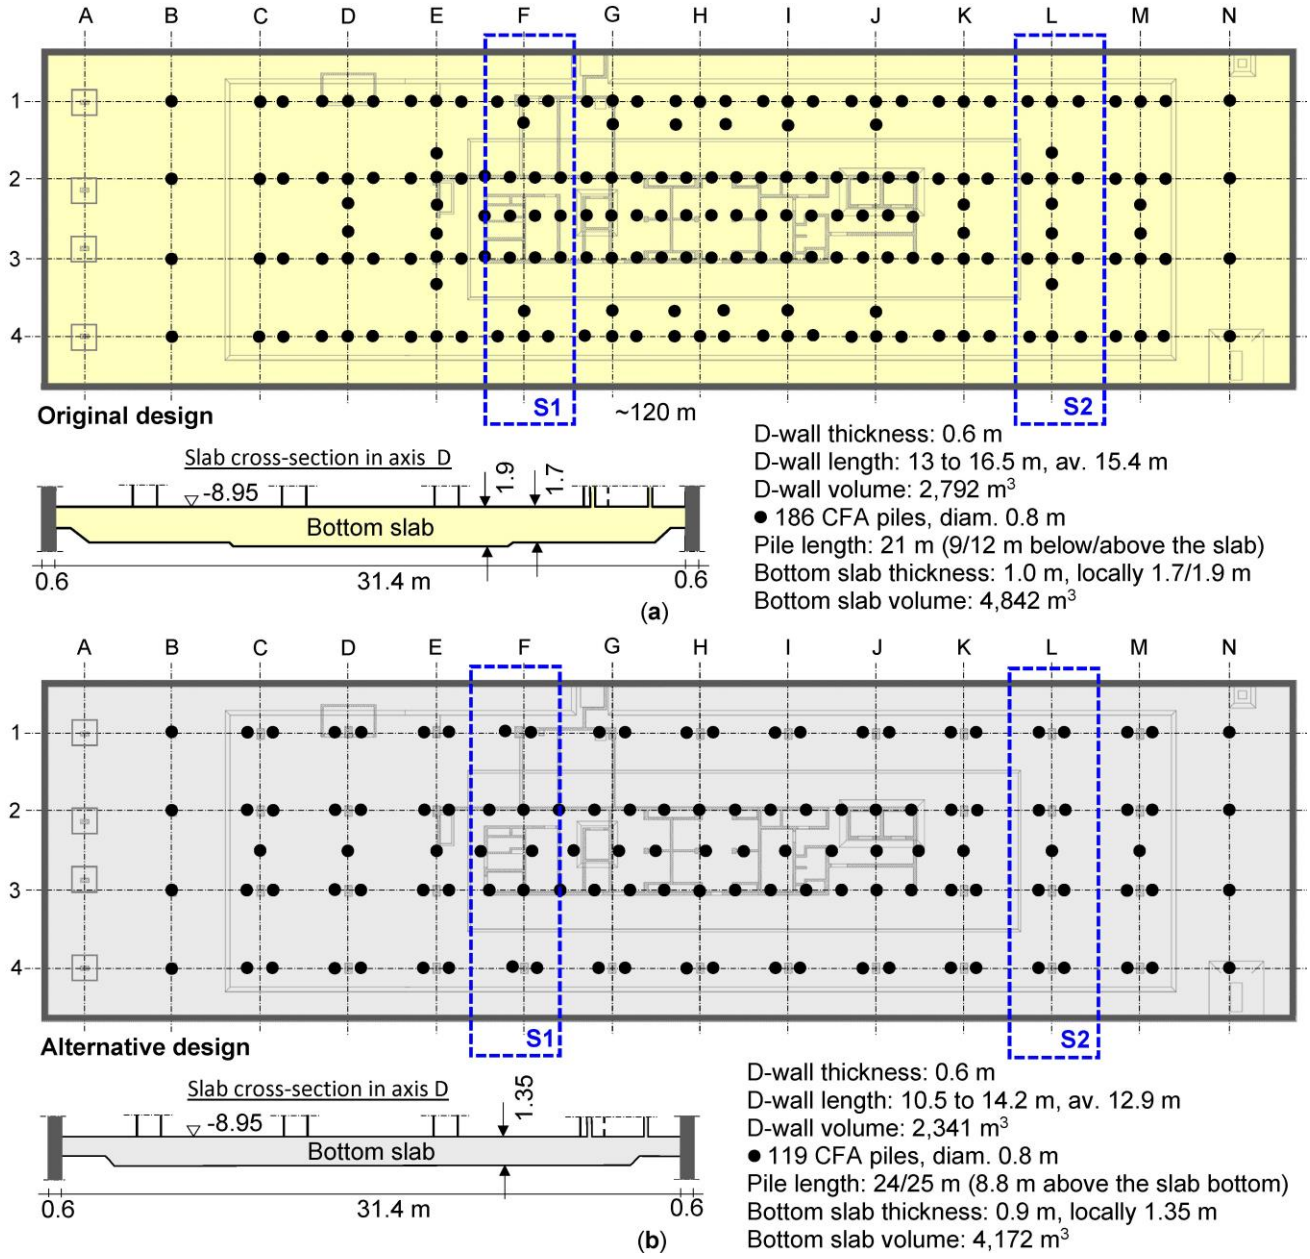

Figure 2. (a) Structural engineer's design with diaphragm wall around the perimeter and CFA piles taking the full applied load; (b) Geotechnical engineer's integrated design using perimeter diaphragm wall, CFA piles, and foundation slab.

Table 1. Concrete consumption and carbon footprint comparison of the two design solutions.

Element	Original design	Alternative design
Diaphragm wall:		
- concrete volume	2792 m^3	2341 m^3
- CO_2 emission	1300 ton	1100 ton
CFA piles:		
- concrete volume	1944 m^3	942 m^3
- CO_2 emission	748 ton	370 ton
Foundation slab:		
- concrete volume	4842 m^3	4172 m^3
- CO_2 emission	2400 ton	2100 ton
Sum CO_2 emission	4448 ton	3570 ton
Sum CO_2 emission in [%]	100%	80%

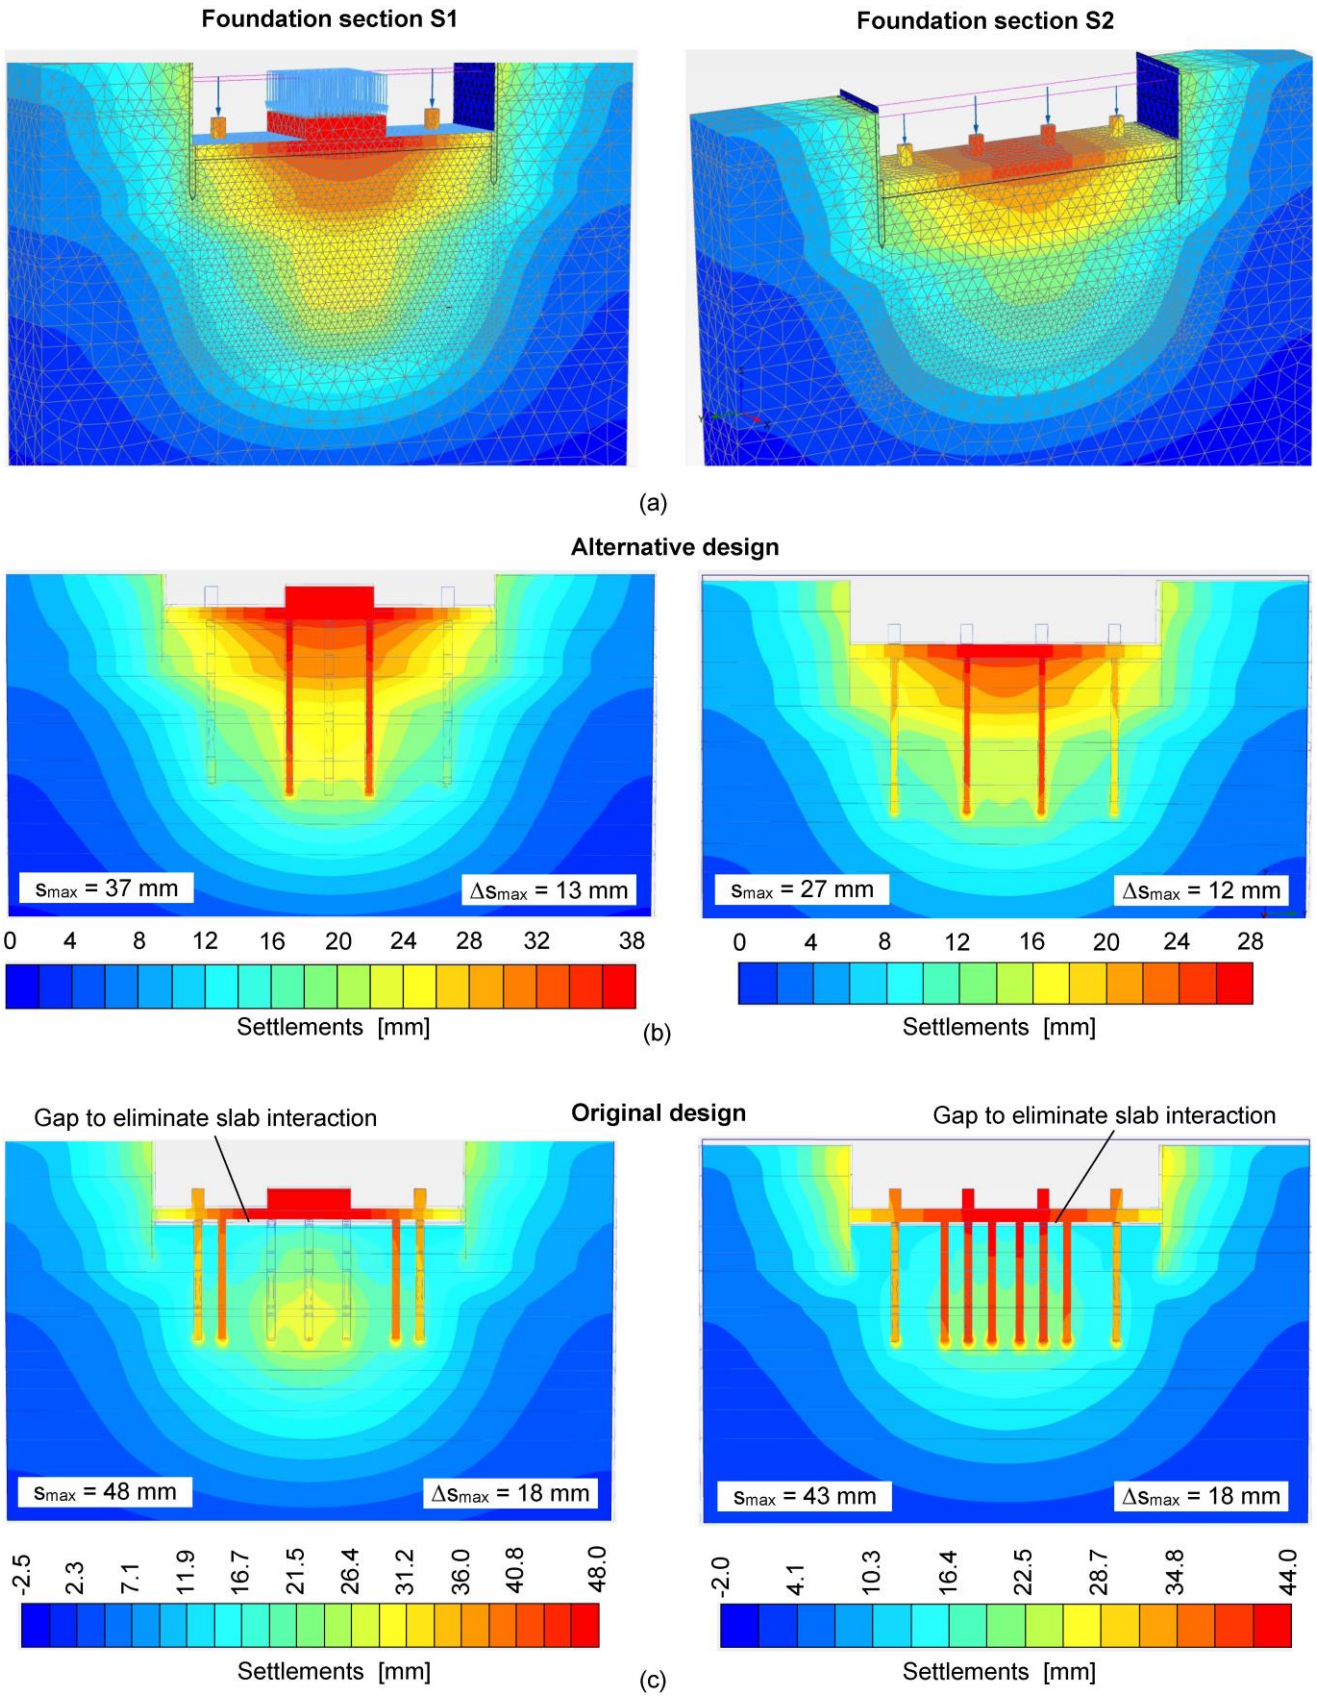

Figure 3. FEM analyses carried out by the geotechnical designer: (a) PLAXIS 3D models of heavily and moderately loaded foundation sections S1 and S2; (b) predicted settlements for the integrated foundation system, consisting of perimeter diaphragm wall, piles, and bottom slab; (c) settlements calculated for the original piling design without the load bearing contribution of the foundation slab.

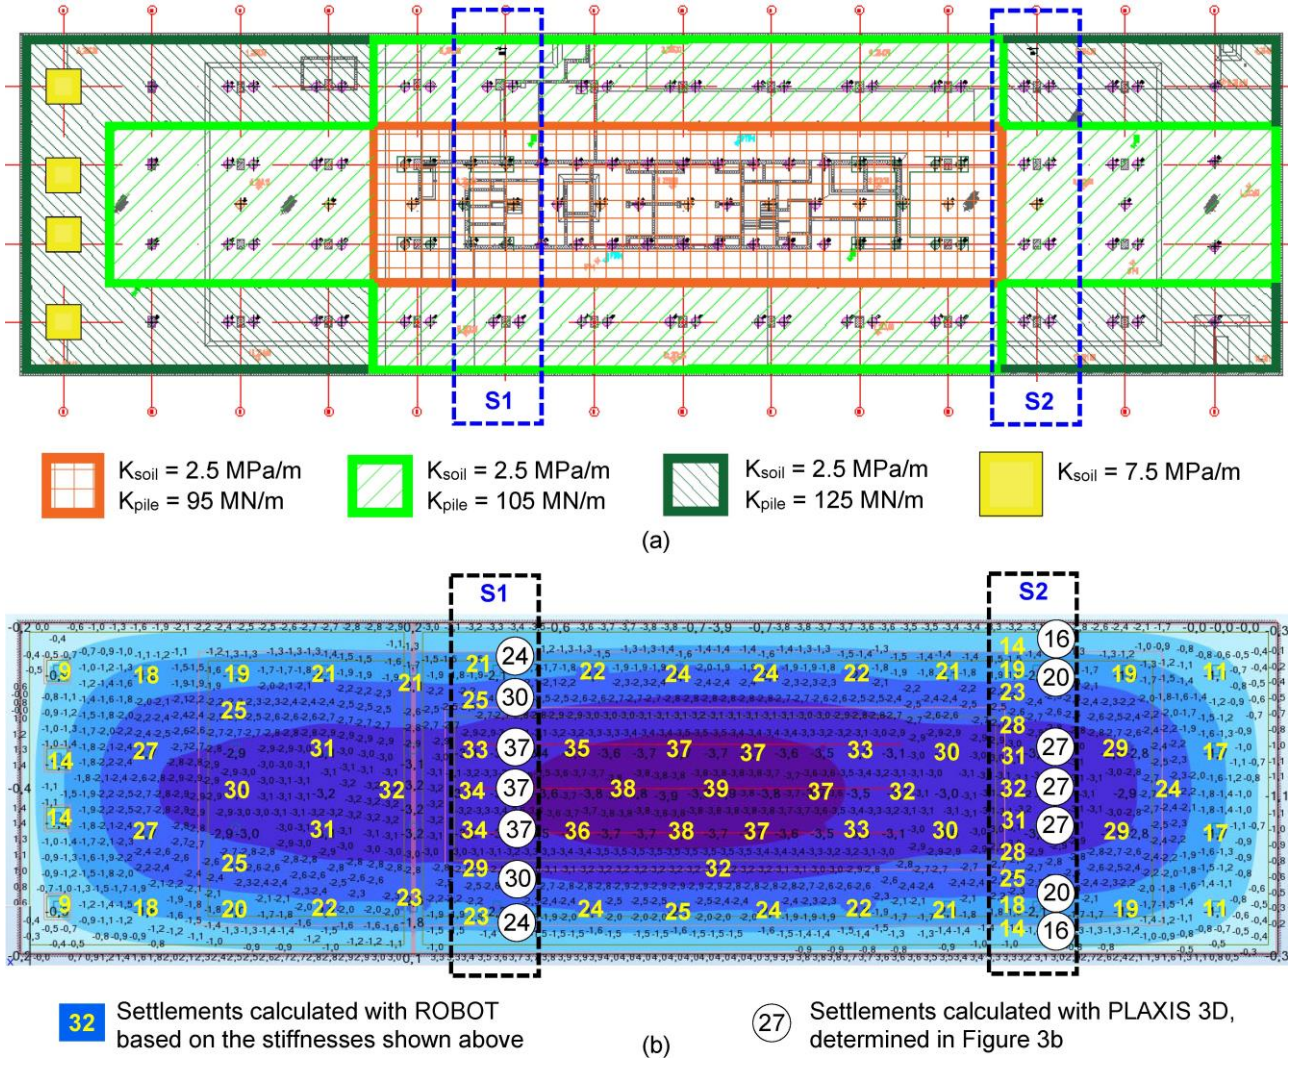

Figure 4. (a) Equivalent stiffness of the subsoil under the foundation slab; (b) Comparison of settlements determined by FEM calculations for sections S1 and S2 with settlements calculated using Autodesk ROBOT for the entire slab based on the equivalent stiffnesses shown in part (a).

3 CASE 2 - LARGE CLINKER SILO

This example illustrates the very close and effective collaboration between silo designers working on behalf of the client and engineers employed by the geotechnical contractor, which ultimately resulted in a very robust foundation support system being adopted.

The silo, with a capacity of approximately 120,000 tonnes of clinker, has a diameter of 55m and a total height of about 65m. The reinforced concrete walls rest on a ring foundation, initially 4.5m wide and 1.2m thick. At the bottom of the silo are three belt conveyor channels, 5.3m wide and 5m high. The relevant characteristic load combinations for the geotechnical design are cases A and B, as defined in Figure 5. The maximum bottom pressure inside the silo reaches 510kPa.

The ground conditions at the silo site are complex with a predominance of cohesive soils of varying thickness and consistency (Figure 6). Based on soil investigations, comprising borings and CPT and DMT tests, the following soil layers have been identified: 1 – a heterogeneous manmade fill with 1 to 3m thickness, 2 – medium dense ($q_c < 12.5$MPa) to dense ($q_c > 12.5$MPa) sands with thickness of 2 to 5m, 3 – sandy clay with soft ($q_c < 2$MPa) to stiff ($q_c = 2$ to 3MPa) consistency and thickness of about 2m, 4 – silt with soft ($q_c < 2$MPa) to hard ($q_c > 5$MPa) consistency and 4 to 5m thick, 5 – silty clay, stiff ($q_c = 2$ to 4MPa) and very stiff ($q_c = 4$ to 6MPa), with thickness of 2 to 10m, 6 – high plasticity clay, very stiff ($q_c = 4$ to 6MPa) and 4 to 6m thick, 7 – limestone rubble filled with sandy/silty clay, with $q_c = 4$ to 40MPa and thickness of 1 to 5m, 8 – limestone rock with a weathered upper zone that has some karst voids filled

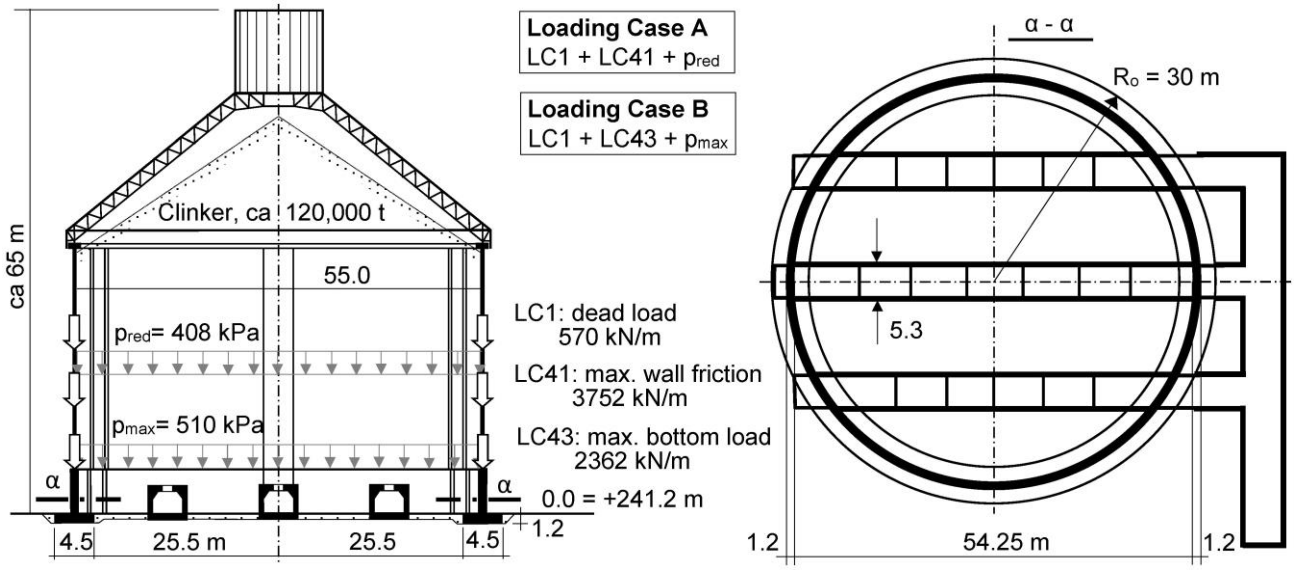

Figure 5. Basic geometry of the silo and two loading cases used for the geotechnical design (characteristic loads).

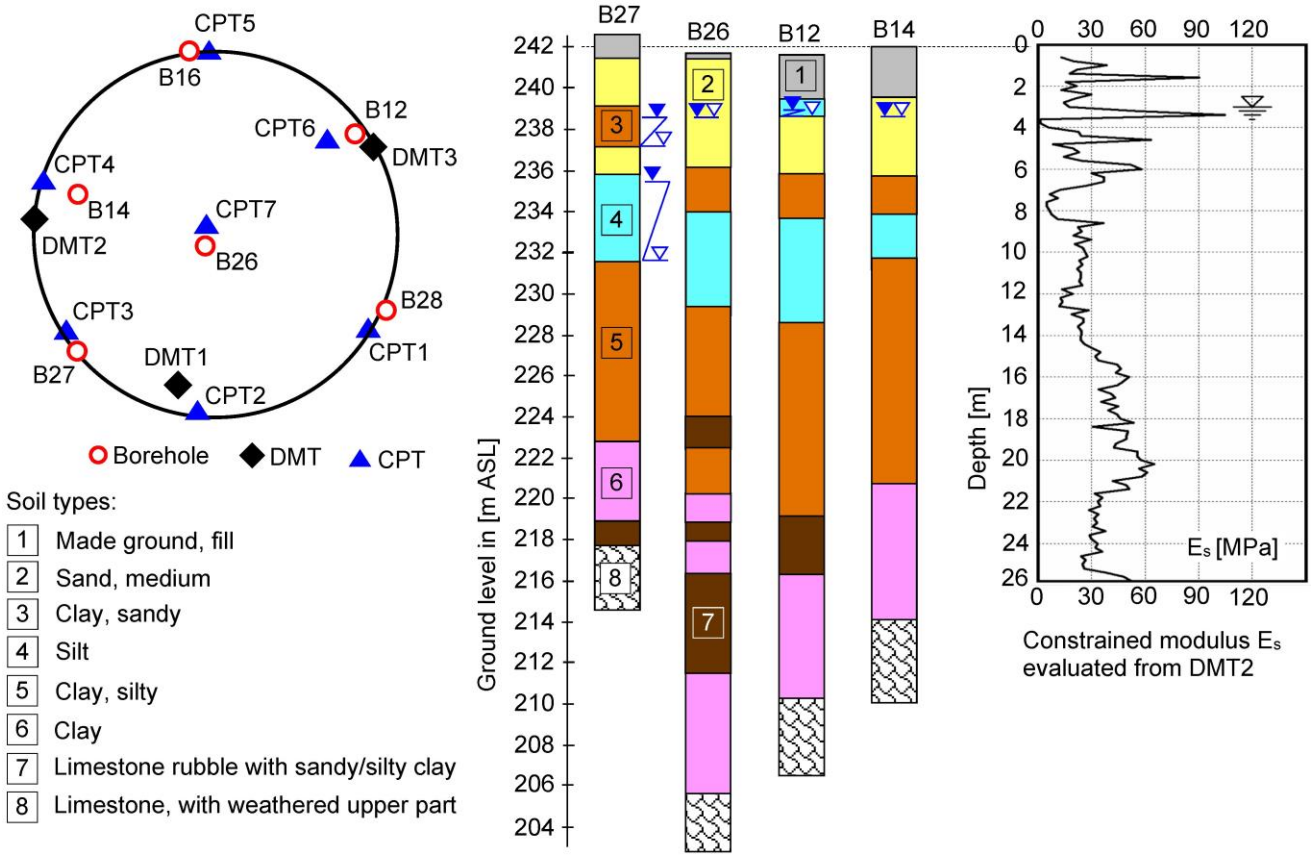

Figure 6. Location and sample results of soil investigations at the silo construction site.

with weathered materials, occurring at the depth of 24 to 35m below ground surface. The groundwater is approximately 3m below the surface.

Given the highly variable nature of the subsoil and the high loads, the first consideration was to support the silo ring foundation and the conveying channels on 180 and 76 CFA piles, respectively. These piles would be long enough to penetrate the limestone and carry the full applied load (Figure 7a). Although this solution was feasible in principle, it was difficult to accurately determine the pile length necessary to achieve the required bearing capacity and the safety margin required by the piling standard. In particular, there was uncertainty in determining the relevant strength parameters for the limestone rubble layer (7) and the weathered limestone rock (8). In addition, the much higher settlement of the silo floor compared to the ring foundation resulted in severe bending of the

piles and torsion of the ring, both of which could lead to overstressing of the piles.

These risks led the designers to consider the piled raft concept for the ring foundation and the use of gravel columns inside the silo (Figure 7b). The number of CFA piles was increased from 180 to 270 and their length was reduced to about 20m by embedding the pile bases in layers (5) and (6). By shortening the piles, the settlement of the ring foundation was increased, allowing the foundation to absorb part of the applied load. The upper zone of the soil immediately below the base of the ring, within a 6m wide perimeter strip, was to be additionally compacted to a depth of 2 to 3m. The gravel columns, 0.6m in diameter and up to 15m long, were introduced to improve the ground and equalise its stiffness within the silo floor, resulting in a reduction of total and differential settlements within the treatment zone. This solution was thoroughly checked by the structural engineer and the geotechnical engineer through independent analyses using 2D and 3D numerical models created in PLAXIS. These studies showed that with a calculated ring foundation settlement of 60 to 80mm, the piles would carry approximately 90% and the ring foundation base approximately 10% of the applied load. However, horizontal pile displacements of between 30 and 40mm and relatively large channel settlements of between 200 and 340mm were still predicted (Figure 8), making their design much more complex.

Taking into account the shortcomings of the two foundation solutions mentioned above, the geotechnical engineer proposed supporting the ring foundation and the conveying channels on 110 barrettes of 2.5×0.8m cross-section, constructed using slurry wall technology and a classic grab (Figure 9). The main arguments in favour of this solution were to increase the load bearing capacity of the supporting elements and to reduce their bending compared to the piles, thus reducing the torsion of the ring foundation. Preliminary calculations for this variant, carried out in PLAXIS 3D Foundation, for fixed barrettes with lengths of 22m below the ring foundation and 20m below the channels, showed promising results and improved the foundation system for the silo. After further consultation with the structural engineer, it was decided that the proposed solution was acceptable, provided that the length of the barrettes was more closely matched to the ground conditions to reduce possible differential settlements. On this basis, after additional SPT tests were carried out to more accurately determine the position and mechanical parameters of layers (7) and (8), the barrettes lengths shown in Figures 10a,b were finally adopted. Plane strain and three-dimensional FEM analyses (the latter for selected silo sectors with an opening angle of 15° to capture the influence of silo wall stiffness) showed that the expected settlements of the ring foundation were between 31 and 51mm (Figures 10b,c), which met the design requirements. The stiffer and less flexible barrettes carry almost the full applied load, and their horizontal displacement is about 10 times less than that of the piles (Figure 10d).

Additional plane strain FEM calculations were carried out to determine settlements of the conveying channels and to assess the increase in vertical stress acting on them due to the greater displacement of the ground relative to the channels supported on barrettes (Figures 11a,b,c). Only the critical loading case B was considered in these analyses. Two loading schemes, both involving a two-stage calculation sequence, were considered to estimate the upper and lower limits of the stress increase. In scheme 1, a uniform pressure of 510kPa was applied to the channels and to the silo floor at the foundation level (Figure 11d). This assumption implies that no friction on the vertical channel walls is taken into account. In scheme 2, the same pressure of 510kPa was applied throughout the silo floor at the level of the top of the channels, together with the assumption that the substitute 'soil' between the channels has zero volume weight and a high internal friction angle of 40 degrees (Figure 11e). This implies that the full friction on the vertical channel walls is included. The resulting channel displacements obtained for schemes 1 and 2 were then applied as the prescribed displacements in the second stage of both calculations. This procedure was repeated separately for each channel and the resulting vertical stress was determined. Based on these analyses, it was recommended that an increased channel load pressure of 10 to 15% be used for their structural design.

In summary, the risks associated with the foundation system were significantly reduced by the use of barrettes. A detailed comparison of the second and third foundation design concepts is shown in Table 2. The costs of both variants were the same. The successful operation of the silo has demonstrated that the chosen foundation system with barrettes has fulfilled its task.

Table 2. Comparison of two foundation design concepts.

Characteristics	Pile-raft and gravel columns	Barrettes
Settlement [mm]: - ring foundation - conv. channels	 60 to 80 200 to 340	 30 to 50 30 to 70
Horizontal displ. of ring supporting elements [mm]	pile 30 to 40	barrette 3 to 4
Duration of geot. works [days]	75	60
Foundation cost	same	
Width of ring foundation [m]	4.5	3.5 (260 m^3 less)

4 CASE 3 - ROAD BRIDGE

The bridge crosses a local road and a river valley. The valley is filled with Quaternary fluvial sediments in the form of peat and gyttjas, highly compressible and up to 11m thick, underlain by silty clays and silts of medium stiff to stiff consistency. Beneath are fine and medium sands, with medium to dense compaction. Shallow groundwater is locally present at depths of 0.5 to 1.5m, depending on river level fluctuations. The main aquifer is located in sandy soils at a depth of 15 to 25m. It is artesian and high flowing, with the water table stabilising at about 6m above ground level. Under these conditions, the geotechnical challenge was not only the low strength and deformation parameters of the organic and cohesive soils, but also the risk of possible uncontrolled artesian water outflows mobilised when penetrating through the confining soil layers.

Such situations actually happened in the past. In the early 1990's, during the drilling of a well about 1.2km from the bridge site, an intense flow of artesian groundwater occurred, washing away large amounts of fine soil. The surrounding area began to settle, threatening the stability of a neighbouring house. In another case, the collapse of a single-family house under construction some 25km away, but only 100m from the same river, was also reported as the result of a sinkhole that was triggered during well drilling (Damicz et al., 2007). Similar cases in different locations include bridge foundations and are therefore particularly relevant. Wojtasik and Różański (2011) describe a significant disruption caused by intensive seepage of artesian groundwater stabilised at 3.5m above the working level, resulting from the driving of 17m long precast concrete piles that penetrated the confining soil layers. The repairs caused a 6-month delay and the additional costs exceeded the planned cost of the foundation work. Świeca and Walczak (2007) reported hydraulic failure during the construction of bridge piers. In this case, loosening of the subsoil due to artesian outflow created a stability risk for the bridge's spread foundations.

The geometry of the bridge spans was dictated by the requirement to provide a passage for large wild animals under the structure, close to the river with a width of at least 100m, not including the river, and with a minimum 5m height. The design used at the tender stage was a three-span cable-stayed (extra-dosed) prestressed concrete bridge with spans of 60, 120 and 60m (Figure 12a). The bridge is 30m wide and has a pair of two-lane carriageways with emergency lanes on a 4m high single box structure. The deck structure is suspended from two 23m high V-shaped steel pylons. The abutments for the outer (ballast) spans are founded outside the marshy area. The approach embankments on either side of the bridge are approximately 9m high.

The bridge foundations are supported on precast concrete piles with a cross-section of 0.4×0.4m. The length of the piles is determined by the required bearing capacity and extends down to the bearing sands with artesian groundwater. The foundations are monolithic reinforced concrete slabs, 2.1 to 3.9m high, in the shape of an octagon inscribed in a 24.6×24.8m rectangle, which form the top of 133 piles under each pylon. The lengths of the piles are 30m and 33m. The foundations of the abutments are monolithic reinforced concrete slabs measuring 1.8×10.4×31m, each supported by 118 piles 14 to 17m long. To mitigate the risk of uncontrolled artesian water seepage, the designer recommended special precautions, including the installation of dewatering wells to reduce artesian water pressure and the use of special expansion seals consisting of bentonite tape fixed in grooves around the perimeter of the piles. It was also recommended that appropriate field tests be carried out prior to installation of the production piles.

The appointed general contractor was aware of the geotechnical challenges of the tender design and undertook extensive studies to find a less risky alternative. These studies eventually led to the design of a single-span tied-arch bridge with a span of 120m, shown in Figure 12b. The superstructure consists of two steel arches with lateral bracing. The deck acts as a tie beam and includes a reinforced concrete slab integrated with the steel deck. The suspension system consists of prestressed hangers arranged in a diagonal network. The frame structure of the western abutment accommodates the local road which passes underneath the new main road. Compared to the tender design, the structure of the single-span bridge is significantly

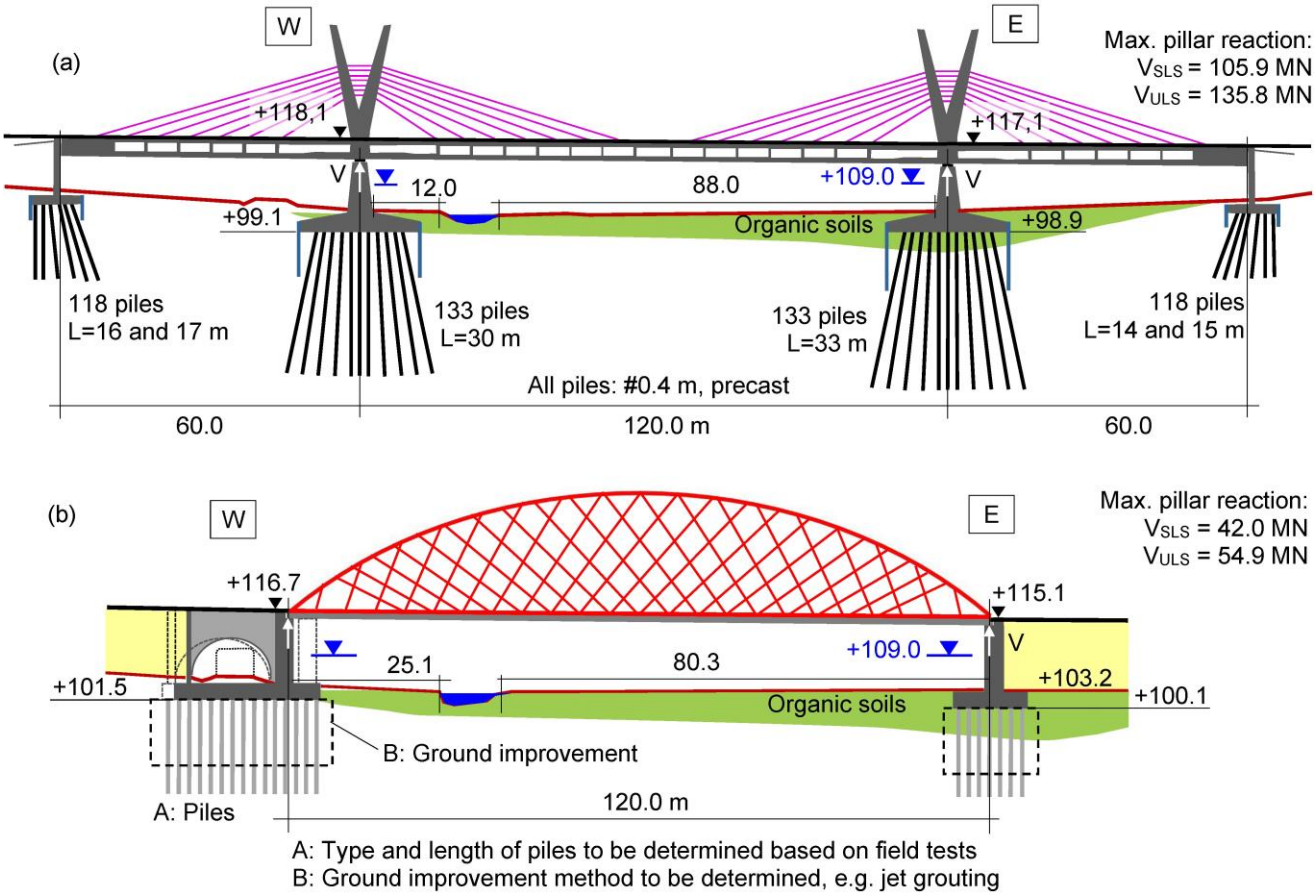

Figure 12. (a) Bridge design at tender stage, comprising a three-span extradosed structure; (b) Alternative bridge design proposed by the structural engineer working for the appointed general contractor, with two foundation concepts.

lighter, resulting in a 60% reduction in the maximum pillar reaction force, which was one of the main objectives of the alternative design (cf. Figures 12a,b).

Based on the advice of geotechnical experts, two foundation systems were considered for the arched bridge. These were the use of piles (option A) or spread foundations on improved ground (option B). In the case of piles, it was assumed that shorter piles would be used, which would not penetrate the water-bearing sands. It was recommended that field tests should be carried out with different types of piles to assess the load bearing capacity that could be achieved. Option B was considered to be the most rational method of foundation for the bridge abutments due to the relatively low ground pressures under the foundation slabs and the lack of interference with the artesian layer. The possibility of using jet grouting technology for the required ground improvement was raised, but no detailed design was subsequently developed.

At this stage, the appointed geotechnical contractor proposed the use of wet deep soil mixing (DSM) instead of jet grouting and prepared the design. The adopted ground improvement scheme included 2.4m diameter and 9.5m and 15m long DSM columns on the west and east sides, respectively (Figure 13). The design column lengths were chosen to ensure that a sufficiently thick layer of clay would remain beneath the ground improvement zone to prevent seepage of artesian water during the soil mixing operations. The design decision to leave a minimum distance of 2m from the sand layer was a difficult choice between mitigating potential hydraulic piping and leaving a layer of plastic clay that could be too thick, which would contribute to increased settlement of the abutments. Additional soil investigations were also recommended prior to column installation to map the actual thickness of the clayey deposits beneath both abutments, which were slightly displaced compared to the tender design. On the east side, organic soil replacement by dredging and high-pressure water jetting was also assumed to help achieve the required compressive strength of the soilmix material.

Two FEM models were created in PLAXIS for each side of the bridge, including the areas where ground improvement was required under the approach embankments. In this way, a coherent foundation system was designed for the entire structure. The

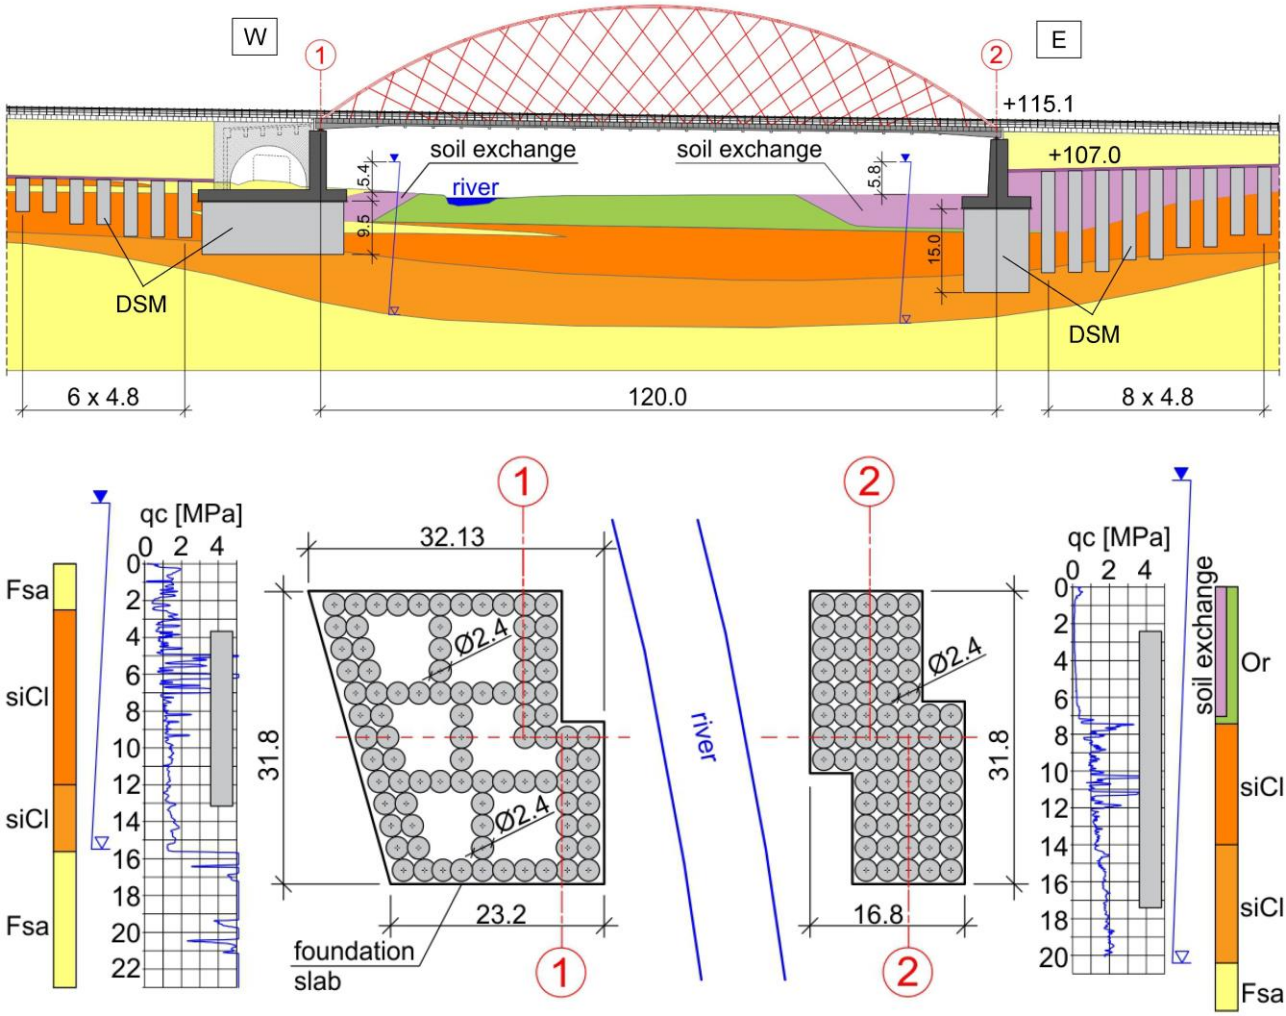

Figure 13. The geotechnical contractor's design for the arched bridge foundation using wet soil mixing (DSM).

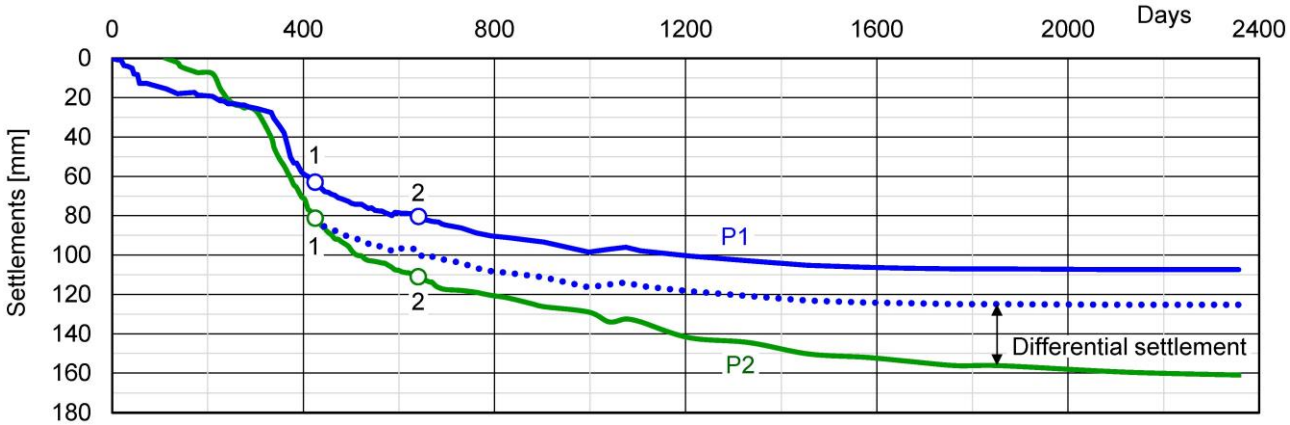

Figure 14. Observed mean settlement of the foundations of the western (P1) and eastern (P2) pillars: 1 - asphalt layers laid, earthworks completed; 2 - start of bridge operation.

calculations showed that for the most critical load combinations, the maximum design stress in the soilmix column was 804kPa, resulting in a required characteristic compressive strength of 1.42MPa. In order to provide a higher level of safety, a conservative 2MPa minimum and 3MPa average soilmix compressive strength was specified in the design. Monitoring of the bridge pillars over a period of almost six and a half years has shown that the foundation method used has met the design expectations (Figure 14). The differential settlement between the two pillars is less than 40mm and well within the design limit of 60mm.

This case illustrates a situation where a change in bridge type by the bridge designer to a lighter and less

settlement sensitive single-span structure enabled the geotechnical engineer to design and implement an innovative foundation solution for the bridge abutments that would not otherwise have been possible. To the best of the author's knowledge, this is the first time in Europe that a bridge of such a long span has been founded on improved ground using the deep wet soil mixing technique (Mitrosz and Skóra, 2021).

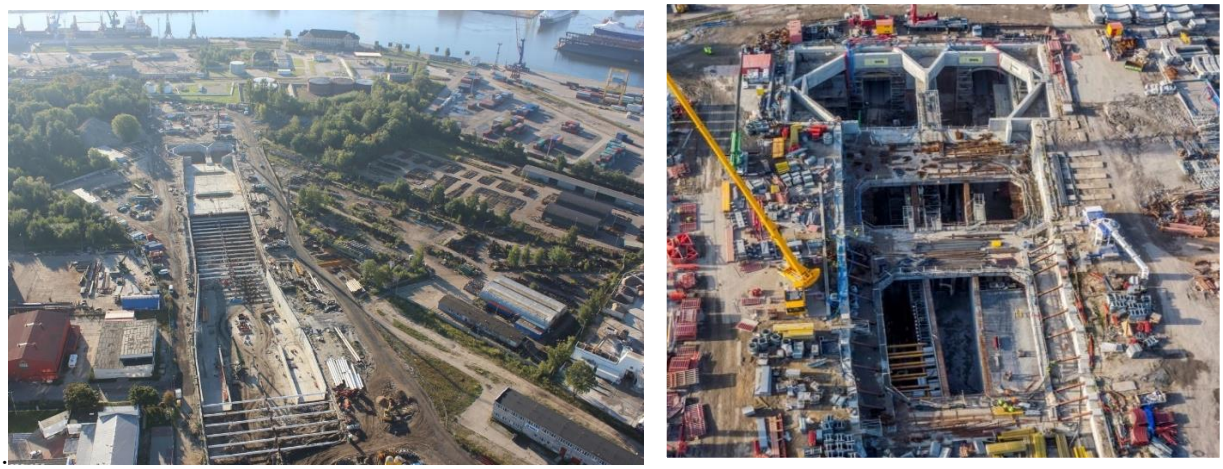
5 CASE 4 - EXCAVATIONS FOR TUNNEL ACCESS RAMPS

The project involved the construction of two large excavations for tunnel access ramps on either side of the river, 750m and 340m long on the west and east side respectively, and up to circa 22m deep (Figure 15). The ground comprised alternating marine and alluvial deposits of medium-dense to dense sands and soft organic silts to a depth of about 24m below ground level (GL), and then underlying silty clay and sand layers. The low-permeable silty clay layer could not be used as a natural cut-off barrier for the deepest parts of the pits because it would be unstable and heave during excavation. The groundwater in the area of the tunnel is mostly confined and stabilises at a depth of about 1m below the GL, corresponding to +0.5m above sea level (ASL). The tunnel structure had to be protected against a maximum water level of +2.5m ASL during normal operation, which represents the extreme flood level. During construction, two design water levels of +0.5m and +1.5m ASL were also used in the analyses.

The original design for the construction and protection of the excavations included permanent and temporary diaphragm walls and a 1.5m thick bottom plug anchored by micropiles, constructed using underwater concrete technology (Figure 16). In the deepest parts (cross-section C), a 1m thick jet grouted (soilcrete) sealing slab was planned below the pit bottom to facilitate initial lowering of the groundwater level for the installation of temporary struts required to ensure wall stability when the final excavation depth was reached. The challenges of delivering the works for this design included:

- the difficulty of removing soil from the excavation supported by closely spaced transverse struts (the same limitation applies to the lowering and lifting of large TBM components);
- the need to use heavy, long-reach excavation equipment working close to the pit edge, imposing high additional loads on the diaphragm walls;
- the need to install a water management system to fill and dewater the excavation and to construct settling ponds that take up working space;
- the accumulation of dusty sediments at the bottom of the pit, making underwater concreting difficult and risky, especially at greater depths;
- achieving a watertight joint between the concrete plug and the diaphragm wall;
- ensuring continuity of the underwater concrete over large areas of the excavation bottom;
- the difficulty of installing micropiles from floating pontoons or an auxiliary platform in long pits with closely spaced transverse struts mounted just above the water surface and to great depths, up to circa 54m;
- the long duration of the associated works.

Based on its own design analyses, the geotechnical contractor proposed to move from working underwater to a dry operation to cut construction time, mitigate risks, and reduce costs. The alternative design included



(a) *(b)*

Figure 15. (a) Construction of the west access ramp to the under-river tunnel; (b) TBM launching shaft on the east side.

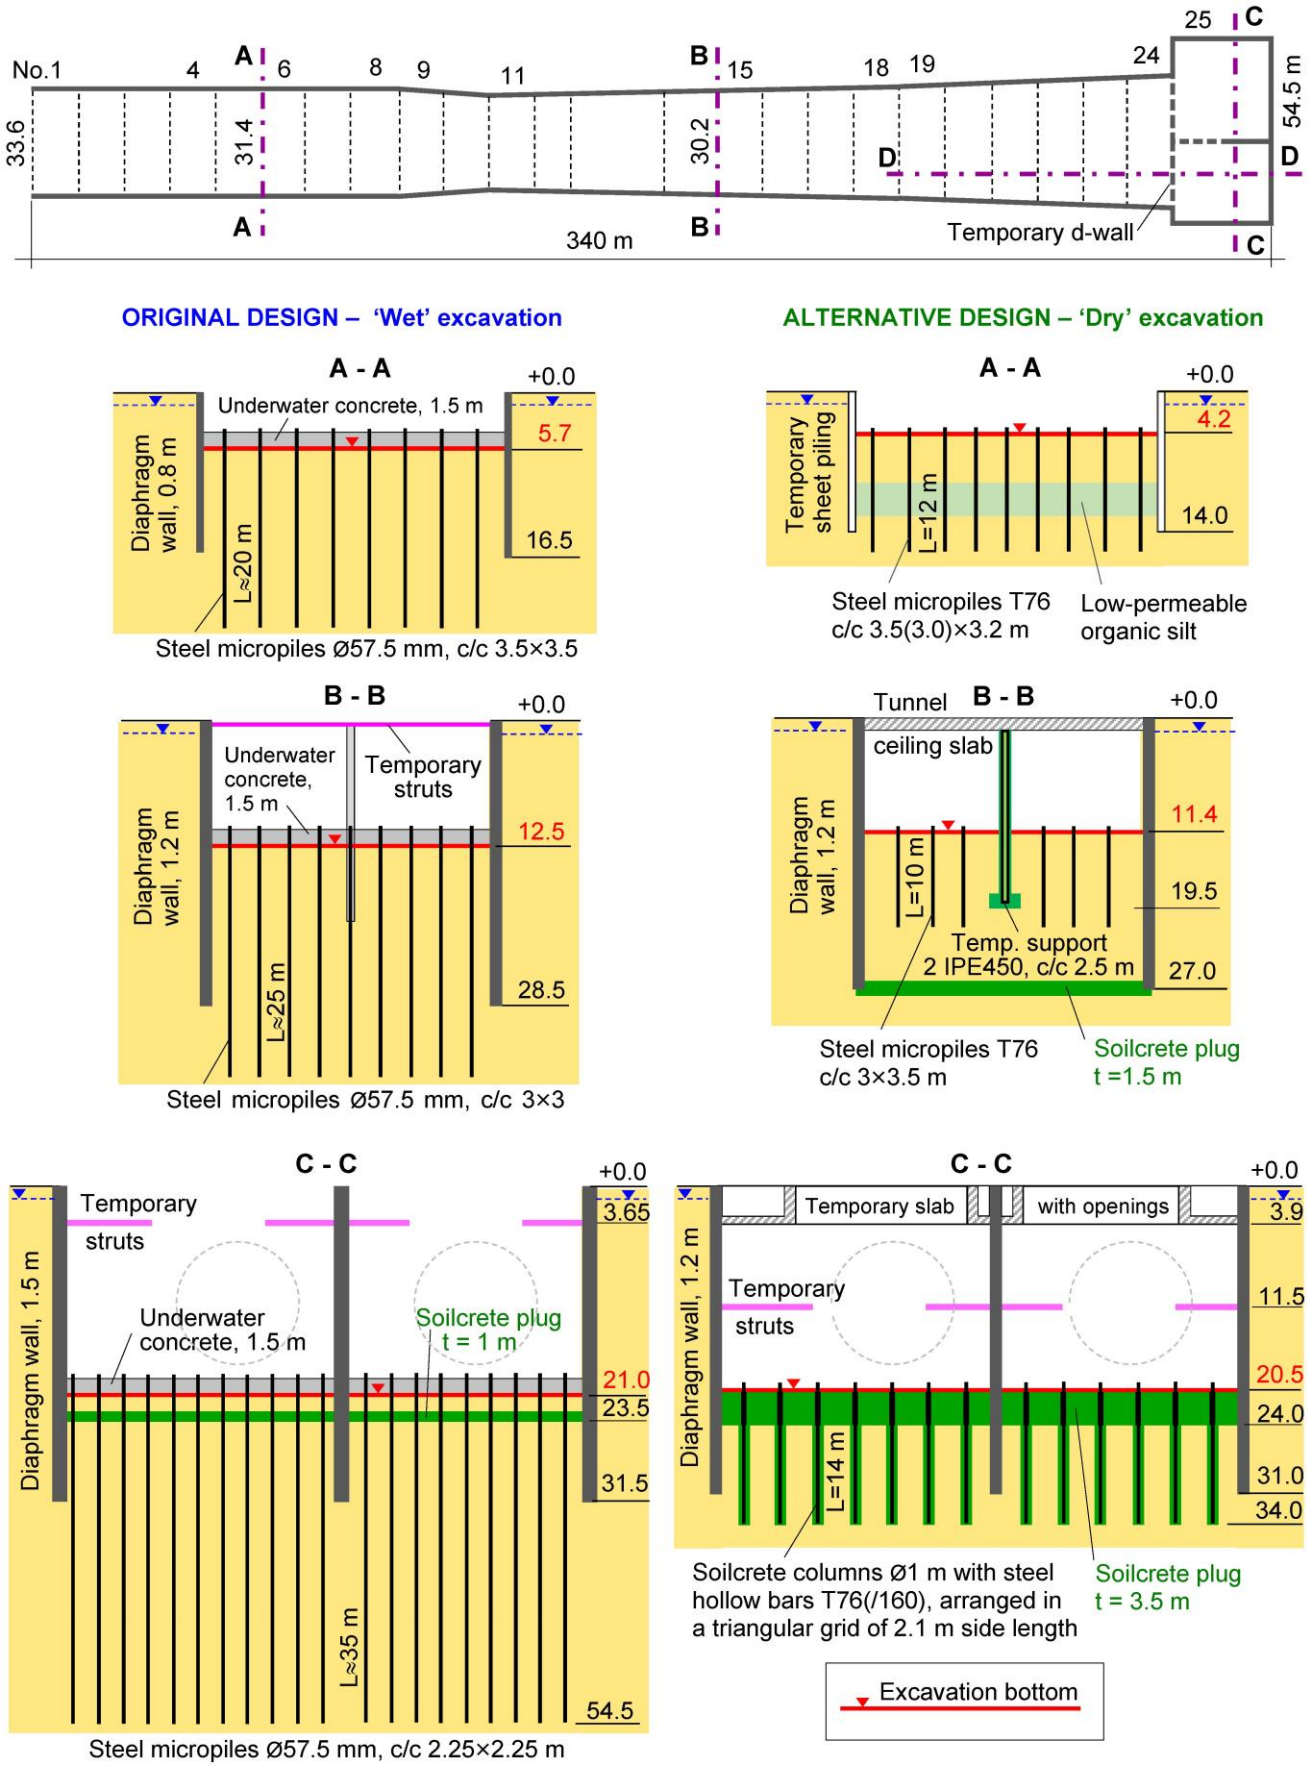


Figure 16. Comparison of the original design assuming 'wet' excavation with the geotechnical contractor's alternative design assuming 'dry' excavation for three cross-sections on the east side.

three main solutions, which are shown in Figure 16 in comparison with the original design.

For the shallow excavation areas, represented by cross-section A, conventional temporary sheet piling was selected as the most economical shoring system. The sheet piling crosses the low permeable organic silt layer, which forms a natural sealing barrier. The uplift resistance of the concrete slab at the bottom was provided by micropiles consisting of 76mm diameter hollow steel bars.

In the central parts of the excavations, represented by cross-section B, a 1 to 1.5m thick soilcrete plug, depending on the actual excavation depth, was designed to create a horizontal cut-off barrier between the walls. The plug is placed at a depth that ensures its stability against uplift by the dead weight of the overlying soil. These sections also include an anchored foundation slab with relatively short steel micropiles.

As the ramps near the TBM launching and receiving shafts, the construction method changes again to include a thicker soilcrete plug just below the foundation slab which is anchored into the soilcrete columns using hollow steel bars (cross-section C). The anchoring bars were installed centrally in 1m diameter soilcrete columns, constructed as part of a single production cycle together with the plug columns that were 3.1m in diameter and 3 or 3.5m in length (Figure 17a). Along the plug section the steel bar diameter was increased to 160mm with factory grouted corrugated sheathing. The anchoring elements were positioned in a grid of equilateral triangles with a c/c spacing of 2.1m or 2.25m, adapted to the basic arrangement of the columns forming the horizontal plug. Due to simultaneous execution of the anchoring elements and plug columns, the monolithic connections between the two elements were improved and thus the required rigidness and water tightness of the whole system protecting the excavation bottom was ensured.

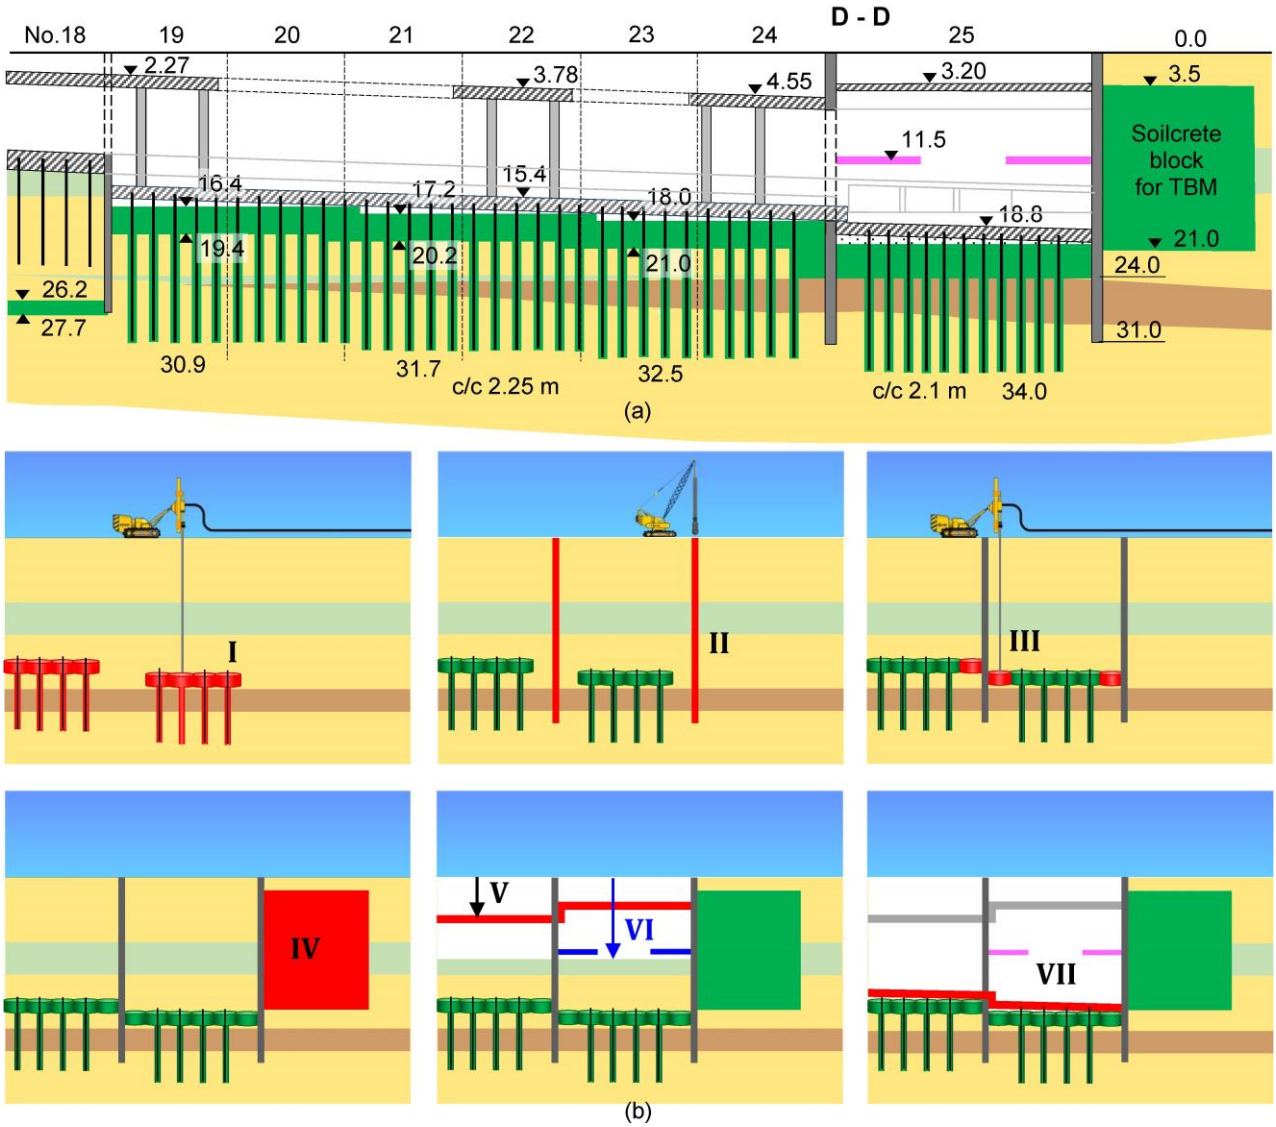

Figure 17. (a) Longitudinal section through the deepest parts of the east tunnel ramp; (b) Phasing of construction works.

The thickness and length of the diaphragm walls were also optimised. Particular attention was paid to the impact of phasing the work, including (Figure 17b):

Phase I – Execution of 1m diameter soilcrete columns, over-reamed at the top to 3.1m diameter to form a sealing plug, leaving an open strip along the planned diaphragm walls, followed by installation of anchoring bars in fresh soilcrete, disconnecting at specified depths and pulling top bar sections;

Phase II – Construction of permanent and temporary diaphragm walls, allowing simultaneous work on several phases;

Phase III – Installation of soilcrete plug columns along diaphragm walls to complete horizontal sealing.

Phase IV – Construction of soilcrete blocks in front of the launching and receiving shafts, stabilising the TBM at the start and end of the shield drilling operation;

Phase V – Primary excavation and construction of a reinforced concrete top slab with openings;

Phase VI – Continuation of excavation to the required depth allowing installation of temporary steel struts inside the launching and receiving shafts;

Phase VII – Final excavation and construction of the bottom slabs, anchored to steel micropiles, followed by dismantling of the temporary struts.

The alternative design helped to make the works much safer and more controllable and was approved for implementation by the tunnel designer and the public client. The geotechnical contractor took the lead and design responsibility for this part of the tunnel works. All designs were checked using different numerical models, as shown in Figure 18a, and the displacements expected from each approach were similar, giving confidence in the solution adopted. Collaboration with the tunnel designers was very efficient and enabled expectations to be met. For example, the structural engineers designed sophisticated concrete slabs with large openings for the launching and receiving shafts, which contributed significantly to limiting wall displacements while allowing convenient excavation and assembly/disassembly of the TBM (Figure 18b).

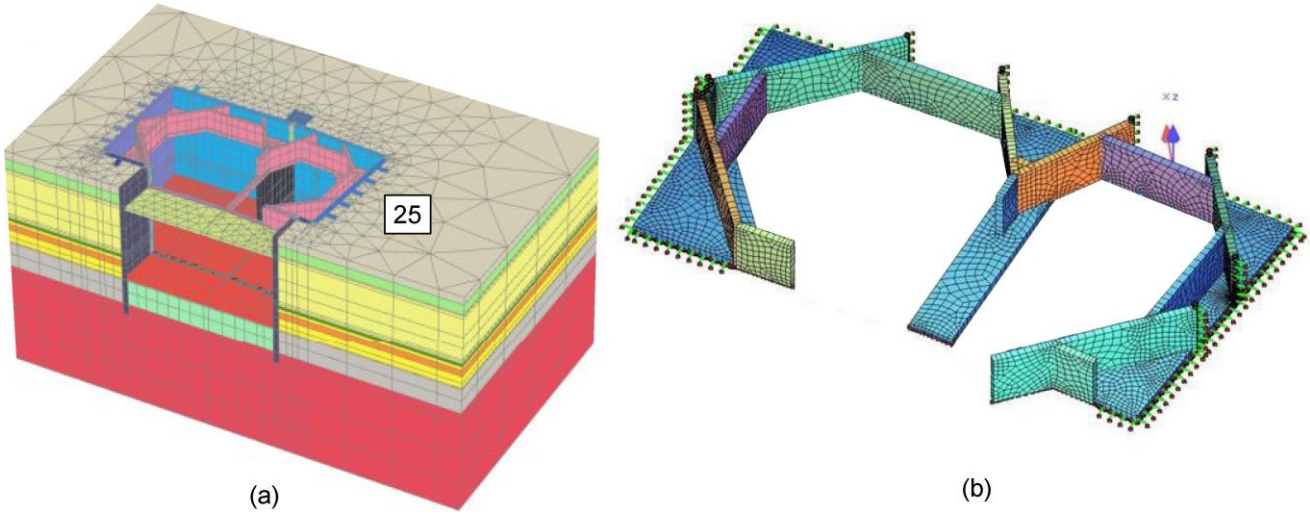

Figure 18. (a) Numerical model of the launching shaft in PLAXIS 3D; (b) Structural engineer's design of the supporting concrete slab at the top of the launching shaft.

6 CASE 5 - FOOTBALL STADIUM

The construction of a stadium for the European Football Championships, which was carried out under great time pressure and therefore split into two separate phases of (1) site preparation and ground improvement and (2) stadium construction, is an example of insufficient co-operation between different contractors and design teams, resulting in the implementation of ad hoc measures to limit potential adverse impacts.

A view of the 41,620-seat stadium, which has an elliptical shape and dimensions of 236×203×45m, is shown in Figure 19a. The architectural concept and initial structural design raised the stadium above the flat, waterlogged site. It was assumed that about 60% of the stadium foundations, supporting the north, east and south stands (Figure 19b), would be founded on a ring embankment approximately 8m high from the original ground level and 55 to 65m wide at the base (Figure 19c). In the western section, the structure of the stands and stadium facilities is supported on a slab and footings founded at various depths, between 2.5 and 4.5m below groundwater level. The roof of the stadium is supported by 82 truss girders spaced 8m apart, transferring a vertical load of approximately 1,800kN and a horizontal load of approximately 700kN to the foundations.

Figure 19. (a) Completed stadium; (b) initial layout of pad and slab foundations; (c) Stadium cross-section in W- E direction; (d) ground conditions (example CPT profile); (e, f) Calculated distribution of vertical strains in the subsoil.

The construction site was a flat former estuary, crossed by numerous drainage ditches, with groundwater at a depth of about 0.4m. At the surface there were organic soils from 1 to about 5.5m thick, underlain by fine and medium sands of varying density and thickness of about 18 to 22m, containing lenses of organic silt. Beneath the sands was a layer of clay from 1.5 to 6m thick, underlain by medium sands and gravels and, at a depth of 32m, also lignite. An example of a CPT sounding is shown in Figure 19d.

The first phase of work consisted of replacing the organic soils with natural aggregate and compacting the backfill and soil beneath the replacement zone. The contract was awarded to a general earthworks contractor who engaged a geotechnical contractor to carry out the deep compaction work. The planned volume of soil replacement to be carried out using conventional excavators and without lowering the groundwater level was about 324,000m^3, the volume of backfill to the working level at +1m ASL was approximately 412,000m^3, and the volume of soil to be treated by vibro compaction (VC) to a depth of 15m below the ring embankment and 10m below the pitch was about 1.27 million m^3.

At this stage of the design, the structure of the stadium was only known in outline. For this reason, the structural designers formulated only general criteria for the required ground improvement, which was to meet the condition of a CPT tip resistance of at least 15MPa within the compacted zone. It was assumed that the foundation pressures would not exceed 300kPa, and that the total and differential settlements of adjacent footings should be limited to values of 30 and 10mm respectively. It was also assumed that the entire ring embankment would be constructed first, and that the consolidation period of the subsoil prior to the construction of the stadium foundations would be between 4 and 6 months. In the area of the western stand, the plan was to remove part of the embankment after the preloading phase, while maintaining safe slopes, and then to construct the deeper foundations by locally lowering the ground-water table.

A detailed ground improvement design was prepared by the geotechnical contractor. The calculations carried out to verify the settlement of the embankment and the stadium foundations showed that the design assumptions could be met by adhering to the planned consolidation period of the subsoil under the embankment, even taking into account the settlement mobilised in the clay layer below the improvement zone (Figures 19e and f).

However, soil compaction using deep vibrators in a triangular grid of 3m proved more difficult than expected. The reason for the unsatisfactory compaction within the soil replacement zone and immediately below, as shown in Figure 20a, was: an excessive content of fine fractions within the backfill, caused by inaccurate excavation carried out in continuous 24h/7d operation; the low quality of the backfill material, which was difficult to obtain in large quantities, and in a short time; and the decreasing efficiency of the VC process at shallow depths. Attempts to reduce the spacing between compaction points and to use more powerful vibrators were also unsuccessful. Under these conditions, the geotechnical contractor added dynamic compaction (DC), carried out from an elevated working level at +2m ASL, with the aim of compacting the soil to a depth of -4 m BSL. Sixteen tonne pounders with a 2×2m base were used, dropped from a height of 19m for the primary and secondary compaction points, arranged in a 7.5×7.5m square grid, and from a height of 10m for the final ironing phase, carried out at intermediate points. The average compaction energy was 550kJ/m^3, and the average aggregate consumption was 6 to 8m^3/point. The use of DC proved to be very successful, as confirmed by the results of the control CPTs shown in Figure 20a. The first phase of work was completed with the handover of the ground prepared for further construction works, and the site levelled and compacted by vibratory rollers at +1m ASL.

For the geotechnical contractor responsible for the ground improvement, the task seemed to be complete. However, this was not quite the case, as the design team undertaking the second phase of work introduced significant changes to the stadium structure that were accepted by the investor. In order to shorten construction time and reduce costs, parts of the ring embankment under the north, east and south stands were replaced by a single-storey reinforced concrete structure (Figure 20b), and on the east side, outside the stands, the embankment was replaced by a new facility providing additional rental space (Figure 20c). As a result, the structure was planned to be built first, with the remaining embankment sections around the perimeter of the stadium built at the end of the works. This also meant that the original plan to consolidate the subsoil under the weight of the ring embankments prior to stadium construction had to be abandoned.

The decisions described were made without consulting the geotechnical contractor. It was assumed that the bearing capacity of the improved ground would be sufficient because the reduced total weight of the structure would result in lower foundation pressures than originally anticipated. However, subsequent check analyses carried out (this time) with the involvement of the ground improvement designers revealed that once the target embankment was in place, and without the planned consolidation of the subsoil,

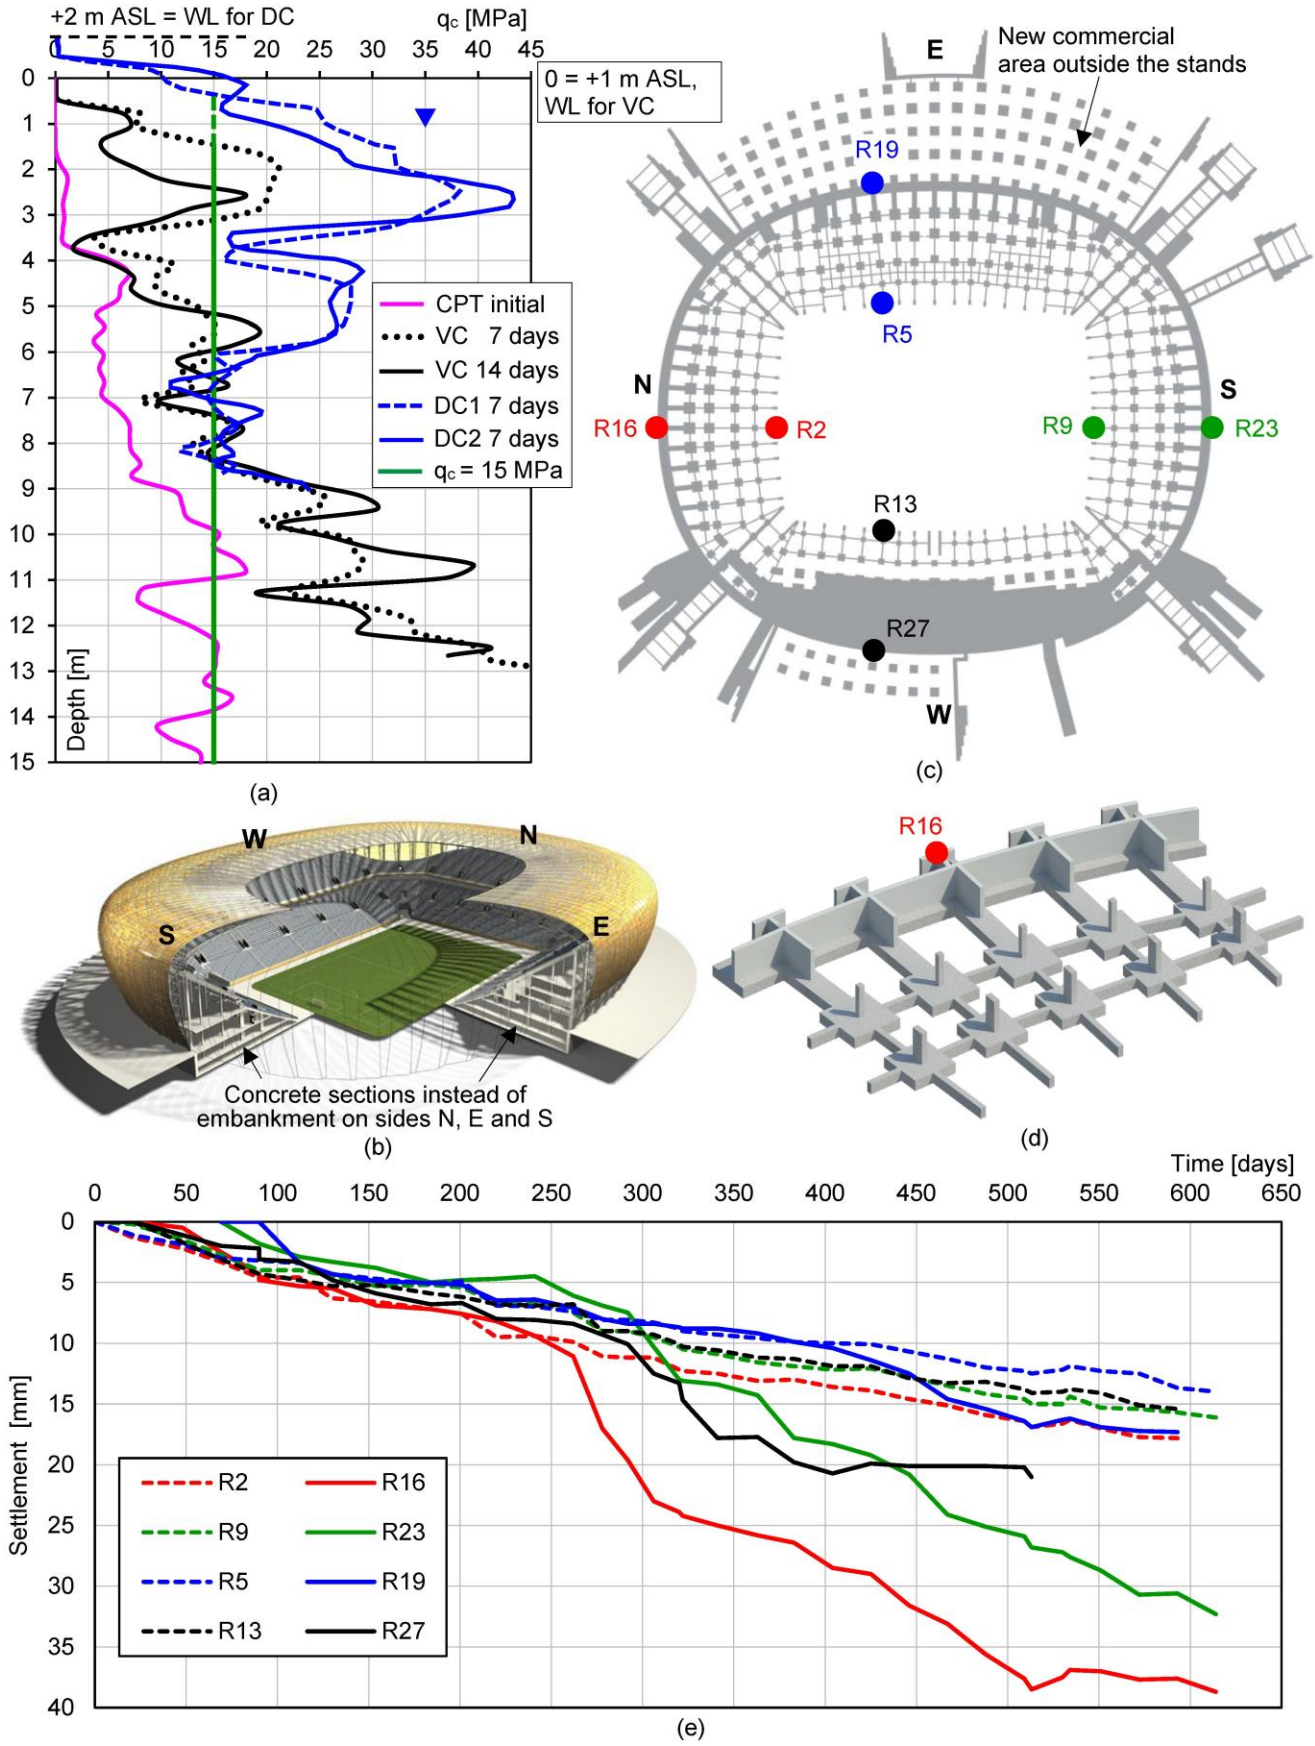

Figure 20. (a) Initial and control CPT tests in relation to the acceptance criterion (VC - Vibro Compaction, DC - Dynamic Compaction); (b) Location of selected control survey points; (c) Modified stadium structure, with concrete sections instead of the embankment; (d) Foundation pads with interconnecting beams; (e) Observed settlement at selected survey points.

there was a risk of excessive differential settlement of the footings and bending of the perimeter foundation supporting the roof truss girders. A stiffening of the entire foundation system was therefore recommended and implemented, consisting of reinforced concrete beams connecting the individual footings, and transverse walls in the plane of the truss girders along the perimeter strip foundation (Figure 20d).

The described intervention in the design of the foundations was essentially the only action that could be taken due to the timing of the construction work that had already begun. The stiffening of the foundation system proved to be necessary and effective, as confirmed by the settlements measured at the survey points shown in Figure 20c. By comparing the settlements on the north (point R16) and south (R23) sides, where the embankment was constructed, with those on the west (R27) and east (R19) sides, where there was no embankment, the impact of the embankment construction on the foundation settlement can be assessed, causing additional displacement of the order of 20mm. The maximum settlement recorded was approximately 38mm, slightly above the design limit, but the differential settlements between adjacent foundations were not exceeded. This case study illustrates that the separation of construction and design into two phases, with the geotechnical part separated from the structural part, carries the risk of overlooking important design assumptions which, if not addressed, could have led to undesirable and serious deformations in the structure and the potential need for significant remedial work.

7 CONCLUSIONS

An attempt has been made to illustrate the relationship between geotechnical and structural design using examples from five projects involving different structures and cases of collaboration between engineers from both disciplines. The projects discussed were carried out in Poland, taking into account national building regulations and practices. They include foundation designs adapted to the soil and groundwater conditions and to the sensitivity of the structures to deformation. An important criterion for the selection of projects was also the consideration of the changing role of structural and geotechnical engineers and their responsibility for the final foundation solution. Detailed comparisons of the original and implemented foundation designs show the benefits achieved. These included not only lower construction costs and shorter construction times, but also reduced CO_2 emissions and the elimination of specific technical risks. Appropriate modifications to the structural design of a bridge also enabled the implementation of a novel foundation solution that would not otherwise have been possible.

The practice of civil engineering design has become increasingly specialised. This includes foundation design and has been driven by the observed and continuous development of foundation techniques and execution capabilities, as well as the use of specialised engineering software for geotechnical design. Experience has also played an important role, as geotechnics is known to be both a science and an art. In this context, geotechnical engineers are usually better prepared than general structural engineers to select the most appropriate foundation solution, taking into account various design criteria. It is therefore becoming increasingly important for the two disciplines to work together. To enable effective collaboration, it is advisable for geotechnical engineers to develop their professional skills in structural design. Similarly, structural engineers should improve their geotechnical knowledge. A better mutual understanding between the two disciplines will help to achieve beneficial results in the future, comparable to the examples presented.

ABSTRACT: The earthquakes that occurred in Pazarcık and Ekinözü-Kahramanmaraş on February 6, 2023, had a profound impact southeastern Türkiye and northwestern Syria. With moment magnitudes of M7.8 and M7.6, these earthquakes, ruptured multiple fault segments within a span of 9 hours, presenting an unexpected scenario for seismic hazard assessments. During the Pazarcık event, the peak ground acceleration levels, corresponding to DD-1 (with a 2475-year return period) and DD-2 (with a 475-year return period) design levels as defined in the Turkish Building Earthquake Code, were exceeded at 5 and 22 strong ground motion stations, respectively. Ground motion prediction equations (GMPEs) underpredicted the recorded PGA levels at stations within 70 km from the fault rupture, particularly for the Pazarcık earthquake. Seismic soil liquefaction emerged as a significant geohazard, notably observed in Gölbaşı-Adıyaman and İskenderun-Hatay regions. The significant shaking triggered more than 3,000 landslides and rock falls, resulting in casualties. Damage to infrastructure was substantial, with 7 bridges sustaining significant damage, two of which were attributed to the liquefaction of foundation soils. Lifelines suffered significant damage due to fault rupture, liquefaction, and permanent ground deformations. Similarly, port facilities in İskenderun reported severe damage due to liquefaction and post-earthquake fires. Although all 140 dams in the influence region preserved their water retention capabilities, the reservoir levels at two of them had to be lowered as part of emergency response actions. While there was a partial collapse in a stone-paved railway tunnel serving the Gölbaşı-Malatya line, no major damage was reported at tunnel structures. Retaining structures, predominantly stone walls, incurred damages, whereas reinforced earth walls displayed greater resilience. The collapse or heavy damage to over 650,000 residential units was the major cause of over 55,000 casualties.

RÉSUMÉ: Les tremblements de terre qui ont eu lieu à Pazarcık et Ekinözü-Kahramanmaraş le 6 février 2023 ont eu un impact profond sur le sud-est de la Turquie et le nord-ouest de la Syrie. Avec des magnitudes de moment de M7.8 et M7.6, ces tremblements de terre ont rompu plusieurs segments de failles dans un intervalle de 9 heures, présentant un scénario inattendu pour les évaluations des risques sismiques. Lors de l'événement de Pazarcık, les niveaux d'accélération maximale du sol, correspondant aux niveaux de conception DD-1 (avec une période de retour de 2475 ans) et DD-2 (avec une période de retour de 475 ans) tels que définis dans le Code de construction parasismique turc, ont été dépassés à 5 et 22 stations de mouvement du sol, respectivement. Les équations de prédiction du mouvement du sol (GMPEs) ont sous-estimé les niveaux de PGA enregistrés dans les stations situées à moins de 70 km de la rupture de la faille, en particulier pour le séisme de Pazarcık. La liquéfaction sismique des sols est apparue comme un géo- risque significatif, notamment observé dans les régions de Gölbaşı-Adıyaman et d'Iskenderun-Hatay. La secousse significative a déclenché plus de 3 000 glissements de terrain et chutes de rochers, entraînant des pertes en vies humaines. Les dommages aux infrastructures ont été importants, avec 7 ponts subissant des dommages significatifs, dont deux ont été attribués à la liquéfaction des sols de fondation. Les lignes de vie ont subi d'importants dommages en raison de la rupture de la faille, de la liquéfaction et des déformations permanentes du sol. De même, les installations portuaires d'Iskenderun ont signalé des dommages graves dus à la liquéfaction et aux incendies post-sismiques. Bien que les 140 barrages de la région d'influence aient préservé leurs capacités de rétention d'eau, les niveaux des réservoirs de deux d'entre eux ont dû être abaissés dans le cadre des mesures d'intervention d'urgence. Alors qu'il y a eu un effondrement partiel dans un tunnel ferroviaire pavé de pierre desservant la ligne Gölbaşı-Malatya, aucun dommage majeur n'a été signalé aux structures de tunnel. Les structures de soutènement, principalement des murs de pierre, ont subi des dommages, tandis que les murs de terre renforcés ont fait preuve d'une plus grande résilience. L'effondrement ou les dommages graves à plus de 650 000 unités résidentielles ont été la principale cause de plus de 55 000 décès.

Keywords: Kahramanmaraş earthquakes; geotechnics; geohazards; liquefaction; dams; bridges; retaining structures; ports.

1 INTRODUCTION

On February 6, 2023, at 04:17 local time, a seismic event with a moment magnitude of M7.8 occurred along the East Anatolian Fault (EAF). This earthquake originated at a focal depth of 8.6 km, with its epicenter located in the Pazarcık district of Kahramanmaraş province in Türkiye. As shown in Figure 1, epicenter of the event lies approximately 40 km northwest of Gaziantep metropolitan city, and about 33 km southeast of Kahramanmaraş, precisely at coordinates 37.288°N, 37.043°E (Cetin et al., 2023). During the Pazarcık earthquake, a fault rupture zone stretching 190 km in length and 25 km in width, oriented in a northeast-southwest direction, was mapped (USGS, 2023a). Remarkably, merely eleven minutes after the main shock, another earthquake with M6.7 occurred in the same region.

At 13:24 local time, 9 hours after the Pazarcık event, another major earthquake shook the region, registering a moment magnitude of M7.6. This subsequent seismic event had a focal depth of 7.0 km, with its epicenter located in Ekinözü, Elbistan district of Kahramanmaraş province. The epicenter of the event is shown in Figure 1, approximately 98 km northwest of Adıyaman, and 62 km northeast of Kahramanmaraş, situated at 38.089°N, 37.239°E (Cetin et al., 2023). The Ekinözü-Elbistan earthquake shares the same left-lateral strike-slip mechanism as the Pazarcık event, rupturing a fault zone spanning approximately 120 km in length and 18 km in width, primarily oriented in an east-west direction (USGS, 2023b). Key attributes of these earthquakes, including their moment magnitudes, focal depths, and mechanisms, are detailed in Table 1 (Cetin et al., 2023; Cetin and Ilgac, 2023), as documented by various national and international organizations.

Table 1. Some characteristics of Pazarcık and Elbistan earthquakes.

Institution	Magnitude, M		Depth (km)		Focal Mechanism	
	Pazarcık	Elbistan	Pazarcık	Elbistan	Pazarcık	Elbistan

In addition to the Pazarcık and Ekinözü events, an independent earthquake struck the Yayladağı district in Hatay province on February 20, 2023, registering a magnitude of 6.3 with a focal depth of 21.73 km. This event occurred approximately 135 km south of the Pazarcık earthquake epicenter and 225 km south of the epicenter of Ekinözü earthquake. Following the earthquake sequence, over 11,000 aftershocks were recorded in the region until the end of March 2023. The intense shaking and resultant damage affected numerous provinces, including the cities of Adana, Adıyaman, Diyarbakir, Elazig, Malatya, Gaziantep, Hatay, Kahramanmaraş, Şanlıurfa, Kilis, and Osmaniye, which collectively house a population of over 15 million. The earthquake sequence resulted in more than 60,000 casualties and caused the destruction of over 650,000 residential units jointly in Türkiye and Syria (Cetin et al., 2023; Cetin and Ilgac, 2023).

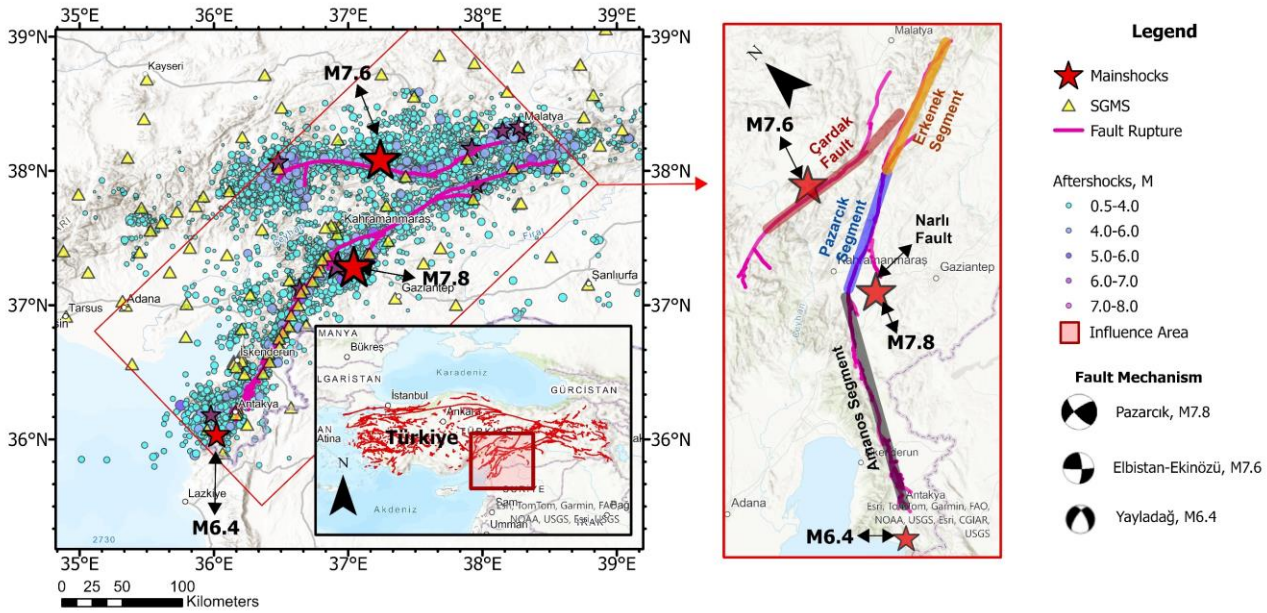

Figure 1. The map of the region, showing the East Anatolian Fault zone, the epicenters of the main- and aftershocks.

The events triggered a wide range of geohazards, including:

A. Soil liquefaction and -induced ground failures, resulting in excessive settlements, lateral spreads and global or local bearing capacity shear failures at or around various structure foundations. More specially they were mapped at:
   a. free field sites,
   b. residential structures,
   c. harbors/ports,
   d. embankments/dams,
   e. bridges/viaducts,
   f. airports.
B. Landslides and Rockfalls,
C. Permanent displacements/deformations due to factors other than soil liquefaction, including fault offset and strong ground shaking, and their effects on:
   a. retaining structures
   b. embankments / earthfill and rockfill dams.

This manuscript summarizes the findings of earthquake and geotechnical engineering reconnaissance field studies performed immediately after the earthquakes, along with their preliminary evaluation results. It presents the geotechnical assessment of residential structures, bridges, hydraulic structures (dams), airports, and retaining structures. Before the discussion of induced geohazards, a brief discussion on fault rupture mechanisms and strong ground motion characteristics will be presented next.

2 FAULT RUPTURE MECHANISMS AND STRONG GROUND MOTION CHARACTERISTICS

Turkiye, located at the convergence point of the Eurasian, African, and Arabian plates, encompasses a significant portion of the Anatolian block. It is surrounded by prominent geological features: the North Anatolian Fault (NAF) to the north, the East Anatolian Fault (EAF) to the east, the Hellenic and Cyprus subduction zones to the south, and an extension regime to the west. The Anatolian block displays a counterclockwise rotation and westward translation in relation to the three surrounding plates (Cetin et al., 2023; Cetin and Ilgac, 2023). The East Anatolian Fault Zone (EAFZ), spanning 450 km from Karlıova-Bingöl to Hatay, is characterized by a northeast-trending left-lateral strike-slip fault system. This zone serves as a significant plate boundary, with the Arabian Plate shifting approximately 10-11 mm northeastward annually, compressing the Anatolian Plate (Cetin et al., 2023).

Seismic activity in the Eastern Mediterranean region, particularly affected by the recent earthquake sequence, is intricately linked to the dynamic interactions among the Arabian, African, and Anatolian plates. In the east, the Arabian Plate collides with the Eurasian Plate, while to the west, the convergence of the African and Anatolian plates brings them close together (McKenzie, 1972). Since the Late Cretaceous period, there has been a gradual convergence between the Eurasian Plate and the Arabian and African plates, predominantly occurring in a north-south direction. This prolonged convergence ultimately led to the closure of the Tethys Ocean, which once separated the Arabian and African plates from the Eurasian plate (Kavuzlu, 2006).

The collision between the Arabian Plate and the Anatolian Plate, occurring along the Bitlis-Zagros Thrust Belt, has been a significant geological process shaping the Anatolia region since the Middle-Late Miocene period (Gülen et al., 1987; Arpat and Şaroğlu, 1975). This ongoing continent to continent collusion and convergence have resulted in the shortening and thickening of the Anatolian block, which is positioned between the Eurasian and Arabian-African plates. Beginning in the Late Miocene-Pliocene period, the Anatolian block, unable to accommodate the compression and deformation, began to undergo lateral translation westward due to the effects of the strike-slip North Anatolian and East Anatolian Faults (Kavuzlu, 2006).

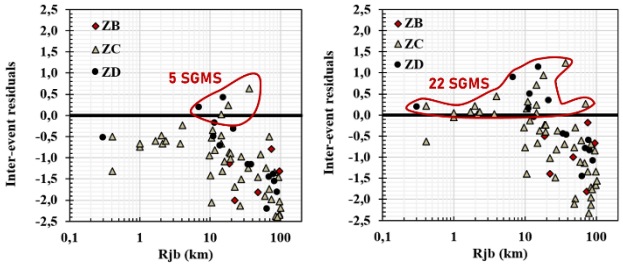
During the collision between the Arabian and the Anatolian Plates, the Arabian Plate separated from the African Plate along the North-South Dead Sea Transform Fault, propelled by the Arabian Plate's faster northward movement compared to Africa Continent (Gülen et al., 1987).

In line with the outlined translational plate boundaries and tectonic context, the moment tensor solution for the Pazarcık earthquake indicates motion along a nearly vertical fault plane, trending northeast-southwest, predominantly left-lateral strike-slip motion. Originating on the Narlı Fault to the south, the Pazarcık earthquake fault rupture propagated bilaterally along the East Anatolian Fault zone, rupturing the Pazarcık and Erkenek fault segments to the northeast and the Amanos segment to the southwest. The distribution of aftershocks linked to this earthquake suggests a unique example of a complex rupture pattern, with the rupture terminating in Hatay to the south and in Doğanyol by the Pütürge segment to the north. Mapping of fault offsets reveals a range of 3-7 meters, while the rupture length surpassed 300 kilometers. Additionally, as noted earlier, a M6.8 aftershock occurred just west of the the

Pazarcık earthquake's epicenter, rupturing the Salçagöz Fault (Cetin et al., 2023).

The Ekinözü earthquake, representing a notable occurrence of short-term seismic triggering, triggered along the Çardak-Sürgü Fault segment, exhibiting predominantly left-lateral strike-slip motion similar to the Pazarcık event. Initiating on the east-west trending Çardak Fault, which extends further south in the west, the Ekinözü event progressed eastward over the northeast-southwest trending Doğanşehir fault zone towards the city of Malatya. Estimated to span approximately 160 km in total rupture length, the earthquake resulted in fault offsets ranging from 2 to 8 meters (Cetin and Ilgac, 2023).

These seismic events were monitored by the Disaster and Emergency Management Presidency (AFAD) stations located throughout the region. AFAD operates a network of 1548 strong ground motion stations (SGMSs) spanning the entire country. During the Pazarcık earthquake, 379 of these stations were activated. Notably, the maximum peak ground accelerations (PGA) were recorded in Hatay-Antakya, aligning with reports of more severe structural damage. Specifically, at SGMS station #3126, PGA levels peaked at 1.23 g in the north-south direction and 1.04 g in the east-west direction. According to the Turkish Building Earthquake Code (TBEC-18), the design basis seismic scenarios for return periods of 2475 and 475 years are referred to as DD-1 and DD-2 levels, respectively. During the Pazarcık event, the DD-1 and DD-2 design basis PGA values were surpassed at 5 and 22 SGMSs, respectively, as shown in Figure 2. This figure illustrates the interevent residuals, representing the difference between the recorded and design basis PGA intensities, plotted against the Joyner and Boore (1988) distance (R_{jb}).



a) DD-1 **b)** DD-2

Figure 2. Variability in PGA residuals with TBEC-18.

Similarly, the Ekinözü event was monitored by 387 SGMS stations. Among these, the maximum PGA values were recorded at Kahramanmaraş-Göksun Station #4612. Here, the PGA levels peaked at 0.65 g in the north-south direction and 0.53 g in the east-west direction.

Figure 3 illustrates the attenuation of the recorded PGA intensities with R_{jb} for both seismic events. It is noteworthy that in close proximity to the fault rupture, recorded ground motions exhibit higher intensity levels compared to the median values estimated by NGA West 2 ground motion predictions equations (GMPEs), as discussed in Cetin et al., 2024a. However, beyond a distance of 70 km from the fault rupture, recorded PGA levels attenuated more rapidly, suggesting that GMPEs overestimated these PGA intensities.

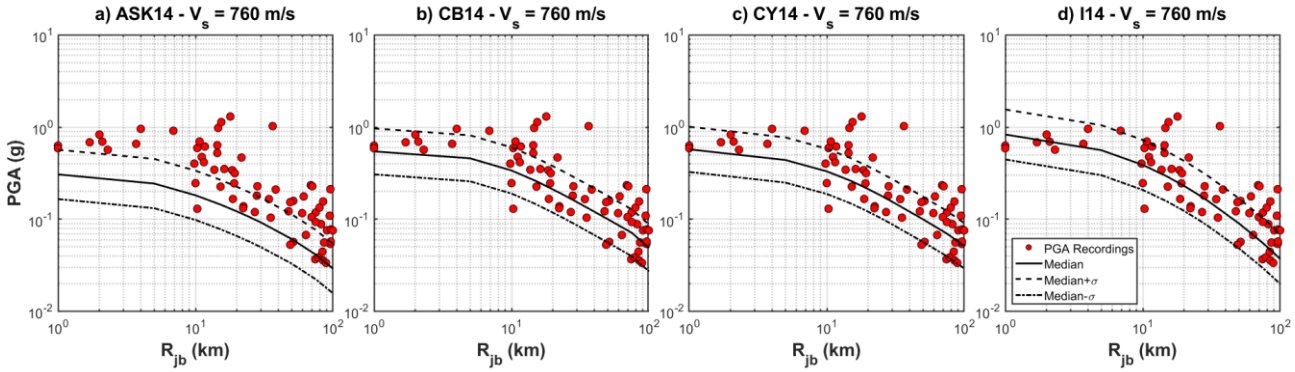


Figure 3. Joyner and Boore distance attenuation of the recorded PGAs as compared with the NGA West-2 GMPEs of Abrahamson et al. (2014)-ASK14, Campell and Bozorgnia (2014)-CB14, Chiou and Youngs (2014)-CY14 and Idriss (2014)-I14 for the Pazarcık earthquake (adapted from Cakir and Cetin, 2024).

In addition to R_{jb} distances, variations in the intensity, duration, and frequency characteristics of strong ground motion records (SGMR) were observed to be influenced by factors such as site conditions and orientation, and rupture velocity (Wu et al., 2023; Abdelmeguid et al., 2023; Ren et al., 2024). Figure 4 demonstrates significant variations in these characteristics within a short distance span in Hatay metropolitan city, as observed at SGMSs #3123, 3124, 3125, and 3126, located within a few kilometers of each other. Detailed discussions on these variabilities and their underlying reasons were thoroughly addressed in Alsaid and Cetin (2023) and Cetin and Alsaid (2023) and will not be reiterated here.

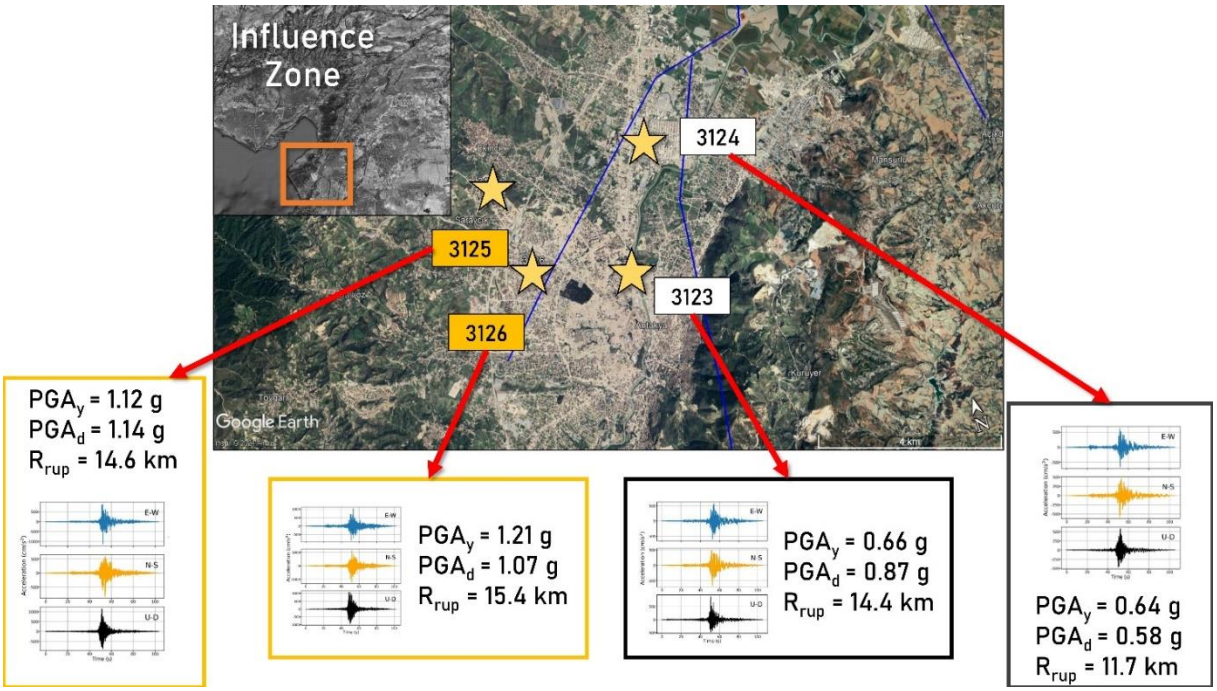

Figure 4. SGMS records in Hatay-Antakya during the Pazarcık event.

In summary, both the Pazarcık and Ekinözü earthquakes occurred within an unusually short timeframe of only 9 hours. This rapid succession of two significant seismic events with large magnitudes was not accounted for in the scenarios outlined in seismic hazard assessments. Moreover, the joint ruptures of three segments during the Pazarcık event, and two segments during the Ekinözü event, were deemed as scenarios with either zero or very low probability in seismic source characterization studies. Therefore, their larger-than-expected moment magnitudes and occurrence within such brief periods classified these earthquakes as unexpected, rare events from both seismological and engineering perspectives.

Moreover, site-specific factors such as soil conditions, basin effects, and the fault rupture propagation characteristics, including its directivity (forward vs. backward) and velocity (sub vs. super shear), contributed to significant variability in the observed characteristics of strong ground motion records. This variability was evident in the wide range of scatter observed in strong ground motion record characteristics, which consequently resulted in widely variable and scattered levels of structural damage.

Finally, it's noteworthy that the median predictions of the Next Generation Attenuation, West 2 (NGA West-2) GMPEs consistently underestimated PGA intensities at R_{jb} distances shorter than 70 km. However, beyond the 70 km mark, the recorded intensities exhibited a faster attenuation with distance, compared to the median intensities predicted by the GMPEs.

3 GEOHAZARDS FOLLOWING THE KAHRAMANMARAŞ EARTHQUAKE SEQUENCE

3.1 Seismic soil liquefaction

Following the Kahramanmaraş earthquake sequence, seismically induced soil liquefaction emerged as a significant contributor to damages observed in both natural and built environments. Reconnaissance field investigations were promptly conducted to gather time-sensitive perishable data and assess the extent of destruction in the aftermath of the earthquakes. Sites displaying visible signs of seismic soil liquefaction, including soil ejecta and pronounced foundation and ground deformations such as excessive settlements and lateral spreads, were systematically identified and documented.

The initial phase of reconnaissance efforts to document liquefied sites began on the third day following the earthquakes and continued for over two months. Numerous national and international research teams, including the teams from Geotechnical Extreme Events Reconnaissance Association (GEER) and Earthquake Engineering Research Institute (EERI), participated in these surveys, leading to the compilation of data on a digital platform named SiteEye (Saha Gözü in Turkish), which is accessible at www.sahagozu.com.

A total of 428 liquefaction case histories were documented from various sources, including studies by Cetin and Ilgac (2023), Cetin et al. (2024a; 2024b; 2024c, 2024d) and Moug et al. (2023). The locations

of these liquefaction occurrences are depicted in Figure 5. These sites were categorized into six geographical regions labeled L1 through L6, as illustrated in the same figure.

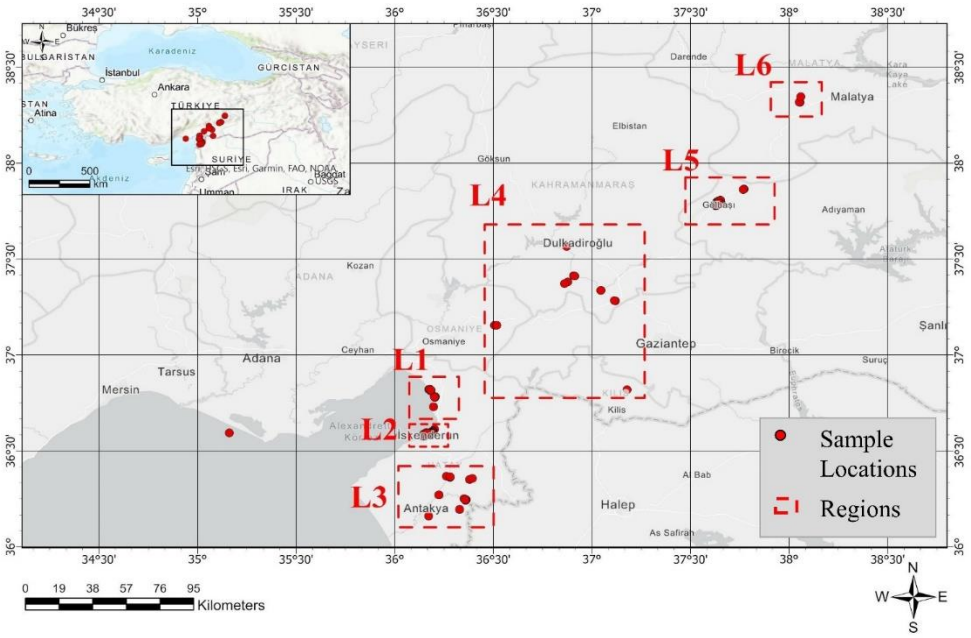

Figure 5. Map of liquefaction case history sites after Cetin et al. (2024b).

When collecting surface soil ejecta from liquefaction sites, particular emphasis was placed on obtaining representative soil samples. To accomplish this, when possible, a continuous sampling method was employed by vertically inserting a tube into the ejecta cone. This technique was chosen to address concerns regarding possible segregation or layering within the ejecta material. Additionally, efforts were undertaken to track the trajectory of the surface ejecta and determine its source, thereby verifying that it accurately represented the liquefied soil layer. This verification was crucial to ensure that the material was not transported to the ground surface due to excessive pore water pressure-induced flow. Whenever possible, existing borelogs were used to support this validation process. However, in cases where site-specific borelog data was unavailable, linking the characteristics of the ejecta soil sample directly to potential liquefied soil layers posed a challenge.

After labeling, ejecta samples were transported to the Middle East Technical University (METU), Soil Mechanics Laboratory. They underwent a 24-hour period of oven drying. Subsequently, a representative portion of the dried sample was immersed in a sodium hexametaphosphate solution (5 ml/1000 g) overnight to facilitate the separation of soil particles. Following this, wet sieving was conducted to isolate and collect the finer portion (< 0.074 mm) of the specimen. The fines portion was then stored in large bottles for further grain size assessments. Coarser portions remaining after wet sieving underwent a second round of oven drying before being subjected to dry sieving. These procedures adhere to the standards outlined by ASTM International, specifically ASTM D6913 (2017) and ASTM D7928 (2016). The Atterberg limits of the retrieved samples were estimated according to ASTM D4318 (2010). Laboratory test results will be presented separately for each ejecta region.

Figures 6a and 6b present the grain size distribution curves of the soil ejecta alongside the liquefaction susceptibility bounds outlined by Tschuida (1970). A complete presentation of the soil ejecta sites, grain size and consistency characteristics of these soil ejecta sites is presented in Cetin et al. (2024b) and will not be repeated herein due to page limitations. For instance, the sample retrieved from the Çay neighborhood in İskenderun-Hatay, with ID #38 exhibits fines and silt contents of 18.4% and 15%, respectively (see Figure 6a). Notably, apart from specimen ID #45, which displays a gravel content of 45%, all grain size distribution curves of the ejecta material fall within the bounds of the "susceptible to liquefaction region" as defined by Tsuchida (1970). Conversely, concerning the samples retrieved from the Adıyaman-Gölbaşı region, a significant number of ejecta grain size distribution curves lie outside the liquefaction susceptibility limits established by Tsuchida (1970), primarily due to their elevated fines content. Among the 31 specimens analyzed, hydrometer tests were conducted on 6 to estimate their clay contents. These

tests revealed clay contents ranging from 13% to 20%, as illustrated in Figure 6b. Most of the CL type soil ejecta are retrieved from Gölbaşı-Adıyaman region. The liquid limits of these samples vary in between 32 and 38%. Their plasticity index values are estimated to be in the range of 16 to 23%. Unexpectedly, two ejecta samples with plasticity indices higher than 30% are retrieved from Hatay Airport, one of which is classified as high plasticity clay (CH).

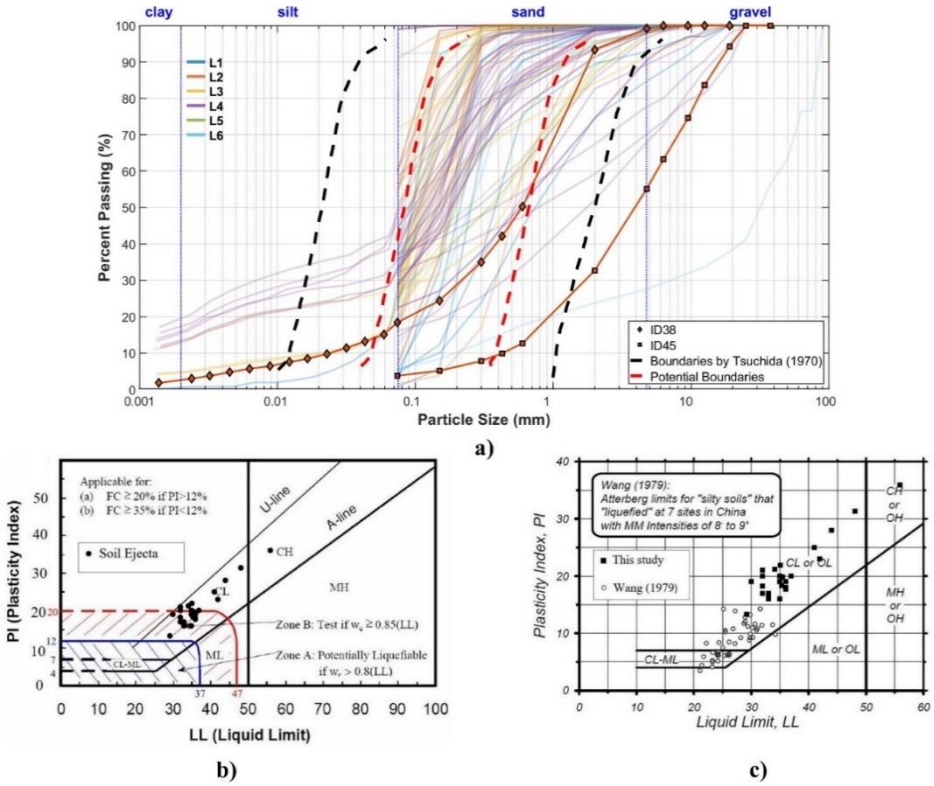

Figure 6. a) Grain size distribution of all samples indicated in Figure 5 b) susceptibility analysis followed by Seed et al. (2003), and c) susceptibility analysis followed by Wang (1979).

The consistency limits of the ejecta samples are shown on the Seed et al. (2003) liquefaction susceptibility chart, as depicted in Figure 6c. Most of the ejecta samples are situated within the "Zone B: Testing Recommended" region of the chart. However, notably, 12 out of 74 samples fall beyond the susceptibility region delineated by the Seed et al. chart. Subsequently, the laboratory test results are collectively presented alongside the Wang (1979) data, which were compiled from samples of liquefied "silty soil" layers at 7 sites in China. Figure 6d provides a comparative view of the overall database on the plasticity chart, indicating that clayey soils are susceptible to liquefaction and capable of producing ejecta under significant cyclic loading intensity and duration. It is imperative to note that additional detailed site investigations and laboratory testing programs are being conducted to scrutinize the liquefaction (cyclic) responses of fine-grained soils liquefied during the Türkiye-Kahramanmaraş Earthquake sequence.

Following a general introduction to the characteristics of the soil ejecta samples, a more in-depth discussion will be provided by grouping them under various headings. These headings will cover soil liquefaction manifestations in different contexts, including those observed in free fields and in the vicinity of building foundations, dams, bridges, ports and harbors, and airports.

3.1.1 Free field liquefaction sites

Following the Kahramanmaraş Earthquake sequence, soil ejecta samples were collected from more than 200 locations, predominantly concentrated along the İskenderun coastal region, Demirköprü, and Kumlu regions in Hatay city. Adiditonally, soil ejecta was manifested in Gölbaşı town in Adıyaman city, along with instances in Türkoğlu and Emiroğlu in Kahramanmaraş metropolitan city. Figure 7 presents images from free-field ejecta sites, with their corresponding locations indicated in Figure 5.

Figure 7. Free-field soil ejecta sites at a) Payaş Dörtyol-Hatay coastal line, b) A Port facility in İskenderun, c) İskenderun-Hatay, d) Demirköprü-Hatay, e) Emiroğlu-Kahramanmaraş, f, g, h, and j) Gölbaşı-Adıyaman after Kahramanmaraş Earthquakes.

3.1.2 Liquefaction around building foundations

In the districts of Savaş and Çay in İskenderun-Hatay, as well as in Gölbaşı town in Adıyaman city, the geological, geotechnical, and hydrogeological conditions played a role in the favor of triggering soil liquefaction. These areas are characterized by loose and soft alluvial and marsh sediments, shallow groundwater levels, and strong shaking intensities and durations. Consequently, substantial bearing capacity failures of building foundations, accompanied by excessive settlements, and lateral translations, occurred. In Gölbaşı, the most severely affected area was primarily situated north of Atatürk Boulevard on the Gaziantep-Malatya highway, particularly near the lake, where loose or soft alluvial sediments are thicker. The reduction in bearing capacity due to liquefaction and cyclic mobility led to settlements ranging from 10 to 90 cm, as depicted in Figure 8a.

In İskenderun, numerous residential building foundations in Çay district experienced settlements induced by liquefaction and bearing failures. The settlements of foundations varied from 3 to 17 cm in the Savaş Neighborhood and reached approximately 42 cm in the Çay Neighborhood. Moreover, differential settlements of up to 30 cm were observed, resulting in the tilting of buildings, as depicted in Figure 8b.

Figure 8. Liquefaction-induced settlement observed at a) Gölbaşı-Adıyaman, and b) İskenderun-Hatay.

3.1.3 Ports/Harbors

Soil liquefaction caused significant damage on port facilities along the Mediterranean coast in İskenderun-Hatay. The liquefaction manifestations were widespread at various locations, including the public beach and shoreline of Dörtyol municipality, several ports within the İskenderun Bay area, and regions of İskenderun Customs and Fishery Port. Pictures taken at these sites are shown in Figure 9. Vertical and lateral displacements and deformations were also evident and mapped near areas with sand ejecta, likely caused by the lateral spreading of quay walls. In more intricate facilities, such as ports, cranes, and weighbridges were surveyed to be tilted or overturned due to liquefaction-induced bearing capacity failures and ground deformations.

Figure 9. Liquefaction-induced deformations at port facilities in, b) A Port facility in İskenderun, c) Fishery Warf, d, e, and f) İskenderun State Harbor.

3.1.4 Dams

The Kahramanmaraş Earthquakes significantly affected 140 dams in the region, with the majority located within a 50 km radius from the fault rupture. Fortunately, these dams retained their water-retaining capabilities, and no instances of uncontrolled water release were reported. However, as part of emergency response measures, the water levels at two earthfill dams, namely Sultansuyu and Arıklıkaş, were gradually lowered in a controlled manner due to extensive permanent deformations (1-2 m) occurring at the dam bodies (Cetin et al., 2024d). Additionally, surface manifestations of liquefaction were observed at these dams, possibly attributed to the inadequate compaction of the filter material layers, as illustrated in Figure 10. A detailed discussion of the deformations mapped at these dams will be presented in Section 3.3.

Figure 10. Surface manifestation of liquefaction observed at a) Sultansuyu Dam and b) Arıklıkaş Dam.

3.1.5 Bridges

Reconnaissance surveys indicated damage to a total of 7 bridges (Caner et al., 2023). Among these, two failures were attributed to soil liquefaction: Demirköprü and Karasu Bridges. Demirköprü Bridge, located in Hatay-Demirköprü, was surveyed by the reconnaissance team from the Middle East Technical University. Detailed field surveys were conducted to map the intricate patterns of displacements, deformations, and surface manifestations of soil liquefaction. All observable displacements and manifestations, including soil ejecta, excessive settlements, and lateral spreads, were accurately located. Figures 11a-c show the two most eastern spans of the bridge, along with the rotational failure observed in the south-east abutment. Notably, in Figure 11b, the reinforced concrete bored piles in the east abutment tilted 20° towards the Asi River, accompanied by settlements reaching as high as 1.0 to 1.5 m at the abutment embankment, as shown in Figure 7c. Figure 11d displays the widespread sandy ejecta and volcanoes induced by liquefaction mapped at the site. Six samples were collected from the ejecta soil, with a focus on obtaining representative soil samples. The retrieved ejecta samples were classified as non-plastic silty sand (SM) with an average 25% fines content (Ocak and Cetin, 2024). Liquefaction susceptibility analysis was conducted following the method proposed by Seed et al. (2003), and Figure 11e indicates that, except for a few data points (less than 5% of available data points), the majority of fine-grained soils are classified as not susceptible, confirming the selection of the suspected critical soil layer as the silty sand (Unit 2, SM) layer.

The second bridge affected by liquefaction-induced ground deformations is the Karasu Bridge, situated over the Karasu River. Both the eastern and western approach embankments exhibited significant differential settlements, ranging between 40-45 cm and 50-55 cm, respectively (see Figure 12c). Moreover, lateral spreading, exceeding 150 cm, was observed within the influence zone of bridge piers and foundations (see Figure 12a-b). The approach embankments of the bridge are underlain by layers of low to high plasticity stiff clay and liquefaction-susceptible clayey and silty medium dense sand units. Specifically, non-plastic silty sands with fines contents ranging from 21% to 42% were identified as the liquefaction suspect soil units during the Pazarcık earthquake. Figure 12d provides a comparative display of the grain size distribution curves of these non-plastic SM samples, alongside the liquefaction susceptibility bounds proposed by Tschuida (1970). It is noteworthy that the grain size distribution curves consistently fall within the recommended susceptible soils range. To evaluate the susceptibility of fully saturated fine-grained soils and their mixtures to liquefaction, assessments were conducted utilizing Atterberg limits and referencing the chart suggested by Seed et al. (2003). As depicted in Figure 12e, fully saturated soils falling within Zone A or B were deemed susceptible to liquefaction, in accordance with the procedure outlined by Seed et al. (2003).

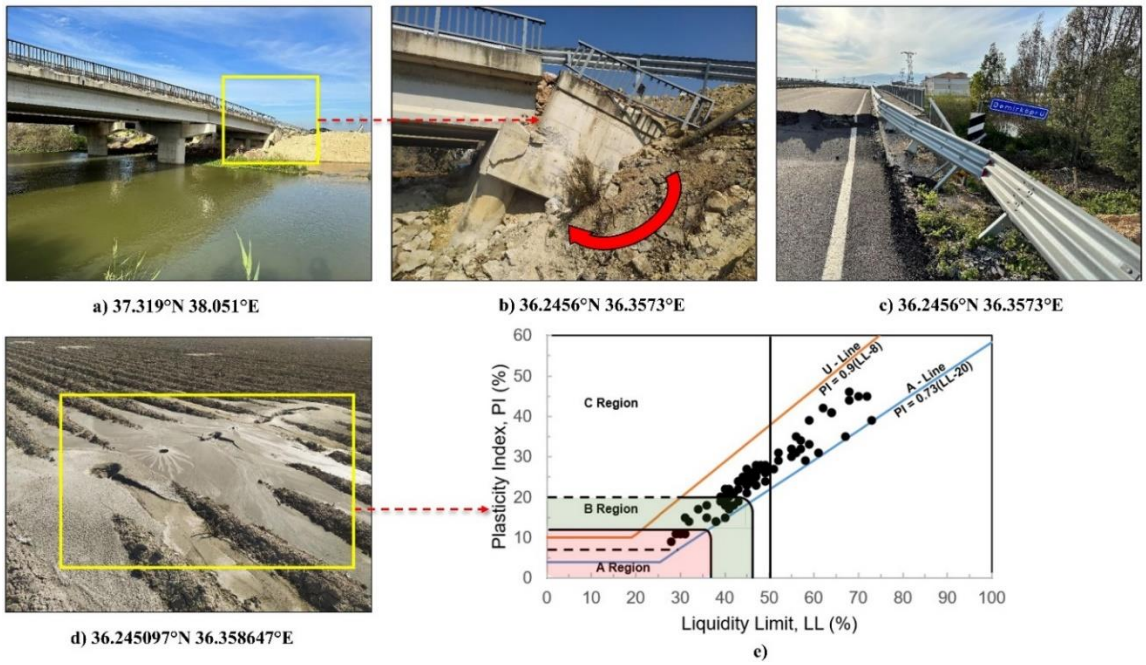

Figure 11. Site investigation at Demirköprü Bridge: a) General overview of the bridge, b) rotational failure at eastern span of the bridge due to seismic soil liquefaction, c) soil ejecta in the vicinity of the bridge, and d) liquefaction susceptibility analysis followed by Seed et al. (2003).

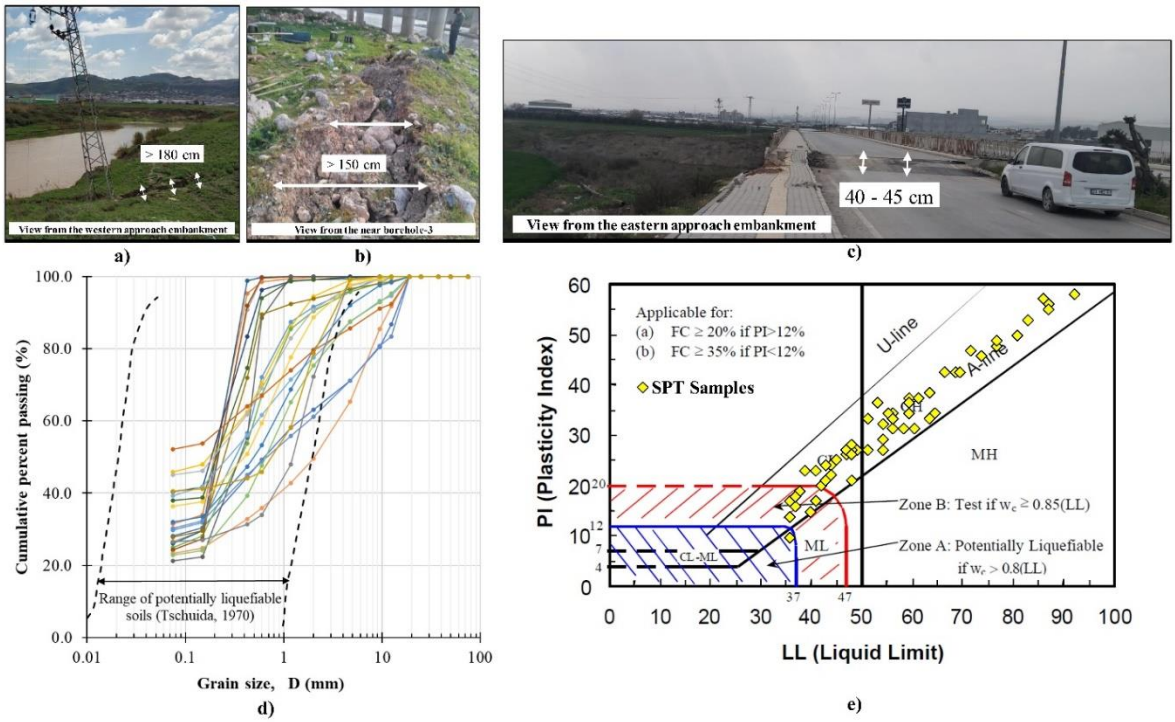

Figure 12. Site investigation at Karasu Bridge: a, b) lateral spreading nearby bridge piers, differential settlements on approach embankments) soil ejecta in the vicinity of the bridge, d) particle size distribution curves for non-plastic silty sands with susceptibility bounds proposed by Tschuida (1970) and e) liquefaction susceptibility analysis followed by Seed et al. (2003).

3.1.6 Airports

A total of 11 airports are present in the earthquake region, as depicted in Figure 13a, and all, except one, performed well despite the high levels of shaking. Unfortunately, the Hatay Airport runway sustained damage attributed to fault displacements and soil liquefaction, as illustrated in Figure 13b-c and 13e-f. Excessive settlement and lateral spreading were documented on airport runway due to reconsolidation and volumetric compaction after liquefaction. As expected, no damage was reported in airport structures such as terminal buildings, where ground improvement and deep foundation design solutions were implemented (see Figure 13d). Five samples were retrieved from these locations, classified as clayey sand (SC), and low to high plasticity clays (CL or CH). Further analyses regarding liquefaction triggering and liquefaction-induced settlements are discussed in Cetin et al. (2024e).

3.1.7 Liquefaction-induced lateral spreading and inundation

Liquefaction-induced lateral spreading and inundation were observed in several regions, notably along the shorelines of Gölbaşı Lake in Adıyaman, and İskenderun Bay in Hatay. A vivid example was documented at the old Gölbaşı Vocational School, situated on the southern shores of Gölbaşı Lake, as shown in Figure 14. The lateral displacements and settlements were clearly evident on the cobblestone-paved yard of the school, as illustrated in the same figure. The total lateral displacements exceeded five meters.

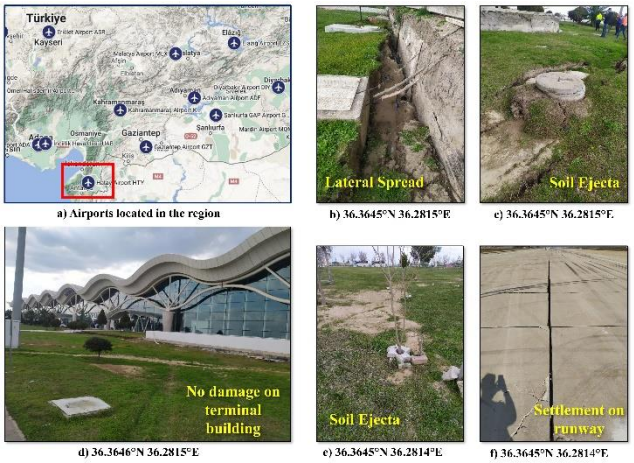

Figure 13. Site photos taken at the Hatay Airport.

In the İskenderun district, lateral deformations were mapped along the ports and shoreline. At certain locations, approximate lateral deformations and vertical deformations were measured as 90 cm and 60 cm, respectively. Some of these lateral spreading sites are shown in Figure 15.

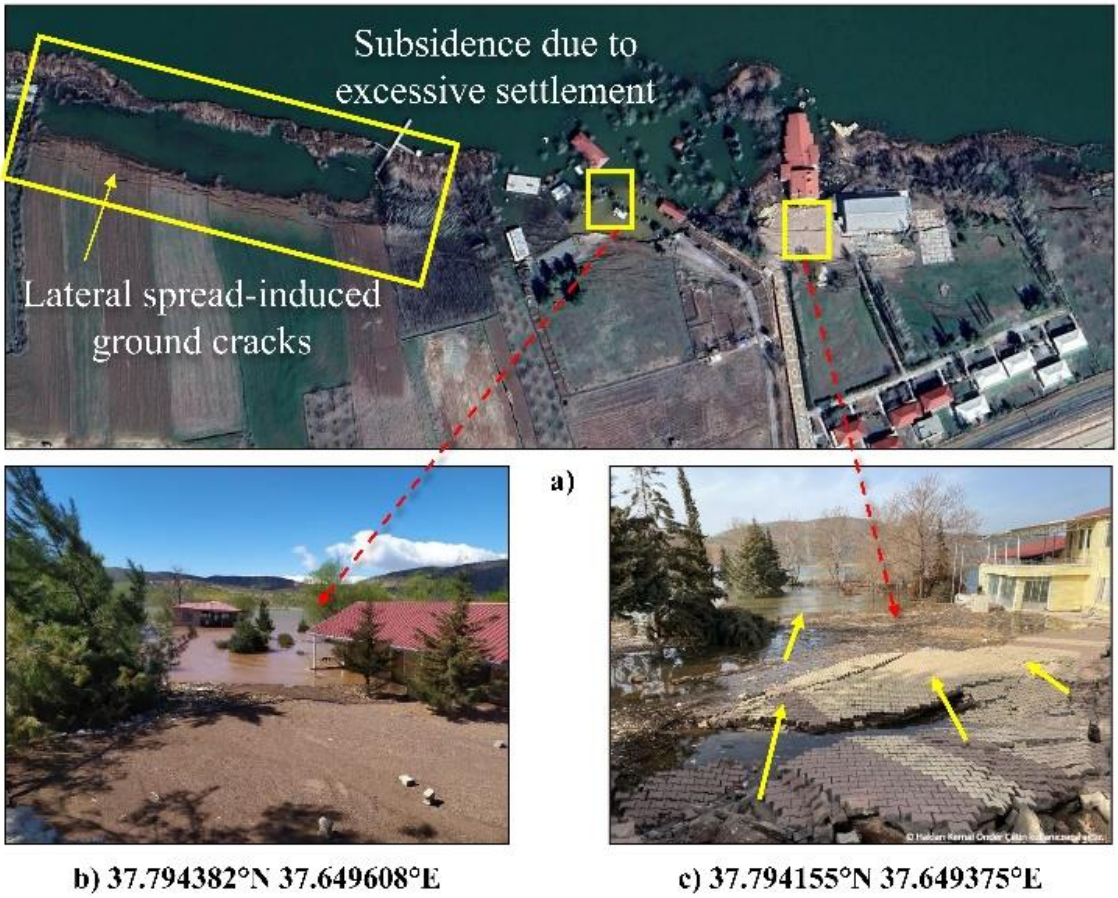

Figure 14. Lateral spreading and subsidence observed in Gölbaşı-Adıyaman adapted from Cetin et al. (2024c).

Figure 15. Lateral spreading observed at Hatay-İskenderun.

3.2 Landslides and rockfalls

Gorum et al. (2023) conducted an extensive evaluation using satellite and aerial imagery to assess the earthquake-affected area, complementing remote observations with field investigations. As depicted in Figure 11, a total of 3673 coseismic landslides

associated with this event were mapped, marking it as the largest compilation of coseismic landslides from a single seismic event in Türkiye. Over 90% of these mapped landslides occurred within a 20-km-wide zone along the fault rupture.

Global observations suggest that coseismic landslides could be triggered in the far field with peak ground acceleration (PGA) values as low as 0.02–0.08 g (Jibson and Harp, 2016), although most occur at higher levels of shaking. Typically, about 90% of landslides occur where PGA exceeds 0.12 g (Tanyas and Lombardo, 2019). Consistently with available literature, the locations of documented coseismic landslides were observed to fall within regions shaken by PGA levels exceeding 0.12 g.

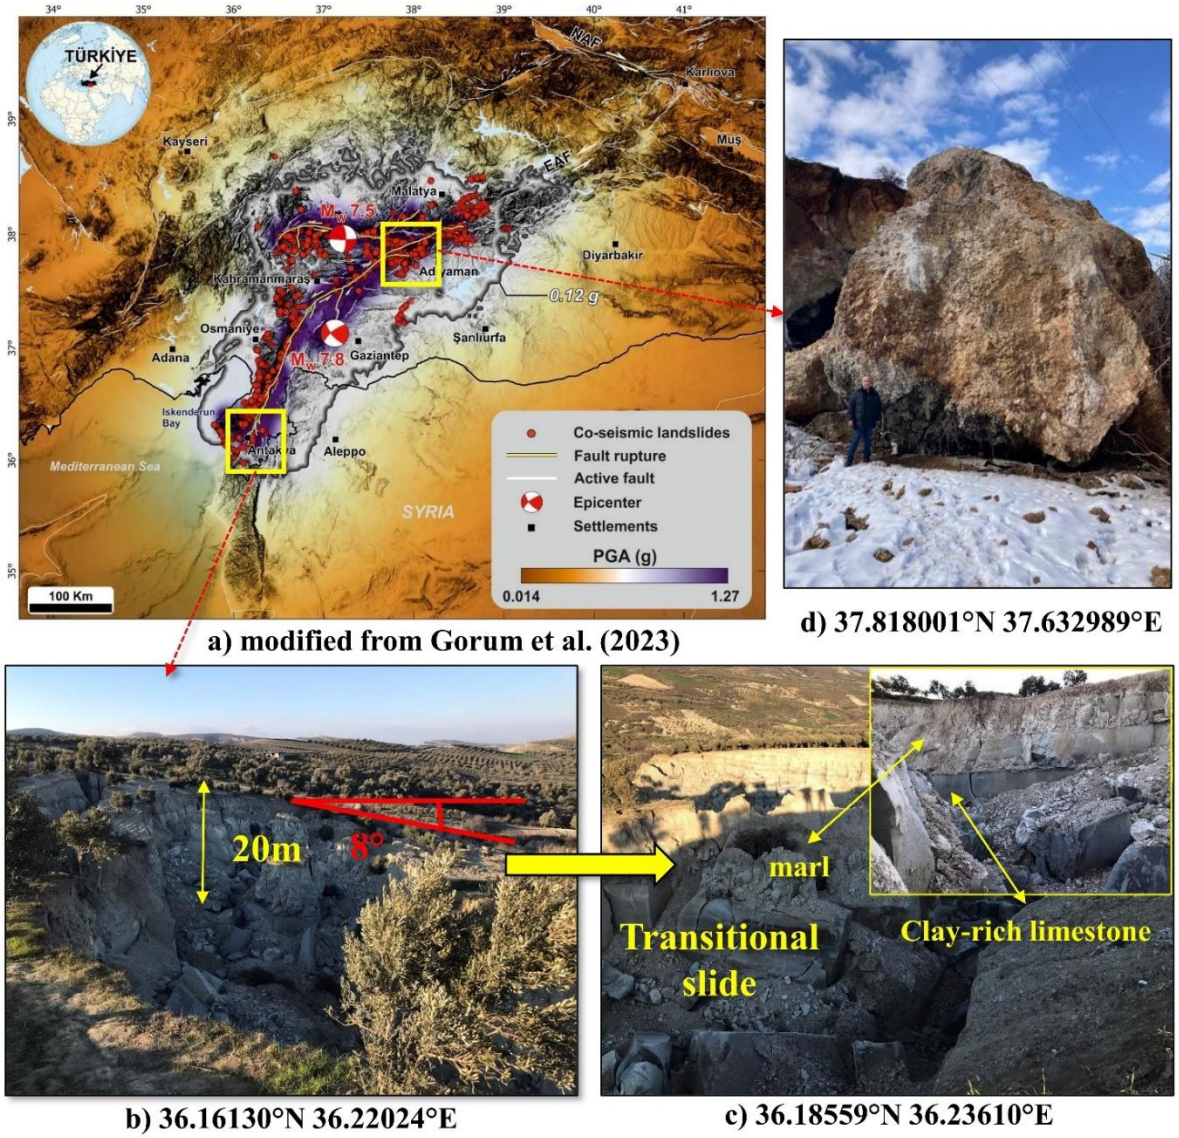

Figure 16. a) Spatial distribution of coseismic landslides overlain by the Kahramanmaraş Earthquakes fault rupture and PGA recordings for M>5.5 modified from Gorum et al. (2023), b, c) representation of transitional slide documented in Tepehan Village, and d) rockfalls reported in Gölbaşı.

In Tepehan village, a significant landslide event took place, characterized as a transitional slide with an area of approximately 1.3 km^2, as shown in Figure 16b and 16c. The slope gradient measured at the site was 8°. The sliding mass primarily consisted of marl and clay-rich limestone, exacerbated by significant rainfall in the area. The failure thickness measured 20 m, with the sliding basal surface identified as the upper bedding surface of a clay-rich limestone unit interbedded with marl, exhibiting intense weathering in the upper parts (Sümer et al., 2023). Additionally, rockfalls occurred across the entire area, with bedrock rotational landslides predominantly observed in the north.

In Adıyaman-Gölbaşı, particularly in the Karamağara locality, large block rockfalls were

documented, as depicted in Figure 16d. The name "Karamağara" translates to "black cavern" in English, indicating its formation through the karstification of limestone units in the region. Following the seismic events, these rockfalls nearly obstructed the entrance to the cavern and blocked the village road adjacent to it for two days, temporarily impeding access to villages located to the north.

3.3 Permanent ground/soil displacements/deformations

In this section, permanent ground displacements resulting from fault offset will be discussed. Additionally, the displacements and deformations surveyed at retaining structures, as well as earthfill, and rockfill dams and embankments, will be presented.

3.3.1 Fault offset

Immediately after the earthquakes, deformation zones and offset features were documented, along with numerous instances of surface ruptures. These displacements were also revealed by Sentinel-2 deformation analyses, conducted by COMET, as illustrated in Figure 17a. Figure 17b-f presents some examples of these instances for the Pazarcık and Elbistan events. During the Pazarcık event, the fault rupture extended over 400 km, with offsets reaching up to 7.2 meters (Kurcer et al., 2023; Cetin and Ilgac, 2023). Unfortunately, during the Pazarcık event, the fault rupture intersected the axis of the Erkenek Dam, resulting in a 3.4 m left lateral offset on the dam body as shown in Figure 17b (Cetin et al., 2024d). In contrast, the Ekinözü event was characterized by a fault rupture of 160 km, with offsets reaching up to 8.8 meters (Parlak et al., 2023).

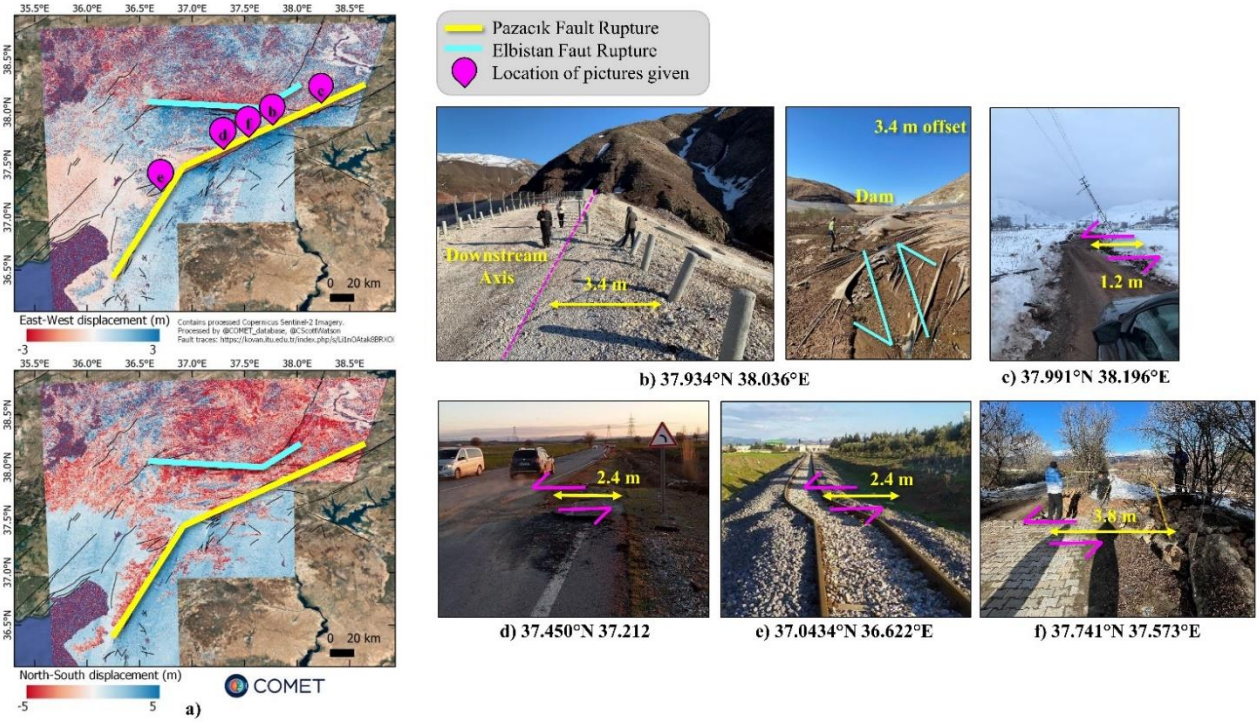

Figure 17. a) Sentinel-2 deformation analyses provided by COMET after Cetin and Ilgac (2023), b) fault offsets mapped b) across the Erkenek Dam, in c) Çelikhan, d) Pazarcık, e) Islahiye, and f) Balkar.

3.3.2 Retaining structures

Many retaining structures were reported to have failed, with failures primarily concentrated on stone gravity-type walls, as depicted in Figure 18a. Additionally, some failures of reinforced concrete walls were attributed to seismic soil liquefaction, as seen in Figure 18b. Conversely, well-designed and constructed anchored, reinforced, piled, or stabilized walls exhibited better performance under high seismicity, as illustrated in Figure 18c-d.

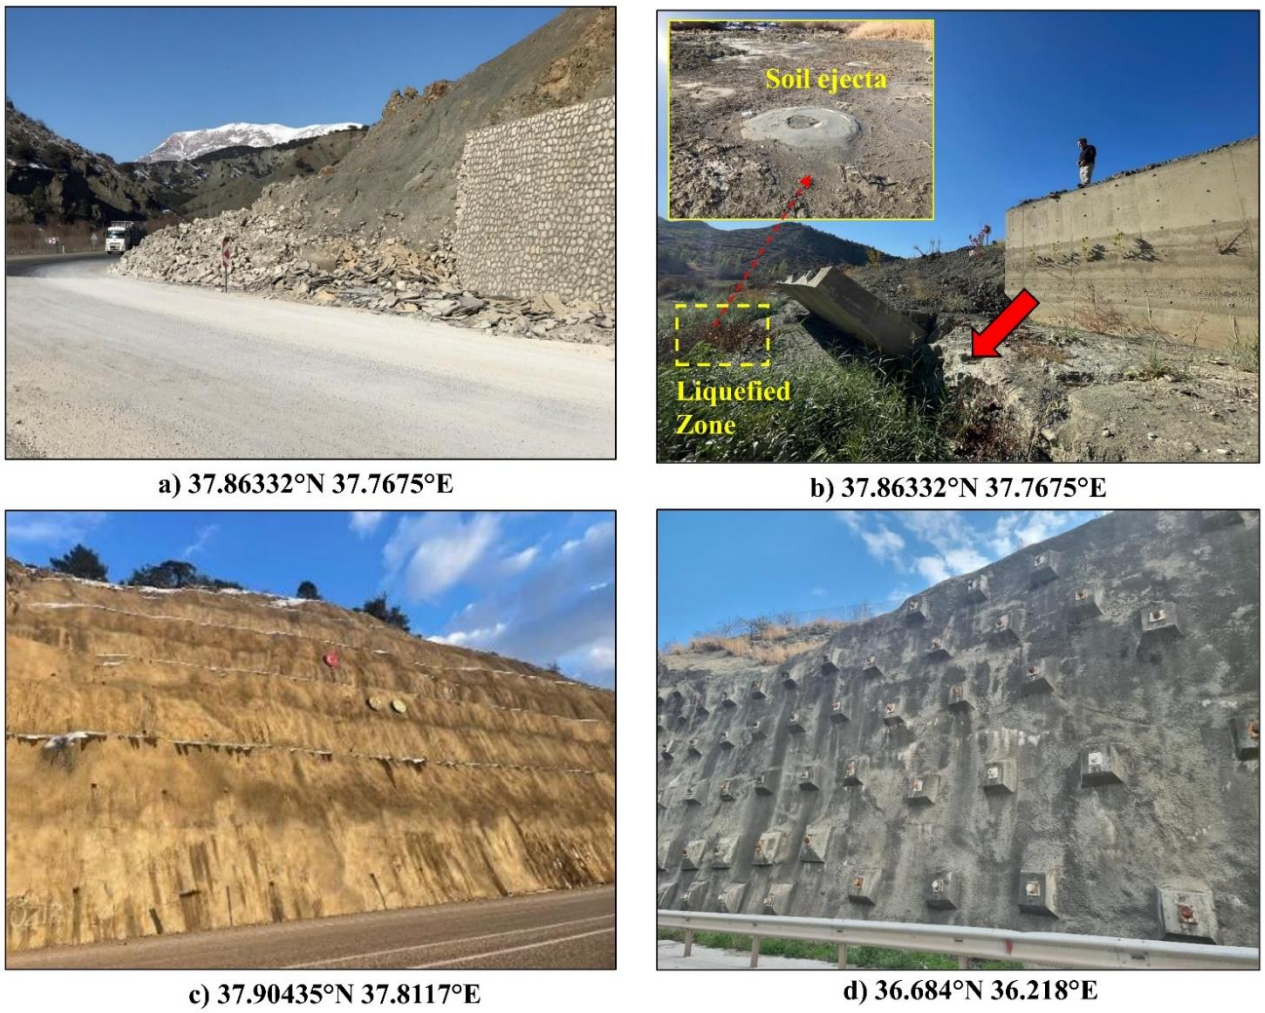

Figure 18. Retaining wall performance after the Kahramanmaraş Earthquakes: a) Stonewall, b) Cantilever, c, and d) anchored walls.

3.3.3 Earth embankments/earthfill-rockfill dams

Over 140 water retention structures in the earthquake-affected area experienced high ground shaking, with most dams falling within the high-intensity shaking zone. The observed levels of damage is illusrated in Figure 19 using a color-coded permanent displacement scale, where yellow and green indicate "no permanent displacements" and "50 cm permanent displacements," respectively. In the figure, square, diamond, and filled circles represent concrete, rockfill, and earthfill dams, respectively. Despite high intensity shaking levels, all dams successfully continued their water retention functions without significant damage. Notably, high-capacity dams such as Atatürk, Keban, Berke, Sır, Karakaya, and Birecik did not experience permanent deformation or displacements. However, some earthfill and rockfill dams were observed to have been more severely affected as compared to concrete dams.

As part of emergency response measures, controlled lowering of water levels occurred at two dams: Sultansuyu and Arıklıkaş. Deformations at these dams primarily are reported as longitudinal cracks extending parallel to the crest, accompanied by lateral translations and settlements. These permanent deformations were associated with inadequate compaction the interface plane in between clay-core and filter materials. Their magnitudes were also evaluated to be correlated with the intensity of shaking. More specifically, they were observed to increase with decreasing R_{jb} distances. Despite permanent displacements reaching 1-2 meters in earth-fill dams, they have managed to retain water, and the absence of permanent deformations on downstream slopes and auxiliary structures is noteworthy. Figure 20 illustrates the dams experiencing permanent displacements at their crests exceeding one meter after the Kahramanmaraş Earthquake sequence.

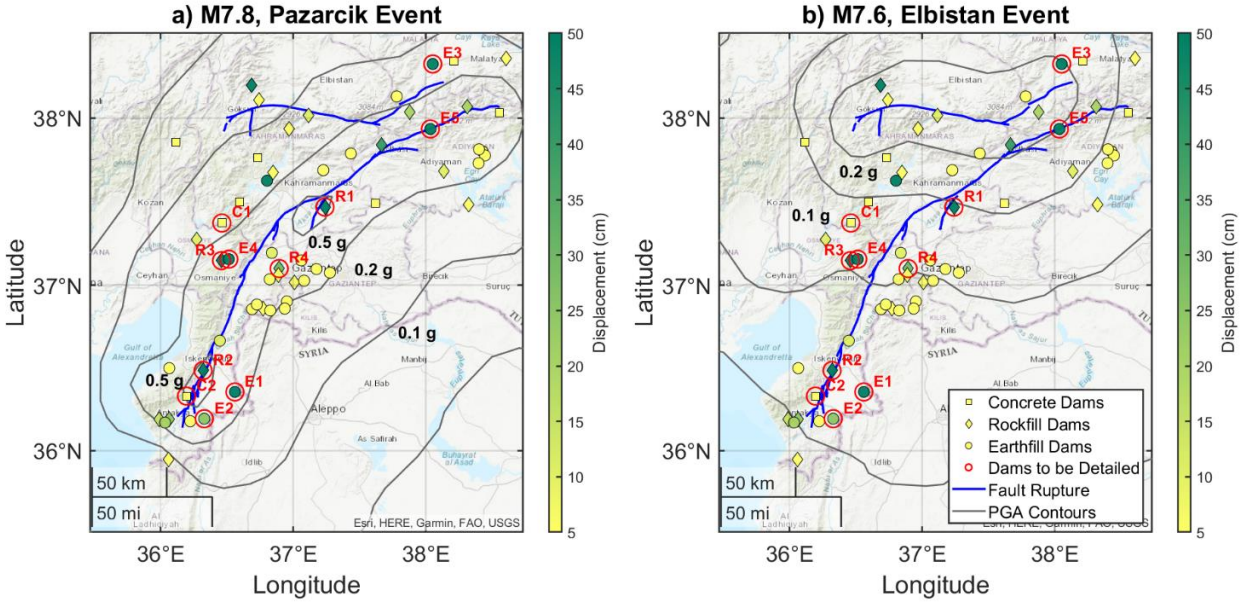

Figure 19. Spatial distribution of dams located within the R_{jb} distance of 50 km for both a) Pazarcık and b) Ekinözü-Elbistan Earthquakes and representation of documented lateral displacements after Cetin et al. (2024d).

Figure 20. Some examples of permanent ground deformations documented at earthfill dams, a) Reyhanli Dam, b) Ariklikas Dam and c) Sultansuyu Dam.

4 LESSONS LEARNED

The February 6, 2023 Kahramanmaraş Earthquake sequence yielded valuable and unique lessons for the earthquake and geotechnical engineering community, particulary in the following areas:

A. Seismic Hazard Assessment:

- Source Characterization: The sequence highlighted the importance of considering the possibility of multiple fault segments rupturing within a short timeframe, which may not have been adequately accounted for in seismic hazard assessments.
- Ground Motion Prediction Equations (GMPEs): It revealed discrepancies between the predicted and recorded ground motion intensities, especially in proximity to the fault rupture, emphasizing the need for improved GMPEs.

B. Geohazards:

- Fault Displacements: The earthquake sequence demonstrated significant fault displacements, underscoring the need for robust structural design and planning in seismically active regions.
- Seismic Soil Liquefaction: Instances of liquefaction-induced bearing capacity failures and ground deformations highlighted the vulnerability of structures built on liquefiable soils.
- Landslides and Rockfalls: The widespread occurrence of landslides and rockfalls emphasized the need for comprehensive slope stability assessments and mitigation measures.
- Strong Ground Shaking-Induced Soil Deformations: Observations of soil deformations in various infrastructure elements, including residential building foundations, retaining

structures, harbors and ports, dams, and airports, emphasized the importance of considering site-specific soil conditions and ground response characteristics in engineering designs and construction practices.

More specifically, the important observations, findings and lessons regarding **earthquake engineering** are detailed as follows:

i) The M7.8 Pazarcık-Kahramanmaraş earthquake was triggered due to the joint rupture of the Narlı, Pazarcık, and Erkenek fault segments along the East Anatolian Fault Zone. Similarly, 9 hours after this event, the Ekinözü earthquake hit the region with the combined rupture of the Çardak, Sürgü, and Doğanşehir fault segments again along the East Anatolian Fault Zone. This unexpected combination of multiple fault segment ruptures in both events, along with the occurrence of two design basis level seismic events within a period of 9 hours, were not fully considered in either deterministic or probabilistic seismic hazard assessment scenarios prior to these events. Multiple segment fault rupture scenarios should be given more consideration in seismic source characterization. Recent events have revealed that they might be more likely and frequent than we have considered them to be. Also, the occurrence of consecutive earthquake events in short periods and affecting the same region needs to be better assessed by the engineering community, with possible implications in earthquake design codes.

ii) The directivity and speed of fault rupture can significantly impact the ground shaking characteristics, including their intensity, duration, and frequency content. Hence, it is timely to seek better ways to represent directivity and fault rupture velocity effects on SGMR characteristics, with possible implications for earthquake design codes.

iii) The earthquake shaking duration should be incorporated as a design parameter. Seismic hazard maps for shaking durations, similar to those prepared for peak ground acceleration (PGA) or spectral acceleration, need to be developed. This will provide engineers and planners with a more comprehensive understanding of the seismic hazard and enable them to design structures that are resilient to the duration as well as the intensity of ground shaking.

iv) Further damaging effects of aftershocks on already damaged structures should be considered as part of design-basis scenarios, especially for critical infrastructure such as hospitals, bridges, ports, harbors, airports, and dams. These structures may need to provide uninterrupted service after a major earthquake, and accounting for the potential impact of aftershocks is crucial for ensuring their resilience and functionality. This consideration should be integrated into the design and planning processes to enhance the overall earthquake resilience of critical infrastructure systems.

v) Probabilistic fault rupture hazard assessments should be mandated for critical structures, including bridges, tunnels, and pipeline systems, located on active faults. By conducting these assessments, engineers and decision-makers can better understand the potential risks posed by fault rupture events and develop appropriate mitigation measures to enhance the resilience of critical infrastructure. This proactive approach can help ensure the safety and functionality of essential structures in the event of future earthquakes, ultimately reducing the overall impact on communities and infrastructure systems.

Similarly, important observations, findings and lessons involving **geotechnical engineering** are detailed as follows:

i) Seismic soil liquefaction is identified as a major cause of damage after the earthquake sequence. The lessons learned from previous earthquake events, such as the 1964 Alaska and Niigata earthquakes, have led to the implementation of additional preventive measures to mitigate liquefaction-induced failures in regions prone to seismic activity. For example, in California, USA, seismic demand corresponding to a 2475-year return period is now utilized for liquefaction triggering estimations in the design of residential buildings. This approach reflects a more comprehensive understanding of the potential risks associated with liquefaction and allows for more robust design solutions to be implemented. Therefore, adopting seismic demands corresponding to return periods longer than 475 years, preferably 2475 years, is recommended for liquefaction triggering evaluations in order to enhance the resilience of infrastructure and minimize the impact of liquefaction-induced damage.

ii) Under intense ground shakings characterized by peak ground acceleration (PGA) exceeding 0.4 g and long durations associated with moment magnitudes (M) greater than 7.0, significant reductions in both the strength and stiffness of fully saturated soft clays are observed. This phenomenon is particularly pronounced in sensitive clays with cone penetration resistance (q_c) less than 1 MPa or Standard Penetration Test (SPT) N_{60} values less than 7 blows per 30 cm. Engineering specifications should include a comprehensive discussion on the softening behavior of soft clays under cyclic loading conditions. Additionally, provisions should be made to address the potential need for mitigation measures to ensure the stability and performance of structures founded on such soils during seismic events.

iii) A guideline for calculating the bearing capacity of soils susceptible to strength and stiffness loss under cyclic loading is essential for ensuring the stability and performance of structures founded on such soils during seismic events. The guideline should offer a systematic approach for engineers to assess the bearing capacity of soils susceptible to strength and stiffness loss under cyclic loading, thereby enhancing the resilience of structures to seismic hazards.

iv) Due to excessive displacements and deformations observed on their approach embankments, despite the absence of structural damage on some critical viaducts (e.g.: Ataturk-Turgut Ozal and Başpınar Viaducts in Nurdagı-Gaziantep), they could not provide full service after the events. Approach embankments should receive equal attention to the structural elements of viaducts or bridges, therefore careful consideration is required in terms of material selection, compaction procedures, or the need for ground improvements.

v) The geometric and geotechnical properties of basins in urban areas should be evaluated, and seismic demand analyses should be performed for sites classified as ZD and ZE, according to TBEC-18 (equivalent to NEHRP site classes D and E).

vi) Deterministic landslide triggering maps should be developed for scenario earthquakes, and probabilistic seismic landslide hazard maps should be developed compatible with PSHA. These will enable to identify structures and settlements which could be affected by seismically triggered landslides and tockfalls.

vii) Stone gravity walls should be avoided as a retaining structure in hisgh seismicity areas. Instead, well-designed and constructed reinforced earth walls should be preferred.

viii) The filter materials in earthfill and rockfill dams typically consist of liquefiable sand and gravel. In adequate compaction of these materials lead to liquefaction and concentrated displacements at the filter interfaces.

5 SUMMMARY AND CONCLUSION

The earthquakes that struck Pazarcık and Ekinözü-Kahramanmaraş on February 6, 2023, along the East Anatolian Fault Zone (EAFZ), resulted in significant life losses and widespread destruction spanning a significant geographical area covering southeastern Turkiye and northwestern Syria. Among over 55,000 casualties, 92 were attributed to landslides and rockfalls. Unfortunately, the majority of casualties resulted from mass collapse and severe damage to residential buildings. Over 650,000 residential structures experienced mass collapse or severe damage during the earthquakes and became uninhabitable.

Peak Ground Accelerations (PGAs) recorded at distances from the fault exceeded anticipated levels, surpassing those specified in the Turkish Building Earthquake Code. In the field of Geotechnical Engineering, numerous case studies emerged, particularly in the regions of Adıyaman-Gölbaşı and Hatay-İskenderun, where soil liquefaction was predominantly observed.

Critical engineering structures such as bridges, viaducts, and tunnels generally performed well and continued service with limited interventions. A partial collapse in a railway tunnel was reported along with 7 bridges experienced moderate to heavy damage. Two of these bridge foundations suffered from liquefaction-induced deformations. In the earthquake-affected region, there are a total of 11 airports, and except the Hatay airport, the rest provided uninterrupted service despite the intense levels of shaking. The runway of Hatay Airport suffered damage due to fault movements and soil liquefaction, impacting its serviceability. The damage distributions spreading across a wide range were observed in retaining structures. While stone gravity walls were observed to suffer from ground displacements more frequent than reinforced concrete retaining systems, reinforced earthfill walls performed exceptionally well even after being subjected to intense shaking levels exceeding 0.5 g. All hydraulic structures maintained their water retention capabilities. Two of the 140 dams in the region, namely Sultansuyu and Arıklıkaş dams, suffered from permanent crest displacements mapped to be in the range of 1 to 2 meters. As part of emergency response measures, the reservoir levels at these were lowered in a controlled manner.

The earthquake sequence yielded valuable and unique lessons for the earthquake and geotechnical engineering community, particulary in the areas of seismology and seismic hazard assessment, more specifically in seismic source characterization and ground motion prediction models. Additionally, it provided case histories and lessons involving geohazards such as fault displacements, seismic soil liquefaction, landslides and rockfalls, permanent ground deformations.

Risk analysis and mitigation in geotechnical engineering – Lessons learned from the collapse of the historical archive in Cologne due to underground construction

Analyse et atténuation des risques dans l'ingénierie géotechnique - Enseignements tirés de l'effondrement des archives historiques à Cologne causé par une construction souterraine

ABSTRACT: In the field of geotechnical engineering, risks that materialise can have a significant impact on the serviceability and stability of a geotechnical structure, as well as its construction timeline. Additionally, these risks can potentially affect the surrounding environment. Those risks arise not alone from variable and complex characteristics of the subsoil and groundwater, as well as from design and modelling of the soil-structure interaction, but also from execution process. Hence, risk management must identify various sources of risk and conduct risk analyses to assess the probability and consequences of undesirable events. Risk control and mitigation measures should cover all stages of ground investigation, geotechnical interpretation, design and construction. These aspects are explored and reflected on the collapse of the Historical Archive of the city of Cologne as an example. On March 3rd, 2009, the collapse of the archive and adjacent buildings occurred during the construction of the new North-South metro line. This incident caused significant damage to the city of Cologne, but also affected the underground construction sector in general. With a total damage sum of around 1.2 billion euros, it stands as the most severe accident on a German construction site to date. The investigation of the damage evidence was a technically challenging task that lasted more than twelve years. It involved numerous steps, including the construction of a 34 m deep investigation shaft. Based on these experiences the consequences for the independent checking of design and execution, for the quality assurance of underground works and their supervision, but also the need for a risk prevention based on communication and partnership between all parties involved in the construction process is reflected.

RÉSUMÉ: Dans le domaine de l'ingénierie géotechnique, les risques qui se matérialisent peuvent avoir un impact significatif sur l'aptitude au service et la stabilité d'une structure géotechnique, ainsi que sur le calendrier de sa construction. En outre, ces risques peuvent potentiellement affecter le milieu environnant. Ces risques découlent non seulement des caractéristiques variables et complexes du sous-sol et des eaux souterraines, ainsi que de la conception et de la modélisation de l'interaction sol-structure, mais aussi du processus d'exécution. Par conséquent, la gestion des risques doit identifier les différentes sources de risques et mener des analyses de risques pour évaluer la probabilité et les conséquences d'événements indésirables. Les mesures de contrôle et d'atténuation des risques doivent couvrir toutes les étapes de l'étude du sol, de l'interprétation géotechnique, de la conception et de la construction. Ces aspects seront explorés et réfléchis à partir de l'exemple de l'effondrement des archives historiques de la ville de Cologne. Le 3 mars 2009, l'effondrement des archives et des bâtiments adjacents s'est produit pendant la construction de la nouvelle ligne de métro Nord-Sud. Cet incident a causé des dommages importants à la ville de Cologne, mais a également affecté le secteur de la construction souterraine en général. Avec un montant total de dommages d'environ 1,2 milliard d'euros, il s'agit de l'accident le plus grave survenu sur un chantier allemand à ce jour. L'enquête sur les dommages a été une tâche techniquement difficile qui a duré plus de douze ans. Elle a comporté de nombreuses étapes, dont la construction d'un puits d'investigation de 34 mètres de profondeur. Sur la base de ces expériences, les conséquences pour le contrôle indépendant de la conception et de l'exécution, pour l'assurance qualité des travaux souterrains et leur supervision, mais aussi la nécessité d'une prévention des risques basée sur la communication et le partenariat entre toutes les parties impliquées dans le processus de construction seront reflétées.

Keywords: Risk analysis; reliability; geotechnical engineering; collapse; risk mitigation.

1 INTRODUCTION

Dealing with uncertainties and risks is an omnipresent task in structural and geotechnical engineering. The key features distinguishing geotechnical and structural engineering are the natural origin of the ground and the lack of sufficient data to characterize the ground using the more familiar frequentist interpretation of probability (Chwala et al., 2022). Therefore, especially for the design of geotechnical structures an appropriate consideration of uncertainties and risks is essential for all engineering stages - from soil investigation, field and laboratory testing, specification of subsoil models and evaluation of soil/ rock properties to calculation with adequate empirical, analytical or numerical models, execution and supervision. The motivation to elaborate risk management and assessment is first and foremost the avoidance of danger to people and property but unquestionable also the elimination of financial and societal consequences a severe failure like the collapse of the historical archive in Cologne considered later can produce. Baecher (2023) discusses four case studies of large infrastructure projects from several continents, stressing remaining challenges of uncertainty quantification and interpretation in practice. Uncertainty in geotechnical engineering has several sources, and its quantification is difficult (Phoon et al., 2022), making risk analysis a complicated task. In geotechnical engineering the risk is related to a probability of failure or the probability of a specific event occurring and its consequence. A risk becomes unacceptable once the probability of failure or the probability of an event occurring and its consequence (directly on human and properties, but also financial or societal) becomes too large. Therefore, geotechnical engineers exert high efforts to estimate probabilities of failure of structures, i.e. their reliability, as accurately as possible using various different techniques (Baecher & Christian, 2003; Ang & Tang, 2007).

Reliability assessment of structures is regulated in ISO 2364, but Phoon et al. (2019) opt for an increased use of reliability-based methods over the conventional deterministic approaches since these are insensitive to variable data.

Ebner & Lesny (2022) investigated the opinion of the engineering practice in view of the second generation of Eurocode 7, where reliability-based design principles are increasingly adapted. The assessment of their survey revealed that one of the major limitations of the application of reliability-based design are perceived to be insufficient data, lack of acceptance and insufficient knowledge. Both, Ebner & Lesny (2022) and Baecher (2023) argue for an increased integration of statistical methods in engineering education.

Chwala et al. (2022) published a recent and detailed state-of-the-art report about risk and reliability in geotechnical engineering. Literature and international standards propose several techniques and guidelines for proper risk assessment, but in practice, risk analysis can lack the precision and unconditional consistency required to avoid disastrous accidents in geotechnical engineering.

The present paper documents some basic considerations on risk management (Section 2) and risk assessment (Section 3) in geotechnical design and on related uncertainty-informed decision making (Section 4) before two examples of back-analysis of failed structures, i.e. so-called forensic analyses, are presented (Section 5). Finally, the aspects of risk assessment are explored and reflected on the collapse of the Historical Archive of the city of Cologne as an dramatic case study (Section 6). On March 3rd, 2009, the collapse of the archive and adjacent buildings occurred during the construction of the new North-South metro line. With a total damage sum of around 1.2 billion euros, it stands as the most severe accident on a German construction site to date. The investigation of the damage evidence was technically a very challenging task that lasted more than twelve years. It involved numerous steps, including the construction of a 34 m deep investigation shaft. The concept for the investigations as well as the identified cause for the damage will be presented. Based on these experience consequences for the independent checking of design and execution, for the quality assurance of underground works and their supervision, but also the need for a risk prevention based on communication and partnership between all parties involved in the construction process is reflected (Section 7).

2 RISK MANAGEMENT

A general and practical guideline for risk management is specified by ISO 31000, which provides the principles and frameworks risk management should adhere to. In some countries, the corresponding national geotechnical societies have published their own technical guidelines, like Phoon et al. (2022), Spross et al. (2017) or van Staveren (2013) which do not deviate substantially from the principles of ISO 31000. According to ISO 31000, the key aspect of risk management is the iterative and systematic application of principles in the scope of value creation and protection. This circular process is illustrated in Figure 1.

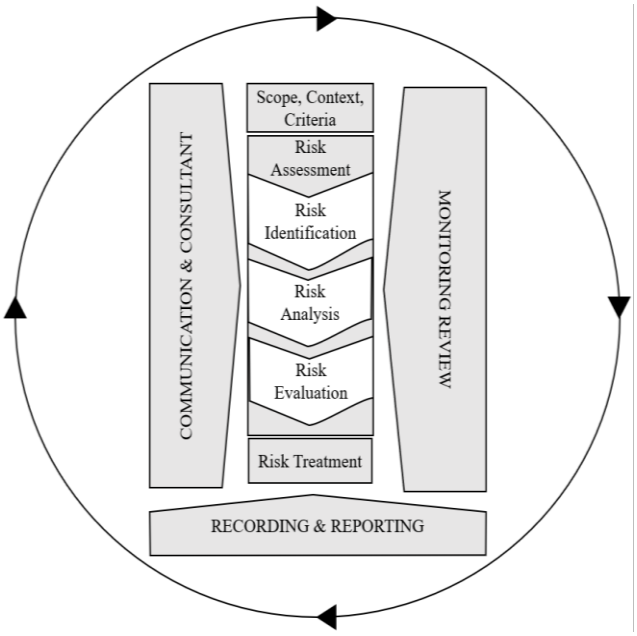

Figure 1. Process of risk management according to ISO 31000, Fig. 4.

The heart of this procedure is the assessment of risks, which is discussed in IEC/ISO 31010 in a general, non-subject-related way. All of these techniques and procedures are supposed to support the decision-making process, in a qualitative or quantitative approach.

2.1 Qualitative approaches

Qualitative approaches generally rank risks systematically, based on their probability of occurrence and their consequence. This is usually done in the early stages of a project, with few project specific data available. Key element is to try to estimate the probability of occurrence and the risk's consequence subjectively. A simple tool is the design of a risk matrix (Fig. 2), also called ´traffic-light matrix´ where identified risks are listed and compared based on their magnitude (Lacasse et al., 2019).

Engineering judgement plays a large role in risk management, assessment and decision making. Nevertheless, Baecher (2023) stresses the importance of "putting numbers on engineering judgement". It is argued that human judgment is flawed and biased, thus subjective estimates should be carefully reviewed.

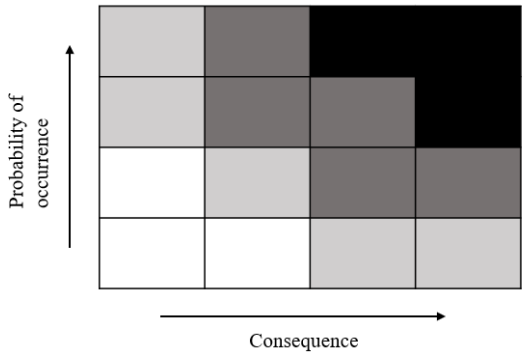

Figure 2. Qualitative 4x4 Risk Matrix.

2.2 Quantitative Approaches

As already mentioned, risk is defined as the probability of occurrence multiplied with its consequence. This common risk definition is flawed, since it accounts for low-probability/high-consequence risks equally as for high-probability/low-consequence risks. Depending on the project stakeholders, risk consequence must be defined differently (Baecher 2003). Quantitative risk management approaches aim to analyse these expected consequences based on known values. A common tool is to build a risk register. There, all risks are listed with their corresponding expected consequence and possibly other important information for the case of the risk occurring. Risk consequence is not trivial to estimate and is often known by a range in terms of cost. In that case, the expected consequence is usually calculated applying Monte-Carlo simulation to obtain the expected consequence distribution (NAP, 2018). A common and effective tool for risk management in a qualitative and/or quantitative manner is the analysis of event trees or logic trees. They provide an intuitive way of illustrating the progress of events. Here, "problems are decomposed into tractably small pieces and then brought back together to shed light on the prospect of system failures." (Baecher 2003). Event trees are similar to fault trees but fault trees start at the systems failure, leading back to an initial state.

Starting from an "initiating event", in the first level there is either a "success state" or a "failure state", both having a specific probability of occurrence. An event tree can have several levels or branches. This structure enables the assessment of different events occurring for complicated systems. An example of an event tree can be found in Figure 3. These risks and their probability of occurrence are usually depicted annualized. Event trees can become complex fast, with hundreds of events and branches. In reality, the probability of an event occurring is only for the simplest cases a constant value, but a function of several different parameters. For example, the grout anchor failure is dependent on its load. Event tree structure simplifies if the tree is regarded as a "model

of a physical system". This entails that only physical states are supposed to be modelled as events in the tree and other "states of nature" should be incorporated in the reliability analysis of the event governing the branch probability. Another option is to model states of nature within a logic tree, preceding event trees corresponding to a system. It is important to analyse geotechnical risks on the equal time axis, especially concerning natural hazards. At the end of an event tree branch one can accommodate a consequence tree, which is different type of event tree that models the failure state in more detail. To summarize, Logic trees can be utilized to model state of natures, event trees single system response and consequence trees the failure states (Baecher & Christian, 2003).

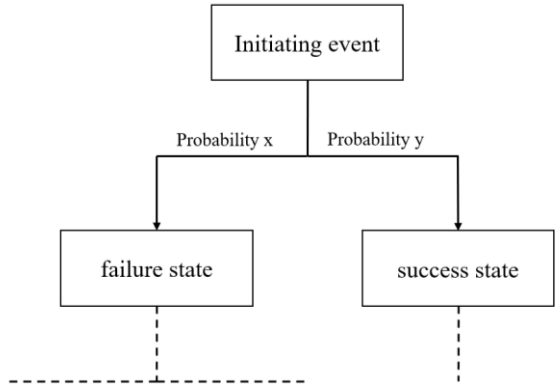

Figure 3. Event tree (simplified) according to Baecher (2003).

3 RISK ASSESSMENT

3.1 Uncertainty in geotechnical engineering

Risk Assessment is closely related to quantifying and estimating uncertainties and unknowns. Uncertainties are often separated in two categories, aleatoric and epistemic uncertainty.

Aleatoric uncertainty or random uncertainty is associated with processes whose variability comes from „a property of nature – independent of anyone's knowledge about it". Examples for these kinds of processes are more general dice throws or coin tosses i.e. repeatable experiments. In geotechnical engineering of soil properties are treated as aleatoric. Aleatoric uncertainties are per definition unpredictable and random, only natural hazard frequencies or spatial variations their relative frequencies of occurrence can be observed (Baecher & Christian, 2003).

Epistemic uncertainty stems from the engineering problem, that all models are imperfect, and cannot simulate completely accurate the conditions of real-world problems. Thus, epistemic uncertainty is characterised by *„imperfect knowledge"*, also *„knowledge based"* (Ang & Tang, 2008). Examples for these kinds of games uncertainties are card, or more geotechnically related model uncertainty or parameter transition uncertainty. Epistemic uncertainty is generally more subjective, meaning it is expressed less by frequencies but by the "*strength of belief"* in the truth or falsity of an event (Baecher and Christian, 2003).

Baecher and Christian (2003) advertise a slightly different naming and classification of uncertainty, which is more intuitive to the general engineer but does not differ substantially from the elaborations above. The authors discuss three categories of uncertainty:

- Natural variability
- Knowledge uncertainty
- Decision Model uncertainty

Thus, natural variability is a naturally random process approximated by statistical simplifications and knowledge uncertainty generally can be a lack of information. Underneath Decision Model uncertainty, the authors summarize other important sources like operational uncertainty, revolving around construction and human factors, or decision uncertainty which captures further construction management aspects of a problem like time preferences.

3.1.1 Spatial variability

The spatial variability of natural soil deposits was already recognised by Terzaghi (Wu, 2011). Currently, many research activities are devoted to the calculation of failure probabilities of complex systems using elaborate calculational models. Earlier publications like Duncan (2000) provide simple estimations, more applicable in a practical environment but less on complicated problems. Spatial variability is generally allocated to the 'natural variability' class of uncertainty. It means that observable geotechnical parameters are variable to different degrees in space, depending on their deposition and geological properties. Huber (2013) and Sudret & Der Kiureghian (2000) provide detailed reviews about how spatial variability can be treated in geotechnical engineering. In the following, common approaches to tackle special variability are elaborated in a simplified fashion.

A common way of describing spatial variability in subsoil is by applying random field theory. There are several ways of defining a random field (Liu et al., 2019), whereby in geotechnical engineering Gaussian random fields are mostly applied. Taking the measurements, the characterisation of spatial variability is carried out by separating the residual variation from a trend within the spatially varying soil property. The residual variation should be similar from the

different locations to be considered homogeneous. The random fields correlation properties are described by a correlation matrix, which is computed with an autocorrelation function. The autocorrelation function is supposed to approximate the statistical relationship of the spatially varying soil property in space. This implies that if data is plenty, a statistical analysis can be performed to determine the autocorrelation function by regression analysis. Common choices are exponential, second-order autoregressive or Gaussian usually calculated based on the scale of fluctuation (Li & Li, 2021).

Ching et al. (2023) investigated the two current trends of modelling spatial variability, sparse Bayesian learning and Gaussian process regression. They report the conclusion that Gaussian processes outperform sparse Bayesian learning in the case of 2D and 3D CPT measurements, and the other way around for 1D CPT measurements.

Random fields can also be utilized for reliability assessment using the Random Finite-Element Method. This numerical Monte-Carlo based approach computes the factor of safety of the system based on the statistical definition of the random field properties using Finite-Element analysis. Depending on the used techniques the calculated factors of safety can deviate substantially, compared to the 5% characteristic value specified by Eurocode 7 (Hicks, 2023). For more details and practical illustrations, the reader is referred to the works of Arnold (2016) and Varkey (2020). Liu et al. (2019) provides a general review about the advances in Gaussian random field generation.

3.1.2 Model uncertainty

Model uncertainty belongs to the class of knowledge- or epistemic uncertainty. It reflects the deviation between a prediction made by a model and measured behaviour. Model uncertainty influences the probability of failure strongly, which is why it should be accounted for (Phoon et al., 2022). ISO 2394 mentions a model factor, which is the ratio between the measured and predicted quantity. Zhang et al. (2015) introduced a technique based on two calculational models, one a numerical simulation, the other a mobilized strength model, calculating the top wall deflection of a cantilever retaining wall. The approach involves splitting the model factor into several different components. Their introduced correction factor splits into systematic and residual component. With the correction factor, first the model factor of the numerical model is determined, second the model factor of the analytical model is evaluated.

Bayesian methods can also be applied for determining the model uncertainty (Zhang et al., 2009) within that framework the model uncertainty is quantified by assuming a normally distributed model error with a mean value and standard deviation. Bayes Theorem is used to update these quantities accordingly. The procedure is illustrated with data of centrifuge modelled slopes to calculate the model uncertainty of common analytical methods for slope stability assessment.

3.1.3 Human factors

Sowers (1993) performed a comprehensive analysis of over 500 case studies of reported civil engineering failures. The author identifies three main causes of failure: absence, ignorance, and rejection of current technologies. Absence of knowledge or current technology denotes the cause of 12 % of failures. This includes lack of data, i.e. the magnitude of a 1000 year return period extreme weather event. It is argued that "blindly" relying on an estimation, based on the observed time period is ignorance or rejection. Ignorance is encountered by the author often in shape of a "know-it-all" attitude of engineers, who are often not properly qualified or experienced enough for specialized and complex problems. This cause is linked to 33 % of failures. Over 55 % of failures are classified in the rejection category, which includes several different aspects. The major ones that lead to rejection are faulty communications, pressures on the engineer like time, economical or ecological constraints. Thus, 88 % of failures can be appointed to human error. Some of the proposed mitigating measures are persisting engineering education, recognition of limitations and "resisting the unbalanced pressures that thwart good engineering" (Sowers, 1993).

Bea (2006) extends this discussion by reflecting the advances made in the field of quantifying uncertainty due to natural variation or model uncertainty even though these sources account for only 12 % of failures compared to the 88% influenced by human errors. The author introduced a framework that aims to include human, organisational, and knowledge related factors with existing reliability-based techniques. Different methods are proposed: proactive, reactive, and interactive. Each approach is linked to a different time where measurements are taken to either decrease the likelihood of failure occurring, adhere failure prevention based on analysis of near failure conditions, or intervening with proper management whilst failure builds up and thereby preventing its occurrence (i.e. the observational method, further discussed in section Decision Making). An example of an initial design for an offshore platform in mudslide prone territory is provided, where the probability of failure is evaluated based on intrinsic uncertainty (here, natural variation of the soil and analytical model

uncertainty), and based on extrinsic factors – probability of failure given a mudslide. The total probability of failure is strongly governed by the extrinsic probability failure, implying a short life time of 25-30 years of the structure. Overall, the author encourages the application of the outlined approaches like the use of the observational method for amending quality and reliability in geotechnical projects (Bea, 2006).

3.2 Reliability assessment

In geotechnical engineering, risk is defined as the product of probability of occurrence and the consequence, where the consequence is often defined in terms of financial cost but can take different shapes depending on the geotechnical structure and the failure mode (Einstein & Baecher, 2023).

The aim of geotechnical reliability analysis is the estimation of a probability of failure. ISO 2394 provides general guidance not limited to geotechnical engineering, Hereby ISO 2394 distinguishes between risk-informed and reliability-based approaches, where the difference lies in the incorporation of the consequences of failure.

3.3 Probability of failure

For the evaluation of the probability of failure, a performance function *g(x)* needs to be defined in dependence of a single parameter (random variable) *x* or a parameter vector $\bar{x}$. The performance function $g(\bar{x})$ indicates the failure domain of the system response if $g(\bar{x}) < 0$. If $g(\bar{x}) > 0$, the system would be in the safe domain (Fig. 4).

The parameters or random variables are described based on their statistical distribution (i.e. mean value and standard deviation for a normal distribution). For the calculation of the probability of failure, the joint probability density function $j(\bar{x})$ is needed, the mathematical formulation is defined as,

$$P_f = \int \dots \int_{g(x)<0} j(\bar{x}) d\bar{x} \qquad (1)$$

where the performance function is integrated with respect to each random variable. Depending on the system and the performance function, the integral usually is not solved analytically, but by simulation.

Another common method in geotechnical engineering is to express the reliability in terms of the reliability index β. If the performance function $g(\bar{x})$ is linear and the random variables are normally distributed,

$$P_f = \Phi(-\beta) \qquad (2)$$

with β being the ratio between mean μ_g and standard deviation σ_g of the performance function $g(\bar{x})$ and Φ being the standard normal cumulative distribution function. Here, a larger reliability index, results in a smaller probability of failure (Ji and Cao, 2023).

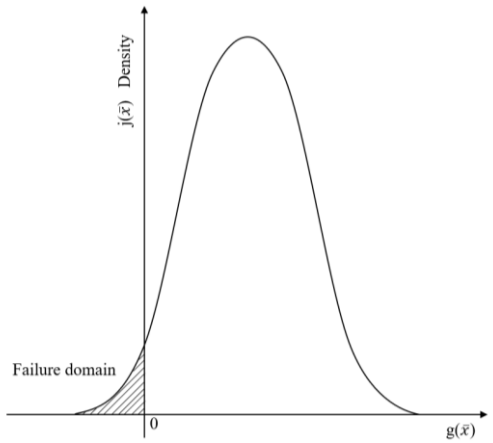

Figure 4. Illustration of the failure domain of a performance function.

The concept of a factor of safety is for many engineers that are not familiar with probabilistic methods more intuitive and the reliability index β can also be expressed in dependence of a calculated factor of safety *F*,

$$\beta = \frac{\mathrm{E}[F]-1.0}{\sigma[F]} \qquad (3)$$

with, *E[F]* being the expected value (or mean) of the factor of safety *F* and *σ[F]* being the standard deviation of the factor of safety (Christian et al., 1994). The formulation of the reliability index β enabled different analytical solutions that are capable of estimating the systems probability of failure, like the First-Order-Reliability-Method (FORM) or the First-Order-Second-Moment (FOSM) which are only discussed conceptually and simplified in this article.

Assuming the statistical distributions of necessary input parameters are known, to calculate the reliability index defined in Eq. 3, the expected value of the performance function (in this case the factor of safety formulation) and its standard deviation are necessary for evaluation. Based on a Taylor series approximation and assuming no correlation of the variables, the standard deviation is

$$\sigma[F] \approx \sum_{i=1}^{k} \left(\frac{\partial g}{x_i} \cdot \sigma_{x_i} \right) \qquad (4)$$

FOSM approximates the second moment of the performance function, using the second moments (standard deviations) of the variables with a first order truncated Taylor series. One limitation is, that the shape of the distribution of the performance function must be known for the calculation of reliability index

and/or probability of failure. A second limitation lies in implicitly assuming constant derivatives over the entire performance function domain using the Taylor approximation, (Baecher & Christian, 2003; (Christian et al., 1994). Further illustrations and more details are elaborated by Duncan (2000).

The FORM estimate eliminates the need of knowing the shape of the performance function. FORM lacks accuracy with increased non-linearity of the performance function. Then more orders of the Taylor approximation can be included into the formulation, making it more complicated but a more accurate linearization. The concept of FORM based on Hasofer & Lind (1974) is to first transform the correlated variables into uncorrelated Gaussian Space with the Rosenblatt transformation. In Gaussian space the joint probability density is supposed to be maximised with regard to the largest area in the failure domain. This corresponds to the minimum distance from the origin to the so-called design point. Thus, the FORM procedure is an optimization problem to find the minimum distance of the design point, which also corresponds to the definition of the reliability index β, which is often done using the Rackwitz-Fiessler iteration sequence. With the reliability index, the probability of failure can be estimated (Bucher. 2009).

FORM is one of the most common tools for reliability assessment in civil engineering, with various literature available. The implementation of FORM can be done in several different computational frameworks. For more details the reader is referred to the original source (Hasofer & Lind, 1974) or works published by Bucher (2009), Baecher & Christian (2003) or Ji & Cao (2023).

Another common approach to reliability assessment is by simulation applying Monte-Carlo analysis. There, the shape of the performance function does not need to be known and it does not need to be linear. Monte-Carlo involves solving the performance function for a large amount of simulations, depending on the accuracy required. The probability of failure can be expressed as,

$$P_f \approx \frac{1}{m}\sum_{i=1}^{m} I(g(\bar{x}^{(i)}) \quad (5)$$

with $I(g(\bar{x}^{(i)}))$ being an indicator function. Its result is either 0 if $g(\bar{x}^{(i)}) > 0$ (safe domain) or 1 if $g(\bar{x}^{(i)}) < 0$ (unsafe domain) for one sample i of $\bar{x}$. The "confidence" in the estimate of P_f becomes larger for a larger number of simulations m. The variance of the failure estimate is expressed as,

$$\sigma_{P_f}^2 = \sqrt{\frac{P_f}{m}} \quad (6)$$

For an infinite amount of simulations, the probability of failure would become exact. Especially the evaluation of low failure probabilities becomes computationally expensive and inefficient, which is why often more elaborate sampling techniques are employed like importance sampling, directional sampling, subset simulation, etc. (Bucher, 2009; Phoon et al., 2022).

Beer et al. (2013) discuss further on numerical reliability assessment techniques such as interval modeling, fuzzy modeling, Monte-Carlo simulations, and the idea of imprecise probabilities.

3.4 Metamodelling

The idea of applying surrogate-metamodeling and other machine learning techniques has gained popularity in recent developments revolving around reliability assessment of geotechnical structures. The motivation lies in the substitution of complex (numerical) formulation with an approximation of less computational cost. The combination of a metamodel with advanced sampling strategies enables the computation of low failure probabilities. One common technique is the Kriging approach, that has its origin in geostatistics for modeling spatial variability of soil properties. Zhang et al. (2011) define a Kriging model with Gaussian correlation and calibrate this model based on N simulations of a numerical model. This is performed by a maximum likelihood estimate, which is defined as a multivariate normal distribution based on the assumption that the N simulations can be modelled as a Gaussian random field. Once the model is calibrated, the performance function is evaluated for additional predictions. This is illustrated for a pile capacity model, a single foundation in layered soil and a slope in layered soil. The authors use the FORM approach for further reliability analysis.

Another application is described by van den Eijnden et al., (2022), where a metamodel is formulated using Gaussian processes, capable of updating the reliability of a river dyke. For the reliability analysis an active-kriging based Monte-Carlo simulation algorithm is proposed, that learns two Gaussian processes - one for prediction, one for classification - based on convergence criteria. The second metamodel is needed to classify the parameter space into separate domains depending on whether a converging solution can be found. This step is important to incorporate survival data i.e. a state of the construction process, where the numerical model calculated failure, but it did not occur in reality. This procedure is separately treated by van der Krogt et al. (2021).

Ordinary Kriging and Gaussian processes are often used and they are quite similar, in procedure and results. One of the main differences can be on how inferences are performed, either based on Maximum likelihood or variography, even though the results are nearly identical (Christianson et al., 2023).

Teixeira et al. (2021) provide a recent review about metamodeling approaches for reliability analyses. They compare the four most common techniques, response surfaces, polynomial chaos expansions, support vector machines and Kriging models. The Kriging model can be described as robust and versatile compared to the aforementioned methods, also being the only one capable of handling strongly non-linear performance functions. Nevertheless, the authors stress the necessity for hierarchical techniques for selection of the modelling approach and its assumptions.

3.5 Bayesian modelling

Bayesian approaches are also a trending field in geotechnical reliability analysis, since they offer the opportunity to draw inferences with a comparably scarce data basis. Based on this inference, uncertainty can be comfortably quantified. Various type of data can be used, completely depending on the statistical model that is defined. In geotechnical engineering, measurement data is frequently used for reliability updating.

One similar application is described by Jiang et al. (2018, 2022) and Geyer et al., (2021), where Bayesian techniques are used to update spatially varying soil parameters, described by random fields using field measurements. De Wolff et al. (2021) propose a Bayesian approach to update the retaining wall performance of deep excavation, using real-time measurement data. Hereby, wall-deflection measurements, obtained through the observational method, are used to update the model parameters of a spring model for computation of wall deflection. Baecher (2017) argues, that Bayesian methodology enables quantitative data analysis with regard to the observational method instead of the qualitative assessment. The author advocates these approaches to permit the observational method a computable interpretation, making stronger use of data and allowing distinct inference.

3.6 Consequence

The consequence in risk analysis is usually expressed in terms of cost, number of fatalities or a combination of both. Therefore, a common way of depicting risk is via probability-consequence charts or frequency-number (*FN*) charts. Figure 5 shows a *FN* Chart for the tolerable risk of different guidelines according to Lacasse et al. (2019) for dams, slopes or in a more general context. The Hong Kong guideline (Mak, 2006) is one of the most frequently used criterions. Even though the lines provide a clear distinction, the difference between acceptable and unacceptable risk is in practice less abrupt but more fluent. For cases where the fatality is larger than 1,000, a detailed assessment is recommended. Furthermore, it is suggested to define ALARP zones (´As Low As Reasonably Possible´), where the risk cannot be decreased without taking excessive and unreasonable measures. These could be generally implemented for low probability-high consequence risks, or for a number of fatalities > 1,000 (Lacasse et al. 2019; Mak, 2006).

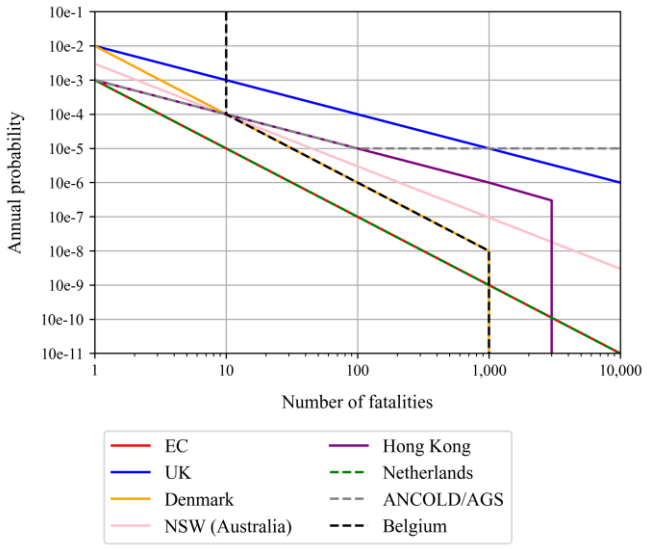

Figure 5. combined FN Chart of different guidelines for slopes, dams and general acceptance according to Lacasse et al. (2019).

4 DECISION-MAKING

Burland (1987) proposed the ´soil mechanic triangle´, later renamed the ´geotechnical triangle´, where he combines the fundamentals of geotechnical engineering, reflecting the views of Terzaghi, Casagrande and Peck, with one of its original purposes of guiding the development of soil mechanic courses. Phoon et al. (2022) extended the triangle by incorporating further sources of uncertainty associated with the main three elements in geotechnical engineering (Fig. 6):

- ground profile
- soil behaviour
- idealised model

All of the assumptions revolving around these key elements are to some extent uncertain, which is why one aims to quantify these uncertainties in the scope of

decision-making and risk management (Phoon et al., 2022). The extended triangle lists techniques and other points of attention to support the decision-making in geotechnical engineering projects.

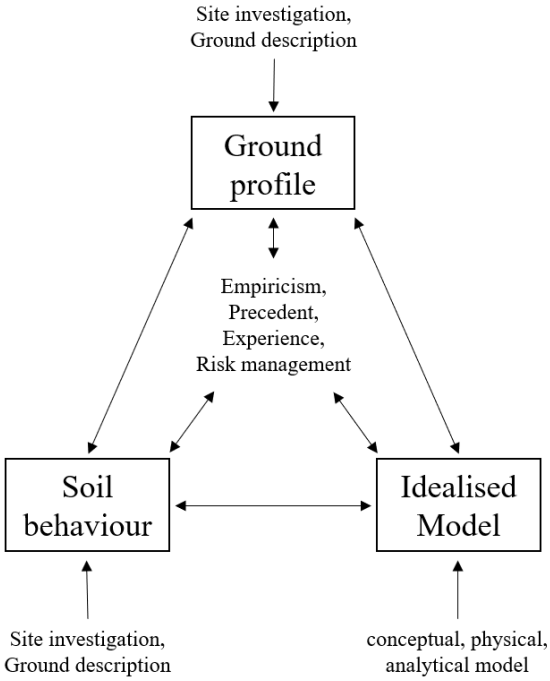

Figure 6. Geotechnical triangle according to (Phoon et al., 2022) and (Burland, 1987).

Phoon et al. (2022) list a large number of tools to quantify uncertainty of various sources and complexities. All of these approaches and numerical methods in general are supposed to aid the engineer to perform uncertainty-informed decision making, stressing the need for uncertainty quantification.

One of the earlier, non-calculational tools for uncertainty assessment is the widely applied observational method. It was first introduced by Terzaghi as "learn-as-you-go" and later backed-up by Peck (1969). It is a common technique in geotechnical engineering supporting risk management and decision-making. The key concept is to propose a design based on the available information at that time whose resulting magnitude can be measured on site. Next, a field measurement concept is introduced, aiming to measure quantities that can be related to the initial design assumptions and reduce uncertainty about site conditions. Based on the measurements, the uncertainty about site conditions decreases and the initially proposed design can be adapted as necessary (Wu, 2011).

Wu (2011) discusses the successful application of the observational method based on several case studies of embankment construction. The applications are versatile, i.e. the improved estimate of highly sensitive model input parameters or Bayesian updating of the material properties of a Finite-Element model.

The observational method is an intrinsically Bayesian concept, which optimally can be coupled. Bayesian thinking and Bayesian analysis enables a quantitative evaluation of the observational method (Baecher, 2017).

Einstein & Baecher (2023) elaborate on Bayesian ways to support decision-making. They provide two examples of large-scale tunnelling projects, the Gotthard-Basis-Tunnel and the Brightwater Conveyance Tunnel Seattle. For the Gotthard-Basis-Tunnel Bayesian methods where applied in combination with the observational method to predict the tunnelling cost and schedule, applying the Decision Aids for Tunnelling computational tool. This is achieved by updating the lithology section-wise using geological data, boring information, etc.

5 FORENSIC ANALYSES

In literature there are several examples focussing on the back-analysis of failed structures, called forensic analyses. In the following, two examples are illustrated.

5.1 Slope collapse in Taiwan

In the year 2010 a landslide occurred on Taiwan's' Freeway No. 3, north of Taipei (Fig. 7). As cause of failure Wang et al. (2013) reported a worsened shear strength of the soil and degenerating anchors.

They obtained this conclusion by conducting a Bayesian probabilistic analysis to calculate the soil shear strength (friction angle) and the ground anchor forces. The adjacent rock stratigraphy exhibits dipped slopes with an inclination of 10° to 30°, thus the slope was highly prone to sliding on a rock surface to begin with (Wang et al., 2013).

Figure 7. Landslide 2010 on Freeway 3 in Taiwan, (source: https://www.nasc.gov.tw).

For Bayesian analysis in geotechnical engineering there are generally no closed form solutions available since the formulated likelihood functions are not conjugate with the prior distributions. Therefore, Wang et al. (2013) utilized a Markov Chain Monte Carlo algorithm called Metropolis-Hastings to calculate the posterior distribution (probability distribution for a given data set) with defined lognormal prior distributions and likelihood function. The likelihood function connects a factor of safety formulation based on a slip surface limit equilibrium formulation with an error term. The study reports only the lognormal marginal distributions and not the joint distribution or the posterior predictive function. The authors focus on an illustrating the comparison of a Maximum Likelihood analysis compared to the full Bayesian approach. Nevertheless, the benefits of performing a statistical analysis of this case study are laid out, since the results aid in interpreting the cause of failure, governing the decision making for the remediation. Based on this collapse, the authors stress the importance of anchor maintenance.

5.2 Levee failure in Breitenhagen

Kool et al. (2019) describe a comprehensive forensic analysis of the Breitenhagen levee breach (Fig. 8). In 2013 the rivers Elbe and Saale in Germany exhibited high water levels which was partly a cause for the breach of a levee located close to the confluence of both rivers, in proximity to the village Breitenhagen.

Figure 8. Levee failure at Breitenhagen, aerial view (source: Kool et al. 2019).

The forensic analysis was conducted non-probabilistic. Therefore, the likelihood of occurrence was estimated subjectively, which is concluded not to be the optimal way of assessment. Furthermore, it is claimed that the results were majorly influenced by the lower bound soil parameters, especially a low cohesion, which had to be estimated based on Dutch and German codes. Nevertheless, the authors provide a detailed framework for the forensic analysis of levee failures. It involves the definition of an initial model based on the available data and modelling boundary conditions to justify the model choice. Based on elaborate sensitivity analysis the model input parameters are systematically varied as scenarios. The evaluation of the scenarios allows insight to identify the most likely scenario corresponding with the failure condition. Kool et al. (2021) extend this study with the incorporation of a Bayesian approach for the back-analysis. The authors use FORM for the reliability assessment, and can reach via the Bayesian method a more objective estimate of the most likely scenario matching the failure.

6 CASE STUDY: COLLAPSE OF THE HISTORICAL ARCHIVE IN COLOGNE

On March 3rd, 2009 the Historical Archive of the City of Cologne, Germany, and adjacent residential buildings collapsed (Figs. 9 and 13). These buildings were located at the square ´Waidmarkt´ in the immediate neighbourhood to the deep excavation ´GWB´ which was part of the construction work for a new 4.3 km long north-south underground line in Cologne. At the time of the accident the final excavation level had just been reached around 26.6 m below ground level. The collapse was a dramatic loss for Cologne's urban society but has also a severe impact on other underground and infrastructure construction activities. With a damage amount evaluated to around 1.2 billion euros it was the most serious accident on a German construction site to date.

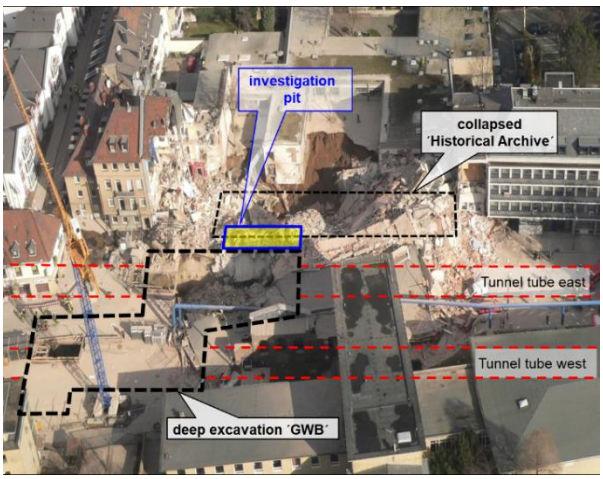

Figure 9. Aerial view of the collapsed Historical Archive and neighbouring residential buildings on Cologne's Waid-markt immediately after the accident on March 3rd, 2009.

After phases of immediate stabilisation, salvage and an initial survey, the cause of the damage was clearly clarified through a technically highly demanding investigation of evidence lasting more than twelve years, during which, among others, a 34 m deep

inspection shaft was executed in direct neighbourhood to the potentially damaged diaphragm wall of the deep excavation ´GWB´. As the measures for the conservation of evidence and for the investigation of the cause of damage were concluded and based on that a settlement between employer and construction joint venture was reached in 2020, it is possible to report on the measures and the identified cause of damage.

6.1 Deep excavation ´GWB´

The excavation pit ´GWB´ was constructed with diaphragm walls with wall thicknesses of 1.0 m and 1.5 m. With regard to the stabilisation against hydraulic ground failure the diaphragm walls were embedded up to 45 m below ground level, i.e. a lower wall edge of 2.8 m above sea level (a.s.l.) in the corner areas and 6.25 m a.s.l. on the long sides of the walls considering the higher hydraulic gradients resulting from the spatial inflow at the corners of the excavation (Aulbach & Ziegler, 2013).

The retaining walls were anchored in the upper part and braced by two reinforced concrete slabs constructed during excavation at 10.0 m (37.8 m a.s.l.) and 17.3 m (30.5 m a.s.l.) below ground level (Fig. 10a).

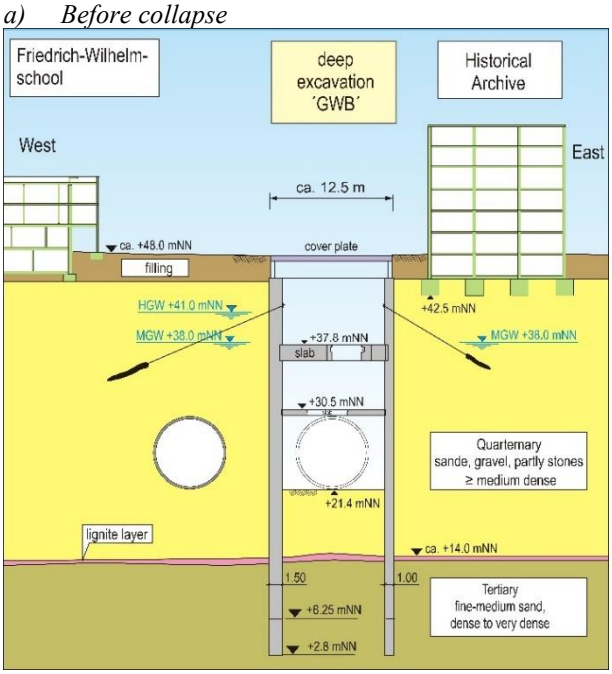
The dewatering in the ´GWB´ pit was carried out via wells arranged in the footprint of the excavation pit and filtered in the quaternary and/or tertiary, which led to a lowering of the free groundwater level in the quaternary and a (partial) relaxation of the tertiary aquifer. Within the diaphragm wall enclosure the groundwater level in the quaternary layers was lowered by open dewatering.

Overall, the realised excavation corresponds to the in the past often successfully realized concept of a "tertiary excavation pit" with water-pressure-retaining walls embedded into the tertiary in conjunction with an internal tertiary dewatering system to relieve the hydraulic head in the Tertiary below the excavation bottom. The relief of the tertiary hydraulic head is essential to ensure the hydraulic stability of the excavation base and to minimise upward flows in the earth resistance area of the retaining walls.

6.2 Subsoil conditions

The subsoil conditions at the ´Waidmarkt´ site are illustrated for a east-west section in Figure 10. Below street level and up to 6 m thick fillings Pleistocene terrace deposits (Quaternary) down to a depth of around 14 m a.s.l. which consist of terrace gravels and sands of the Rhine of varying grain size and composition, into which cohesive, slightly silty secondary sediments and isolated cohesive layers of decimetre thickness can be incorporated in some areas.

a) Before collapse



b) After collapse

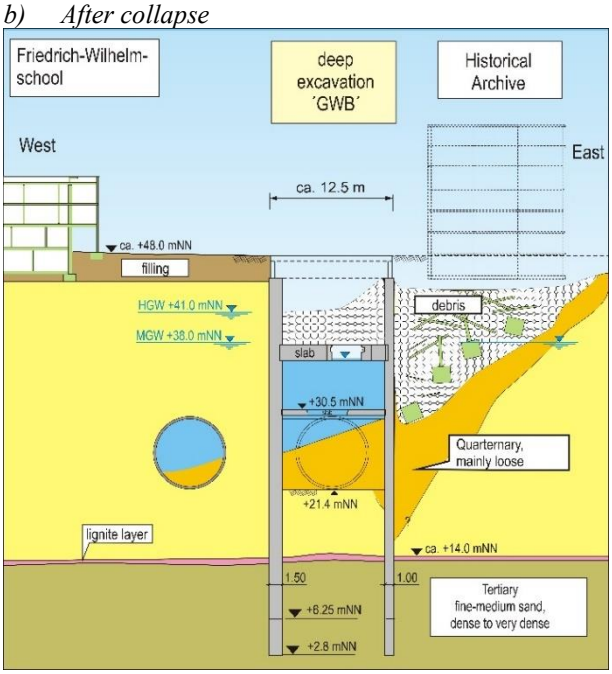


Figure 10. East-west section through the deep excavation ´GWB´ with neighbouring buildings and subsoil situation (position of section corresponds to section 1-1 in Fig. 11).

Separated from the terrace body by a thin layer of tertiary fine sand, the surface of an Oligocene lignite layer is reached at approx. 14.0 m a.s.l. which was explored in predominantly continuous thicknesses of 0.7 m to 1.8 m, but is also exposed locally.

The lignite is underlain by tertiary dense to very dense fine-medium sands which were exposed as a largely uniform layer with a thickness of approx. 48 m down to a depth of -35 m a.s.l. Due to their high uniformity ($C_U \leq 2$) and their mica content, the water-filled tertiary sands can be easily hydraulically

mobilised what must be considered for dewatering, drilling works etc.

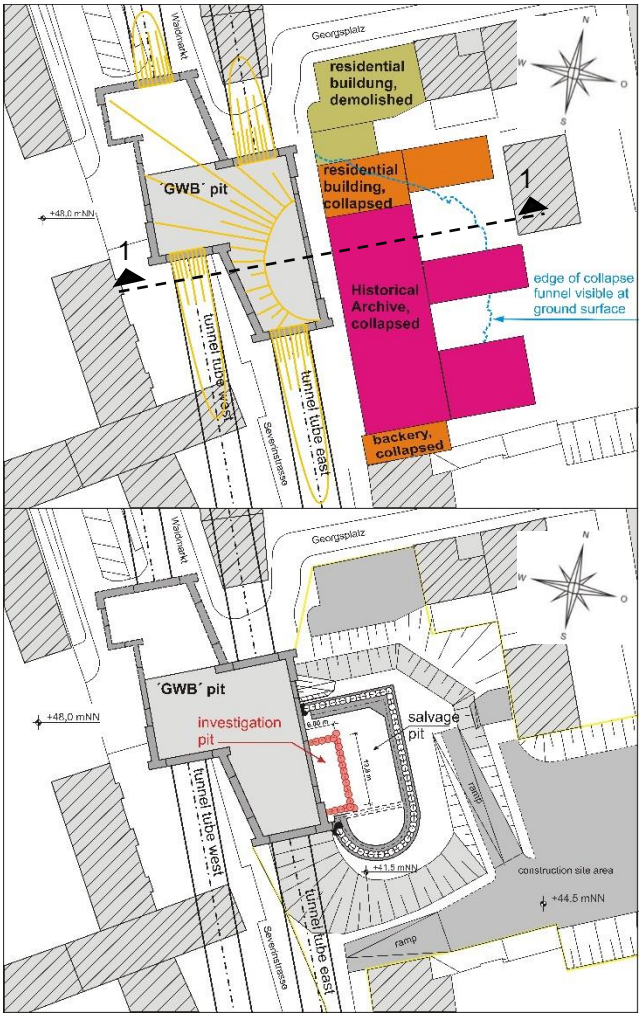

Figure 11. Site plan of the deep excavation ´GWB´ at ´Waidmarkt´ square in Cologne, a) at the time of the collapse with existing buildings and upper edge of the failure funnel, b) with salvage pit and investigation pit after the accident during salvage and preservation of evidence.

Concerning the groundwater situation, two aquifers have to be considered, a quaternary and a tertiary aquifer. The local hydrogeological conditions at the ´Waidmarkt´square are strongly influenced by the river Rhine and its water levels, both in terms of groundwater levels and the direction of groundwater flow. The groundwater levels in the Quaternary follow the water levels of the Rhine, which is located approx. 400 m east from ´Waidmarkt´, with a slight attenuation and generally fluctuate between approx. 36.5 and 40 m a.s.l.; at high tide whereat water levels of 41.5 m a.s.l. and more are reached in exceptional cases. The groundwater levels in the tertiary aquifer are at around 36 to 39 m a.s.l. and also follow the changes in the Rhine level with slight attenuation.

6.3 Execution of the deep excavation

The diaphragm wall was already constructed in 2005 using the conventional two-phase method. As joint system lost flat steel profiles were used which had a smooth surface on the side of the subsequent panel. When excavating the neighbouring panel, the tool used for cleaning the joint and removing concrete that has flowed in behind the joint profiles was therefore not guided by the joint construction. In fact, the cleaning of the diaphragm wall joints resp. stop ends was only partially successful, so that in the course of the excavation leaks occurred in several places at the joints, which required sealing measures to stop local water inflow.

An analysis of the execution records of the diaphragm wall carried out after the accident shows that obstacles were encountered during the production of panels #10 and #11 (Fig. 12) of the eastern diaphragm wall. During the construction of bite #10.3, obstacles were encountered at a depth of approx. 25 m (21.8-22.8 m a.s.l.) which made the use of a chisel necessary. The problems were even more severe during the following construction of the neighbouring panel #11, which was planned as a 3.4 m wide single bite closing panel being the last panel to be executed for the whole ´GWB´ pit. Massive obstructions were encountered in this panel at a depth of approx. 23 m (23.2-22.8 m a.s.l.), which caused a damage to the grab shells used. This obstruction could not be removed even with the use of chisels. In consequence, the grab shell was changed from 3.4 m to 2.8 m wide and the excavation of panel #11 was continued to the final level. An evaluation of the recorded concrete consumption shows a lower additional consumption for panel #11 compared to the theoretical concrete consumption than for the other panels. It was not possible to precisely analyse the increase or decrease in concrete consumption over the height due to the small number of measuring points; however, a decrease in concrete consumption up to the height of the obstacles encountered is recognisable.

With regard to the quality assurance and records of the diaphragm wall construction, further anomalies were identified, e.g. identical logs of the verticality measurements of panels #5 and #11 as well as missing acceptance records of the reinforcement cages and indications of missing shear reinforcement which had to be added on site in the course of coupling the reinforcement cage sections over the open trench.

After excavation of the ´GWB´ pit to the lower edge of the cover plate (Fig. 10a) and construction of the cover plate at street level, excavation was interrupted for tunnelling with TBMs passing in 2007 the non-excavated pit during the shield drive for the

construction of the eastern and western tunnel tubes, before further excavation below the cover plate was continued applying a top/down method in 2008.

Parallel to the further excavation, dewatering was carried out in the excavation pit, initially with four discharging wells (B1 to B4) and four relief wells (E1 to E4) connecting the tertiary with the quaternary aquifers (Fig. 12). As it was not possible to achieve with these wells a groundwater drawdown corresponding to the excavation progress and, in particular, the necessary relief of the hydraulic head in the tertiary aquifer three further discharging wells and a total of 19 additional wells were successively installed (Fig. 12). The recorded water extraction rates show that despite the roughly constant water level differences between the outside and inside water levels over a longer period of time, a significant increase in the extraction rate from around 115 l/s (corresponding to 414 m³/h) to around 180 l/s (648 m³/h) and a maximum of >200 l/s (720 m³/h) was recorded at the beginning of December 2008 in connection with the commissioning of additional wells. These pumping rates were significantly higher than the expected water extraction rates.

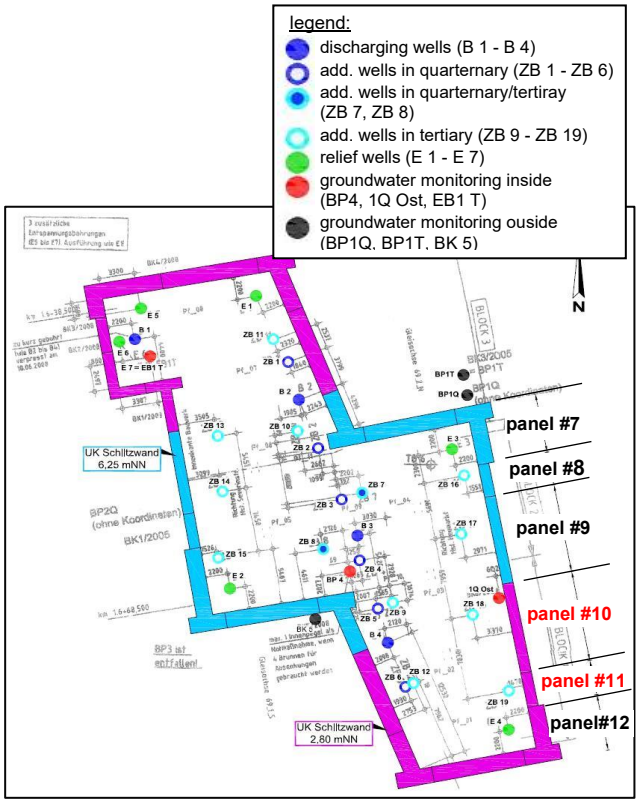

Figure 12. Ground plan of the excavation pit ´GWB´ with groundwater discharching and relief wells; status before collapse in March 2009.

At the time of the accident in March 2009, the ´GWB´ pit had largely been excavated to the final excavation level: while the reinforcement of the floor slab had already been laid on the clean layer in the western section, the excavation of the last 0.3 m for the construction of the final subgrade was carried out in the eastern section, starting from the rough subgrade. At midday on March 3rd, 2009, work began on the construction of a pump sump for water collection below the planned final excavation level in order to control water ingress from the diaphragm wall in the area of the joint between panels #10 and #11 (positon of panels marked in Fig. 12).

6.4 Collapse of March 3rd, 2009

On March 3rd, 2009, at 13:58 pm, an accident occurred in the deep excavation ´GWB´ during which about 5,000 m³ of sand and gravel flowed into the excavation pit, causing the collapse of the adjacent ´Historical Archive´ of the City of Cologne, a massive 7-storey reinforced concrete skeleton building, immediately adjacent to the excavation pit to the east, as well as of parts of the adjacent multi-storey residential buildings on both sides (Fig. 11a). The spread foundation of the Historical Archive, consisting of single and strip foundations founded in the quaternary sands and gravels, sank into the ground (Fig. 10b); foundations were later recovered from a depth of up to 20 m below ground level. This sudden “loss of foundation” caused the building to tilt towards the street, then to completely collapse, thereby partly falling into the excavation pit, breaking through its covering (Figs. 9, 13). The soil inflow at the lowest level of the excavation pit resulted in the formation of a cone of debris up to 7 m high consisting of quaternary sands and gravels, the foothills of which reached into the four tunnel tubes (Fig. 11a) and whose greatest height was directly in front of the eastern diaphragm wall (Fig. 10 b and 11b). Although the workers fleeing from the final excavation level of the ´GWB´ pit who had noticed a rapidly increasing water and then soil ingress during final excavation and construction of the pump sump in front of the eastern diaphragm wall, warned the visitors to the Historical Archive and the residents of the neighbouring residential buildings of the impending accident at the proverbial last minute, two young residents tragically died in the subsequent collapse of the residential buildings. At that moment, around 30 linear kilometres of archives from 1,200 years of Cologne´s city and regional history, the city's memory that has grown over the centuries, seemed to have been destroyed within seconds and lost forever.

6.5 Immediate stabilisation measures

On the evening of March 3rd and on March 4th, 2009, initial inspections of the damaged area and immediate measures to stabilise the excavation were carried out

by placing around 1,600 m³ of concrete on the base of the excavation (´ballast concrete´) via the northern staircase and on March 8th, 2009, an inspection of the tunnel tubes was carried out in order to decide on further safety measures to avert danger. This was followed by the demolition of the neighbouring residential buildings being at risk of collapse. In addition, a comprehensive monitoring programme was installed for the excavation pit and on the existing buildings and continuously adapted in order to detect any further risk to stability at an early stage.

Figure 13. Salvaging the archives from the rubble of the collapsed Historical Archive at Waidmarkt, looking west with the eastern diaphragm wall of the ´GWB´ pit.

In an initial salvage phase, the fire brigade and the Governmental disaster relief organization carefully removed the huge cone of rubble and debris under the protection of a temporary lightweight hall erected over the excavation pit (Fig. 13) and handed over the archive material that came to light to archivists and many volunteers. In the east of the ´GWB´ pit, in the area of the collapse funnel recognisable here by its tearing edge (see Fig. 11a), the debris from the historical archive was removed to just above the mean groundwater level, i.e. around 9 m below street level. In this way, by September 2009, 85 % of the archive material had already been recovered, albeit mostly severely damaged. The recovered relics were initially stored temporarily in almost 20 asylum archives throughout Germany. Damp archive materials were partially freeze-dried to prevent mould growth.

6.6 Deep excavation for salvage

After salvaging the rubble and archival material down to the mean groundwater level (38 m a.s.l.), investigations carried out up to that point revealed that further rubble from the Historical Archive had ´slipped´ down to a depth of around 20 m below ground level (28 m a.s.l.) in a comparatively narrow collapse funnel. For the City of Cologne, the obligation towards its own historical heritage and to the various lenders of archive items made it necessary to take all reasonable measures to salvage these archival materials buried below the groundwater level, so that a so-called ´salvage excavation pit´ was planned and realised for this purpose.

Figure 14. Salvage pit (in the foreground) in front of the eastern diaphragm wall of the ´GWB´ pit.

Based on a conceptual study, the excavation pit was constructed in the form shown in Figures 14 and 15 with ground plan dimensions of around 16.5 m by max. 30 m and a rounded section (´apse´) in the south, as a particularly large amount of archival material was suspected here. The excavation pit thus enclosed significant areas of the explored excavation funnel. The construction pit was secured on three sides by a secant bored pile wall (pile diameter D = 1.2 m, pile length 29.5 m) and braced against the eastern diaphragm wall by a circumferential reinforced concrete beam with three tubular steel struts and a reinforced concrete strut which were pre-stressed by hydraulic presses.

An additional 24 micro-piles which together with the bored pile wall formed a type of pile-trestle construction were installed at the eastern wall of the salvage pit in order to transfer the strut forces into the ground with minimal deformation. The horizontal loads were thus transferred from the west side of the ´GWB´ pit via the concrete slabs and the damaged eastern diaphragm wall into the salvage pit. The connection of the bored pile walls to the diaphragm wall of the ´GWB´ pit was realized with ground freezing after an initial stabilisation using foam injections proved to be insufficient. The rubble and archives were excavated under water. Possible horizontal displacements of the eastern diaphragm wall of the ´GWB´ pit at the level of the upper concrete slabs had to be limited to 2 mm to 3 mm at maximum. Construction of the salvage pit began in spring 2010.

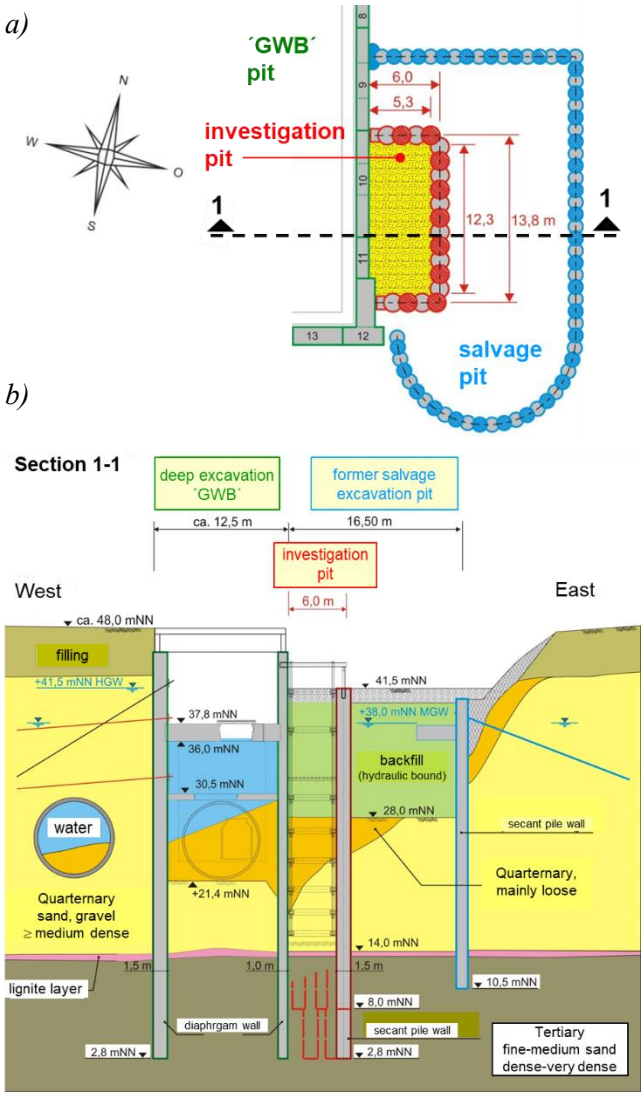

Figure 15. Salvage pit and inspection pit to the east of the ´GWB´ pit: a) ground plan, b) cross-section 1-1.

Due to some difficulties in the construction process and due to unexpectedly large and difficult to salvage foundation bodies weighing up to 30 t, the salvage of the archival material was completed just in summer 2011. The area covered with archival material ended above the predicted depth of 28 m a.s.l. Nevertheless, excavation was carried out to this depth and the remaining debris in the excavation pit was removed to ensure a clear construction area for the subsequent investigation pit. This work and the subsequent collection of evidence within the salvage pit by the court-appointed expert and the experts from the public prosecutor's office lasted until spring 2012, after which the salvage pit was backfilled with a flowable, hydraulically bound material and the temporary struts were removed. During this process, a pre-stressed reinforced concrete structure was installed in the salvage pit at the level of the upper concrete slab of the ´GWB´ pit to provide low-deformation support for the eastern diaphragm wall, taking into account the requirements of the subsequent inspection pit (Fig. 18).

6.7 Investigation of the cause of damage

The clarification of the cause of the damage was the subject of technically extremely demanding and extensive investigations, which - interrupted by construction measures to create the necessary boundary conditions for the preservation of evidence - lasted from 2009 to 2020. In addition to the investigations by the public prosecutor's office in Cologne, evidence on the cause and avoidability of the collapse was collected in an independent preservation of evidence procedure initiated by the owner immediately after the accident. Prof. Dr.-Ing. H.-G. Kempfert, Hamburg, was appointed by the Cologne Regional Court as geotechnical expert in the independent evidence proceedings.

From the outset, two possible scenarios were analysed in parallel with regard to the cause of the collapse of the ´Historical Archive´ building:

- "Suspected area of diaphragm wall quality" with horizontal soil ingress, for example through a void area in the diaphragm wall;
- "Suspected area of vent formation" with vertical soil ingress into the excavation pit through its base, for example through breakthroughs in the lignite layer.

6.7.1 Indirect investigations

Immediately after the collapse subsoil investigations were carried out to clarify the subsoil conditions and to examine the stability of the excavation pit and of the surrounding buildings including several public secondary schools. These investigations already formed a dense grid, which was supplemented with further investigations by the expert in the court evidence from 2009 to the beginning of 2010. Further investigation campaigns followed, including investigations requested by the parties involved in the preservation of evidence process. The scope of the exploration finally realised (Fig. 16), including a total of 113 core drillings, 260 heavy dynamic probing tests (DPH), 186 borehole dynamic probing tests (BDP) and 18 cone penetration tests (CPT), was so intensive that further condensation of the grid was no longer technically reasonable, particularly in the vicinity of the eastern diaphragm wall. In addition, extensive laboratory tests were carried out also. These investigations made it possible to identify the centre of the damage to a tightly confined area in the vicinity of panel #11 in the eastern part of the diaphragm wall of the ´GBW´ pit.

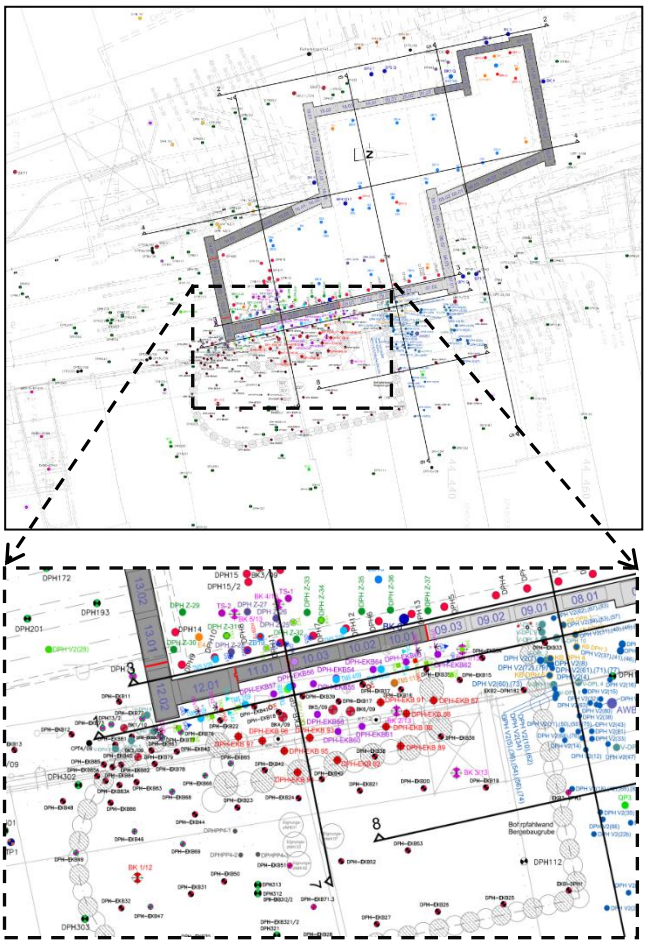

Figure 16. Ground plan: Soil investigation focusing on the south-eastern corner of the ´GWB´ pit.

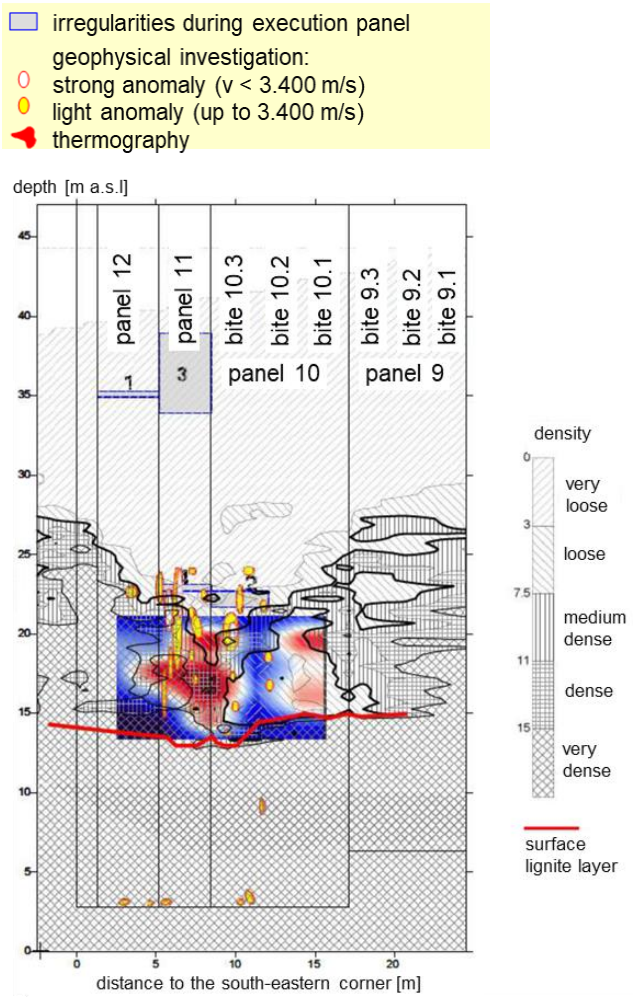

Figure 17. View of the eastern diaphragm wall of the ´GWB´ pit (looking west) with comilation of the results of all indirect exploration measures (source: expert report by Prof. Kempfert (2011-2020), modified).

The core drillings being modified to monitoring wells were used by the court-appointed expert to investigate the integrity of the eastern diaphragm wall of the ´GWB´ excavation pit by applying indirect methods. In particular, seismic cross-hole tomography was successfully used to check the presence, quality and integrity of the diaphragm wall panels. The planned geometric embedment of the diaphragm wall panels could be verified, but at the same time, in the area of the joint between the adjacent panels #10 and #11 at a depth of approx. 16 m to 23 m a.s.l., i.e. between the final excavation level down to the quaternary base, significantly reduced local wave velocities were clearly recognisable identifying anomalies (Fig. 17).

Supplementary thermographic investigations in the form of fibre-optical temperature measurements in combination with the heating method (heat pulse method) showed clear and significant temperature anomalies in the groundwater flow and thus clear indications of hydraulic pathways in the area of the joint between the diaphragm wall panels #10 and #11 in a depth range of approx. 13 m to 20 m a.s.l. (Fig. 17). However, there were no indications for a vertical flow around the base of the diaphragm wall.

In accordance with the anomalies identified during the construction of diaphragm wall panel #11 (see section 6.3), the results of the investigation gave rise to the suspicion that the accident was probably due to one - or possibly several - defects in the joint area of the eastern diaphragm wall, in particular in the joint area between panels #10 and #11 at a level between the final excavation level and the lignite layer (Fig. 17), while a hydraulic ground failure was largely ruled out as the cause of the failure and an erosion ground failure due to a thin vent appeared unlikely even as a (co-) cause of the damage event (Sieler et al. 2012).

6.7.2 Investigation pit: concept

While the numerous indirect investigations had already provided reliable indications of the cause of the damage related to "Suspected area of diaphragm wall quality", a direct visual inspection of the suspected areas was required to dispel the last possible doubts regarding the cause of the damage.

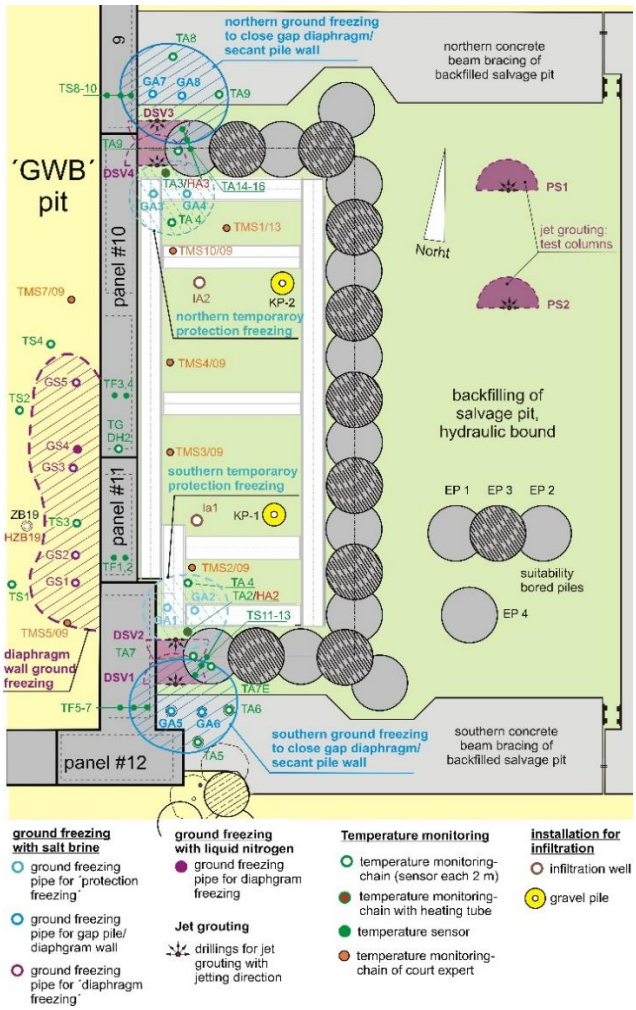

Figure 18. Ground plan of the investigation pit with secant bored pile wall and connecting construction to the diaphragm wall of the ´GWB´ pit plus ground freezing for the diaphragm wall.

In this regard, the construction of an inspection pit inside the ´GWB´ pit (as part of the recovery of the excavation pit) and the construction of an external excavation pit were discussed as alternatives. After the decision on the recovery concept was delayed, the Cologne Regional Court ordered the construction of an external investigation pit in December 2010 in accordance with the specifications of the court-appointed expert. This investigation pit, located in the centre of the collapse funnel in front of the diaphragm wall panels #10, #11 and #12 of ´GWB´ pit, had comparatively small ground plan dimensions of around 6.0 m x 13.8 m (axial dimensions) or 5.3 m x 12.3 m (clear internal dimensions, see Figs. 11b and 15) and was intended to allow inspection of both the diaphragm wall and - layer by layer - the subsoil conditions down to the surface of the lignite layer, which was expected at 14.0 m to 14.8 m a.s.l. in the construction area of the investigation pit, i.e. at a depth of 34 m below street level resp. 27.5 m below working level. The investigation pit was designed for underwater excavation and inspection by divers. In a second stage, it was considered as a supplementary option, and this was also taken into account in the planning and design of the pit, to deballast the inspection pit using compressed air. However, the use of compressed air was considered optional and made dependent on the findings obtained during the underwater exploration. The design of the investigation pit is reported in detail in Moormann et al. (2014). The main elements are presented hereinafter.

6.7.3 Investigation pit: Retaining wall

The investigation pit enclosure was constructed on three sides as a secant bored pile wall with large diameter bored piles (D = 1.50 m) (Fig. 17). The pile base level was initially planned uniformly at 2.8 m a.s.l., corresponding to the depth of the diaphragm wall of the ´GWB´ pit. The planned pile length was therefore almost 40 m. The piles had to be executed fully cased while maintaining a water load inside the casing to be controlled depending on the quaternary groundwater level and a sufficient advanced penetration of the casing below borehole level in order to minimise construction-related loosening, particularly with regard to the sensible evidence situation. Under the special requirements, test piles were initially executed in order to test suitability of the execution process. Despite the use of a powerful rotary drilling rig (´BG 40´), the first test pile could unexpectedly not be drilled down to its final depth at the end of 2012, as after drilling through the lignite layer it was not possible to drive the casing into the tertiary sands with the required forward penetration. As a result of the execution of further test piles, various optimisation approaches were identified, in particular a reduction in the statically required embedment depth of the secondary piles by 5.2 m to 8.0 m a.s.l. (see Fig. 15), the use of a separate hydraulic unit ('PowerPack') for the casing oscillator ('Leffer 2000'), with which the casing could be torqued independently of the excavation process and kept in continuous oscillation, as well as soil replacement ahead of the actual pile drilling (backfilling with 0/32 mm gravel sand) in the area of the hydraulically bound backfill material of the ´salvage pit´ (28.5 m to 41 m a.s.l.), with which the influence of abrasion in the binder-stabilised sands of the backfill could be minimised. In addition, a method called ´gravel shuttling´ was developed to reduce casing friction: After the lignite layer had been passed with the casing, the borehole was backfilled with gravel (8/16 mm) to a height of approx. 3 m, the casing was then initially pulled back to 0.5 m below the gravel filling level and the drilling process was then continued with advance casing to the final depth.

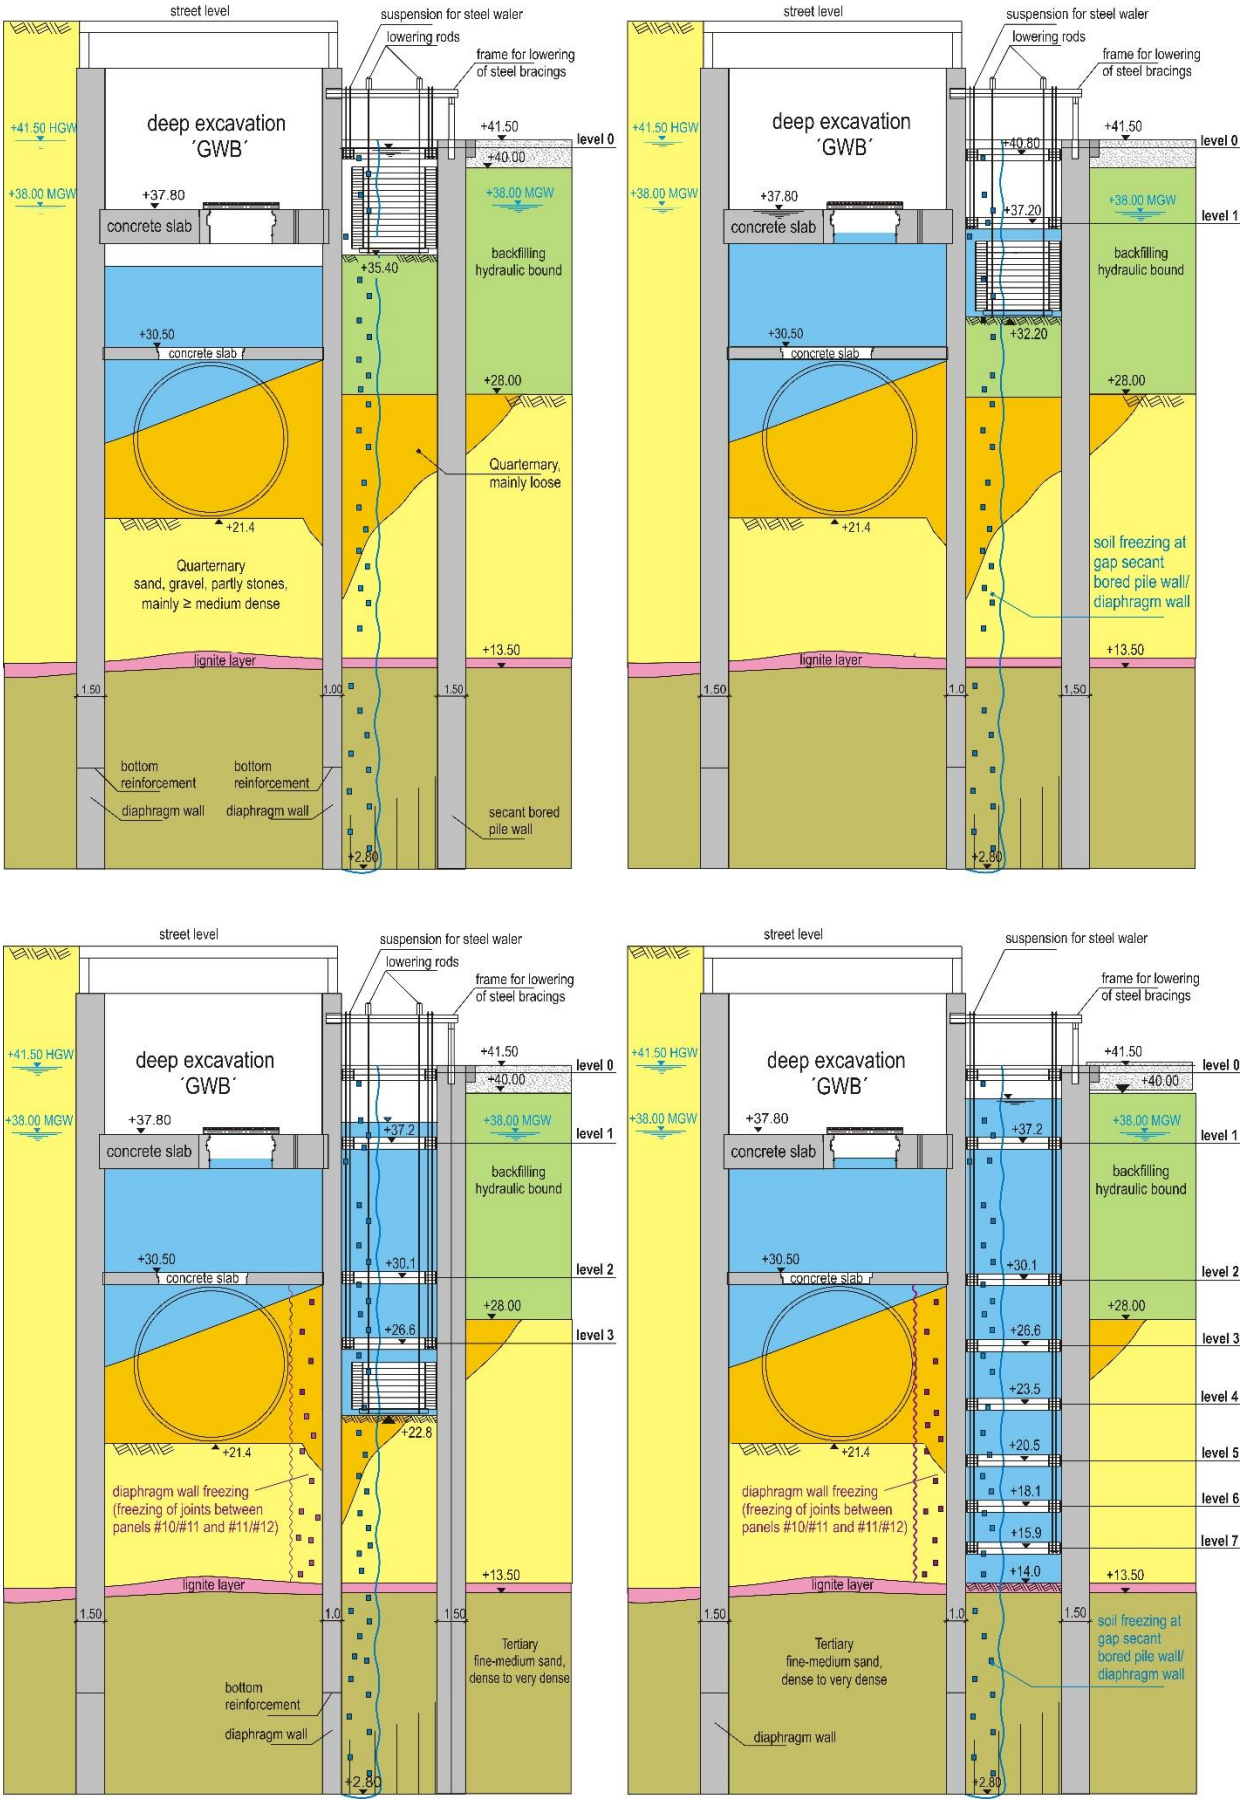

Figure 19. Construction sequence of the inspection pit (west-east section, selected stages).

A multi-stage construction was chosen for the mechanical and hydraulically sealed connection of the secant pile wall of the inspection pit to the diaphragm wall of the ´GWB´ pit with jet grouting as the main element (Fig. 18). As a preliminary step, a temporary ´protection freezing´ was realised inside the inspection pit. Under its protection, it was possible to grout the soil body, which would later be in contact with the free groundwater in the connection area, using the jet grouting method without having to worry about any impact on the soil situation inside the inspection pit. As a fall-back level and to seal the gap below the excavation level, a further ground freezing, the so-called ´connection freezing´, was realized on the outer side of the gap and operated for the construction period. The shielding and connection freezing were both carried out using the salt brine freezing method.

6.7.4 Investigation pit: Inner bracing system

The investigation pit was braced by steel bracing frames in a total of eight levels (Figs. 18 and 19). This bracing solution ensured that the eastern diaphragm wall of the ´GWB´ pit was supported almost over its entire surface, thus ensuring that the earth pressure effects on the diaphragm wall from the east remained as unchanged as possible and were distributed almost evenly, so that overall the boundary conditions of the stable initial situation of the ´GWB´ pit were not significantly changed and at the same time the diaphragm wall could be safely supported even in the event of larger defects. Due to the cramped conditions in the investigation pit and the fact that the bracing had to be installed under water, a concept was developed in which the pre-assembled steel frames for all eight bracing levels were lifted into the investigation pit after an initial excavation phase (35.4 m a.s.l.) and then lowered as a 'package' following the excavation using hydraulic devices, whereby the topmost frames were successively fixed in place (Fig. 19). The dead weight of the prefabricated, horizontally telescopable frames made of sectional steel was between 17.5 t and 27.5 t per bracing layer.

6.7.5 Investigation pit: Freezing of the eastern diaphragm wall

To stabilise the diaphragm wall joints, a frozen ground body was arranged on the inside of ´GWB´ pit, i.e. to the west of the eastern diaphragm wall, within the soil volume deposited in this area ('cone of debris') in the course of the accident and in the quaternary sands and gravels between the former final excavation level in the ´GWB´ pit (21.8 m a.s.l.) and the lignite layer in the area of the two diaphragm wall joints of panels #10 and #11 and of panels #11 and #12 to be inspected (Figs. 18 and 19). This so-called 'diaphragm wall freezing' served to stabilise the soil in the diaphragm wall joints as well as the soil behind them and at the same time to hydraulically seal possible defects in the diaphragm wall, whereby the planning of this freezing measure was based on an assumed defect geometry.

Four brine freezing pipes (GS1 to GS3 and GS5) and a nitrogen lance (GS4) were installed for the diaphragm wall freezing (Fig. 18), whereby the latter could be used to generate increased heat extraction locally and in defined depth sections that could be varied by moving the feed pipes if the exploration work required this, for example when faults were encountered, which was almost always the case during the execution. The freezing area extended from approx. +28 m a.s.l., i.e. the surface of the debris cone reaching just below the lower concrete slab bracing, to the surface of the lignite at approx. 14.0 m a.s.l., so that this frozen soil body had a height of approx. 14 m.

6.7.6 Investigation pit: Underwater excavation

The excavation of the investigation pit was carried out under water and, due to the dimensions of the ground plan and the multi-layer bracing, in very confined conditions using a suction pump. The suction pump, which was suspended from an excavator and lowered into the working areas defined by the bracing frames, was guided underwater at the current excavation level by a diver of the court-appointed expert.

The excavation was carried out in layers of 0.50 m increments from the relevant level of 28 m a.s.l. to the surface of the lignite layer. In the vicinity of the diaphragm wall, the excavation was carried out particularly carefully, if necessary by manually loosening and conveying the soil to the suction pump. Holding points were provided at several levels to secure the diaphragm wall and the base of the excavation pit. The mixture conveyed by the suction pump was channelled through a desanding/separation system to separate the soil material from the process water. The excavated material was laid out field by field, addressed in terms of engineering geology and geotechnics and anthropogenic finds which were of particular importance with regard to the demarcation of the collapse funnel and which were identified (e.g. with regard to their possible origin from the historical archives) and mapped. Furthermore, extensive soil mechanical and mineralogical analyses were regularly carried out on soil samples taken.

Particular challenges for the securing and exploration of evidence arose when diaphragm wall defects and their filling were encountered, as a joint filling frozen by the aforementioned ´diaphragm wall freezing´ gradually thaws in direct contact with the 'free' water of the inspection pit and therefore only has

a very limited ´service life´. This service life, which defined the time window available to the expert´s divers for the collection of evidence and for the installation of appropriate mechanical protection, depended on the respective boundary conditions (geometry, water temperature, etc.). Temporary (air-filled pressure cushions) and permanent mechanical securing systems (including mortar-filled ´Bullflex´ cushions and securing plates) had to be developed with which defects could be sealed after the preservation of evidence. After the installation of a suitable cavity-filling mechanical system, stationary conditions were again established with regard to the freezing, also depending on the boundary conditions. The concept had to be further developed in the detected open void area (see section 6.7.8) and additional horizontal freezing lances and protection by steel tubes had to be installed underwater in layers in the void area what proved to be time-consuming.

The excavation and exploration of evidence in the inspection pit began in January 2014 and was completed in July 2020 with the excavation of the surface of the lignite. All of the work had to be carried out by divers at increasingly great depths, which was a key boundary condition.

6.7.7 Collection of evidence: Approach

During the successive excavation of the investigation pit, not only the detailed documentation of the excavated soil material was carried out as described, but also a comprehensive survey of the diaphragm wall surface. The underwater recording consisted of several elements that were applied in each 0.5 m excavation step: In addition to an initial video recording by the diver´s helmet camera, a) a recording with a high-resolution video, b) a recording with an underwater laser scanner and c) a manual-electronic measurement of the geometry of the diaphragm wall surface (only in the case of anomalies) were carried out geometrically referenced by a guide construction. In addition, the diaphragm wall surface was recorded with a sonar device. As a result of these recordings, the expert and his divers were able to provide a complete graphic-visual and photogrammetric documentation of the diaphragm wall surface down to a depth of 34 m below street level in outstanding quality. The underwater laser scanner obtained from the United States proved to be particularly efficient (Fig. 20).

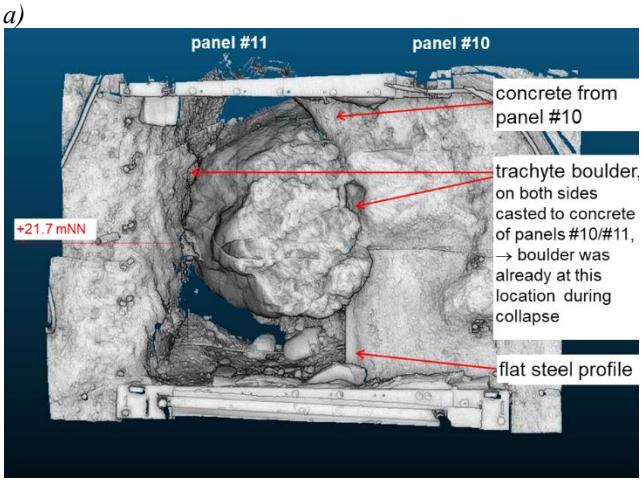
The area of the joints between panels #10 and #11 as well as between panels #11 and #12 was examined with particular care. When joint fillings and defects were encountered, the joint or void material was completely collected in special trays and the joint/ defect geometry was documented using the afore-mentioned methods and with the additional use of smaller GoPro cameras for the interior and flanks of the joints/defects.

In selected sub-areas, in particular in the overlapping area of the reinforcement cages of the diaphragm wall panels "reinforcement windows" were exposed in order to check the position and dimensions of the reinforcement cages and the possible absence of reinforcing bars (Fig. 20).

6.7.8 Collection of evidence: Findings

In the course of the exploration of evidence carried out in this way, in the area of the joint between panels #10 #11, from a depth of approx. 25.2 m a.s.l. on, concrete increasing in width by depth was detected, which extended from panel #10 into panel #11 (Fig. 22) and reached a width of around 600 mm at a depth of approx. 23.0 m a.s.l. A large natural boulder was encountered beneath this concrete from panel #10 at a depth of 22.1-21.4 m a.s.l. and thus directly at or below the final excavation level in the ´GWB´ excavation pit to the south of the panels #10/#11 joint, i.e. in the cross-sectional area of panel #11 (Figs. 21a and 22).

a)



b)

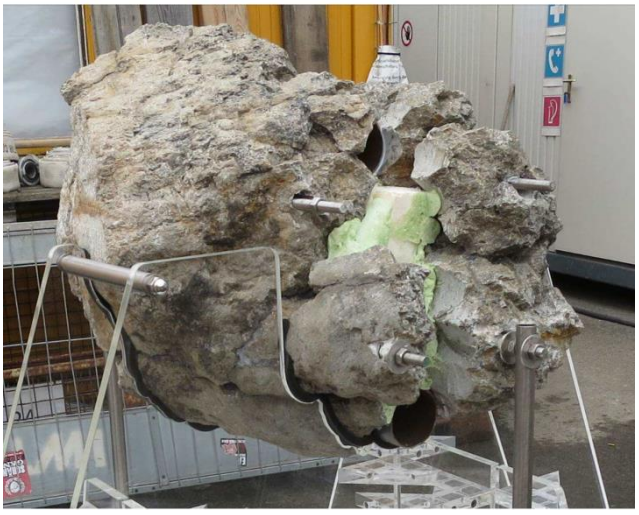


Figure 21. Natural boulder (trachyte) from the joint Lamellen 10/11, a) underwater laser scan in situ, b) recovered and assembled block (basis: Kempfert (2011-2022), reworked).

The trachyte boulder with a diameter of around 600 mm and a length of around 1.20 m was first extensively documented in situ. It was then divided into two half-shells with the help of guided overcut horizontal drillings, which were carried out with an underwater drilling template approximately in the centre of the block, and recovered from the joint using anchors. In dry conditions, the boulder was re-assembled and examined (Fig. 21b). Traces of the teeth of diaphragm wall grabs were found on both the northern and southern sides of the boulder; traces from the reinforcement cage of panel #11 were also found on the southern side. These traces prove that the natural boulder was already in the position encountered during the exploration of the evidence when panel #11 was executed (Fig. 23). In conjunction with the triangularly growing concrete from panel #10 found above it, it can be concluded that the natural boulder was encountered in the course of the execution of panel #10 and was displaced into the ground section of the later panel #11 during the attempt to salvage it, without the salvage being successful (Fig. 23). During the construction of panel #11, the boulder was then not removed from under the overlying concrete; after the change to the 2.4 m wide grab shells, the teeth of the diaphragm wall grab merely "scraped" along the natural boulder (Fig. 23).

Under the trachyte boulder, a continuously open void up to 600 mm wide and filled with quaternary material was encountered in the further excavation over the depth, which, although only explored up to the surface of the lignite, is expected to be in fact open to the lower edge of the diaphragm wall.

Based on the distribution of anthropogenic findings, colour changes of the in-situ soil material and other indicators such as the erosion/ presence of the filter cake in the joint surfaces, it was possible to identify and to prove that the base of the "moving" masses (collapse funnel) in the void lies at a level of around 18.7m a.s.l. In consequence it can be concluded that the area of the void through which around 5,000 m³ of quaternary material flowed in the course of the accident is only around 2.3 m high and about 600 mm wide and therefore has an area of only approx. 1.5 m² in total.

Based on an independent evaluation of the laser scan images taken by the expert Prof. Kempfert and his divers in the inspection pit, Figure 22 shows the area around the joint between panels #10 and #11 with the "open" void area filled with quaternary sands and gravels from 21.7 m a.s.l. downwards, the trachyte boulder above it and the triangle shaped concrete that flowed in behind the flat steel profile (stop end) when panel #10 was poured and which was not removed in the course of the excavation of panel #11.

At the time the damage occurred on March 3rd, 2009, the excavation level in the ´GWB´ pit in front of panels #10 and #11 was around 22.0 m a.s.l.; the planned final excavation level would have been 21.7 m a.s.l.

The discovery of the natural boulder in the northern area of panel #11 and the open void below it, filled with quaternary material and 450 mm to 640 mm wide in the further course, as well as the successful demarcation of that part of the void area that was passed by the granular-fluid mixture during the accident, provide a clear and forensic clarification of the cause of the damage. Despite this the layer-by-layer excavation and exploration of evidence in the inspection pit was continued down to the depth of the surface of the lignite layer at approx. 14.0 m a.s.l.

In a final step, the lignite was also exposed in sections using a specially manufactured excavation box using the caisson method in order to verify that the

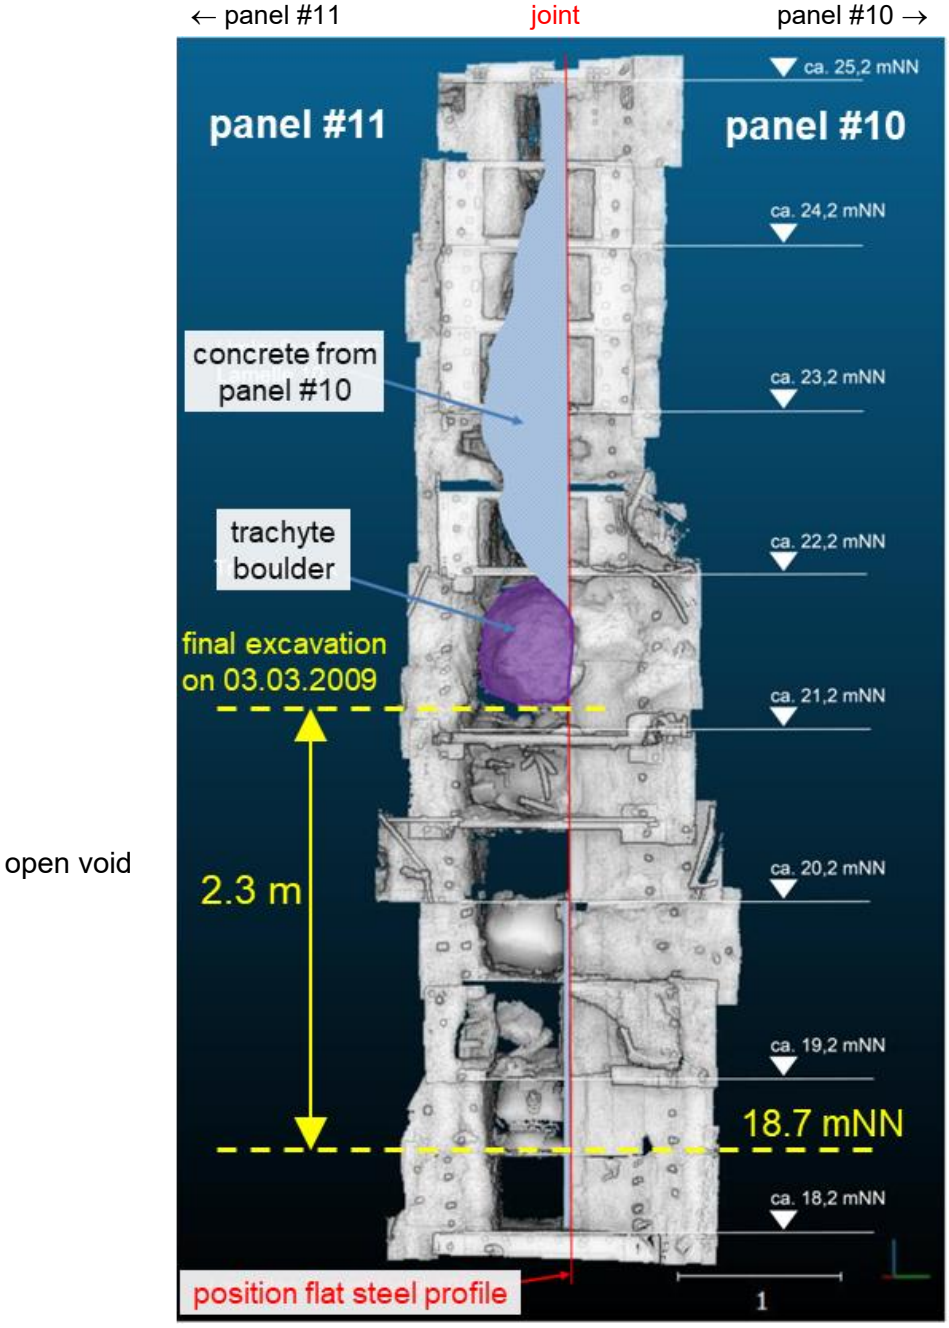

Figure 22. Compiled visualisaiton of the explored situation in the joint area of the diaphragm wall panels #10/#11 (evaluation of the underwater laser scans based on Kempfert (2011-2022)).

lignite layer in the ground plan of the inspection pit was intact and without defects. This additional proof was provided in 2020. This meant that the thesis of a suspected area of "vent formation" with a vertical material entry through the base of excavation could be definitively and legally ruled out in the sense of a ´counter-evidence´.

The results of the very demanding investigation of evidence were documented by Prof Kempfert in several expert reports (Kempfert, 2011-2020).

6.8 Cause of the collapse

As a result of the highly complex preservation of evidence procedure and investigations it was possible to clarify the cause of the damage clearly and beyond doubt. As a result of the investigations carried out from 2009 to 2020, the accident on March 3rd, 2009 can be attributed solely, i.e. mono-causally, to a defect that remained in the joint area between two panels during the construction of the diaphragm wall. In the area of the joint between the panels #10 and #11 an approxi-

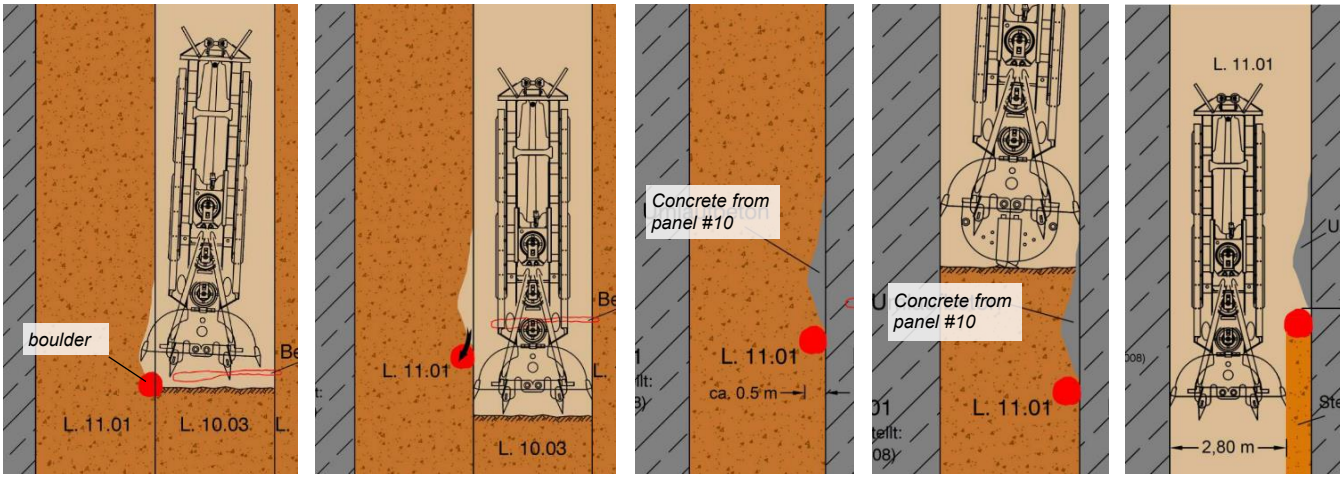

Figure 23. Construction sequence of the panels #10 and #11 of the eastern diaphragm wall with the natural boulder (trachyte, marked in red) encountered during execution of both panels.

mately 600 mm wide void was found below approx. 21.7 m a.s.l., i.e. at about the level of the final excavation of the ´GWB´ pit downwards. This defect results from the fact that the existing soil material in this area had not been excavated and replaced by concrete during the construction of diaphragm panel #11. A triangular wedge of concrete, which protruded into the cross area of panel #11 (Figs. 22 and 23), had not been removed in the course of the excavation of panel #11 and was therefore the initial of this defect. The triangle-shaped concrete originates from previous execution of adjacent panel #10: during excavation of this panel the trachyte boulder was hit in the southern outer edge of the panel´s cross section and trials to catch and remove the boulder creates a void in the area of the adjacent panel 11 which was poured by concrete which flowed behind the flat steel profile that was used as joint resp. stop end element (Fig. 23).

As a result of the challenging investigation of the evidence, it was proven that during the accident on March 3rd, 2009 around 5,000 m³ of quaternary material flowed through the void in the depth section between 21.2 m a.s.l. and about 18.7 m a.s.l., which led to the collapse of the historical archive, literally as the ground was removed from under the foundations. It can be assumed that this void in panel #11 continues below the section through which the granular-fluid mixture flow passed to the lower edge of the diaphragm wall.

The cause of the damage can therefore be traced back to an execution issue respectively to the fact that suitable countermeasures were not taken in response to the difficulties encountered during the execution of panel #11 of the diaphragm wall in 2005. The obstacles encountered during excavation of this panel and the failure to remove these obstacles, finally the change of the grab shells from 3.40 m to 2.80 m wide for excavation of the 3.4 m wide, single bite panel #11 were an unambiguous evidence that the panel #11 was not executed in a regular way and that from the depth where the grab shells were changed most probably a 600 mm wide void filled with quaternary sand and gravels was left.

Technically, it would have been possible to reliably seal the remaining defect in panel #11, for example with one or two columns executed using the jet grouting method.

Against the background of these results of the investigation of the evidence, the City of Cologne and the construction JV, which still assumed an alternative course of events, reached an out-of-court agreement in a moderated procedure to settle the financial loss incurred by the City of Cologne and concluded finally on a settlement in June 2020. According to this settlement the construction JV paid 600 million euros in damages to the City of Cologne and committed themselves to reconstruct the damaged ´GWB´ excavation pit and to finalize this structure at its own expense and under its own responsibility.

Currently it is expected that the very challenging reconstruction activities will last until about 2032, what means that it will have taken nearly 25 years from the occurrence of the damage to its removal and to the moment the first metro train will have run through the ´GWB´ underground structure at the ´Waidmarkt.

7 CONLUSIONS

7.1 Dealing with serious damage cases

The accident at the deep excavation pit for the ´GWB´ structure at ´Waidmarkt´ in Cologne on March 3rd, 2009 was a dramatic case of damage with far-reaching

consequences for the city of Cologne, in particular due to the collapse of the adjacent historical archive, for the north-south metro project and local residents, but also for all those involved in the project. Contrary to the expectations of many of those involved, the cause of the damage was clearly and unequivocally clarified in an unprecedented process of preserving evidence in terms of complexity, technical challenges and scope, but also in terms of duration and effort. All of the independently obtained evidence from the indirect and direct investigations form a complete and consistent overall picture. The only cause was a 0.6 m wide void in a diaphragm wall panel located just at resp. below the excavation pit´s final excavation level, which was a consequence of an execution error. The fact that it was possible to identify and document this mono-causal cause of damage in an extremely challenging environment in such a clear and qualified manner, and thus in a way that would stand up in court, is first and foremost the merit of the court-appointed expert witness, Prof. Dr H.-G. Kempfert and his team, who led the evidence proceedings through all the technical difficulties with great commitment and professional expertise.

The technical challenges that arose during the underwater preservation of evidence in an up to 34 m deep excavation pit next to a damaged diaphragm wall was a daily companion for all those involved in the realisation and creation of the structural condition for the investigation over years. New solutions and prototype-like concepts had to be developed, tested and implemented for many tasks relating to the preservation of evidence and the realisation of the construction work. The successful realisation of the investigation of the evidence and the clear clarification of the cause of the damage were the prerequisites for ending the evidentiary proceedings with an out-of-court settlement between the parties involved, thus avoiding a lengthy legal dispute.

Nevertheless, the fact that more than 15 years have passed since the damage occurred should be motivation for further considerations regarding the prevention and handling of (major) damage cases in ground engineering.

The example of the Waidmarkt accident shows that it is often not possible to quickly clarify the cause of the damage, as extensive and time-consuming investigations of the subsoil situation and the structural conditions, which are initially not accessible to direct inspection, especially in underground construction, are required. Promising approaches for alternative concepts for dealing with damage events and for accelerating following procedures e.g. by combining measures for investigation and reconstruction are documented in international context for other major damages, such as the Nicoll Highway Collapse in Singapore (Whittle & Davies, 2006).

7.2 Risk prevention and mitigation

Risk prevention and risk mitigation are even more important tasks than dealing with damage cases as these are the only tools to avoid collapses and damages.

Based on experiences from damages consequences for the independent checking of design and execution, for the quality assurance of underground works and their supervision, but also the need for a risk prevention based on communication and partnership between all parties involved in the construction process needs to be discussed and implemented especially but not solely for major projects.

Besides measures and approaches for risk management and assessment during design, as discussed in sections 2 to 4 of the present paper the successful realisation of geotechnical structures in engineering practice requests the following additional measures especially related to checking and quality assurance:

1. An independent structural *and* geotechnical checking is essential and must include both,
   a. the checking of the design and all verifications and
   b. the supervision and monitoring of the execution.
2. For all stages of soil investigation, design, execution, checking and supervision geotechnical expertise and experience is required; therefore it is mandatory to involve an independent geotechnical checking engineer at least for structures of the Geotechncial Category 3 according to EN 1997-1.
3. The (independent) supervision of execution of special geotechnical works like e.g. piling, diaphragm walls, ground improvement and injections has to be carried out by qualified and experienced experts on site.
4. A risk prevention in partnership needs to be established and practiced in all phases of planning and realisation. In this context a regular communication on technical level between client, contractors, designers and the independent checking engineer is essential. Such a regular communication, e.g. organisationally to be implemented by jour fixes, allows also to identify and discuss any irregularities and anomalies occurred during execution.

All of the above measures are relevant and needs to be established but especially a regular technical communication between all parties is considered to be an essential tool for risk prevention and mitigation during the execution.

In this regard the presented case study of the collapse of the ´Historical Archive´ at the Waidmarkt in the city of Cologne is an example where irregularities during execution of the diaphragm wall were observed and documented but were subsequently not pursued further neither internally inside the construction companies nor in communication with the owner´s independent supervision and by the owner itself. As shown in section 3.1.3 of this paper human factors have been identified as main cause for failure on site and one of the major impacts are faulty communications as well as pressures on the involved people like time, economical or ecological constraints. In this regard, an open-minded communication focused on technical aspects and a partnership-based approach are considered to be effective mitigating measures for risks in geotechnical engineering and execution.

How AI and IoT are transforming geotechnical site monitoring and construction

Comment l'IA et l'IdO transforment la surveillance des sites géotechniques et la construction

A. Gomes Correia*

ABSTRACT: Artificial intelligence (AI) and internet of things (IoT) are the most transforming advancements in geotechnical site monitoring and construction. Indeed, the increasing integration of AI and IoT devices and technologies into construction processes have enhanced construction management as a benefit from real-time feedback that provides early warning systems, facilitating timely interventions and ensuring construction site safety, as well as structural health monitoring of built environment. This presentation will start summarising the state of the art of these advancements in geotechnical works. Two field works in Portugal, one on infrastructure earthworks and another on a metro line in an area of dense urbanisation with new and old buildings, including historical monuments, involving trenches, load transfer platform solutions and main station, serve to demonstrate the benefits of applying these developments in comparison to traditional management techniques.

RÉSUMÉ: L'intelligence artificielle (IA) et l'internet des objets (IdO) sont les technologies les plus transformatrices en matière de surveillance des sites géotechniques et de construction. En effet, l'intégration croissante des dispositifs et des technologies de l'IA et de l'IdO dans les processus de construction a amélioré la gestion de la construction grâce à un retour d'information en temps réel qui fournit des systèmes d'alerte anticipés, facilitant les interventions en temps réel et garantissant la sécurité du site de construction, ainsi que la surveillance de l'état structurel de l'environnement bâti. Cette présentation commencera par résumer l'état de l'art de ces avancées dans les travaux géotechniques. Deux chantiers au Portugal, l'un sur des travaux de terrassement d'infrastructures et l'autre sur une ligne de métro dans une zone d'urbanisation dense avec des bâtiments neufs et anciens, y compris des monuments historiques, impliquant des tranchées, des solutions de plate-forme de transfert de charge et la station principale, servent à démontrer les avantages de l'application de ces développements par rapport aux techniques de gestion traditionnelles.

Keywords: Artificial intelligence; internet of things; monitoring; earthworks; metro line.

1 INTRODUCTION

The Internet of Things (IoT) and Artificial Intelligence (AI) technologies offer immense potential for revolutionizing geotechnical monitoring, enhancing efficiency, accuracy, and safety across construction projects. By coupling IoT sensors with AI algorithms, geotechnical monitoring systems can collect vast amounts of data in real-time, enabling proactive decision-making, allowing to implement timely interventions and preventive measures to mitigate risks (Tan et al., 2022). In this context, A/D converters play a crucial role in this coupling by digitizing analogue signals from sensors, thus enabling the processing and analysis of data by AI algorithms. These converters bridge the gap between the physical world of sensor measurements and the digital facilitating the seamless operation of IoT-based monitoring systems. These systems exhibit the ability to detect structural impacts, monitor buildings through tilt sensors, and issue alerts upon surpassing predefined thresholds. Moreover, IoT generates novel datasets, revolutionizing risk assessment, design, construction, and maintenance practices (Kumar et al.,

2023). Furthermore, AI algorithms analyse the data collected by IoT sensors to identify patterns, anomalies, and trends indicative of potential hazards, construction deficiencies or structural weaknesses. Machine learning techniques, such as neural networks or decision trees, among others, can learn from historical data to predict future events or assess the health status of the structural elements (Singh and Tyagi, 2023; Zhang et al., 2023). This predictive capability enhances the effectiveness of Early Warning Systems (EWS), enabling proactive measures to prevent catastrophic events (Kumar et al., 2023).

These developments that have emerged over the last decade are now maturing, offering significant advancements in construction site monitoring. These advancements primarily benefit from three key technologies: IoT, the availability of low-power, long-distance communication protocols, and the development of AI methods. These technological achievements enable the acquisition, transmission, and synthesis of geometric and structural geotechnical data, which are crucial for monitoring and mitigating risks on construction sites, especially in underground environments.

However, the integration of IoT, A/D converters and AI also presents challenges, including data privacy concerns, cybersecurity risks, and the need for interoperability among heterogeneous sensor networks (Liang et al., 2024). Addressing these challenges requires robust data governance frameworks, encryption protocols, and standardized communication protocols to ensure the reliability, security, and scalability of integrated geotechnical monitoring systems.

In this paper, we begin with this concise overview, underscoring the advantages of integrating IoT, A/D converters, and AI in geotechnical construction. Subsequently, we delve into a detailed exploration of emerging communication tools, web monitoring platforms, and AI applications. These considerations are contextualised within two field projects conducted in Portugal: one centred on transport infrastructure earthworks, and the other on a metro line located in an area marked by dense urbanization and a blend of new and historic structures, including monuments. The analysis underscores the superiority of these cutting-edge technologies when compared to conventional approaches and technologies.

2 EMERGING COMMUNICATION

Recent advances in geotechnical and structural monitoring are primarily linked to the emergence of wireless data transmission methods that are compatible with the scale of construction sites and make it possible to solve the recurring problem of powering sensors on these sites.

2.1 LoRaWAN radio networks

LoRaWAN (Long Range Wide Area Network) radio networks have gained significant attention in recent years for their ability to provide long-range, low-power communication suitable for various IoT applications, including geotechnical monitoring in construction projects. These networks operate on radio bands, offering excellent coverage even in challenging environments like urban areas or underground construction sites (Raza et al., 2017; Shanmuga Sundaram et al., 2020; Centenaro et al., 2016).

The LoRaWAN was developed in 2015 by the LoRa Alliance following research conducted from 2009 onwards in Grenoble, France (LoRa Alliance, 2024).

The LoRaWAN radio protocol has found unexpected applications in construction projects. Its key characteristics include the utilization of free and Europe-approved frequency bands, capable of transmitting data up to one kilometer in urban environments and up to 10 kilometers in open fields. Moreover, the protocol consumes minimal energy, and its limitations are compatible with geotechnical instrumentation, as geotechnical measurements are relatively low-frequency and require minimal digital space.

The LoRaWAN protocol enables the transmission of information from autonomous battery-powered sensors dispersed across the entire surface area of a construction site via radio, covering distances typical of extensive worksites for several years.

Deploying LoRaWAN networks necessitates the installation of fixed gateways and antennas to provide coverage for construction sites. This network of gateways must be managed by a "network core" linked to a supervision platform. This platform is essential for configuring the radio communication network, managing communications, and decrypting information received from the sensors.

LoRaWAN technology is not the sole low-power radio technology making strides in the construction sector; it is one of the LPWAN (Low Power Wide Area Network) communication technologies fueling the advancement of the IoT. Other promising communication protocols, such as LTE-M or NB-IoT, which utilise telephone operator infrastructures, are also emerging (Bajic et al., 2023; Malik et al., 2020; Rastogi et al., 2022). However, their adoption is

currently limited by the availability of sensors compatible with these protocols.

2.2 Cellular communication and 5G

Significant advancements have been achieved in cellular communication technologies, facilitating their deployment in the niche yet rapidly expanding field of surveillance, which demands handling large data streams (such as acoustic measurements, vibration monitoring, real-time scanner tracking, video image analysis, etc.).

Particularly noteworthy progress has been made in managing cybersecurity risks associated with communication lines, eliminating coverage gaps, and optimizing communication throughput. It is worth noting that the advent of 5G communications, with their capacity for handling vast amounts of data, paves the way for numerous applications, albeit raising concerns regarding the sustainability of the volumes of data transmitted, analyzed, and stored.

3 WEB MONITORING PLATFORMS AND AI

Downstream, handling increasingly large data flows from construction sites has become feasible only with the emergence of robust, secure platforms capable of storing this data in data lakes. These platforms offer user-friendly, real-time internet access to pertinent, verified, translated, and summarized information for remote users with diverse needs.

The development of hosting platforms accessible in Software as a Service (SaaS) mode on trusted European clouds has facilitated high-speed access to technical information streams on all construction sites. This is done in compliance with cybersecurity and sovereignty requirements mandated by the General Data Protection Regulation (GDPR) and forthcoming AI Act regulations (CoC, 2020; CISPE, 2021).

One of the most promising aspects of these ongoing developments is the ability to train artificial intelligence models using the vast quantities of data collected from construction sites. These models can then operate in real-time to enhance the value of the gathered information. AI can now be leveraged for trend forecasting, expert filtering, and advanced alarms, offering powerful tools for engineers (Zhang et al., 2023).

Furthermore, AI has potential offline applications, particularly in information synthesis and construction design.

Again, it is crucial to emphasize the ethical and environmental implications of AI usage (Liang et al., 2024). The storage and processing of vast amounts of information for AI model creation require significant energy consumption, contributing to companies' carbon footprints and potentially hindering efforts to combat climate change. The benefits of AI usage must be balanced against the carbon cost of its production.

Moreover, significant ethical risks may arise during the development of AI models. The AI Act provides valuable clarification by categorizing applications into four distinct risk levels (unacceptable, high, low, minimal), thereby enabling the responsible use of AI models with minimal ethical risks in the construction sector (Taddeo and Floridi, 2018).

4 APPLICATION TO EARTHWORKS – CASE STUDY

Earthwork processes often encounter significant uncertainties, requiring flexibility from planning and management teams to address unforeseen events like severe weather or equipment failures. Successful solutions for these challenges relies heavily on the expertise of the teams involved. However, since this expertise is not always readily available, decision support systems become invaluable. These systems not only compile and organize knowledge and experience from past projects but also foster collaboration across different specialties and teams throughout all phases of construction projects, aligning with modern concepts like Construction 4.0 and Building Information Modeling (Han et al., 2022).

In the context of earthworks, decision support systems serve various purposes, from predicting material behavior and equipment productivity to monitoring equipment positioning and optimizing resource allocation (Gomes Correia et al., 2013; Gomes Correia, 2018; Marques et al., 2008; Parente et al., 2015, 2016, 2018). These systems leverage on technologies such as artificial intelligence, simulation, and optimization algorithms, to tackle different problems and objectives (Choi and Han, 2023).

To illustrate the effectiveness of these systems, a real case study from Portugal involving road construction is presented (Neves et al., 2024). This study aimed to optimize resource allocation across multiple construction and excavation fronts, minimizing costs and project duration through multi-objective optimization (Jaafar and El-Halawani, 2022).

4.1 Technologies

In the specific case of earthworks, decision support is generally sought in order to predict (e.g., behavior of geomaterials, slope safety, equipment productivity as a function of working conditions), monitor (e.g.,

position of transport equipment, downtime, mechanical breakdowns), and/or optimize (e.g., distribution of geomaterial volume between excavation and embankment fronts, minimization of transport distances, optimal allocation of mechanical resources).

Based on technologies such as artificial intelligence, simulation, optimization algorithms, and sensing, these systems can be divided according to the methodology adopted and the objectives of decision support.

On the one hand, there is planning support, typically based on forecasting or robust optimization systems, which aim to create robust plans that not only encompass the predictable work to be carried out, but also include contingency plans for potential disruptive situations. On the other hand, there is construction support, focused on monitoring and reactive optimization systems, which advocate maximum flexibility in adjusting the initial plan in response to more volatile environments or the possibility of unforeseen occurrences.

Figure 1 shows the workflow of the optimization system paired with IoT system for earthworks projects. In the following subsection, it is presented an illustrative example of the potential of this type of systems in planning and construction phases, respectively, adopting as reference a real case study associated with the earthwork phases of a road construction project in Portugal. The project consisted of 24 embankment construction fronts, fed by 15 excavation fronts. The total volume of processed geomaterial was approximately 1,500,000 m³ over an approximate extension of 20 km of highway, with the average estimated duration of the work being approximately 6 months. The equipment fleet consisted of a total of 6 compactors, 14 spreading equipment, 29 excavators, and 39 geomaterial transport trucks.

For this application, a simulation of conditions close to real was carried out, using only the aforementioned available resources to develop the work according to the practices already commonly used in the industry. The adopted methodology described in Neves et al. (2024) was based on the work developed by Correia and Magnan (2012), Parente et al. (2018, 2022), aiming to find optimal solutions for the allocation of equipment fleet by work fronts and over time, simultaneously minimizing costs and work execution duration (multi-objective optimization).

4.2 Application to planning/design

As previously mentioned, the aim of this simulation was to showcase the potential of integrating these technologies for optimal equipment fleet allocation. Given the dynamic nature of the problem, with multiple work fronts such as excavations/ cuts and embankments progressing simultaneously, the solution must also be dynamic. This means that as teams complete work on one front, they need to transition to another, considering factors like varying transport distances, types of geomaterials, and available space. To achieve these objectives, the system requires input on available mechanical resources, including compactors, spreaders (e.g., bulldozers, graders), excavators, and transport trucks, along with specifications for each. Additionally, information on the work to be carried out, such as excavation and embankment fronts, their locations, types, volumes of associated geomaterials, and maximum number of active equipment, is needed. With access to this data, the optimization algorithm, based on a non-dominated sorting genetic algorithm II (NSGA-II) (Deb et al., 2002), seeks the best resource allocation solution throughout the project.

The multi-objective optimization process encompasses multiple stages. These range from the choice of the optimal distribution of geomaterial volumes between fronts, while minimizing transportation distances (which can alternatively be defined by the user based on project requirements), to the optimal allocation of all available equipment over time throughout the workfronts, adopting a scheduling methodology that defines where each equipment should be and for how long, resulting in the minimization of global execution costs and duration. The process takes approximately 3 hours in a conventional laptop (in this case, Intel i7-10750H 2.60GHz, with16GB RAM and running Windows 11) and presents solutions in a Pareto format. Each point on the Pareto front represents an equipment allocation, evaluated based on duration and cost (Figure 2). These solutions offer optimal trade-offs between time and cost, allowing flexibility in decision-making.

Results can be accessed in various formats, such as spreadsheets or maps, enabling visualization of equipment allocation for each work phase. This facilitates analysis of different scenarios and selection of the best option based on time, cost, and allocation details provided for each solution.

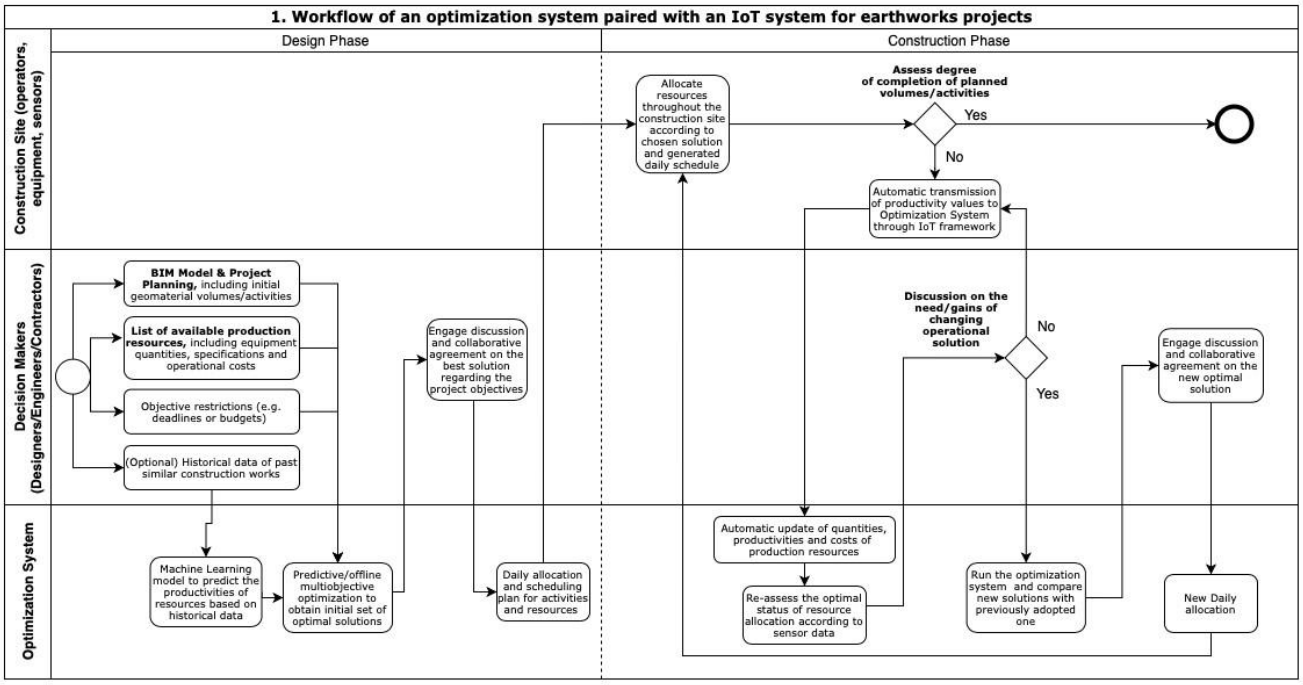

Figure 1. Workflow of the optimization system paired with IoT system for earthworks projects.

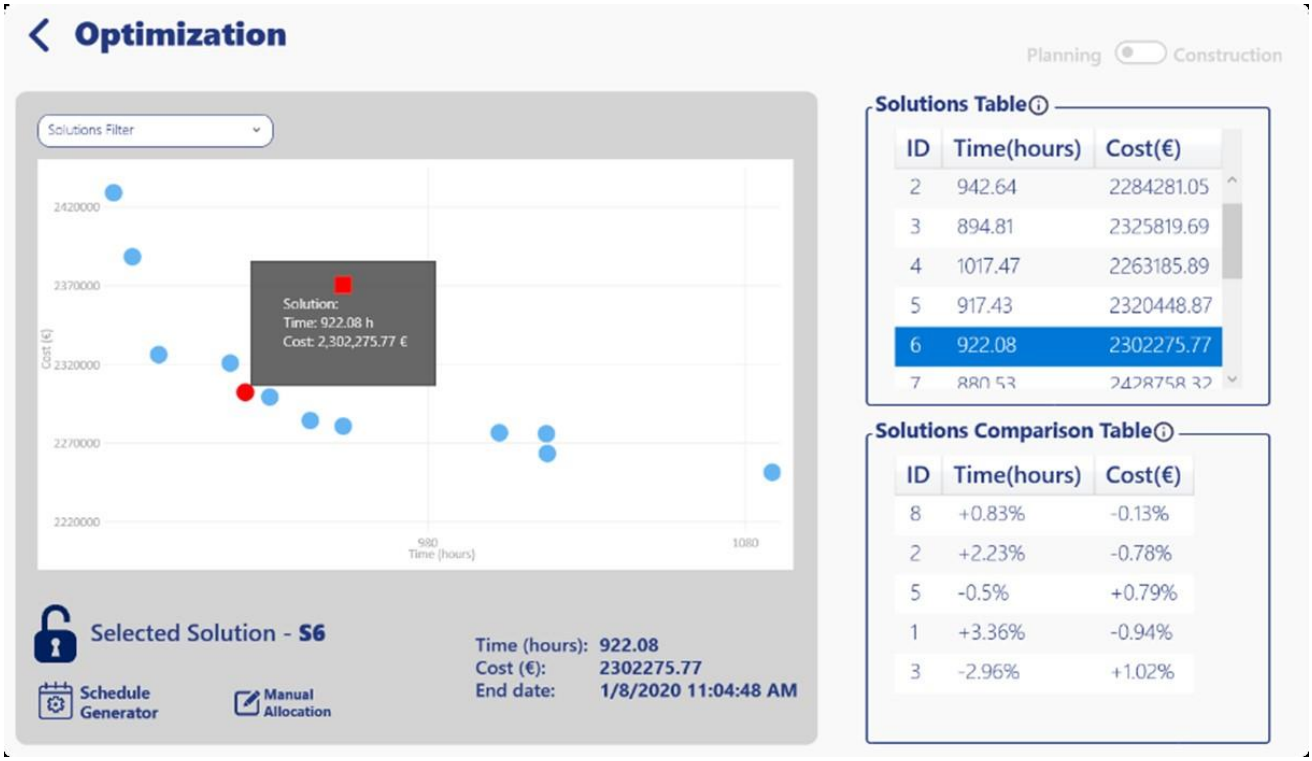

Figure 2. Pareto front solutions output from the planning/design phase of the system.

4.3 Application to construction phase

This simulation incorporates GPS positioning sensors in transport trucks during construction, enabling productivity assessment based on cycle counts within specified periods. This system also infers excavation and compaction team efficiency during loading and unloading cycles. These assessments are conducted with minimal intervention, as GPS is only installed on the transport trucks. Initially, productivity measurements are indicative, assuming trucks are fully loaded. However, these values are adjusted monthly based on topographic measurements at each work front. These measurements, part of regular quality control processes, provide accurate volumes of

excavated and embanked geomaterials, allowing for comparison with system estimates.

To address variations between actual and estimated volumes, a corrective factor, 'k', is applied to truck productivity. This factor is proportional to the ratio of actual volumes measured topographically to those estimated by the system. The system operates in monitoring and control mode from the beginning of the construction phase. A control dashboard offers real-time project progress monitoring, productivity tracking at each work front, and live transport equipment location updates (Figure 3). It also issues notifications for potential issues and provides access to activity history and project parameters.

In case of project changes, such as equipment breakdowns or alterations to material types, the system recalculates costs and duration for subsequent phases. Users can choose to accept revised forecasts or request resource reallocation to optimize work efficiency.

During re-optimization, a third minimization objective, Re-Allocation Disruption (RAD), considers the cost of reallocating equipment between work fronts. RAD minimizes disruptions caused by equipment changes, optimizing the reorganization process. In both planning/design and construction phases, the system not only allocates resources but also selects the optimal fleet, ensuring efficient resource utilization. Nomenclature for solutions in re-optimization facilitates tracking of adjustments throughout the project. The system maintains a descriptive database of project development, enabling future analyses and applications of artificial intelligence for knowledge extraction. It can also illustrate the normal operation of the control dashboard, offering a comprehensive overview of project status, productivity metrics by work front, real-time transport equipment tracking via map visualization, and notifications for potential issues. This dashboard also provides access to activity history and project parameter editing functions.

In the event of re-optimization, the system generates a new set of solutions, with each solution evaluated based on minimization objectives, once again presented in Pareto format. The system adjusts solutions dynamically, accounting for changes in project conditions and constraints.

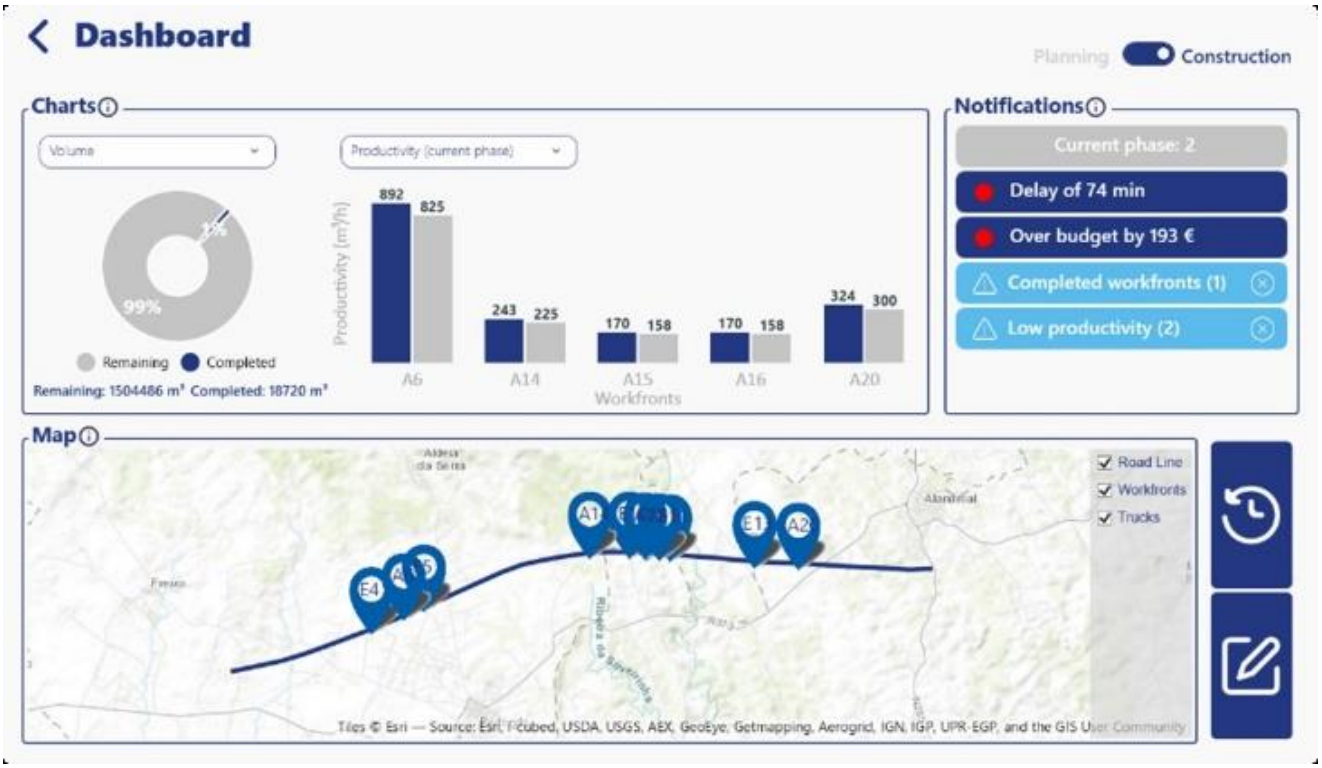

Figure 3. Monitoring and control dashboard for the conducted construction simulation.

Figure 4 displays the allocation adjustments resulting from re-optimization. Each solution corresponds to a specific equipment allocation, evaluated by associated duration and cost metrics. The system also evaluates the Re-Allocation Disruption (RAD) associated with each solution, providing additional decision support for users.

4.4 Intelligent compaction

The concept of Industry 4.0 (i4.0) offers new opportunities for intelligent optimization of

compaction operations (Parente et al., 2018; Gomes Correia, 2018). By leveraging smart sensors and real-time monitoring, i4.0 enables the creation of virtual models to simulate compaction processes and continuously assess geomaterial properties. Machine learning algorithms enhance predictive capabilities and facilitate classification of geomaterials based on their properties, leading to improved compaction quality.

Figure 5 illustrate the most representative tools of i4.0 applied in intelligent compaction (Gomes Correia, 2018).

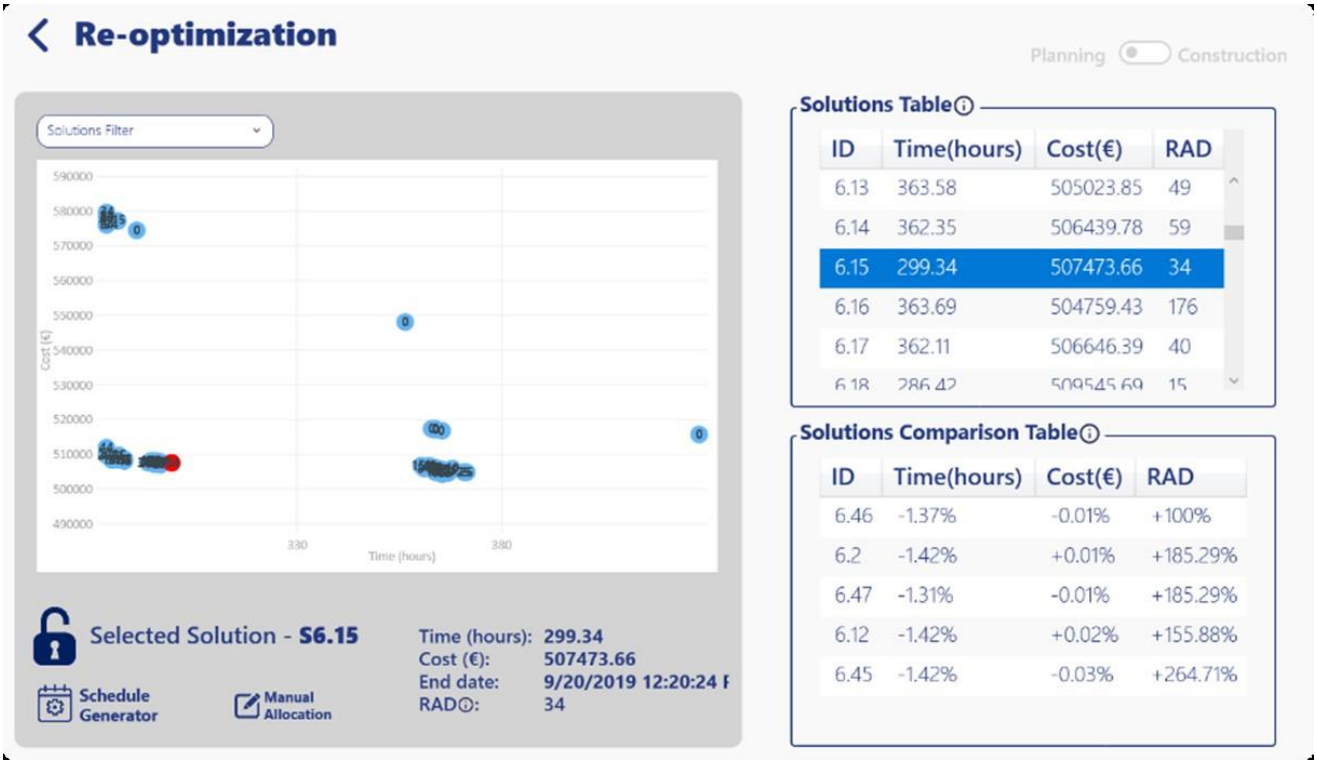

Figure 4. Pareto front solutions output of adjustments that arise from the re-optimization process.

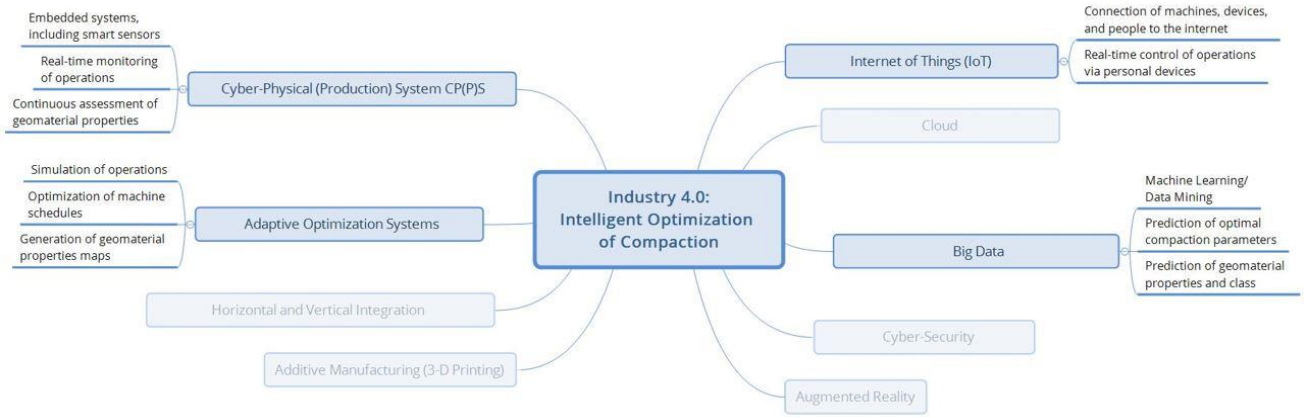

Figure 5. Industry 4.0 technologies applied to intelligent optimization of compaction.

Indeed, this approach can provide an agile and autonomous decision-making facing the challenges posed by dynamic and unpredictable environments, such as those encountered in compaction operations. To achieve this, it prioritises the utilisation of technologies like smart sensors for real-time monitoring of the compaction process. This enables the creation of a virtual representation of physical compactors within a simulation model and facilitates continuous assessment of geomaterial properties and continuous compaction control. Indeed, unlike traditional methods that may only sample certain areas, these technologies can monitor and assess the entirety of the compacted area in real-time.

On one hand, this forms the foundation for real-time scheduling and optimization of compactor tasks,

while simultaneously processing the feedback data from the geomaterial. On the other hand, this data can also be subjected to machine learning and data mining algorithms. These techniques not only enable the prediction of optimal compactors parameters but also allow for the continuous compaction control and classification of geomaterials based on their properties, the so-called intelligent compaction (IC). This offers opportunities for further enhancement and refinement of the compaction process and deliver quality control parameters that can be directly compared with design parameters (Tatsuoka and Gomes Correia, 2018; Gomes Correia and Ramos, 2022).

Furthermore, this entire process is underpinned by the connectivity of compactors, devices, and personnel to the internet, aligning with the principles of the Internet of Things (IoT). This connectivity fosters transparency, enhances communication, and facilitates real-time control of operations from any location worldwide with internet access, using personal communication devices such as smartphones.

In summary, intelligent compaction emerges as a pivotal technology, particularly during the construction phase, facilitating automated functions such as perception, analysis, decision-making, and execution (Xu et al., 2022). This technology holds significant importance in global engineering construction endeavours. At its core, intelligent compaction plays a crucial role in accurately perceiving compaction quality information, involving dynamic solutions to the interaction between rigid cylinders and elastic half-spaces (Paulmichl et al., 2022). However, there remains a need for further exploration to meet the precision requirements of quality control and dynamic solutions in this area. In this context, the integration of intelligent compaction within the previously discussed optimization framework holds significant promise for enhancing the efficiency and effectiveness of earthwork projects. It will improve project management by enabling proactive decision-making based on accurate and up-to-date information. For instance, the optimization system can dynamically adjust compactor routes and operating parameters in response to variations in soil type, conditions, or unexpected obstacles encountered during construction. By analysing compaction data in real-time, the system can identify areas of suboptimal compaction and allocate resources accordingly to ensure uniform compaction, thereby ensuring consistent compaction levels and meeting specified engineering design criteria across the entirety of the construction site.

5 APPLICATION TO AN URBAN METRO LINE – CASE STUDY

The Lisbon metro construction site, spanning between Santos and Cais do Sodre stations, serves as an intriguing showcase for the utilization of these technologies. This multifaceted construction project faces numerous challenges, including the construction of a sizable station on the urban side of the Santos hill, the excavation of a traditional tunnel within Lisbon's historic district, the creation of a trench in a densely populated urban area adjacent to sensitive buildings, the building underpinning through which the line passes, and the seamless integration with the operational station at Cais do Sodre. More detailed information is available at Martins et al. (2024).

Addressing these diverse challenges necessitated the implementation of an advanced monitoring system comprising robotic measurements, IoT sensors, a web platform, and real-time processing leveraging artificial intelligence. Figure 6 identify the monitoring devices (liquid level sensor and extensometer) for the specific case of underpinning building, solution adopted to facilitate the deactivation of the foundation piles of existing buildings within the tunnel projection area and to start excavation for the construction of the tunnel structure, part of Lisbon Metro line - new circular line.

5.1 Database process

The ARGOS platform was selected to centralize, store in Software as a Service (SaaS) mode, and manage monitoring data for the entire site during the extension of the works. The measurements encompass a wide range of data types, including manual and automatic topographic measurements, convergence measurements, borehole extensometer measurements, stress measurements, crack openings, altimetric liquid level monitoring, piezometric measurements, inclinometric measurements, and automatic high-end vibration measurements.

Figure 6. Lisbon Metro line new circular line: Underpinning building - Monitoring devices.

5.2 Monitoring data management and visualisation

All data are securely stored on a hyper-secure, trusted European cloud that complies with GDPR as well as European requirements regarding artificial intelligence. These data are accessible in real-time through a responsive web interface, presented in various formats such as plans, multi-layer GIS interfaces, dynamic maps, 3D views, dashboards, graphs, and reports.

5.2.1 Sensors technologies, wireless, communication protocols, cloud platform

The extensive coverage of the site, combined with the high number of sensors and measurement frequencies, along with the presence of various challenging traffic lanes, necessitated the adoption of automated measurements for the robotic theodolites, vibration sensors, and geotechnical and structural IoT sensors.

To ensure comprehensive coverage, both above and below ground, a network of radio bases was deployed across the entire site. Managed by the ARGOS core network, this radio network facilitates the secure and encrypted transmission of field data back to the central system.

5.2.2 Prediction models and anomaly detection

All raw data are securely transmitted to the cloud-based database where they undergo real-time processing to generate actionable information for the users.

Raw measurements may not always be immediately usable due to various reasons. These could include the need for transformation of electrical data for comprehension, presence of statistical errors such as artifacts or parasites, or excessively high data flow rates that are impractical for direct analysis by engineers. For instance, in the field of vibration monitoring, each instrument may generate thousands of measurements per second, which must be condensed into manageable indicators for site monitoring purposes.

In addressing these challenges, the monitoring platform assumes a critical role in real-time data processing. It employs mathematical, statistical, and logical algorithms, as well as artificial intelligence models, to perform tasks such as summarizing data, reducing noise, and making real-time forecasts based on historical data. For example, artificial intelligence algorithms can be trained to recognize and eliminate erroneous topographical data, enhancing the reliability of the information delivered and fortifying the overall robustness of the monitoring system. This sophisticated tool leverages the expertise of topographic engineers to ensure the integrity and accuracy of the monitoring data.

5.2.3 Alerts and actions

Once processed, the availability of reliable real-time measurements forms the cornerstone of effective site risk management. Customized detection thresholds are established for each sensor, triggering advanced alarms instantly upon their surpassing. These alarms are configured with various levels of sensitivity, conditional triggers, differentiated responses based on thresholds, schedules, and alarm groupings, among other details tailored to the site's configuration and

management requirements. Table 1 illustrates the criteria for alerts, references, and alarms utilized for monitoring settlements in column 10 (Figure 6) of the building during load transfer operations as part of the underpinning process. These settlements are associated with the load step values applied by the jacking.

Table 1. Lisbon Metro line new circular line: Underpinning building - Monitoring thresholds for column 10.

Column	Estimated Load (kN)	Load step	Load (kN)	Settlement measured in Liquid Level Sensors (mm)		
				Alert	Reference	Alarm
10	3362	10%	336	0,4	0,5	0,6
		20%	672	0,7	0,8	1,1
		30%	1008	1,0	1,2	1,6
		40%	1344	1,4	1,7	2,3
		50%	1680	1,8	2,2	2,9
		60%	2016	2,1	2,5	3,4
		70%	2353	2,5	3,0	4,1
		80%	2689	2,8	3,4	4,5
		90%	3025	3,1	3,7	5,0
		100%	3362	3,5	4,2	5,7

The alarms activated by the ARGOS platform are integrated into a comprehensive action plan detailing proactive and corrective measures to be taken when thresholds are breached. Upon activation, the ARGOS software promptly dispatches notifications in real time to designated stakeholders, providing details of the triggered alarm, the observed value, and the timestamp of the occurrence.

This proactive approach enables the site management team to swiftly intervene and mitigate any potential risks that could jeopardize the safety of personnel or structures within the construction site perimeter.

6 CONCLUSIONS

The integration of IoT and AI technologies in geotechnical engineering has led to the development of advanced Early Warning Systems (EWS) capable of real-time communication of critical events. These technologies facilitate efficient monitoring through reliable connections between sensors, control units and communication methods. Challenges include scalability, sustainability, and security. Best practices involve integrating AI-powered systems that can collect vast amounts of data in real-time and analyse it to provide actionable insights. By analysing trends and correlations in the data, AI models can forecast potential incidents and trigger early warning systems, allowing for proactive intervention and risk mitigation measures.

Earthwork construction projects often face uncertainties, requiring flexibility from planning and management teams to handle unforeseen events like weather changes or equipment failures. Decision support systems play a vital role by compiling past knowledge and facilitating collaboration among teams, aligning with modern construction principles like Construction 4.0 and Building Information Modelling (BIM). These systems utilize technologies like artificial intelligence and optimization algorithms to predict, monitor, and optimize earthwork processes.

A case study from a road construction project in Portugal illustrates how these systems optimize equipment fleet allocation, considering factors like cost, duration, and resource availability. In planning, the system creates robust plans with contingency measures, while during construction, it monitors productivity and adapts to disruptions. Historical data from projects enable future analysis and knowledge extraction, contributing to continuous improvement in earthwork construction.

In this context, intelligent compaction, as part of earthworks, leverages IoT and AI technologies to enhance the efficiency and effectiveness of soil compaction processes. Furthermore, the application of the previous optimization systems for earthworks, allows for informed decision-making by dynamically adjusting compaction equipment deployment and work schedules based on compaction performance. Smart sensors allow monitor compaction in real-time, providing data for optimization of the compaction. AI algorithms analyse this data to predict optimal parameters of the interaction roller-soil, and classify soil types, improving compaction quality and allowing assessment of design parameters. IoT connectivity enables remote monitoring and control, enhancing transparency and communication throughout all the earthwork process.

A second case study involving a metro construction site in Lisbon, illustrates also the use IoT and AI. In this case, the data, securely stored on a trusted European cloud complying with GDPR and AI regulations, are made accessible in real-time via a responsive web interface, offering various formats like plans, GIS interfaces, dynamic maps, and dashboards. To cover the extensive site and high sensor count, automated measurements using robotic theodolites, vibration sensors, and IoT sensors were deployed, managed by the ARGOS core network. Raw measurements undergo real-time processing to produce actionable insights, overcoming challenges like data transformation and high flow rates. A monitoring platform employs AI to enhance data reliability, recognizing and eliminating errors. Customized thresholds trigger advanced alarms,

enabling proactive risk management. Notifications alert stakeholders to potential risks, ensuring swift intervention to maintain site safety.

As a concluding note, the couple of IoT and AI technologies presents unparalleled prospects for transforming geotechnical construction and management methodologies. This synergy heralds the era of safer and more resilient project developments, delivering substantial advantages for all the players across the design, construction, and maintenance sectors, ultimately enhancing societal well-being.

ACKNOWLEDGEMENTS

The authors conceived and wrote the paper, but they incorporated figures and drawings from collaborative work of colleagues of the team, duly cited in the paper. Regarding the earthwork topic, developed applied research based on Manuel Parent's PhD thesis, conducted in 2015, under the supervision of the first author, has been instrumental. Additionally, the collaborative efforts within the framework of intelligent compaction, including the International Society for Intelligent Compaction (ISIC), as well as the Technical Committee 202 "Transportation Geotechnics" of the International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE), and its counterpart in Portugal, CPGT of the Geotechnical Portuguese Society (SPG), are also acknowledged.

Additionally, the first author acknowledge FCT / MCTES through national funds (PIDDAC), allocated to the R&D Unit Institute for Sustainability and Innovation in Structural Engineering (ISISE) under reference UIDB / 04029/2020, project UID/QUI/00686/2020 of CQ, and the Associate Laboratory Advanced Production and Intelligent Systems ARISE under reference LA/P/0112/2020.

The authors are also grateful to Lisbon Metro (Metropolitano de Lisboa) for the permission to use technical information, as well as to the contractor's consortium (Mota Engil, Spie Batignolles and Itmsol) and to the designer's team (COBA and JETsj Geotecnia).

ABSTRACT: Addressing the pressing need for sustainable and efficient engineering solutions as an alternative to traditional chemical synthesis, this paper highlights the emergence of bio-geotechnical engineering, specifically focusing on Microbially Induced Calcite Precipitation (MICP). MICP presents itself as a promising and sustainable approach to soil stabilization, mitigating environmental concerns linked with cement-based products. Through harnessing microorganisms present in soil and groundwater, MICP not only enhances soil mechanical properties but also contributes to geohazard mitigation. This comprehensive paper spans MICP studies, ranging from microscopic characterizations to lab-scale testing and large-scale applications, showcasing its adaptability and versatility. It delves into the bio-chemo-mechanical principles of MICP, emphasizing the increasing interest and expanding research within the field. The discussion extends to advancements in modeling tools, crucial for evaluating and optimizing MICP processes. These innovations play a pivotal role in bridging the gap between theoretical research and practical applications, guiding the design of MICP for real-world scenarios. Furthermore, the paper stresses the necessity of shifting focus towards MICP application at natural sites, highlighting its potential to become a standard in sustainable geotechnical engineering. The call for more attention to practical implementations reinforces the paper's contribution to advancing MICP as a viable and eco-friendly alternative in the field.

RÉSUMÉ: Répondant à la nécessité pressante de solutions d'ingénierie durables et efficaces en tant qu'alternative à la synthèse chimique traditionnelle, cet article met en lumière l'émergence du génie bio-géotechnique, se concentrant spécifiquement sur la Précipitation de Calcite Induite par les Micro-organismes (MICP). Le MICP se présente comme une approche prometteuse et durable pour la stabilisation des sols, atténuant les préoccupations environnementales liées aux produits à base de ciment. En exploitant les micro-organismes présents dans le sol et les eaux souterraines, le MICP améliore non seulement les propriétés mécaniques du sol mais contribue également à la mitigation des risques géotechniques. Cet article couvre les études sur le MICP, allant des caractérisations microscopiques aux tests à l'échelle laboratoire et aux applications à grande échelle, mettant en avant son adaptabilité et sa polyvalence. Il explore les principes bio-chimiques-mécaniques du MICP, soulignant l'intérêt croissant et l'expansion de la recherche dans ce domaine. La discussion s'étend aux progrès des outils de modélisation, cruciaux pour évaluer et optimiser les processus du MICP. Ces innovations jouent un rôle clé dans le comblement de l'écart entre la recherche théorique et les applications pratiques, guidant la conception du MICP pour des scénarios du monde réel. De plus, l'article souligne la nécessité de déplacer l'attention vers l'application du MICP sur des sites naturels, mettant en avant son potentiel pour devenir une norme dans le génie géotechnique durable. L'appel à accorder davantage d'attention aux mises en œuvre pratiques renforce la contribution de l'article à faire progresser le MICP en tant qu'alternative viable et respectueuse de l'environnement dans le domaine.

Keywords: Sustainable geotechnical engineering; bio-geotechnics; microbially induced calcite precipitation; soil stabilization.

1 INTRODUCTION

The geotechnical market is rapidly expanding in response to a growing global population and increasing urbanization rates. This growth compels the industry to explore new land sites that often have poor soil quality and are more exposed to geohazards, necessitating stabilization. As a result, the soil stabilization market is expected to grow to become a

$ 33.3 billion industry by 2025 (IndustryARC, 2021) in response to these challenges.

Traditional soil stabilization methods have predominantly depended on cement grouting. However, in light of escalating environmental challenges and increasing awareness of the substantial impact of cement-based products on the ongoing climate crisis, there is an expanding legislation framework advocating for the adoption of more environmentally sustainable techniques (ENVI, 2020).

Bio-geotechnical strategies, which replicate natural forms, processes, and systems, are at the forefront of alternative soil improvement methods. These strategies leverage nature's time-tested designs and innovations to create environmentally friendly solutions. A notable example is Microbially Induced Calcite Precipitation (MICP) which uses soil and groundwater microorganisms, to control the rate and intensity of calcite mineralization. This biocementation process forms a natural binder that stabilizes the soil and improves its mechanical properties, offering a sustainable alternative for soil stabilization and geohazard mitigation (Dejong et al., 2013; Terzis and Laloui, 2019a; Harran et al., 2023a).

This paper delves into the fundamentals of Microbially Induced Calcite Precipitation (MICP), encompassing the current research landscape and its bio-geo-chemo-mechanical principles. It thoroughly examines the core concepts of the process and their implications across various scales of study addressing how these principles are tackled both experimentally and through modelling. These scales range from microscopic characterization to lab-scale mechanical testing, extending to large-scale applications and pilot projects.

2 STATE OF THE RESEARCH IN THE FIELD

As Figure 1 illustrates, there has been a notable surge in publications delving into the fundamentals and applications of MICP, highlighting the growing interest in the field. These articles focus on using MICP to catalyze the bio-chemical reactions of calcite mineralization using both local and introduced microorganisms, enabling mineralization within practical engineering timescales. The comprehensive review of this interdisciplinary body of research includes those by Terzis and Laloui (2019a) and Harran et al. (2023a), which highlight the wide array of biological, chemical, and mechanical factors involved as well as the global efforts to establish representative models and upscale the technology. The reviews also detail the influence of several factors, such as the physical properties of soils, and the type and concentration of bacteria and reagent solutions, on the efficacy of the MICP process. Furthermore, they discuss how these variables can be tailored to suit a diverse range of uses such as:

- Soil strengthening
- Leakage control
- Slope stabilization
- Liquefaction mitigation
- Fugitive dust control
- Erosion control
- Land reclamation

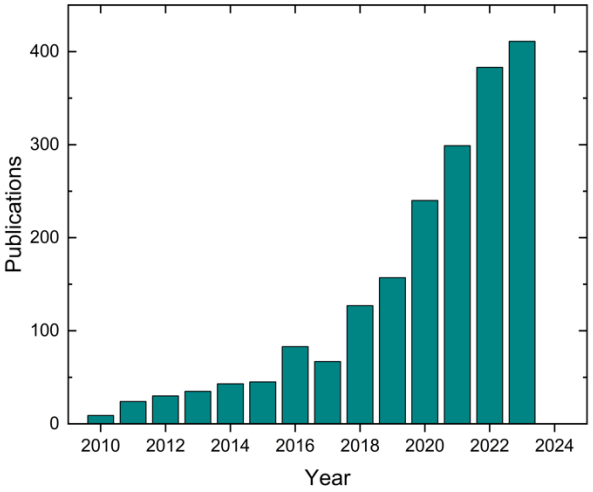

Figure 1. Number of published research articles tackling MICP per year (Scopus).

The large number of applications demonstrates the versatility and adaptability of MICP in practical applications.

3 MICP BIO-CHEMICAL PROCESSES

To consider the MICP process, a good understanding of the underlying chemical reactions is essential. Calcite mineralization can be achieved through multiple bio-chemical pathways including sulfate reduction, denitrification, and ureolysis. The latter is particularly efficient for most geotechnical applications and has consequently been the subject of extensive study. This process involves the hydrolysis of urea Eq. (1), that is catalyzed through the urease enzyme. This reaction produces ammonium ions, which increase the pH, and carbonate ions. In the presence of a natural or introduced calcium source, the alkaline environment favors the precipitation and formation of calcite Eq. (2). The urease enzyme significantly accelerates this process making it feasible in an engineering timeframe.

$$CO(NH_2)_2 + 2H_2O \xrightarrow{urease} 2NH_4^+ + CO_3^{2-} \quad (1)$$

$$Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3 \downarrow \quad (2)$$

Although multiple bacteria strains can produce the urease enzyme, *S. pasteurii* has been the most abundantly researched due to its activity in temperature and pH ranges that align with typical geotechnical project sites. Enzymatically Induced Calcium Carbonate Precipitation (EICP) is another approach which involves the ex-situ extraction of urease, which is then introduced directly into the soil. This technique facilitates the catalyzation of the reaction while circumventing the need to introduce live bacteria into the soil, offering a different approach to soil stabilization and mineralization (Terzis and Laloui, 2019b).

A significant drawback of the ureolysis process is the production of ammonium as a byproduct, which poses risks of groundwater and soil contamination. However, new techniques such as chemically induced calcite precipitation (Park et al., 2020) and ex-situ MICP (Terzis and Laloui, 2021) have been developed to mitigates the risk of ammonium contamination.

4 A MULTI-PHYSICAL, MULTI-SCALE PROCESS

4.1 Microscopic processes

A comprehensive investigation of the mechanical properties of biocemented soils begins with an analysis of the microscopic mechanisms that govern the macroscopic behavior. Central to these investigations is identifying of the soil's microstructural properties and the transport processes that occur during biocementation.

One of the most important microstructural properties is the different forms calcite can take as it precipitates in the soil. Precipitated calcite can create active bonds in the form of interparticle bonds, passive bonds by coating the grain surfaces, and filling the pore space. Each of these forms, shown in Figure 2, uniquely contributes to the mechanical response of biocemented soils, highlighting their importance in understanding and optimizing soil stabilization processes.

Advancements in imaging techniques through Scanning Electron Microscopy (SEM) and X-Ray micro-Computed Tomography (micro-CT) have allowed us to gain deeper insights into the particle-level interactions in biocemented soils. These techniques can provide a detailed 3D reconstruction of the soil's micro-structure as well as quantitative analysis of the calcite distribution in the soil and the different forms it takes. Terzis and Laloui (2018) reconstructed a 3D micro-CT scan of a biocemented sample, successfully identifying the different solid components, sand grains and calcite, as well as outlining the pore spaces as shown in Figure 3

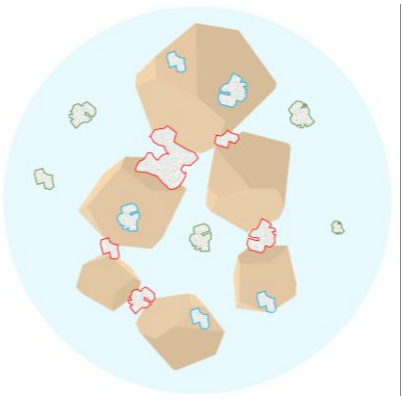

Figure 2. Schematic of precipitated calcite in the soil as: inter-particle bonds (red), grain coating (blue), and filling the pore space (green).

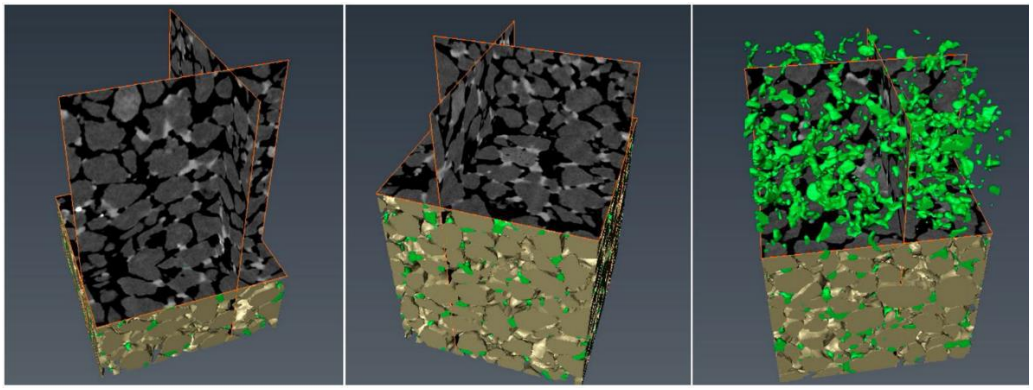

Figure 3. 3D volume reconstruction of a bio-cemented sand sample, with a horizontal section of $1.5\ mm^2$*, obtained through micro-CT scans: sand grains in brown calcite bonds in green (as shown in (Terzis and Laloui, 2018)).*

Through advanced image analysis techniques, these 3D reconstructions were used to accurately estimate the number of active bonds in the scanned samples, shown in Figure 4 producing a range between $75 - 84\%$ depending on the soil gradation and other microscopic soil properties (Terzis and Laloui, 2018, 2019b).

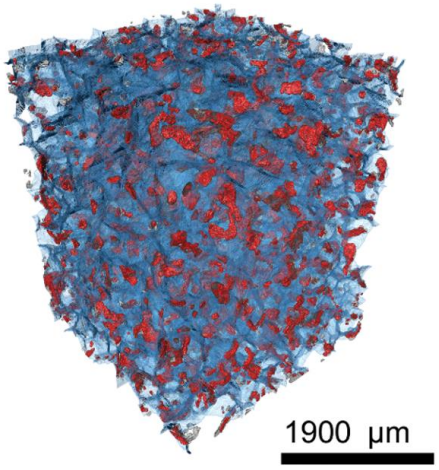

Figure 4. 3D view of active bonds (red) and spline lines (blue) in a bio-cemented sand (Terzis and Laloui, 2018).

More recently, Roy et al. (2023) were able to thoroughly analyze the contact and pore networks of biocemented sands using similar 3D micro-CT scans gaining a deeper understanding of the flow within the pore networks and the resulting calcite precipitation. Their findings particularly highlight the pivotal role of the initial microstructure in influencing these processes.

Fluid flow during the MICP process as well as after cementation is also thoroughly investigated through the use of microfluidic chips. These physical models allow the simulation of flow channels or porous geomaterials with varying properties. They particularly facilitate continuous microscopic observations, making it possible to track the evolution of calcite formation and the influence of micro-parameter at all stages of the MICP process. Elmaloglou et al. (2020, 2022) used a meter-long chip with varying pore-size distributions to track the formation of calcite crystals, following their evolution at different treatment stages with time-lapse microscopy, which helped quantify calcite formation and repartition (Figure 5).

These microscopic insights are pivotal to unraveling the primary mechanisms governing the MICP process, laying a crucial foundation for formulating reactive transport models that simulate the precipitation process. Additionally, they are essential in developing representative mechanical models that accurately incorporate the distinct contributions of the various forms of precipitated calcite.

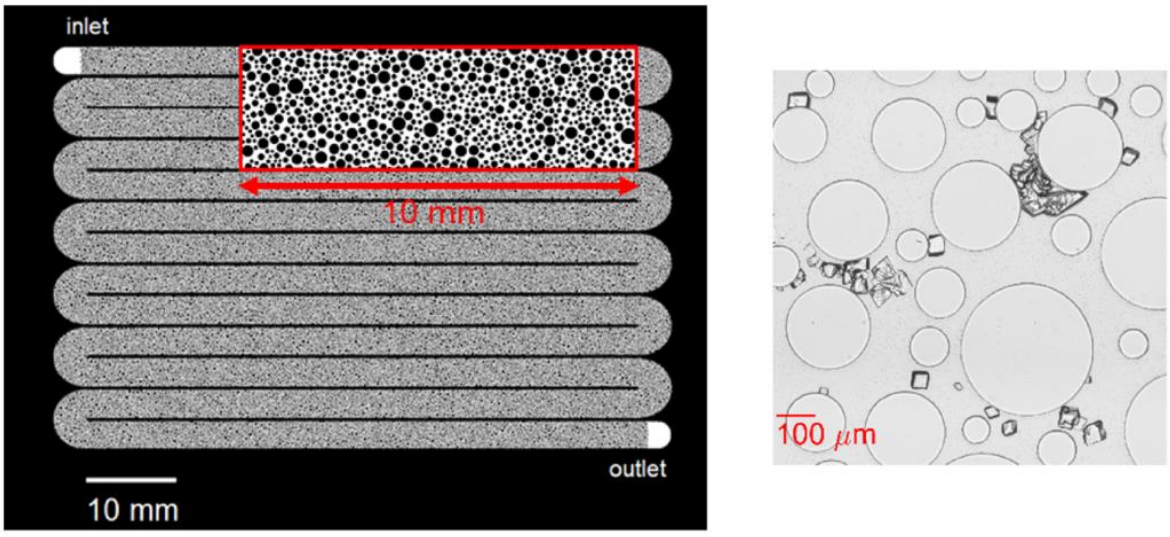

Figure 5. Microfluidic chip of a heterogeneous porous medium (adapted from Elmaloglou et al. (2022)).

4.2 Meso-scale mechanical performance and modeling

Although microscopic tests provide valuable information about the behavior of biocemented soils, laboratory tests at the representative elementary volume scale remain essential to characterize these soils for practical applications.

Biocemented soils, while sharing certain similarities with soils treated using traditional grouting materials, exhibit unique complexities in their characterization. This uniqueness is largely due to the

multiphysical processes involved in their formation. A primary distinction lies in the binder distribution within the soil. Traditional cementation methods involve mixing cement uniformly with soil, resulting in a homogeneous distribution. In contrast, MICP employs less invasive injection techniques, which can lead to a heterogeneous distribution of calcite. This variability often translates into distinct mechanical behaviors when compared to their traditionally cemented counterparts.

These complexities underline the necessity of establishing specific, representative metrics for analyzing and comparing biocemented soil samples. The gravimetric calcite content is a commonly used metric since it can be easily determined from laboratory and field samples through methods like acid digestion. However, it is important to note that it can only provide a global indication of the calcite content in the sample and does not fully distinguish the calcite distribution, causing two samples with identical calcite mass content to exhibit different mechanical properties. Despite this limitation, gravimetric calcite content remains a crucial and practical metric for estimating the behavior of biocemented soil samples.

The impact of various bio-chemical and mechanical factors on mechanical performance, as depicted in Figure 6, has been assessed through standardized geomechanical tests. Terzis et al. (2016) used triaxial tests to explore the effects of different treatment protocols on the chemical reaction efficiency and mechanical performance. They observed that a pulse injection scheme achieved a reaction efficiency – defined as the ratio of effluent to injected calcium ions – of over 80% when a longer reaction time was allowed between pulses, as shown in Figure 7. Conversely, with a recirculation injection protocol, reaction efficiency improved as the reagents were circulated through the sample for extended periods. These results provide valuable insights for the design and execution of field-scale treatment protocols. Such insights are crucial in facilitating the broader adoption and practical application of this technique, as they help optimize the treatment process for enhanced efficiency and effectiveness.

Moreover, the study found that the mechanical performance of the treated samples also showed significant improvement. With a calcite content of around 8.5%, there were notable increases in both the shear strength angle and apparent cohesion, underlining the effectiveness of the treatment protocols in enhancing the soil's structural integrity.

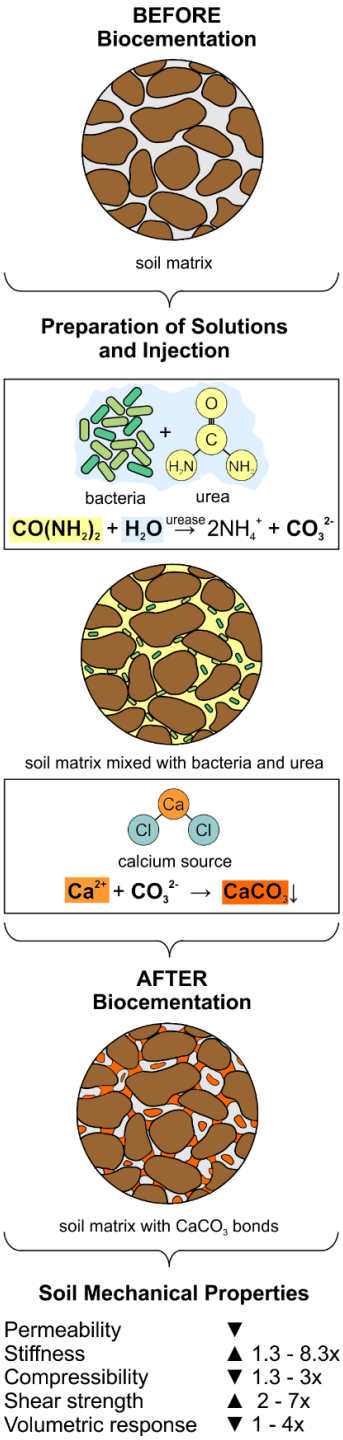

Figure 6. Schematic view of the biocementation process and its effects on soil properties.

In their 2019 study, Terzis and Laloui expanded their investigation to include additional bio-chemical factors, such as applying a novel freeze-dried bacteria powder, and examining its impact alongside soil gradation on mechanical performance. They conducted multiple unconfined compression tests on fine, medium, and coarse sand samples with varying calcite contents, the results of which are depicted in Figure 8. The figure reveals that fine sand exhibited significantly lower strength at comparable calcite

contents than medium sand. This observation was further supported by triaxial tests on these sands, shown in Figure 9. While an improvement in strength was evident in both fine and medium sands compared to their untreated counterparts, the medium sand showed a substantially larger enhancement in strength at each level of confining pressure (Terzis and Laloui, 2019b).

Recent research by Harran et al. (2022) investigated the deformability characteristics of bio-cemented sands, particularly focusing on how these properties change over time and under varying stress conditions. A key observation from these studies is the notable reduction in deformability attributed to biocementation. When subjected to sustained loading, biocemented samples observed smaller axial strains as demonstrated in Figure 10(a). Additionally, the study revealed that samples with higher calcite content demonstrated significantly reduced axial deformations when subjected to uniaxial loading. Samples with a calcite content of around 5% exhibited approximately four times less axial strain than compared to their untreated state, as illustrated in Figure 10 (b).

The experimental findings accumulated thus far serve as a vital foundation for developing and validating multi-physical models, which are indispensable for designing and optimizing of practical applications. The four principal physical processes of MICP — biological, chemical, hydraulic, and mechanical — are intricately interconnected, as depicted in Figure 11. Fauriel and Laloui (2011, 2012a, 2012b) used these interconnections to develop a comprehensive bio-chemo-hydro-mechanical model that successfully captured both calcite distribution and the resulting mechanical performance. Building upon this groundwork, Bosch et al. (2024) recently introduced an advanced fully coupled model that incorporates elasto-plasticity. The model could fully simulate the treatment process and the mechanical response of a shallow foundation making it particularly suited for practical applications.

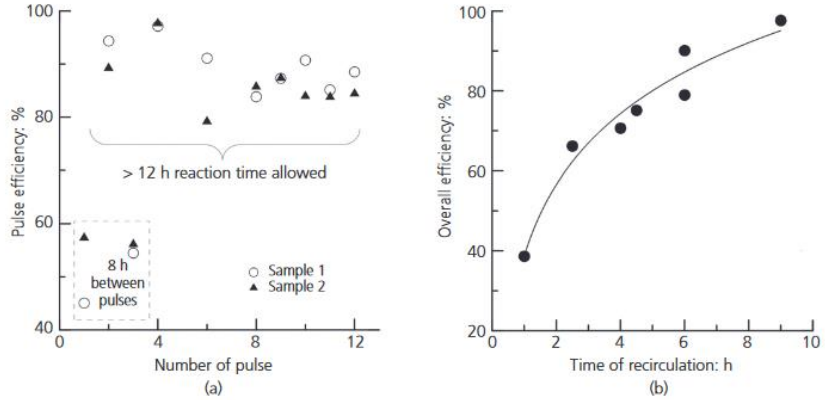

Figure 7. (a) reaction efficiency for samples treated using pulse injections, (b) reaction efficiency for samples treated using recirculation (as shown in (Terzis et al., 2016)).

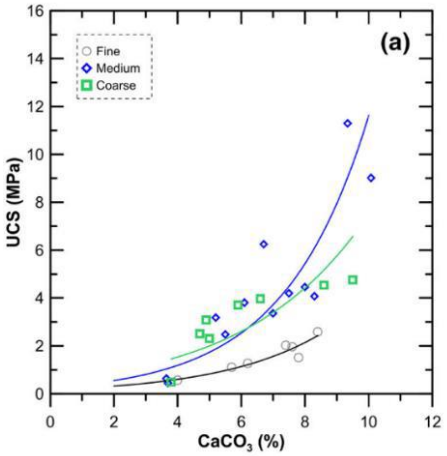

Figure 8. Unconfined compression strength for fine, medium and coarse sand (as shown in (Terzis and Laloui, 2019b).

Modeling approaches can also be tailored to concentrate specifically on the mechanical performance of biocemented soils. This for, of modeling involves developing advanced constitutive models capable of replicating the soil's mechanical behavior given a specific calcite content. A notable example is the Advanced Constitutive Model for Environmental Geomechanics – Biochemistry (ACMEG-B), which was introduced by Fauriel (2012). This model, building on the ACMEG framework originally developed by Laloui and François (2009), incorporates the impact of calcite through parameters related to densification and bonding. Such an approach allows the model to accurately reflect the distinct mechanical performance of biocemented soils under various loading conditions, as illustrated by Figure 12.

4.3 Large scale applications

Transitioning insights from micro and meso-scale studies to field applications represents a critical advancement in incorporating MICP into standard industrial practices. MICP stands out as an environmentally conscious soil improvement technique and boasts distinct advantages over traditional methods. As illustrated in Figure 13, a key benefit is the superior penetrability of bio-cementation solutions. The relatively small dimensions of microorganisms, typically ranging from 0.5-1 μm in diameter and 2-5 μm in length, allow for enhanced permeation within the pores and microfractures of porous media, a stark contrast to the larger particles of traditional cement. This characteristic, combined with the low viscosity of the treatment solutions, facilitates effective permeation grouting at lower injection pressures compared to the high-pressure fluid mixing required in traditional grouting methods. This approach lowers energy consumption and reduces operational costs, as it can be achieved with standardized equipment. Combining these benefits, with the mechanical improvements that are comparable to traditional cement reinforcement establishes MICP as a serious alternative to traditional grouting methods. The application range of biocementation compared with various treatment methods is shown in Figure 14.

To demonstrate the applicability of biocementation for field applications, the technique was used, alongside traditional stabilization techniques, to stabilize a slope encompassing approximately 3000 m3 of earth mass, shown in Figure 15. The bio-cementation treatment involved 51 injection boreholes, each 4.5 m deep, targeting the failure slip surface Despite the natural terrain's low permeability, local fissures facilitated the rapid dispersion of the reactants. Bio-cementation's efficiency was evaluated using a comprehensive assessment which included laboratory tests, in-situ monitoring, microstructural inspections, and aerial surveillance post-stabilization. This holistic assessment revealed that the bio-stabilized zone experienced slower displacement rates than compared to the rest of the slope, demonstrating biocementation's potential in real-world conditions.

More recently, Harran et al. (2023b) made significant progress in upscaling biocementation in a novel large-scale experimental basin ($8\,m \times 10\,m \times 2.5m$), shown in Figure 16. The concrete basin is equipped with drainage at the bottom to avoid the accumulation of reagents that produces unrealistic precipitation patterns that are normally observable at the bottom and edges of other large-scale basins. In this unique setup, various MICP techniques and injection protocols were tested to optimize the MICP process.

The tests were accompanied by a comprehensive monitoring and assessment campaign that included both field scale and laboratory tests. In the field, an extensive dynamic penetrometer campaign evaluated the spatial distribution of calcite and the resulting increase in mechanical performance.

Additionally, chemical monitoring of both injected and effluent solutions was conducted to track reagent consumption and evaluate MICP efficiency. In the lab, mechanical performance was assessed using unconfined compression tests and microscopic observations to view the changes at the pore level.

Buyuklu et al. (2023) later used the same basin to investigate the impact of various injection techniques and protocols on the spatial distribution of calcite.

The resulting cemented sand columns shown are shown in Figure 17. The tests used a similar comprehensive testing campaign using dynamic penetrometer measurements and triaxial tests as well as laboratory calcite content measurement.

Building on these insights Ten Bosch et al. (2022) developed a representative reactive transport model, capturing the calcite precipitation patterns from these experiments as shown in Figure 18.

This advancement in modeling tools is crucial for guiding MICP's design and optimization for practical applications. It equips practitioners with invaluable knowledge and empirical data, bridging the gap between theoretical research and real-world implementation, and underscores the growing maturity of MICP as a viable solution in geotechnical engineering.

5 CONCLUSION AND FUTURE PERSPECTIVES

In conclusion, the comprehensive exploration of biocemented soils across various scales has significantly advanced our understanding of their mechanical properties. The intricate interplay of the bio-chemo-hydro-mechanical properties in biocemented sands has been elucidated, showcasing their potential for a wide range of geotechnical applications. This detailed understanding is critical in evaluating the potential of biocemented soils to withstand and adapt to various environmental conditions, making them a viable solution for geotechnical challenges.

The journey from laboratory-scale experiments to large-scale applications marks a pivotal moment for the field of biocementation. Recent advancements have successfully bridged the gap between small-scale controlled environments and real-world scenarios. These large-scale trials have been instrumental in replicating the complexities of natural sites, thereby providing a more realistic assessment of the potential and limitations of biocementation techniques.

The insights from the laboratory and large-scale experiments have led to the introduction of robust modeling tools that enable better evaluation and optimization of biocementation, allowing for more precise predictions and efficient designs. They facilitate the simulation of various scenarios, including different soil types and environmental conditions, thus enhancing the adaptability of biocementation techniques. This modeling capability is crucial for practitioners, offering a reliable means to predict outcomes and tailor approaches to specific site conditions.

Future work in biocementation is poised to expand its applications and focus on implementation in natural sites. Continued research and development are needed to refine techniques, enhance efficiency, and reduce costs, making biocementation more accessible and feasible for widespread use. The potential for this technology to contribute to sustainable development and environmental conservation is immense, particularly in the context of mitigating geohazards and enhancing soil stability. As we move forward, the integration of biocementation into standard geotechnical practice is not just a possibility but an impending reality, paving the way for more sustainable and resilient infrastructural development.

3D planning in the Lisbon of the future: requirement or necessity?

La planification en 3D dans la Lisbonne du future: exigence ou nécessité?

C. Pinto*
Lisbon Municipality, Lisbon, Portugal
**claudia.pinto@cm-lisboa.pt*

ABSTRACT: Current cities already use part of their underground space for several uses, such as the water supply systems, sewage and communication networks, heavy mobility solutions as the subway, highway tunnels, and also parking; however, these interventions are not carried out in an integrated manner, sometimes leading to constraints, especially in terms of impact on the natural resources with significant consequences on the surface level. Therefore, it is necessary to envision future cities as contributing to the implementation of sustainable development goals, which, in our understanding, requires the integration of the subsurface into planning and management strategies that are crucial to address contemporary environmental and social challenges. To implement this strategy, it is essential to involve several stakeholders, including local governments, communities, private companies, technical experts, and real estate, to ensure that the solutions are viable from a technical and economic point of view and benefit the city.

RÉSUMÉ: Aujourd'hui, les villes utilisent déjà une partie de leur espace souterrain à des fins diverses, telles que l'approvisionnement en eau, les réseaux d'assainissement et de communication, les solutions de mobilité lourde comme le métro, les tunnels routiers ou encore les parkings; cependant, ces interventions ne sont pas réalisées de manière intégrée, ce qui entraîne parfois des contraintes, notamment en termes d'impact sur les ressources naturelles, avec des conséquences importantes au niveau de la surface. Il est donc nécessaire d'envisager les villes du futur comme contribuant à la mise en œuvre des objectifs de développement durable, ce qui nécessite selon nous l'intégration du sous-sol dans les stratégies de planification et de gestion qui sont cruciales pour répondre aux défis environnementaux et sociaux contemporains. Pour mettre en œuvre cette stratégie, il est essentiel d'impliquer plusieurs parties prenantes, notamment les gouvernements locaux, les communautés, les entreprises privées, les experts techniques et le secteur immobilier, afin de s'assurer que les solutions sont viables d'un point de vue technique et économique et qu'elles profitent à la ville dans son ensemble.

Keywords: Underground use; planning strategy; impact mitigation; integrated sustainability solutions; society engagement.

1 INTRODUCTION

In the 20th century there was a population increase and its concentration in urban areas, leading to the need for new buildings and infrastructures to improve people's living conditions (Almeida *et al.*, 2008). In Lisbon the need for space led to the occupation of sensitive areas with less favourable geotechnical characteristics, reflected in increased construction costs.

Technological development allows for construction in height and depth; however, it requires specific geotechnical knowledge, usually obtained through geotechnical survey campaigns and *in situ* and laboratory testing (Almeida *et. al*, 2008; 2010).

The increase in projects for the construction of underground structures, with a strong geotechnical component, sometimes with serious implications for surrounding buildings, led the Lisbon Municipality to establish rules determining that excavation and foundation works could only be carried out by specialized companies and technicians (Pinto, 2020).

This municipal document was the basis for standardizing excavation work in urban areas, defining a set of rules for geotechnical projects. (Pinto, 2020).

Based on the municipal regulations and in close collaboration with the Engineers Portuguese Order, the Geotechnical Specialisation Commission developed some recommendations for the excavation design, implemented in 1991.

The final version of this work, entitled "*Recommendations for geotechnical surveys to support the design of foundations and excavation of current buildings*", was presented in 2003 and defined

the procedures to be considered in the reconnaissance of sites, the requirements for the geotechnical project, execution phases and the monitoring and observation of the soil's behaviour during the construction (Pinto, 2020).

For decades, site investigation campaigns and projects produced a large amount of data that has been collected and integrated into databases, enabling the implementation of a geoscientific information system with a special focus on the elaboration of the Lisbon geotechnical mapping (Almeida *et al.*, 2008; 2010; Matildes *et al*, 2010; Pinto, 2020; Pinto *et al.*, 2023a; 2023b).

In addition, a survey and design of a database for underground occupation have been carried out, and the survey of basements in some areas of the city has now been completed (Pinto *et al.*, 2020).

This paper will present the ongoing projects in Lisbon Municipality. This information has a high potential for 3D planning and management in future cities and should be considered fundamental for projects optimization, cost reduction, and decision support.

2 CONTEXT INFORMATION

2.1 Lisbon geological setting

Lisbon geology is well documented in several studies developed since the 19th century; however, the most detailed geological mapping for Lisbon city, was produced by Fernando Moitinho de Almeida in 1986, at a scale of 1:10.000. The author introduces an innovation using in addition to the classic stratigraphic criterion the representation of alluvial cover and man-made deposits (not always differentiated), using information from geotechnical boreholes and excavations, which gives the geological map a geotechnical component (Moitinho de Almeida, 1986). Including depth information made it possible to define the geological structures present and the thickness of the surficial deposits (Moitinho de Almeida, 1986).

According to Pais *et al.* (2006), Lisbon city presents different subsurface geological formations, from the Cretaceous to Miocene periods, which are covered by Holocene materials (alluvium fills), as a result of the installation of a fluvial network (Figure 1).

Except for the Lisbon Volcanic Complex (CVL), formed by effusive and explosive episodes, which resulted in basaltic rocks and interspersed deposits of ash and pyroclasts, the Lisbon subsurface consists of sedimentary formations, including cretaceous limestones and the clays and conglomerate rocks from the Benfica Complex.

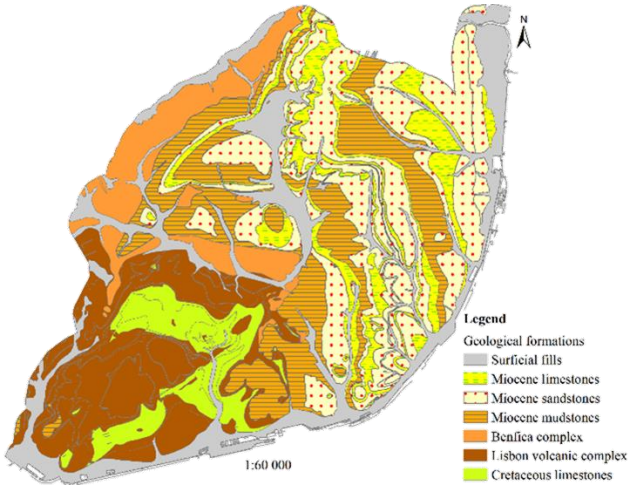

Figure 1. Simplified geological map (adapted from Pais et al., 2006).

The Miocene series comprises 15 stratigraphic units characterized by clayey, sandy, and silty soils, carbonate sandstones and limestones. All these units present significant lateral and vertical facies variations, reflecting the alternance of sea and continental environments (Almeida, 1991; Pais *et al.*, 2006).

The surficial fills include the alluvial deposits associated with the Tagus River and those from its subsidiary watercourses (Ribeira de Alcântara, Benfica, Campo Grande, Vale do Pereiro, Arroios, Chelas).

2.2 Lisbon masterplan

Territorial management instruments are regulatory and establish the land use regime, defining territorial occupation models and the organisation of urban networks and systems in a bi-dimensional representation. They also aim to articulate the sectoral policies established in the national and regional instruments with local development strategies (Pinto, 2020).

Although these instruments define the land use models, they do not consider the underground occupation carried out without any strategic planning. (Pinto, 2020).

Lisbon Master Plan (CML, 2012) is a policy instrument that seeks to define strategic guidelines for the development of Lisbon city. It was approved in August 2012, and for the first time, incorporates a set of natural and man-made risks mapping, such as landslides susceptibility, seismic hazard (Figure 2), flooding vulnerability, and the impact of direct tidal effect in the riverfront area.

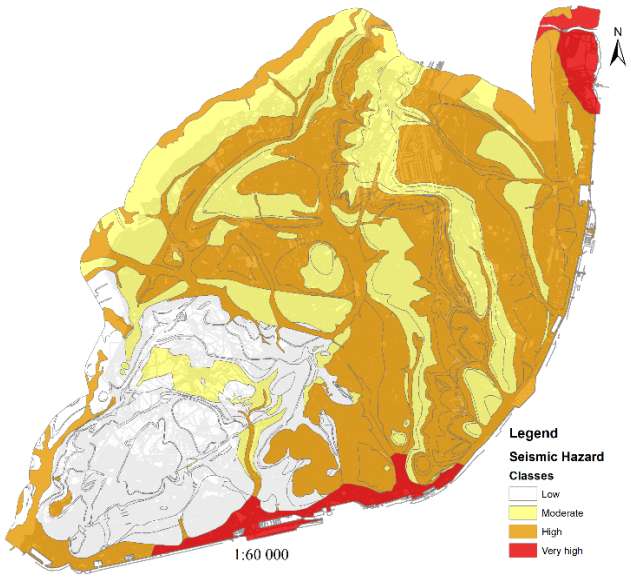

Figure 2. Seismic hazard map. Lisbon Master Plan.

In addition to the graphic elements, some rules have been defined for the intervention/occupation in the most vulnerable zones. As an example, in areas of high and very high seismic hazard, it is necessary to deliver geological, hydrogeological, and geotechnical studies to define technical solutions compatible with the characteristics of the territory and to implement, at the same time, mitigation measures (CML, 2012).

The Lisbon Master Plan's bi-dimensional approach is clearly insufficient to overview all the variables at stake (Pinto, 2020).

In the author's opinion, the definition of planning policies for the cities of the future should be based on a 3D approach, considering both surface development models and underground occupation, integrating city demands with sustainable use of existing resources.

Geology and geotechnics are essential disciplines for the development of a sustainable underground occupation policy. However, solutions should consider different variables, which requires detailed knowledge of geological and geotechnical characteristics as well as the existing structures and infrastructures that converge on them.

It is also urgent to consider that the engineering solutions could be compatible with local resources, such as groundwater, but considering them as an opportunity and not a constraint.

Several projects managed by the author have been implemented in Lisbon Municipality to help achieve this goal.

3 ONGOING PROJECTS

3.1 GeoSIG Project

The Municipality of Lisbon has an important collection of geological and geotechnical data obtained through numerous campaigns carried out over the last few decades.

This data is a valuable resource and, when properly organised, provides highly applicable information in many areas of urban planning and management. However, the value of this information depends on the standardisation of the source data, its constant updating, its availability, and the existence of metadata to assess its origin and quality (Pinto, 2020).

Based on the above assumptions, over the last few years Lisbon Municipality has sought to develop data structures supported by management systems, with the aim of restructuring the processes of entering and updating existing data and enabling not only the data's logical storage but also its effective management, aiming at the production of the necessary outputs.

As a result of the evolution of computer technology, new storage technologies were developed that made it possible to effectively manage the large volume of data obtained from geotechnical surveys (Almeida *et al.*, 2003; Culshaw *et al.*, 2006; Almeida, 2011; Silva, 2015; Pinto, 2020).

The spread of GIS has boosted new tools for analysing and spatially visualising data, making it possible to produce geological/geotechnical thematic mapping, on common computers, at low cost (Silva, 2015). The interpolation tools associated with these systems allow for 3D modelling, which optimises mapping production (Zuquette & Gandolfi, 2004; Silva, 2015; Pinto, 2020).

Through a project financed by the FEDER (LISBOA-01-0527-FEDER-000894), the GeoSIG application was developed. The app has a web interface but a restricted access (Figure 3). That condition was imposed by the companies that provides the data; however, the municipality uses this information to support decision-making and municipality initiatives and intends to provide some thematic analyses based on borehole data that will be part of the geotechnical map (Pinto, 2020). In general terms the users of the GeoSIG app can:

- Georeference boreholes and other *in situ* testing.
- Upload data resulting from a campaign.
- Visualize the distribution of sampling in Lisbon area.
- Filling data into alphanumeric tables.
- Produce thematic analyses.
- Download the geological report.

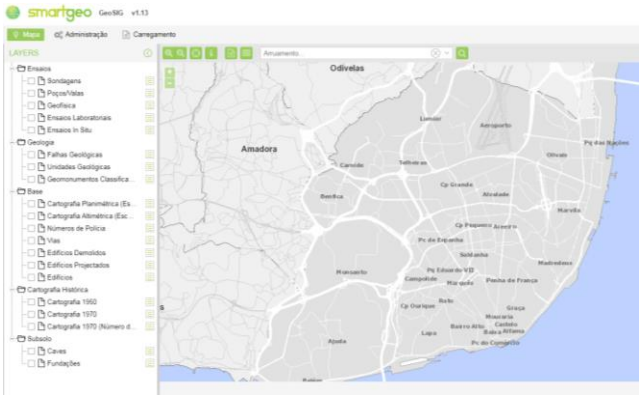

Figure 3. Main interface of the GeoSIG platform.

This platform integrates more than 13.000 boreholes distributed heterogeneously throughout the municipality area (Figure 4). The user can access data related to the lithology, the water level, SPT values, recovery rates, laboratory tests, and other relevant information associated with each borehole.

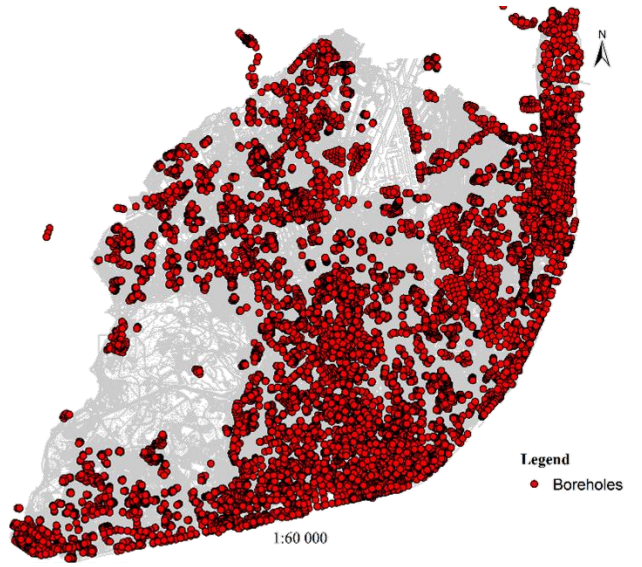

Figure 4. Distribution of boreholes in Lisbon city (Source: GeoSIG).

The GeoSIG database is intended to provide macro-scale analysis and outputs, so a local study is still required for projects in a specific area.

The analysis and modelling of lithology, lithostratigraphy, soils resistance (through SPT) and water levels allow the production of information suitable for urban planning (Pinto *et al.*, 2023). They can also be used to perform more specific studies, such as seismic microzonation based on geotechnical data (Oliveira *et al.*, 2019), enabling several actors, including designers, planners and others, to assess the constraints and estimate the order of magnitude of the costs for carrying out a particular geotechnical project, making it possible to optimise projects from an early stage (Gonçalves *et al.*, 2017; Pinto, 2020).

3.1.1 Case study 1: thickness of the coverage deposits

Due to its heavily urbanised landscape, non-natural processes such as excavations and landfill deposits often change the terrain morphology. Nowadays, the exact location of these exploitations is unknown.

In addition these materials have also resulted from the extensive mining industry, which had an essential role in the reconstruction of Lisbon after the earthquake of 1755, related to the extraction of limestones, basalts, sandstones and mudstones in ancient quarries (Pinto, 2005; Cunha *et al.*, 2017).

Through geological campaigns performed in Lisbon, several anthropogenic deposits, highly heterogeneous in nature, extension, and thickness, were intersected (Pinto, 2020).

To perform a detailed subsurface dynamic analysis aiming at the location of ancient quarries and their landfill material thickness, cartographic and topographic information dating from 1911, 1950, 1970, 2012 was used to create digital terrain models, which allowed the terrain morphology changes to be identified and the volume of landfill materials to be obtained (Figures 5).

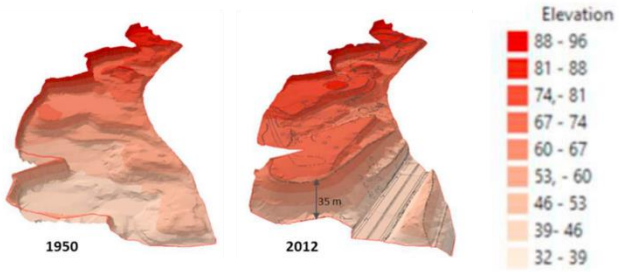

Figure 5. 3D model of a quarry in 1950 and 2012.

The analysis shows that the area contains several landfill deposits, particularly in the NW part of the quarry, where the deposits reach 35m in thickness.

Other studies have used several sets of aerial photographs with stereoscopic coverage (Vasconcelos, 2011).

A map representing the landfill and excavation areas and indicating their thickness, whenever possible, has been created to compile the information obtained from these studies.

3.1.2 Case study 2: thickness of alluvium fills

Alluvial deposits are related to the ancient watercourses and the deposits from the Tagus River. Their composition reflects the erosion of the bedrock or, when close to the Tagus River, presents sandy and muddy layers.

Gravitational deposits, or colluvium fills, are found at the base of some outcrops. They are essentially

made up of disaggregated materials and are generally small in thickness (Pinto *et al.*, 2012).

The lithologies and thicknesses of alluvium fills are highly variable, ranging from centimetres to 40 metres in the riverside area (Lopes, 2001). Tagus River alluvium has been recognised in countless boreholes, particularly those that resulted from the interventions made by the Administration of the Port of Lisbon and the construction of the "*25 de Abril Bridge*". According to this data, the alluvium reaches a thickness of around 58 metres in the area of the Tagus River embankment (Zbyszewsky, 1963).

The GeoSIG database assessed the thickness of alluvium fills in Lisbon Downtown. The borehole data were interpolated using the IDW (inverse distance weight) interpolator (Pinto, 2020).

The main alluvium thickness is related to the ancient water lines, such as *Ribeira de Arroios*, *Vale do Pereiro and Esteiro da Baixa* and the Tagus alluvium (Figure 6).

Figure 6. Thickness of alluvial deposits (Lisbon Downtown).

The high thickness of these materials could constrain urban occupation because they have unsatisfactory resistance and high deformability.

Geotechnical survey campaigns are demanded to characterise the soils' properties to evaluate the project conditions in an early stage. Poor recognition could have implications during the construction phase, increasing the risk already inherent to the geological uncertainty associated with engineering works and the cost of construction (Almeida *et al.*, 2008; Pinto, 2020).

3.1.3 Case study 3: groundwater level position

Most of the requests in urban areas aim to improve population living conditions and accessibility. In consolidated areas, these improvements are the construction of basements for space optimisation.

These underground structures directly impact the water table and, in some cases, the piezometric level, especially in situations where they have a significant volume, such as underground parking, and tunnels related with mobility solutions ou water supply, which can intersect free or confined aquifer layers (Pinto, 2020).

When affecting shallower flows, the hydrogeological regime tends to adapt, and as the formations are more decompressed at the top, this readaptation is favoured. However, when the impact is developed at deeper flows layers and exhibits significant dimensions, the barrier effect may have long-term effects as the ability to adapt will be less and slower.

In either situation, the consequence is a decrease in the foundation elements' resistance capacity and impulses in adjacent buildings' buried structures (Almeida, 2003).

The impact on the evolution of the water table must be recognised at the design stage to allow the adoption of solutions that are both feasible for their intended purposes and mitigate the impact on the surroundings, which can increase construction costs (Pinto, 2020).

In 2012 some rules were implemented by the author in the Lisbon Master Plan, consisting of the presentation of hydrogeological studies for areas affected by land development operations, demanding the determination of hydrogeological characterisation parameters for local contexts. This obligation applies to wetland areas, those with a high to very high flooding vulnerability, and areas subject to direct tidal effect, according to articles nr. 13 and 22 of the Masterplan regulation.

Some analyses were carried out in some areas of Lisbon city as proof of concept. As performed to the assessment of the thickness of the coverage deposits, the water level data were also interpolated using IDW, aiming to generate groundwater surfaces (Figure 7).

This information allows Lisbon Municipality to optimise water use for different purposes, essentially to promote sustainable use of undergorund resources in a climate change context (Pinto, 2020).

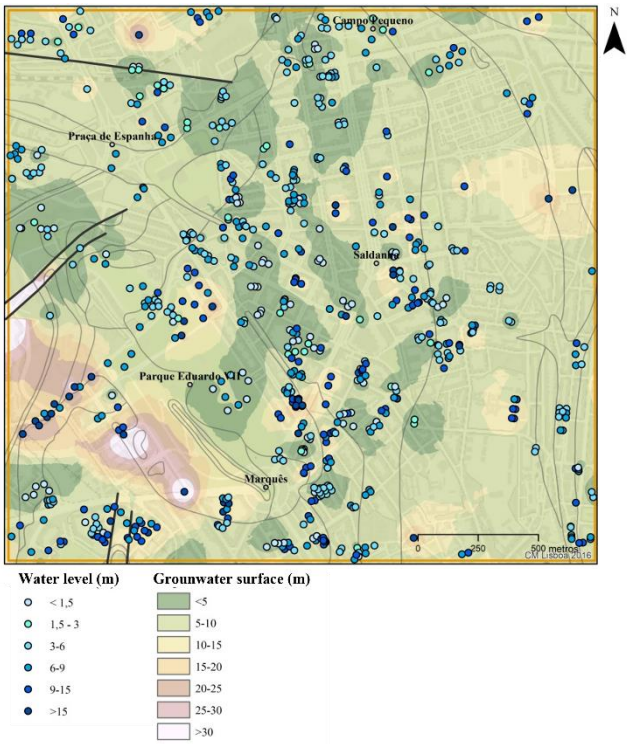

Figure 7. Water level position and surfaces (Avenidas Novas area).

Points of different intensities represented the water level according to depth, and polygons reflected the water surface, defining depth classes.

In general, the water table is located between 5 and 10m, which is also related to the geological formation's permeability (Pinto, 2020).

Knowledge of this variable allows assessment of potential impacts on buildings since water percolation affects mechanical behaviour. Discontinuities in rocks allow water percolation to deeper levels, promoting erosion phenomena. In soils, the circulation of water can cause the dragging of the smallest materials, leading to internal erosion phenomena and the subsidence of surface structures, often at the level of the road network.

Rising water levels can result in settlement and uplift phenomena, which also impact structures and infrastructures (Pinto, 2020).

Assessing flooding risk in urban environments can also be emphasized because the probability of flooding will be heightened in areas with flat and a surface water table.

3.2 ModSub 3D Project

In addition to geological, geotechnical, and hydrogeological characteristics, proper subsurface planning requires knowing the location, characteristics, geometry, and deployment levels of buried structures and infrastructures, such as water pipes, sewage systems, gas lines, electrical and communication cables, tunnels, basements, and parking.

Accurate information enables more efficient planning and execution of underground construction projects. It prevents accidental damages during excavation or construction activities, which sometimes cause service disruptions and high repair costs. It also allows for avoiding last-minute adjustments or delays due to unexpected conditions during excavation.

From a sustainable perspective, this information helps assess the environmental impact of excavation and construction on groundwater flow, considering the possibility of reusing the resource for other purposes (Pinto, 2020).

The strategy defined by Lisbon Municipality to address the identification and representation of basements in buildings, parking, and tunnels was based on the development of a tool called ModSub 3D, built on ESRI software, in particular ArcGIS Pro.

Besides the general characteristics of those elements, the database model incorporates tables for the edition of attributes related to:

- Foundations – geometry, type of foundation and deployment levels;
- Building basements – geometry, partial or fully buried, primary use, existing pumping and deployment levels (Figure 8);
- Retaining walls – excavation method, retaining wall type and deployment levels;
- Tunnels – The section type, primary use, excavation and containment methods, base and top elevation and pumping.

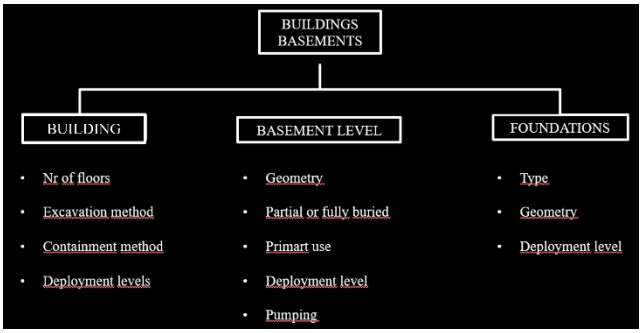

Figure 8. Database scheme: building basements (ModSub 3d).

To optimise the fulfilment of the attributes and help the user during the process, a series of guided steps and a pre-configured workflow were designed using the ArcGIS *Tasks* tool (Figure 9).

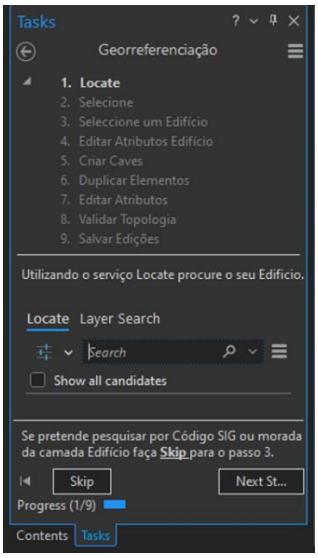

Figure 9. Example of a screen from the Tasks tool showing the workflow related with the georeferencing process.

Nowadays, 8.900 buildings in specific parts of the city (Parque das Nações, Baixa Pombalina, Benfica) have been analysed and integrated into the ModSub 3D app. Figure 10 presents an example of an area where information about building basements has already been uploaded. The polygons with the geometry of the buried elements are shown in yellow.

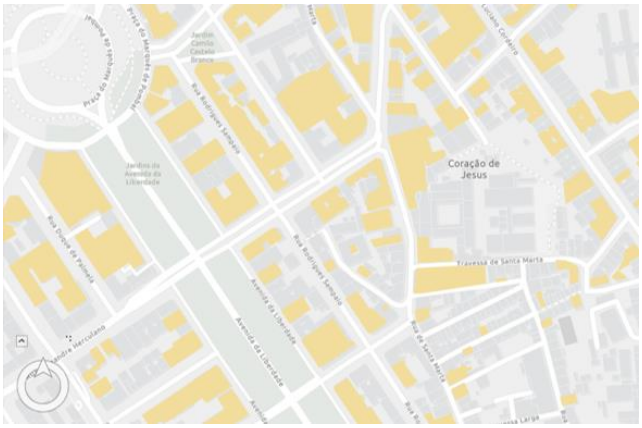

Figure 10. Building basements in Avenida da Liberdade.

This information enables a more detailed understanding of subsurface occupation, which should serve as the basis for planning interventions and defining integrated strategies for the city's development.

At a more specific level, will allow for assessing the impact of underground construction on the local hydrogeological regime (Pinto, 2020).

Developing 3D models for the surface and subsurface occupation is a goal. A few exercises have been performed resulting in general models, such as the one in Figure 11.

Figure 11. Representation of a three-dimension model (Parque das Nações); in green and grey we see the surface occupation and in brown the building basements.

BIM (Building Information Modeling) models have revolutionized 3D representation. The process involves creating and managing digital representations of places' physical and functional characteristics.

These digital models are used throughout the building's lifecycle, from initial planning and construction to operation and maintenance. BIM allows architects, engineers, and construction professionals to collaborate more effectively, analyze potential issues before construction begins, and streamline the overall building process. It can also enhance sustainability efforts and improve facility management.

Although this technology is widely applied in construction management, its future use on the scale of underground planning in cities should be considered and in the figure 12 is presented the use of BIM to manage the Lisbon Drainage Master Plan (Gomes *et al.,* 2023).

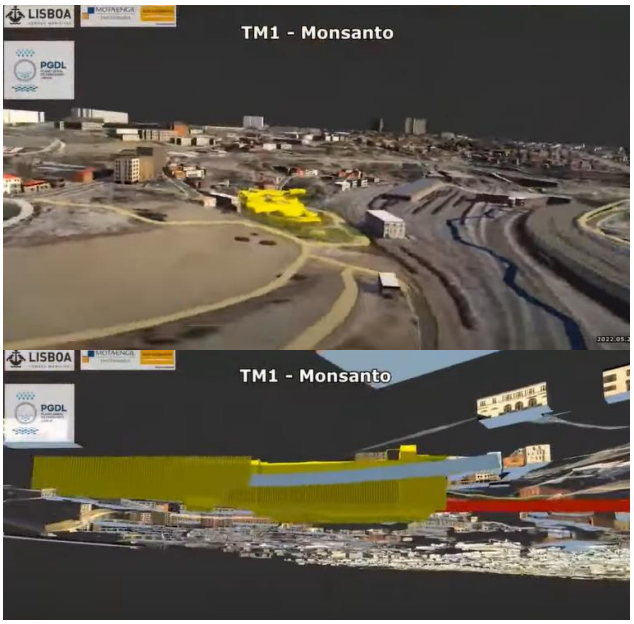

Figure 12. Image of the BIM model used for the Lisbon Drainage Master Plan (source: municipality services).

3.3 LisbonSlides Project

A map of susceptibility to mass movements was provided in Lisbon's Master Plan. The map results from a physical model drawn up by the Faculty of Sciences, University of Lisbon (Vasconcelos, 2011), that took into account the geological, geotechnical and hydrogeological data available in Lisbon Municipality databases, resulting in the identification of moderate to very high susceptibility areas (Figure 13).

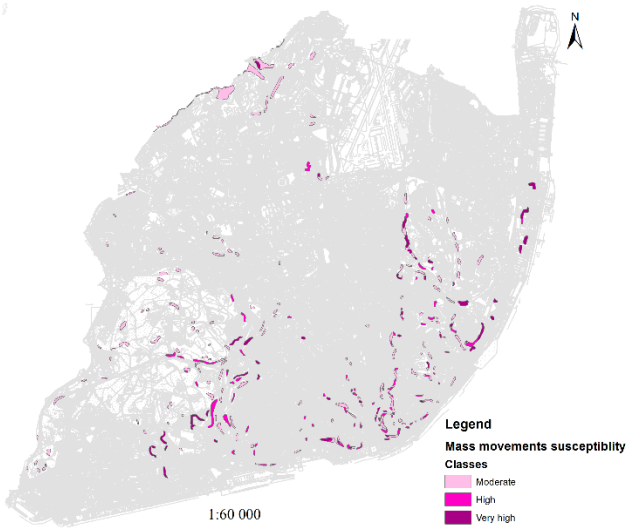

Figure 13. Mass Movements Susceptibility Map. Lisbon Master Plan.

The results show that the susceptibility areas are related with natural slopes, retaining walls, and buildings.

3.3.1 Case study: Rua Damasceno Monteiro

On the 27th of February, 2017, a support wall collapsed. The movement affected several buildings in Rua Damasceno Monteiro (Figure 14).

The intervention involved the construction of a retaining wall, the structural recovery of the affected buildings, and the relocation of the affected populations. The intervention cost was ten times higher than reinforcing the retaining wall.

This example shows that mass movements, especially related to built structures, should be managed through a proactive approach rather than a reactive one.

Figure 14. Set of photos of the mass movement occurred in Rua Damasceno Monteiro (source: municipality services).

3.3.2 Implementation of a managing strategy

The municipality hired specialised companies to survey all the situations identified on the map. The work involved visiting the sites and filling out a database with various parameters.

Regarding the prioritisation of interventions and implementation of a mitigation strategy by the municipality services, the final results were presented considering the need for an intervention or monitorisation.

Additionally, each type of result was requested to be classified into three classes: A, B, or C. Depending on the class, the intervention or monitoring procedure was required within a maximum period of 1, 3, or 5 years (Figure 15).

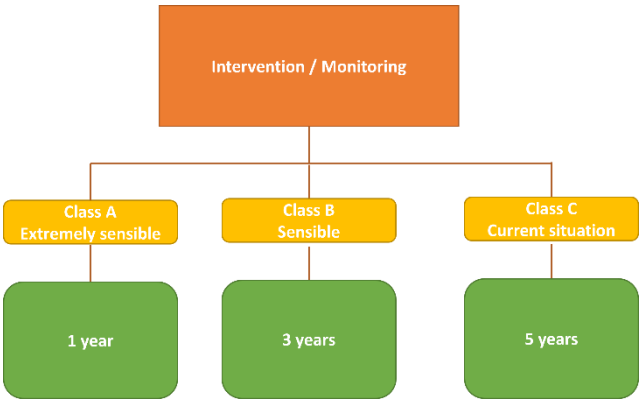

Figure 15. Diagram with the management model implemented for mass movement susceptibility.

The situations that didn‘t present any evidence were removed from the initial list.

In summary, the work carried out allowed for the identification of the following situations:

- 64 buildings needing urgent intervention – class A;
- 74 buildings needing intervention – class B;
- 101 buildings needing intervention – class C;
- 54 buildings needing monitorisation – class A;
- 203 buildings needing monitorisation – class B;
- 991 buildings needing monitorisation – class C;
- 560 buildings removed from the list;
- 26 retaining walls needing urgent intervention – class A;
- 49 retaining walls needing intervention – class B;
- 77 retaining walls needing intervention – class C;
- 40 retaining walls needing monitorisation – class A;
- 95 retaining walls needing monitorisation – class B;
- 354 retaining walls needing monitorisation – class C;
- 123 retaining walls removed from the list;
- 25 natural slopes needing urgent intervention – class A;
- 24 natural slopes needing intervention – class B;
- 20 natural slopes needing intervention – class C;
- 22 natural slopes needing monitorisation – class A;
- 31 natural slopes needing monitorisation – class B;
- 172 natural slopes needing monitorisation – class C;
- 30 natural slopes removed from the list.

Not all situations identified are the responsibility of the municipal services, as many of the sites are privately owned. Tables 1 and 2 summarise the situations for which Lisbon Municipality is responsible.

Table 1. Municipality and co-ownership buildings.

	Co-Ownership	**Municipality property**
Intervention – Class A	0	6
Intervention – Class B	1	8
Intervention – Class C	0	19
Monitorisation – Class A	3	3
Monitorisation – Class A	2	13
Monitorisation – Class A	10	55
Removed from the list	20	46

Table 2. Municipality retaining walls and natural slopes.

	Retaining walls	**Natural slopes**
Intervention – Class A	5	16
Intervention – Class B	21	13
Intervention – Class C	30	10

This approach allows the municipality's services to better manage this situation and affect the budget needed for each project. Several of these interventions have already been executed.

3.4 GeoSustained Project

GeoSustained is an ongoing research project financed by the Portuguese Foundation for Science and Technology (PTDC/ECI-CON/1866/2021).

Several actions aim to assess the use of geothermal solutions for building and infrastructure acclimatization (Inácio *et al.*, 2023), which would make cities more sustainable and resilient to climate change.

Lisbon Municipality is a partner in the consortium, involved in implementing the mandatory elements for installing the system and disseminating the solution's potential among private and public entities and real estate agents.

LNEC coordinates the project, and in addition to Lisbon Municipality, the consortium includes the University of Aveiro and the Lisbon Energy Agency - Lisboa E-Nova.

Two actions were defined to achieve this goal. The first consists of defining the best practices for implementing shallow geothermal solutions in urban environments; the second is developing a workflow guide with the necessary information to implement the system's municipal licensing procedure.

Besides these actions, and considering decision-support, Lisbon Municipality intends to develop a dynamic map to identify the shallow geothermal systems in Lisbon (Inácio *et al.*, 2023). The purpose is to support the preliminary assessment of the viability of shallow geothermal systems for new buildings, challenging project developers and planners to consider using this clean energy resource in their projects.

Three boreholes were made in different locations within the municipality territory to collect samples from the Lisbon's geological formations (Figure 16).

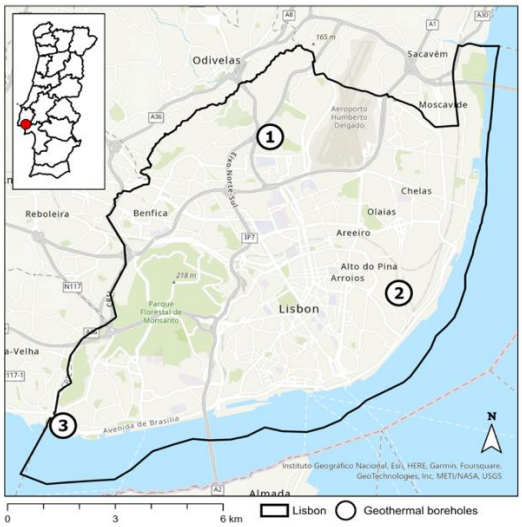

Figure 16. Location of the 3 boreholes performed in the framework of GeoSustained Project.

Undeformed samples were also collected at these sites. Laboratory tests are being performed to determine these formations' thermal and thermomechanical characteristics. In addition, temperature and thermal conductivity measuring sensors were installed along the drilled depths (every 5 m) to detect seasonal and in-depth temperature variations (Inácio *et al*.,2023).

3.4.1 Geothermal systems concept

From 15-20 meters depth onwards, the subsurface temperature is not dependent on seasonal variations in air temperature but rather on the heat flux from the earth's and the geological, hydrogeological, and geothermal characteristics of the bedrock (Ramalho *et al.*, 2013).

Very low-enthalpy or surface geothermal systems are renewable energy systems that use the Earth's natural heat to warm and cool buildings and other structures, such as roads and tunnels. They are an efficient and clean technology (excluding pumps), contributing to reducing carbon footprint.

In terms of concept, they are heat exchange systems that use the ground, aquifers, or effluents as a medium of exchange (Lapa, 2024).

This is achieved by placing geothermal probes (primary circuit) in vertical boreholes, horizontal planes, or buried structural elements such as piles, walls, or slabs, which are thermally activated and transmit the ground temperature to a geothermal heat pump.

Thermal distribution can also follow central heating systems; however, geothermal systems with thermally activated building structures (Figure 17) are the most efficient as they use the thermal mass of these structure elements (Lapa, 2024).

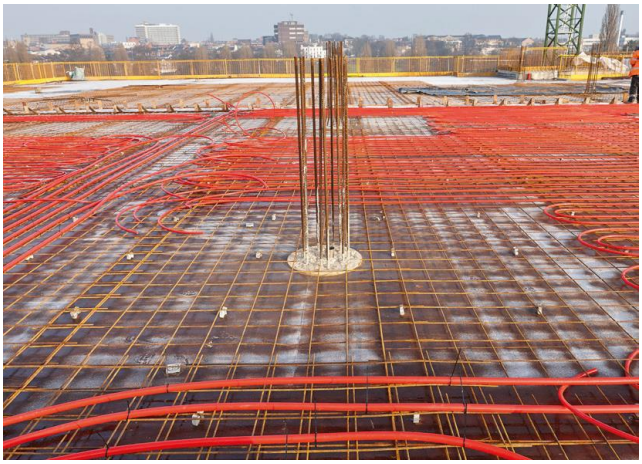

Figure 17. Thermally activated ground slab (Lapa, 2024).

The various combinations of thermal sources, such as soil (geothermal probes or heat exchangers in

structural elements), air (cooling towers), water (using sewage networks or pools), and sun (solar panels and photovoltaics), represent an opportunity to improve the efficiency and sustainability of geothermal systems. Connecting different systems is the starting point for applications in residential buildings, increasing the interest of property owners in finding efficient solutions based on renewable energy sources. Research on the complementarity of these solutions has led to more competitive prices for equipment and materials (Lapa, 2024).

3.4.2 Advantages of using geothermal systems to buildings acclimatization in urban areas

Geothermal systems offer three advantages: energy savings, thermal comfort, and environmental sustainability.

The systems have low maintenance requirements and a long lifespan, resulting in energy savings. This, combined with reducing carbon emissions and dependence on fossil fuels, leads to greater environmental sustainability. Additionally, they promote greater thermal comfort by maintaining a constant temperature regardless of external weather conditions (Lapa, 2024).

Geothermal systems have a higher initial cost (around 15%), than traditional HVAC systems but offer long-term returns. The return on investment for school facilities can be realized in 5 to 6 years, while for residential buildings, it may take between 10 to 15 years.

The work carried out under GeoSustained Project can be extrapolated to other municipalities.

Lisbon is a pilot city for defining the best approaches to increasing the use of geothermal energy in Portugal. This approach is aligned with the best practices ongoing in other European countries.

4 SUSTAINABLE DEVELOPMENT GOALS

The 2030 Agenda for Sustainable Development defines a strategy with 17 main goals that all countries must implement (Figure 18).

In the framework of this paper, and regarding Lisbon Municipality strategy, the sustainable goals that could be achieved are nr. 7, 9, 11 and 13 (United Nations, 2015).

Figure 18. Sustainable development goals. (United Nations, 2015).

4.1.1 Goal 7: Ensure access to affordable, reliable, sustainable, and modern energy for all.

GeoSustained Project is an excellent example of promoting new technologies that use clean energy sources, such as low-enthalpy geothermal, ensuring access to information and good practices for project developers.

4.1.2 Goal 9: Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation

The reuse of excavation materials, the storage and reuse of groundwater exploited during the excavation, and the use of underground heat for urban climatization could constitute a sustainable and resilient infrastructure. The necessary knowledge was obtained from the data collected in the geological/geotechnical prospecting campaigns carried out in Lisbon and compiled in different databases in the GeoSIG, ModSub 3D and GeoSustained Projects framework.

4.1.3 Goal 11: Make cities and human settlements inclusive, safe, resilient, and sustainable

The proactive approach used to manage natural risk and climate change presented in GeoSIG, ModSub 3D, LisbonSlides, and GeoSustained contributes to achieving this goal. Geological, geotechnical, and hydrogeological data permit the territory manager and the designer to address different situations as constraints or resources.

The action lines of the various projects result in policies and plans based on the necessary knowledge to be able to develop and implement mitigation and adaptation measures to the impacts resulting from natural and climatic phenomena at various scales: a more local scale with the adoption of specific

measures for the territory's vulnerability and a more holistic and integrated vision aiming at risk management and planning.

4.1.4 Goal 13: Take urgent action to combat climate change and its impacts

The GeoSIG project contributes to the knowledge of natural resources such as groundwater. A proper planning and integrated management of urban operations will allow reusing groundwater for other purposes. This action will promote the reduction of the impact of climate change, specifically water scarcity.

Through the GeoSustained Project, Lisbon Municipality intends to integrate climate change measures into local policies and strategies for urban planning. Shallow geothermal energy is a clean energy that enables the reduction of greenhouse gas emissions and the carbon footprint. Built awareness through stakeholders' education will increase the capacity to implement mitigation and adaptation measures.

5 FINAL CONSIDERATIONS

Urban development strongly pressures natural resources, especially in densely urbanised areas. The needs for housing, commercial and service areas, the underground occupation for parking, mobility systems and urban infrastructure networks could cause problems such as soil and groundwater contamination and create barriers to groundwater flow with significant impacts on the surface (Figure 19).

Geological features are rarely an impediment to urban development. Still, they can condition it through questions related to urban design and construction costs (Marker, 2009), making it imperative that decisions regarding development in large cities should be based on guidelines to promote sustainability and resilience.

Territorial management instruments must incorporate the mapping that supports the regulations seeking to adapt planning to the physical reality of the territory, optimising the use and occupation of the land to the nature of the geological substrate, safeguard the preservation of natural resources and values, and promote the quality of life and safety of the population, considering economic, political, and social factors.

This study has shown that underground space can and should be integrated into urban planning policies, not only from the perspective of mitigating the impact of natural risks but also in defining the best locations for certain urban operations, allowing for cost savings and new projects optimisation. The correct use of underground space, particularly its natural resources, will also help to boost the city's resilience in future scenarios, such as water scarcity.

This work reinforces the role of the municipality as a land manager, which is responsible for providing essential information on land constraints, providing decision-makers with the means to support their decisions, municipal technicians with information to help analyse projects, and developers with information on the constraints and costs associated with urban operations.

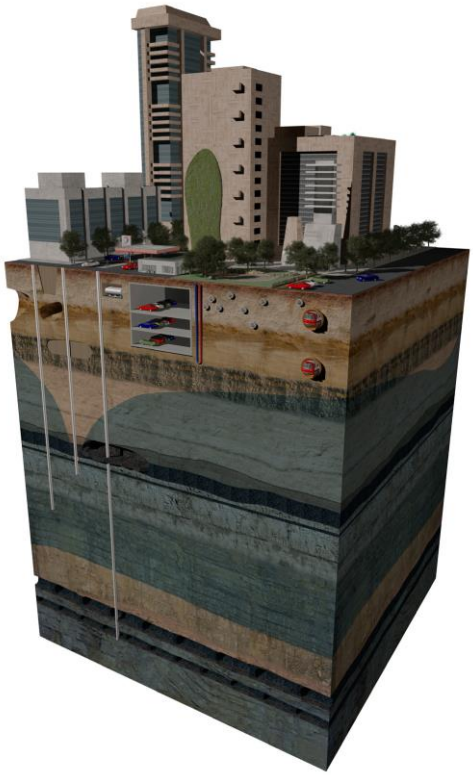

Figure 29. Conceptual model - Underground occupation in urban areas (parking, mobility network and urban infrastructures).

3D planning in the Lisbon of the future: requirement or necessity?

It can be both. A necessity if future societies aim to be environmentally, politically, economically, and socially sustainable, and it may have to be achieved through a requirement.

ACKNOWLEDGEMENTS

The author would like to thank to the Foundation for Science and Technology for the funding obtained through the GeoSIG LISBOA-01-0527-FEDER-000894) and the GeoSustained Projects (PTDC/ECI-COM/1866/2021).

Recent trends in monitoring tunnelling-induced displacements of structures

Tendances récentes en matière de surveillance des déplacements induits par le creusement des tunnels sur les structures

E. Bilotta*
University of Napoli Federico II, Naples, Italy
**emilio.bilotta@unina.it*

ABSTRACT: Monitoring and control of tunnelling induced displacements in urban areas are a matter of primary importance to minimise excavation risks and enhance project acceptance. For this purpose, suitable and reliable monitoring techniques are routinely adopted in underground construction. Fast progresses in sensor technology have boosted the development of innovative monitoring for tunnel projects through prototypes and field trials. The latter have been generally carried out in conjunction with the routine conventional monitoring, allowing for comparison and validation. Consequently, a wide interested has been generated around some innovative techniques that permit real-time control of induced strain of structures (e.g. fibre optics), allow for historical movements trends (e.g. InSAR), and may provide cost-effective additional information (e.g. LiDAR and photogrammetry). At the same time, resolution, power supply and communication potential of conventional measuring techniques for displacement monitoring have largely improved in recent years. This paper reviews the state-of-art of monitoring the displacements induced by tunnel construction and explores the current trends in developments of innovative sensing techniques.

RÉSUMÉ: La surveillance et le contrôle des déplacements induits par le creusement des tunnels dans les zones urbaines sont d'une importance primordiale pour minimiser les risques liés à l'excavation et améliorer l'acceptation du projet. À cette fin, des techniques de surveillance appropriées et fiables sont régulièrement adoptées dans les constructions souterraines. Les progrès rapides de la technologie des capteurs ont stimulé le développement d'une surveillance innovante pour les projets de tunnels à travers des prototypes et des essais sur le terrain. Ces derniers ont généralement été associés à la surveillance conventionnelle de routine, ce qui a permis de les comparer et de les valider. Par conséquent, un grand intérêt a été suscité par certaines techniques innovantes qui permettent un contrôle en temps réel de la déformation induite des structures (par exemple, la fibre optique), permettent de suivre les tendances historiques des mouvements (par exemple, l'InSAR), et peuvent fournir des informations supplémentaires rentables (par exemple, LiDAR et photogrammétrie). Dans le même temps, la résolution, l'alimentation électrique et le potentiel de communication des techniques de mesure conventionnelles pour la surveillance des déplacements se sont largement améliorés ces dernières années. Cet article passe en revue l'état de l'art en matière de surveillance des déplacements induits par la construction de tunnels et explore les tendances actuelles en matière de développement des techniques de surveillance innovantes.

Keywords: Tunnelling; monitoring; structures; displacements; innovation.

1 INTRODUCTION

Tunnel construction in the built environment requires careful control of induced displacements through suitable and reliable monitoring techniques (Mair, 2008). In the last decade, innovative monitoring systems have attracted wide interest and they have been progressively applied in tunnel projects in addition to conventional sensing. Nonetheless, conventional monitoring techniques have been not discontinued and their resolution, power supply and communication potential have largely improved in recent years (Ma et al., 2021). Nowadays monitoring tunnel construction provides a large volume of data to be processed, to alert of potential risk and trigger immediate corrective actions (Meyer et al., 2013; Gonzalez-Arteaga et al., 2020). Further, gathered data can feed existing digital twins of the construction process (Boje et al., 2020; Pan and Zhang, 2021), thus expanding the potential use of sensing techniques to "performance monitoring" in the whole tunnel life-cycle (Soga et al., 2019).

Starting from the state-of-art of techniques for monitoring displacements induced by tunnel construction on adjacent buildings, this paper explores the current trends in the development of innovative sensing technologies, focusing on the results of pilot applications that have proven their reliability and potential to enhance the whole structures' life-cycle.

2 MONITORING IN TUNNEL PROJECTS

In tunnel engineering, displacements need to be measured inside the tunnel cavity, for safety reasons and to ensure that the tunnel deformation falls within prescribed limits that guarantee its stability in both the short- and the long-term (e.g. convergence, extrusion, lining deflection), as well as above the tunnel to control induced ground and building movements (Figure 1). Deformation of the lining structures and tilt of buildings also require to be measured. The emphasis of structural health monitoring in tunnelling has traditionally been put on displacements (Brownjohn, 2007), and more recently on strain.

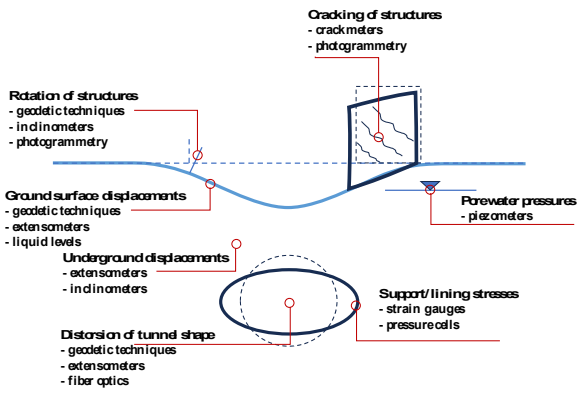

Figure 1. Tunnel construction and associated monitoring (modified from Hoult and Soga, 2014).

An overview of currently adopted measurement techniques for displacement, rotation and strain is shown in Table 1, with an indication of their range, resolution, and accuracy (BTS/ICE, 2004; ITA-AITES, 2011; Hoult and Soga, 2014; Morino et al., 2023).

Digital optical levelling is routinely performed to measure with high accuracy vertical movements on staffs and pins. *Laser distance meters* are also used for automatic and continuous measurement of convergence of the tunnel section, with accuracy up to ± 0.5 mm. *Total stations* (either manually or automatically operated) are primarily used to measure tunnel lining inflection and tunnelling-induced building deformation with an accuracy of ± 1 mm, or ± 2 mm if reflector-less (Hoult and Soga, 2014).

Laser scanner technology is also widely used in tunnelling since it enables a distributed assessment of convergence and deformation of the tunnel cavity as well as displacements of aboveground structures. Compared to point measurements, such as those operated by total stations, laser scanners can detect up to 2 million points per second, thus generating large point cloud data sets (cf. § 3.3). Light-Detection-And-Ranging (*LiDAR*) technology, adopted by high-resolution terrestrial laser scanners, is suitable to detect movements inside the tunnel with good accuracy (about ± 1.5 mm) since it does not require external lighting and it is robust in wet environments containing air particulate. Using the latest technology and in the most favorable conditions displacements may be detected with an accuracy up to ± 0.5 mm (Walton et al., 2018).

Global Navigation Satellite Systems (GNSS), providing signals from space that transmit positioning and timing data to receivers on Earth, allow the height of a point above sea level (orthometric height) to be measured with an accuracy of 10 mm without conventional levelling (Meyer et al., 2005). Hence, they are suitable for monitoring "visible" building displacements (i.e. along the line of sight to at least five orbiting GNSS satellites). Currently, by installing a network of high-frequency receiving antennas and adopting the best-performing Real-Time Kinematic (RTK) positioning technique (Odolinski and Teunissen, 2020), an accuracy of about ± 1 mm may be achieved on quasi-static structural displacements, compared to Precise Point Positioning technique (PPP, Zumberge et al., 1997), that reaches about ± 5 mm (Qu et al., 2022).

Satellite constellations equipped with SAR, Synthetic Aperture Radars, permit radar images of the Earth surface to be acquired, providing information on the distance between the radar and the reflecting point (Cumming and Wong, 2005). Interferometric analysis of phase differences between two images (InSAR) allows the ground elevation to be measured with high accuracy (Digital Elevation Model, DEM), while movements of points on the ground surface can be detected by Differential Interferometry (DInSAR), as it will be discussed in § 3.2. For instance, the *Persistent Scatterer SAR Interferometry* (PS-InSAR) is suitable for measuring deformations in urban areas and its use to detect displacements induced by tunnelling on buildings has increased recently, achieving millimetric accuracy. Terrestrial applications of SAR interferometry have been also developed, where the antennas move on a track in front of the object, rather than along the satellite orbit.

Table 1 also provides information on the accuracy of *hydrostatic levelling systems* for measuring vertical displacements through pressure head changes with respect to a reference tank, of *inclinometers*, using

biaxial servo-accelerometers or MEMS for monitoring horizontal ground displacements at depth, through *inclinometers*, and *borehole extensometers* for monitoring displacements in the ground. Structural tilt is measured by means of electrolevels, servo-accelerometer or MEMS sensors (*tiltmeters*).

Changes of crack width in structures undergoing movements are locally monitored by installing on their surface *wire extensometers* or *crackmeters* (for smaller measurement base). *Photogrammetry* is increasingly being used for crack detection (Stent et al., 2016), as discussed in § 3.3.

Monitoring structural strain is very important to control the performance of both the supporting tunnel lining and the tunnelling-affected nearby structures and buildings, either directly or through stresses that can be derived. Although structural strains can be computed from measured displacements, it is common to measure them directly, by using dedicated sensors. The most used are *electrical strain gauges*, either measuring change of electrical resistance due to strain (*resistive type*) or measuring change of vibration frequency of a metallic wire upon stretching (*vibrating wire type*). The latter are widely used in tunnel monitoring since they are cheap, high reliable and durable (Morino et al., 2023). Alternatively, *fibre optic* strain gauges have been increasingly used in the last decades (Moss and Matthews, 1995; Soga and Schooling, 2016; Floris et al., 2021), and they are becoming more common in tunnelling, as discussed in § 3.1.

Table 1. Features of monitoring techniques/sensors.

	device	range	resolution	accuracy
displacement and rotation	Digital optical levels	distance up to 30 m	0.1 - 0.01 mm	± 0.3 mm/km
	Laser distance meters	distance up to 150 m	0.1 mm	up to ± 0.5 mm
	Total stations	distance up to 1 km	0.1 mm	up to ± (0.6 mm+ $10^{-6}\times$ dist. in mm) up to ± 0.1mm diff disp.
	Laser scanner	distance up to 30 m	variable	up to ± 1.5 mm up to ± 8 arcseconds
	GPS/GNSS	distance up to 15 km	variable	± 5 mm in plan ± 10 mm in height
	PS-InSAR	any	variable	± 1 mm/year
	Hydrostatic levelling	up to 100 mm	0.01 mm	up to ± 0.1 mm
	Inclinometer	± 53°from vertical	0.04 mm/m	± 0.2 mm/m
	Tiltmeter	50 to 175 mm/m	0.05 to 0.3 mm/m	± 0.1 mm/m
	Wire extensometer	meters	0.01 mm	± 1 mm
	Crackmeter	up to 150 mm	0.01 mm	up to ± 0.01 mm
	Borehole extensometer	up to 200 mm	up to 0.01 mm	up to ± 0.1 mm
strain	Electrical strain gauges	vib. wires: up to 0.3%	0.5 to 1 $\mu\varepsilon$	vibrating wires: up to ± 1 $\mu\varepsilon$
	Fibre-optic strain gauges	up to 1%	up to 1 $\mu\varepsilon$	up to ± 10 $\mu\varepsilon$

3 EMERGING TECHNOLOGIES

Most of the well-established "conventional" geodetic techniques to monitor tunnelling induced displacements, namely digital optical levels and automatic total stations, share the common feature to achieve accurate measurements with relatively few data collection and processing. On the other hand, these measurements are spatially discontinuous. For this reason, in some cases critical mechanisms can be hard to reveal. Emerging techniques, such as laser scan or photogrammetry, and at a larger scale SAR differential interferometry, provide clouds of point measurements, that may be processed to obtain distributed information about change of surface conditions, hence continuous displacement profiles and deformation patterns. Fibre-optic sensing also results in distributed or quasi-distributed strain measurements over long distances. All these "emerging" techniques produce data of high resolution and large spatial coverage at relatively low cost at the field scale. Over the past decade, they have undergone significant validation in pilot applications that hint at a step change in tunnelling-induced displacement and strain monitoring.

3.1 Fibre-optics sensors

An optical fibre is a cylindrical structure that transmits light along its axis and is essentially made of three coaxial parts (Figure 2): a photosensitive core that carries the light, usually made of pure silicon dioxide (SiO_2) glass, a surrounding cladding made of glass with a lower refractive index (by means of a different level of impurities), a buffer coating outside, made of acrylate or polyamide, that protects the brittle fibre. Due to the core higher refractive index (RI), compared to the cladding, the light travelling in the core is reflected at the core-cladding interface. Single- or multi-mode fibres differ each other for the number of potential paths that light can take, depending on the size and refracting index variation in the core. Since propagation at higher modes decreases the signal-to-noise ratio (Nöther, 2010), single-mode fibres are generally preferred for long distances. In addition to glass fibres, polymer optical fibres (POFs) are also available, where the core is commonly made with polymethyl methacrylate (acrylic glass). However, POFs have very high attenuation compared to silica, which results in very low transmission distances.

Optical reflectometry techniques are useful to characterize optical fibres, in the time (Optical Time Domain Reflectometry, OTDR), coherence (Optical Coherence Domain Reflectometry, OCDR) and frequency domain (Optical Frequency Domain Reflectometry, OFDR).

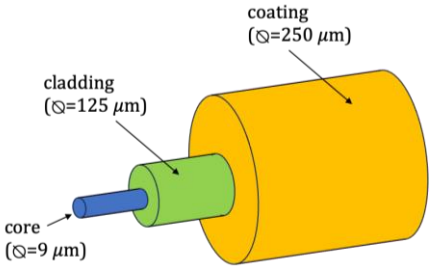

Figure 2. Structure of a single-mode optical fibre.

By using a visible laser propagating along the fibre core, Hill et al. (1978) created a periodic structure (grating) in the core with an increased refractive index, which generates a wavelength-specific dielectric Bragg mirror. The possibility to scan over the signals returned by the gratings kick-started the use of communication optical fibres as testing sensors to measure strain or temperature that, affecting their central wavelength, modify their ability to reflect and transmit light. Meltz et al. (1989) engraved the first Fibre Bragg Grating (FBG) sensor in the core of a germanosilicate optical fibre exposed to an interference pattern of ultraviolet laser light with a specific wavelength (Figure 3a). Since then, several different techniques were developed to permit the multiplexing of many FBG sensors along a single fibre (Davis and Kersey, 1997), hence their use in many structural sensing applications. Optical frequency domain reflectometry (OFDR) can nowadays be used to measure the wavelength of light reflected form thousands of low reflectivity Bragg gratings, distributed along single-mode fibres (Childers et al., 2001), allowing for quasi-distributed FBG (DFBG) technology (Vlachopoulos, 2023).

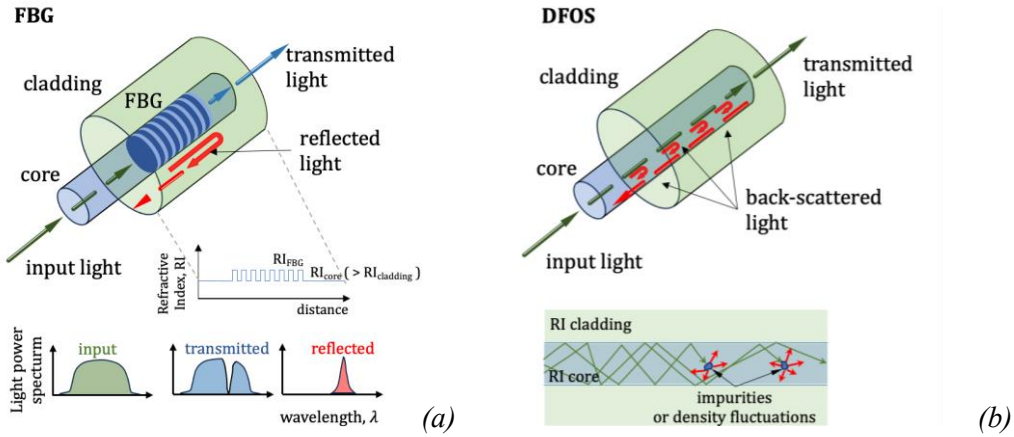

Figure 3. (a) FBG structure; (b) backscattered light along an optical fibre (modified after Kechavarzi et al., 2016 and Chai et al., 2019).

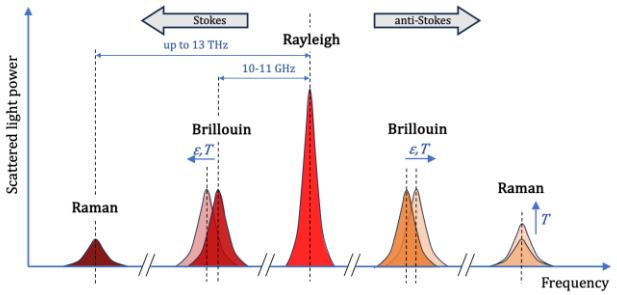

Figure 4. Backscattered light power spectra. ε, strain; T, temperature (modified from Kechavarzi et al., 2016).

Optical Backscatter Reflectometer (OBR), based on OFDR, uses light backscatter caused by random fluctuations in the refractive index profile along the fibre for the same purposes (Güemes et al., 2010). In fact, such perturbations, caused by the interaction of photons with impurities or density fluctuation within the fibre's core, behave like weak natural gratings engraved all along the fibre length (Figure 3b). Three types of light scattering exist: the linear Rayleigh scattering, where the backscattered light has the same frequency as the transmitted light; the non-linear Brillouin scattering, that produces a shift in frequency of the backscattered light; the Raman scattering, that produces new photons with lower (Stokes-component) or higher (Anti-Stokes component) energy (Figure 4). Distributed fibre optic sensing technique (DFOS) takes advantage of the influence of strain and temperature change on the fibre refractive index, hence on the properties of the backscattered light.

The Rayleigh backscatter undergoes a shift in the local spectral frequency and a time shift, produced by the cumulative changes in the refractive index. Such spectral and temporal shifts can be measured by performing a cross-correlation on the backscattered light signals in the time-domain (OTDR) or in the frequency-domain (OFDR), and scaled to return distributed temperature or strain measurements (Güemes et al., 2010).

The frequency of the Brillouin peak, ν_b, is directly proportional to the acoustic velocity and refractive index and it shifts linearly with changes in longitudinal

strain and temperature in the fibre core (Soga, 2014; Kechavarzi et al. 2016):

$$\Delta\nu_b = C_\varepsilon \cdot \Delta\varepsilon + C_T \cdot \Delta T \quad (1)$$

C_ε and C_T slightly vary around values of 500 MHz/% and 1 MHz/◦C, respectively, for standard telecommunication single mode fibres and at the operating wavelength of 1550 nm as used with Brillouin OTDR. Their value can be obtained by accurate calibration. Since the distance where the scattered light is generated can be calculated from the time interval between the launch of the pulsed light and the arrival of the backscattered light, once the fibre refractive index is known, the distribution of strain along the fibre can be obtained.

Another sensing method called Brillouin Optical Time Domain Analysis (BOTDA) can be used, that generally achieve larger accuracy. However, since it requires analysing the power difference between a pulse (pump) light and a continuous (probe) light sent in opposite direction from the two ends of the fibre, to stimulate the Brillouin scattering, it is unsuitable in case of fibre breakage during installation and monitoring (Soga and Luo, 2018).

For both FBG and DFOS the characteristics of FO measurements depend on the analyser (Table 2).

Table 2. Typical features of FO analysers (Vlachopoulos, 2023).

technique	FBG	DFBG	BOTDR/ BOTDA	Rayleigh OFDR
max sensing length	> 1000 m	< 50 m	> 1000 m	< 40 m
repeatability	± 0.1-10 με	± 1 με	± 1 με	± 5 με
spatial resolution	0.10 m	~ 6 mm	0.1-1 m	0.65 mm
max number of measurement points	10-20	> 1000	> 1000	> 1000
sensing range	± 17500 με	± 30000 με	± 30000 με	± 30000 με
acquisition frequency	< 1000 Hz	< 250 Hz	< 1 Hz	< 60 Hz
unit price (approx. EUR)	15k-120k	> 60k	90k-250k	50k-150k
sensor price (approx. EUR)	~ 250 – 1000 per sensor	~ 250 – 5000 per sensor	0.10 per m of fibre	0.10 per m of fibre

An application of FBG to monitor the displacements induced to two heritage buildings by the excavation of a new tunnel for Bank Station Capacity Upgrade (BSCU) is described by Acikgoz et al. (2021, 2022).

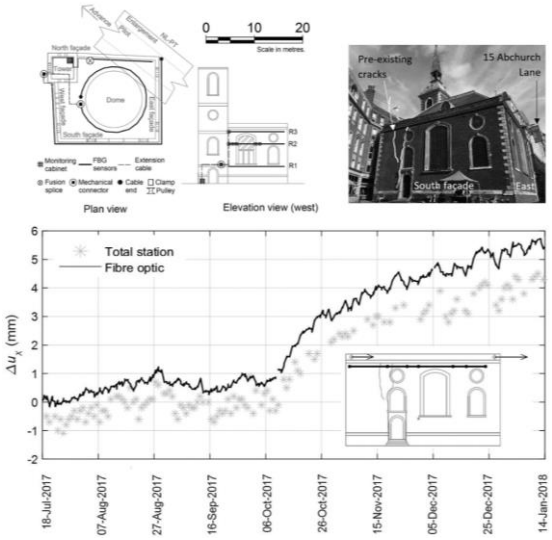

Figure 5. Monitoring St Mary Abchurch during BSCU: validation of FBG measurements against total station (modified after Acikgoz et al., 2021, 2022).

Figure 5 summarises the instrumentation installed on the masonry façades and dome of St. Mary Abchurch, including levelling targets, prisms and FBG optical fibres. The strains measured by FBGs deployed along the South façade of the church were integrated to obtain the relative horizontal displacements between the top corners of the façade, to be compared with displacements measured by a total station on a series of prisms. The time series plotted in Figure 5 along a period of about 6 months, corresponding to the pilot tunnel excavation and the enlargement, show the same trends in both datasets. The observed 1 to 2 mm differences were explained by the different locations of the prisms and fibre-optic sensors. Since the FBG data were validated by conventional measurements, fibre optic monitoring was continued after construction to measure the long-term effects on the church. Strain measurements confirmed that the consolidation-induced movements generally had a negligible effect on most of the structure. However, they produced an unexpected increase of the major pre-existing cracks in the South façade. This justifies careful crack detection and long-term monitoring of heritage buildings adjacent to tunnel excavation.

Kechavarzi et al. (2016) describe three case studies of pilot application of DFOS to monitor the deformation of existing tunnels due to adjacent tunnelling: an old-brick tunnel at the Thameslink King's Cross station in London (Mohamad et al., 2010), a cast-iron Royal Mail tunnel at the Liverpool Street Crossrail station in London (Gue et al., 2015), and a segmental bolted tunnel lining of the Singapore MRT Circle Line 3 (Mohamad et al., 2012). In the earliest case, dating back to 2005, in addition to conventional monitoring of displacements induced by

the underpassing new tunnel in the existing old-brick tunnel, two innovative systems were used: displacement measurements by digital camera imaging (cf. § 3.3) and DFOS (Alhaddad et al., 2014). The DFOS measurements using BOTDR allowed to identify localized high strains in the masonry and to detect the associated cracking.

Two examples of tunnel lining monitoring with DFOS to measure the strains arising during construction, using BOTDR, and check the design assumptions are also given by Kechavarzi et al. (2016): the National Grid London Power Tunnel, where DFOS were embedded in the pre-cast SFR concrete lining segments, and a SCL tunnel for Crossrail Liverpool Street station. In the latter, DFOS were embedded to monitor the strain change in the lining in correspondence of the opening of a cross-passage (breakout and excavation).

It is also worth mentioning the long-term structural health monitoring of an existing concrete-lined tunnel facility at CERN (Geneva; Switzerland), where Brillouin optical time domain analysis (BOTDA) allowed detecting strain changes that did not exceed 20 με (Di Murro et al., 2016).

The application of DFOS to measure tunnelling induced ground horizontal strains and displacements has been tested in field trials by Klar et al. (2014), that deployed a shallow fibre optic sensing cable (0.5 m deep) at two sites: during the TBM excavation of a 3 m-diameter, 18 m-deep tunnel, and for pipe-jacking a 1 m-diameter, 6 m-deep water main. Measurements were taken using two different optical technologies, the Brillouin OTDA (with accuracy of 5 με) and the back scattered Rayleigh reflectometry (with accuracy <1 με). The fiber optic readings allowed accurate measurements, providing information about volume loss, trough width (position of the inflection point) and ratio between trough length and width. The comparison between the measurements obtained by the two different technologies demonstrated an excellent agreement, although the Rayleigh reflectometry would be a better candidate to obtain the trough length, thanks to its higher spatial resolution. An investigation at laboratory scale on the performance of Rayleigh reflectometry to monitor soil horizontal strain induced by deep underground movements – involving comparison with Particle Image Velocimetry and numerical Finite Element back-analysis – has been recently carried out by Della Ragione et al. (2023a).

3.2 Differential SAR interferometry

Interferometric Synthetic Aperture Radar (InSAR) uses the phase difference between two high-resolution radar images to extract information about topography within a specific area. A Synthetic Aperture Radar (SAR) is a side-looking imaging radar system that exploits the Doppler effect (i.e. the change of frequency wave perceived by an observer moving relative to the source of the wave) due to the motion of the receiving antenna, to synthesize a much larger aperture. This improves the azimuth resolution, otherwise limited by the ratio between the antenna size and the range, or distance to the target (r_o in Figure 6). Airborne and spaceborne (satellite) SAR systems allow retrieving a large amount of information on the Earth's topography. As mentioned in § 2, Differential InSAR (DInSAR) can be used to detect the displacement occurring between two subsequent images. However, to discriminate from measurement the effect of atmospheric changes in the same time interval, suitable procedures are required. Since the early 2000's, many techniques have been proposed.

In this framework, Persistent Scatterers Interferometry (PSI) aims at identifying targets on the Earth surface that have a stable phase in time (persistent). These targets (PS) are characterized by high reflectivity and often correspond to point-wise scatterers.

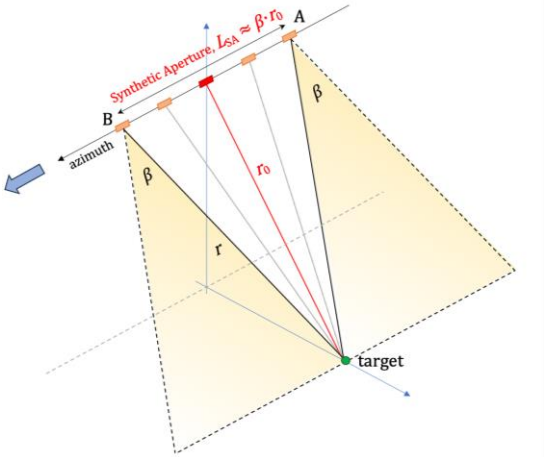

Figure 6. SAR schematic (modified after Meyer, 2019).

The first PSI technique is the pioneering Permanent Scatterers approach (PSInSAR®) proposed by Ferretti et al. (2000, 2001), later extended to include in the analysis less bright Distributed Scatterers (Ferretti et al., 2011). The Small BAseline Subset (SBAS) technique (Berardino et al, 2002), developed immediately after PSInSAR®, is one of the most extensively used. Several other PSI techniques have been developed, as Hooper et al. (2004) or Perissin and Wang (2012): a careful review is provided by Crosetto et al. (2016). Since brighter pixels are characterized by high signal-to-noise ratio, all the mentioned methods achieve improved measurement accuracy.

Once targets are selected, their movement along the sensor-to-target direction (or Line of Sight, LoS) can be detected from the phase variation between two SAR acquisitions. This requires that an accurate Digital Elevation Model is available, and the corresponding phase variation removed, that the geometrical decorrelation, resulting from two distinct viewing geometries is purged, and that the so-called residual topographic error (the difference between the true elevation of the PS centre and that resulting from DEM) is accounted for. Finally, several algorithms have been proposed to estimate and filter out from the interferograms the atmospheric phase component (e.g., Zebker et al., 1997; Ding et al. 2008; Perissin et al. 2011).

The lack or low density of Permanent Scatterers, occurring mostly in non-urban areas, can be partially addressed by using X-band (frequency from 8 to 12 GHz, wavelength, $\lambda = 25$ to 37.5 mm) very high-resolution SAR data — e.g. from TerraSAR-X or COSMO-SkyMed constellations— in comparison to C-band (4 to 8 GHz, 37.5 to 75 mm) — e.g. from Envisat or Sentinel constellations. In addition, artificial Corner Reflectors (CRs) can be deployed on site, that result in good interferometric phases to derive the displacement with higher accuracy. Under optimal conditions (high quality PSs and minimum atmospheric effects) sub-millimetre accuracy was obtained in PSInSAR time series (Ferretti et al. 2007).

However, two limitations of DInSAR and PSI must be mentioned: the one-dimensional nature of measurements (along the LoS) and the "*wrapped phase*" ambiguity. The former implies that only one component of the target displacement is directly measured: its projection into the LoS direction. When ascending and descending SAR data are available, they can be independently processed to calculate vertical and East-to-West horizontal components, hence partially addressing the issue. Different methods have been proposed to derive 3D deformation from DInSAR (Hu et al, 2014), either by combining different datasets, or by making use of auxiliary GNSS, or by making assumptions, the latter being the most widely adopted. On the other hand, wrapped phase limits the ability of PSI to measure "fast" (compared to the satellite revisit time) or, equivalently, "large" displacements. When the differential displacement over the revisit time is larger than $\lambda/4$ – corresponding to the limit "wrapping" value of phase, π – the phase information would be affected by phase cycle loss, hence the actual displacement would be underestimated and difficult to be retrieved unambiguously. Despite several research efforts this issue does not seem completely solved. Wu et al. (2022) have recently proposed a method for phase unwrapping suitable for displacement monitoring in urban areas.

A review of the use of InSAR to displacement monitoring in geotechnical engineering has been carried out by Shimizu (2022). A few applications to monitor tunnelling induced displacements have been carried out in the last decade. Barla et al. (2016) performed a multi temporal-InSAR analysis on Cosmo SkyMed SAR images in both the ascending and descending direction. The measured displacements agree well with the conventional survey (robotic total station and GNSS). In urban area, a series of works dealing with the use of InSAR data in post-tunnelling damage assessment procedures were carried out by Milillo et al. (2018), Giardina et al. (2019) and Macchiarulo et al. (2021). These papers focus on the construction of Crossrail tunnels in London (UK) showing how multi-temporal InSAR was used to assess the extent of damage to over 800 affected buildings. Applications in the urban area of Naples (Italy) have been carried out by Santangelo et al. (2021) and Della Ragione et al. (2023), the latter aimed to get a "remote" assessment of volume loss.

Recently, Di Mariano et al. (2024) have compared the ground movements measured with conventional optical survey nearby Fonerìa station during tunnel construction for a branch of metro Line 9 (now Line 10 South) in the city of Barcelona (Spain) with those measured by PSInSAR® analyses of TerraSAR-X images. Figure 7 shows a comparison between the two data sets in transverse section, in approximately greenfield conditions. A large scatter can be seen in the PSInSAR® measured settlement that were fitted by a Gaussian curve. Nevertheless, fitting curves corresponding to the conventional monitoring (highly correlated) and to the InSAR monitoring are very close to one another and result in similar values of volume loss and inflection point distance. In the same figure a comparison between the InSAR profile of the tunnelling-induced settlement of a monitored building block and the corresponding readings from the total station survey indicates that both trend and magnitude are very close. In fact, the higher "visibility" of PSs on the building roof likely improved the quality of the backscattered radar signal, hence the measurements.

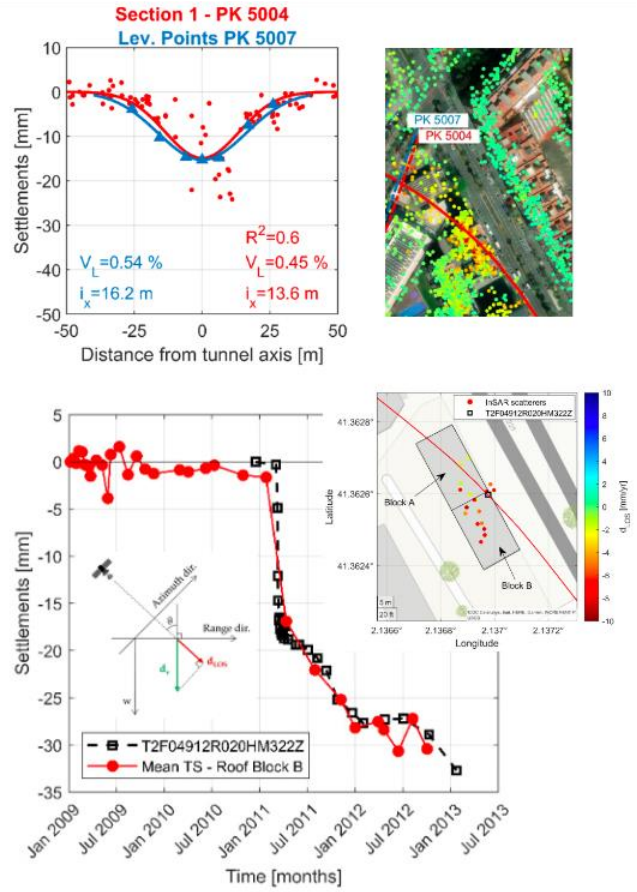

Figure 7. Barcelona Metro Line 10: comparison between conventional monitoring and PSInSAR® (modified after Della Ragione, 2024; Di Mariano et al., 2024).

This allowed to validate PSInSAR® monitoring, showing how it can be used after tunnel construction to expand the existing dataset from conventional survey and to control reliably the evolution of displacements in the long-term.

Serrano-Juan et al. (2016, 2017) carried out an application of both satellite and ground-based InSAR (GB-SAR, or Terrestrial In-SAR) in a construction site affected by underground works in Barcelona, in addition to conventional levelling, highlighting that besides accurate displacement measurements, the GB-SAR automation allows for high-density temporal coverage and concluding that the combined use of different techniques may result in a deeper understanding of the impact of subsidence on nearby buildings. A review of GB-InSAR for deformation monitoring is made by Monserrat et al. (2014).

3.3 From range sensing to range imaging sensing

As mentioned in § 2, among range sensing techniques, high-precision terrestrial laser scanning (TLS) can capture spatial coordinates of a target with sub-millimetric accuracy. Typically, several laser beams are used to scan the objects, producing a point cloud that is used to construct a detailed model. This technique is suitable to measure ground and structure deformation in contactless mode and in a wide range of environmental conditions, including low-light underground excavations. Deformation monitoring is carried out using change detection methods to track the target position or shape change at different epochs. Different detection methods can be adopted: point-to-point, line-to-line and surface-to-surface: an exhaustive review has been done by Shen et al. (2023).

The current practice for engineering applications focuses mainly on point-based methods since they generally achieve the required accuracy. In the framework of monitoring, these methods need to consider that since distinct scans cannot be identical, it is not possible to sample the same point in two different acquisitions. Therefore a "deformation monitoring block" should be identified and used for tracking. The *Fitting method* and the *Geometric Centre method* are suitable to carry out coordinate calculations of the target thus identified, the former often involving regular shape targets (even artificial), the latter suitable to process more irregular shapes. Alternatively, *Cloud-to-Cloud comparison* (C2C, Girardeau-Montaut et al., 2005) can be carried out. The simplest application of C2C is the *Nearest Point method*, that finds the closest corresponding points in clouds from two subsequent epochs and assumes their distance as relative displacement. If a model surface can be interpolated among the cloud points, the method evolves in a *Cloud-to-Model method* (C2M), where the detection of displacement is based on the distance between cloud points and the reference model surface, along the normal direction to the surface. A further evolution is the *Multiscale Model-to-Model Cloud Comparison*, M3C2 (Lague et al, 2013). The large amounts of data that is produced by point-based approaches can be overcome by feature-based approaches, that involve line or surface fittings on the features extracted from the point-cloud. However, within the framework of terrestrial laser scanning there is still a need for further research about line-based and surface-based deformation monitoring (Shen et al., 2023). In tunnel monitoring, TLS has been generally applied for deformation monitoring during the operational phase, in terms of profile and section deformation, clearance inspection and crack detection.

For the case of St. Mary Abchurch described above (Acikgoz et al. 2022, Pascariello et al. 2023a, b), TLS was successfully employed to monitor displacements of the building façades. Changes in the bottom elevation of the parapet wall were detected using the Piecewise Alignment Method, PAM (Teza et al., 2007) and M3C2 (Lague et al., 2013). The point clouds (Figure 8) were post-processed to determine the

tunnelling-induced displacements. The figure presents a comparison between a near-continuous profile of vertical displacements along the South façade, calculated using the PAM method from changes between the point cloud obtained on March 23rd, 2017 (before tunnelling) and January 16th, 2018 (after the tunnel face completely passed the building) and the corresponding socket displacements.

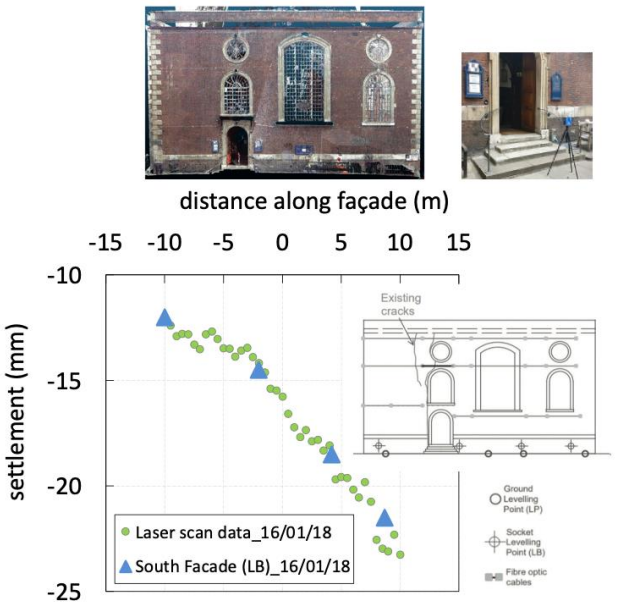

Figure 8. Monitoring St Mary Abchurch during BSCU: South façade point cloud; TLS derived displacements compared to socket settlements (Pascariello et al., 2023a, b).

The agreement between the two data sets is very good. However, the laser scan continuous profile additionally reveals a change of gradient above the doorway, corresponding to the pre-existing crack. Therefore, the profile obtained from levelling is not due to a gradual façade hogging but produced by a local relative rotation between the two edges of the pre-existing crack. This confirmed the measurements of FBG sensors (see Figure 5), indicating that the crack further opened during tunnel construction.

Nowadays, digital photography has reached a technological level that it can potentially replace more traditional and expensive surveying technologies (Soga and Schooling, 2016). Similarly to LiDAR scanners, time-of-flight (ToF) cameras can be employed for ranging, where the entire "scene" is captured with a single light pulse, rather than point-by-point with a rotating laser beam (as in LiDAR scanners). This class of imaging techniques, able to measure the distance of points as a function of time travel of a particular wave emitted from the sensor and bounced back from an object surface, allows to perform a so called "*range imaging sensing*".

Advances in digital imaging quality enable the use of different types of sensors for non-contact range sensing that can create 3D point clouds based on multiple overlapping of 2D images (Soga et al., 2019). Lighting is of course a crucial issue to be carefully addressed. In proper light conditions, even consumer-grade digital cameras can be successfully used to produce a point cloud by taking multiple overlapping 2D images of a scene and applying photogrammetry or by employing Structure-from-Motion (SfM) technique to extract a 3D model from a series of images taken from different viewpoints (Schonberger and Frahm, 2016). A system which can detect visual changes on concrete tunnel linings, such as cracks and leakage, has been recently developed by Stent et al. (2016).

Photogrammetry involves processing images to obtain geometric and physical information about the photographed objects: details on its industrial applications can be found in Luhmann (2010). In civil engineering, both aerial and close-range image capturing are carried out for monitoring purpose. However, in underground engineering, the former is less usual due to the complex construction environment, although it is receiving increasing interest. Close-range photogrammetry and DIC (Digital Image Correlation) or PIV (Particle Image Velocimetry; Stanier et al., 2016) have received more attention in the last fifteen years for the periodical inspection of existing tunnels (Attard et al., 2018).

An interesting application of close-range photogrammetry to monitor the structural displacements induced by tunnelling is reported by Alhaddad et al. (2018) for a case study at Moorgate station in London, as part of the construction of the Elizabeth line. A new connection tunnel was built to link the new station to the existing platform tunnels. This required a new stair adit tunnel (5.2 m wide SCL inclined tunnel with varying heights) to be constructed upwards, directly beneath an existing escalator tunnel (D = 4.3 m, cast-iron segmental lining). Tight limits to the escalator deformation were set, hence continuous monitoring was needed during construction. Three digital single lens reflex cameras (with 55 mm focal length) were installed to monitor three separate spaces of the escalator, in addition to conventional monitoring with total stations. The cameras were set to take images every 5 minutes. Up to 18 targets were installed in each monitored section of the escalator tunnel. Each camera was equipped with a tiltmeter, allowing monitoring target settlements relative to the camera, and a retro target, needed for a direct comparison with less frequent total station measurements. This comparison showed a good match between photogrammetry and total station monitored settlements (Figure 9). The Authors showed that with

photogrammetric monitoring a sub-millimetric accuracy of measurements can be reached, compared to millimetric accuracy of automatic total stations, at a much lower cost of the equipment. Moreover, the DIC system's high precision (i.e. random difference between multiple measurements of an unchanged value) enabled measuring the escalator curvatures over very short chords, that are highly sensitive to noise.

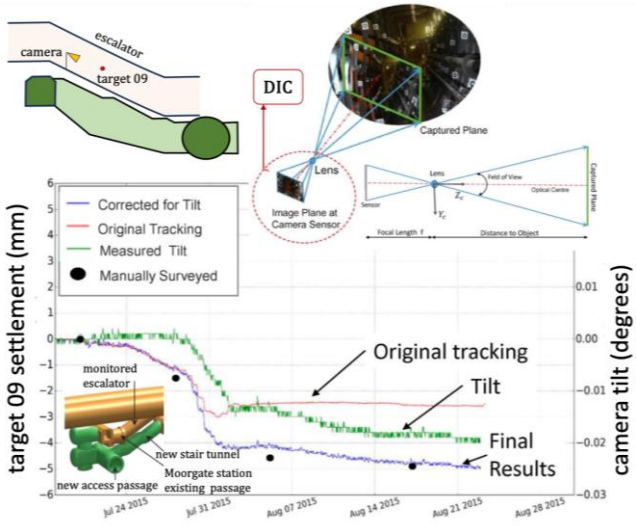

Figure 9. DIC system compared to total station results at Moorgate station (modified after Alhaddad et al. 2018).

Recently, Dalgic et al. (2023) described an experimental campaign aimed at measuring the response of two-storey masonry buildings to foundation settlement profiles mimicking those induced by tunnelling. In the experiments, synchronized video cameras and 2D DIC were used as the primary measurement system for crack detection and to estimate the crack size and length. The photogrammetry was complemented by secondary measurement systems consisting of displacement transducers (LVDTs) and FBG fibre-optic strain gauges to capture the deformed shapes of the structures. The comparative analysis of the collected data sets demonstrated their consistency.

3.4 Wireless Sensor Network (WSN)

On-site cables connecting sensors in large construction sites can be difficult to handle and to protect from possible damages, due to the extensive works that characterise those sites. For this reason, wireless technology has been increasingly applied in tunnel projects in the last decades to avoid deploying too many transmission cables. For instance, Bilotta & Russo (2013) used wireless data loggers to gather frequency measurements from vibrating wire strain gauges embedded in precast reinforced concrete segments for tunnel lining, thus monitoring their structural behaviour throughout the entire life cycle: from the production phase, during installation and in the long term. Since then, technological improvements permitted to reduce the size of the sensors and their power consumption while the development of new communication protocols allowed larger distance to be covered. Many "established" sensors listed in Table 1 have been innovated in recent years to improve their resolution, to reduce power consumption and to enable them to be integrated in a network, thanks to wireless communication. Micro-electromechanical system (MEMS) sensors combine mechanical and electronic modules, allowing for both sensing and data processing and transmission in a very small space. Due their high resolution, low power consumption, easy deployment in large number, and high potential for integration in a wireless network, they have been increasingly applied during underground construction in the last years, as pilot Wireless Sensor Networks (Soga and Schooling, 2016). However, expert knowledge is needed to reliably set up the wireless network environment and the interoperability of different WSN is very limited. Therefore, their use in construction projects remains limited, primarily by the contractors' perception of a lower reliability compared to a wired system, that is not compensated enough in terms of structural safety by the MEMS high sensing accuracy (Ma et al., 2021). To boost their acceptance, guidelines for the application of WSN to civil infrastructures have been developed by the Cambridge Centre for Smart Infrastructure and Construction (Rodenas-Herráiz et al., 2016).

4 CONCLUSIONS

The main features of both established and emerging technologies to monitor tunnelling-induced displacements and strains have been discussed in the paper. Future trends for structural health monitoring during tunnel construction should be identified in the perspective of an ideal extension of the use of sensors to monitor the performance of structures in their whole life cycle. This includes not only the construction process, but also the use, service, and dismantling of structures.

The increasing use of the emerging sensing technologies presented in the paper (Fibre-optic sensors, InSAR based techniques, imaging and photogrammetry, WSN) to monitor the effects on existing structures and infrastructures of adjacent tunnelling and underground construction can provide evidence of their ability to secure high safety levels, thus making the way to life-cycle structural "performance" monitoring. However, potential

obstacles to their wider adoption should be overcome. For instance, optical fibres take time to install, which may discourage their use, also in view of their mechanical vulnerability. Therefore, a technological breakthrough is needed to make fibre-optic sensors more robust and easier to install. On the other hand, the use of photogrammetry and range imaging will advance more through improved lighting (which is a major problem in underground environment) than through upgraded equipment.

Monitoring technologies will also be enhanced by advances in algorithms. It is the case of PS-InSAR: PSI algorithms should be improved to reduce the errors due to wrapped phase that affect measurements. Although the current space agency plans to expand the number of SAR missions in the future suggest an increasing use of InSAR monitoring, PSI experts and professionals in charge of interpreting and using PSI results, such as geotechnical engineers, should intensify their collaboration to improve the usability of this technique for monitoring tunnelling-induced displacements on structures.

Overall, the combined adoption of various sensors, as shown in some of the examples in this paper, can better exploit the advantages of each technique, thus helping to capture more accurately both the current state of the structure and its evolution.

Finally, the integration of distributed sensors into wireless systems and the development of increasingly intelligent high-precision micro-sensors (such as MEMS) hint at the possibility of developing machine-learning-based algorithms to increase the accuracy of target identification and of training artificial neural networks to process data sets.

ACKNOWLEDGEMENTS

The Author wishes to acknowledge the collaborative research projects with Cambridge CSIC and UPC-BarcelonaTech that provided some of the results presented in this paper, and the many colleagues that shared their experience on emerging monitoring technologies. He also warmly acknowledges the unvaluable contribution of former and current research students to those projects.

High-speed rail earthworks design developments and innovative trials – building Britain's technical legacy

Travaux de terrassement pour un train à grande vitesse, development de conception et essais innovants - construire l'héritage technique de la Grande-Bretagne

ABSTRACT: Selection of appropriate engineering mitigations for Britain's new high speed rail line HS2 earthworks to ensure compliance with track slab performance criteria reflective of the railway's high operating speed represents a major technical challenge which is exacerbated by the challenging ground conditions encountered in the central section (Contract C23) of Phase One. High plasticity over-consolidated clays and extremely weak and weathered mudstones are prone to large magnitude and long duration movements due to loading or unloading. To overcome the technical challenges associated with uncertainty in predicting long-term ground behaviour and ensuring subgrade performance with limited previous case studies on ground formations that had not been extensively studied, the C23 team developed and implemented collaboratively with the Client a number of large-scale innovative Earthworks trials to increase confidence in heave and settlement predictions, pursue significant design efficiencies, validate the geotechnical performance of engineering fill materials and maximise the material re-use of the site won soils. This paper provides an overview of some of these large-scale earthwork trials and the design and construction lessons learnt describing how the C23 team set new standards of practice for the industry while building a strong technical legacy which will be passed on to future infrastructure projects in the UK and abroad.

RÉSUMÉ: La sélection des mesures d'atténuation technique appropriées pour les travaux de terrassement de la nouvelle ligne ferroviaire à grande vitesse britannique HS2, afin d'assurer la conformité aux critères de performance de la dalles de la voie ferrée reflétant la grande vitesse operationelle du chemin de fer, représente un défi technique majeur qui est exacerbé par les conditions de sol difficiles rencontrées dans la section centrale (contrat C23) de la première phase. Les argiles sur-consolidées à haute plasticité et les mudstones extrêmement faibles et altérés sont sujets à des mouvements de grande magnitude et de longue durée dus au chargement ou au déchargement. Pour surmonter les difficultés techniques liées à l'incertitude dans la prédiction du comportement du sol à long terme et assurer la performance de la plate-forme avec des études de cas antérieures limitées sur des formations géologiques qui n'avaient pas été étudiées de manière approfondie, l'équipe C23 a développé et mis en œuvre en collaboration avec le client un certain nombre d'essais de terrassement innovants à grande échelle pour accroitre la confiance dans les prédictions de soulèvement et de tassement, poursuivre des efficacités de conception significatives, valider la performance géotechnique des matériaux de remblai d'ingénierie et maximiser la réutilisation des matériaux des sols gagnés sur le site. Cet article donne un aperçu de certains cas de ces essais de terrassement à grande échelle et des leçons tirées de la conception et de la construction, décrivant comment l'équipe C23 a établi de nouvelles normes de pratique pour l'industrie tout en construisant un solide héritage technique qui sera transmis aux futurs projets d'infrastructure au Royaume-Uni et à l'étranger.

Keywords: Earthworks; high-speed rail; heave, settlement; materials; lime.

1 INTRODUCTION

1.1 The HS2 project

In January 2012, the UK Government announced its intention to proceed with a new high-speed railway line (HS2) and published the preferred line of the route from London to the West Midlands as the first phase (Phase 1) of a national high-speed rail network. Phase 1 involves the construction of a new railway line of approximately 230 km in length between London and the West Midlands. For construction purposes, the

overall route was subdivided into three Delivery Areas:

- Southern
- Central
- Northern

The delivery areas were further subdivided into seven areas, each representing a main works civils contract (MWCC).

1.2 The C23 Project

EKFB, a joint venture that brings together international expertise from four leading civil engineering construction companies: Eiffage, Kier, Ferrovial Construction and BAM Nuttall, have been appointed by HS2 Ltd to deliver Civil Engineering works across an 80km section of the new high speed rail link between the Chiltern Tunnel and Long Itchington Wood. The C23 project represents the biggest single geotechnical contract ever awarded in the UK and the scope includes 45 high-speed rail (mainline) embankments and 30 cuttings, 15 viaducts, over 5 km of green (cut and cover) tunnels, 22km of road diversions and 81 overbridges. The earthworks operations include over 30 million cubic metres of excavation.

The Arcadis, Setec, Cowi Design Joint Venture (ASC) has been appointed by EKFB to provide detailed design services for the civil engineering assets with additional support being provided by TYPSA, ARUP and WSP.

1.3 Technical challenges

What differentiates HS2 from other earthworks projects in the UK is the tight end product performance criteria for the high-speed rail earthworks assets required to be achieved over the design life of 120 years, reflective of the selection of slab track system and the high operating speed of the rail line. The minimal operational maintenance of the slab track means that it cannot accommodate as much movement as a ballasted track, and therefore any movement of the supporting platform must be kept within specified limits to maintain the safe operation of the railway. Hence, strict post track slab installation heave and settlement performance criteria are imposed by the HS2 Technical Standards - Earthworks to ensure the required geometrical accuracy and stability of the track. Selection of appropriate engineering measures to achieve compliance with the HS2 performance requirements, represents a major technical challenge for the project and has been the key focus area of the geotechnical design teams.

This technical challenge is exacerbated by the particularly challenging, uncertain, and variable ground conditions encountered across the length of the C23 contract. Over-consolidated and high plasticity clays such as the Gault, Ampthill, Kimmeridge and Clay formations and weak mudstones such as the Lias Group Whitby, Dyrham and Charmouth formations are particularly prone to large magnitude and long duration ground movements due to loading or unloading, resulting from variable soil stiffness and low soil permeability.

The severity of impact on the track system combined with the uncertainty presented by the prevailing ground conditions create specific ground risks within the C23 Project area, the key earthworks risks identified by HS2 as the project developed included deep cutting heave, embankment settlement and dynamic amplification.

Overall, the biggest and most pressing challenge for EKFB and ASC has been to identify, specify and build appropriate earthworks design measures to effectively mitigate these technical risks whilst at the same time ensuring that the carbon footprint and the impact on the environment are minimised.

At an early stage in the development of the Scheme Design HS2 and EKFB agreed that investing in a series of earthworks trails during the design stage would enable greater understanding of some of the specific performance characteristics of some of the key strata. This approach reduced uncertainty and enabled efficient solutions to be incorporated into the design. The key to receiving the Client's support for these early trials was to demonstrate their potential to enable cost efficiencies into the design by reducing uncertainty.

2 SETTLEMENT

2.1 Predicting settlement

In saturated clay soils of low permeability, the loading due to embankment weight initially results in an immediate settlement and the development of excess pore pressure. This is followed by time dependent consolidation settlement.

The prediction of settlement and comparison against acceptability criteria for the project requires an estimation of both the magnitude of total potential settlement and the time period over which that settlement will occur. Settlement is calculated considering 3 components: immediate (i.e. undrained, elastic or instantaneous), consolidation (i.e. primary, time dependent) and secondary (i.e. creep). Total long-term settlement is the sum of the three components although secondary creep settlement is often assumed to be negligible in over-consolidated clays.

2.2 Settlement criteria

The HS2 Technical Standard - Earthworks (HS2, 2019a), defines "earthworks settlement" as *the permanent downward displacement of the earthwork due to static effects (such as consolidation) and any accumulated effects of dynamic loading.* The following sources of settlement were addressed by the design: a) settlements within embankment materials; and b) settlements in natural soils below embankments, including secondary consolidation.

The total settlement limit value to be satisfied by design is 60mm for *long* (i.e. more than 800m long earthwork asset without a discontinuity) high-speed line embankments and 30mm for *short* high-speed line embankments. This further drops to 15mm for the areas within 150m of switches and crossings (S&Cs). The design also needs to satisfy the 1:1000 maximum longitudinal distortion criterion when assessed over less than 15m reducing to 1:2000 when assessed over 120m and 1:1000 maximum transverse distortion to the alignment. The above limit values are to be applied from the time of installation of slab track and for a design life of 120 years.

Several typical mitigations for earthworks settlement are suggested by the HS2 Technical Standards with the ones listed below selected by the C23 JV:

- Excavate and replace (E&R): where the unsuitable material is at shallow depth, and groundwater conditions are favourable to open excavation.
- Consolidation by temporary surcharge: accelerate consolidation of compressible soils.
- Consolidation with band drains: in association with surcharging to reduce time to achieve consolidation.
- Hold period: a duration of time within the MWCC contract where the majority of settlement is allowed to occur prior to track construction. Surcharging and band drains may be used to accelerate settlement and reduce the duration of the hold period.
- Piled foundation with load transfer platform: soft, compressible soil that cannot be improved by other methods, and deep E&R is impractical.

Moreover, for earthworks where the predicted ground movements approach the limits specified in Technical Standards, in-ground instrumentation (e.g. extensometers, piezometers) needs to be installed as appropriate to monitor the ground movements and changes in the porewater pressures during and following construction, in order to verify the predicted magnitude, timescale and rate of ground movement. Where instrumentation is needed to monitor settlement, both internal settlements within newly constructed embankments and settlements of natural ground beneath embankments is monitored.

2.3 Scheme design

The design of HS2 requires a relatively low alignment but visual and noise mitigation creates a need for large scale landscape bunds associated with many of the mainline embankments. Thus, while the mainline may only be typically 8 to 10m above existing ground level, in some cases the total embankment loading applied by the earthworks may be the result of up to 15m of fill placed over a footprint up to 100m wide.

Stage 1 Scheme design indicated that predicted settlement under these large embankment loadings could be significant with deformation possibly extending to notable depth, particularly within the Charmouth Mudstone formation. This resulted in extensive settlement mitigation measures being proposed under the mainline embankments, in the form of pressure relief drains (PRDs), which accelerate consolidation by providing shorter path for excess pore water pressures to dissipate, and piled load transfer platforms (PLTPs), which reduce settlement by transferring the load to deeper more competent strata. The majority of settlement mitigations were concentrated on viaduct transitions where HS2 longitudinal distortion criteria are particularly onerous when combined with construction programme constraints. The total proposed design mitigations across the 45 mainline embankments included up to 95,000 PRDs and over 4,000 reinforced concrete piles. Requiring over 5,000m^3 virgin sand aggregate and 22,000m^3 of concrete including 3,250 tonnes of reinforcement, these were costly and carbon intensive settlement mitigation solutions.

2.4 Settlement trials

2.4.1 Trials scope and objectives

To mitigate uncertainty and assess the actual settlements that will occur with depth (magnitude, depth of influence, consolidation and immediate settlement, duration of settlement), embankment settlement trials were carried out inform detailed design and support the design optimisations. Two trial embankment monitoring sites were identified (see Figure 1) in the northern section of C23. These are referred to as Boddington Settlement Trial 1 and 2. The embankments were formed from material excavated from the adjacent cutting trial and were located within the footprint of future landscape earthworks to minimise double handling. The embankments loading induced settlement of the

underlying soils which was monitored using several different techniques.

The purpose of the trials was to provide data on the settlement and corresponding stiffness and consolidation characteristics of the underlying soils. In order to measure this, shape arrays were installed in shallow trenches below the embankments. In addition, further instrumentation, comprising load cells, extensometers, and piezometers, were installed below Settlement Trial 2.

2.4.2 Settlement trials location

Settlement trials 1 and 2 are located 7.5 km approximately southeast of Southam and 14 km north of Banbury, on the outskirts of Wormleighton Village, Warwickshire.

Figure 1. Settlement Trials aerial view.

2.4.3 Ground conditions

The published geological map for the area shows the site located on solid geology of the Charmouth Mudstone Formation of the Lias Group, with no overlying superficial deposits. However, the ground investigation data records show locally Head is present within the footprint of the embankments. The Charmouth Mudstone Formation comprises grey mudstone with sporadic thin bands and nodules of occasionally shelly limestone. The Charmouth Mudstone Formation typically reaches thicknesses of 100 m to 150 m.

Based on the ground investigation information, the Charmouth Mudstone formation is inferred to have a highly weathered thickness of about 10 m. The formation has been distinguished in two facies: CHAM-C Z described as firm to very stiff slightly sandy slightly gravely CLAY; and CHAM-MDST extremely weak becoming weak with depth, thinly laminated/bedded dark grey slightly calcareous to calcareous MUDSTONE. Locally at settlement trial 2 at the sides of the stockpile, HEAD deposits of variable thickness from 0.3 m to 0.85 m, overlies Charmouth Mudstone Formation. This formation comprises generally very soft to stiff slightly sandy slightly gravelly CLAY.

2.4.4 Trial embankments construction

Prior to instrumentation installation and embankment construction the site was cleared of ecology and archaeology, temporary drainage was installed and the upper 300 to 400 mm of topsoil and soft subsoil was removed. For Settlement Trial 1, the construction started on 23rd of July 2019 and took about 2 months to reach the full height of the embankment. The geometrical characteristics of the first trial embankment are as follows:

- Embankment width at the base: 70 m
- Crest maximum width: 30 m
- Side slopes: 1V to 2.5H
- Embankment height: 8 m
- Embankment length: 170 m

For Settlement Trial 2, the construction started on 05th of November 2020 and took about 1 month to reach maximum embankment height of 8m. The geometrical characteristics of the second trial embankment are as follows:

- Embankment width at the base: 95 m
- Crest maximum width: 55 m
- Side slopes: 1V to 2.5H
- Embankment height: 8 m
- Embankment length: 150 m

2.4.5 Testing, results and analysis

The values measured by the total earth pressure cells installed below the trial were compared to the construction history which allowed an estimate of the bulk density of the fill to be made which was used to estimate the loading imposed on the underlying strata by both embankments.

Installation and performance of the magnetic extensometers was largely successful. When plotted, the extensometer results suggested, as might be expected, that the elastic settlement ceased shortly after the completion of the embankment. For Settlement Trial 1, the settlement at the end of construction was 55mm, compared to the observed settlement below Settlement Trial 2 of 40mm at the same point in time.

The Asaoka (Asaoka, 1978) method was used to interpret and extrapolate settlement observations for both Settlement Trials. The observed settlement during Settlement Trial 1 was plotted using four different time intervals, Δt (10, 25, 50 and 100 days) and the total settlement was estimated to be around 85mm.

It was concluded that the drainage paths are shorter than might be assumed from the ground investigation infromation, possibly suggesting that the discontinuities within the weathered and unweathered Charmouth Mudstone act as drains. If the ground

model is forced to fit the initial drainage scenario, with longer drainage paths, then the values of the coefficient of consolidation (cv) needed to provide a match to the settlement data are significantly larger than the values measured from oedometer tests. Based on the above, the drainage path length was assumed to be 4.8m which would give a height of the assumed compressible layer of 4.8m for one way drainage and 9.6m for two-way drainage. Using these lengths, the cv was estimated to be 1.3m^2 per year for one-way drainage and 1.8m^2 per year for two-way drainage.

The observed settlement during Settlement Trial 2 was plotted using the same time intervals (10, 25, 50 and 100 days) and the total settlement was estimated to be around 96mm. Drainage path lengths of 3.1 and 6.2m or one and two-way drainage were adopted while two way drainage into the underlying limestone was also checked. Using these lengths, the cv was estimated to be 1.0m^2 per year for one-way drainage and 1.3m^2 per year for two-way drainage.

While consolidation was still ongoing at slower rate when the embankments were decommisioned to allow for construction of the permanent works to proceed, the extensometers showed that 65% of the settlement occurs in the weaker soils between ground level and 2.5m. These soils will likely be dug out and replaced (E&R mitigation) during the HS2 permanent embankments construction. In addition, only 4% of the total movement was measured in extensometers installed below 15m which enabled the designers to succefully establish the zone of influence of the embankment loading.

Several vibrating wire piezometers were installed to monitor pore water pressure at different depths below Settlement Trial 2. The smoothed data from these plots allowed the excess pore water pressures to be calculated and plotted with time. Upper piezometers, installed from 10 to 20m depth, showed, as expected, that the excess pore water pressures increased at the end of loading and decreased through the monitoring period.

2.5 Settlement design efficiencies

Based on the observations from both Settlement Trials, the settlement analyses were refined in the detailed design, supported also by information from the targeted ground investigation and laboratory soil testing results within the high-risk areas of the C23 embankments and transitions zones to viaducts. The horizontal permeability was assumed to be greater than the vertical permeability due to conditions such as particle orientation, fissures and jointing in the rock due to geological processes and the possible presence of silt partings while a moderate increase in soil stiffness values for Charmouth Mudstone was also confirmed. The implementation of the findings in the detailed design of the permanent embankments eventually resulted in the elimination of 3,070 load transfer platform piles (59km total piling length) and removal of over 80,000 PRDs (640km total vertical drain length) as part of the settlement mitigations. This contributed to approximately 20,000 tC02 emissions savings including material embodied carbon and emissions related to transportation and construction works.

3 HEAVE

3.1 Predicting heave

The HS2 Phase 1 alignment creates the requirement for several deep (up to 30m) cuttings within the C23 area which will be underlain by high plasticity over consolidated clay and mudstone deposits. Since the early stages of the scheme design, there has been an appreciation of the level of risk associated with heave occurring at the base of such excavations with magnitudes and time to completion which could cause unacceptable deformations in the sensitive HS2 track slab.

During the excavation of a cutting, many tonnes of soil are removed and the ground below the formation level experiences a reduction in vertical stress which causes the ground to relax or rebound; this upward expansive movement is defined as heave (Butler et al., 2020).

Heave has been observed in over-consolidated high plasticity clay soils across the UK and is expected to occur in deep cuttings excavated in Gault, West Walton, and Oxford Clay formations and in mudstone and clay geological formations of the Lias Group of Jurassic age. The heave movement is anticipated to comprise of two main components:

- Immediate heave due to vertical unloading (elastic confining stress relaxation)
- Plastic and time dependent heave which is assumed to be the inverse of a consolidation settlement mechanism.

The time-dependent component is the main concern as it has the potential to extend well into the operational phase of HS2. It was recognised at an early stage that there were limited case studies of the heave phenomenon in the strata present in the C23 project area and that this created significant uncertainty in predicting long-term ground behaviour. The predicted heave behaviour largely depends on the soil stiffness; stress history and locked in horizontal stresses; and the soil permeability which are parameters notoriously

hard to confidently measure even with advanced laboratory or in-situ soil tests.

Initial analysis undertaken at concept stage suggested that cuttings greater than 12m depth in the high plasticity clay strata likely to be encountered by the HS2 could exhibit significant long-term heave and thus present a risk of long-term deformation.

3.2 Heave criteria

The HS2 Technical Standard for Earthworks (HS2, 2019a), defines "earthworks heave" as *the permanent upward displacement of the earthwork due to static effects, including hydraulic uplift.*

The total heave limit value to be satisfied by design is 60mm for *long* high-speed line cuttings and 15mm for *short* cuttings. This further drops to 10mm for the areas within 150m of S&Cs. The design also needs to satisfy the 1:1000 maximum longitudinal distortion criterion when assessed over less than 15m reducing to 1:2000 when assessed over 120m and 1:1000 maximum transverse distortion to the alignment. The above limit values are to be applied from the time of installation of slab track and for a design life of 120 years.

3.3 Scheme design

During scheme design, heave was assessed by ASC DJV, and numerical analyses were undertaken. Based on these studies, 6 deep mainline cuttings were identified as high-risk where the predicted long-term heave movements exceeded the HS2 Technical Standards limits and hence provision for robust heavily engineered mitigation was considered necessary. Following optioneering studies, a piled supported 1m thick reinforced concrete slab was selected as the most appropriate heave mitigation. Within the 6 identified cuttings of concern the total proposed mitigation slabs encompassed over 2.3km of the route and incorporated over 640 tension piles. Requiring a total of 37,800m3 concrete and 5,700 tonnes of reinforcement, this was a costly and carbon intensive heave mitigation solution.

3.4 Heave trial

3.4.1 Trial scope and objectives

Due to uncertainty in predicting long-term ground behaviour, particularly estimating magnitude, and duration of deep cutting heave below formation level during 120 years of operation, it was proposed to undertake a heavily monitored trial cutting to inform the understanding of the heave. The aim of the heave trial cutting was to provide an increased level of certainty in the estimation of heave that could be incoperated into the detailed design of the earthworks to enable the optimisations of mitigation measures for the potentially heaving cuttings.

A combination of in-ground magnetic extensometers and inclinometers, and surface topographical targets were specified to record ground movements. Vibrating wire piezometers were specified to record changes in pore pressures. Generally, the design of the extensometers and piezometers considered the depth of influence of anticipated ground movement due to stress relief while the inclinometers were installed in lower and mid-upper slope. Moreover, a weather station was installed to allow seasonal trends to be investigated.

3.4.2 Trial location

The site selected for the trial was located 7.5 km approximately southeast of Southam and 14 km north of Banbury, on the outskirts of Wormleighton Village, Warwickshire. The topography of the site is characterised by the rolling hills of the area and was constructed on the HS2 line of route and will ultimately form the northern-most 300m of the approximatley 2 km long Boddington Cutting.

Figure 2. Heave Trial aerial view.

3.4.3 Ground conditions

The site is underlain by the Charmouth Mudstone formation of varying weathering grades with minor head deposit in the vicinity of the transition to the Oxford Canal South Embankment. The formation typically comprises grey mudstone with sporadic thin bands and nodules of occasionally shelly limestone. A potentially continuous limestone band was identified in the ground investigation that had the potential to impact the observed response to excavation.

3.4.4 Heave trial construction

The cutting slopes were designed at an angle of 1V:4H with a platform width of approximately 17m and a maximum depth of about 15m to closely resemble the geometry of the permanent works. The total projected volume to be excavated, based on the trial cutting geometry, was 271,000 m^3. It was intended to undertake the excavation in one phase but due to

adverse weather conditions and flooding events, the construction programme was carried out in 3 phases. After the clearing of ecology and archaeology, the construction of access routes and drainage, and the installation and baselining of instrumentation bulk earthworks commenced in August 2019, but the works were hampered by inclement weather throughout October culminating in a significant rainfall event at the end of the month. At the beginning of December 2019, EKFB were able to drain and recommence works on the site and the final excavation level was reached on the northern part of the cutting with approximately 2.50m of excavation remained on the southern part (volume excavated up to end of December 2019 was 257,500 m3 with 13,500 m3 left to excavate). Continuing restrictions due to weather and then the Covid-19 pandemic resulted in the final excavation works only re-starting in June 2020 with the final level of excavation reached at the end of July 2020.

Figure 3. Heave Trial at formation level.

3.4.5 Testing, results and analysis

Monitoring periods have been defined to ensure the ground response was recorded over the relevant periods.

- Monitoring Period 1 (pre-excavation): the period prior to the excavation, after installation of the in-ground monitoring instruments. This period was used to establish stable readings and set a baseline for each instrument.
- Monitoring Period 2 (excavation): the period from start of the excavations works, until the bottom of the excavation profile (formation level of the cutting) is reached. This period was originally specified to last 3 months in the design but actually lasted for approximately 1 year between August 2019 and July 2020 and has been sub-divided into 3 phases.
- Monitoring Period 3 (post excavation): the period from reaching final excavation profile to the decommissioning of the trial and commencement of the main works for the Boddington Cutting and Oxford Canal South Embankment. Monitoring over this period was critical, as the response of the trial cutting to unloading was expected to occur mainly on this period, and results from this monitoring would allow to confirm design assumptions and so possibly impact the specified heave mitigations for the permanent works. This period lasted for approximately 2.5-3 years from summer 2020 until early 2023.

The results from the Heave Trial indicated that the mechanism of heave movement in the base of the excavation is a distributed movement over a significant depth which can be attributed to swelling due to stress relief due to the excavation of the cutting. This occurred as both immediate (during excavation) and long-term swelling with a maximum value being recorded at the deepest part of the cutting.

The conclusion was that a maximum movement of 30-50mm occurred in the deepest parts of the cutting. The immediate heave was estimated at approximately 30% of the total observed movement (i.e. 10-15mm) which is distributed over a shallower depth than the longer term swelling. The magnitude of ground movement reduces with depth, with the proportion of immediate to long-term reducing as well. Negligible movement was considered to be occurring 35m below the base of the cutting. The swelling in the upper 2.5m was estimated to have reached 95% of the predicted total at after 2.5 to 3 years. The period to reach 95% of the predicted movement reduces with depth, reaching 1-1.5 years 25 m below the base of the cutting. A forward projection was undertaken for the surface monitoring points and upper most magnets located along the centreline of the cutting which indicated that there was a further 5-15mm of movement still to occur albeit at a very slow rate. This residual movement (which was below the HS2 Technical Standards total heave limit) was expected to be concentrated over the upper 2.5m located directly below the base of the cutting.

The trial also provided valuable lessons in relation to the installation and commissioning of the instruments and subsequent monitoring phases. The most prominent issue was the result of the flooding of the excavation during the works and the subsequent build-up of debris in several of the magnet extensometer monitoring ducts. The flooding also caused delays in the construction programme, resulting in 3 phases of excavation instead of the single, continuous phase of excavation specified as part of the design. There were also lessons learnt associated with the survey control and impact to the measurements due the casing reductions required during excavation.

In additon to heave, a second mechanism of ground movement occurred during the trial. This was a downslope ratcheting mechanism attributed to the

seasonal drying and wetting in the near surface (1-2m bgl). A seasonal fluctuation of up to 10mm was recorded in the vertical inclinometers installed in the upper clay slope with approximately 50% being irrecoverable. This movement was comparable with observations in other cut slopes and is indicative of the "Vadose Zone" effects that are identifed as risks in the HS2 Technical Standard for Earthworks (2019a).

3.5 Heave design efficiencies

The Heave Trial observations indicated that the total measured heave was about half the original cautious prediction, and the rate of the movement was faster than the initially estimated rate. This greater certainty in the heave mechanism reduced the uncertainty and enabled a reduction in conservatism to be fed into the detailed design of the earthworks. The soil stiffness and anisotropic permeability values were refined supplemented also by information from the targeted ground investigation and laboratory soil testing results within the high-risk areas of the C23 deep cuttings.

The concentration of the observed residual movements over the upper 2.5m below the base of the trial cutting provided the sufficient evidence to the designers so that the heave of the permanent deep cuttings to be mitigated with a combination of 2-3m E&R with well graded Class 1 material (which in many cases were also required to satisfy the static and dynamic subgrade performance requirements) and a Hold Period ranging from 9 months to 22 months. This represented a more cost-efficient response to the remaining residual heave risk and resulted in the removal of all 6 areas of pile slabs in the detailed design eliminating the need for 37,000 m^3 of concrete and 5,700 tonnes of steel reinforcement and contributing to approximately 70,000 tC02 emissions savings including material embodied carbon and emissions related to transportation and construction works.

4 PERFORMANCE OF EARTHWORK MATERIALS

4.1 Earthworks scale

C23 is the single largest earthworks contract ever awarded in the UK requiring about 30,000,000 m^3 engineering fill materials for high-speed line (mainline) embankments, highway earthworks and landscape (environmental) bunds. This large volume of material is being sourced from the C23 cutting and green tunnel excavations and needs to be properly handled and transported in line with the EKFB's complex and sophisticated mass haul plan representing a significant planning and operations challenge.

4.2 Embankment requirements

HS2 mainline Upper Embankment Fill (UEF) and Lower Embankment Fill (LEF) consist of either structured chalk, stabilised chalk, stabilised glacial till or granular fill e.g., Class 1A1, 1B1, 1C1, 9G, 9J or 9K (HS2 SCEW 600, 2019b). Cohesive soils (Class 2) with high sulphate contents are not suitable for reuse as mainline or highway embankment fill due to risk of swelling while low to intermediate plasticity cohesive soils (LL <50%) with low sulphate content are suitable for reuse as mainline embankment fill after stabilisation. High plasticity cohesive soils (LL>65% and PI>40%) are Class 4 (HS2 SCEW 600, 2019b).

In addition to the material and compaction requirements of the mainline fill, there are static and dynamic stiffness performance criteria required for the constructed earth structure i.e. Modulus of Deformation based on EV2 measurement and dynamic performance based on Raleigh Wave Velocity criteria.

In order to secure the C23 mass haul plan baseline and introduce further carbon and cost efficiencies by maximising site won material re-use, EKFB in collaboration with ASC and HS2, planned and executed a number of large-scale earthwork material trials utilising materials and construction techniques proposed for the main works. The aim of these trials was particularly to confirm the suitability of a number of earthworks materials for high-speed rail UEF, LEF and E&R (i.e. foundation treatment).

4.2.1 Trial scope and objectives

The earthwork material trials were planned based on the availability of an area of land, the published geology, the underlying ground conditions, and the likely nature of locally available fill. The objectives of the trials included the review of suitable improvement options (e.g. stabilisation) for re-use of any excavated materials for embankment fill; determination of in situ Modulus of Deformation (EV2) and dynamic performance parameters; verification of the foundation conditions; earthworks control and verification to validate performance of earthworks during construction; and review of SCEW 600 contract specific Tables 6/1 and Table 1/5 requirements.

As mentioned before, many of the C23 embankments are built with Glacial Till stabilised with lime to increase its strength, density, stiffness, and shear wave velocity. A 3m height embankment trial was carried out in Newton Purcell area with lime stabilised locally sourced Glacial Till, obtained from a borrow pit excavated adjacent to the trial embankment.

The Glacial Till was encountered below the glaciofluvial deposits and was described to comprise firm, becoming stiff, grey to dark grey, slightly gravelly to gravelly clay. The gravel comprised limestone, flint, and mudstone, suggesting that the till is derived from local and distant rocks.

The design geometry of the embankment, which was governed by the surface geophysics testing requirements, comprised of target height of 3.5m, including 16 layers of 200-250 mm compacted thickness; and total length of 60m and width 20m including 2 testing areas 30m x 20m. For the construction of the embankment, the material was improved using binder contents of 1%, 1.5%, 2%, and 2.5% and produced the stiff to very stiff material generally seen throughout the trial. After adding lime, the Glacial Till classifies as 9J lime stabilised cohesive material.

4.2.2 Testing results

Strength/stiffness tests (UCS, triaxial, CBR, shear box) and the classification tests (particle density, pulverisation, calcium carbonate content, PSD) were conducted and samples were tested for optimum moisture content using modified (4.5kg hammer) and standard (2.5kg hammer) proctor tests and also for the natural moisture content tests.

Plate Load Tests were performed for measuring the EV2 of the material and Light Weight Deflectometer (LWD) for measuring the bearing capacity (deflection) of the subgrade/subsoils. The HS2 Technical Standard (2019a) requires minimum EV2 values of 45MPa – 60MPa and a maximum EV2 value of 500 MPa to be measured. For the measurement of EV2, the French standard procedure was specified which uses a 600 mm diameter plate and has an approximate depth of influence of 1.2m. The results showed that EV2 values remain mainly within the same range of 60-200 MPa and very small increases were observed as the embankment height was ascending. No significant differences were observed between the two test areas for each layer.

There was also an opportunity for the Continuous compaction control (CCC) to be tested in Newton Purcell trial. CCC is a roller integrated compaction measurement method for dynamically excited rollers, which allows for the compaction success to be continuously measured online. During the trial, the optimum number of compaction passes were assessed in line with the specification for the fill material and an optimized compaction rate was applied in the remainder of the embankment construction after the assessment.

Upon assessment of the trial results and considering the compaction and static performance requirements, an 1.5% minimum lime content was recommended by the DJV for HS2 permanent embankment fill. Minimum dry density of 94% and Maximum Air Voids of 5% were proposed as appropriate acceptance criteria for the 1.5% lime stabilised material.

Moreover, surface wave geophysical tests, namely MASW and CSW, were undertaken while rotary open hole boreholes were drilled through the completed trial embankment to a depth of 15m below formation level, to undertake downhole and crosshole seismic testing through the embankment fill and foundation strata to validate the inverted values of shear wave velocity from MASW/CSW surveys. The results from both the surface wave and intrusive geophysical methods succesfully confirmed exceedance of the shear wave velocity design assumption of 250m/s for the stabilised fill material for all minimum binder contents tested as part of this trial.

4.2.3 Material efficiencies

Overall, the earthworks materials trials successfully enabled the re-use of site won materials as engineering fill for mainline embankments and E&R. They also successfuly demonstrated the potential to reduce the minimum (lime) binder content from 2.5% to 1.5% while also satisfying the materials performance criteria, EKFB were able to eliminate up to 30,000 tonnes of lime for C23 permanent works, securing significant cost savings and over 50,000 tC02e reduction.

5 CONCLUSIONS

The planning and execution of the settlement and heave earthwork trials in advance of detailed design enabled the C23 teams to refine design parameters and incoperate significant cost efficiencies into the design by reducing or eliminating heavily engineered heave and settlement mitigations. The greater certainty as a result of these trials also enabled a reduction in the risk provision reduired for the project as it moved into construction. Ongoing construction stage monitoring installed in the permanent HS2 earthwork assets will further validate the information gathered from the field trials, in relation to settlement and heave in these challenging ground conditions and should enable further risk reduction and potential efficency in terms of the active managment of hold periods within the construction programme.

The C23 heave and settlement trials are amongst very few large-scale, instrumented earthwork trials carried out in the UK and will provide valuable

information for the design of similar earthworks in the future.

Moreover, a large number of site won materials trials succesfully confirmed the improved performance through stabilisation and the suitability as engineering fill for permament works securing EKFB‘s mass haul plan but also introducing efficiencies by reducing the total volume of lime binder required in C23 embankments by 40%.

Figure 4. Lime Stabilised Glacial Till Trial in Newton Purcell,

Further earthworks design and material re-use efficiency opportunities have already been mapped out and are being pursued at the late stages of the detailed design, with particular focus on the remaining carbon hot spots.

EKFB technical teams working collaboratively with the DJV and the Client are delivering technical excellence while building a lasting technical and sustainability legacy that will be passed on to future earthworks projects in the UK and abroad.

ACKNOWLEDGEMENTS

The author would like to thank his colleagues from HS2 Ltd, EKFB JV and ASC DJV involved in the planning and design of the earthworks trials, the execution of works and the interpretation of the results and implementation of the findings in the detailed design of the C23 permanent earthworks. An acknowledgement is also due to the HS2 and EKFB Project and Risk Management teams that recongnised the value that the early implementation of those proposed trials represented.

ABSTRACT: A large landslide immediate to a reservoir, identified in 2006, is the guiding case to discuss its triggering, namely a consequence of fast reservoir drawdown, and its post-failure response. The reactivation of the landslide, twelve years later, allowed the validation of some hypotheses assumed in the first study (2012). The risk of landslide acceleration, for a constant residual friction and an assumed thermal pressurization of the sliding surface, was not realistic since the landslide never accelerated. In recent years, efforts have been addressed to gain further knowledge by developing advanced numerical tools and a better understanding of clay shear strength. The paper presents the developments achieved. The results of a comprehensive experimental program to investigate the effect of shear strain rate and temperature are presented for a variety of soil types. The expected landslide response under rapid drawdown conditions was simulated by a material point method-based numerical tool that handles, in a dynamic formulation, large displacements and soil /rock materials characterized by temperature, strain rate, and strain softening dependence. The risk of landslide acceleration, predicted in the 2012 analysis looks, at present, as a remote event.

RÉSUMÉ: Un important glissement de terrain à proximité immédiate d'un réservoir, identifié en 2006, est le cas directeur pour discuter de son déclenchement, à savoir une conséquence de l'abaissement rapide du réservoir, et de sa réponse après la rupture. La réactivation du glissement de terrain, douze ans plus tard, a permis de valider certaines hypothèses retenues dans la première étude (2012). Le risque d'accélération du glissement de terrain, pour un frottement résiduel constant et une pressurisation thermique supposée de la surface de glissement, n'était pas réaliste puisque le glissement de terrain ne s'est jamais accéléré. Au cours des dernières années, des efforts ont été déployés pour acquérir de nouvelles connaissances en développant des outils numériques avancés et une meilleure compréhension de la résistance au cisaillement de l'argile. Le document présente les développements réalisés. Les résultats d'un programme expérimental complet visant à étudier l'effet de la vitesse de déformation et de la température de cisaillement sont présentés pour une variété de types de sols. L'avenir attendu des glissements de terrain dans des conditions de rabattement rapide a été simulé par un outil numérique basé sur la méthode des points de matériau qui traite, dans une formulation dynamique, les grands déplacements et les matériaux sol/roche caractérisés par la température, la vitesse de déformation et la dépendance à l'adoucissement de la déformation. Le risque d'accélération des glissements de terrain, prédit dans l'analyse de 2012, semble, à l'heure actuelle, être un événement lointain.

Keywords: Landslide; residual strength; strain-rate and temperature effects; drawdown; case history.

1 INTRODUCTION

1.1 Background to a reactivated landslide

The detection of a 2 km long crack parallel to a reservoir in 2006 in the north of Spain led to the geological and geotechnical identification of a landslide. The work carried out during 3 years included: (a) interpretation of air photo, field mapping, 16 borehole logs; (b) installation of monitoring systems and their interpretation; (c) laboratory tests for the characterization of the materials involved; (d) back-analysis of slope stability to determine possible

causes; (e) the study of the stability of the landslide in future situations of exploitation of the reservoir; and (d) the assessment of the risk of acceleration. The case was described in Pinyol *et al.* (2012).

The observed crack delimited the crest of a reactivated ancient compound translational landslide of 40 million m^3. Figure 1 shows three representative profiles showing the geology, the position of the boreholes, and the position of the landslide sliding surface estimated in 2009.

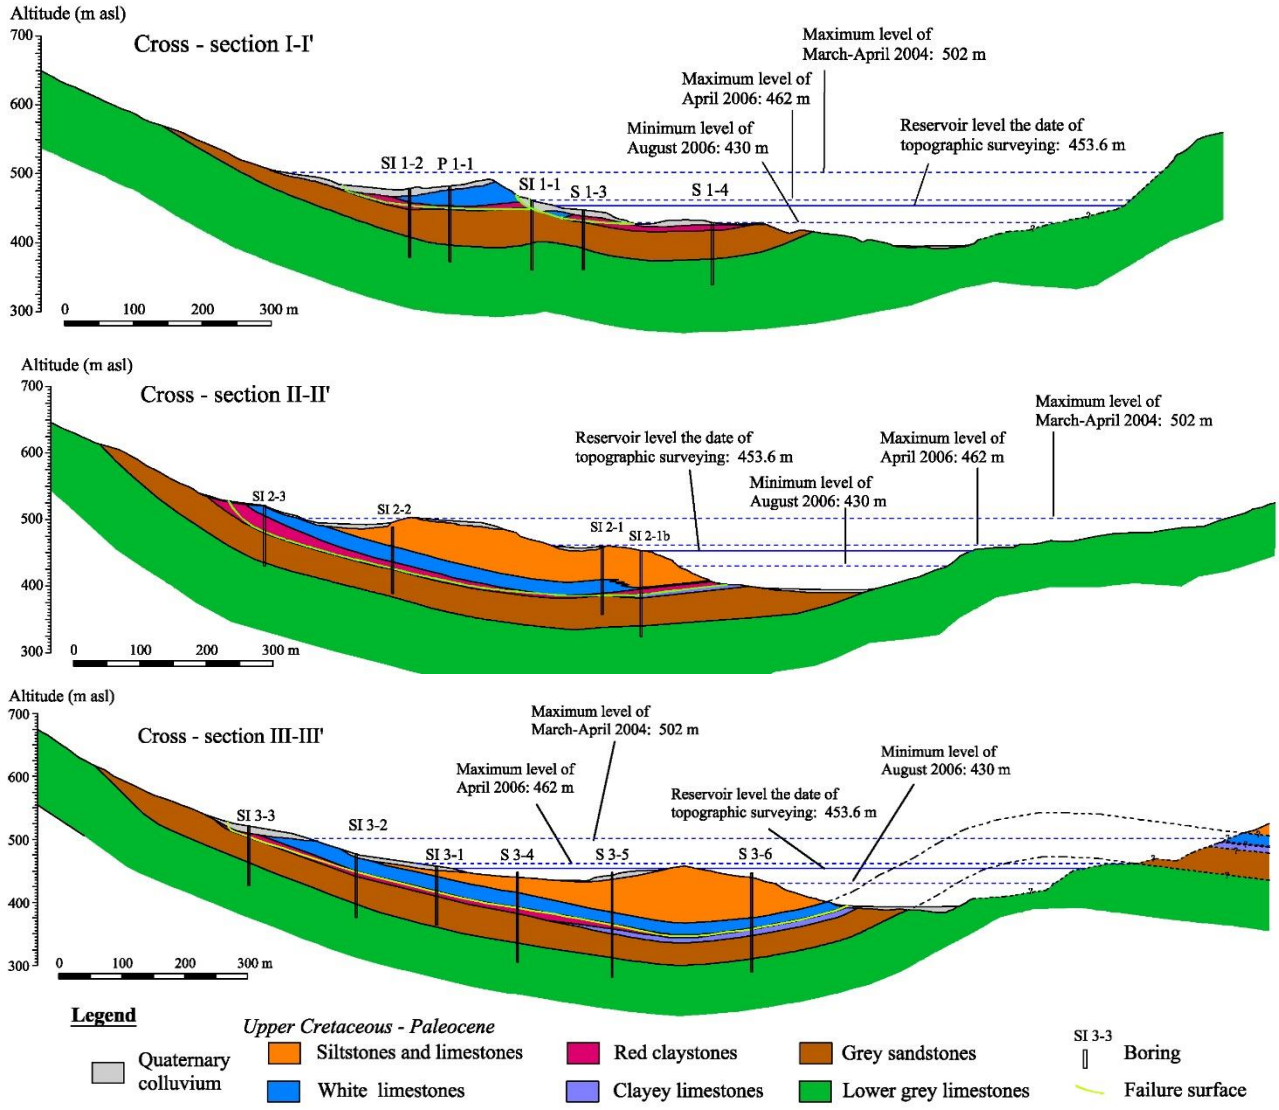

Figure 1. Geological cross-section. Same legend for all of them (Pinyol et al., 2012).

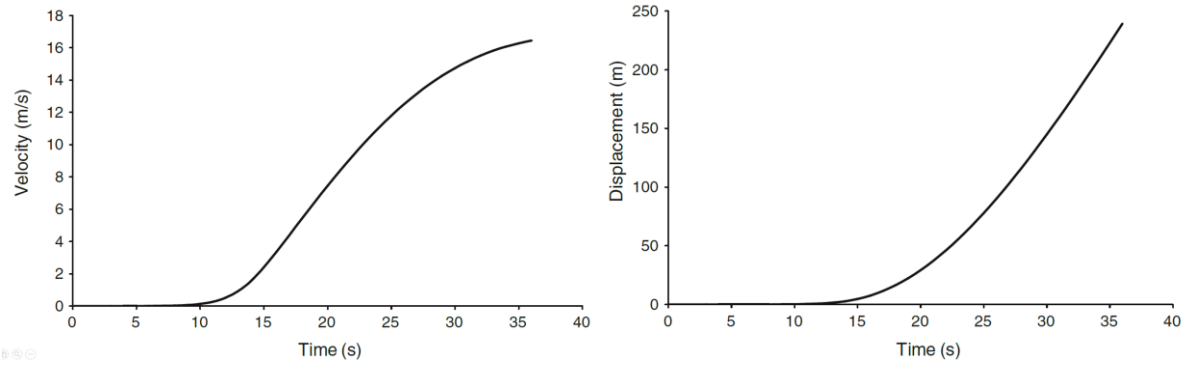
According to the conclusions of the geological and geomorphological work, the rupture surface was located in a Garumnian claystone layer (LL=45%; PI=23%, %<2μm=30%), interstratified between rock units. However, the slide movement, recorded by inclinometers after their installation in 2006, for three years, between the time of inclinometer installation after the identification of the landslide (2006) and the completion of the initial study (2009), did not allow us to confirm precisely the position of the slip surface. The clay was analysed in the laboratory using conventional identification tests and mechanical and hydraulic experiments (ring shear test and permeability test).

The stability of the landslide, affected by rainfall and the level of the reservoir submerging the toe of the slope was evaluated. With this purpose, the distribution of the water pressure into the slope was calculated using a flow-deformation coupled calculation model using the finite element-based code (Code_Bright, 2024). The changes in water level that occurred in 2002-2009, as well as the average rainfall, were introduced as boundary conditions to estimate properly the pore water pressure distribution. The

model followed the approach presented in Pinyol *et al.* (2008).

The results of this analysis, in terms of pore water pressures, were validated with pressure records provided by vibrating wire piezometers installed in the claystone layer and the limestone and sandstone layers above and below the claystone.

The stability analysis performed, by means of a limit equilibrium method, considering the water pressure distribution previously calculated by the coupled hydro-mechanical calculation, showed that the conditions considered, in terms of geometry, the variation of reservoir levels, and the available shear strength at the failure surface consistent with laboratory shear tests, could justify the rupture observed in 2006.



(a) *(b)*

Figure 2. Calculated evolution of the sliding velocity and run out, considering thermo-hydro-mechanical coupled effects (Pinyol et al., 2012).

The stability analysis concluded that slope stability was lost when the water pressure along the sliding surface, located in a layer of clay of low permeability, was significantly higher than the value corresponding to the reservoir level. This situation occurred when the reservoir level dropped during 2005 and 2006 after a long period of high levels at relatively high velocity (up to 25 cm/day).

The expected evolution of the landslide was evaluated in 2012, having in mind the risk of acceleration and the potential effect of a tsunami as occurred in the well-known case of Vajont landslide (Italy, 1996) (Alonso & Pinyol, 2010). The analysis of the acceleration risk, described in Pinyol *et al.* (2012), introduced the possible generation of pore pressures inside the basal shearing band of the sliding surface due to the heat generated by frictional work that, in turn, leads to an increase in interstitial pressure and, consequently, a reduction of available shear strength. The phenomenon of temperature increase during fast shearing has been recently measured in Kohler *et al.* (2023) in a ring shear apparatus.

This analysis was carried out with the tools available at the time, following the approach presented in Pinyol & Alonso (2010), also applied in the case of Vajont landslide. Other contributions addressed also this problem (Vardoulakis, 2002).

The modelling work performed indicated that the unstable slope could accelerate, by heat-induced pore water pressurization, and reach a maximum velocity of 16 m/s and a displacement of hundreds of meters (Figure 2). This estimation was not realistic since the landslide never accelerated. However, in the case of Vajont landslide, during the three years previous to the catastrophic acceleration, the landslide exhibited accumulated displacements whose rate could be correlated with the reservoir elevation history and accumulated rainfall. Therefore, even though we could not provide a consistent explanation of the causes of the landslide motion without an abrupt acceleration, the risk of acceleration was accepted as possible.

1.2 Twelve years later

At present, the landslide remains active and, as occurred during the dry period between 2004 and 2006, the recent drought in north-east Spain in 2021-2023 forced the reduction of the reservoir elevation to very low levels (Figure 3). This drawdown was preceded by 7 years in which the reservoir remained at high elevation. The consequence was a reactivation of the landslide. Fortunately, since 2009 the landslide has been instrumented with inclinometers and piezometers and valuable information is available.

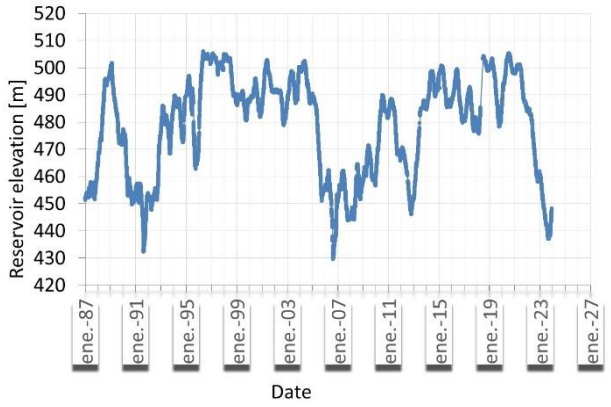


Figure 3. Reservoir level in time.

Again, the instability observed by accumulated displacements of the landslides, triggered by the drawdown, did not induce its abrupt acceleration predicted by the thermally-induced pore water pressurization.

During these twelve years, our effort has been addressed to gain further insight into the response of the landslide behaviour and the factors affecting its velocity, as well as its modelling through recently developed tools. With this aim, advances in numerical developments and the characterization of the soil of the sliding surface have been carried out.

1.2.1 Advanced modelling

The methodology presented by Pinyol et al. (2012) exhibited some limitations, especially regarding the definition of landslide geometry. The geometry had to be simplified and pre-defined by interacting wedges. In addition, the shear bands, where the thermal coupling may develop, had to be also imposed "a priori". At that time, no more sophisticated numerical tools allowing the simulation of thermally-induced accelerated landslides were available, to the knowledge of the authors. With the aim of overcoming such limitations, the thermal, mechanical, and hydraulically governing equations were implemented in numerical software suitable to model large displacements and deformations. The material point method (MPM) (Sulsky *et al*., 1994) was selected. This method can deal with large deformations and avoid the problems of mesh distortion associated with standard finite element methods thanks to two spatial discretizations: an Eulerian computational mesh, where the equations are solved and cover the whole domain, and Lagrangian material points that are used to discretise the mass of materials as well as to store all the relevant data (properties, independent and state variables) (Zhang *et al.,* 2017; Fern *et al.*, 2019). The material points can move during the calculation throughout the computational mesh according to the computed results (Figure 4).

The modelling of thermally-induced pressurization due to the dissipation in heat of the frictional work generated in shear bands required a new approach to avoid the pathological dependence on the computational mesh that appears when using the standard formulation. This limitation was solved by defining embedded numerical shear bands that develop as a result of the computed shear strains. In these embedded shear bands, the frictional work is computed. The thickness of the embedded joints, representing the thickness of the actual shear bands developed in the field, is imposed as an input parameter and does not depend on the size of the computational mesh. All the details of the developments for the MPM-based modelling of thermally accelerated landslides are presented in Pinyol *et al.* (2018).

The advances in numerical development consist of an MPM-based software able to introduce the thermo-hydro-mechanical couplings in the post-failure behaviour of landslides. In addition, this generalized numerical tool allows the implementation of additional improvements (i.e. non-constant properties, more advanced constitutive models, unsaturated conditions, and additional boundary conditions).

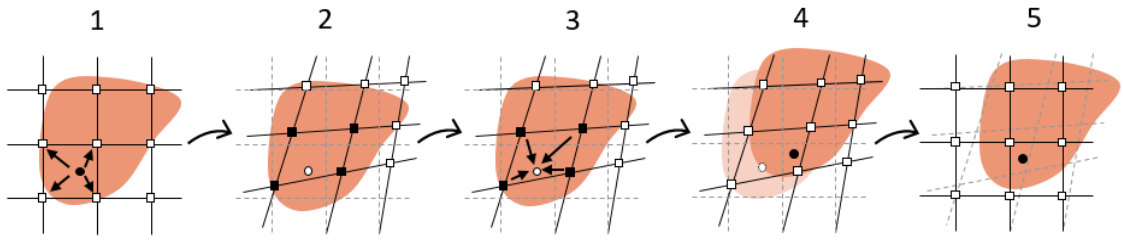

Figure 4. MPM discretization scheme and computational cycle: (1-2) all the physical properties of the continuum are transferred from MPs to the mesh nodes where governing equations are solved (lagrangian phase); (3-4) solutions are mapped back from nodes of the deformed mesh to MPs and their positions are updated (convective phase); (5) nodal displacements are discarded and the computational mesh is reset to the initial configuration (Di Carluccio, 2021).

1.2.2 An insight into shearing strength

Regarding the observed slow motion, the focus has been recently addressed to evaluate in more detail the nature of shear strength, which is a key factor controlling the behaviour of landslide velocity. The soil strength is far from being a constant property. For a given soil and pore fluid, it depends on stress state, pore pressure, accumulated strain, and strain rate (all of them are variables that may change during the landslide motion), as well as aging. Several contributions to these topics can be found in the literature.

In first-time failures, the available strength in shearing bands varies from peak to residual values when shearing strains accumulate, especially in soils with significant clay content (Lupini *et al*., 1981; Skempton, 1985; Stark & Eid, 1997). Residual strength controls the behaviour of ancient or reactivated landslides. In the first estimation of stability, a constant residual shear strength is adopted for the sliding surface. However, for more advanced analysis of the evolution of creeping slides, eventually evolving towards a rapid failure, such a simple assumption prevents a proper understanding of the observed behaviour.

One phenomenon invoked to explain the slow motion of landslides is the rate-hardening of shear strength of shear bands (a concept equivalent to viscous resisting forces). The increment of the strength with the shear rate can prevent the acceleration. Once a landslide becomes unstable, because of a non-equilibrated balance between acting and resisting forces, and accelerates, the increment of the strength (or viscous forces) with shearing velocity may lead to reducing the acceleration and, eventually, to a situation of constant creeping velocity even if the intensity of the triggering factors is maintained in time. Viscous resistant forces, proportional to the shearing rate, were considered by Angeli *et al.* (1996) and Corominas *et al.* (2005) to analyse the response of creeping landslides. Other approaches include the rate effect on the frictional angle (Bowden and Tabor, 1964; Mitchell, 1976; Rice & Ruina, 1983; Davis *et al.,* 1993; Wedage *et al.,* 1998b). Seguí *et al.* (2020) included also the strain rate effect on the friction angle in the energy-based approach, combined with thermal interaction due to frictional work.

From an extensive account of experimental work available in the literature (Tika *et al*., 1996; Saito et al., 2006; Scaringi & di Maio, 2016; Scaringi *et al*., 2018; Wang *et al*., 2020; Ma *et al*., 2021, Kohler et al., 2023) it is observed that the effect on the residual strength of varying the shearing velocity depends on the properties of the tested material and the range of the applied velocities. The effects observed can be positive, neutral, or negative, in the sense that increasing the shear rate, leads to a larger (positive) or smaller (negative) value of the residual strength, compared with the strength measured at very small deformation rates. Sometimes, no effect is observed (neutral).

In this paper, the effect of the shear strain rate on the residual strength is evaluated for different types of soils including the clay of the landslide discussed here. In case of a positive strength effect for the clay of the landslide analysed, this phenomenon may explain the slow velocity observed, because it could prevent its frictional heating-induced acceleration. These ideas were evaluated for planar and compound landslide by Alonso *et al*. (2016) and by Seguí *et al.* (2020).

Another factor affecting the variation of the available shear strength on the sliding surface discussed and evaluated in this paper is the temperature. Seguí & Veveakis (2021) evaluate a real case with the previously developed mathematical model and provide measurements of the temperature inside of the shear band.

Temperature increments induced by the frictional work, which may induce excess pore water pressure, as discussed before, may also affect the intrinsic friction. In addition, the temperature may be due to external factors. In the case of active landslides, the temperature on the sliding surface can be affected by atmospheric conditions, and its changes may become more relevant due to climate change. A few studies on this topic are available in the literature, although the interest in evaluating the effect of temperature on the strength of soils has grown in recent years.

The effect of the temperature on residual shear strength is evaluated by Bucher (1975), Shibasaki & Yamasaki (2010); Yavari *et al.* (2016); Shibasaki *et al.* (2017); and Loche & Scaringi (2023). Bucher (1975) concluded that the temperature effect was not relevant in two low-plasticity soils for temperatures ranging from 10 ◦C to 60 ◦C. The effect was observed more relevant in Shibasaki & Yamasaki (2010), who tested smectite-rich soil. They concluded that the tested soils exhibited less strength at a lower temperature under slow shearing velocities. This research was complemented by Shibasaki *et al.* (2017) where soils with different smectite content were sheared at different velocities (ranging from 0.0025 to 5 mm/min) at temperatures from 6 ◦C to 29 ◦C and normal stresses of 50, 100, 150, and 200 kPa. They concluded that the strength of smectite-bearing soils reduces at lower temperatures under relatively slow shearing rates (< 0.1 mm/min) whereas the effect is opposite under relatively high shearing rates (> around 0.1–0.5 mm/min): the soil strengthened when

temperature decreases. Soils without smectite content exhibited a slight weakening due to heating (and strengthening at cooling) at the whole range of shearing rates (0.0025–0.5 mm/min) applied.

Loche & Scarinigi (2023) evaluated the effect of temperature on two pure clays (ca-bentonite and kaolin) until temperature of 55ºC and shear rates of 0.018-44.5 mm/min. They conclude that the effect of the temperature depends on the type of clay, and, furthermore, the magnitude and sign of the temperature effect change with the rate of shearing. In the interpretation of the results, they incorporate the heating-induced swelling and contraction upon cooling.

To evaluate the effect of the temperature of the clay of the landslide analysed here, velocity- and temperature-controlled shearing tests were carried out. With the aim of getting a better understanding of the observed results, a systematic and consistent program of ring shear tests on samples of different soils characterized by different plasticity and grain size distribution was carried out.

1.3 Outline of the remainder of the paper

According to the above introduction, this paper first presents the main conclusions of the landslide analysis presented in Pinyol *et al.* (2012), and a discussion comparing the back-analysis, hypothesis, and prediction carried out at that time with the new field data.

A second section is addressed to show experimental data on the effect of the shearing rate and temperature on the residual strength.

Third, the landslide motion is evaluated by numerical modelling including internally-generated increments of temperature and potential pressurization of water. A sensitivity analysis is performed to evaluate the effect of some hypothesis and properties to prevent thermal acceleration, among them, the shear-rate hardening or temperature, based on the experimental data.

A section with conclusions and ongoing and future works closes the paper.

2 UPDATED ANALYSIS OF THE LANDSLIDE STABILITY

During the operation of the reservoir from 2009 until the present (2023), the landslide was monitored by means of manual inclinometers (some of them installed in newly excavated boreholes located close to the previous ones Figure 1), piezometers and surface displacements using geodesy, and INSAR technique.

2.1 Verification of the sliding surface position

It would have been desirable to verify the precise position of the sliding surface by means of inclinometric records. However, this was not possible because during the period analyzed before the publication of the 2012 paper, the inclinometers installed after the detection of the landslide did not provide relevant movement, except for inclinometer 3.1, located in the central part of profile III (Figure 1), in which 6 mm of accumulated displacement was recorded between December 2006 and December 2009.

The new inclinometric measurements made it possible to validate the position of the slip surface proposed in 2009 (Figure 1) which was considered in the stability analysis. The inclinometer measurements are not included here due to the limited space. Table 1 shows the depths of the sliding surface estimated in 2009, and the depth according to the more recent data. It should be noted that the estimated position of the rupture surface, according to geological studies and the interpretation of the shear surface in the borehole cores, fits well with inclinometer measurements. The only relevant difference is in the sliding surface position at the top of Profile II (SI 2-1). In this case, several shear surfaces were identified, and the position of the sliding surface selected for the calculations was the bottom of the clay layer and, it actually appears, according to the inclinometers, at the top.

The differences detected in the geometry and position of the landslide surface in the previous studies are not considered relevant in terms of the conclusion reached regarding the slope stability analyses.

Table 1. Estimated position and measurement of the sliding surface at the position of inclinometers.

Profile	Inclino-meter	Estimated depth in 2009 [m]	Average depth according to the relative motions observed in the inclinometers [m]
I	SI 1-1	4 and 14	7
	SI 1-2	25	22
II	SI 2-1	74	67
	SI 2-2	60	55
	SI 2-3	37	15
III	SI 3-1	41	40
	SI 3-2	28	24
	SI 3-3	17	10

2.2 Response of landslide to reservoir elevation

Slope stability analyses indicated that the slope is stable under the hypothesis of a hydrostatic pressure distribution inside the slope at the reservoir elevation. The safety factors obtained by limit equilibrium are relatively high as shown in Figure 5.

As verified by Pinyol *et al.* (2012), the lowering of the reservoir level is a cause of slope instability, especially when the drawdown reaches a high velocity and occurs after long periods in which the reservoir level is maintained at high levels. In this case, pore pressures in the clay are high and in equilibrium with the reservoir level. This situation explains the failure observed in 2006 due to the intense drawdown (Figure 3) and the lack of any symptoms of instability in the summers of 1991 and 2012. In addition, other factors such as the direct contribution of rainfall or the underground water supply from the upper part of the hillside can also increase the pressure and promote instability.

The more recent drawdown, initiated in the summer 2021, reached the lowest level in the summer 2023, (Figure 3), and triggered the instability of the landslide. According to INSAR measurements, displacements between November 2022 and August 2023, in the upper area of the slide between the position of profile I and II (Figure 1), were maximum and reached up to 40 mm, which corresponds to an average sliding speed of 4.5 mm/month.

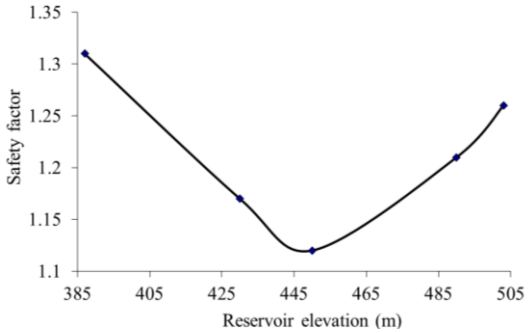

Figure 5. Safety factors calculated by limit equilibrium under a hydrostatic pressure distribution corresponding to a given reservoir level (Profile II).

According to the piezometer installed in SI 2-2 inside of the clay layer, the pore water pressure remained relatively high during the last drawdown (2022-2023), indicating that the process of dissipation of water pressure is slower than the drawdown velocity. On the contrary, the pressure registered in the deepest sensor, inside of the rock unit, follows the level of the reservoir almost immediately. It was also observed, between 2006 and 2009, that the pressure of the limestone and sandstone strata, above and below the clay layer, is mainly controlled by the level of the reservoir at low elevations, an indicator of its high permeability.

The accumulated excess pore water pressure on the clay layer was significantly high when the water level of the reservoir dropped from 480 to 440 m in 2022. It should be noted that drawdowns in the range of relativelly low elevations (lower than 500 m.a.s.l.) lead to the accumulation of excess water pressures larger than a drawdown, of the same magnitude, between higher reservoir elevations. The reason is that the stress relief due to changes in the total stress, because of the removal of the water weight induces a water pressure discharge and, therefore, an instantaneous reduction in pore water pressure. This effect is greater at higher reservoir levels where the loss of total stress directly affects the submerged area. Drops in water level from low levels only affect the area near the foot of the slide, and therefore, the pressure accumulated in upper zones inside of the slope does not reduce instantaneously due to the stress relief and must be dissipated by flow, which takes time.

3 TESTED MATERIALS AND EXPERIMENTAL PROGRAM

Six different types of soils were tested to evaluate the effect of the shear rate and temperature (Figure 6). The clay corresponds to the material where the sliding surface of the landslide was localized. These materials were selected to have a wide range of soils in terms of physical properties and mineralogical composition. Figure 7 and Figure 8 show their grain size distributions and plasticity.

Figure 6. Tested materials.

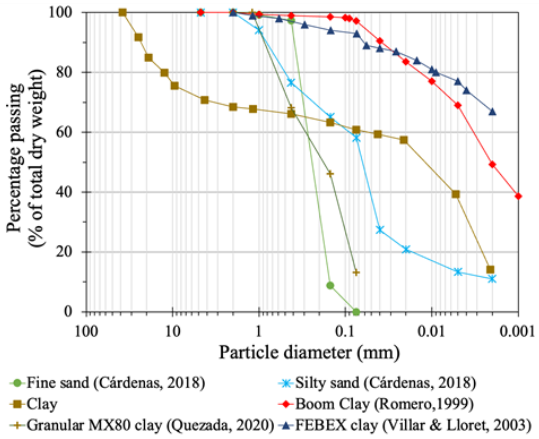

Figure 7. Grain size distribution of tested materials.

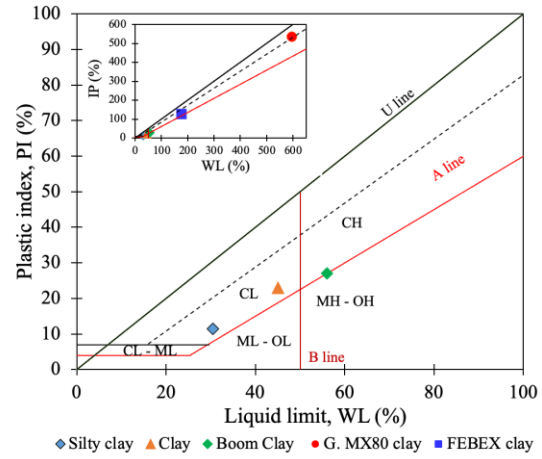

Figure 8. Plasticity chart of tested clayey materials.

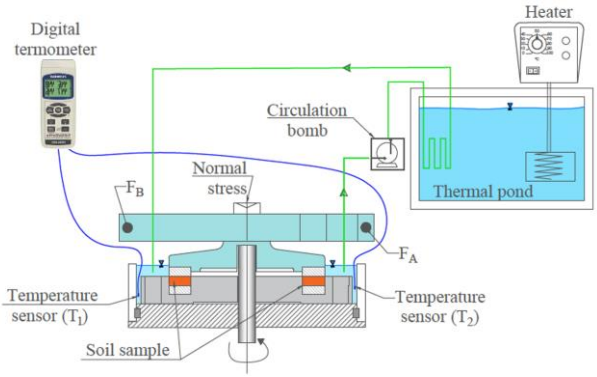

Figure 9. Control temperature system in the Bromhead shearing cell.

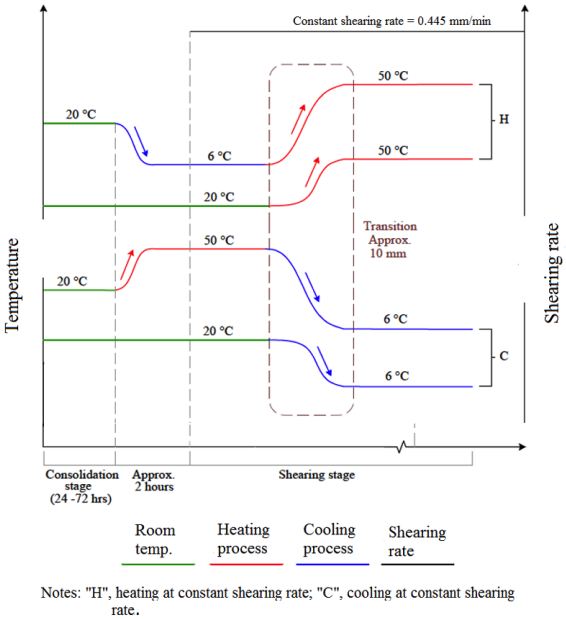
Shear tests at different shearing velocities and temperatures were carried out in a modified Bromhead ring shear equipment (Bromhead, 1979). The temperature conditions of the test specimens were controlled by cooling or heating water within the thermal bath surrounding the cell (Figure 9). The soil temperature is assumed to be equal to the bath water due to the high thermal conductivity of metal surrounding the soil and the slow rate of temperature changes.

The specimens were manufactured with the fraction of the remolded soils that pass through an ASTM#40 sieve (0.425 mm). Their initial water contents were small and corresponded to their hygroscopic conditions prevailing in the laboratory (T≈20 ºC, RH=60%). The powder obtained was placed carefully inside the shearing cell and compacted using a controlled displacement press machine at a relatively low velocity until reaching 10 MPa of normal stress. In the case of the bentonite samples, Boom, G.MX80, and FEBEX clay, the normal stress increased to a small value to maintain a relatively low density and reduce the swelling during subsequent wetting.

The tests at constant temperature and increasing shear velocity were carried out at dry conditions to reduce the wall friction that is generated in saturated specimens while the soil samples are extruded from the shearing zone during the test. The leakage of the material is a limitation of the shear box because of the gap between the fixed upper part and the rotating lower part. To prevent the leakage of soil, the gap can be sealed as discussed in Kohler et al. (2023). However, testing dry samples also avoids the effects of the generation of excess pore water pressure due to the contraction or dilation of the sample during shearing and to the temperature increasing by friction, especially at relatively large velocities. The combined effects make it difficult to isolate the effect of the shearing rate.

However, it should be noted that the residual strength measured includes the effect of suction on the strength (Lai *et al.,* 2010; Merchan *et al*., 2011; Hu *et al.,* 2018; Hoyos *et al*., 2020), which is expected to be substantially higher than the strain rate effect.



Notes: "H", heating at constant shearing rate; "C", cooling at constant shearing rate.

Figure 10. Schematic experiment stages for shearing rate and temperature-controlled tests (García et al. 2023).

Two tests were carried out for each material at two normal stresses (100 kPa and 200 kPa). The shearing stage under constant normal stress starts with a slow velocity (v_0^l) of 0.089 mm/min until the soil reaches residual conditions. Later on, 4 velocity steps were applied in the following ascending order: 0.445, 2.226, 11.13, and 45 mm/min. They range between moderate to rapid landslide according to Varnes classification (Hungr *et al.,* 2014).

In the case of temperature-controlled tests at constant shearing velocity, after compaction of the dry samples in the shearing cell, all the samples were loaded to the target normal stress of 100 kPa, a value that remained constant during the shearing test. Subsequently, the samples were saturated in the shear box by immersion at room temperature (≈20 ºC). The tests were carried out at 0.445 mm/min. From the initial condition of room temperature (≈20 ºC), temperature changes ranging between 6ºC to 50 ºC were applied. The transient period of temperature before equilibrium lasted approximately thirty minutes. Figure 10 shows schematically the stages applied in the temperature-controlled tests.

4 SHEAR RATE EFFECTS

Figure 11 shows the results for the Garumnian landslide clay. The large values obtained, compared with the 12º measured in the saturated direct shear test, is a consequence of the well-known effect of suction on the strength. For the range of applied shearing velocities the frictional angle increased up to 2º.

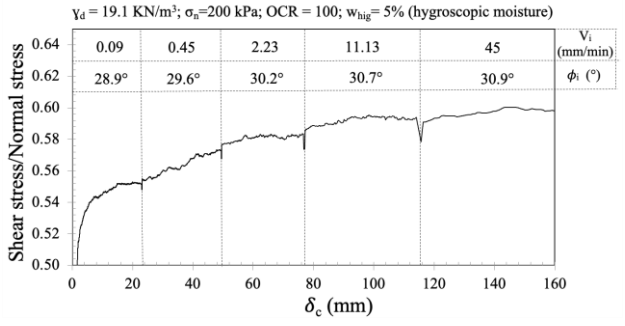


Figure 11. Ratio between residual shear strength (τ) and normal stress (σ_n) in ring shear tests at different shearing velocities on remolded samples of the clay of the landslides at hygroscopic humidity.

Figure 11 shows the results in terms of residual strength obtained at different shearing velocities normalized by the value obtained at slow (minimum) velocity applied at the beginning of the test for all the materials. During some tests, it was observed some dispersion in the shear stress/displacement relationship. The criteria to define the residual strength for each displacement rate was selected to be the minimum strength after the measured first maximum (peak) strength. The effect of normal stress is not discussed here. In general, all materials experienced a positive rate effect (strengthening behaviour), except for the silty clay that, in three tests described a negative rate effect.

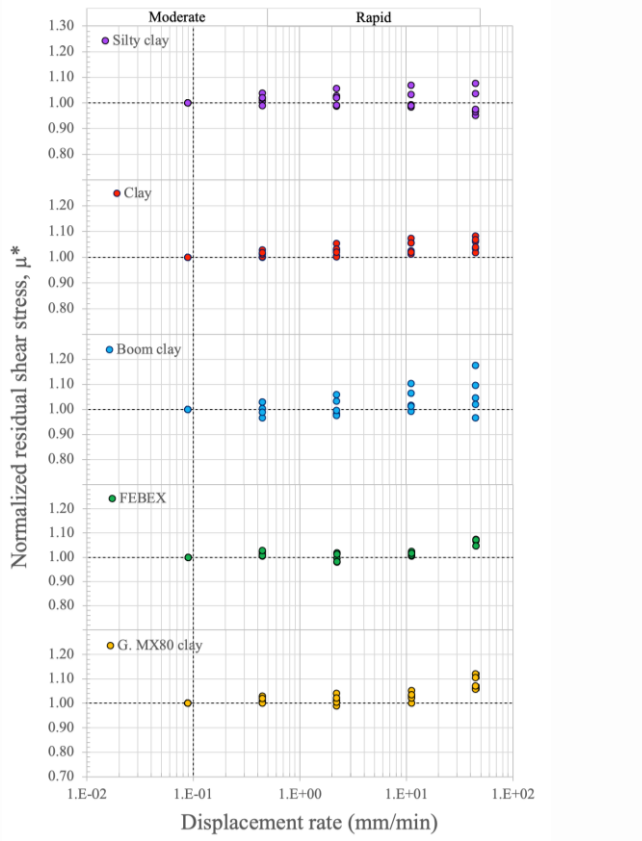

Figure 12. Normalized residual shear stress variation with the displacement rate measured in ring shear tests.

5 TEMPERATURE EFFECTS

The temperature effect was evaluated in 67 samples of the one-component soil-type. Temperature steps of increasing and decreasing the temperature in the range of 6ºC and 50ºC were applied.

Figure 13(a) shows one of the experimental results for the cooling test on the landslide clay sample. Initially, the temperature is equal to 51ºC and at a certain time during shearing, it is reduced to 6ºC. To show the temperature evolution without oscillations, the measured temperature is fitted by an exponential function in terms of accumulated displacement. At the beginning of the test at a constant temperature, the remolded sample exhibits a softening response. Initially τ increases linearly up to a peak value and, afterward, the shearing strength reduces gradually with the accumulated displacement increment towards a

residual value. The applied step of temperature induces a transient regime and a subsequent steady-state stabilization.

Figure 13(b) shows the response of a Boom clay sample subjected to heating (from 5ºC to 51ºC).

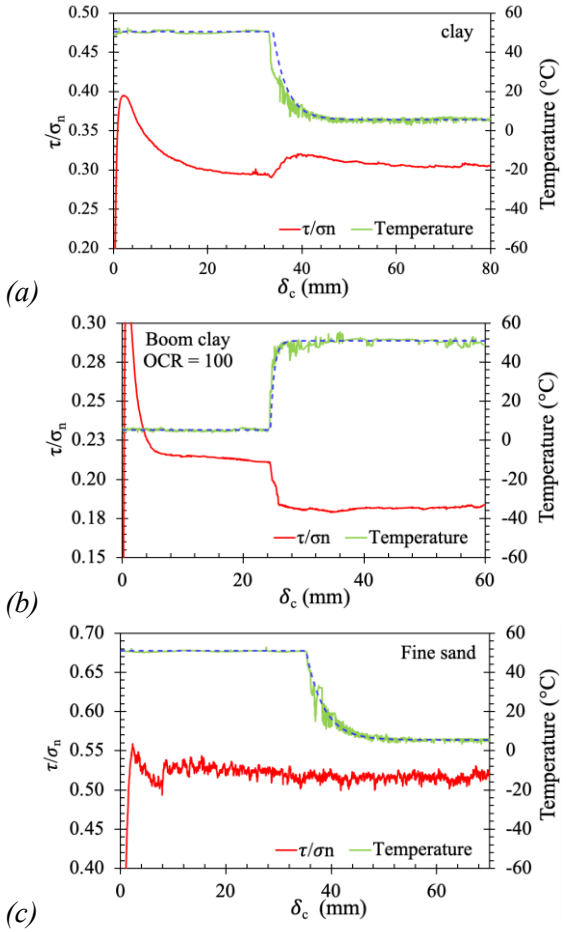

Figure 13. Normalized shear strength (τ/σ_n) and measured and fitted temperature during shearing displacement (u) at the constant shearing rate of 0.445 mm/min and normal stress of 100 kPa for (a) the clay of the landslide; (b) Boom clay; (c) Fine sand. (García et al. 2023).

Again, an initial softening response is observed, as well as the instantaneous change of the strength with the temperature change.

In both clays, increments of temperature in the range evaluated indicate that an increase in temperature leads to a decrease in strength, and an equal and opposite trend is observed when temperature decreases. A cooling-hardening and heating-softening is observed.

The response due to temperature changes was similar in FEBEX clay. Samples of G. MX80 exhibit a behaviour that does not follow the general trends observed in the rest of the samples. G. MX80 samples continuously expanded during shearing, which was not observed in the rest of the tests. In the case of fine sand samples, the effect was almost negligible (Figure 13(c)).

The temperature effect is plotted by transforming all the values of the friction coefficients into their equivalent friction angle. It is convenient to plot the increment of the friction angle measured in each test when a controlled change of temperature is applied. The slope, $\Delta\phi/\Delta T$, for each soil (Figure 14) increases from an essentially zero slope (Castelldefels sand) to a higher slope when fine's content and plasticity increase (except for G. MX80 samples) for the evaluated temperature range (from 6ºC to 55ºC and from 55ºC to 6ºC).

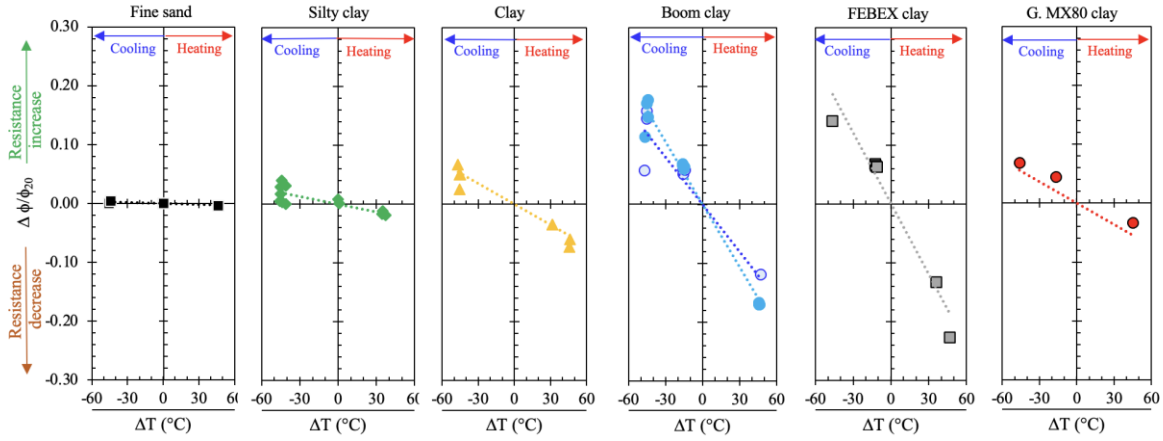

Figure 14. Effect of temperature variation (ΔT) on the residual friction angle variation ($\Delta\phi$) of the basic soils measured at a constant shearing rate of 0.445 mm/min. Experimental values and trend line (García et al. 2023). ϕ_{20} is the residual friction angle for a temperature of 20ºC.

6 MODELING LANDSLIDE RUN-OUT INCLUDING THERMAL AND STRAIN RATE EFFECTS WITH MPM

6.1 Features included in the MPM modelling and its effects

The analysis presented by Pinyol *et al.* (2012) evaluated the run-out including the thermal acceleration of the landslides with a simple geometry of two blocks (Figure 15) obtaining the run-out indicated in Figure 2. The modelling in MPM allowed us to introduce: (a) a more realistic cross- section (Figure 16) without predefining the basal sliding surface and internal shearing planes; (b) modelling of the rock stratum above the clay layer whose elastoplastic properties follow a strain-softening Mohr-Coulomb model; (c) incorporation of water as an incompressible (high volumetric stiffness) material and no shearing strength.

These modifications added to the initial modelling some features that contributed to preventing the acceleration of the landslide because of different causes:

(a) The basal landslide failure, which is part of the solution, follows the counter-slope that the clay layer exhibits at the lower part of the landslide because of the syncline. It helps to stabilize the unstable mass, unlike the planar shearing surface pre-defined in the two-block model.

(b) The advance of the landslide motion requires the generation of shear localization bands inside of the mobilized mass, a necessary result to get a movement kinematically admissible. These shearing planes can be observed in Figure 17. The resistance provided by these shearing surfaces plans, developing in a strain softening material, was not included in the first analysis.

(c) The weight and inertia of the reservoir water, incorporated in the MPM, oppose the movement and tend to reduce its velocity.

However, these additional considerations included in the MPM calculation cannot prevent the acceleration of the landslide.

The resulting run-out and velocity are shown in Figure 17 in terms of displacements and, in Figure 18, in terms of velocity versus displacements. The initially predicted maximum velocity of 16 m/s reduces to 12 m/s in the new calculation and the unstable mass stops after 120 m of run-out. This is smaller than the distance predicted previously.

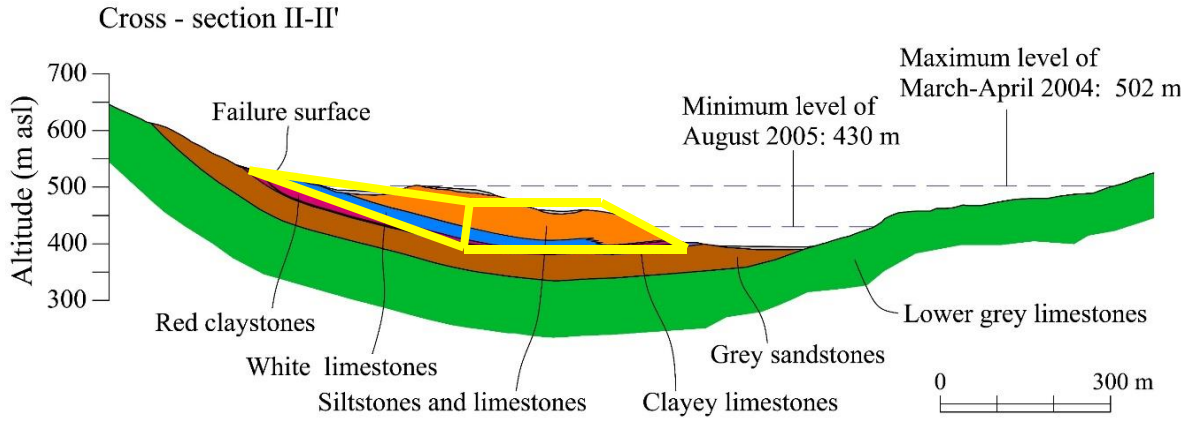

Figure 15. Two-block geometry for simplified analysis of the thermal acceleration of the landslide.

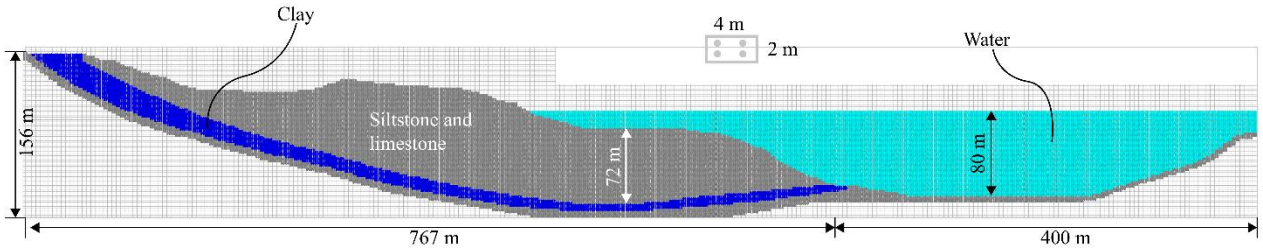

Figure 16. MPM discretization of the landslide: computational mesh and material points.

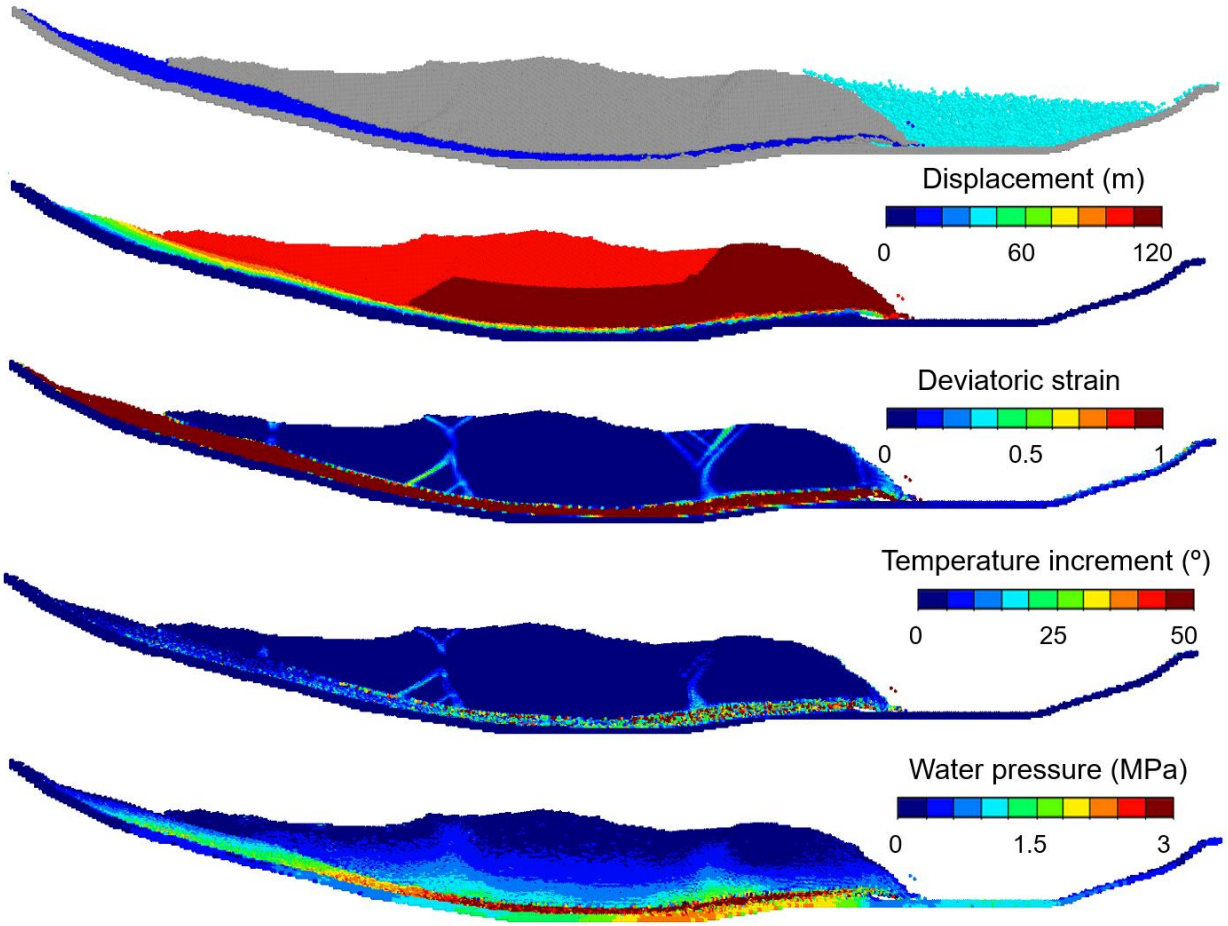

Figure 17. MPM results considering first estimation of parameters, without including shear rate effects.

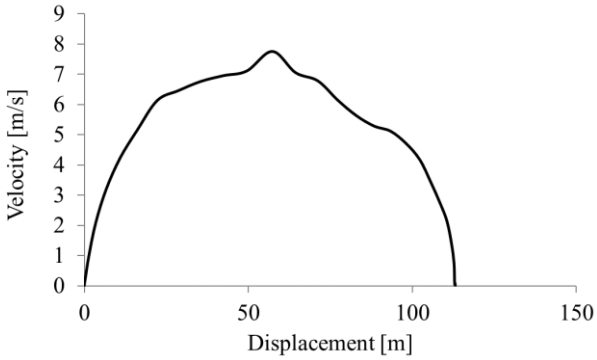

Figure 18. Displacement and velocity of the toe of the landslide calculated by MPM considering the first estimation of parameters and without including shear rate effects.

Figure 17 shows also the temperature increments and pore water pressure generated due to thermal effects. Note that increments of temperature are also observed in the mobilized rock along the generated shearing plans and not only in the basal shearing band. However, the subsequent induced excess pore water pressures are not so significant as those observed in the clay layer due to its dissipation during the motion because of the high permeability of the rock (10-6 m/s, 5 orders of magnitude larger than the permeability of the clay).

6.2 Review of some properties and shear strain effects

The MPM-based model of the landslide including thermal effects also predicted a large acceleration not observed in the field even if considering additional factors. The previously presented MPM results came from a pessimist estimation, considering the selected values of relevant parameters that favour the acceleration of the landslide due to thermal effects. The permeability value was selected as $5 \cdot 10^{-11}$ m/s, being the value measured in the laboratory, despite knowing that in the field the permeability is usually higher. A larger value, around 10^{-10} – 10^{-8} m/s, may be likely a good estimation of the field permeability. A larger permeability allows a larger dissipation of the thermal pressurization of pore water, generated during the motion, and reduces the thermally-induced acceleration.

The thickness of the basal shear band was assigned to be 5 mm. As discussed in Pinyol *et al.* (2012), it is difficult to estimate accurately the thickness of the

shearing band, even if recovered samples are examined. A larger value could have been considered.

On the other hand, to incorporate the strain-rate effects, hardening of the frictional angle is implemented in the MPM code by means of the following general equation, which also includes strain softening:

$$\phi' = \phi'_{res} + \left(\phi'_{peak} - \phi'_{res}\right) e^{-\eta \varepsilon_d^p} + \bar{\phi}' \left(1 - e^{-\alpha \dot{\varepsilon}_d^p}\right) \quad (1)$$

where, ϕ'_{peak} and ϕ'_{res} are the maximum and minimum effective friction angles associated with shearing at a slow strain rate, η is a model parameter that controls the loss of strength from the peak to residual friction at slow rates, $\bar{\phi}'$ is the maximum increment of the effective friction angle due to rate effects, and α is the parameter controlling the rate strain effects. ε_d^p is the deviatoric plastic strain and $\dot{\varepsilon}_d^p$ is the deviatoric plastic strain rate.

The selected law (Ec. 1) is expressed in terms of deformation because constitutive models are implemented in terms of deformation and stress. However, the laboratory experiments provide the strength variation in terms of shearing displacements. To correlate deformations and relative displacements, the thickness of the shear band should be estimated.

Considering these aspects, an updated case is simulated, if compared with the previous MPM model, in which the clay permeability is assumed equal to 10^{-8} m/s and the thickness of the shear band equal to 200 mm.

In addition, the strain-rate hardening law (Eq. (1)) is calibrated, inspired by the velocity-controlled ring shear test carried out on the clay samples of the landslide presented above. The maximum increment of friction angle with the shear strain is assumed to be equal to $\bar{\phi}'$=2º. $\phi'_{res}$is equal to 11.5º, and no strain softening is included. Figure 20 shows the friction angle evolution with the rate of shear strain. The value of $\alpha=10^{-7}$ 1/s has been selected. The residual friction angle varies from a minimum value, 11.5º, for shear strain rates smaller than 10^{-9} s^{-1}, to a maximum value of 13.5º when the strain rate reaches values of 10^{-6} s^{-1} (approximately). This range of shear strains corresponds to $1.2 \cdot 10^{-5}$ mm/min (= 0.5 mm/month) and $1.2 \cdot 10^{-2}$ mm/min (= 518 mm/month) for the assumed shear band thickness value of 200 mm. This threshold covers the measured velocities in the landslide, around 10 mm/month (= $2.3 \cdot 10^{-4}$ mm/min).

The shear strain rate-dependent law of friction angle introduced into the calculations has been inspired by laboratory results. However, one should be aware of the limitations of the available experimental data. Unfortunately, the increase in resistance is obtained for a range of speeds in the order of 1 mm/min (= 43200 mm/month), much higher than the speeds recorded in the field.

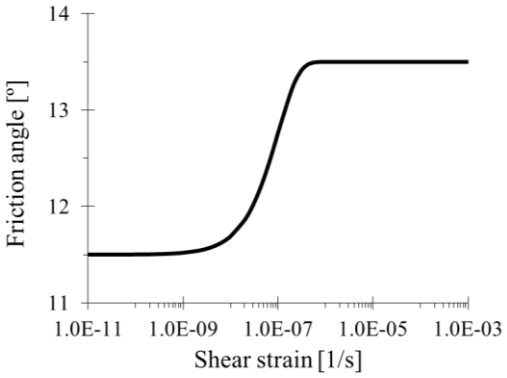

Figure 19. Shear strain-dependent friction angle considered in MPM calculation.

The results obtained by MPM calculation models are presented below. Different cases are distinguished to highlight the effect of the phenomena considered: thermal interaction and shear strain rate hardening (Table 2). Case 1 is the same as the case presented above, but with a shear band thickness of 200 mm instead of 5 mm. Case 2 includes, with respect to Case 1, the positive effect of the shear strain rate. In Case 3, the thermal interaction and shear strain rate effects are disabled in the code. Finally, in Case 4, shear strain rate hardening is included, but the possibility of thermal interaction is nullified.

Figure 21 shows the evolution of the movement in terms of displacement and velocity of a material point located in the landslide toe for Case 1. The maximum velocity achieved is reduced with respect to the MPM results previously obtained. This is explained because in Case 1 a thicker shear band is considered. The significant velocities and displacements calculated for Case 1 were not observed in the field.

Strain rate hardening leads to completely different results (Case 2) (Figure 21). The increased strength prevents the acceleration of the slide. Thermal effects, although activated in Case 2, do not lead to the accumulation of relevant excess pore pressures to induce a loss of clay shear strength. This can be seen in Figure 22, which shows the evolution of the excess pore pressure calculated at three points inside the clay layer for Cases 1 and 2. In Case 1, pressure increase of the order of MPa leads to a sharp drop in frictional resistance (Figure 22(a)). However, in Case 2, the pressure does not exceed a few kPa (Figure 22(b)), irrelevant values compared to the effective stresses applied along the sliding surface located at a depth of several tens of meters in the central part.

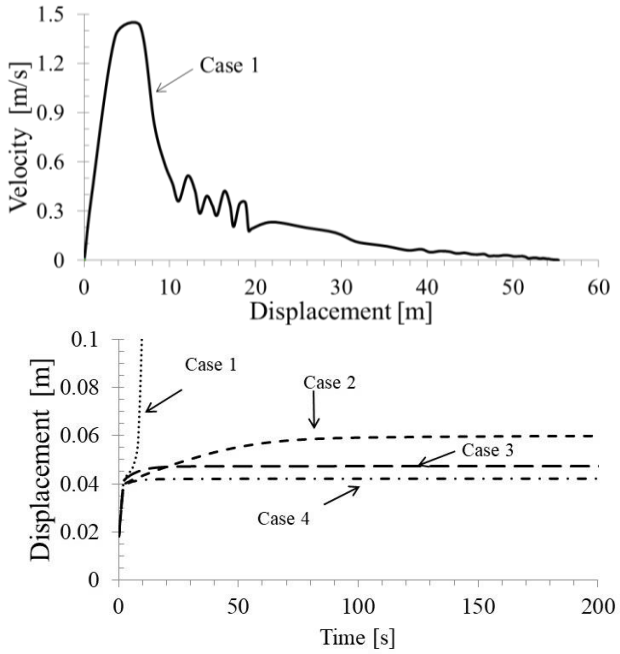

Figure 20. Velocity and displacement of the toe of the landslide, calculated by MPM for different cases (Alvarado et al. 2019).

Table 2. Cases analysed in MP and incorporated effects.

Case	THM	Strain rate hardening
Case 1	Yes	No
Case 2	Yes	Yes
Case 3	No	No
Case 4	No	Yes

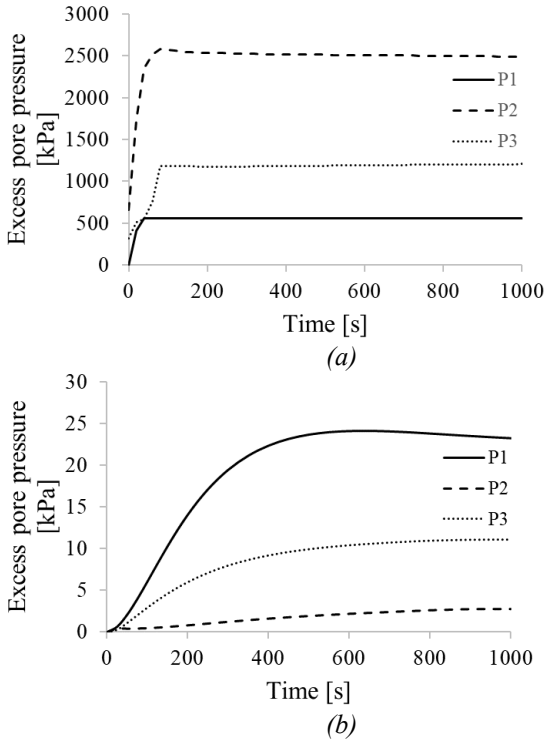

Figure 21. MPM calculated excess pore pressure in materials points P1, P2, and P3. (a) Case 1; (b) Case 2 (Alvarado et al. 2019).

According to these results, the shear strain rate hardening can prevent the acceleration of the landslide. The motion stops after a displacement of 6 cm. A new equilibrium position is restored. The thermal-hydro-mechanical effects are not developed in Case 2. The behavior observed in this case (Case 2) is similar to the behaviour obtained in Cases 3 and 4 in which heat generation by frictional work is disabled. As expected, the displacement is the smallest one in Case 4.

7 CONCLUSIONS

The paper describes the research work developed to estimate the risk of acceleration of a large landslide affected by reservoir level variations and, in particular, by a rapid drawdown scenario. The reported results cover almost 20 years. The landslide was reactivated twice in this period, in both cases as a consequence of a rapid drawdown (2006 and 2023). The working methodology departed from previous standard practice, largely based on the calculation of safety factors. The described approach followed two lines of thought: (a) the application of a calculation procedure (MPM) capable of dealing with large displacements, in a dynamic formulation of the problem; and (b) a review of phenomena controlling shear strength, namely strain rate effects and temperature.

A comprehensive set of shearing tests at controlled strain rate and temperature shows that friction increases when the shearing rate increases and decreases when temperature increases. The strain rate effect contributes to stabilizing (in the sense of avoiding the acceleration) a creeping landslide. Increasing temperature leads to a decrease in residual friction, an effect progressively more pronounced when soil plasticity increases.

Temperature changes have two different effects on soil strength: (a) an 'intrinsic' effect that may be conceptually understood as a modification of the soil skeleton, and (b) an induced effect, especially in saturated (clay) soils, because temperature dilates the water and, in impervious soils, it will induce pore water pressure increments, a reduction in effective stress, and a decrease of shear strength. This phenomenon and its effects on landslide mobility were explored in the previous contribution mentioned in the paper. Note that the two mentioned effects of temperature, intrinsic and water pressurization, go in the same direction, namely increasing the risk of acceleration.

The reported experimental findings go in parallel with the application of the results to modelling the expected behaviour of the landslide. The initial MPM

calculation procedure was upgraded to include the favourable effect of strain rate and the thermally-induced pore pater pressurization of the sliding surface material as a result of the frictional work and its dissipation in temperature increase.

The results of sensitivity analysis that combines the opposite effects of thermal pressurization and shearing rate show that the risk of a fast acceleration of the landslide is small provided its creeping velocity remains below a critical value. Further research is needed to incorporate strain rate, intrinsic temperature, and thermal pore water pressurization effect into the computational model.

Specificities of floating offshore wind turbines for risk and safety evaluation of anchoring systems

Spécificités des éoliennes flottantes pour l'évaluation du risque et de la sécurité de leurs systems d'ancrages

B. Cerfontaine*, S.M. Gourvenec, D.J. White

ABSTRACT: Floating offshore wind turbines (FWT) are still in their infancy and represent only 0.2% of currently installed commercial offshore wind capacity (193 MW of 65 GW) but will be critical to achieve net-zero objectives by 2050. The design of mooring systems and anchors for FWTs relies heavily on established Oil and Gas (O&G) practice, although governed by different design requirements. Reassessment and refinement of anchor system design methods and practices is necessary, recognising the different risks from FWT failure and the imperative for mass-production within the next 25 years. This paper identifies first the main differences between floating O&G and FWT and the associated geotechnical challenges and risks; then four key developments relevant to industry needs are selected and the solutions to reduce risk and uncertainty are then detailed: (i) Shared anchors; (ii) Farm-wide reliability assessment; (iii) Whole-life geotechnical design; and (iv) Screw pile installation. These examples show how physical, numerical and theoretical modelling can compensate for the current lack of FWT field experience to reduce design risk and raise project viability. Finally, technical project-wide risk is put into perspective by a comparison with the planet-wide risk resulting from delayed offshore wind farm installation.

RÉSUMÉ: Les éoliennes flottantes en mer (EFM) ne représentent que 0,2% de la capacité éolienne offshore commerciale disponible (193 MW sur 65 GW), mais seront essentielles pour atteindre les objectifs de zéro émission nette d'ici 2050. Une réévaluation et un raffinement des méthodes de conception des systèmes d'amarrage et des ancres pour les EFM, basée sur les pratiques et l'expérience de l'industrie pétrolière, sont nécessaires pour prendre en compte leurs spécificités (e.g. conséquences limitées d'une défaillance) et la nécessité de les produire en masse dans les 25 prochaines années. Cet article identifie les principales différences entre les technologies flottantes pétrolières et éoliennes, ainsi que les défis et les risques géotechniques associés. Quatre développements clés pertinents pour l'industrie sont ensuite sélectionnés, et les solutions pour réduire les risques et les incertitudes sont ensuite détaillées: (i) Ancres partagées; (ii) Évaluation de la fiabilité à l'échelle du parc; (iii) Conception géotechnique tout au long de la vie; et (iv) Installation de pieux vissés. Ces exemples montrent comment la modélisation physique, numérique et théorique peut compenser le manque d'expérience de terrain avec les EFM afin de réduire les risques de conception et d'accroître la viabilité des projets. Enfin, le risque technique à l'échelle du projet est mis en perspective avec le risque planétaire résultant du retard de l'installation de parcs éoliens offshore.

Keywords: Offshore geotechnics; anchoring; risk and reliability; physical modelling; numerical modelling.

1 INTRODUCTION

1.1 Decarbonisation and offshore wind

Weaning society off fossil energy sources is an urgent challenge to limit the impact of future climate change (IPCC, 2021). Among the multiple solutions that must be deployed, the development of offshore wind energy sources is key to achieve climate neutrality, i.e. 'net zero', across Europe and worldwide. The Global Offshore Wind Energy Compact (IRENA et al., 2021) sets a global ambition of 380 GW of offshore wind capacity by 2030 and 2000 GW by 2050 to meet the aims of the Paris Agreement.

Europe and the UK have led in offshore wind installation over the last twenty years, almost entirely in shallow waters where bottom-fixed foundations, such as monopiles, are cost-effective. However, Floating Wind Turbines (FWT) are needed to unlock more than 70% of the offshore wind potential in the European Economic Area, where floating structures are required in water deeper than 50 m (International Energy Agency, 2019). FWT will also unlock areas

further away from shore, where stronger and more consistent winds can be harnessed to generate more energy. The pace and scale of necessary offshore wind development, in conjunction with the development of new technologies introduces new geotechnical risk and safety challenges to be evaluated and overcome.

1.2 Floating offshore wind

Floating offshore wind is a nascent technology, comprising < 0.2% of total global offshore wind capacity at the close of 2023 (GWEC, 2022). Currently, only four commercial floating offshore wind farms, totalling 24 FWTs, have been installed – all across Europe, located in Scotland (Hywind Scotland – 30 MW, Kincardine 50MW), Norway (Hywind Tampen – 88MW) and Portugal (WindFloat Atlantic – 25MW). The high scenario 2050 projections for UK offshore wind alone involve between 5,000 and 20,000 FWTs, which must be built in the next two decades (Putuhena et al., 2023). By comparison, there are currently 25 floating Oil & Gas (O&G) production facilities operating in the North Sea and East Atlantic (Gourvenec et al., 2022) – a population that will soon be eclipsed by floating offshore wind platforms.

Multiple concepts of FWT platforms exist and are still under development (Figure 1), but all need at least three mooring lines to stabilise and maintain the platform in position. Catenary mooring, formed of heavy metal chains, are the currently favoured configuration, but taut and semi-taut mooring concepts are under development for FWTs.

Mooring lines are anchored to the seabed by a diverse range of anchor technologies (Cerfontaine et al., 2023b), many of which have been used for decades for O&G platforms. However, the scale and pace of FWT development will put the existing supply chain under considerable strain, from vessel availability (site investigation and installation) to lab testing facilities, raw materials and anchor manufacture capability. Therefore, a reassessment of anchor design and the associated risk, built on previous O&G experience, is necessary to reflect specificities of FWT and unlock their large-scale deployment.

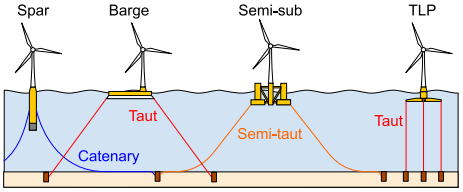

Figure 1. Different types of floating offshore wind platforms (Spar, Barge, Semi-submersible and Tension Leg Platform) and mooring systems (Catenary, Semi-taut and Taut). Various mooring systems are suitable for different platforms with exception of TLP. Drawing not to scale.

1.3 Risk and reliability evidence from O&G

The O&G industry has operated floating structures of comparable size to a floating wind turbine for around 50 years (Randolph et al., 2011; Ronalds, 2005). Ship-shaped, spar-shaped or semi-submersible floating O&G production systems are typically moored by 6-12 mooring lines designed for an operating life of 20-30 years, and have been used across a range of water depths to more than 3000 m (e.g. Moore et al., 2017).

The population of floating O&G platforms is relatively small, compared with the >3000 fixed platforms installed in the Gulf of Mexico, which provide a statistically-significant population to assess their reliability. However, recent pan-industry projects have examined the reliability of floating O&G platform moorings and anchors (Horte et al., 2017), based on failure data from operating facilities and from probabilistic analysis using existing design methods.

A mooring system reliability of 2×10^{-4}/annum is often targeted, although this is linked to the consequences of failure associated with the release of hydrocarbons (Goodwin et al., 2000). For the mooring lines, observed failures lead to an estimated average failure rate of 3×10^{-3}/annum (Ma et al., 2013). For the anchoring system, designed to a target 4×10^{-4}/annum (Gilbert et al., 2005), there are insufficient case studies of failures to develop a corresponding average observed failure rate. This suggests an inconsistency between design practice for moorings lines and anchors since the anchors are in practice more reliable than mooring lines, which represent the station-keeping 'weak link'.

Insights from these experiences can provide lessons learnt for FWT and have 3 key implications:

1. Current design practice for anchors is leading to a higher anchor reliability than the attached mooring line based on target reliabilities and practical observations.
2. Adjusted design approaches for FWT need to be calibrated against different target reliability, because failure consequences of FWT do no entail the same environmental and human risk.
3. 'Unrecognised' components of anchor capacity (such as consolidation-driven whole-life response, or inertial effects for very fast loading), which require quantification and adoption in design methods.

1.4 Reliability-based design for FWT

Reliability-based design optimisation of offshore renewable energy structures (Clark et al., 2018) can contribute to the reduction in design conservatism and cost, adapted to the specificities of FWT detailed in the next section. Probabilistic approaches for the design of

bottom-fixed offshore wind turbines have been introduced (Charlton et al., 2022; Shittu et al., 2021; Zhang et al., 2023), but fewer studies exist for FWT (Devin et al., 2021; Hallowell et al., 2018).

While thousands of bottom-fixed structures have already been installed and provide a statistically-significant population to assess existing design practice, the several tens of installed FWT provide only limited ability to assess their reliability (Kolios et al., 2009; Li et al., 2022) and identifying critical modes of failure. This is even more prevalent for anchors, although advances in anchoring design will be supported by a rapid growth in performance data as new FWTs are deployed. For example, at a nominal failure rate of 2×10^{-4}/annum, across a population of 10,000 FWTs, each with 3 mooring lines and anchors, 6 failures per year might be expected.

Geotechnical aspects are often neglected or oversimplified in reliability-based approaches, due to the inherently high geotechnical uncertainties, either epistemic (i.e., uncertainty on predictive models) or aleatoric (i.e., uncertainty on design variables). It is more complex to measure, quantify and predict soil properties and soil-foundation responses, than for human-made materials or structures.

The goal of this Paper is to review geotechnical challenges and risks induced by the specificities of FWT, and to demonstrate how physical, numerical and theoretical approaches can be leveraged to reduce both epistemic and aleatoric uncertainty, by identifying new modes of failure, by developing new predictive models or by enhancing soil characterisation.

2 SPECIFICITIES OF FLOATING OFFSHORE WIND

In the following section, the specific challenges and opportunities of FWT are detailed, and compared with current floating O&G (Figure 2) and bottom-fixed wind practice. The consequences for the anchor design and risk analysis are highlighted in each case.

2.1 Generalities

Consequence of failure: Failure of a FWT represents only a minimal risk to human life or the environment, as structures are uncrewed and do not lead to hydrocarbon release, unlike hydrocarbon drilling or production platforms. Without these hazards, a higher probability of failure (i.e. lower reliability) may be acceptable and need only be weighed against economic considerations.

How deep is deep? Bottom-fixed O&G have been built up to 535m water depth (Petronius Platform), while bottom-fixed wind becomes impractical and uneconomical beyond 60m water depth. This is due partly to technical consideration, e.g. the need to limit riser movement for O&G (Randolph et al., 2011), and partly to different business models, which makes gigantic fixed structures unaffordable for wind.

Development size: While O&G platforms are built across a limited number of isolated sites, tens of thousands of FWT will be built in farms of hundreds of structures, over hundreds or thousands of km^2.

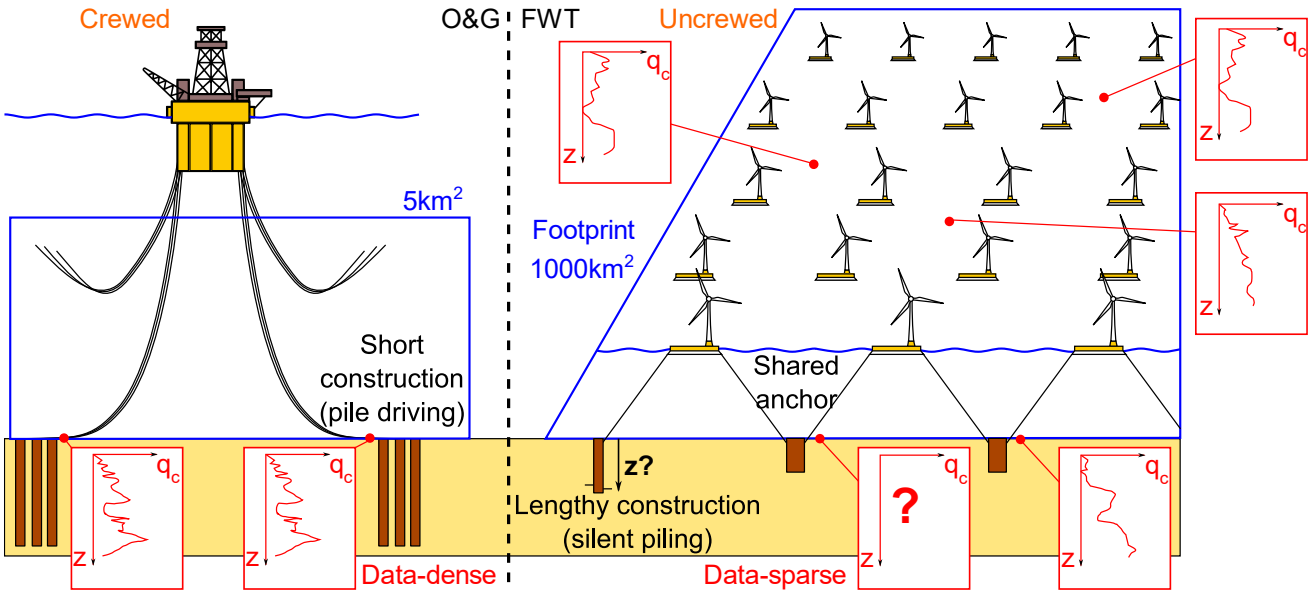

Figure 2. Comparison of floating Oil and Gas (O&G) and Floating Wind Turbine (FWT) farm.

The scale and pace of this deployment will put additional constraints on the supply chain. The industry has to move from the O&G template of bespoke anchor design and production to mass-production, which requires greater understanding of anchor and mooring performance and enhanced guidelines for engineers.

2.2 New technologies

Reducing size of mooring line systems: New technologies offer potential to increase efficiency of mooring lines and anchors. Efficiency in mooring lines can be achieved by (i) reducing the number of lines, at the expense of a lower system resilience (Fontana et al., 2018); and (ii) reducing the length of lines with taut or semi-taut synthetic mooring configurations. The latter solution improves platform compliance in relatively shallow water, reduces steel consumption and FWT footprint. However, those two solutions impose greater magnitude of loads and greater vertical uplift component of loads to anchors increasing the challenge of geotechnical anchor design (Huang et al., 2020), even if load-reduction devices can mitigate load increase (e.g. Festa et al., 2024).

Reducing number of anchors: The number of anchors required across a FWT farm can be reduced by linking multiple lines from different FWT to a common "shared" anchor (Fontana et al., 2018). This can reduce the number of anchors by up to 60%, but also introduces complexity of loading onto the anchor, which could be detrimental to its cyclic performance (Herduin, 2019) and induce strength degradation risk in the longer term.

Silent anchor installation: New environmental restrictions aim at reducing underwater noise, which makes pile driving either impossible or more expensive. This has led to development of new installation methods, such as vibro-piling (Kementzetzidis et al., 2022), or new anchor types, such as screw piles (Cerfontaine et al., 2022). Existing uncertainties due to the lack of field experience are being progressively reduced through field, laboratory and numerical studies.

2.3 New ground modelling approaches

Different sizes: The design of floating wind farms face greater uncertainties in ground conditions than O&G or even bottom-fixed wind farms, due to their scale and the need for at least 3 anchors per turbine. For example, the recently-installed Seagreen wind farm located offshore Scotland covers an area comparable to the city of Lisbon, extending from the Vasco de Gama bridge out to the Atlantic Ocean (Figure 3). By comparison, the footprint of a single O&G platform or development is a few 100s of m^2 to a few km^2 (Randolph et al., 2011).

Uncertainties in ground conditions increase risk in both predicting installation refusal and holding capacity of anchors. Ground conditions can vary considerably across a site and a thorough soil investigation at all potential anchor points, including along the installation path for drag anchors, may be too expensive and time consuming (Jenner et al., 2002).

Site investigation approach: Early assessments of the right strategy for site investigation across offshore wind farms advocated for greater geophysical-geotechnical data integration to estimate engineering parameters, to reduce uncertainties in ground models (Sauvin et al., 2019; Vardy et al., 2017) and to speed up the site investigation process. Developing anchor technologies and design methods resilient to uncertainties in ground conditions is a key pathway to reduce the risk.

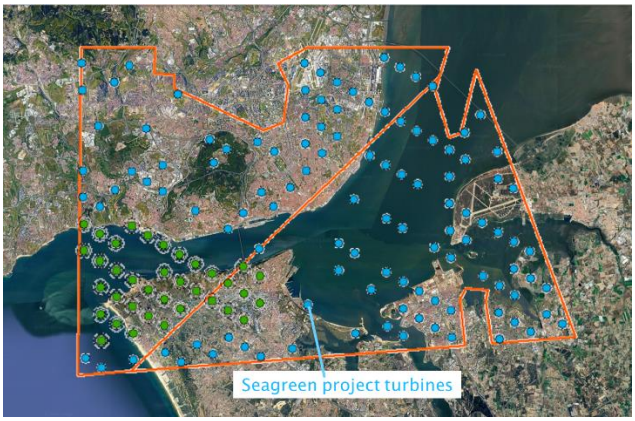

Figure 3. Footprint of a typical offshore wind farm (Seagreen).

Farm-wide assessment: Another consequence of the large population of structures in a wind farm is that the design must consider the likelihood of multiple failures. Although a design storm event may impose the same sea state throughout a farm, this will not exert the same maximum load on all turbines. Assessments of reliability therefore are more realistically performed considering the full farm-wide population.

2.4 New design philosophies

Traditional geotechnical design of anchors compares the maximum peak static load sustained by the anchor to its minimum drained or undrained capacity. Reduced soil strength due to cyclic loading from wave and wind effects on the soil properties, is typically considered by a quasi-static approach, and is accounted for by a degradation factor on the static properties (Jostad et al., 2014).

Whole-life design: A more realistic and less conservative design approach should account for the through-life variation in soil strength, by capturing the complex, physical mechanisms taking place into the soil, beyond the drained/undrained dichotomy. For instance, consolidation episodes (pore water pressure dissipation) in between storm events (pore water pressure accumulation) lead to soft clay densification and to a progressive increase of its undrained strength with time (Laham et al., 2021). This effect is encapsulated into a "whole-life geotechnical design" philosophy and has implications for anchor design, life extension and decommissioning (Gourvenec, 2022).

Rate effects: Loads induced by wind and wave action usually have a period ranging from 5s to 15s. At this loading rate, some anchor will experience partial drainage (Cerfontaine et al., 2023b), which can unlock significant temporary uplift resistance when compared to a purely drained loading, as demonstrated for plates (Chow et al., 2020) and suction caissons (Cerfontaine et al., 2016). In addition, FWT systems are dynamic in essence, and the highest loads often happen at a fast loading rate, e.g. due to mooring line snatch loading. Considering inertial effects into the ground can also unlock additional anchor resistance (Kwa et al., 2021).

3 KEY FOCUS TOPICS

To illustrate how the aforementioned challenges are being addressed, four key focus topics have been selected for more detailed discussion, as topics of high importance for the industry. These are (i) Shared anchors, (ii) Farm-wide design for reliability and risk, (iii) Whole-life geotechnical design approach, and (iv) Installation of screw piles. It is shown below how adequate physical, numerical and theoretical modelling can reveal new modes of failure and eventually reduce their associated design risk.

3.1 Shared anchors

Shared anchors can experience a reduction in peak lateral load between 30% and 50% (Fontana et al., 2018; Pillai et al., 2022) with respect to unidirectionally loaded anchors, as mooring lines are pulling in opposite directions, as shown in Figure 4. However, the angle of the resulting load to the horizontal direction is always greater than the angle of the mooring line itself, as horizontal components of each line oppose each other, but vertical components add up. This effect will be reinforced for taut mooring lines, which should become more common with the development of synthetic mooring systems but can also be true for catenary mooring lines if the anchor padeye is below ground level.

Pile type anchors are the most adapted to anchor sharing, due to their vertical symmetry (Cerfontaine et al., 2023), but can be vulnerable to cyclic inclined loading. Indeed, it was shown by Huang et al. (2020) that such loading had a positive impact on the lateral resistance, but a detrimental impact on the vertical resistance. The risk associated with shared anchors is increased by the lack of data and prior experience with this technology. A single commercial floating wind farm (Hywind Tampen) is secured by shared anchors and has been fully in operation since the summer 2023. Observations from real-life case studies should give more confidence in their use in the future.

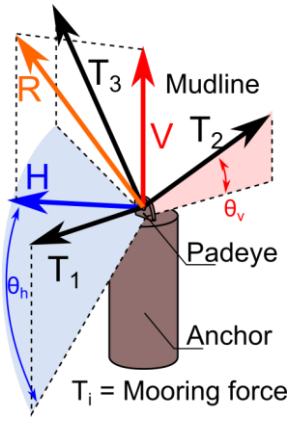

Figure 4. Simplified representation on the loads applied to a shared anchor by three mooring lines (Ti=1,2,3), vertical (V) and horizontal (H) components of the resulting load (R), θ_v is the inclination of any force to the horizontal direction, θ_h is the position of the resulting load in plane with respect to a reference direction.

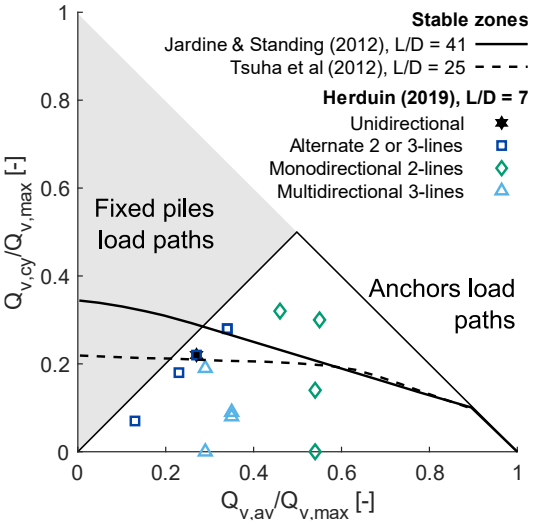

Figure 5. Stability diagrams for piles cyclically loaded axially, after (Herduin, 2019; Jardine et al., 2012; Tsuha et al., 2012). Dots indicate loading configurations that led to failure of the anchor, from Herduin (2019). Mooring lines were inclined of 40° to the horizontal. ($Q_{v,av}$, $Q_{v,cy}$, $Q_{v,mon}$) are the average and cyclic applied vertical loads, and monotonic vertical resistance of the pile.

The epistemic uncertainty associated with the behaviour of shared anchors can be reduced by careful experiments, such as centrifuge testing. The most comprehensive set of tests was undertaken by Herduin (2019) on relatively short and rigid piles for mooring lines inclined of 40° to the horizontal and embedded in sand. However, no framework for shared anchor design exists to date.

Results can be represented by using the stability diagram framework, which depicts stable combinations of purely vertical average and cyclic amplitude loads normalised by the maximum vertical resistance, e.g. the combinations that lead to a vertical displacement lower than 0.1D after 1000 cycles. For comparison, stable zones identified by previous researchers are depicted in Figure 5, (Jardine et al., 2012; Tsuha et al., 2012), for relatively long piles with L/D in the range 25-41.

Results from centrifuge tests of an anchor under shared loading conditions (Herduin 2019) were analysed in the stability diagram framework, by considering the projected vertical components of the applied load. Each test also had a horizontal component, which was either fixed in direction (unidirectional, $\theta_h = cst$), took different discrete directions (alternate, $\theta_h = \theta_{h1}$ or θ_{h2}), had a narrow range of variation (monodirectional $15° < \theta_h < 75°$) or was changing continuously in multiple directions (multidirectional $0° < \theta_h < 360°$). The most detrimental loading paths were those involving large variation in the horizontal load components, as they led to an unstable response for vertical loads much lower than previously identified for purely vertical loading. However, mooring lines in the research were inclined of 40° to the horizontal, representative of mooring systems for wave energy converters. More research is needed to cover lower mooring line angles ($\theta_v < 20°$), more representative of realistic conditions for floating wind turbines.

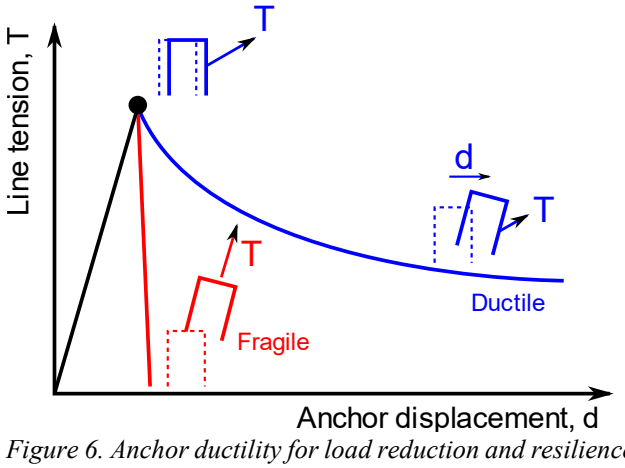

Figure 6. Anchor ductility for load reduction and resilience.

A higher reliability and resilience can be unlocked by using anchoring technologies with enhanced resilience and ductility, as shown in Figure 6. While vertical anchor resistance is often fragile and drops fast post-peak (e.g. for a pile), lateral resistance is more ductile and exhibits residual resistance. Therefore, a "failed" anchor laterally loaded can still mobilise some resistance, while the induced anchor movement can reduce the load applied by the mooring line (reduced pre-tension for taut mooring lines).

This resilience can be particularly critical for shared anchors, where the failure of one anchor or mooring line can lead to a cascading effect and progressive failure of more anchors, thus reducing the reliability of the system with respect to a non-shared configuration (Hallowell et al., 2018).

3.2 Farm-wide design for reliability and risk

The difference in failure consequences for FWT compared to O&G structures justifies a revisiting of load and resistance partial factors where these have been inherited from O&G design practice and should prompt wider adoption of probabilistic methods to meet a target reliability identify the optimum design approach from both a cost and safety perspective.

A benefit of assessing design reliability using a probabilistic approach is that uncertainties and variations can be readily incorporated allowing their effect on reliability to be quantified. For example, as well as the natural temporal variations in annual maximum storm intensity, it is also possible to allow for the uncertainty in designed capacity across the multiple structures in a wind farm, as well as temporal variations in geotechnical properties due to whole life effects (see Section 3.3).

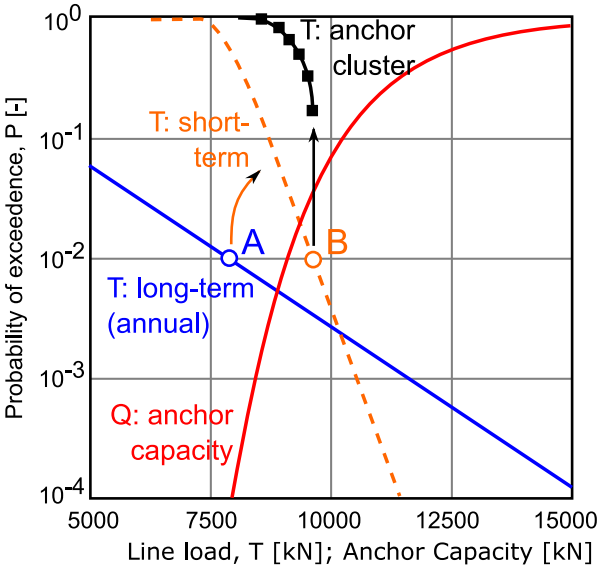

Figure 7. Wind farm-wide load (T) and resistance (Q) variations, based on analysis in Stanisic et al. (2019).

This farm-wide approach is illustrated here by considering a farm-wide analysis of mooring line loads and anchor resistances during a design event. Figure 7 illustrates the complexity of assessing farm-wide uncertainty in load and resistance for a wind farm comprising many turbines, each with multiple mooring lines and anchors. This example is based on the floating system reported by Stanisic et al. (2019), which analysed a floating barge structure stabilised by four clusters of 6 mooring lines and anchors.

Considering first the design loading actions, the characteristic annual maximum mooring line load – termed the most probable maximum, MPM, Stanisic et al. (2018) is assigned a distribution, usually developed from time domain simulations, which is referred to as the long term variability (blue solid curve in Figure 7). In this example, the distribution of the MPM mooring load for multiple floating units in the same sea state for which the long term MPM is T = 7800 kN, and has a 1% chance of annual exceedence (P = 0.01, point A).

If the same floating unit is exposed to a given sea state for different periods of time, or on different occasions, the actual maximum load will differ – this is referred to as short term variablity. The short term variability associated with a long-term (annual) maximum marked as A (P = 0.01) is shown as the orange dashed curve in Figure 7. Due to this short term variability, given the occurance of a sea state that causes A (P = 0.01), there is a 1% probability (P = 0.01) of T = 9600 kN. That is, among an array of 100 floating units, for a long term MPM of 7800 kN, one unit would be expected to see 9600 kN. This defines the variation in loads across an array of floating units when the farm is subjected to the same sea state. It therefore controls the potential for multiple failures.

In addition, there is a further variability to consider within the maximum loads among multiple anchors in the same cluster of mooring lines/anchors. In Figure 7, Point B shows an illustrative MPM anchor load from short and long term variablity. The neighbouring anchors in the 6-anchor cluster are exposed to loads that are lower, but within 11% of this maximum (as indicated by the black markers). This in-cluster variation in loading influences the potential for a single line failure to cascade into a full loss of station-keeping (Stanisic et al., 2019).

The geotechnical anchor capacity is always uncertain due to (i) uncertainty in the ground properties and (ii) uncertainty in the model used to assess the anchor capacity from the ground properties, and is represented by a fragility curve in reliability-based design. In Figure 7 an example fragility curve is shown (Q, red solid line in), which is based on the typical uncertainty in foundation capacity envelopes presented by Shen et al., (2023) using random fields analysis. Their analyses capture the variation in capacity for a foundation placed at random locations on ground with known mean and coefficient of variation in undrained shear strength.

Usually the long term and short term variabilities are combined in the assessment of a design load distribution (e.g. Stanisic et al. 2019). However, it is useful to decouple these effects for farm-wide design because this allows the farm-scale spatial variation in loading to be estimated. This can be achieved by sampling the design loads across the array using the short term variability superimposed on a single representative case from the long term variability.

When combined with the spatial variability in geotechnical capacity, this approach allows the probability of failure of multiple structures within a farm to be quantified, incorporating the correlation between the design loads and resistances across different turbines within a farm.

3.3 Whole-life geotechnical design approach

Accumulated soft soil strength degradation, i.e. softening, over the life of an offshore foundation or anchor is typically captured by so called ‘SN’ curves, to account for the reduced strength (S) due to undrained cyclic loading over a number of cycles (N) for the design life (Andersen, 2015). However, in reality, stormy weather periods (high load amplitude), typically winters, alternate with quiet weather periods (low load amplitude), during which accumulated pore water pressures, that have led to softening, dissipate, leading to a recovery and even enhancement of the soil strength in normally and lightly overconsolidated clays (Gourvenec, 2020, 2022; Kwa et al., 2023c). Therefore, considering only strength degradation in soft soils is often overly conservative.

The “whole-life” geotechnical design approach applied to soft soils explicitly includes the effect of consolidation periods throughout the life of an anchor or foundation. The approach is exemplified in Figure 8, which represents the theoretical state of a representative soil element close to an anchor over 3 years of operation, divided in 3 winters and 3 summers. Significant storms are assumed to occur during winter time, and lead to the accumulation of pore water pressure (u, in Figure 8b) and a reduction in the current undrained strength (s_u, in Figure 8b).

Each storm takes place in undrained conditions, hence at constant void ratio, depicted by a horizontal line in Figure 8a. Dissipation of pore water pressure and subsequent consolidation occur in between storm events and mostly during summer time, leading to a soil densification (reduction in e in Figure 8a).

The time necessary to fully dissipate pore water pressures depends on material, geometric properties and load applied (Kwa et al., 2023b), so the consolidation process is not complete after every summer, but the undrained strength still progressively increases beyond its initial value ($\Delta s_u > 0$ in Figure 8b). Similarly, the potential rise in s_u depends on the initial over-consolidation ratio of the soil (Gourvenec et al., 2014).

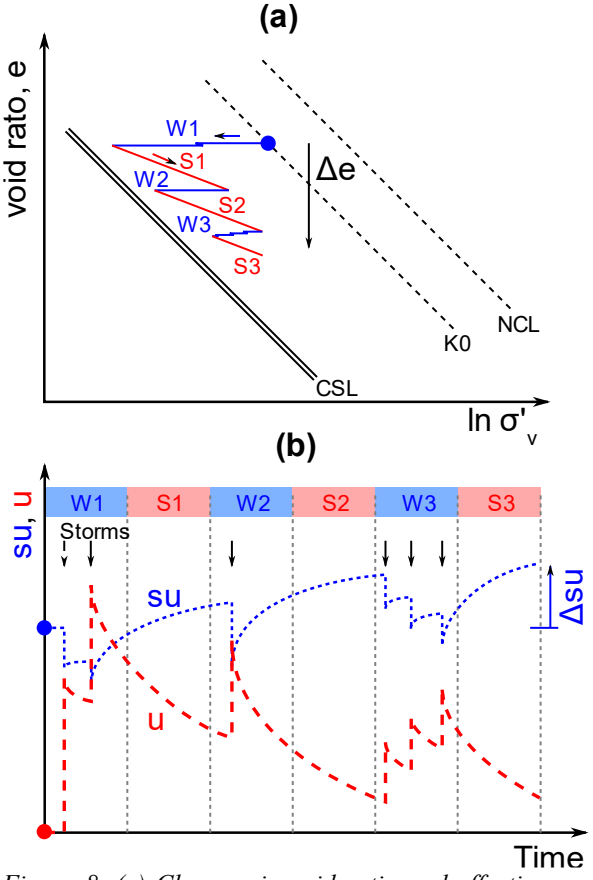

Figure 8. (a) Changes in void ratio and effective vertical stress of an element of soil close to an anchor due to episodes of cyclic loading during winters (W) and summer (S) periods. (b) Change in pore water pressure (u) and mobilizable undrained strength in the soil element (su) with time. Schematic representation of whole-life effect, not to scale. Based on (Laham et al., 2021).

The whole-life approach illustrates that the drained/undrained dichotomy is insufficient for modern design. It is possible to unlock additional anchor resistance, if a more complex physics is taken into account, and if probabilistic design is adopted, as the soil strength increase depends on its loading history. 10,000 3-year long histories representative of a wave energy converter attached to a plate anchor have been considered in combination with an anchor macro-element, capable of tracking average undrained strength degradation and pore water pressure dissipation (Kwa et al. 2023a). The anchor diameter necessary to limit the probability of failure to 10^{-3} was extrapolated from those results and ranges between 5 and 6m across different coefficients of consolidation (Figure 9). By comparison, a diameter of 7.5m would have been necessary if only undrained strength degradation had been considered, without any consolidation.

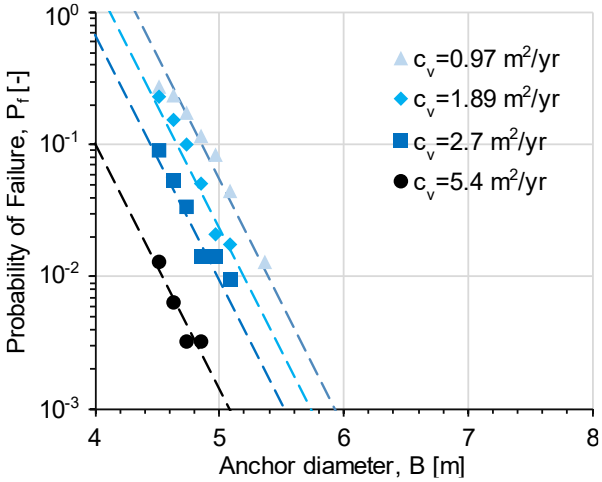

Figure 9. Probability of failures for a given anchor diameters as a function of the coefficient of consolidation (c_v), calculated based on 10,000 load history simulations, (Kwa et al., 2023).

A similar approach has been adopted coupling the anchor macro model with hydrodynamic mooring line analyses for floating wind, predicting minimum plate anchor areas of half that from traditional design by considering whole-life soil response and load reduction devices (Kwa et al., 2023a).

3.4 Installation of screw piles

Screw piles are composed of one or several helices attached to a steel shaft (see Figure 10), which are very efficient to sustain axial uplift loading and can be "silently" installed by applying axial force and torque at their head to screw them into the ground (Cerfontaine et al., 2023a). Screw piles have been widely used onshore, but their use offshore requires a significant upscaling in their dimensions and the development of bespoke installation tools (Cerfontaine et al., 2020).

Figure 10. Sketch of a screw pile (rotated 90°). D_h and p_h are the helix diameter and pitch and D_s is the shaft diameter.

So far, the risk of refusal during installation due to insufficient force and torque capabilities has impeded their adoption, despite a continuously growing interest. Indeed, the magnitude of the vertical reaction (crowd) force required to install large-scale screw piles according to onshore guidelines ranges from 10-20MN, which cannot be sustained by current installation vessels. Those guidelines require a pitch-matched installation, which means that the helix will advance axially by one helix pitch per rotation of the helix, and is often referred to as perfect installation.

Geotechnical centrifuge modelling and DEM simulations were used to prove the feasibility of large screw pile installation in sand (Cerfontaine et al., 2021) with limited reaction force, thus reducing the perceived installation risk. It was shown that a change in installation parameter (AR = advancement ratio) below the range allowed by the design guidelines ($0.8 \leq AR \leq 1.2$), could lead to a significant reduction in the measured crowd force (Figure 11). The AR is the ratio of the vertical displacement of the pile for each pile revolution. It is equal to 1 in pitch-matched conditions and lower than 1 during overflighting.

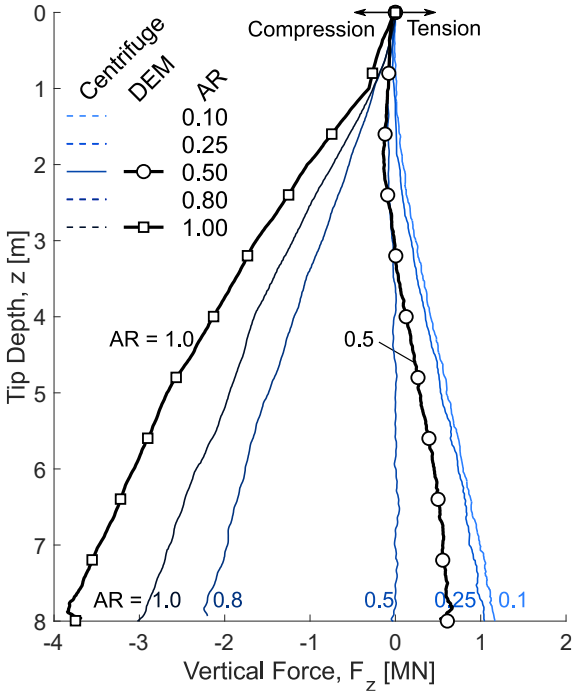

Figure 11. Vertical (crowd) force measured in centrifuge and DEM modelling of single-helix screw pile installation in a medium-dense sand at fixed ARs. AR = advancement ratio, = 1 for pitch-matched and <1 for overflighted piles. After Cerfontaine et al. (2021).

The overflighting physical mechanism was revealed by DEM simulations. During pile overflighting, the helix edge picks up some soil and forces it to move upwards, which is constrained by the existing soil acting as a non-linear spring. The resistance of the upper soil to this imposed movement creates a reaction force acting on the helix and oriented downwards. The lower the imposed AR, the more the resulting force is reduced, and a tensile force was eventually measured. This means that the pile pulls itself into the ground. It was also shown that the tensile resistance was enhanced by the installation, which created some preloading of the ground.

The installation in the field is not AR-controlled as per the experiment, but is undertaken at constant resulting force. The sum of reaction forces acting on the shaft, helix and tip is equal to the screw pile and installation tool weight. The AR of a given pile would then vary during installation to adapt to ground conditions, with a lower AR expected in a denser sand. A pile could then overcome undetected harder soil layers, which de-risks the installation, though some research on overflighting in clay and boulder effects still has to be undertaken. A significant torque still has to be provided during installation, which can reach tens of MNm, but was deemed less of an issue than the required reaction force by contractors.

The powerful combination of physical and numerical modelling, enabled a mechanism-based theoretical framework to be developed, leading to further pile geometry optimisation to further reduce installation requirements and reduce risk (Cerfontaine et al., 2022).

4 RISK – A WIDER PERSPECTIVE

4.1 Project-wide and planet-wide perspectives

It is useful to close this review of risk and safety evaluation of floating offshore wind by considering the wider risk perspective, including the impact of climate change (Figure 12).

So far, this paper has focused on a *project-wide* (or company-wide) perspective, which considers the risk and safety associated with company personnel and the general public who are exposed directly to hazards during the project operations. The environmental impact assessment, or other activities required to meet regulatory requirements, widen this scope by ensuring that nearby ecosystems remain safe from harm.

On the other hand, the perspective that an individual may have, or that society collectively has is called here a *planet-wide* perspective. It is not unique, as different social groups, nationalities and regional populations will have varying views on the relative importance of wider risks. However, there is an international consensus that global warming must be kept below 1.5° and we must develop offshore

renewable energy sources to reach carbon neutrality by 2050. Therefore, the *planet-wide* perspective on offshore renewables includes the climate-related risk from *not* developing a project – or delaying the construction and development process – as well as the risks associated with going ahead (Figure 12).

Any delay to the growth of offshore renewable energy (ORE) raises the risk of not reaching climate neutrality by 2050 and causes harm through the climate impacts from that prolonged fossil fuel use. This harm reaches the same individuals as the project-based risk field of view, but it also has the potential to affect the entire global population, due to the distributed impact of carbon emissions.

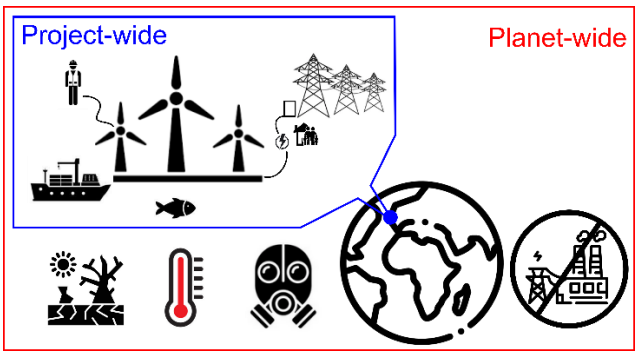

Figure 12. Risk views: project-wide vs planet-wide.

4.2 Human risk linked to carbon emissions

The consequences on human health (heat/cold, air pollution, loss of habitable areas…) of carbon emissions occur through the many cascading impacts outlined in the major national and international reports produced by organisations such as the Intergovernmental Panel on Climate Change (IPCC).

The simplest approach to quantify these *planet-wide* impacts so they can be weighed against *project-wide* risks, is to use the mortality cost of carbon. That is, the estimated cost, in human lives, per unit of additional carbon emissions. Bressler (2021) describe an analysis of more than 100 studies into the human risk from climate change across a wide range of impact. It is concluded that 4,400 tonnes of carbon emitted in 2020 is expected to cause one excess (i.e. additional) death during the period 2020-2100.

4.3 *Planet-wide* human risk linked to Offshore Renewable Energy

Using the metrics from Section 4.2, it is simple to assess the difference in human risk from the *project-wide* and *planet-wide* perspectives given in Figure 12. For instance, It was estimated by The Crown Estate (2022) that an additional 17Mt of CO_2 would have been produced in 2022 if the 45 TWh offshore wind energy had been produced by fossil fuel-based energy. Therefore, each TWh of UK offshore wind currently saves 86.5 lives globally over this century. The 2022 UK offshore wind production will have saved 3900 lives by 2100 and these outcomes will grow and accumulate with each future year of offshore wind production.

The same logic can be applied to a future offshore wind farm that is currently being proposed and designed. A 2 GW capacity floating wind farm operating at a typical capacity factor of 50% will produce 260 TWh of electricity over a 30-year operating life. Based on the fossil fuel abatement and carbon mortality rates above, this wind farm will save 22,700 lives that would otherwise be lost as excess deaths due to climate change impacts from fossil fuel burning.

This saving of $>10^4$ lives by mitigating climate risk far exceeds the human risk seen in the *project-wide* perspective. Figures for industrial injuries and deaths show that the wind, solar and nuclear industries are safer than coal and fossil fuel production, on a global average, although high regional variations are present. The wind power industry has a death rate estimated to be 0.04 deaths/TWh production (Ritchie, 2020), or 10 deaths over the operating life of a 2 GW wind farm.

These simplified comparisons illustrate the increasing importance of a holistic perspective on risk, and the need for carbon and risk literacy among practising engineers. A holistic perspective, understood and acknowledged by all stakeholders, will ensure that the planning and development of energy systems including ORE will maximise the societal benefits and minimise overall human risk, not only the risk to those directly involved in projects.

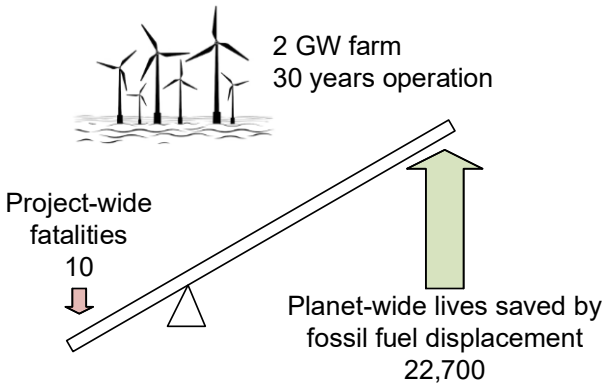

Figure 13. Human mortality from an offshore wind farm.

5 CONCLUSIONS

The design of floating offshore wind turbines (FWT) has so far been based on the experience accumulated by the Oil and Gas (O&G) industry. However, the scale and pace of floating offshore wind developments

to reach net-zero by 2050 is such that new design practices, technologies and guidelines must be developed to better suit FWT specificities and reduce their associated risk. By comparison with O&G, floating wind farms extend over a much greater area, are expected to be more than 100 times more numerous and their failure have a much lower impact.

Among various enhancement possibilities, two new design approaches (e.g. "whole-life" design or farm-scale reliability assessment) and two new technologies (e.g. shared anchors or "silently" installed screw piles) were discussed in this paper. The perceived risk associated to each innovation is magnified by the lack of field experience, which does not allow for a real-life estimation of their reliability. In each case, it is shown how physical, numerical and theoretical modelling can be combined to identify to new failure modes or provide sound evidence to reduce their associated risk.

Finally, it is argued that the *project-wide* risk related to those innovations should be put into perspective with the *planet-wide* risk associated with the delayed operation of new offshore wind units and prolonged operation of fossil-fuel energy systems. A holistic approach is necessary to encompass risk at different scales and maximise the benefits to society at wide.

ACKNOWLEDGEMENTS

This project received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement no. 753156. This research was partly funded by the EPSRC (SEAMLESS project) through the Supergen Flexible Fund award. This study forms part of the activities of the Royal Academy of Engineering Chair in Emerging Technologies Centre of Excellence for Intelligent & Resilient Ocean Engineering (IROE) at the University of Southampton. Susan Gourvenec is supported by the Royal Academy of Engineering through the Chairs in Emerging Technology scheme. David White is supported by the EPSRC Offshore Renewable Energy Supergen Hub (EPSRC grant EP/Y016297/1).

ABSTRACT: For the safe and cost-effective design and construction of geosynthetic-reinforced pile-supported (GRPS) embankments, four components are essential: (1) A well-validated design model that closely aligns with measurements, (2) A model factor that transforms the results of this design model into 'characteristic' values, ensuring that the results of the model are on the safe side in over 99.7% of the cases, (3) A set of partial factors, calibrated in such a way that the required safety level is achieved and (4) Experience and lessons learned. This paper guides the reader along these four components. The paper shows that the Concentric Arches model offers the closest match to measurements and explains the determination of the model factor and the set of partial factors, as conducted for the design guideline for GRPS embankments CUR226. The paper concludes with some examples of lessons learned from cases involving failures or near-failures.

RÉSUMÉ: Pour une conception et une construction sûres et économiques des remblais renforcés par géosynthétiques sur inclusions rigides (GRPS), quatre éléments sont essentiels: (1) un modèle de conception bien validé qui correspond étroitement aux mesures, (2) un facteur de modèle qui transforme les résultats du dimensionnement en valeurs "caractéristiques", garantissant que les résultats du modèle sont du côté de la sécurité dans plus de 99. 7% des cas, (3) un ensemble de facteurs partiels, calibrés de manière à atteindre le niveau de sécurité requis et (4) l'expérience et les enseignements tirés. Cette publication guide le lecteur le long de ces quatre composantes. Il montre que le modèle des arcs concentriques est celui qui correspond le mieux aux mesures et explique la détermination du facteur de modèle et de l'ensemble des facteurs partiels, comme cela a été fait pour le guide de conception des remblais du GRPS CUR226. L'article se termine par quelques exemples de leçons tirées de cas d'ouvrages défaillants ou proche de la rupture.

Keywords: State of the art; safety and risk analyses; geosynthetic-reinforced pile-supported embankments; lessons learned.

1 GEOSYNTHETIC-REINFORCED PILED EMBANKMENTS, RISKS AND SAFETY

The construction of geotechnical infrastructure often faces challenges associated with soft soils with low strength and high compressibility. Risks include bearing failure, excessive settlement, and slope instability. Furthermore, time and cost are also key elements in the design and construction phases.

To address these concerns and risks, geosynthetic - reinforced pile-supported (GRPS) are a practical and cost-effective solution. They find frequent application in supporting roads, highways, railways, storage tanks, industrial areas, and even buildings. GRPS embankments are quick to build, settlement-free and they cause no damage to nearby sensitive constructions due to horizontal soil deformations. Van Eekelen and Han (2020) published a state-of-the art review of the technology.

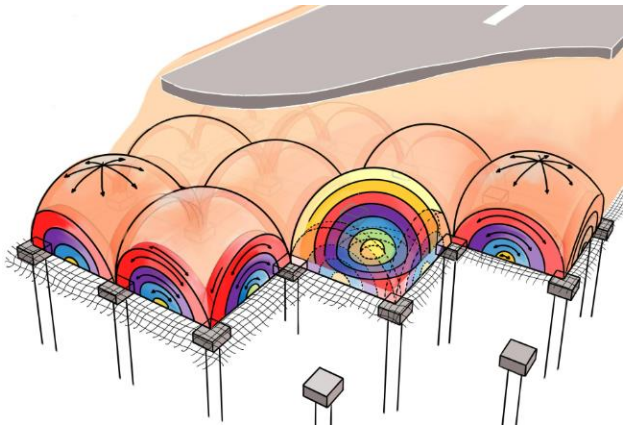

Figure 1. A geosynthetic-reinforced pile-supported embankment. Design methods employ soil arching, as depicted through the Concentric Arches (CA) model of van Eekelen et al. (2013 and 2015). The largest principal forces follow the curves of the hemispheres and 2D arches.

A GRPS embankment includes (Figure 1):

- Piles with or sometimes without pile caps.
- Basal reinforcement, in most cases a geosynthetic reinforcement (GR), positioned at the embankment's base.
- The embankment itself, with the bottom layer (the 'mattress') made of high-quality frictional material, like sand or crushed aggregate (crushed rock or crushed recycled construction material). In some regions, alternatives like high-quality laterite are used.

For the safe and cost-effective design and construction of GRPS embankments, four components are essential:

1. **A well-validated design model (Section 2):** An accurate model that precisely predicts the tensile strain in the GR. This means that the stress distribution, GR forces and deformations are also known.
2. **A model factor (Section 4):** The model factor transforms the calculated GR strain into a 'characteristic' value, ensuring that the calculated GR strain is on the safe side in more than 99% of the cases.
3. **Partial factors (Section 5):** A set of partial factors for load and material properties, to meet the required safety level. The Eurocode gives reliability indices β for this purpose.
4. **Experience and lessons learned (Section 6).**

This paper guides the reader through these four components.

2 VALIDATION OF DESIGN METHODS FOR GRPS EMBANKMENTS

The three main European design methods for GRPS embankments are:

The Concentric Arches (CA) model of van Eekelen et al., (2013, 2015, adopted in the Dutch CUR226, 2016, see Figure 1);

The model of Zaeske (2001), adopted in the German EBGEO, (2011);

The model of Hewlett and Randolph (1988) adopted in both the French ASIRI (2012) and the British Standard (BS8006, 2010).

These models calculate the GR tensile strain and the corresponding GR tensile force. During designing, it should be checked that the design value of the GR tensile force $T_{s;d}$ is smaller than the design value of the long-term GR tensile strength $T_{r;d}$.

We prefer a model that predicts measurements as accurately as possible. Safety will be addressed later and discussed in the next sections.

Figure 2 compares the three European models with 115 measurements from various sources. No model factor or partial factors were applied in these calculations. The figure shows that the Concentric Arches model on matches the measurements best. Although its standard deviation is smaller than for the other models, it remains considerable. Because of its best match with the measurements, the CA model was adopted in CUR226 (2016). Therefore, this paper focuses on the determination of the model factor for the CA model and the partial load- and material factors for CUR226.

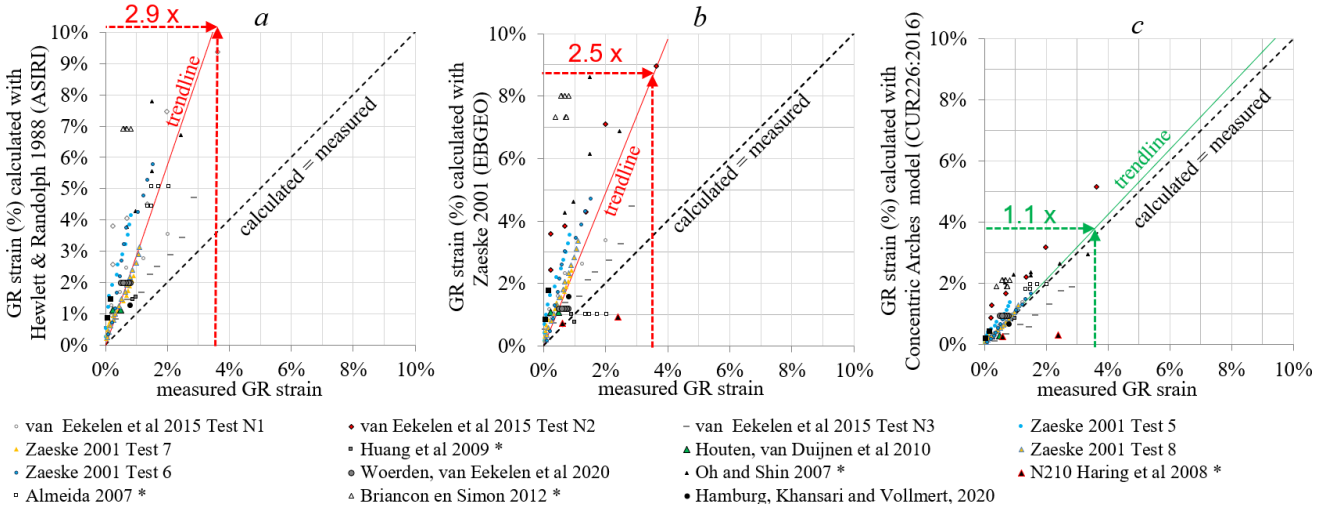

*Figure 2. Comparison of calculations and measurements in field projects and series of experiments. Figure modified after van Eekelen et al., 2015. Calculations were conducted using (a) The soil arching model of Hewlett and Randolph (1988) and uniform load distribution, as adopted in ASIRI (2012), with subsoil support**; (b) Zaeske's soil arching model (2001) and triangular load distribution, as adopted in EBGEO (2011); (c) The Concentric Arches (CA) model for the soil arching (van Eekelen et al., 2013, 2015) and inverse-triangular or uniform load distribution, depending on the subgrade reaction, as adopted in CUR226 (2016).*

***The soil arching model of Hewlett and Randolph (1988) and uniform load distribution was also adopted in BS8006 (2010), but BS88006 does not include subsoil support. This results in higher calculated values and less match with the measurements than in this graph (a).*

3 THE FOUR REFERENCE CASES FOR THE MONTE CARLO ANALYSES

Van Duijnen et al. (2015) presented Monte Carlo (MC) analyses conducted for calibrating both the model factor for the CA model, and the partial factors for CUR226 (2016). This section provides the starting points for these MC analyses. The results of the MC analyses will be presented in Section 4 (model factor) and Section 5 (partial factors).

3.1 Four cases: geometry and soil properties

Table 5 details the four cases that were examined in the MC analyses. Case 3 represents a typical Dutch piled embankment. Cases 1, 2 and 4 are exceptional situations, representing the extremes of the design method.

Table 1. Details of the four cases for the MC analyses.

	Case	1	2	3	4
Pile spacing s_x and s_y	(m)	3.25	1.75	2.25	2.25
Embankment height H	(m)	10	1.5	3.5	3.5
Width square pile cap a	(m)	1.25	0.40	0.75	0.75
Fill friction angle φ	(deg)	35	45	45	35
Surcharge traffic load p	(kN/m^2)	20	50	20	20

In all four cases, the fill unit weight was 19 kN/m^3. The piles, arranged in a square pattern, had square pile caps. The calculations were conducted for a subgrade reaction modulus k of 0 and 100 kN/m^3. Van Duijnen et al. (2015) demonstrated non-square pile arrangements ($s_x \neq s_y$) only slightly affected the resulting values of β.

3.2 Variation coefficients for geometry and embankment fill

Table 2 lists the variation coefficients applied in the calibration study for both geometry and fill and soil properties. These values were determined as follows:

The values for the pile centre-to-centre distance were determined by analysing the measured pile positions in a railway project in Houten in the Netherlands (van Duijnen et al., 2010).

Table 2. Variation coefficients V for soil properties and geometry in the calibration study.

Property	V
Centre-to-centre pile spacing s_x and s_y	0.10 m
Embankment height H	0.05 m
Fill friction angle φ	0.10
Unit weight of the fill γ	0.05
Subgrade reaction modulus k	0.25

The values for the fill and soil properties were default values for common soil types, as recommended in the national annex of EC7.

The student-T distribution for the 95% value was used for the probability distribution of fill and soil, as illustrated in Figure 3 and Figure 4.

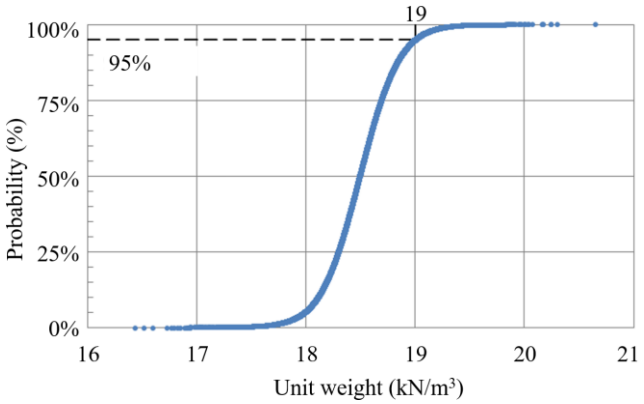

Figure 3. Relationship between the characteristic value of the unit weight γ of the fill (19 kN/m³) and the student-T distribution used in the MC analyses.

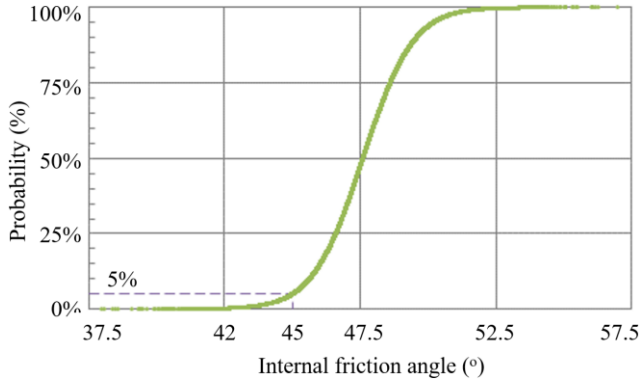

Figure 4. Relationship between the characteristic value of the fill friction angle (45°) and the student-T distribution used in the MC analyses.

3.3 Geosynthetic Reinforcement (GR) properties and variation coefficients

The tensile strength on the label of a GR role represents the short-term strength of the GR leaving the factory. Suppliers of geosynthetic reinforcement (GR) must test the short-term tensile strength for each production batch. Batches are approved only if all tensile strength results exceed the short-term strength indicated on the label.

The strength reduces in time, due to environmental factors, installation damage, and material behaviour (creep, relaxation). The long-term strength is the tensile strength at the end of the lifetime (100 years). This long-term strength was used for the present calibration study, although this resulted in an underestimation of the lifetime reliability.

In the MC analysis, the variation coefficient of 0.05 was applied for the tensile strength. This is a slightly conservative estimate, as the variations provided by the suppliers are somewhat lower.

The GR axial stiffness was chosen at 22 times the design value of the long-term tensile strength, with a variation coefficient of 0.1, resulting in the combinations of long-term tensile strenth and stiffness given in Figure 5. Note that this way to determine the GR axial stiffness differs from design practice, where it is calculated from the short-term strength, using isochronous curves (CUR226; 2016).

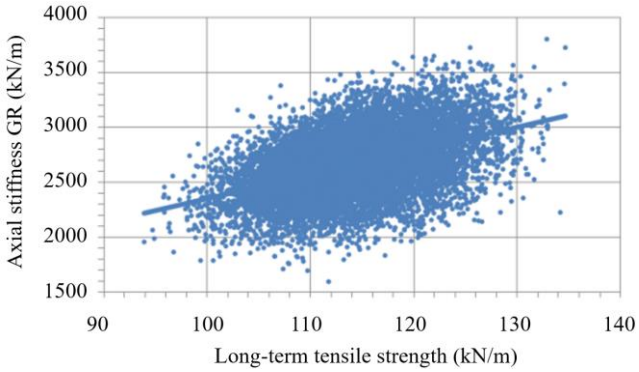

Figure 5. Scatter plot of the applied combinations of long-term tensile strength and axial stiffness of the GR in the MC analyses.

3.4 Surcharge traffic load: reduction of target reliability index β

Eurocode EC1-4 gives characteristic traffic loads. With their current insights, the authors would create a stochastic model for traffic load, with a variation coefficient of 0.14. This was not done at the time. Instead, the loads applied in the calibrations were nominal values from EC1-4. Since the uncertainty in the load had already been accounted for in these nominal values, the target reliability index β was reduced, as further detailed in Section 5.3.

4 CALIBRATION OF THE MODEL FACTOR

4.1 Statistical analysis

Figure 6 shows the ratio between the measured GR strains r_e (experimental value) and calculated GR strains r_t (theoretical value) for the 115 tests of Figure 2. For 22 of the 115 measurements, we find $r_e/r_t > 1.0$, meaning that the calculation under-predicted the measurement. So, these 22 were predictions on the unsafe side. The remaining 115 calculated values matched or exceeded the measured values ($r_e/r_t \leq 1.0$). NEN-EN 1990 (2011, Eurocode 0, annex D) recommends determining the model factor using the mean model error factor (correction factor) $b = r_e/r_t$, which is 0.727 with a variation coefficient about 0.702 for the 115 measurements considered. The distribution is assumed lognormal.

Table 3 lists the model error statistics for different subsets of data, with an increasing maximum subgrade reaction modulus. Soft soil areas are most relevant for

the safety analyses of GRPS embankments. Therefore, we focus on the 22 data sets with k ≤ 236 kN/m^3. Figure 7 shows these 22 data sets.

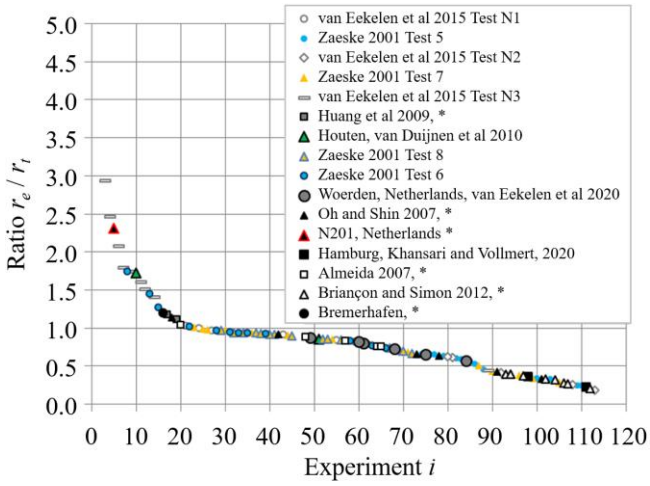

*Figure 6. Ratio of measured GR strain (r_e) and calculated GR strain (r_t), in descending order. Two results (values 5-8) are beyond the displayed scale. The symbol * in the legend refers to references given in Van Eekelen et al., 2015. The data in the figure is the same as in Figure 2c but presented differently.*

Table 3. Mean value model error factor $b = r_e/r_t$ and its variation coefficient, based on subsets of the 115 considered measurements, with different maximum subgrade reaction moduli k.

Subgrade reaction modulus k (kN/m^3)	Number of data sets N	Mean correction factor $b = r_e/r_t$	Coefficient of variation V
0	11	0.833	0.163
≤ 158	17	0.806	0.246
≤ 236	**22**	**0.775**	**0.306**
≤ 480	46	0.679	0.857
≤ 1200	54	0.700	0.868
≤ 3138	115	0.727	0.702

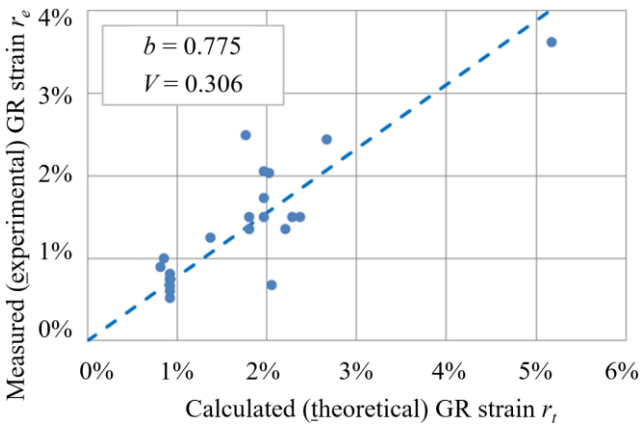

Figure 7. Measured versus calculated GR strain for the 22 data points of Figure 6 with subgrade reaction modulus k ≤ 236 kN/m^3.

4.2 Determination of the model factor

The model factor was determined for the SLS, as follows. First, the GR strain was calculated for case 3 in the SLS (no partial factors), using the Concentric Arches (CA) model. The resulting maximum GR strain was about 2.7%.

Then, an MC analysis was conducted. For each draw, the GR strain, calculated with the CA model, was multiplied with a factor b, whose value was determined using the above determined mean value for b of 0.775 and its variation coefficient of 0.306.

Figure 8 shows a detail of the result of the MC analysis of case 3. From this result, we determine the GR strain for the SLS target reliability index, which is 2.8, corresponding with the target probability of failure is 0.24% (≅ 5% · 5%, $P_f = \Phi(-2.8)$). The figure shows that the GR strain for 0.24% failure is about 3.60%.

The model factor was calculated with:

$$\gamma_{model} = \frac{\varepsilon(P_{f=0.24\%})}{\varepsilon_t} = \frac{3.6}{2.7} \approx 1.4 \qquad (1)$$

If the GR strain is calculated using the CA model in CUR226, using characteristic input values, and the calculated GR strain is multiplied with the model factor γ_{model}, then, the resulting calculated GR strain exceeds the measured GR strain in 100% - 0.24% = 99.76% of the cases. In other words, reality is worse than the calculation in 0.24% of the cases in the SLS (β = 2.8). Van Duijnen et al. (2015) conducted this analysis for all four cases, and further elaborated on this model factor determination.

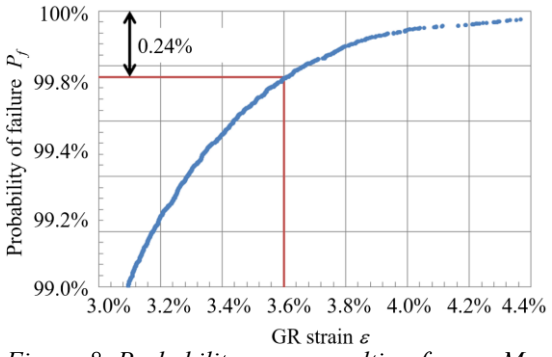

Figure 8. Probability curve resulting from a Monte Carlo analysis in SLS (all partial factors = 1.0) for case 3, to determine the model factor for the Concentric Arches model.

5 CALIBRATION OF THE PARTIAL FACTORS

5.1 Introduction

An advantage of using partial material- and load factors is that it allows for taking into account the influence of uncertainty in input parameters.

Van Duijnen et al. (2015) calibrated a set of partial material and load factors for CUR226 (2016). They demonstrated that using these factors ensures meeting the reliability indices β as required by NEN-EN 1990 (2011, Eurocode 0). This section summarizes the calibration of the partial factors for CUR226 (2016).

To the best of the knowledge of the authors, CUR226 (2016) was the first to base these factors for a GRPS embankment on statistical analyses, utilizing measurement data and probabilistic analyses.

5.2 Failure mechanisms and target probability of failure

Table 4 gives the target reliability index β, and the corresponding probability of failure P_f, for the three reliability classes (RC), as recommended by Eurocode 0 EN 1990 for new structures. In Section 5.3, we will adjust these values to account for the fully probabilistic treatment of resistance, while using the design values of the surcharge load (i.e. already including a safety margin). As previously mentioned, the authors would not adopt this approach today. Instead, they would create a stochastic model for traffic load and keep the same values of β.

Table 4. Required reliability classes (RC) and the corresponding probability of failure P_f for new GRPS embankments. From Eurocode 0 EN 1990.

Reliability index β / Prob. of failure during lifetime P_f		Service function (selection and experience of the authors)	Design service life (years)
RC 1	3.3 /4.8·10^{-4}	Roads, greenhouses	50
RC 2	3.8 / 7.2·10^{-5}	Abutments viaducts/bridges	50 to 100
RC 3	4.3 / 8.5·10^{-6}	Railways, important bridges	50 to 100

For CUR226, these target values were interpreted to apply to the entire structural system, comprising various failure mechanisms. Figure 9 shows a simplified fault tree, with the most relevant failure mechanisms for a GRPS embankment.

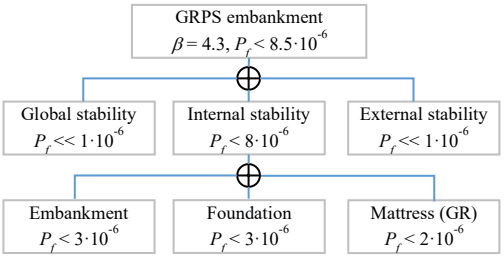

Figure 9. Fault tree with the most relevant failure mechanisms for a GRPS embankment (RC3).

The system's failure probability depends on how individual failure mechanisms interact. For example, if the reinforcement ruptures or the bearing capacity is lost, the entire system may fail. In such cases, the upper limit of the system failure probability is the sum of individual failure mechanisms (an OR-gate ⊕).

We assigned target probabilities of failure to individual failure mechanisms based on their role in the system, as defined in the fault tree (Schweckendiek et al., 2012). When designing, the assignment of target probabilities of failure is somewhat arbitrary, as long as the required system target reliability is achieved. It is economic to assign higher target values to failure mechanisms with costly mitigation. For CUR226 (2016), we defined fault trees for the three reliability classes and used them in the Monte Carlo (MC) analysis.

Notice that defining target reliability values based on system reliability considerations, as common for flood defences in the Netherlands (Schweckendiek et al., 2013), leads to stricter target values compared to the commonly used approach in the Eurocodes context, which is assigning the target reliability values stated in EN 1990 directly to individual failure modes and structural members. In that sense, the calibration presented here is slightly conservative.

5.3 Reduction target reliability index β to account for using design values of traffic load

Unfortunately, no appropriate statistical model was available for explicit uncertainty of the traffic load. As mentioned in Sections 3.4 and 5.2, EC1-4 gives characteristic nominal values of the traffic loads. Since the uncertainty in the load has already been accounted for in these nominal values, we reduced the target reliability index β using a standardized influence coefficient $\alpha_R = 0.8$ for the resistance as suggested by ISO 2394.

$$\beta_{T|s_d} = \Phi(-\alpha_R \beta_T) = \Phi(-0.8\beta_T) \qquad (2)$$

Table 5 presents the resulting target reliability indices in de ultimate limit state (ULS) for the three reliability classes with and without surcharge load.

Table 5. Target reliability index for the ULS.

	RC 1	RC 2	RC 3
Without surcharge load β_T [1]	3.5	4.0	4.6
Conditional target reliability index $\beta_{T\,|Sd}$ using the design/characteristic value of the surcharge load [2]	2.8	3.2	3.7

[1] *These values for ‚no traffic' are higher than the Eurocode values, this is the result of the fault space allocation in the fault tree of Figure 9.*
[2] *These values for ‚traffic' were determined from the fault tree of Figure 9 and then reduced using equation (2).*

5.4 Calibration of the Partial Factors

The calibration of the partial factors was done for the four reference cases of Section 3. The partial factors for RC1 and RC2 were determined iteratively, as shown in the flow chart in Figure 10.

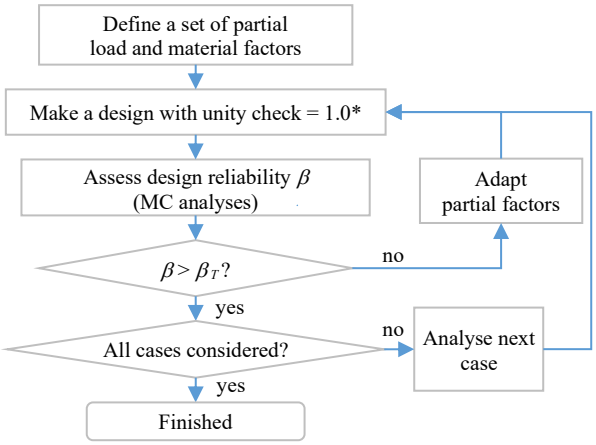

*Figure 10. Flow chart of the calibration workflow for the determination of a set of partial factors that ensures compliance with the target reliability for all four test cases. *Unity check = 1.0 means: design value of the GR tensile strength = design value of the tensile force.*

Back in 2015 however, it was unrealistic to conduct the eighty million calculations necessary for an MC analysis for RC3. Therefore, the approach of Figure 10 was altered, with the purpose of producing Figure 11. Instead of making a design with unity check = 1.0, MC analyses were conducted for various chosen values of tensile strength. Each MC analysis resulted in one dot in Figure 11. For case 3, all necessary calculations were conducted, while for the other cases, the lines were extrapolated as shown in Figure 11.

5.5 Results

Table 6 presents the partial factors that meet the required reliability for all cases without overdesigning the construction.

Table 6. Resulting partial material- and load factors and the model factor. These were adopted in CUR226 (2016).

	SLS	ULS		
Partial factor		**RC1**	**RC2**	**RC3**
Angle of internal friction	1.00	1.05	1.10	1.15
Unit weight	1.00	0.95	0.90	0.85
Tensile strength GR	1.00	1.30	1.35	1.45
Axial stiffness GR	1.00	1.00	1.00	1.00
Subgrade reaction modulus	1.00	1.30	1.30	1.30
Surcharge load	1.00	1.05	1.10	1.20
Model factor	1.40	1.40	1.40	1.40

Van Eekelen and Vollmert (2018) compared the safety levels achieved by the safety approaches of EBGEO (Lastfall 1) and CUR226 (RC1 and RC3, Table 6). They concluded that the safety level of EBGEO exceeds that of CUR226 in most cases. This suggests that there is room for optimization on the German side, as CUR226 meets the reliability requirements of Eurocode 0 EN 1990.

Figure 11 presents the calculated relation between the characteristic (95%) long-term tensile strength and the calculated reliability index β (the dots) for the four reference cases of Table 1. The figure was produced using the partial factors of RC3, as explained in the previous section.

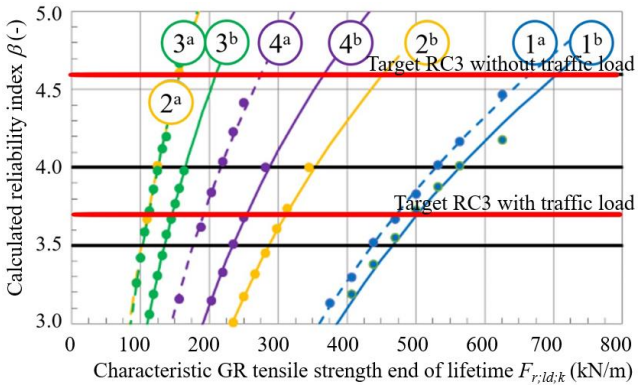

Figure 11. Reliability indices β, calculated using MC analyses with the RC3 partial factors of Table 6, for the four cases of Table 1, (a) without surcharge load and (b) with surcharge load. Subgrade reaction modulus k = 0 kN/m³.

The figure shows for example the following:

- For a thick embankment (case 1), the reliability index β is much less sensitive for the GR tensile strength than for thin embankments (case 2).
- Traffic loading affects the reliability of a thick embankment much less than for a thin embankment (1a and 1b of the thick embankment of case 1, are positioned close to each other, while there is a large distance between 2a and 2b, that belong to the thin embankment of case 2).
- The influence coefficient for the surcharge load ($\alpha_R = 0.8$) may be overestimated for GRPS embankments, reducing the target β_T too much

in certain cases. Let us consider case 1, without surcharge load (1a). For the target β_T without surcharge load for RC3 (4.6, see Table 5), Figure 11 gives an required tensile strength of about 650 kN/m. However, for the case with surcharge load (case 1b, and β_T=3.7, see Table 5), Figure 11 gives a required tensile strength of about 500 kN/m. It is evident that it is not logical to require less tensile strength for the case with surcharge load. So, the target reliability index β_T for the cases with surcharge load (denoted as $\beta_{T|s_d}$) should be considered as a lower limit. Therefore, the results in Figure 11 were assessed using engineering judgement, to finalize the final decisions on the partial factors for surcharge load.

Table 7 shows the calculated reliability indeces β for the four cases for the serviceability limit state (SLS) and the three reliability classes (RC1, RC2 and RC3) in the ultimate limit state (ULS). The table was made using the procedure of Figure 10.

The table illustrates that it was not possible to find a set of partial factors that exactly match the required reliability for all cases. The red-coloured italicised values in Table 7 are slightly below the target reliability index. The situation without surcharge load is not realistic for practical designs, and therefore these relatively low values were accepted.

Table 7. Calculated reliability index β.

	Without surcharge load				With surcharge load			
	SLS	**RC1**	**RC2**	**RC3[1]**	**SLS**	**RC1**	**RC2**	**RC3[1]**
Target β	2.8	3.5	4.0	4.6	2.8	2.8	3.2	3.7
Case								
1	2.82	3.56	4.05		2.81	3.58	4.02	
2	*2.67*	*3.31*	*3.67*		2.63	3.28	3.65	
3	2.78	3.50	3.98	4.75	2.76	3.49	3.95	4.31
4	*2.72*	*3.42*	*3.84*		2.70	3.38	3.80	

[1]*Due to time limitations, not all cases were analysed in RC3 because at least eighty million calculations were required for these RC3 cases.*

6 EXPERIENCE, CHALLENGES AND LESSONS LEARNED[1]

The preceding sections looked at the safety philosophy of GRPS embankments. Combining the well-validated CA model with the explained model factor and partial factors, makes it possible to create a safe and cost-effective design.

GRPS embankments are increasingly being constructed worldwide, and in most cases, perform excellently. They show minimal to no settlement and deformations. As a result, minimal maintenance is required, saving both costs and hindrance. However, occasionally, failures or near-failures occur before, during or after the construction of the GRPS embankment. Piles may lose their bearing capacity, and sometimes the GR ruptures or a significant instability occurs. This section addresses some of those cases of failures or near-failures. The purpose of this section is to be educational.

6.1 Case 1 – GR rupture

Case 1 in Figure 12 shows a road that was excavated after the rupture of a significant portion of the GR. In this case, the GR strength was found to be insufficient. The authors speculate that three factors may have contributed to this failure.

1. The embankment height was insufficient, measuring less than the 66% of the net diagonal spacing between the piles, which is the minimum embankment height required by CUR226. Van Eekelen and Han (2020) list minimum height requirements from various standards or guidelines. Most require more height than CUR226. In the past, insufficient embankment height has been identified as a contribution factor to failures. In the 1980s, attempts to reduce the load on the geosynthetic by decreasing the embankment height proved counterproductive. The soil arching became less efficient, and the structure became more susceptible to local loads. It was later understood that sufficient embankment height is crucial for proper soil arching development. Gue and Tan (2015), for example, described an example of 'punching through the embankment like 'mushrooms' and studied the case with numerical analyses. They attributed the mushroom problem to ineffective soil arching due to unsuitable fill and a large pile spacing relative to the fill height.

[1] *Chapter 6 provides narratives of failure cases on the brink of collapse or cases of failure. The authors have carefully crafter their words to investigate the causes of the damages, approaching the subject with both care and respect. It is acknowledged that the authors may nog possess full or accurate information about certain details, potentially leading ot incorrect conclusions. In an effort to shield the privacy of those involved, some details have been altered or stories combined. Furthermore, this section will never achieve completeness. The goal of this passage is to facilitate learning.*

Figure 12. Case 1. Ruptured GR in a GRPS embankment.

2. The GRPS embankment was designed using FEM only, raising the risk of overlooking numerical calculation errors and resulting in under-design. It is advisable to employ a well-validated analytical model in addition to the numerical model.
3. Finally, the geosynthetics were applied directly on top of piles caps with relatively sharp edges, despite attempts during construction to smoothen them. The geosynthetics were not protected with a protection layer of sand or for example a nonwoven between pile cap and reinforcement.

6.2 Case 2 – Pile rupture

In case 2, nearly all piles ruptured due to a change in the construction sequence.

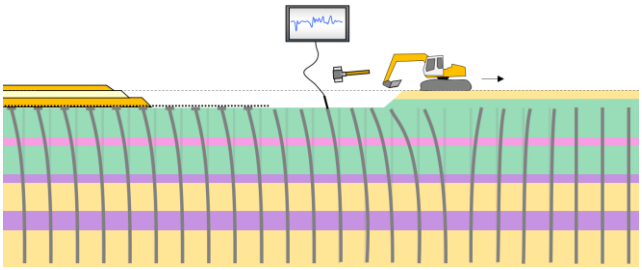

Figure 13. Case 2. The GRPS embankment was designed with the assumption that excavation would take place first. The deformations in the figures were based on FEM calculations but exaggerated.

A highway had to be constructed on a thick layer of peat and organic clay. The piles had to be installed up to 2.0 m below ground level. The top two meters, were excavated to install the pile caps and the reinforced mattress.

The designers had anticipated installing the piles after excavation. Expecting limited bending moments, the piles were lightly reinforced and prestressed. This provided a significant cost saving due to the large quantity of piles.

However, the decision was made to change the construction sequence. The piles were first driven up to 2 m below the ground surface, followed by excavation using a relatively lightweight excavator.

The piles found themselves between the excavated area on one side and the yet-to-be-excavated soil with the excavator on the other side. As the excavator continued working, all the piles bent first in one direction and then in the other direction, breaking one by one, as shown in Figure 13.

It is particularly bitter that, in this case, all piles underwent acoustic testing to assess their condition. However, the cracks visible in the measurement charts went unnoticed until after the completion of the full embankment.

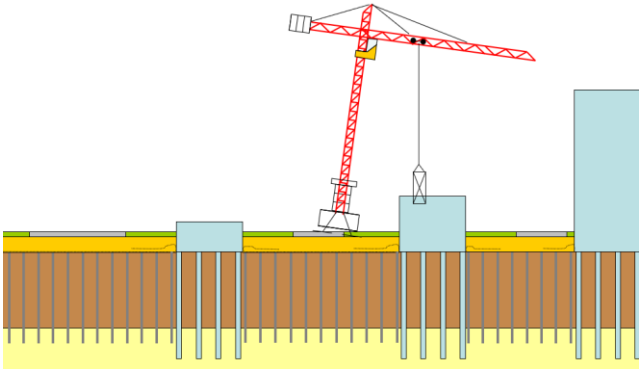

Figure 14. Case 3. Residential area. The GRPS embankment was not designed for the crane loading during the apartment construction.

6.3 Case 3 - Overloading

In case 3, a residential area was built, with the surrounding infrastructure, such as roads and green spaces, founded on GRPS embankments. The GRPS embankments were constructed first, followed by the construction of the apartments. Heavy cranes were employed for apartment construction. Unfortunately, during the design phase, the anticipated crane loads were underestimated, resulting in severe damage to the GRPS embankments.

6.4 Cases 4 and 5 – Loss of subsoil support

In the 2010s, some failures were related to the use of a design method that did not anticipate the decrease in and loss of subsoil support. Cases 4 and 5 are examples that experienced excessive post-construction deformations due to this reason. In both cases, the columns or piles stayed intact.

Case 4 (Camp and Siegel, 2006), located in coastal South Carolina, involved a road on a GRPS embankment, constructed on reclaimed marshland with 6.5 m of svery soft highly plastic clay. Shortly after completion, the GRPS embankment developed an irregular surface with humps at the column locations and depressions in the areas between the

column locations. The differential deformation was so significant that the road had to be closed almost immediately after completion.

In this case, the design method implicitly assumed a lifelong subsoil support, resulting in the use of three layers of PP geogrid with a total tensile strenth of 20 kN/m, significantly less than the current European guidelines require. Subsoil settlement caused overloading of the GR, leading to further loading of the subsoil and excessive deformations.

Additionally, the low embankment height (1.1 m) compared to the pile spacing (centre-to-centre 2.5 m) contributed to the issues.

Case 5 was a residential area in Europe, founded on a GRPS embankment, installed on a 10 m soft soil layer. Again, subsoil settlement overloaded the GR, causing rupture and transferring most of the load to the soft subsoil, resulting in substantial differential settlement. The area experienced widespread cracking and deformation of the buildings and other structures soon after construction. As a consequence, many of the houses became uninhabitable and substantial portions of the site had to be demolished.

Cases 4 and 5 had been designed in using the same design method that does not anticipate the decrease in and loss of subsoil support. Nowadays, most well-validated design methods can include the consequences of settling subsoil.

6.5 Cases 6 and 7 – Adjacent fills

The site of case 6 site faced poor accessibility due to soft soil. To enhance accessibility, a geotextile was installed before the construction phase began. The geotextile extended beyond the embankment and was left in place.

Later, a heap of fill was placed adjacent to the embankment, causing significant horizontal ground deformation. This resulted in the displacement of the edge pile row from beneath the mattress. Case 7 also suffered from damage to an adjacent fill, except that there was no geotextile underneath.

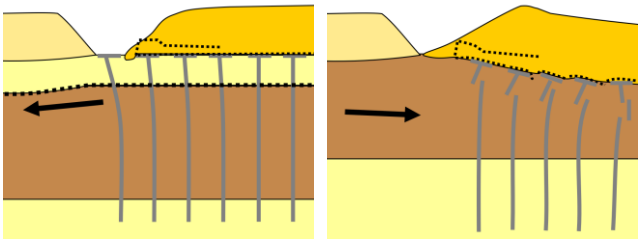

Figure 15. Cases 6 and 7. Fill adjacent to GRPS embankment. Left: with a left-in-place geotextile underneath. Right: without.

6.6 Recommendations

The following recommendations were based on the above listed, and other personal experiences:

- Use one widely accepted design guideline or standard that uses a well-validated analytical method to design the GR. Do not combine partial factors from different guidelines.
- In addition to the analytical design method, use numerical analyses to determine the pile bending moments and check for excessive deformations or instability. Switch on secondary effects.
- Be sure to include the various construction and loading phases in the design calculations. Stick to the plan or make additional calculations.
- Be sure to account for future reduction in subsoil support, which often occurs due to consolidation under the weight of the working platform, erosion, or groundwater changes.
- Be sure to meet boundary conditions, like the minimum embankment height, given by the design guidelines. Keep within the geometries for which the calculation rules were validated.
- Be sure to calculate with correct values for the long-term GR characteristic strength, including strength decreases due to factors such as installation damage, UV light exposure, the environmental conditions it encounters, and time-dependent behaviour, such as creep or relaxation. In the Netherlands, a Code for Design Parameters of Geosynthetic Reinforcement (2023) has recently been published for this purpose, encompassing all existing requirements for determining the design parameters of geosynthetic reinforcement, including end-of-lifetime tensile strength and GR stiffness. Additionally, the Code clarifies requirements where necessary.
- Never hesitate to seek a review of your design.

State-of-the-art Report

Tremie Concrete for special geotechnical works – a story about performance and sustainability

Tremie Concrete pour travaux géotechniques spéciaux – une histoire de performance et de durabilité

K. Beckhaus*
BAUER Spezialtiefbau GmbH, Schrobenhausen, Germany
**Karsten.Beckhaus@bauer.de*

ABSTRACT: Five decades ago, when the first standards on concrete were written, concrete technology was relatively simple. Modern "high-performance" concrete is far more complex. Specifying the essential criteria for successful placement of concrete in submerged conditions using tremies at depths in excess of 100 m is a major challenge. A joint task group of EFFC and DFI (European Federation of Foundation Contractors and Deep Foundations Institute) has brought together a broad church of industry experts to find a common understanding on this topic. The group is presently updating the 2nd edition of the EFFC/DFI Guide to Tremie Guide for Deep Foundations, and edition 3 will be released by the end of 2024. It will also highlight the need for sustainability, to which the Tremie Guide contributes with its performance-based concept to design concrete, giving all options to materialize a lower-carbon concrete without diminishing quality aspects. Future approaches may be founded on lessons learned from numerical modelling which is a key to better understanding the complex interactions governing concrete flow mechanisms. The task group continues its work to validate simulations to justify new requirements, e.g., a reduction in workability retention for long pours. It is hoped that the recommendations in the Tremie Guide will become contractually binding norms to make them broadly applied in practice, resulting in a higher quality reliability in quality and optimised sustainability.

RÉSUMÉ: Lorsqu'il y a plus de 50 ans les premières normes sur le béton et le béton trempé ont été rédigées, la technologie du béton était assez simple. Le béton moderne est beaucoup plus complexe, ce qui permettrait de le qualifier également de béton « à hautes performances ». Préciser les critères nécessaires à une mise en place réussie du béton en conditions immergées dans les fondations actuelles, qui peuvent dépasser des profondeurs de 100 m, est un défi. Un groupe de travail conjoint de l'EFFC et de la DFI (Fédération européenne des entrepreneurs en fondations et Deep Foundation Institute) a réuni des experts du secteur mais également des consultants pour trouver une compréhension commune sur des sujets connexes. Le groupe met actuellement à jour la 2e édition du Guide to Tremie Guide for Deep Foundations, et l'édition 3 sera publiée d'ici fin 2024. Elle mettra également en lumière le besoin de durabilité, auquel le Guide Tremie contribue avec son concept basé sur la performance. Concevoir du béton, en offrant toutes les options pour matérialiser un béton bas carbone sans diminuer les aspects qualitatifs. Les approches futures pourraient s'appuyer sur les enseignements tirés de la modélisation numérique, clé pour mieux comprendre les interactions complexes régissant les mécanismes d'écoulement concrets. Le groupe de travail poursuit ses travaux pour valider les simulations afin de justifier de nouvelles exigences, par ex. concernant une rétention d'ouvrabilité réduite pour de longues heures de mise en place du béton. À terme, les réglementations révisées sur le béton seront fusionnées dans des normes pertinentes et contractuellement contraignantes pour les rendre largement appliquées dans la pratique, pour une plus grande fiabilité de qualité et pour optimiser la durabilité de la construction.

Keywords: Fresh concrete; performance; quality; sustainability.

1 HISTORY

The very first meeting of the EFFC/DFI Concrete Task Group (CTG) took place on 23rd of January 2014 in Amsterdam. It was initially set up by the European Federation of Foundation Contractors (EFFC) that had discussed, in their annual general meeting in October 2013, the quality of geotechnical works in the light of concrete quality. It was decided that a broad group of experts should discuss the lack of suitable test methods and sufficient testing of relevant properties of fresh concrete for placement in deep foundations and

provide a state-of-the-art report. The CTG, presently comprising 15 full members, has been working in a very trustful and target-oriented atmosphere for more than 10 years. With a constant overall target to reduce defects in deep foundations, see Figure 1, caused directly by inadequate workability or stability of concrete, or indirectly by a lack of consideration of related parameters effecting the flow of concrete and/or proper filling of the excavation.

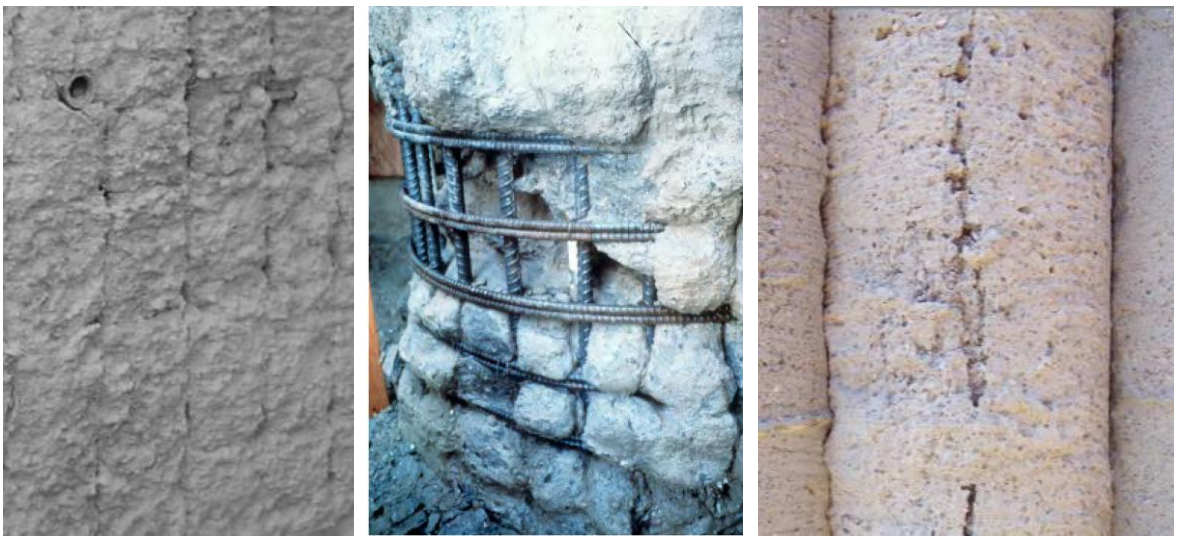

Figure1. Imperfections in deep foundations.

The CTG decided from the very start to invite consultants to join the group to bring their technical views on these complex and exclusively quality-related topics. A group of corresponding members, consulting the group and reviewing status papers and drafts, was also established as well as a group of academics to give scientific advice.

The major focus has always been on the specification and testing of fresh concrete as the core of a "Tremie Guide". It was intended to use the Australian tremie handbook [CIA Z17, 2012] as a start-off, which was created in the same sense to give updated recommendations better suited for modern tremie concrete. Given the fact that the CTG chairman was also a member of the Australian working group it was guaranteed that all relevant information beyond the published recommended practice was considered in its entirety.

The basic scope and structure of the "EFFC/DFI Guide to Tremie Concrete for Deep Foundations" (Tremie Guide) set out in the 1st Edition (2016) was repeated in the 2nd Edition (2018) and will remain the same for the 3rd edition. To the core of the fresh concrete specification and testing, other topics were added including design, execution, and the need or benefit of monitoring the quality by non-destructive test method. The 1st edition also contained recommendations on support fluids. The task of supporting open boreholes and trenches using support fluids is a complex subject which cannot be adequately covered in a simple sub-section. A separate support fluid task group was therefore established, and a guide was issued in 2019. This group is currently working on the 2nd edition, implementing lessons learned from a field research study that is ongoing. That same approach had been applied for the evolution of the Tremie Guide.

Based on a comprehensive study of international standards and literature the CTG acknowledged the demand for a detailed test program for fresh concrete properties. By that time, colleagues representing the Deep Foundation Institute from America joined the Group. Meetings attended by up to 20 full members took place in European cities, as well as the USA.

A big step forward occurred when approximately €150,000 was received from industry sponsors. The money was used to carry out an extensive test program in the laboratory and in the field, in Europe and the USA. This was contributed to by specialist contractors opening their construction sites for a detailed investigation of the concrete used. Researchers from the Technical University in Munich and from the Missouri University of Science and Technology collected data for multiple concrete mixes, reflecting also their technical boundary conditions of application, for later interpretation and assessment of results, with the main findings merged into the 2nd Edition 2 of the Tremie Guide.

Finally, it was already decided for the preparation of the 2nd Edition to add a chapter on Numerical Modelling Methods for backing up the Group's understanding of tremie flow and cross-checking

reasonable conclusions regarding flow mechanisms within an excavation during casting. A sub-group with mainly academics was established and worked separately on what computer programs can and cannot prove without exceeding their limited capabilities to deliver reliable simulations.

After the 2nd Edition had been released – again for free download from the homepages at effc.org and dfi.org – the Group was silent for a period of 4 years until it met again during the DFI/EFFC Conference on Deep Foundations and Ground Improvement in Berlin in May 2022. It was decided to produce a 3rd Edition, in order to: -

- emphasise the need to reduce greenhouse gas emissions,
- strengthen the recommendations regarding acceptance criteria with respect to testing,
- add new findings from numerical modelling,
- update individual sections where users had asked for clarifications.

2 THE TREMIE GUIDE EDITION 3

As the name suggests, the Guide to Tremie Concrete for Deep Foundations is limited to the application of the "tremie method" to install cast-in-situ elements like bored piles, diaphragm walls or elements, for which a typical set-up is shown in Figure 2. The Guide defines the tremie method as follows:

„*Concrete pouring method by use of a tremie pipe in order to prevent the concrete from segregation or contamination by the fluid inside the excavation, where the tremie pipe – after the initial placement – remains immersed in previously poured, workable concrete until the completion of the concreting process*".

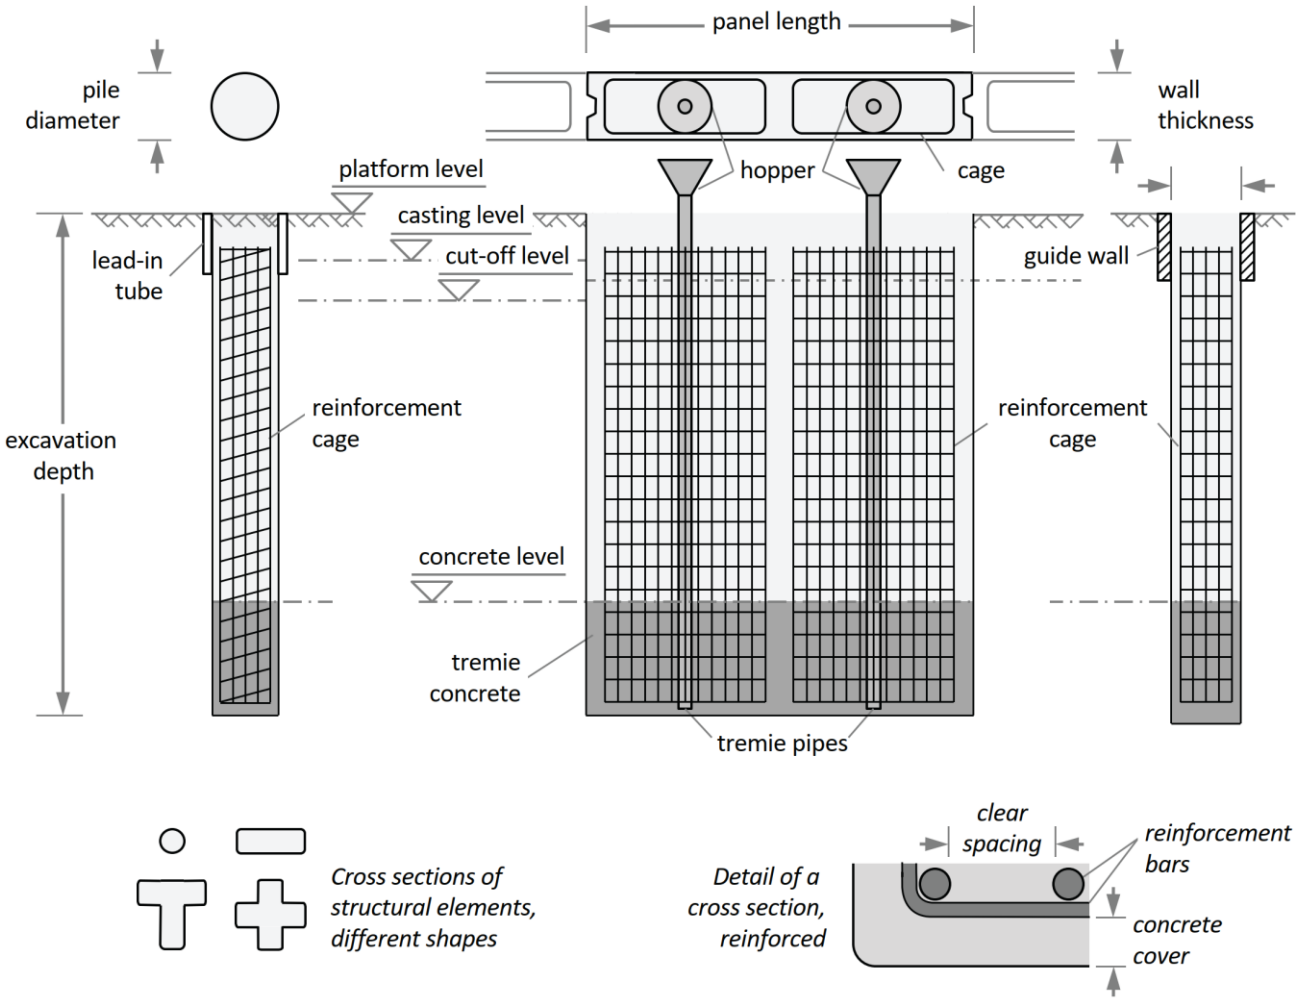

Figure 2. Examples of deep foundations.

Anyone working in the deep foundations sector will know that concrete and additive technology continually advances and becomes ever more complex. When normative regulations were established decades ago, a blend of Portland cement and aggregates mixed with enough, but not too much water framed the boundaries of concrete technology. Bored Piles or Diaphragm Walls had not been 100 m

deep, or even deeper, at that time. Concrete technology advanced drastically at the same time, as the deep foundation industry expanded the boundaries. However, test methods have not evolved at the same rate. That means in turn, that a single test for the concrete‘s consistency, like a slump test, is no longer sufficient to test fresh concrete for geotechnical works with much higher requirements on workability than decades ago.

The water to cement ratio as one of the main factors to control strength and other physical properties after hardening, remains the prevailing parameter in concrete mix design. In order to meet execution demands, both sufficient workability and stability of the fresh concrete are the essential pre-condition to ensure a complete filling, and a full integrity of the completed works. The focus of the Tremie Guide!

2.1 General

The background has been presented by the history of the Concrete Task Group founded to reduce defects in deep foundations.

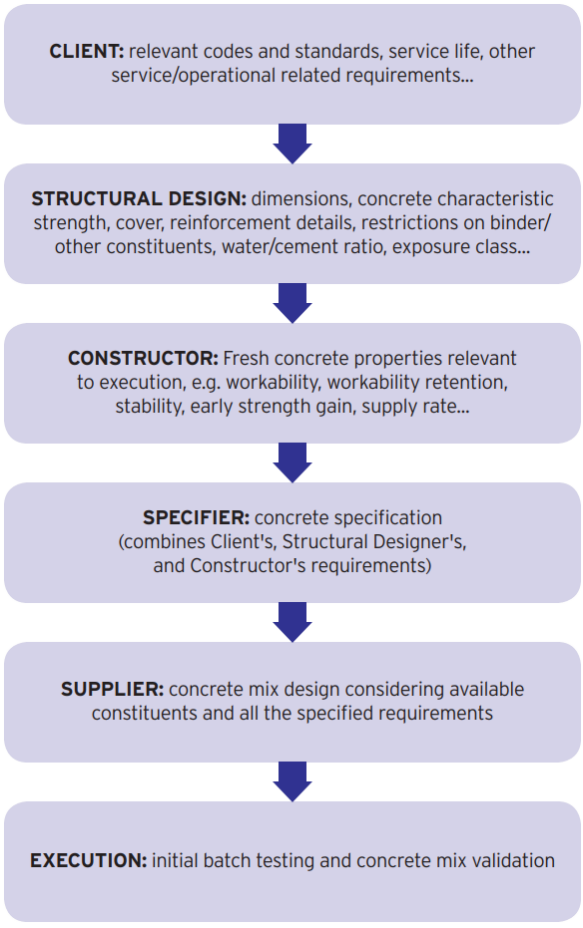

Figure 3. Typical evolution of concrete mixes.

The primary purpose of the Guide to Tremie Concrete for Deep Foundations (Tremie Guide) is to give guidance on fresh concrete characterisation with respect to its performance, the concrete mix design process, and the methods used to test the fresh concrete. The principles of this Guide apply to tremie concrete for deep foundations but may also be applied for other forms of deep foundations (e.g., continuous flight auger piling).

Figure 3 summarises how the demanding and often conflicting requirements should be considered throughout the development of a concrete mix. The Guide highlights the important areas that require careful consideration in order to minimise the potential risks, including the appropriate structural detailing and the use of state-of-the-art execution methods.

It is strongly believed, and that’s why the Tremie Guide is addressing all stakeholders, that getting the mix right can only be achieved via a joint approach between the Constructor, the Structural Designer, and the Concrete Supplier.

2.2 Design considerations impacting concrete flow

The structural design of deep foundations is a specialist subject requiring both structural and geotechnical input, as it must also consider the conditions for the execution of the deep foundation works. However, within the context of the Tremie Guide, the recommendations are limited mainly to the detailing of the reinforcement cages.

It is obvious that the reinforcement bars, in their longitudinal (usually vertical) and transversal combined configuration present a considerable obstruction to flow. The main criteria to obey are subsequently enough clear space for the concrete to flow through „windows“, and the concrete cover to allow complete filling of the excavation and embedment of the reinforcement. It should be recognised that the required minimum cover for execution $c_{min,execution}$ for ensuring concrete placement is independent from the structural need for a minimum cover to ensure bond or durability. The designer should consider specifying a minimum clear spacing and a nominal cover respecting both demands.

Figure 4 summarises these main recommendations, which are explained in more detail in the Tremie Guide. It should also be noted that for the concrete placement in deep foundations a larger clear distance in relation to the maximum grain size of concrete aggregate D_{max} is needed to avoid blocking, and that for practicable reasons the outer dimensions of the cage need to include a tolerance, Δd_c for its installation into the excavation with a nominal dimension equal to that of the excavation tool.

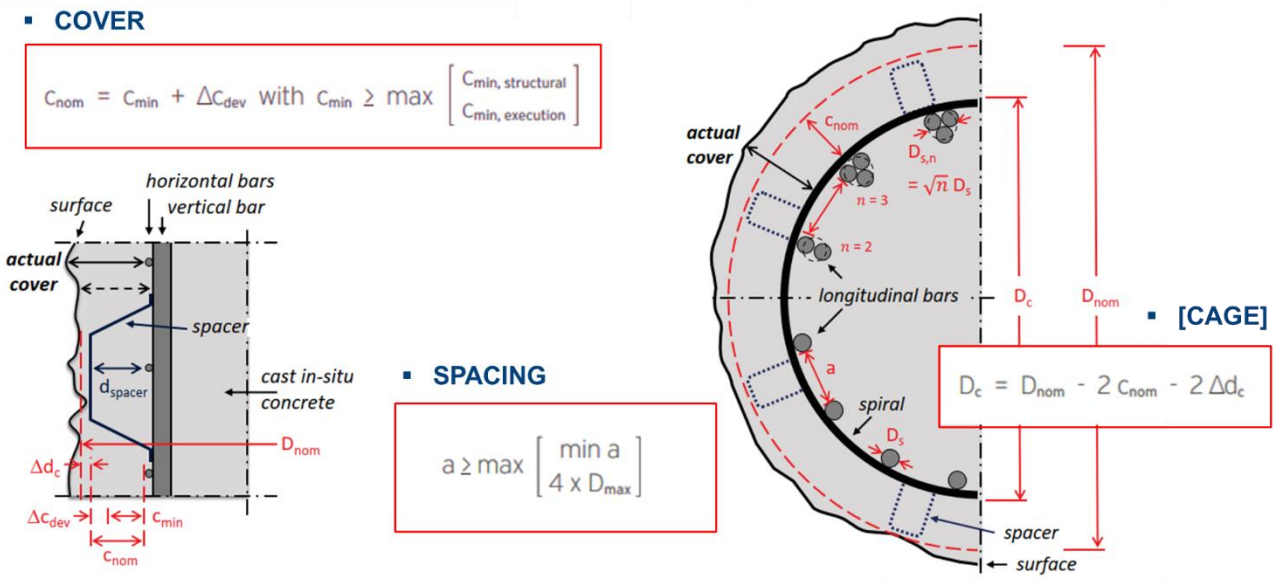

Figure 4. Considerations for detailing a reinforcement cage in deep foundations (also applicable to rectangular).

2.3 Properties of tremie concrete

It has already been explained that a principal task for the CTG has been to consider modern concrete technology. There was a consensus to focus on the right performance of fresh concrete, driven by the rheology of the bulk concrete mix, but also – on a microscale – of the paste where inter-particle mechanisms and chemical actions become relevant. In this context, the principle – normative – requirements for self-levelling, self-compacting by gravity, and filling the excavation, are all governed by the concrete's workability characteristics. Stability characteristics must avoid the negative effects of segregation, bleeding or filtration. A sufficient control of stiffening (with time) is a matter of workability retention.

Figure 5 explains Tremie Concrete performance in simple rheology terms, and gives evidence why Tremie Concrete should not be mistaken with a self-compacting or self-consolidating concrete, often referred to as ‚SCC'. In comparison to normal concrete that is vibrated to overcome the yield value to initiate flow, Tremie Concrete and SCC both have a much lower yield and a much lower viscosity, which is the resistance to flow, once started. However, Tremie Concrete does need a significantly higher yield than SCC mainly in order to control stability e.g., avoid segregation over often long workability retention times, achieved by retarding admixtures (that are seldom used for SCC). At the same time, the viscosity of Tremie Concrete is significantly lower than for SCC, mainly to ease distribution and to limit the time to empty a truck i.e., to reduce total pouring times, which in turn limits the time for any segregation to occur.

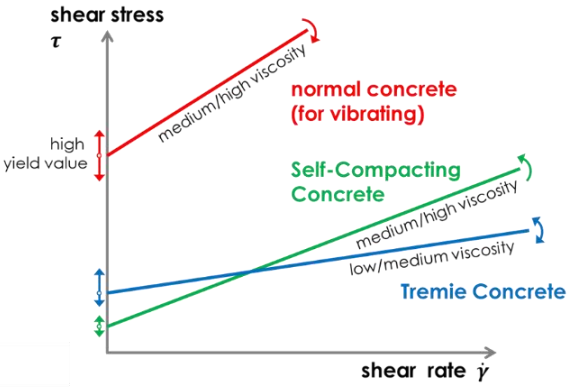

Figure 5. Qualitative comparison of rheology for different types of concrete.

2.4 Concrete mix design

The right concrete mix design has to be based on a good general knowledge of concrete technology. The section just highlights typical steps in developing a concrete mix design for deep foundations and assumes that suppliers have a sufficient range of established concrete mix designs. However, as the Tremie Guide also presents non-normative test methods to better characterise fresh Tremie Concrete, additional considerations on mix design, constituents, and proportioning might be useful also for concrete technology generalists.

2.5 Specifying and testing of concrete, and quality control of concrete production

In this central section of the Tremie Guide, "A New Approach to Specifying Fresh Concrete" is presented.

As indicated in the sections above, fresh tremie concrete cannot be described by a single measure of consistence (workability) only. As stated in the Guide,

the consistence of a concrete is the best characterisation for its ability to fill the excavation and to "squeeze" through openings in the reinforcement cage. However, more characterisation, and testing, is needed to ensure good performance.

The EFFC/DFI research program has clearly revealed that for fresh Tremie Concrete, the Slump Flow (SF) test is much more sensitive than the widely used slump or flow table tests. Figure 6 comprises a preferred range for a SF target value to be specified as recommended in the 2nd Edition of the Guide that will be narrowed down to a default value for typical applications in the 3rd Edition.

In combination with the Slump Flow test, it is literally no extra effort to also get an indication of the concrete's viscosity and stability, two more important characteristics. As the test equipment for this "triple test" is the standard slump test equipment, as shown in Figure 7, plus a stopwatch, there should be no issue at all to implement such testing on a regular basis i.e., also on site for standard acceptance testing if specified.

In fact, the Slump Flow test not only shows the initial workability but also, by repeated testing, its development over time. The workability retention test validates the end of workability that occurs after placement, see Figure 8.

In the context of necessary workability retention, the decisive question to answer is, how long the concrete load is being moved or displaced before finally cast. This could happen, for example for the first load, before the pour is completed. And Numerical Modelling can help to better understand dependencies, as explained in section 2.9.

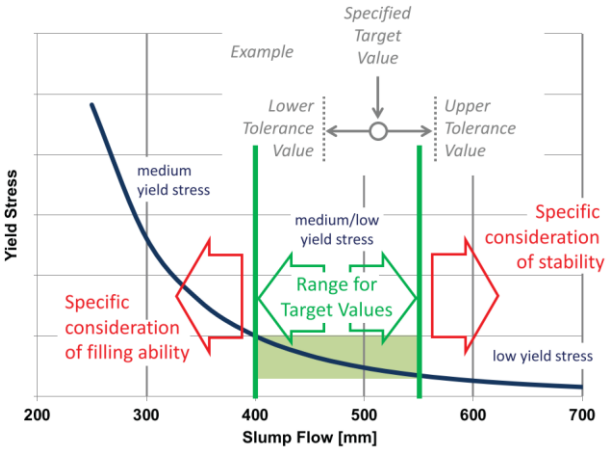

Figure 6. Slump Flow curve related to yield stress and recommended range for tremie concrete (Figure 11, ed 2).

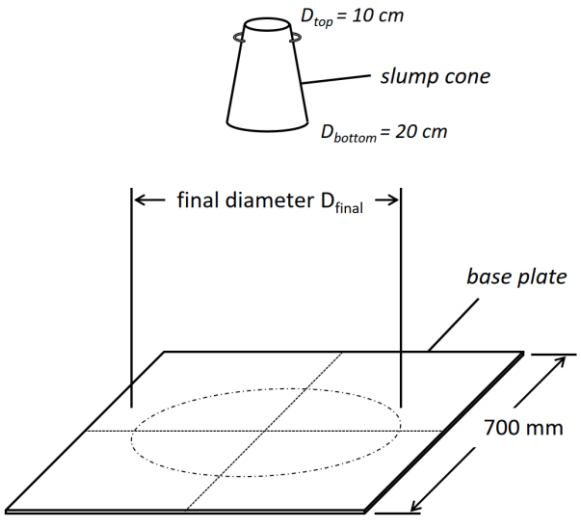

Figure 7. Test equipment for combined slump flow, slump flow velocity and VSI test.

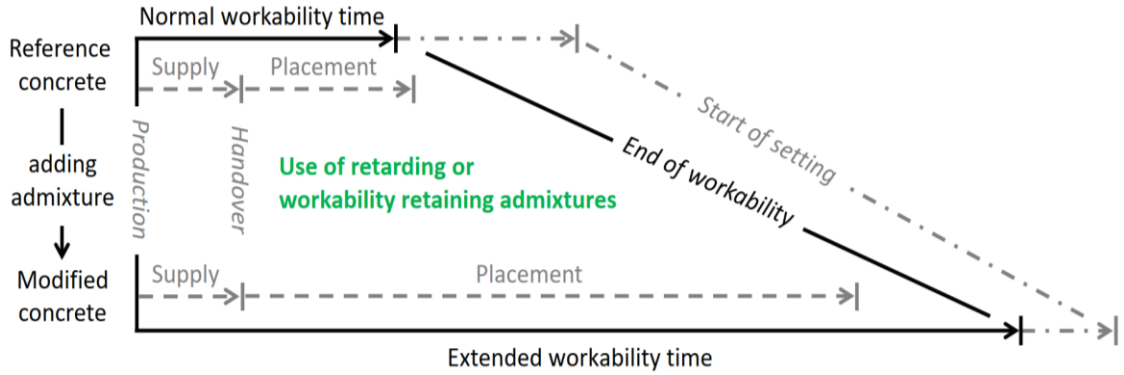

Figure 8. Extension of workability time.

2.6 Execution

Techniques and methods used prior to concreting and for the actual tremie pouring operation are clearly within the scope and responsibility of the specialist contractor. However, a quality control inspection & test plan may vary according to country or region. As European, American and International Standards and Codes of Practice vary, the Guide limits its recommendations to what is considered good practice, without scrutinising individual state-of-the-art practices. Execution parameters contribute greatly to a successful concrete placement and will have influence on the final distribution of concrete in a completed element.

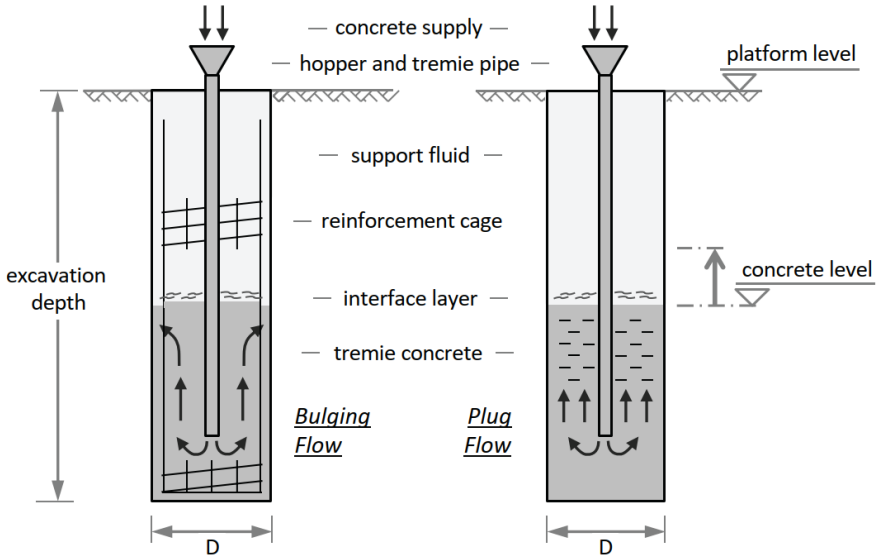

Figure 9. Schematic of bulging and plug flow.

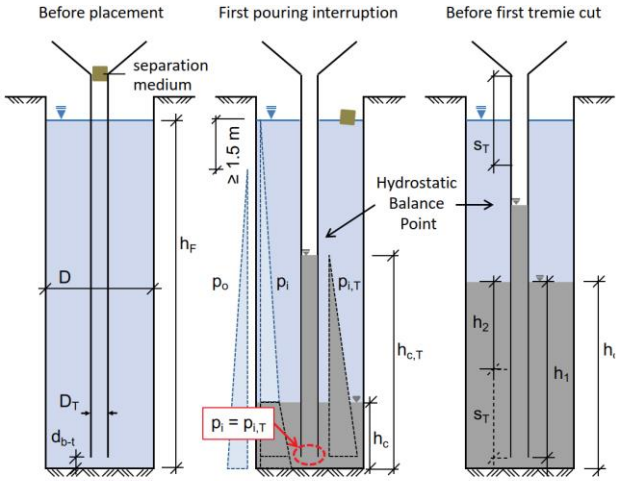
Consensus in the Group was built on a principle of understanding concrete flow mechanisms. Based on experience and observations on many tremie concrete pours, and backed up by numerical modelling, there are two extremes of how fresh concrete displaces earlier poured concrete and distributes through an excavation. Figure 9 shows, in a simplified schematic, the bulging flow path in the case of maximum friction at the outsides of the excavation e.g., by a reinforcement cage, and the plug flow in case of literally no friction restricting the flow at the outside.

The most critical step in the tremie concreting process is attributed to the initial placement. The first batch or batches of concrete have to be continuously poured until a safe embedment of the open tremie pipe is achieved, by a concrete level in the excavation affecting an outside pressure at the outlet (equal to the inside hydrostatic pressure in the tremie pipe (levelled after the dynamic flow downwards), high enough to let the concrete level in the tremie pipe above the outside concrete level. This stage is shown in the centre of Figure 10. Other relevant parameters are discussed in detail in the Tremie Guide.



Where:

h_F	Fluid level in excavation
D_T	Diameter of tremie pipe
D	Dimension (diameter or thickness) of excavation
d_{b-t}	Distance from bottom of excavation to tremie pipe outlet
h_c	Concrete level in excavation
$h_{c,T}$	Concrete level in tremie pipe (= hydrostatic balance point)
h_1/h_2	Embedment of tremie pipe before (1) / after (2) tremie pipe cut
s_T	Section length of tremie pipe section to cut, with: $h_2 \geq 3$ m [10ft]
p_o/p_i	Hydrostatic pressure outside (o) / inside (i) of excavation
$p_{i,T}$	Hydrostatic pressure inside the tremie pipe

Figure 10. Phases in the tremie pour sequence.

2.7 Full scale trials

This brief section in the Tremie Guide emphasises the potential of full-scale trials to identify problematic conditions and address these before commencement of the permanent works. These might not be obvious before starting a new project. The extent and scope should be proportionate to the project size.

The components to be tested should be selected from a review of:

- the design and detailing,
- the fresh concrete performance,
- the constructor's placement methods, overall experience and capability, and
- the experience in the given ground properties.

Any extra time and costs needed for such trials must be recognised by the client at an early stage and specified in detail in the tender documents. In any event, it is recommended to perform on-site conformity testing to verify or allow adaption of the concrete mix design usually developed in the supplier's laboratory.

2.8 Quality control of completed works

It is essential that the Constructor complies with relevant standards for quality assurance and control, and that the production process is supervised and undertaken by competent persons with suitable training, qualifications and experience.

Some imperfections of the hardened concrete of the deep foundation element are possible even though good practice construction methods were applied by the Constructor. Quality control requirements for the completed works should therefore make allowance for acceptance of some imperfections where these are not significant with regard to the structural performance and durability of the completed works. To support efficient and consistent inspection and acceptance, acceptable imperfections should be clearly identified in work procedures and inspection and test requirements. Optional non-destructive testing methods might assist, and their use should be planned upfront in detail. To give one example with relevance to execution: testing pipes are usually pre-installed in the excavation by attaching them to the reinforcement cage, and their configuration must obey the same rules as for the reinforcement bars to ensure the required clear spacing for concrete flow.

2.9 Numerical modelling of concrete flow

This section is the most dynamic regarding reaction on consideration of the latest developments. To cope with the new knowledge generated at a scientific level, it requires time to publish the validated results.

A 4th Edition of the Tremie Guide is planned which will present further modelling results once completed. This will allow a better understanding of concrete flow mechanisms and the sensitivity to changes in various parameters such as concrete rheology, clear spacing, cover thickness, volume and height of the open excavation to be filled.

It should be noted that numerical modelling is used to understand principal interrelations resulting in flow patterns. It has not been, and will not be, intended to use a numerical model as a realistic digital twin. To do so, the methods would need to allow realistic simulations not only of bulk flow but also for stability issues like concrete segregation which in turn would affect the workability and filling ability of the fresh concrete in a real and usually very complex situation.

3 FUTURE

A key objective of the CTG was to translate the Tremie Guide's approach to applying the performance concept to the design and testing of tremie concrete into standards. A significant step has been to move away from a descriptive minimum cement content, which is required in the older generation execution standards for Bored Piles and Diaphragm Walls (EN 1536 and EN 1538) in Europe. New, performance-related, but also more specific regulations not only improve the quality of completed works, but also make it possible to improve sustainability by reducing cement and thus the carbon footprint of foundations.

In favour of a clear assignment of concrete topics to the relevant European standard EN 206 on Concrete – Specification, performance, production and conformity, concrete related regulations were copied and pasted from the standards for the execution of special geotechnical works (EN 1536, EN 1538, EN 12699 and EN 14199) without any harmonisation, let alone a revision of the content in the context of modern concrete technology and modern execution aspects.

Subject to the formal approval of CEN, Figure 11 shows the relationship between the future EN 206-3 and the relevant execution standards for concrete placement. For bored piles and diaphragm walls produced in accordance with EN 1536 and EN 1538, tremie concrete is standardised due to the applied excavation method, amongst others.

It should also be noted that EN 206 defines tasks for the specifier, the producer and user in its parts -1 and -3 which are relevant for concrete in general and for tremie concrete in particular. This establishes the mutual endeavour of all parties involved to work together, as is also defined in the scope and purpose of the Tremie Guide. The right concrete will never be a

product that is blindly taken off the shelf in future either. But the new EN 206-3 paves the way for specifying and testing the required performance in the respective area of application more precisely. Engineering assessment and concrete-technology expertise remain essential.

EN 206-3 not only opens up the standard for plastic concrete to cover applications that may go beyond load-bearing structures, but also prescribes the Slump Flow test method for tremie concrete as the future main criterion. The relevant clause states that "Tremie concrete shall be specified by slump flow, by a target value, based on a detailed engineering assessment." The standard allows to choose the actual target value from the range from 400 to 550 mm or to set to 450 mm, with a maximum tolerance of +/- 50 mm, as recommended in the Tremie Guide.

Regarding all three main characteristics of fresh concrete (workability, workability retention and stability), EN 206-3 refers to normative and non-normative test methods based on the Tremie Guide, which are described in an informative annex. This informative annex will become superfluous once the same test methods have become normative. Standardisation within the EN-12350 series for fresh concrete test methods has been applied for at corresponding task group under the umbrella of CEN/TC 104 for Concrete and Related Products.

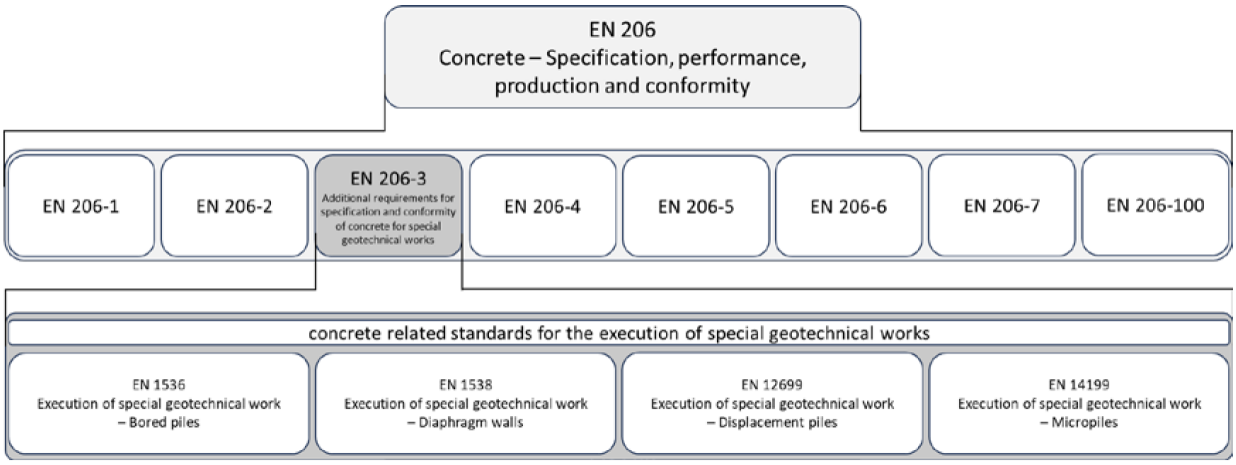


Figure 11. Relationship between EN 206-3 and concrete related standards for the execution of special geotechnical works.

4 CONCLUSIONS

Up to date, in a 10-year period, the joint EFFC/DFI Concrete Task Group has made great efforts to establish a Guide to Tremie Concrete for Deep Foundations in its 3rd Edition to be published shortly. A 4th Edition is already in preparation, which will incorporate the last validated findings from Numerical Modelling.

Already from the 1st Edition in 2016, the Guide has focused on improving the quality throughout the whole process of in-situ casting of deep foundations. To do so, the Guide has always been intended as a practical addition to existing standards, not a substitute. Project specifications, standards and codes should always take precedence.

However, the Guide assists individuals and corporations involved in the procurement, design, and construction of bored piles and diaphragm walls including Owners/Clients, Designers, General Contractors and Specialist Contractors.

ACKNOWLEDGEMENTS

The author is grateful for the continuous and extraordinary support provided by the members of the EFFC/DFI Concrete Task Group and wishes to express his sincere thanks to all experts and sponsors who have contributed to the Tremie Guides.

Cutoffs in dams: Overview and recent developments

Les parois étanches dans les barrages: Aperçu et développements

G. Pereira*
Soletanche Bachy, Rueil Malmaison, France
**gustavo.pereira@soletanche-bachy.com*

ABSTRACT: The purpose of dams is to retain water or, in the case of tailings dams, to retain saturated materials. In most cases, the body of a well-performing dam can be considered impervious; however, seepage through the foundation depends on the geological conditions and is often excessive. This seepage is usually controlled by grout curtains, cutoffs, or a combination of both. Illustrated by recent case studies, this paper will present and discuss cutoffs and their recent technological developments: different construction techniques and materials constituting the cutoffs; excavation equipment; and the monitoring technologies used during and after excavation to ensure the quality of the final product. The challenges of new-build construction and of dam repair will also be addressed.

RÉSUMÉ: Les barrages ont pour but de retenir l'eau ou, dans le cas des barrages à stériles, de retenir des matières saturées. Dans la plupart des cas, le corps d'un barrage en bon état peut être considéré comme étant imperméable ; cependant, les infiltrations à travers les fondations dépendent des conditions géologiques et sont souvent excessives. Ces infiltrations sont généralement contrôlées par des rideaux d'injections, des coupures étanches ou par une combinaison des deux. Illustré par des études de cas récentes, cet article présentera et discutera les coupures étanches et leurs développements technologiques récents : différentes techniques de construction et matériaux constituant les coupures ; équipement d'excavation ; et les technologies de contrôle utilisées pendant et après l'excavation pour s'assurer de la qualité du produit final. Les particularités associées à la construction de barrages neufs et à la réparation des existants seront également abordés.

Keywords: Dam, cutoff, dam remediation.

1 INTRODUCTION

Following very intense development in the 20th century, and in particular until the 1970s, dam construction has slowed significantly in recent decades. The reasons for this slowdown are multiple; nevertheless, dams remain today fundamental infrastructures for irrigation, human consumption, power generation, energy storage and flood control, among others.

In the near future, at the same time that energy consumption will maintain its upward trend, worldwide population will keep increasing and climate change will compound the effects of water scarcity and floods, the installed storage capacity worldwide will dwindle (due to sedimentation of reservoirs), and dams built in the mid-20th century will be many decades old. For these reasons, dam construction and remediation initiatives are likely to increase, globally as a whole if not in every country. Due to the relevance of dams, this paper aims to present developments that may be used in the future, both for new build and remediation projects. So as to accomplish their general role of storing water, dams need to be as watertight as possible. Dams rely on the use of practically impervious materials to ensure that minimal seepage occurs through the body of the dam (be it concrete, low permeability backfill, synthetic membranes, asphalt, or others).

Seepage through the foundation, however, depends above all on the hydraulic conductivity of the *in situ* geological formations, which can vary greatly depending on its nature (e.g. alluvium, rock) and state (fine or coarse alluvium; fractured or massive rock; etc.), but is frequently incompatible with the dam's intended purpose and needs to be controlled. This is commonly achieved by grouting and/or cutoffs. It should also be noted that, besides limiting the amount of seepage through the foundation and hence the loss of water in the dam, grout curtains and cutoffs play a key role in the stability of the dam by limiting downstream uplift pressures.

A cutoff is formed by impervious elements installed in the ground up to an impervious stratum. It

requires the removal (or at least restructuration) of the *in situ* material during its installation. This is contrary to grouting, which materializes a barrier by filling the voids of the foundation material. This paper will only address the specific case of grouting when it is performed in conjunction with cutoffs.

The subject of cutoffs is vast, be it in terms of construction techniques, materials, or other aspects. This paper does not intend to perform an exhaustive review of the subject; instead, its focus will be on interesting recent developments and techniques, as well as less common aspects of construction and design. A more exhaustive review, albeit one with less updated information and references, can be found in ICOLD (2018).

2 CONSTRUCTION METHODS

Cutoffs can be broadly divided into positive cutoffs and semi-positive cutoffs (ICOLD, 2005). Positive cutoffs are those in which the *in situ* ground is excavated to allow the installation of an engineered material. This is the case of diaphragms and secant-pile cutoffs, among others. Positive cutoffs can be further sub-divided into single-stage cutoffs, in which the fluid used to stabilise the trench will harden and serve as the permanent cutoff material (in the case of a cemente-bentonite slurry wall), and two-stage cutoffs, in which the drilling fluid will be displaced by the final material (usually a tremied concrete formulation).

Semi-positive cutoffs are those where the original soil is mixed in place with a binder. This is, for example, the case of soil mixing and jet grouting.

2.1 Diaphragms

Diaphragms are a type of positive cutoff that includes soil-bentonite walls, cement-bentonite walls and concrete diaphragm walls (plastic or conventional concrete). Soil-bentonite walls, excavated with backhoe or similar, are common in America as a cost-effective method for shallow cutoffs; these will not be addressed in this paper.

The other types of wall use the diaphragm wall technique, developed since the 1950s, in which alternate primary panels are installed followed by secondary panels, and the interface between both is ensured by different types of joints (which will be adressed in chapter 2.3). The excavation equipment has evolved continuously, from rope grabs to the efficient and powerful hydraulic grabs still used today for excavation of soil and soft rocks. Depths over 125 m can be attained, with thicknesses up to 2000 mm.

Arguably the single most important diaphragm wall development for cutoffs was the development of the hydromill (Hydrofraise) by Soletanche in the 1970s, for it allowed the excavation of much stronger rocks. Hydromills have since been continuously developed, namely in terms of capacity and precision.

Roller bits have been used in hydromills for hard rock excavation (Figure 1), being clearly superior to standard cutting teeth when rock UCS (unconfined compressive strenght) exceeds 100 MPa. The drilling progresses as the roller bits locally punch through and crunch the rock; in order to do so, the bits need to mobilize significant vertical reaction force.

Figure 1. Roller bits for hard rock excavation.

A substantial innovation in this context is the Gripper Hydrofraise, patented by Soletanche Bachy. The advance rate of the drilling equipment is proportional to the vertical force that can be exerthed on the cutting tool; this force, however, was generally limited by the reaction provided by the weight of the hydromill, which is pendular (i.e. hangs from the carrier). The Gripper Hydrofraise does not suffer from this limitation: through the hydraulicaly operated Gripper pads in its anchor module, it will react laterally against the excavated ground (see Figure 2, on the left). This allows it to mobilize friction on the excavated ground, and therefore to apply additional force when the drilling module is jacked against the drilling face (see Figure 2, on the right).

Depending on the Gripper Hydrofraise model, up to 2000 kN of pull-down force can be deployed. At the same time, the tools and carriers are prepared to exceed depths of 200 m. The Grippers have the added benefits of stabilizing the cutting tool and reducing vibration levels during excavation, minimizing wear and tear. The conjunction of Gripper Hydrofraise and roller bits has allowed viable penetration into rocks with UCS up to 300 MPa in the ongoing NSC105 project in Singapore.

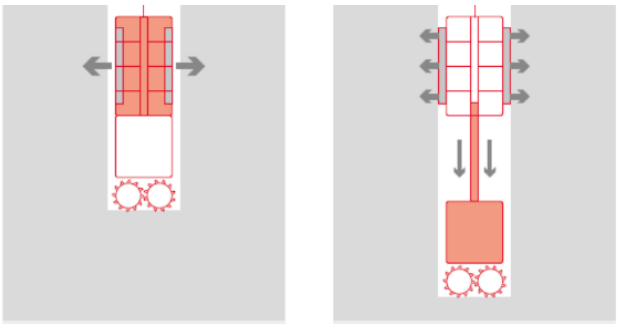

Figure 2. Gripper Hydrofraise operating principle: gripping stage (left) and drilling stage (right).

Compact rigs have also been developed in recent years, based on the need for high-capacity equipment capable of working in constrained spaces. This allows for example its use inside dam galleries (figure 3), something that would not be possible with standard hydromill equipment. In the case of the Subansiri project in India (Mallet et al., 2019), the Hydrofraise rigs operated inside 7x7 m^2 galleries located at different platform levels and had frequently to be hoisted from one platform to the other.

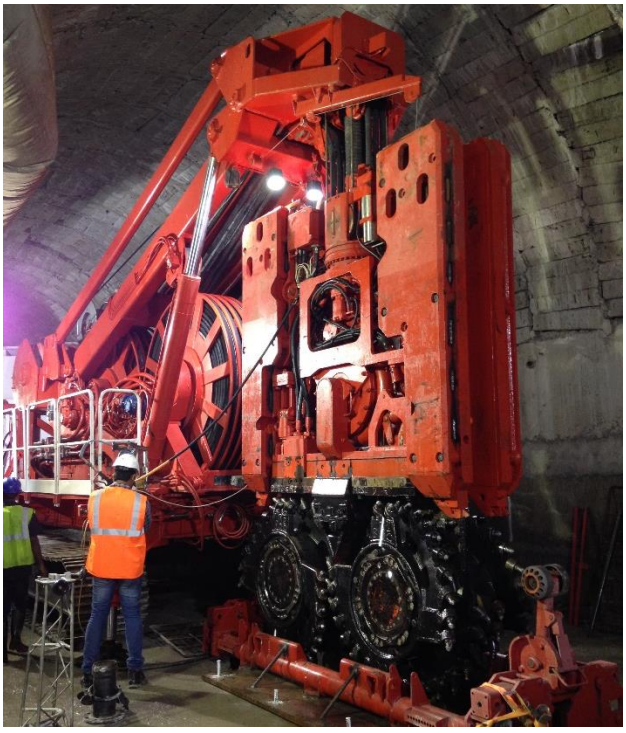

Figure 3. Compact Hydrofraise equipment operating inside a gallery in Subansiri dam.

Another development of the compact Hydrofraise that will further increase its capabilities for use in dams is the adoption of a detachable powerpack: besides further reducing the size of the rig, it simplifies operations and ventilation requirements while working inside galleries by eliminating a source of exhaust gases. Another development still is the adoption of Grippers in these compact machines, further optimizing rock excavation.

2.2 Piles

In order to form a seepage barrier, circular piles will need to overlap, forming what is commonly known as secant piles. Alternate primary piles are installed and, following some days of curing, secondary piles will be installed in between them. Pile cutoffs will intrinsically possess more interfaces between overlapping elements than is the case for diaphragms, and as such are more prone to defects in these areas. Depths in excess of 100 m can be attained; however, the production of a conventional Kelly-bar rig installing drilled shafts at large depths does not compare favourably to the production of hydromills or of RCD (reverse circulation drilling) piling equipment.

A recent example of piling cutoff in difficult conditions is the remediation works in Boone dam in the USA (Barredo et al., 2021). In this project, the karstic limestone exhibited marked pinnacles that risked triggering unacceptable deviations, if conventional piles or diaphragm walls were to be used: the drilling tool would touch the hard pinnacle rock and, instead of penetrating the limestone, would slide along the pinnacle feature. The chosen solution was to use directional drilling (capable to actively correct deviations, but limited to small diameters unsuitable for cutoff implementation) to drill a 196 mm pilot borehole. Then, an RCD equipment (Wirth 818 from HMH) drilled the final 1270 mm pile coaxially with the pilot borehole, using a stinger inserted into the borehole as a guide (Figure 4). Piles up to 55 m in depth were installed, with deviations below 0.25 %.

Figure 4. RCD hard rock drilling tool with protruding stinger used in Boone dam remediation.

Another interesting solution to a specific problem was developed by Trevi for the Arapuni remediation project in New Zealand (Wharmby et al., 2007). In this remediation project, 400 mm piles at 350 mm centres were installed up to a depth of almost 90 m with an RCD tricone. Such a small overlap up to such a large depth was only possible with a specific, custom-built guide (Figure 5, from Wharmby et al., 2007), that would slide through the previously excavated pile to guide the drilling of the next pile. This solution required, of course, a sufficiently stable ground to allow safe operation of the guide-tool combo.

Figure 5. RCD tricone drilling tool with guide (left) and overlapping drillholes in the Arapuni dam remediation.

2.3 Soil mixing

Amongst the various methods used for soil mixing, possibly the most useful development for cutoffs concern CSM (cutter soil mixing), as well as the patented Trenchmix method. Like other soil mixing techniques, these systems are suited to soils (overburden, residual soil) and cannot be used in hard ground.

Cutter soil mixing can be considered a derivative of hydromill technology, hence constructing rectangular panels in depth (thicknesses up to 1200 mm and depth, depending on carrier, up to 35 m). Panels are built side by side, with sufficient overlap between them to ensure continuity of the cutoff. Figure 6 shows the CSM tool from Bauer.

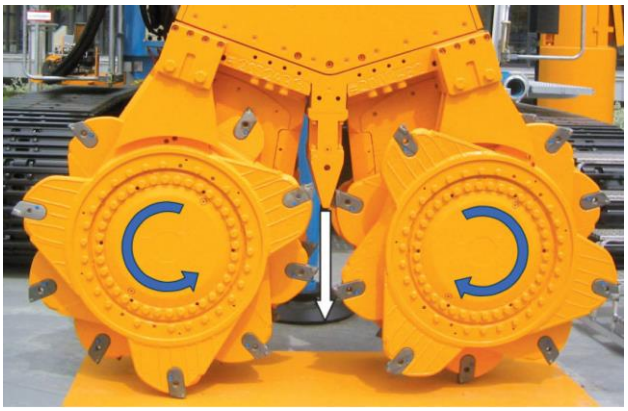

Figure 6. CSM operating principle indicating slurry flow (in white) and cutter drum rotation directions (in blue).

Trenchmix is a patented technique by Soletanche Bachy, consisting of a trencher capable of producing continuous cutoffs in a very efficient and rapid way (Figure 7). Thicknesses are limited to 500 mm, while depths depend on the size and power of the equipment, but cannot reasonably exceed 30 m. This technique has proven to be very effective in dyke remediation, for example in the Rhyne valley.

Figure 7. Operating Trenchmix equipment in a dyke remediation project.

2.4 Jet grouting

Jet grouting consists of cutting the soil with high velocity jet of fluid(s), and mixing the eroded soil with a self-hardening grout, to form columns and other structures in the ground. The classification of jet grouting into single, double or triple jet grouting pertains to the fluids being used (Figure 8).

Figure 8. From left to right: single, double and triple jet grouting.

An innovative development of jet grouting for cutoffs is the E-JET Elliptical Jet patented by Trevi (Leoni and Pianezze, 2017), as the system allows to optimize the shape of the jetted element. By carefully managing the rotation speed of the monitor, an approximation of a rectangular shape can be obtained (Figure 9 and Figure 10, from Trevi and Soilmec) leading to savings in time and materials. Panel sizes are heavily dependent on geology (overburden or residual soil), while depths up to 100 m can realistically be reached.

On another note, jet grouting advances have focused on the sustainable construction and on minimising environmental impact. For example, several case histories of reuse of jet grouting spoil have

been identified. Depending on the techniques, water consumption can be reduced, evacuation of cuttings can be limited, and cement consumption can equally be reduced.

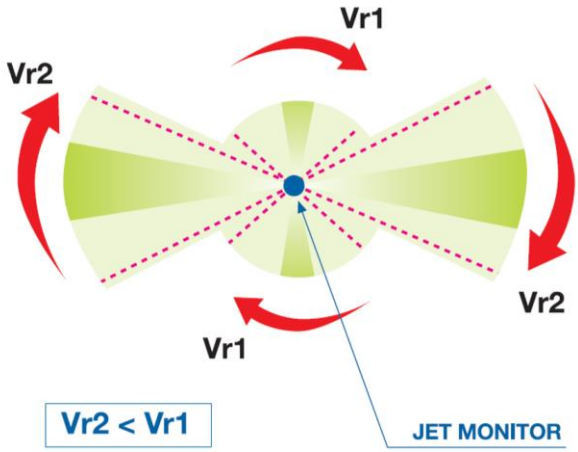

Figure 9. E-JET operating principle.

Figure 10. Excavated E-JET panels.

2.5 Cutoffs complemented by grouting

As noted previously, grouting is addressed in this document only for cases where it serves as complement to a cutoff.

The first case relates to the continuation of a cutoff by a grout curtain. This may be the case when the cutoff will be limited to a certain depth of overburden soil, whereas grouting will be applied to the fissured rock mass below. In this case, much care is to be taken in overlapping both solutions. A typical method is to install the cutoff and then to drill through it to instal a grout curtain on the same axis of the cutoff, and to thoroughly grout the contact between the cutoff and the grout curtain.

The other case concerns mostly the execution of the cutoff itself: in cases when the ground is extremely pervious, drilling fluid for diaphragm wall or piling will be lost into the ground, making excavation impossible. In this case, prior grouting will limit the loss of drilling fluid, as well as having a beneficial effect on the stability of the materials adjoining the excavation.

3 MATERIALS

The following sub-chapters will focus on the main attributes of the different types of cutoff materials.

In the case of positive cutoffs, these materials will range from cement-bentonite mixtures, to plastic concrete, to conventional concrete. The properties of each mixture will be tailored according to the project's requirements.

In the case of semi-positive cutoffs, the *in situ* soil plays a large role in the final parameters of the treated ground. For example, it is well known that soil mixing or jet grouting of granular soils leads to higher strength and stiffness than in fine grained soils.

3.1 Permeability

The first criterion for the material in a cutoff is its imperviousness, on which will depend the barrier's performance. Considering the cutoff material in itself, very low permeabilities are to be expected. For example, for plastic concrete, permeabilities in the order of 10^{-10} to 10^{-11} m/s are typical. This permeability will be increased by the presence of discontinuities, either those introduced by unwanted defects, or those associated with the construction methods, in particular joints between discrete cutoff elements.

Vidil (2018) indicates the following equivalent permeabilities for dwalls, accounting for the use of several types of joints (see Table 1).

Table 1. Estimates of equivalent diaphragm wall permeability, for different types of joints (adapted from Vidil, 2018)

Type of joint	Permeability (m/s)
Stop end tubes	10^{-8}
CWS	10^{-10} to 10^{-9}
"Dry" joint	10^{-8}
Milling	10^{-10} to 10^{-9}
Milling + joint sealant	10^{-10} to 10^{-9}

The well-known CWS (Complete Water Stop, Figure 11), patented by Bachy in 1982 and subsequently adopted at a global scale, represents a marked improvement compared to the previously used stop end tubes. However, for several reasons it is not practical to use a CWS joint beyond 60 m in depth. Milled joints (Figure 12) implemented with hydromills

can, on the contrary, be implemented to the bottom of the excavation.

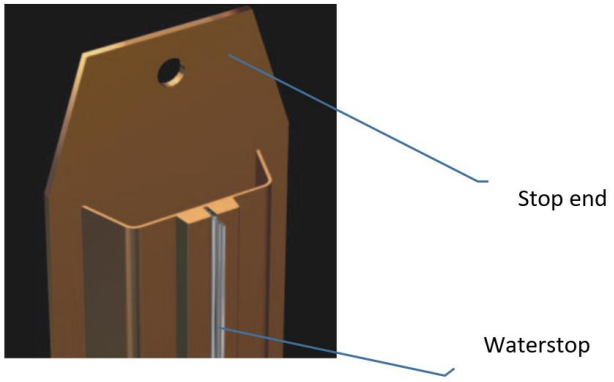

Figure 11. CWS joint complete with waterbar.

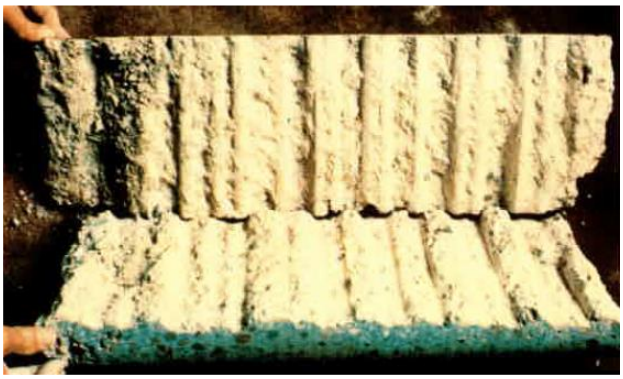

Figure 12. Milled concrete in a hydromill joint.

Another innovative development (Mosser and Monleau, 2020) concerns the inclusion of a hydroswelling joint sealant in conjunction with a milled joint. The patented system requires an auxiliary steel cage to keep the join sealant in place (Figure 13) and also the installation of sacrificial hydraulic jacks in depth; these hydraulic jacks will be pressurized just after concreting the panel and will push the joint sealant against the previously cast panels on either side of the newly cast panel. The system has been successfully implemented in cutoffs in Chile and an improvement of the permeability coefficients indicated in Table 1 is expected with additional return of experience.

In the case of secant pile walls, it is reasonable to assume similar permeabilities to those indicated for milled joints in diaphragm walls. In the case of soil mixing and jet grouting, realistic permeabilities, obtained from return of experience, are in the order of 10^{-7} m/s to 10^{-8} m/s.

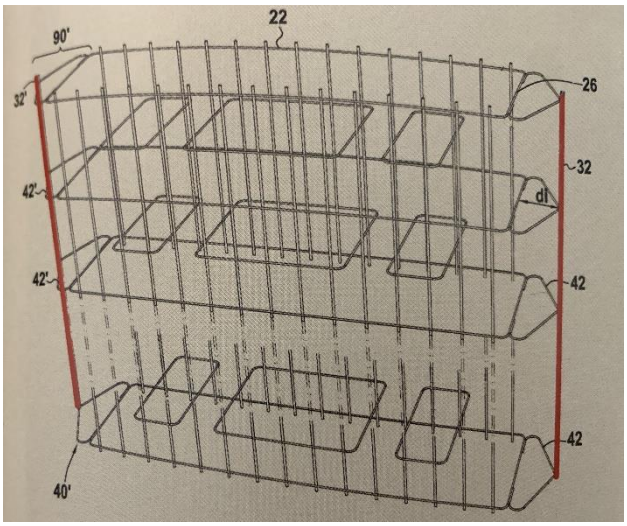

Figure 13. Hydroswelling joint sealant and milled joint: sealant location and auxiliary support cage.

3.2 Strength and stiffness

An equally relevant criterion concerns the stiffness and the strength of the cutoff material. It is advisable that the material has low stiffness, i.e. a matching stiffness to that of the ground on which it is installed (say a cutoff material no more than 5 times stiffer than the ground), so as to minimize stress concentrations on the barrier.

On the other hand, the material needs to be strong enough to resist the loads imposed on the cutoff, the largest of which are often the differential hydraulic pressures acting on both upstream and downstream faces (see Figure 14), which induce substantial bending and shear stresses on the wall. In the case of seismic regions, the kinematic interaction of the cutoff with the adjoining ground may also govern the design, by imposing shear and bending on the cutoff (see Figure 15).

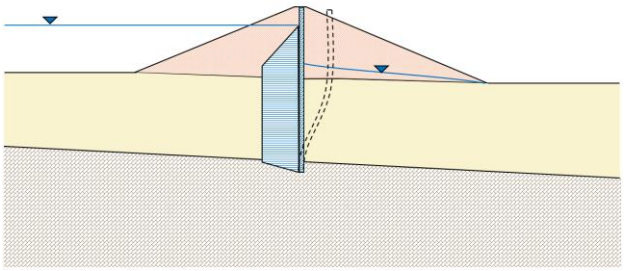

Figure 14. Exaggerated deformed shape of cutoff under differential hydraulic pressures.

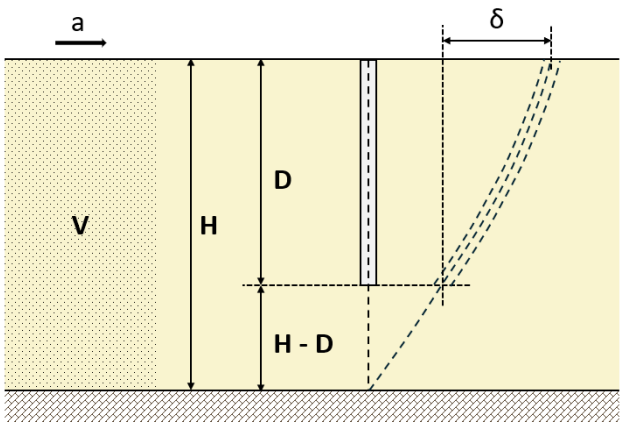

Figure 15. Exaggerated deformed shape of cutoff under seismic conditions - case of homogeneous ground underlain by bedrock (adapted from Soulomiac, 1986).

The significance of ductility (the capacity of the material to accumulate extensive plastic deformation) should also be noted, as the aforementioned load cases are likely to induce more or less localized yield zones. Similarly, it is important to assess the strength and ductility of the material under realistic confinement pressures: cutoff walls being frequently very deep, the confining pressures will increase considerably in depth. Hence the interest in establishing triaxial testing programs by specialized laboratories to assess and adjust the mixes. For all these reasons, plastic concrete formulations and cement-bentonite mixes have been used more and more frequently. Ongoing studies, by a joint working group of the German associations DWA, HTG and DGGT, are expected to provide guidance and objective design criteria on these materials (Beckhaus et al., 2023).

The same comments apply to soil mixing and jet grouting, which typically have strength similar to those of plastic concrete (UCS < 10 MPa, in general), with the caveat that soil mixing and jet grouting, contrary to plastic concrete, are not industrial man-made products and show much larger variability than batching plant mixes: the stiffness and ductility of these materials is very dependent on the ground type and should be assessed carefully. A final remark, valid for cement-bentonite slurry, plastic concrete, soil mixing or jet-grouting materials, concerns the slower increase in strength of these materials as they harden, when compared to the behaviour of conventional concrete. As such, it is nowadays broadly accepted to measure strength at 56 days or 90 days in the case of the former materials, instead of the 28 days commonly used for the latter.

Regarding conventional concrete (with strengths above 20 MPa), either as plain concrete or with reinforcement, its use has diminished greatly, namely due to cost and to the aspects detailed above. To be noted that reinforcement cages add further cost and installation complexity but provide a degree of ductility that plain concrete would not possess and may be required, depending on the load cases.

Finally, readers are invited to peruse the guides developed jointly by the European Federation of Foundation Contractors and by the Deep Foundations Institute of the USA: the first guide concerns tremie concrete for deep foundations (EFFC/DFI, 2018), while the second guide addresses support fluids for deep foundations (EFFC/DFI, 2019). Both documents are applicable to diaphragm wall or piling cutoffs, in large part if not in full.

3.3 Sustainability

In terms of environmental impact and carbon emissions in particular, most of the emissions in an infrastructure project are usually linked to the fabrication of construction materials, and not to installation processes. In the case of cutoffs, as in other geotechnical works, carbon emissions are mostly due to cement and may be reduced with selection of appropriate alternatives, such as furnace slag, fly ash or other alternative binders.

Figure 16 below (with data from Soletanche Bachy's EXEGY low carbon concrete) provides indicative values for scope 3 carbon emissions for plastic concrete (kg CO2 eq/m^3), depending on the type of binder used. It can be observed that: if the project's requirements can be met with alternative binders, if these are readily available and if the associated cost is compatible with the project, very important reductions in carbon emissions can be obtained. The internal laboratory of a specialized geotechnical contractor will be able to establish the viability of such alternatives.

Target compressive resistance (in MPa)	0,5	1	2	5	10
CEM I	280	337	394	490	547
CEM II	279	328	427	476	541
CEM III/A	127	141	151	218	268
CEM III/B Low Carbon	111	121	129	182	222
CEM III/C Very Low Carbon	74	81	92	121	152
Slagsol 95/5 Ultra Low Carbon	60	64	73	93	106

Figure 16. Indicative values of carbon footprint of plastic concrete (kg CO2 eq/m3) for different types of binder.

4 MONITORING AND CONTROL

The continuity of the cutoff is fundamental to ensure adequate performance of the dam's foundation, since a small opening between adjacent cutoff elements

increases the equivalent permeability of the wall by many times. As such, knowledge of the real location of the discrete elements forming the cutoff is necessary to ensure continuity.

This chapter will differentiate between monitoring of construction, performed during installation of the cutoff, and quality control verification, performed following partial or full installation of the cutoff element.

4.1 Monitoring during installation

Monitoring of the drilling tool location during installation is arguably more valuable because of the possibility, depending on the cutoff method being used, to retrieve part or all of the deviation. Hydromills and in particular Hydrofraise monitoring devices have been able to reliably locate the drilling tool in real time in xx, yy and zz directions, but also in terms of the twist of the tool (rotation around zz). The operator can then trim the tool's trajectory, by independently adjusting the torque of both motors and by actioning guiding jacks on the tool's frame (Figure 17). Verticality tolerances of < 0.25% are nowadays common, but have frequently been bettered, even at large depth, especially in homogeneous ground conditions. It should be noted that the more advanced hydraulic grabs can also adjust their positioning via guiding plates, albeit with more limited correction capability and with achievable verticality tolerances in the order of 0.5%.

Figure 17. Command panel of Gripper Hydrofraise. At the centre of the touch screen, the real time position of the tool (in vertical planes xz and yz) is depicted in green, while the deviation limits are represented in grey.

Directional drilling can, by definition, correct deviations, and therefore to achieve negligible tolerances; however, the maximum diameter of commonly available tools is small, around 300 mm, and not suitable for cutoff piling works (exception made for pilot holes for guiding other tools, as presented before). Other piling techniques are not able to significantly redress deviations.

Jet grouting and soil mixing techniques are also not able to correct deviations, with the exception of CSM which, being related to hydromill tools, has some ability to do so. However, both jet grouting and soil mixing equipment are fitted with sensors to measure deviations in depth. Finally, while verticality tolerances are higher for these methods (in the order of 1%), it should be noted that both techniques are used for relatively shallow cutoff depths, and that deviation control is therefore less critical.

Regarding the particular case of Trenchmix, the fact that the tool has a comparatively high deviation tolerances (< 3%) and cannot readily correct any deviation are not problematic, because the cutoff is continuous, without overlap of discrete elements.

4.2 Post-installation control

In the case of two-stage post-concreted cutoffs (e.g. concrete diaphragm walls and piles), location in depth can be verified by several methods. Indirectly it can be verified through geophysics, before concreting, for example via ultrasonic echo-detection (with the well-known Koden system from Koden Electronics) or by sonar calipering (the SONICaliper system from Fugro Loadtest). Typically, the geophysical readings from all the cutoff discrete elements will be assembled on a 3D visualisation software and compared with the drilling tool's on-board results, to ensure that overlap is obtained throughout the cutoff.

These techniques cannot be used for single-stage methods like slurry walls, soil mixing and jet-grouting. However, an interesting alternative technique can be used to estimate the diameter of jet grout columns. The Cyljet (proprietary technique from Sixense) is based on the spatial variability of electrical resistivity, and it requires the installation of a non-metallic tube inside the columns, into which electrodes are introduced at regular intervals. By analysing the differences in potential generated by an induced electrical current, it is possible to estimate the geometry of the jetted column.

Direct verification via coring (Figure 18) can also be used for assessing positioning but, due to its inherent cost, is more useful for inspecting the cutoff material and the interfaces between discrete cutoff elements, both inside the borehole (via CCTV or OPTV Optical Televiewer, Figure 19) and with analysis of the extracted core. It is worth mentioning that the use of a pigment in the concrete of either secondary or primary elements is very helpful in identifying and analysing the interfaces. Finally, coring boreholes can be used to directly assess

performance of the cutoff via stable water level tests or falling head tests.

Figure 18. Coring of interface between two adjacent castings (note pigmented concrete of secondary piles).

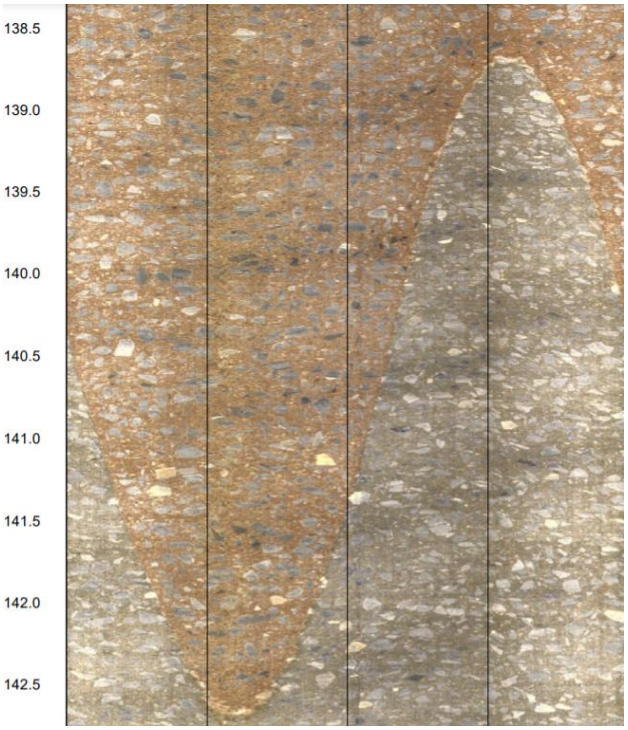

Figure 19. OPTV 360-degree image of a cutoff borehole (note pigmented concrete of secondary piles).

5 NEW BUILDS VS REPAIR

The case of new build is, by definition, less constrained than the case of dam repairs. Although limitations do exist in such cases, for example with cutoffs being built in valleys with often steep slopes, difficult accesses, and restricted space, at least the structure of the dam is not built yet.

Remediation works, on the other hand, are often very constrained; in terms of planning and logistics, but also because of the possible impacts on the existing dam, which sometimes continues operating with full reservoirs. The works are to be monitored so that strict limits are not exceeded, for example in terms of vibration levels or inclinometric or topographical displacement readings. Furthermore, evaluating the dams' stability during all stages of the cutoff works is often required, sometimes involving complex geomechanical modelling.

One such example of the type of analysis to be carried out is depicted in Figure 20. A remediation project where a cutoff was to be installed at the downstream toe of an embankment dam was value-engineered with a cement-bentonite cutoff. This cement-bentonite slurry wall was to be excavated with hydraulic grabs, deploying a construction sequence such that considerable lengths of trench would be left open for some time, with cutoff material in fresh or not fully hardened states.

This required an analysis of the excavation stability, but also of the global stability of the embankment, as the critical failure surfaces often extended well beyond the dam toe (these problems being intrinsically tridimensional, they are better addressed resorting to 3D numerical models).

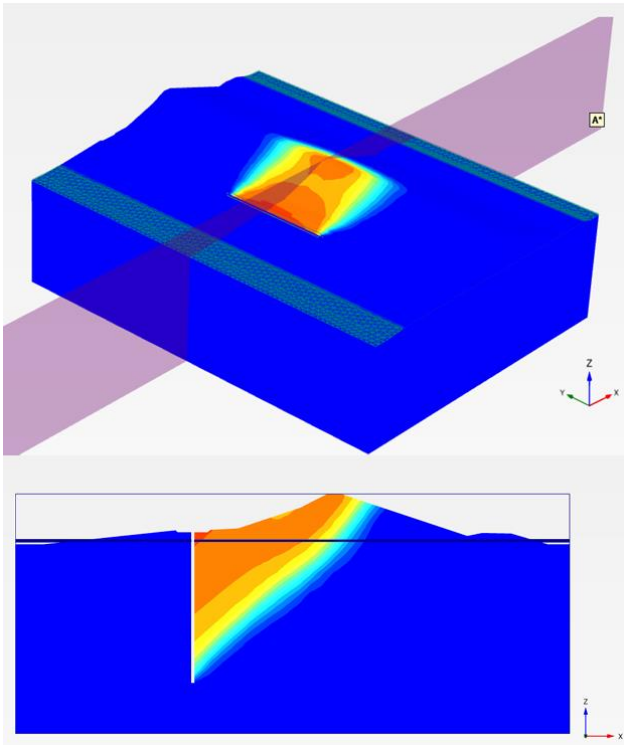

Figure 20. 3D FEM stability assessment of a dam during cutoff excavation: displacement contours associated with mobilization of a failure surface: 3D view (top) and 2D section through the middle of the failure surface (bottom).

Besides stability analysis, other fundamental axis are the development of the cement-bentonite mixes, in order to render its rheology predictable and reliable, and the fine tuning of construction sequences so that the required safety factors are met for all the load scenarios.

6 FUTURE DEVELOPMENTS

It is not possible to avoid mentioning the spectacularly fast development of machine learning and other AI techniques.

While construction equipment has been equipped with a multitude of sensors for decades, and that real time data transfers from drilling rigs to and from cloud storage has been done for several years now, these new techniques seem very promising in terms of making the most of the vast amounts of data being generated.

These will be important not only in terms of production (e.g. fine tuning of excavation rates), or quality control (e.g. articulation with BIM models), but also in the development of new technical solutions.

7 CONCLUSIONS

In view of the maintenance requirements of existing dams, and of the likelihood of an increase in dam construction to deal with the cumulative effects of diminishing storage, growing water scarcity, and increasing energy demands, growth of dam-related work is foreseeable in the upcoming years. The construction of cutoffs, which are a fundamental part of many dams, both for seepage control and for uplift pressure reduction, should similarly experience growth.

The techniques presented in this paper, while not all groundbreaking, show a track record of continuous and sustained development by the profession, with marked improvements in the applicability, efficiency and quality of the works that can be built. The efforts on sustainability and the need for limitation of carbon emissions are highlighted by the search for alternative binders. A full range of methods is available to improve and verify the quality of cutoffs, serving the needs of a wide range of dam projects, from the simplest and shallowest green field cutoff to the deepest and most challenging remediation project.

Future developments are likely to continue to focus on the axis above, but the accelerating developments of machine learning and other AI techniques should bring valuable insights into the large amounts of data that construction sites and equipment now generate.

ABSTRACT: The European Large Geotechnical Institutes Platform (ELGIP) is a group of 15 leading research organizations in geotechnical engineering that aims to promote internationally the profession and its societal relevance. One of ELGIP's objectives is to drive sustainability in geotechnical engineering and establish a common platform for sustainable practices and knowledge transfer across national borders in Europe through its working group on Sustainability. This paper summarizes the latest efforts of ELGIP's Sustainability working group (WGS), with contributions from ten national organizations in Europe. The current practice in geotechnical engineering is evaluated both qualitatively, by highlighting selected projects with significant components related to sustainability within WGS, and quantitatively, by presenting the level of involvement of the partner institutes in relation to each specific sustainable development goal (SDG) of UN's 2030 Agenda. Finally, general recommendations with respect to the future development of current practice are made based on the outcome of the evaluation. The paper demonstrates the important role that geotechnical engineering can play in achieving sustainable development goals.

RÉSUMÉ: Le Groupement Européen des Grands Instituts de Géotechnique (ELGIP) comprend 15 organismes de recherche dans l'ingénierie géotechnique et vise à élever au niveau international la profession et sa pertinence sociétale. L'un des objectifs de l'ELGIP est de promouvoir le développement durable dans l'ingénierie géotechnique et d'établir une plateforme commune pour les pratiques durables et le transfert de connaissances au-delà des frontières nationales en Europe par son groupe de travail sur la durabilité. Ce document résume les derniers efforts du groupe de travail avec des contributions de dix organismes nationaux en Europe. La pratique actuelle de l'ingénierie géotechnique est évaluée qualitativement, en mettant en évidence projets sélectionnés avec des composantes significatives liées à la durabilité au sein de ces organisations, et quantitativement, en présentant le niveau d'implication des instituts partenaires par rapport à chaque objectif de développement durable (ODD) de l'Agenda 2030 de l'ONU. Enfin, des recommandations générales concernant le développement futur des pratiques actuelles sont formulées sur la base des résultats de l'évaluation. Le document démontre le rôle important que l'ingénierie géotechnique peut jouer dans la réalisation des objectifs de développement durable.

Keywords: Geotechnical engineering; research; sustainability; knowledge transfer; collaboration.

1 INTRODUCTION

The evolution of society in relation to the sustainable development goals (SDGs) set by UN's 2030 Agenda for Sustainable Development (UN, 2015) is a very complex process easily affected by factors such as lagging policy making and implementation, or concurring crises. Rather than being independent, such factors tend to cascade and produce cumulative effects and chain reactions, given their origin in the interlaced environmental, economic, and social threads of the society. Typical examples for the past decade are the

COVID-19 pandemic or the armed conflicts, which, beyond the tremendous death tolls, cascaded in food shortage, job losses, supply chain issues, increasing energy costs, or inflation, just to mention some of their global and local effects.

Unfortunately, UN's evaluation of the current global state of progress towards the SDGs of the 2030 Agenda indicates a rather slow implementation and even regression in some specific areas, caused mainly by such interdependent crises experienced in the past years. Consequently, the fundamental questions that need a timely answer are "Where are we now?" and "Where are we heading?". Sharply defined answers to these questions can identify necessary steps required to achieve the desired progress on the path towards a more sustainable future, as shown by the Global Sustainability Report 2023 (Miranda et al., 2023).

Experience has shown that sustainable progress is impossible while focusing only on specific areas of interest. The compounded risks affecting the various interlaced threads of the society call for a holistic approach in evaluating the current state and planning mitigation and development strategies. Collective effort at all levels is essential, along with a clear path of knowledge transfer between society and decision-makers.

In this context, the role of research cannot be overstated, as it has the potential to provide valuable insights and guidance in decision-making processes to achieve the SDGs. Catalysed by the complex interplay of the compounded risks projected on interdependent societal layers, the research interest related to UN's SDGs has advanced significantly in the past decade, and an exponentially increasing number of relevant scientific contributions has been generated (Figure 1).

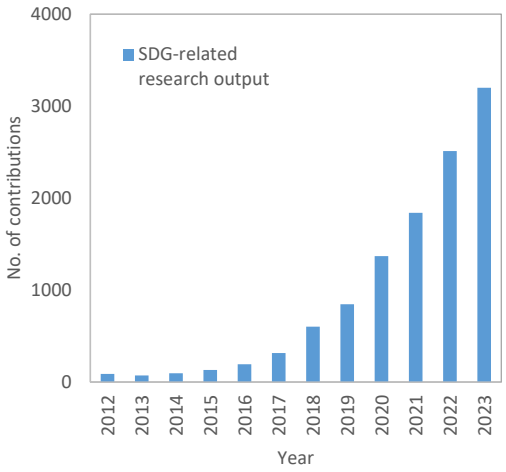

Figure 1. Scientific output relevant to the SDGs generated in the past decade (SCOPUS, 2024).

According to SCOPUS the contributions cover 27 different fields of interest, out of which social sciences, environmental science, and engineering are the most relevant ones, collectively attracting a total number of contributions comparable to the other fields cumulated.

Geotechnical engineering, as part of the broader engineering area and with ramifications in environmental sciences, has the potential to contribute significantly to the advancement of UN's Sustainability Agenda. The current paper provides a summary of the sustainability status in geotechnical engineering research reported by members of ELGIP, with the intent to encourage further development in this direction, catalyse the knowledge transfer from ELGIP to the decision-makers, and accelerate the achievement of the relevant SDGs.

2 METHODOLOGY

The results presented herein were obtained by processing the answers provided by the members of the Working Group Sustainability (WGS) of ELGIP to three main questions: (i) "What is the current strategy or policy for sustainable development in your organisation?" (ii) "How do you work towards specific sustainable development goals (SDGs) from a geotechnical perspective?" (iii) "What is the ongoing and recently finished work of relevance to sustainability?" The detailed input can be found in the recently published report of ELGIP (Christiansen et al., 2023).

Out of the 15 ELGIP members, 10 organisations from 10 European countries (Figure 2) are part of WGS and provided input on their current strategies and policies for sustainable development, and their specific activities and projects towards achieving sustainability goals from a geotechnical perspective. These organisations are Spanish National Public Works Research Centre (CEDEX), Czech Technical University in Prague (CTU), Swiss Federal Institute of Technology in Zürich (ETHZ), Norwegian Geotechnical Institute (NGI), Polish Geological Institute (PGI), Politecnico di Torino (PoliTo), Swedish Geotechnical Institute (SGI), Technical University of Darmstadt (TUDa), Université Gustave Eiffel (UGE), and University of Maribor (UM).

Initially, a qualitative evaluation of the activities of WGS members is conducted. The main relevant topics are identified using approximately 60 recent projects provided by each institute and classified in relation to sustainable development. Subsequently, most significant projects (Table 1) are briefly described to

showcase their relevance to sustainability. Moreover, the leading areas of interest for future development of geotechnical engineering within the framework of sustainability are identified and briefly discussed.

In the next step, the activity is evaluated quantitatively by roughly assessing the level of involvement in relation to the SDGs. The assessment is performed by determining the number of institutes of WGS actively working towards each SDG. The quantitative evaluation is put into perspective using the global level of achievement of the SDGs estimated by averaging the realisation of the specific targets presented by Miranda et al. (2023) for each SDG in UN's Global Sustainability Report 2023.

Figure 2. European countries represented in the WGS of ELGIP.

3 RESULTS

3.1 Qualitative evaluation of current activities in relation to sustainability

The qualitative evaluation revealed four topics in which WGS members are involved: (1) climate change, (2) environmental impact of (geo)structures, (3) circularity and reuse of geomaterials and (4) social sustainability (Table 1). In terms of SDGs, the most relevant ones, attracting most of the activity in geotechnical engineering are:

- SDG-7 - Ensure access to affordable, reliable, sustainable, and modern energy for all
- SDG-9 - Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation
- SDG-11 - Make cities and human settlements inclusive, safe, resilient, and sustainable
- SDG-12 - Ensure sustainable consumption and production patterns

Further SDGs were reported by the WGS members covering almost the entire spectrum of goals, with the exception of Poverty Eradication (SDG-1), Zero Hunger (SDG-2) and Peace, Justice and Strong Institutions (SDG-16). The apparent irrelevance of these goals to geotechnical engineering could be explained by a rather strict interpretation of their definitions by the WGS members. Given the interdependent nature of SDGs, geotechnical engineering makes indirect contributions to these seemingly unrelated goals by addressing societal needs relevant to SDGs 7, 9, 11 and 12 with effective solutions.

Moreover, less technical goals such as gender equality (SDG-5), decent work and growth (SDG-8), and reduced inequalities (SDG-10) are, on the one hand, an essential part of the intramural organisational strategies of the institutes often including established and dedicated internal strategic-operational units. On the other hand, these aspects can be found in the implementation of the various projects, in which the institutes are involved.

As an example, project GEOLAB (GEOLAB, 2021), involving 11 experimental installations from nine European countries with the purpose of addressing challenges faced by the Critical Infrastructure of Europe (relevant to SDGs 7, 9, 11, 12), is committed in its implementation to SDGs 5, 8 and 10. More specifically, the project contributes to the reduction of inequalities between potential researcher groups with unequal financial and technical means (SDG-10) by offering free access to experimental infrastructure. Besides the essential role of scientific merit and relevance of the intended research, the free access is granted by taking into account the participation of female (SDG-5) and early stage (SDG-8) researchers, which tend to be under-represented in such projects. Moreover, the specific composition of the management team and international advisory board of GEOLAB was set-up to meet minimum criteria related to gender balance.

Further on, the activity of WGS members related to ongoing and recently completed projects relevant to sustainability is briefly summarized to offer a clearer overview of the specific actions currently driving the progress towards the SDGs at the European level. Table 1 provides a summary of some major projects mentioned by the WGS, categorized by topics.

Table 1. Collaborative European projects relevant to sustainability divided into topics.

Topic	Projects
Climate change	GEOLAB (GEOLAB, 2021)
Environmental impact of (geo)structures	SENSE-ACT (SENSE, 2023)
Circularity and reuse of geomaterials	ARV (ARV, 2022), URGE (URBACT, 2022), CINDERELA (CINDERELA, 2018)
Social sustainability	FP3-IAMRAIL (Europe's Rail, 2022) RID (RID, 2023) REMEDY (Langford et al., 2021) 2015 Gorkha Earthquake Relief (Amdal et al., 2018)

For topic (1) climate change, most projects listed by WGS members focus on three main sub-topics: (i) identification/detection/assessment, mapping and visualisation, (ii) prevention, and (iii) mitigation/adaption strategies against natural hazards (e.g. landslides, flooding) associated with climate change (Insana et al., 2021).

In terms of collaborative involvement at European level on this topic, the already mentioned project GEOLAB (ongoing) (GEOLAB, 2021) stands out as a one-stop-shop of high-end physical research infrastructure. The aim of the project is to address challenges associated with climate change faced by the critical infrastructure of Europe by facilitating ground-breaking research and innovation through experimental testing. In this sense, a wide spectrum of problems related to climate change, which do not focus necessarily on one of the sub-topics mentioned above, are investigated. Furthermore, geotechnical institutes from France, Italy, Norway, and Sweden are involved on a relatively independent basis with the topic of nature-based solutions (NBS) in relation to coastal geotechnical infrastructure, river dykes, large embankments, land use and land cover. The use of NBS for both prevention and mitigation/adaption strategies against the impact of climate change is explored in the relevant projects.

Within topic (2) environmental impact of (geo)structures, more than 20 ongoing or recently finished projects were indicated by the WGS members, dealing with subjects such as: life-cycle assessment (LCA) and eco-geo-analysis tools for geotechnical structures, management of tailings storage, construction on contaminated soils, design methods achieving the reduction of carbon footprint of (geo)structures without compromising safety, geospatial tools for site optimization and environmental impact reduction, thermal energy, and geo-structures. The high number of nationally funded projects is an indication of the strong interest of local decision-makers in the various applications of this topic in relation to geotechnical engineering.

A notable example of collaborative involvement in this topic is the project SENSE-ACT (ongoing) (SENSE, 2023), which involves 14 partners from 10 countries (four of which are outside Europe). The main objective of the project is to demonstrate reliable and cost-efficient CO2 storage solutions using ground surface deformation detection combined with geomechanical modelling and inversion to provide information on pressure distribution and hydraulic behaviour of storage sites.

Topic (3) circularity and reuse of geomaterials includes projects mostly concentrated around three sub-topics: (i) re-use and life-cycle extension of existing structures, (ii) circularity of materials and (iii) management of waste and earth materials. In this area of interest, multiple projects stand out by their large-scale collective effort at European level.

Project ARV (ongoing) (ARV, 2022) involves 35 partners from eight European countries and aims at implementing six large-scale demonstration projects of climate positive circular communities and subsequently developing guidelines and a policy framework for future energy-efficient, circular, and digital solutions in the construction industry.

Project URGE (recently finished) (URBACT, 2022) involved nine European cities, which committed to exchange knowledge and experience, while implementing integrated urban policies focused on circularity in the construction tasks. Similarly, project CINDERELA (recently finished) (CINDERELA, 2018) involved 13 partners from seven countries and aimed at developing and demonstrating a new business model for companies in setting up successful circular economy business cases based on waste-to-resource opportunities. The project provided full-service assistance in terms of know-how for manufacturing and application of secondary raw materials in buildings and civil engineering works.

The last topic identified during the qualitative evaluation of the activity of WGS members is (4) social sustainability, with subtopics such as sustainable communities and infrastructure, or improved living conditions. One of the main projects reported here is FP3-IAM4RAIL (ongoing) (Europe's Rail, 2022), involving 94 partners at European level. The project aims to provide innovative technical requirements, methods, and solutions to minimise lifecycle costs and extend service life while meeting safety requirements and improving the reliability, and capacity of the railroad system. As expected for such a

large project, its impact extends beyond the topic of social sustainability. An interesting aspect investigated is the use of alternative materials in the railway track section, a typical application of the topic related to circularity and reuse of materials mentioned before.

Further projects worth mentioning in this topic are: (i) the earthquake relief project (finished) (Amdal et al., 2018) supported by FORUT, NGI and Engineers Without Borders in Norway, providing geotechnical assistance for the reconstruction of primary schools in the areas affected by the 2015 earthquake from Gorkha (M7.8) in Nepal; (ii) the RID project (ongoing) (RID, 2023) aiming at developing safe infrastructure by up-to-date guidelines for investigation and selection of soil improvement solutions for national roads and motorways in Poland; (iii) the REMEDY (recently finished) project (Langford et al., 2021) aiming at reducing the risk of damage to neighbouring structures caused by groundworks during and after execution of a project.

The qualitative evaluation of the current activities of WGS members provided the opportunity to explore some of the main directions for future development in geotechnical engineering in relation to sustainability. In this context, the first identified area of interest is circularity. The circular use of materials and structural elements (e.g. existing foundations) is already engaging the geotechnical community and is expected to generate even more interest while new methods for reusing, recycling and repurposing of construction materials are being developed.

A further area of interest is the use life-cycle assessment (LCA) in geotechnical design. This is already established in general product development, where the evaluation of environmental impact and costs are done using LCA. Nevertheless, this concept has not been extensively addressed and used in geotechnical engineering. The implementation of an LCA-based perspective is expected to optimize geotechnical design and increase its sustainability levels.

Energy optimization is a further area of interest expected to gain more traction in the years to come, considering the intensive use of energy in geotechnical works and the potential of improving associated processes in terms of energetic efficiency. In addition to sustainability concerns, the recent European energy crisis resulting from the conflict between Russia and Ukraine underscores the critical importance of efficient energy use across all sectors.

Sustainability assessments are expected to become more important in the decades to come. With the second generation of Eurocodes to be published and implemented at national level roughly by the end of 2027, sustainability will be one of the elements that must be considered during design of geotechnical structures. New methods will be required to evaluate projects from another perspective, by taking into account factors such as impact on environment and economy, equality and social justice.

Finally, yet importantly, nature-based solutions (NBS) emerged as a further area of interest for future developments on geotechnical engineering. On the backdrop of sustainability enhancement of geotechnical structures provided by the second generation of EC7, the use of renewable resources, environmentally friendly materials calls for implementation of NBS for a wide range of problems. Already attracting attention in countries with extensive coastal exposure (France, Italy, Norway, Sweden), where the effects of erosion processes can be mitigated using NBS, the topic is expected to become more relevant in further areas of geotechnical engineering.

As briefly mentioned before, the identified areas of interest for future development overlap with the general rules, measures and strategies for sustainability that will be included in the second generation of Eurocodes relevant to geotechnical engineering. This is a clear confirmation of the significance of sustainability at European level, and an indication of the ongoing common efforts of the relevant national institutions to promote this aspect in geotechnical engineering.

3.2 Quantitative evaluation of current activities in relation to sustainability

The results of the qualitative evaluation presented in the previous section demonstrate that the WGS members generally have holistic strategies in terms of sustainability, contributing with their activities and organisational strategies to the entire spectrum of SDGs. However, the focus of this paper is more on the activities of the WGS members and their specific projects with outcomes influencing the local, national and global achievement of the most relevant sustainability goals.

On average, each WGS member reported most of their projects as relevant to five out of the 17 SDGs of the 2030 Agenda, indicating a high level of commitment to sustainability, which goes beyond the sphere of science and technology. Figure 3 shows the distribution of the cumulated self-assessed activity of WGS members along the entire range of SDGs. As mentioned in the previous section, the current activity is mostly concentrated on topics such as affordable and clean energy (SDG-7), industry, innovation and infrastructure (SDG-9), sustainable cities and communities (SDG-11), and responsible consumption and production (SDG-12). The emphasis on the

specific SDGs is not a surprise, considering the specific character of applications of geotechnical engineering. Nevertheless, it is still unclear to what extent this is caused by a spatial variation of focus and development among European countries and how much it originates from a rather subjective interpretation of the SDG definitions.

In addition to the activity distribution, Figure 3 displays the estimated level of achievement for each SDG. On average, the current global progress towards all SDGs rates at 2.8 out of 5, which means that the current state is far from the final target. Generally, the influence of the recent crises such as the COVID-19 pandemic, the sharp increase of cost-of-living, armed conflicts and natural disasters can be clearly seen in the relatively low level of achievement combined with significant recessive trends outlined in the UN report.

Interestingly, SDG 9 related to industry, innovation, and infrastructure, which displays the highest level of achievement, is the same goal that attracts most activities and projects of WGS members (i.e. all participating institutes have reported project with outcomes contributing to this goal). In this context, a correlation can be seen between increased activity of relevant stakeholders, such as the geotechnical institutes in this case, and an increased level of achievement. The high number of projects also confirms the increased research and development spending from the part of the decision-makers acknowledged by Miranda et al. (2023).

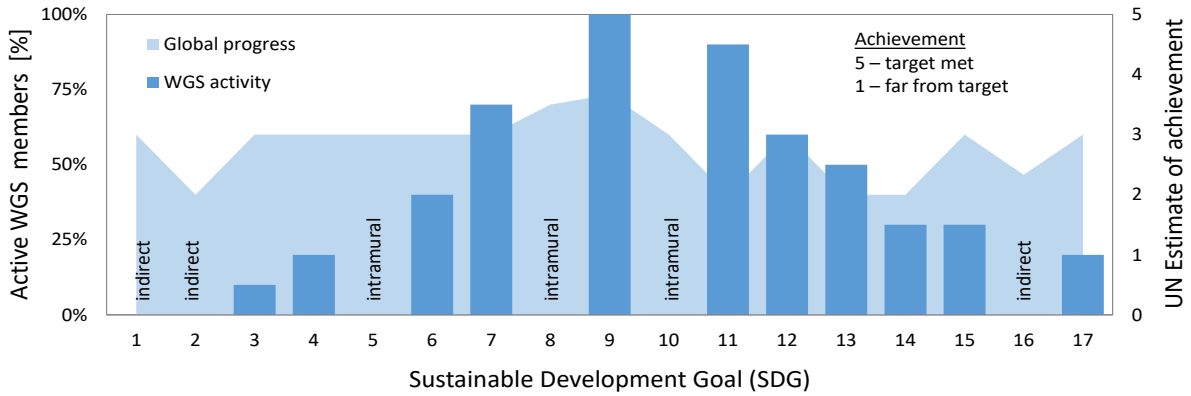

Figure 3. Involvement of WGS members in SDGs and UN estimated achievement according to Miranda et al. (2023).

4 CONCLUSIONS AND RECOMMENDATIONS

In the assessment of the sustainability status of ELGIP approximately 60 projects from 10 European geotechnical institutes were analysed. The assessment included a qualitative and quantitative evaluation of the activities of the institutes in relation to sustainability.

The qualitative evaluation of the projects indicates that geotechnical engineering can play a significant role in sustainable development. The four main sustainability-related topics identified in the assessment include projects with direct relevance to 14 out of the 17 SDGs of UN's 2030 Agenda for Sustainable Development. Nevertheless, the number of institutes participating in the evaluation is a strong limitation of the results presented herein. Consequently, more data with a higher level of granularity is required to prove clearly that the wide range of SDGs to which WGS members contribute is the result of the spatial variation of focus and development among European countries and not just a consequence of the subjectivity of the institutes while interpreting the description of the goals.

Various institutions may hold different perspectives regarding their contributions to SDGs. The self-assessed extent of the contributions strongly depends on the acquaintance with a goal definition: a cursory understanding of the goal might lead to a more reduced self-assessed contribution, whereas a more thorough one could yield a different conclusion. This complexity is a challenge in assessing an institution's impact on the SDGs solely through their self-reported alignment with specific goals.

Furthermore, the qualitative evaluation revealed the importance of pursuing less technical SDGs in the definition, organisation, and implementation of projects (e.g. gender balance targets, social inclusion measures). In this way, sustainability levels can be improved irrespective of the size and technical scope of the project.

Although not specifically analysed in this paper, the intramural adoption of a sustainability perspective at the organisational level of the institutes is a further important contribution towards a more sustainable community and has the potential to add the same perspective to the activities of researchers steering them towards more sustainability-oriented topics.

The quantitative evaluation of the projects confirms the holistic approach of the WGS members towards sustainability. Nevertheless, the limited amount of data collected and compiled in the assessment represents a limitation of the general applicability of the results, as already mentioned in the case of the qualitative analysis.

The correlation observed between the concentrated activity of the institutes towards SDGs 7, 9, 11 and 12, and the increased level of global achievement reported by Miranda et al. (2023) demonstrates the positive effect of collective effort. Moreover, broadly defined collaborative projects have the potential to contribute to multiple SDGs and to attract more funding. In this context, collaboration proves to be the key to a successful sustainable approach, and it is highly recommended in future projects, considering that sustainability-related challenges are global rather than national.

Finally, yet importantly, the results showed that increased research and development spending generates a greater number of projects in a specific area of interest, and consequently leads to a higher level of achievement of relevant SDGs. In this sense, reinforcing cross-network dissemination between research institutes, decision makers, funding agencies, businesses, and society is highly recommended. This can be done both nationally, in the case of individual WGS members, and internationally at European level, in the case of the entire ELGIP consortium, by using simple tools such as regular sustainability status reports as a basis for dialogue.

ABSTRACT: Correct measurement of emissions from the geotechnical industry has been a challenge for the last 10 years and remains a key process to achieving the environmental transition objectives towards 2050. In this context, there have been multiple calculation tools developed in Europe, coming from different actors, such as contractors, consultants, federations, and associations. In view of their importance and multiplicity, it is essential to evaluate their use, reliability, and effectiveness for a correct orientation of future efforts. This study aims to analyse the use of European calculators in a practical way at the local and project level, as well as their reference position worldwide. The role of the calculators coming from geotechnical associations and federations as regulators and guarantors of transparency in the sector has been another important axis of evaluation. And finally, the complexity and the level of detail required in the indicators of the tools to achieve the highest possible utilization and support of the commercial departments in a project bidding phase were compared.

RÉSUMÉ: La mesure correcte des émissions de l'industrie géotechnique a été un défi au cours des dix dernières années et reste un processus clé pour atteindre les objectifs de la transition environnementale à l'horizon 2050. Dans ce contexte, de nombreux outils de calcul ont été développés en Europe, provenant de différents acteurs, tels que des entrepreneurs, des consultants, des fédérations et des associations. Compte tenu de leur importance et de leur multiplicité, il est essentiel d'évaluer leur utilisation, leur fiabilité et leur efficacité afin d'orienter correctement les efforts futurs. Cette étude vise à analyser l'utilisation des calculateurs européens de manière pratique au niveau local et au niveau des projets, ainsi que leur position de référence au niveau mondial. Le rôle des calculateurs provenant des associations et fédérations géotechniques en tant que régulateurs et garants de la transparence dans le secteur a été un autre axe d'évaluation important. Enfin, la complexité et le niveau de détail requis dans les indicateurs des outils pour obtenir la meilleure utilisation possible et le meilleur soutien des départements commerciaux dans la phase de soumission d'un projet ont été comparés.

Keywords: Life cycle assessment; carbon footprint; calculator; environmental product declaration.

1 INTRODUCTION

Over the past 10 years, it has become evident that the building and construction sector plays a crucial role in global energy consumption and carbon emissions. In 2021, the building and construction sector alone was responsible for 37% of global energy and process-related carbon dioxide (CO2) emissions, with carbon emissions from building operations reaching a unprecedented high of 10 GtCO2, and those related to

materials production (e.g. concrete, steel, aluminium, glass and bricks) contributing an additional 3.6 GtCO2.

The European context of regulations and directives on sustainable development and energy efficiency of buildings (RE2020, CSRD, Tertiary Decree, European Taxonomy, etc.) is getting stronger and stronger and is pushing companies in the building sector to better measure the emissions released during the manufacturing, transport, construction, and end-of-life phases of all built infrastructures. But this momentum is even more driven by the expectations of clients and investors, who already at the project bidding stage are particularly interested in knowing the environmental impact of their future projects.

Geotechnical engineering projects play a large role in the civil infrastructure system, making substantial contributions to the construction sector in terms of energy and resource consumption. As such, practitioners can apply sustainability as a design criterion and to value that effort by presenting emission calculations and comparisons to clients. To accomplish this, several tools have been developed over the past decade that quantify embodied carbon through environmental product declarations (EPDs) or life cycle assessments (LCAs).

The European Federation of Foundation Contractors (EFFC) and the Deep Foundation Institute (DFI) developed one of the first tools to calculate the embodied carbon of geotechnical construction projects, the EFFC/DFI Carbon Calculator, a decade ago.

However, other tools have been used for some time in the market, such as (EC3, eTool, ECOM, SimaPro, e-CO2ncerned). A comparative review of these tools and their use over the last decade was conducted to understand the differences in scope, calculation methods and applicability to the industry. The market reaction to the use of the EFFC-DFI calculator by commercial teams has been analysed to understand the necessary improvements to be made to the tool.

2 ENVIRONMENTAL IMPACT QUANTIFICATION METHODS

Numerous methodologies are available for evaluating environmental impacts, each serving distinct purposes.

Among the most used approaches are life cycle assessment, carbon footprinting, and environmental product declarations. Although these methods share certain similarities, each has distinct characteristics and adheres to different standards.

2.1 Life cycle assessment

Life cycle assessment (LCA) is a systematic analytical framework to evaluate the environmental impacts of a product or system over its entire life cycle. Several organizations have created standards to define the perimeter, processes and principles of the calculations, however, the most recognized procedures are included in the ISO14000 standards. It is primarily concerned with the process-based methodology, which is usually defined in four phases: goal and scope definition, life cycle inventory (LCI), life cycle impact assessment (LCIA), and interpretation (ISO 2006).

The scoping phase of an LCA is often described as "cradle-to-grave" (A-C), which includes impacts from the raw material extraction phase to the end of the useful life of the product or system, or "cradle-to-gate", which only includes impacts up to the last stage of the manufacturing process before the product passes through the site (A1-A3).

The LCI quantifies the relevant environmental flows of inputs (e.g. raw materials, water and energy resources) and outputs (e.g. emissions to air, water and soil and waste generation) of the system. Then, in the LC phase, the environmental flows contained in the LCI are translated into environmental and human health impact indicators. A LCI and an LCIA can be compiled in a spreadsheet or in a specific computer program, as explained later in this document.

2.2 Carbon footprint

Carbon footprinting (CF) and LCA are related but distinct methods for assessing the environmental impact of a product or system. Although CF applies life cycle principles and accounting methods, it is based on a single impact category: GHG emissions related to climate change, often quantified as GWP. LCAs, on the other hand, evaluate other environmental impacts, such as energy use, water consumption and air pollution (Motta 2022).

As with LCA, several standards exist to standardize CF procedures for both corporate and product analysis. The Greenhouse Gas Protocol Corporate Standard (GHG Protocol) is the most widely used international emissions accounting standard and has served as the basis for most other standards, including those developed by ISO.

2.3 Environmental product declaration

An EPD is a verified and registered document that conveys information on the life-cycle environmental impact of a product adhering to standards like ISO 21930 and EN 15804 for the building and construction

sector (EN 2012; ISO 2017). These provide a valuable open data source for comprehensive LCAs.

3 EXISTING TOOLS: PHASE 1

In the first stage of the study, five carbon calculation tools from organizations, associations and external suppliers were compared. A summary of these is presented in Table 1.

Table 1. Summary table of major characteristics of the carbon calculation tools.

Tool	EC3	eTool	Embodied Carbon Estimator (ECOM)	SimaPro	EFFC DFI Carbon Calculator
Organization	Building Transparency	Cerclos	Structural Engineering Institute	Pre Sustainability	EFFC-DFI
Activity Sector	Building	Building	Structural Engineering	Several	Geotechnical Engineering
Geographic Regions	Global	Global	North America	Global	Global*
Standard	ISO 21930 EN 15804	ISO 14040/44,27001, 21930 EN 15978, 15804 PAS 2080	EN15978	ISO 14040/44	ISO 14067 PAS 2050:2011
Impact Categories	GWP**	GWP **	GWP	GWP **	GWP
LCA Scope	A1-A3	A-C	A1-A3	A-C	A-B, C2
LCIA Method	Various***	CML	CML	Various***	Assigned Factors***
BIM Plug-In	✓	✓	×	×	×
Cost	Free	600-7,500 USD/yr (based on features)	Free	2,600-7,275 EUR/yr (based on features)	Free

3.1 Embodied carbon in construction calculator (EC3)

EC3 is a web-based tool developed by Building Transparency, a nonprofit organization, that allows users to determine the embodied carbon of building materials and structures based on third-party verified EPDs.

An important characteristic of this tool is the life cycle scope included in the GWP calculation, considering a 'cradle-to-gate' life cycle.

Two of the most notable advantages of this tool are that it is free and user-friendly. The interface makes it extremely easy for inexperienced users. It also takes into account uncertainties, providing more realistic ranges of GWP than if a single, deterministic value were given. However, the scope of the tool is more oriented to superstructures, which may limit its applicability to other types of projects.

3.2 ETool

ETool, a web-based application developed by Cerclos, serves as a tool for evaluating the environmental impacts of projects and identifying areas for improvement. eTool offers templates for building components, energy, and water use. Users have the flexibility to choose from these templates or create their own to determine GHG emissions. This tool provides a financial cost analysis, combining environmental impact assessment with financial analysis.

eTool offers robust functionality for the environmental and financial assessment of projects, but can be difficult to understand for users unfamiliar with sustainability assessment and life-cycle analysis.

eTool focuses on building and construction projects, which restricts its applicability and the quality of data related to other sectors.

3.3 ECOM - Embodied Carbon Order of Magnitude

Embodied Carbon Order of Magnitude (ECOM) is a web-based estimator developed by the Structural Engineering Institute (SEI) that allows users to determine approximate embodied carbon of material products, assembling of framing, or entire structural frame. This tool relies on data sourced from publicly available EPDs.

The interface is easy to comprehend and does not require significant research prior to use. However, users are limited to a small selection of material types and strengths and cannot model life cycle stages beyond material production. Consequently, results may not provide a comprehensive assessment of the total environmental impacts associated with structural projects.

3.4 SimaPro

SimaPro is a software and web-based tool developed by PRe-Sustainability widely used for sustainability reporting, carbon, environmental, social and water footprinting, biodiversity assessments, and sustainable product design.This tool allows users to model LCAs of products, processes, and systems, as well as auxiliary products within a life cycle chain.

SimaPro houses an extensive database of LCI data, which can be used in a wide range of industries and sectors.

SimaPro offers tools to generate comprehensive reports and visualizations of calculated impacts. While SimaPro is a powerful and multidisciplinary tool for performing LCA, it has some potential drawbacks, such as cost and complexity.

3.5 EFFC-DFI Carbon calculator

The EFFC-DFI Carbon Calculator is an Excel-based tool dedicated to calculating embodied carbon of foundations and other geotechnical systems. The calculator accounts for several emission sources within the embodied carbon calculation, including material manufacturing, material transportation, energy consumption, people's transport, equipment transportation, equipment manufacturing, waster transportation, and waste management.

The EFFC-DFI calculator requires a series of inputs for each emission source category. For instance, in material manufacturing, users are prompted to specify material type, quantity, and additional information like cement type and steel shape.

These details enhance the accuracy of embodied carbon estimates, recognizing that emission factors differ based on these aspects.

It is important to highlight that this tool assigns recommended emission factors from different databases for each input, although users have the option to utilize country specific databases for materials (France, United Kingdom, and United States) and electricity grids, following ISO 14067 and PAS 2050:2011 standards.

Moreover, users can create subprojects, allowing them to compute the carbon footprint of specific project segments. These can be consolidated to model the embodied carbon of an entire project. Results can be generated for subprojects, projects, and comparisons between multiple projects. The calculator automatically creates pie and bar charts of results, providing a visual representation of the data.

5 EXISTING TOOLS: PHASE 2

In phase 2 of the study, we have incorporated a look at possible internal tools developed by construction companies, which are not accessible to the public, but are used in the bidding stage, and what impact they may have with those already studied.

The French global Group VINCI has been taken as an example, with implementation in more than 120 countries around the world, and with a specific business line of foundations. The Group has developed the e-CO2ncerned calculator, which includes a specific development for geotechnical activities.

E-CO2ncerned is a Carbon Footprint tool common to all VINCI entities that allows both to calculate the greenhouse gas (GHG) emissions of a project and to compare the GHG emissions of several variants. It is Carbon Footprint® certified by the Bilan Carbone Association and ADEME. The calculator started as an Excel file, which was later moved to a web development. The calculator counts emissions with a VCA approach, from "cradle-to-grave".

The emission factors (EF) used in e-CO2ncerned come from different databases: ADEME (Environmental and Energy Maitrise Agency) carbon database, EcoInvent database, Environmental and Health Declaration Sheets (FDES) from INIES, and VINCI Group internal data.

The web interface used is one of the advantages of the tool, as well as the reports that are automatically

obtained at the end of the project, which allow to compare a base solution with an alternative in a quick way and with appropriate graphics.

Likewise, the possibility of incorporating in the analysis other stages of the project that are not specific to geotechnical engineering, according to user comments, has allowed to analyze the integrity of the project and shows the client a general and wide vision of the project.

However, being an internal calculator, at a tender stage, it has been impossible for the client to compare the environmental impacts with those of other competitors' tenders.

Feedback from users has shown a lack of confidence on the part of clients in the emissions factors used, due to their internal origin.

6 COMPARISON BETWEEN TOOLS

To date, the EFFC-DFI Carbon Calculator is the only tool specifically designed to model environmental impacts of geotechnical projects. Other internal calculators for individual companies, such as the e-CO2ncerned calculator, have geotechnical modules.

In contrast, tools like EC3 and eTool primarily target the building sector, while SimaPro offers broader applicability across various industries.

While it is possible to adapt these tools for geotechnical projects, doing so requires extensive data manipulation to align inputs with the specific requirements of each calculator.

The EC3 calculator, on the other hand, allows users to specify certain material characteristics, but this is dependent on EPD availabilities. Other more comprehensive tools, such as SimaPro, allow users to incorporate specific elements, such as aggregates, based on available LCI datasets, leaving the practitioner to correctly manipulate inputs to model different concrete contributions.

The e-CO2ncerned calculator is limited to a list of materials, with specific strengths, which could be limiting in case of adding a new material.

Another point of comparison is ease of use. Although tools like SimaPro offer more flexibility in modeling processes and scopes, this introduces a further level of complexity. This could add a barrier for new users. In contrast, the EFFC-DFI Carbon Calculator streamlines much of the user activity required in other tools, making it more accessible and efficient to implement. However, this comes with some trade-offs, as users are limited to a predefined set of materials, energy, and transportation options based on the emission factor database.

A comparative study of a point project has been carried out with the EFFC and e-CO2ncerned calculators, presenting base solution and alternative solution data, and analyzing the feedback obtained by the client. A summary of these is presented in Table 2.

The base solution presented included: Sheet Piles Anchors; Soil improvement, RC, Earthworks, Dredging, Pavement, and utilities.

Alternative solution: Slurry wall, Starsol Piles, Anchors, Soil improvement, RC, Earthworks, Dredging, Pavement, and utilities.

Table 2. Total emissions expressed in (TCO2eq).

Tool	Emissions basic solution	Emissions alternative solution
EFFC-DFI	4518	2716
e-CO2ncerned	3700	2900

The differences in emissions are mainly based on the EFFC-DFI concept of ratios versus a detailed approach in the e-CO2ncerned calculator, based on power and equipment usage.

From an action analysis point of view, it was concluded that detailed energy consumption analyses can be useful to understand future actions to be implemented by the company on that topic, such as Scope 1 and 2 emission reduction trajectories. However, in the overall view of a project, and for the practical purposes of showing general data to a client, the ratios are sufficient, since in both cases it is noted that the impact due to materials accounts for about 70% of emissions, and at a tender stage, and when comparing with an alternative design, it is the overall data that is of commercial interest.

To further improve its usefulness, the EFFC-DFI Carbon Calculator could consider expanding its database to include additional input streams, which would allow more diverse processes and systems to be modeled.

7 CONCLUSIONS

Four tools were analyzed in phase 1, in addition to the EFFC-DFI carbon calculator, to understand their scopes of application, standards and characterization factors, calculation methodologies, etc.

Then in phase 2 the EFFC-DFI calculator has been compared with a company internal calculator to understand the commercial impact and customer requirements in Europe.

Based on this study, the following conclusions can be drawn:

- To date, the EFFC-DFI Carbon Calculator is the only tool specifically designed to model the

environmental impacts of geotechnical projects, with a focus on deep foundations.

- eTool, and SimaPro stand out for their ability to perform comprehensive LCA, as opposed to other that are limited to CF assessments. These tools enable users to evaluate multiple environmental impact categories concurrently, allowing for a more holistic analysis that ensures design changes do not inadvertently shift environmental burdens from one category to another.
- From a commercial aspect, the automatic report produced by the e-CO2ncerned calculator makes it easier for commercial teams to sell and compare an alternative solution with a base solution. The EFFC-DFI carbon calculator could improve this aspect and provide a commercial report in Word format.
- The EFFC-DFI Carbon Calculator could be enhanced by expanding its database to encompass additional input flows. This would broaden the range of applications and adaptability to meet specific project needs.
- In most of the applied projects, the EFFC-DFI calculator generates more confidence in the customers than the internal calculators of the companies, because it comes from a neutral organization. One way to further improve the future positioning of the calculator in the market is to obtain new external certifications.

In the context of geotechnical engineering projects, the EFFC-DFI carbon calculator stands out as the most suitable and user-friendly option. By incorporating the recommendations made here, this tool could be further enhanced for improved applicability.

ACKNOWLEDGEMENTS

The authors would like to thank the Deep Foundation Institute (DFI), the European Federation of Foundation Contractors (EFFC), and the American Society of Civil Engineers (ASCE) Geo-Institute (GI) for their support of this effort.

The Cube system - a new diaphragm wall technique for future cities

Le système Cube - une nouvelle technique de paroi moulée pour les villes du futur

F.-W. Gerressen*
BAUER Maschinen GmbH, Schrobenhausen, Germany
**Franz-Werner.Gerressen@bauer.de*

ABSTRACT: Diaphragm wall technique is usually used to construct structural elements in the ground, commonly used for retaining systems, permanent foundation elements or deep ground-water barriers, named Cut-Off-Walls (COW). It can be anticipated that global urbanization and increasing demands on environmental considerations will need to be accommodated in underground space in the future. These trends show an increasing requirement for diaphragm walling in even more complex conditions, especially in inner-city applications with limited space. Therefore, there is the demand to minimize the size of equipment to accommodate such projects. Following this demand, a new trench cutter system, the so-called CUBE System, was recently developed. The complete trench cutter system has been fit into container size dimensions so that it can work in very limited space conditions. In addition, complex conditions in terms of space limitations require specifically adapted solutions for slurry, spoil, reinforcement and concrete handling and the related logistics to ensure smooth production. Due to the limited space requirements, the impact on the surrounding environment is limited. As the system is electric driven, an additional reduction of carbon footprint can be expected. First tests of the system have been carried out and the results will be shared. The paper will explain the construction process and the specific challenges and experiences made for these extreme conditions.

RÉSUMÉ: La technique de la paroi moulée est généralement utilisée pour construire des éléments structurels dans le sol. Elle est généralement dédiée à des systèmes de soutènement, des éléments de fondation permanents ou des barrières de retenue des eaux souterraines profondes appelées "cut-off walls" (COW). Les tendances et projections mondiales nous démontrent un besoin croissant en termes de demandes de projets de productions de parois moulées et ce dans des conditions encore plus complexes en particulier concernant les applications en zones urbaines aux espaces limités. En conséquence de quoi il existe une demande de réduction drastique de la taille des équipements dédiés afin de pouvoir réaliser les travaux. Afin de répondre à cette demande, un nouveau système de création de parois-moulées appelé « CUBE System » a été récemment mis au point. Le système complet a été adapté aux dimensions de containers afin de pouvoir travailler dans des espaces très limités. En outre, les conditions complexes en termes de limitation de l'espace nécessitent des solutions spécifiquement adaptées pour la manutention des boues, des déblais, des armatures, du béton ainsi que pour la logistique connexe afin de garantir une production sans heurts. En raison de cette demande de réduction d'espace, l'impact sur l'environnement est limité étant donné que le système fonctionne à l'électricité. Nous pouvons donc nous attendre à une réduction supplémentaire de l'empreinte carbone. Les premiers essais du système ont déjà été effectués et les résultats pourront être communiqués. L'article expliquera le processus de construction, les défis spécifiques ainsi que les retours d'expériences faits dans ces conditions extrêmes.

Keywords: Diaphragm wall; trench cutter; cube system.

1 INTRODUCTION

Urbanization trends showed an increasing population in recent years. Hand in hand the number of peoples living in cities is growing subsequently. To date, over 50% (around 4 billion people) of the world's population already lives in cities and urban areas. The expand of the cities calls for new infrastructure like new underground metro lines, water systems, logistic centres, underground parking and much more. This and rising prices in cities ask for solutions for future projects. Further, the demand for more resources and existing structures in the urban areas request

technology, which can deal with great depths and challenging soil conditions.

Equipment suppliers facing challenges with competing trends of developing small equipment for inner city jobsites but also provide solutions for increasing depths. The challenge to develop machines with low emissions and solutions to reduce impact on daily lives sets restriction to fundamentally rethink methods and processes. In addition, the developments must be more and more powerful, to meet tight schedules and therefore are able to carry out cost effective projects.

One chance to confront these trends is the diaphragm wall method. It combines many features like the ability to be used in various soil and rock conditions with high performance or the possibility to use it in inner-city regions.

1.1 The history of diaphragm wall technique

Searching in the history of the diaphragm wall technique, one can find a first patent which was approved back in 1912 by a company called “Carl Brand” in Germany. This is based on the experiences for the use of clay slurries and it’s stabilizing effect in uncased boreholes. Another patent was approved in the US by Ranney back in 1936. Both patents were almost forgotten before the method really started. A kind of revival and the real start could be seen in the late 1940’s and early 1950’s. Several publications discussed the thixotropic fluids and were patented by Hans Lorenz 1950/51. Also, Christian Veder received an Austrian Patent in 1950 for a methodology of installing water tide walls by using contiguous, uncased boreholes, stabilized by slurry and concreting after excavation. As well company “ICOS” applied for patents on slurry wall constructions by the end of 1940’s in Italy. First full-scale projects have been finally carried out by ICOS for the Metro in Milan e.g., in 1956. With the success of the projects the interest in this technology increases. In addition, with expiring patents, several international construction companies, mainly in Europe and Japan, started to develop additional and alternative equipment for the purpose of installing Diaphragm walls (Gerressen, 2019).

1.2 Equipment history

1.2.1 The grab

To install the first rectangular diaphragm wall panels, ICOS designed a first special grab/clamshell, named crocodiles (Figure 1), which can be seen as the predecessor of today’s grab/clamshell technology.

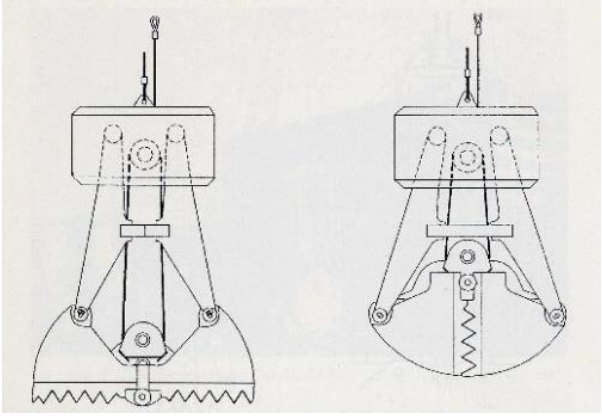

Figure 1. Wire rope grab (ICOS 1960).

A mechanically operated wire rope grab was used as the first type of excavating tool. The closing mechanism is actuated by a pulley block system inside the grab body, whilst the opening of the jaws is actuated by the weight of the block sliding on guides. The grabbing capacity of the initial generations of grabs was limited. The development of heavy-duty crawler cranes with two hydraulically operated winches made it possible to build grabs with jaw widths up to 4.5 m and a weight of over 15 tons. The excavation capacity of the grab system could therefore be increased significantly (Figure 2).

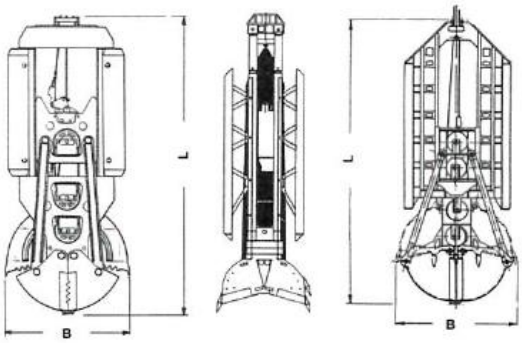

Figure 2. Wire rope grabs, Casagrande (left), Bauer (middle), Leffer (right).

Over recent years, the mechanically operated wire rope grab has been improved by replacing the pulley block system with hydraulically operated rams. Now, with both closing and opening of the jaws being actuated by hydraulic rams, the output capacity has increased significantly. Because of their heavy weight, these types of grabs do not need to be operated in a freefall mode. Hydraulic hoses and electric cables can, therefore, follow the grab into the trench without difficulty. The electric cables attached to the grab also allow the installation of inclinometers, and if necessary, deviations can be corrected by hydraulically operated steering plates as shown in Figure 3.

Figure 3. Hydraulic grab with steering plates.

The grab excavation technology is a widely used and common system. There are, however, some limitations in the system:

- The excavation output reduces with increasing trench depth because of the intermittent excavation process.
- It is difficult to excavate hard soil formations.
- For deep walls it is difficult to construct a sufficient joint system.

The introduction and development of the hydraulic trench cutter system made it possible to overcome these problems and it opened new horizons for the use of the diaphragm wall technique (Gerressen, 2019).

1.2.2 The cutter

In 1962, a kind of suction cutter unit was launched in Germany, which can be seen as one of the predecessors of today's cutter/hydro-fraise technology. Also, two Japanese companies (Tone Boring and Okumura Corporation) developed in the early 1960's a new reverse circulation concept for rectangular panels. While Tone Boring cutting blades rotated around vertical axes, Okumura used two cutting wheels, driven by a chain, and rotating around horizontal axes. The idea of a hydraulically driven cutter was introduced in Europe around 1975 by the French company Soletanche with the brand name "Hydrofraise". The arrival of the cutter technology in Europe prompted other companies to greater activities during the 1980's. Casagrande of Italy brought a system with a chain drive, like Okumura. In 1984 Bauer in Germany brought their system of trench cutter BC on the market. The BC system was designed from the beginning to penetrate rock layers. The cutter wheels are driven by vertically mounted high speed hydraulic motors. A special gear system converts the high-speed rotation of the hydraulic motors into slower rotation of the cutter wheels. With this system, the torque on the wheels can be increased in comparison to other design concepts. The torque of the cutter wheels combined with the weight of the cutter is strong enough to cut into hard soils, crush stones up to a certain grade and overcut into the concrete of adjacent panels. An overview of the various concept is shown in Figure 4.

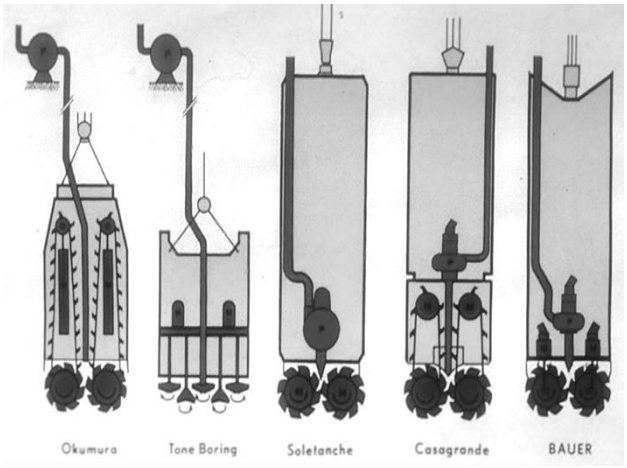

Figure 4. Cutter development.

The trench cutter itself is a reverse circulation excavation tool (Figure 5).

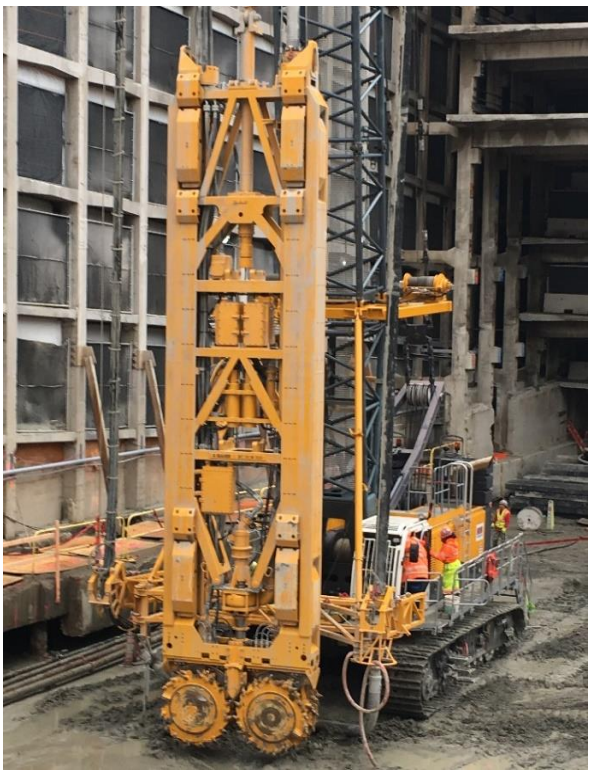

Figure 5. Trench Cutter.

It consists of a heavy steel frame with two drive gears attached to its bottom end, which rotates in opposite direction around the horizontal axis. Cutter wheels are mounted onto the drive gears.

As they rotate, the soil beneath the cutter wheels is continuously broken up, removed, mixed with the bentonite slurry in the trench and moved towards the opening of the suction box of the pump. A centrifugal pump located right above the cutter wheels conveys the slurry via a hose system up to a desanding plant.

Then the slurry loaded with soil and rock particles is cleaned and returned into the trench.

The torque of the cutter wheels combined with the weight of the cutter is strong enough to cut into hard soils, crush stones up to a certain grade and overcut into the concrete of adjacent panels.

Depending on the soil, different types of cutter wheel configurations and teeth can be deployed, ranging from aggressive teeth for cutting fine-grained soil to percussive teeth for crushing boulders. Cutter wheels may conveniently be changed to suit different types of rock.

2 WHERE WE ARE TODAY

2.1 Construction sequence

The working steps usually follow a pre-defined sequence. The main steps are shown in Figure 6. After a pre-excavation, which is necessary to allow starting the suction pump installed in the cutter frame, the excavation of a primary panel starts. Most common is to install multiple bite primaries as shown in Figure 6.

After finishing several primary panels, the installation of secondary, single bite panels takes place while overcutting the adjacent primary panels. The Overcut Joint System is a well proven way for the installation of diaphragm walls using the trench cutter system. In confined conditions the use of special auxiliary equipment (e.g., for installation of reinforcement cages) might become necessary. During excavation the open trench is stabilized by supporting fluid.

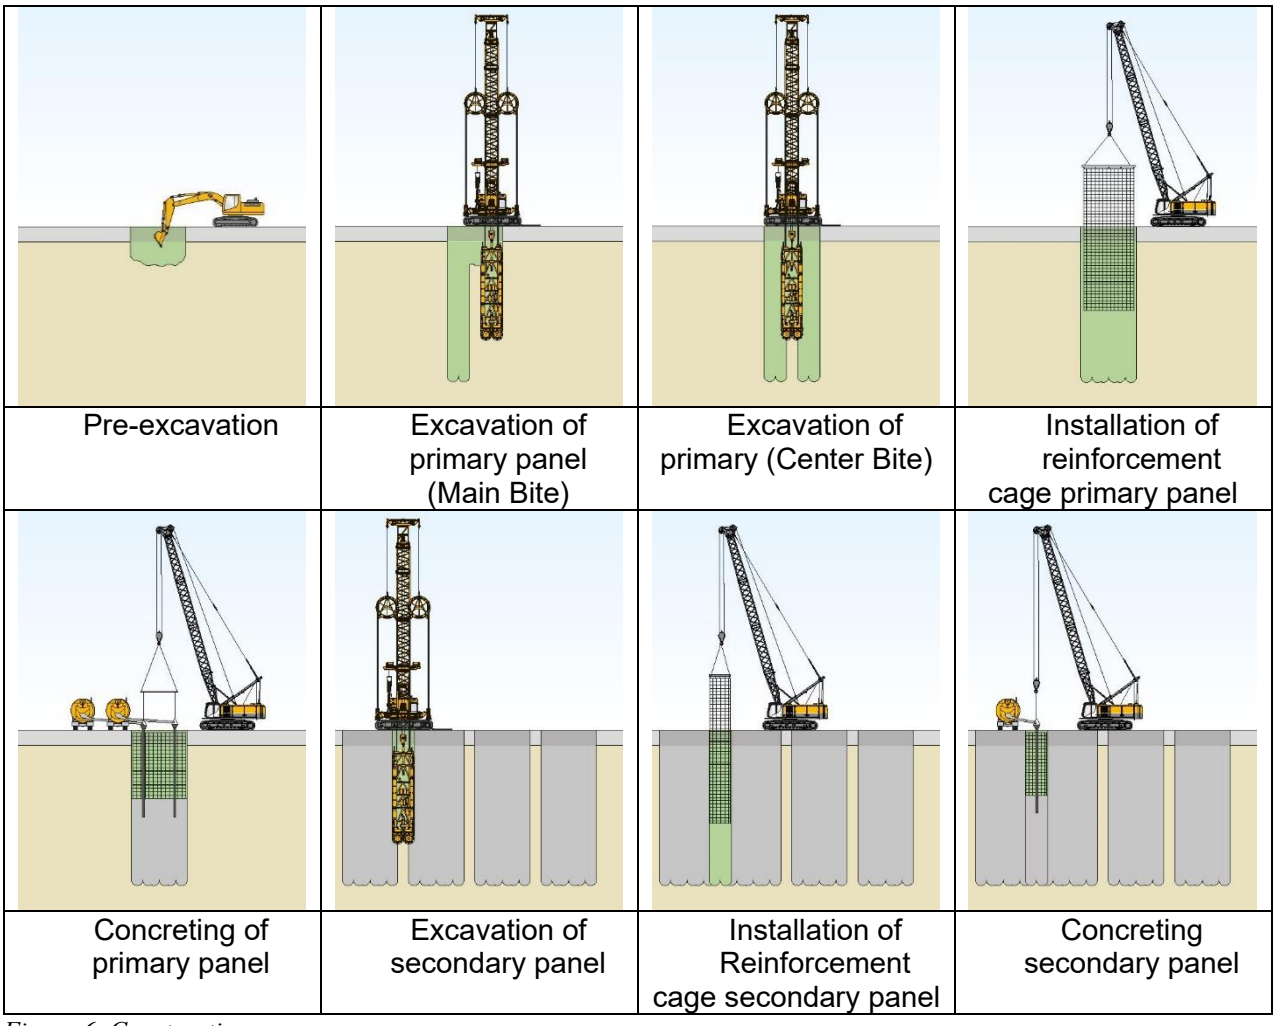

Figure 6. Construction sequence.

2.2 Site set-up and logistics

For diaphragm walling, the handling of the slurry is crucial and compared to other methods, a more complex site set-up becomes necessary.

Beside the cutter and its base carrier, other equipment such as desanding plant, mixing plant, different pumps and storage of the slurry requires space. Further access areas, for the supply of reinforcement cages, concrete and the transport of the excavated material are needed as well as storage of spare parts etc.

As the technique possesses many advantages, the demand to use it also in limited site conditions already led to a special carrier of reduced height, for so called low-headroom applications.

2.3 Development of equipment

Currently it is possible to monitor two different trends in the development of the equipment. On the one hand, it shall be possible to reach greater depth (Figure 7) and higher performance.

Figure 7. Cutter system for great depth up to 250 m.

On the other hand, small and confined situations require small flexible equipment (Figure 8) with low emissions (Gerressen and Blatt, 2020). Especially inner-city jobsites set challenges with the demand to new infrastructure. Over the years different contrary developments to satisfy demands took place. But all these developments had in common that it was possible to identify the diaphragm walling equipment. A completely new approach to widen the range of application is the so-called CUBE system, shown in Figure 9. The system is the next step in the miniaturization of the diaphragm wall technique.

Figure 8. Low-headroom cutter system.

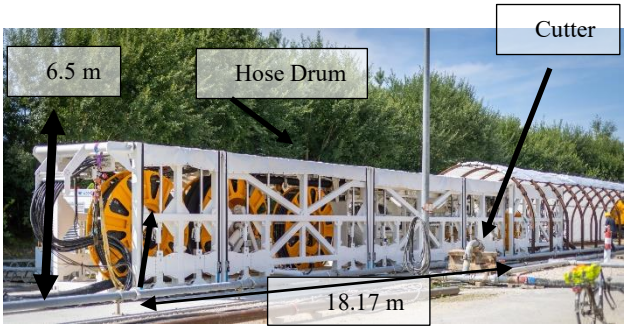

Figure 9. CUBE-System.

2.4 Aim of the system

The aim of the system is to provide additional possibilities. For example, it is possible to create walls out of underground structure, such as metro stations or tunnels. This new flexibility widens the range of possibilities during the planning stage of new infrastructure (for example underground car parking's, water reservoirs, storage areas, etc.). Currently new planned projects often cannot be planned and executed where it would be needed, as existing structures set restrictions. So, in some cases projects are not even started because of lack of technical solutions or enormous efforts in case of execution. In those cases, compromises must be made, e.g., find new not ideally locations, postpone or even cancel projects. With compromises always come additional costs over the lifetime of such a project.

Underground use of space is an important topic in that regard. If cities want to remain cultural, social, and economic centres, they will have to build as compactly as possible within the currently available space. The use of underground spaces as an extension of the urban public domain is an important part of this. But there is one major problem: much of the available space is already taken up by above-ground structures and traditional construction methods becomes increasingly difficult to justify. Now, in a

"Future City world Vision", the system allows planning of underground structures exactly where it is needed in conjunction with minimum impact on the environment above ground level. This creates new options and solutions for planers and urban development with an opportunity to explore the cities underground space better and safely. Due to its flexible application possibilities, great things can be created below ground, while life on the surface goes about its usual business. Execution of D-Wall out of a tunnel as shown in Figure 10 is one of the options. The depth of the tunnel is flexible and can be adjusted to the existing structures. To avoid additional works like e.g., groundwater lowering, it is recommended to have the tunnel above groundwater level.

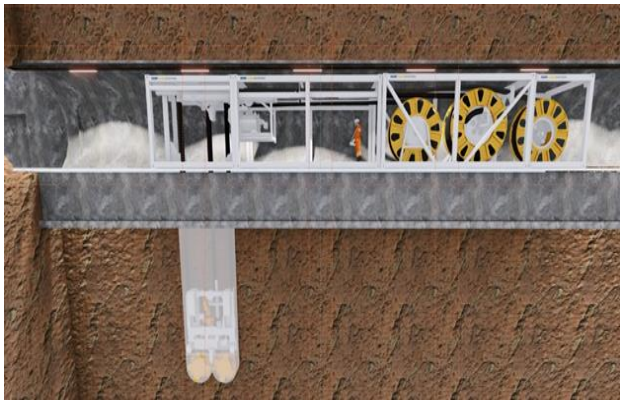

Figure 10. Cube system working in tunnel.

Figure 11. Cube system in very tight spaces.

An alternative of course is to use the system in very tight space conditions keeping e.g. the traffic alive, as shown in Figure 11.

3 THE CUBE SYSTEM

As the ones who have shaped the cutter technology in special foundation engineering, we thought it is time to redefine industry boundaries once again by the development of the BAUER Cube System. As the name indicates, the components are aligned in high cube container. The dimensions of the system can be seen in Figure 11. Within 4 high cube container it contains all known components of a diaphragm wall cutter. As displayed in Figure 12, panels with a length of 2400 mm and widths of up to 1000 mm are possible. To fit the cutter into the containers, it needs to be separated into two pieces. The first container accommodates the cutter head, where the cutter wheels and gearboxes are mounted. Within the second container the pumping unit is placed. To start the cutting process, this unit needs to be placed over the cutter head. For that a pre-excavation of only 1.5 m is necessary to lower the first part and therefore enable the second unit to move over. After both parts are connected, the cutter unit can work. The working principle is identical to standard trench cutting systems.

Because of the containerized dimensions, the need of heavy transports becomes irrelevant, which makes the system flexible and easy to transport. By connecting the containers with so-called quick ties, a fast and uncomplicated assembling can be ensured.

On both sides of the containers, passages make it possible to walk through (see Figure 12 at the right). This is an important factor to meet the safety standards for first aid access and material transport within a tunnel. Further it guarantees a safe environment for service tasks, such as teeth change on the wheels.

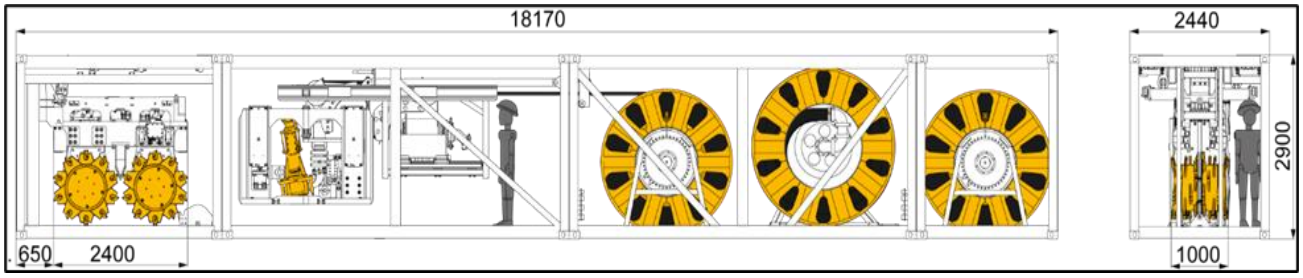

Figure 12. CUBE system - dimensions in mm.

3.1 Test site

In order to understand the processes and restrictions as well as to get a feeling for very confined conditions, a test was carried out first. Scope of the test was the construction of 7 single bite panels. Therefore, a complete jobsite set-up was assembled (Figure 13). In addition, a working platform, which included the rail system was constructed. Further a tunnel was simulated to work within height and width restrictions.

In total, five primary and two secondary panels were executed, whereby one primary was constructed to the maximum depth of 40 m. This is the actual maximum depth capability of the CUBE System. All other panels had a depth of 15 m. All panels were concreted using a concrete pump. Different reinforcement cages were tested. Further different equipment tests were carried out as well.

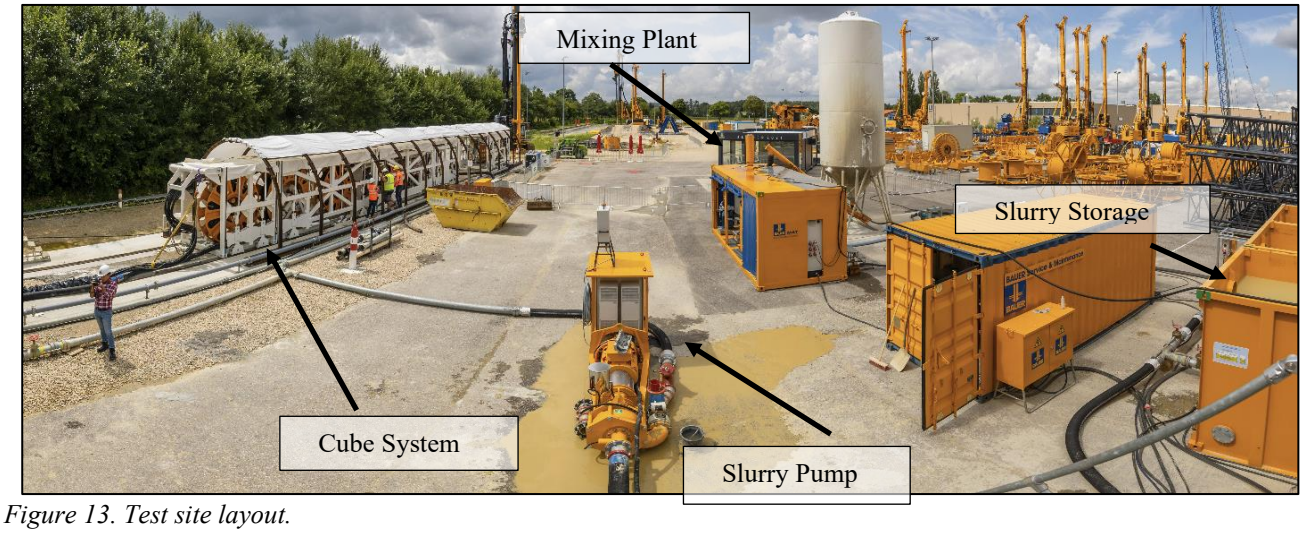

Figure 13. Test site layout.

As the cutter system is not mounted on a carrier with tracks, a new idea for the movement of the system was developed. The movement now is generated by a clamping device and by hydraulic cylinders, as shown in Figure 14. The device clamps hereby on a rail system and a cylinder push or pull the system in the desired direction. In the meantime, the opposite clamping device moves into position and ensures a continuous movement. Using this system, the CUBE system can move at a speed of 1.2 m/min.

Figure 14. Clamping device.

Like any other cutter system, a pre-excavation is required. The system can work with a reduced pre-excavation depth of 1.5 m, which can be carried out by a small excavator also within confined conditions.

The cutting process itself is not different compared to standard equipment. The loosened material is transported via the stabilizing fluid to a desanding plant. Here the solids are separated from the liquid medium, which is afterwards ready for reuse. Cutting performances on the test site were comparable with performances on sites with similar ground conditions.

Figure 15. Reinforcement and concreting container.

Although the cutting process is quite like the standard procedure, reinforcing and concreting are a bit more challenging due to the very limited height restrictions. Therefore, two different types of reinforcement cages were tested to assess the handling and installation during the construction within a tunnel. Each segment of the cages had a height of 1.85 m and were transported to an independent container. This container (Figure 15) contains all handling devices for the installation of the reinforcement cages and tremie pipes. Thus, it is also responsible for the concreting process.

During the test, it was found that the use of prefabricated cages in conjunction with the use of Lenton couplers as shown in Figure 16 was the most favourable solution for practical application. The connection time of two segments was approx. 15 min.

Figure 16. Cage coupling.

A concrete pump (Figure 17) supplied the concrete through the simulated tunnel to the trench (Gerressen et al, 2022).

Figure 17. Concrete supply via concrete pump.

4 CONCLUSION

With an increasing number of people moving into urban and inner-city areas, the demand for new infrastructure will also soar in the future. Existing buildings and structures as well as high prices for areal spread, set restrictions and for these new infrastructure facilities. In addition, environmental aspects will become more important and will raise the question for new strategies. The impact of these demands will further influence for the construction process and the design of equipment.

The importance to provide solutions for confined space jobsites with challenging soil conditions already rises difficulties for logistics, storage, and methods, as well as equipment to solve the restrictions. Today, suppliers already provide compact machines of high performance.

The CUBE System with its new design, new thinking of system and its reduced dimensions will make numerous projects possible, which lack of solutions until today.

The test proofed the functionality of the system and therefore provides opportunities for projects which had never been thought before.

With this, the system can become part of the “Future City world Vision”.

Thermal behaviour of soils: studies and applications in current energetic and climatic contexts

Comportement thermique des sols: études et applications dans les contextes énergétiques et climatiques actuels

A. Vieira*
LNEC (National Laboratory for Civil Engineering), Lisbon, Portugal
**avieira@lnec.pt*

ABSTRACT: The study of the thermal behaviour of soils dates back several decades, often associated with its strain rate dependency. More recently with the diversification of soil use, such as in the exploitation of shallow geothermal systems and other applications, this study has gained renewed interest and an enlarged scope. Moreover, in the current climatic context, both the different amplitudes of thermal cycles and the expressive, sometimes sudden, variations in water table levels, especially at geological shallower levels, are likely to impact the performance of structures and infrastructure. The assessment of the sustainability of soil use as a resource and its structural study must be based on an adequate knowledge of its behaviour from a multiphysical perspective, where thermal, mechanical, and hydraulic processes interact. A phenomenological description of the thermal behaviour of soils is presented in an integrated view, considering experimental and numerical characterization, aiming a proper planning and a sustainable use, furthermore with reference to ongoing studies on the geological formations of the city of Lisbon.

RÉSUMÉ: L'étude du comportement thermique des sols remonte à plusieurs décennies, souvent associée à leur comportement visqueux. Avec la diversification de l'utilisation des sols, comme dans l'exploitation des systèmes géothermiques et d'autres applications, cette étude a connu un regain d'intérêt. De plus, dans le contexte climatique actuel, les amplitudes variables des cycles thermiques et les variations importantes, parfois soudaines, du niveau de la nappe phréatique, en particulier dans les niveaux géologiques peu profonds, sont susceptibles d'avoir un impact sur les performances des structures et des infrastructures. Tant l'évaluation de la durabilité de l'utilisation des sols en tant que ressource que leur étude structurelle doivent être basées sur une connaissance adéquate de leur comportement d'un point de vue multiphysique, où les processus thermiques, mécaniques et hydrauliques interagissent. Une description phénoménologique du comportement thermique des sols est présentée dans une vision intégrée, s'appuyant sur une caractérisation mathématique et expérimentale, visant une planification appropriée et une utilisation durable, en référence aux études en cours sur les formations géologiques de la ville de Lisbonne.

Keywords: Soil thermal behavior; shallow geothermal systems; sustainability; urban planning.

1 INTRODUCTION

From a Soil Mechanics and Geotechnics perspective, the thermal study of soil has evolved significantly, not only in its phenomenological description and constitutive analysis but also in its scope and approach, over the last few decades. Particularly regarded as a construction material, foundation, and support for civil engineering works, its value as a resource in the energy context becomes apparent, especially it what concerns to the exploitation of shallow geothermal systems, among other applications. Consequently, the importance of this study for the performance and safety of constructions, infrastructure and geotechnical structures, is now expanding, especially at the urban level, to the issues of planning and sustainable management, which also impact, in different ways, directly or indirectly, with the former. Thus, from the point of view of Geotechnical Engineering and Environmental Geotechnics, the thermal study of soil, its understanding, characterization, modelling and approaches, have become more complex, sometimes substantially, at a time when the study of georesources off the planet has already begun (Delage et al., 2023).

The study of soil behaviour should be considered in a multiphysical perspective, in which mechanical, thermal, hydraulic, and sometimes chemical and electrical processes interact in a non-trivial way. For example, in the case of shallow geothermal systems, and more specifically, in energy geostructures, there is an interaction between them and the surrounding ground, due to the heat exchange over the seasonal heating and cooling cycles, which causes stresses and strains both in the soil and in the geostructure that must be properly considered in design. This interaction is dependent on many factors and its evaluation remains a topic of research. In turn, thermal actions in the soil can induce changes in the pore water pressures. Additionally, the existence of water flows through the soil can also induce heat transport by convection and advection, depending on the grain size of the soil and the flow velocity, with consequent coupled effects. Upstream of these interactions, and determining their occurrence, the process of heat transfer by conduction between the soil and the shallow geothermal system determines its sizing and energy efficiency alongside the evolution of temperature distribution in the soil over time.

Involving higher temperature ranges than those generally associated with the operation of shallow geothermal systems, the thermal behaviour of soils and rocks assumes particular relevance in cases of radioactive waste disposal, in slope sliding and instability processes, in landslides on faults (where the heat produced by friction, leading to water expansion can cause thermoplastic collapse of the soil skeleton, in addition to the direct and significant impact on the mechanical properties of the solid skeleton) (Cecinato and Zervos, 2012, Alonso et al., 2015), among other examples.

The phenomenological, instrumental (laboratory and field), constitutive and numerical study of the thermal behaviour of soils (and other geomaterials), a relatively recent field of research, is of scientific relevance to society, at a time when the effects of climate change and the search for renewable energy sources, promoting the reduction of CO_2 emissions, are at the centre of society's concerns. It is believed that the progressive increase in temperature and extreme events, where, for example, long periods of drought (with drying and increased cracking of surface soils) interspersed with short periods of extreme precipitation, is liable to create conditions for the occurrence of collapse processes and large deformations. Additionally, the predicted increase in the amplitude, number and duration of heat waves, as is expected, for example, in Iberian Peninsula Mediterranean region, which is considered a climate change hotspot (Soares et al., 2024), might induce changes in soil state conditions and properties, particularly impacting the most superficial soil geological deposits. These effects will pose increasing challenges to the functionality and safety of current and future engineering works.

In the contexts of the most recent use of soil as a resource, namely for shallow geothermal applications, including district heating and cooling (DHC) and thermal storage, in the perspective of more efficient energy use, sustainability planning, and under circular economy scope, a proper thermal characterization of soil is essential. It is intended to allow the geothermal potential to be assessed, the sizing of air conditioning systems, the optimization of their performance and the evaluation of interferences, also enabling the proper geotechnical and structural design of structures and infrastructure. Thermal tests in soils and rocks and the knowledge of temperature distribution at depth, new numerical and geospatial modelling techniques and tools, advanced instrumentation using next-generation sensors, data processing, machine learning and process optimization, are of particular relevance here. These and other tools aim at a more precise and integrated characterization of the soil, which will contribute to the development and promotion of a more sustainable future.

From the point of view of both Soil Mechanics and Environmental Geotechnics, the consideration of temperature dimension in the behaviour and characterization of soils is crucial for a comprehensive understanding of the performance of civil engineering constructions and the assessment of their impact on the surrounding environment, especially in urban areas.

2 THERMAL BEHAVIOUR

In 1943, Terzaghi established a mathematical comparison between the consolidation process in soils and other processes, such as heat diffusion and the propagation of electric current in solids. The heat diffusion equation, also known as the heat equation, describes the rate of change of temperature in a material as a function of its position and time. In a homogeneous and isotropic medium without external heat sources, it takes the following form:

$$\frac{\partial T}{\partial t} = -\alpha . \nabla^2 T \qquad (1)$$

where T is the temperature at a specific point and time and α is the thermal diffusivity (thermal diffusion coefficient), which depends on the thermal conductivity λ, density ρ and specific heat capacity c ($\alpha = \lambda/(\rho . c)$).

Mitchell (1993) established a series of parallels between the different flows that can occur through soil and their respective governing laws: fluid (Darcy's law), electric (Ohm's law), chemical (Flick's law), and thermal (Fourier's law), contextualizing their importance and noting that all these physical processes interfere in geotechnical problems through direct or coupled processes.

Regarding heat conduction, Fourier's Law establishes that:

$$q = -\lambda . \nabla T \quad (2)$$

where q is the thermal flux vector.

Heat transfer in soils involves various mechanisms, as identified by De Vries (1958) and Farouki (1981), mainly conditioned by the soil's degree of saturation and particle size distribution, being thermal conduction the predominant process. These seminal works describe the fundamentals of heat transfer in soils. In his monography Farouki (1981) provided a comprehensive analysis of this physical process, particularly focusing on the description of different methods to evaluate thermal properties, from which thermal conductivity is the most relevant, and how they are influenced by different factors, considering soil´s multiphase composition. It is worth mentioning that thermal conduction is also clearly the dominant process in the case of energy geostructures (Brandl, 2006). The degree of saturation is the parameter that most influences thermal conductivity, it can vary by about an order of magnitude between fully saturated and unsaturated conditions. Other factors such as porosity, particle shape, mineral composition, among others, might also significantly influence this property.

More recently, with a special focus on of shallow geothermal systems, the thermal characterization of soils has sparked renewed interest in the field of engineering, driving a series of fundamental and applied studies in this area, especially due to its influence on the design and performance of these systems and other applications.

The evaluation of thermal conductivity, which quantifies the ability of materials to conduct heat, can be done empirically through direct correlation of data compiled in different lithological units, semi-empirically through the application of mathematical relationships involving the conductivity and volumetric fractions of the different soil phases, among other parameters, and through field or laboratory measurements (Vieira et al., 2017). As for experimental measurements, Enhanced Thermal Response Tests, deserve special mention, as they allow distributed determination of thermal properties, along the depth and thus along the different soil and rock layers. These field tests, by taking into account the specific conditions of a particular site (stress state, water level depth and possible water flows), eliminate the inherent difficulties of laboratory sampling and specific limitations of transient and steady-state conditions tests (analytical approximations, testing times, thermal losses, among others).

Low et al. (2015) published a compilation of conductivity measurements through laboratory and in situ tests, which showed that in situ measurements consistently reveal higher values. Possible explanations for these discrepancies include hypotheses of sample disturbance, alteration of their stress state (effect of confinement stress) and migration and/or loss of water within the sample. The effect of the confining stress was confirmed by Maranha and Vieira (2018) through numerical analysis by FEM in an assemblage of quartz spheres in void, considering different spatial arrangements. An increase in the applied isotropic stress level resulted in higher thermal conductivity due to the increase in contact area caused by the thermal expansion of the spheres. These results were in agreement with the analytical expression proposed by Sakatani et al. (2017). In-depth study of conductivity has been carried out through analysis of thermal tests in transient conditions by Aljundi et al. (2024) using a high-precision probe. In addition to variations in state parameters, the influence of control parameters (temperature and test duration) was analysed. The effect of heterogeneity was minimized by conducting systematic tests on the same sample. This study also involved the evaluation of thermal conductance at the contact surface between the thermal probe and the soil sample and its relevance for the numerical reproduction of the tests and in the conductivity evaluation. Overall, the importance of state parameters was confirmed, and regarding test control parameters, the significant influence of temperature (eventually due to the increased particles contact area due to thermal expansion of soil particles) and test duration was observed (Figure 1). In the case of dry soil, it was shown that the standard test duration of 100 s is not sufficient to eliminate the boundary effect of the probe.

The determination of thermal parameters can also be done through inversion techniques using field measurements, thus eliminating the difficulties of evaluating thermal conductivity and volumetric heat capacity across heterogeneous soils (Romio et al., 2019; Li et al., 2022).

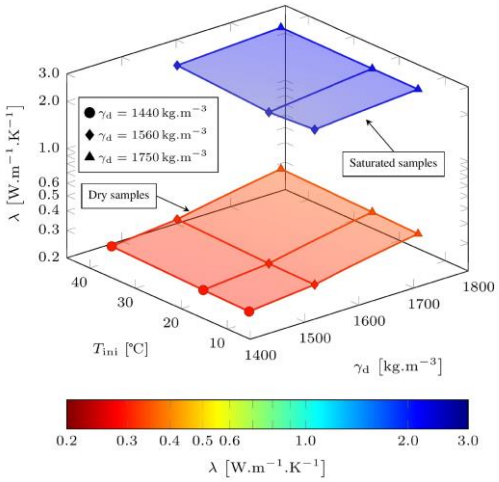

Figure 1. Thermal conductivity measurements (effect of saturation, density and temperature) (Aljundi et al., 2024).

Recent works highlight the potential of these techniques. Figure 2 shows schematically the proposal of Li et al. (2022), based on the inlet and outlet temperature data recorded in borehole heat energy storage (BTES) and soil temperature, which through a modified duct thermal energy storage method and an iterative procedure allow the progressive correction of initially adopted parameters, consequently enabling the optimization of the performance of the system. This method was verified with operational data based on long-term monitoring conducted in a large-scale BTES project in Chifeng, China.

The increasing installation of shallow geothermal systems and the recognition of their great potential have resulted in growing research, also making available a considerable amount of data across a range of environments and operational conditions, contributing to expanding knowledge in this field, allowing for a greater understanding of the parameters and factors which influence thermal parameters, their determination and the importance of their proper evaluation.

Soil thermal conductivity depends on state parameters and its determination, in what concerns to laboratory evaluations, as occurs in geotechnical parameters, depends on the quality of sampling, among other factors that might modify the structure and composition of the soil (such as stress and strain dependence), the direction (due to anisotropy) and type of test. Thermal characterization is already an integral part of soil studies and will continue to play a crucial role as increasingly complex environmental challenges are faced, involving a multidisciplinary approach. It is import to pursuit the development of advanced techniques and methods to characterize soil thermal properties.

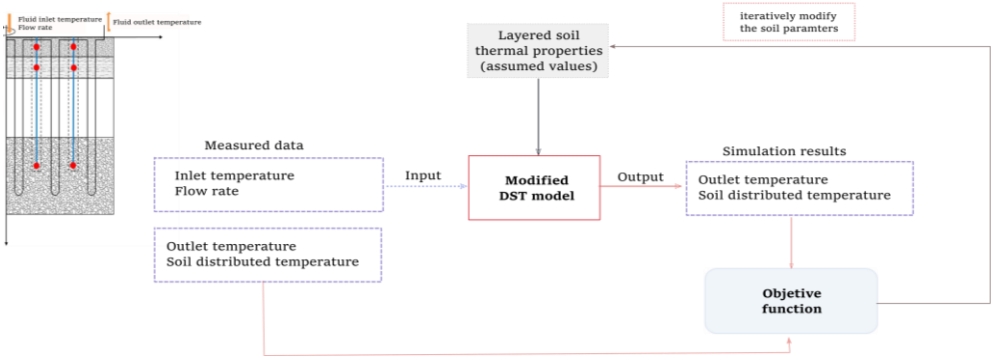

Figure 2. Parameter estimation method (adapted from Li et al., 2022).

3 THERMOMECHANICAL BEHAVIOUR

The temperature variation is directly related to the kinetic energy of molecules, inducing consequent mechanical effects in a system. Temperature changes generate volume variations and/or alterations of pressure in the pores of soils. A first insight into the parameters that influence the soil response to a temperature rate can be obtained for the problem involving a saturated soil element under isotropic conditions. In this case, the analytical solution for the rate of volumetric deformation induced by temperature rate is:

$$\dot{\varepsilon_v} = -\beta \dot{T} \quad (3)$$

Under these conditions, it is possible to determine the coefficient of volumetric thermal expansion and the rate of variation of interstitial pressure for any drainage condition, respectively, β and $\dot{u}$. These quantities depend on the coefficients of volumetric thermal expansion of the solid particle β_g and water β_w, on the volumetric elasticity moduli of the solid skeleton and Biot's modulus, K e K_f, respectively, on the porosity n ($K_f = K_w/n$, where K_w is the volumetric compressibility modulus of water) and on the rate of flow per unit volume that enters or leaves the soil voids, $\dot{\zeta}$, according to:

$$\beta = \frac{[K+(1-n)K_f]\beta_{g+K_f}\left(n\beta_w - \frac{\dot{\zeta}}{T}\right)}{K+K_f}\,\dot{T} \qquad (4)$$

$$\dot{u} = K.K_f\,\frac{[n(\beta_w-\beta_g)]-\frac{\dot{\zeta}}{T}}{K+K_f}\,\dot{T} \qquad (5)$$

In fully drained conditions $K_f = 0$ or if $\beta_w = \beta_g$, no interstitial pressures develop, otherwise (under undrained or partially drained conditions), there is a change in water pressures in the pores. The tendency is such that with an increase in temperature, as the coefficient of expansion of water is greater than that of solid particles, the solid skeleton restricts expansion and the pressure in the pores increases, consequently reducing effective stress (and strength). The opposite occurs when the temperature decreases. Understanding how these variables interact is essential to understand the mechanical processes caused by thermal actions, for example, for assessing thermo-mechanical effects in energy structures.

However, the effect of temperature is more complex, because soil behaviour is essentially irreversible. As referred by Leroueil and Marques (1996), temperature has two major effects on soils: thermal expansion of soil particles and pore water, and thermally induced modification of strength at the contacts between particles. In other words, temperature induces elastic and plastic effects.

Mitchell (1993) explained the combined effect of these phenomena on the temperature-volume-effective stress behaviour of soils in both drained and undrained conditions, based on thermal tests in isotropic conditions in a normally consolidated saturated illite under a temperature loading cycle (an initial increase from 18.9 to 60.8ºC followed by cooling to 18.9ºC) under a constant isotropic total stress of 200 kPa. These tests allowed the observation of irreversible volumetric deformation, known as thermal compaction and the induction of residual pressure under undrained conditions. This contractant behaviour may be explained by compressive plastic strains caused by heating, due to a decrease in the soil's yield strength which supersedes the thermal elastic dilation. According to Mitchell, these effects must be taken into account, both in the field and in the laboratory.

It was observed, for subsequent thermal cycles of loading and unloading, of the same amplitude, that the behaviour observed is similar to that of secondary compression reloading, that is the irreversible deformation tend to disappear.

However, for overconsolidated soils, the situation is more complicated, and soils, during heating in drained conditions, can initially exhibit a dilatant behaviour as a result of the prevailing influence of elastic effects, followed, for higher temperatures, by volume reduction caused by thermoplastic strains. The results obtained by Hueckel and Baldi (1990) in natural Pasquasia clay clearly show the effect of the thermal loading history on the volumetric behaviour during heating. Qualitatively similar results were obtained by Cekerevac and Laloui (2004), which once more demonstrated the influence of stress history on thermal behaviour. They also analysed the response to thermal loading and unloading cycles. Again, with the consideration of thermal cycles, processes become considerably more complex. The effect of thermal compaction for lower OCR values is evident, although the cause of the high inelastic deformations observed for higher OCRs in cooling cycles is not as clear. In subsequent cycles, the behaviour tends to be essentially elastic.

Also for tests under isotropic conditions, Sultan (1997) investigated experimentally the effects of the thermal loading rate on the contraction curve, with results showing a very significant effect of the cooling rate, with a decrease in thermal expansion as the discharge (cooling) rate decreased. Conversely, Cui et al. (2000) drew attention to the likelihood of results showing expansion during cooling.

For non-isotropic stress states, the thermal influence processes become even more complex. Leroueil and Marques (1996) merit special mention for their work analysing the effect of temperature and viscosity, under different conditions, from a critical state perspective. They observed a decrease in the preconsolidation stress and in the yield surface with increasing temperature (similar to what happens with decreasing strain rate), as well as an increase in compressibility. Regarding the critical state friction angle, the results are contradictory. Laloui et al. (2014) also provided a very comprehensive and detailed compilation of the main aspects observed in the thermohydromechanical behaviour of soils, in the context of shallow geothermal applications, emphasizing the difficulty regarding some behavioural trends for non-isotropic conditions.

These briefly described aspects are largely based on laboratory characterization. This has been done mainly through traditional Soil Mechanics testing equipment properly adapted for testing under non-isothermal conditions.

Significant progress has been made in constitutive modelling with proposals for advanced models that increasingly accurately reproduce observed behaviours. A thorough review of the main constitutive models for soils was compiled by Christodoulides et al. (2020), categorizing thermal models into thermoelastic, thermoelastoplastic, and

thermoviscoplastic. Thermoelastic models encompass analytical solutions and stress-strain-temperature elastic relationships. Different types of elastic models extended to non-isothermal conditions can be found in the literature, such as extensions for isotropic elasticity, which can be categorized as linear thermoelasticity, thermohypoelasticity and thermohyperelasticity.

In thermoplasticity, irreversible deformations can be induced by non-uniform temperature fields, which is compliant with the systematic experimental evidence showing the occurrence of plastic strains caused by thermal loading. This type of models includes analytical solutions, models with critical state structure involving temperature dependence in the hardening law, thermoplastic models with multi-mechanisms - involving isotropic and deviatoric thermoplastic deformations - and others. In thermo-viscoplastic models, rate dependency, one of the most relevant features of soil behaviour, is considered to overcome limitations of thermoelastoplastic models.

The subloading concept due to Hashiguchi was also used to reproduce the influence of non-isothermal conditions on the stress-strain-time behaviour of soils. A version of the viscoplastic subloading soil model proposed by Maranha et al. (2016), restricted to isotropic stress and strain conditions, was extended to non-isothermal conditions by Maranha et al. (2017), introducing temperature dependence of the size of the yield surface and the position of the centre of homothety. The first version of the model allowed for the capture of the large volumetric expansion strains observed in highly over-consolidated clays by Cekerevac and Laloui (2004) in the initial stages of heating tests. These strains were considered irreversible and the corresponding coefficient of thermal expansion variable and much larger than that directly resulting from the constituent minerals of the soil's solid phase. In order to reproduce these trend, it was necessary to assume that the previous unloading stress (necessary to obtain the over-consolidated state) was fast enough so that creep was still occurring at the beginning of the heating stage. However, this change was not sufficient to reproduce the behaviour of the subsequent unloading cycles (cooling). Thus an improved version of this model, introducing temperature dependence motion to the centre of homothety, was presented in Maranha et al. (2018). Using this model, a very good adjustment of the three heating and cooling tests presented in Cekerevac and Laloui (2004), considering the variability between the three soil samples and the same material model constants for all, was achieved (Figure 3).

The extension of this thermoviscoplastic model for generalized stress states is under development. This study will be supported by new tests in a triaxial chamber adapted for non-isothermal conditions for Lisbon soils under the scope of Project Geosustained (PTDC/ECI-CON/1866/2021). Isotropic stress thermal cycles at different strain will be carried out in order to obtain the evolution of thermal expansion for different soils and gather additional information to support the above referenced model assumptions and obtain data for parameter calibration. Thermal tests in axisymmetric stress conditions will also be carried out.

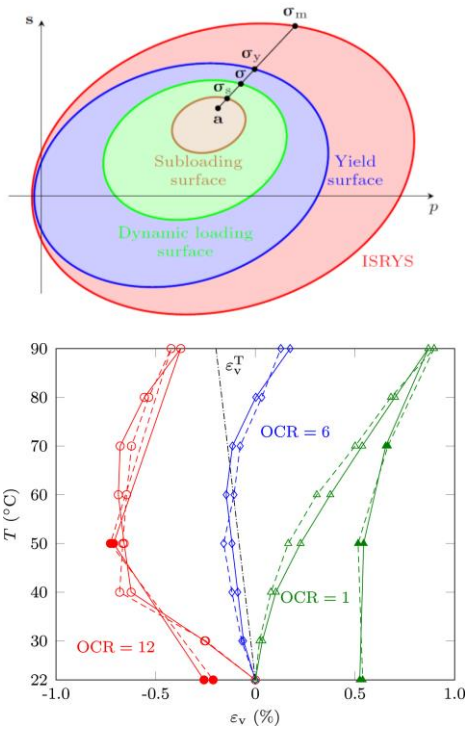

Figure 3. Surfaces of original model (top figure) (Maranha et al., 2016) and numerical reproduction of experimental thermal tests of Cekerevac and Laloui (2004) (dashed lines) (Maranha et al., 2018).

Alongside developments in mathematical and computational reproduction of the thermo-hydromechanical behaviour of soils, especially in the context of shallow geothermal applications, advances in deformation measurement systems in laboratory and field settings (in terms of quality and volume of data), notably high-precision stereophotogrammetry, and genetic algorithm techniques for model calibration, and other technological advancements, will continue to allow further progress in the study of the thermohydromechanical behaviour of soils.

The compilation above presented, mainly focused on geothermal systems, did not made reference to partially saturated states, anisotropy, localization of deformation, spatial variability, dissection and fissuring, which all affect soil thermomechanical. It is believed that some of these aspects will become increasingly relevant in future climatic contexts.

4 PLANNING AND SUSTAINABILITY

The utilization of surface soil layers as a renewable and stable thermal energy resource and reservoir through shallow geothermal systems, here with a special focus on closed-loop systems and ground source heat coupled systems, including district heating and cooling (DHC) and thermal storage, has been changing the paradigm of soil study, utilization, planning and management in a more interdisciplinary perspective. Shallow geothermal energy is a promising low-carbon source to meet the heating and cooling demands of buildings and infrastructure. In this context, new solutions are emerging with the aim of harnessing thermal energy from the soil across various climatic conditions. For instance, capturing energy released in industrial settings for later use in space heating, domestic hot water systems, and other applications. Overall, a seasonal balance between heating and cooling is sought to avoid introducing changes in soil temperature fields and thus potential undesirable effects.

In this context, it is worth mentioning the approach of Walch et al. (2022), proposing a rational utilization methodology of the resource, taking into account the geothermal potential for the use of Ground Source Heat Pumps (GSHPs), defining this potential as the one that ensures seasonal regeneration of soil energy exchanges through re-injection of excess heat from space cooling. The goal is to estimate the usable energy to meet the energy demand of buildings at the regional scale, calculated for both direct heat exchange and urban DHC systems under different scenarios of climate change and market penetration levels of cooling systems.

Accounting for the seasonal regeneration of GSHP systems required matching the geothermal technical potential with the energy needs of buildings. This study involved not only mapping potential installations near buildings but also the one of DHC, noting that while individual GSHPs are directly connected to nearby buildings, DHC permits the transportation of heat between areas with high geothermal potential to areas with high energy demand. The methodology includes three phases (Figure 4): the first involves geospatial processing to match potential GSHP systems to building energy demands, the second analytical modelling to quantify the technical potential of heat exchange for GSHP systems, and the third analysis to optimize the location of the technical potential between individual GSHP systems and DHC. Applications were carried out by Walch et al. (2022) in Swiss cities (Geneva and Lausanne), where heating needs prevail but is foreseeing a significant increase in cooling demand. The results indicated that individual GSHPs could cover up to 63% of cooling demand and 55% of heating demand by 2050. With the use of DHC, these values increase to 87% and 85%, respectively

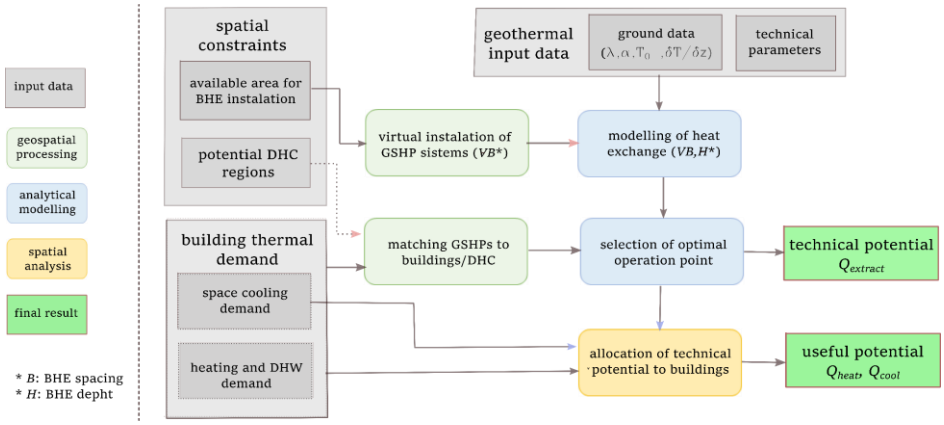

Figure 4. Three stages workflow for modelling the technical potential of GSHP and the useful potential for heat and cooling supply (adapted from Walch et al., 2022).

A rational and structured management at the urban level, as above proposed, always has at its basis an adequate thermal characterization of the soil. A similar approach, adapted to different climatic contexts where cooling needs prevail, emerges as a promising path for planning these systems. Thermal conductivity (and specific heat) geospatial mapping serve as the initial basis for the systems sizing, design and energy efficiency evaluation. In the absence of this information, thermal conductivity can be estimated from direct correlations with the lithological type. Dalla Santa et al. (2020) recently published a comprehensive compilation of thermal conductivity range values based on measurement results in different lithologies, which served as the basis for the initial estimation of this property for the geological formations in the city of Lisbon (Figure 5). This proposal was complemented with estimates based on

mineralogical composition and geotechnical parameters. This work is being complemented based on geotechnical information (derived from a large database of boreholes in the city available on GIS platforms available from the Lisbon Municipal Council), and also, with a higher level of detail and precision, with laboratory measurement data on undisturbed samples. This will entail characterization at three scales (city, site, and sample) which will be systematically updated. In a subsequent stage, based on the characterization of the soil at depth, sustainability analyses will be conducted for different types of buildings, taking into account the city' climate in climatic scenarios where cooling needs predominate, as is typical of Mediterranean climates.

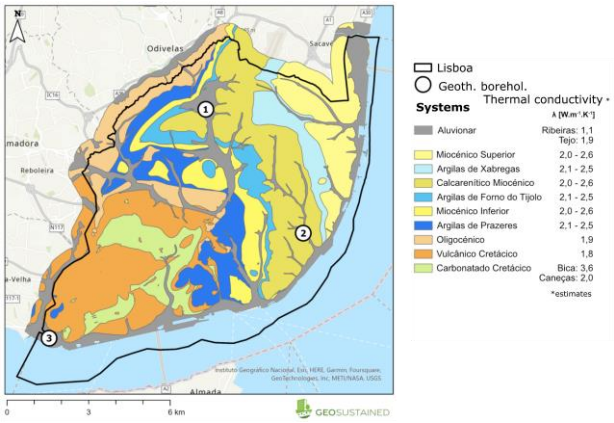

Figure 5. First estimate of Lisbon geological systems thermal conductivity (Inácio et al., 2023).

Soil temperature at a given location and its evolution at depth is also essential elements for the sizing and planning of geothermal systems. In general, the temperature at a particular location equals the average annual temperature at that location. However, in urban areas due to subsurface occupation and a variety of structural alterations and neighbourhood and boundary effects, ground temperature field can be altered. In addition to the study mentioned above for the city of Lisbon, continuous temperature recording is being carried out with fibre optic sensors in different locations of the city up to a depth of 120 m. Similar records exist at the University of Aveiro Campus since 2019, where temperature evolution is monitored in 15 research boreholes, placed around a shallow geothermal system integrating composed of 43 BHEs, with a 10-minute interval. This study aims to assess the long-term influence of a geothermal system operation on ground temperature.

Results of temperature profiles in this system are shown in Vieira et al. (2024), where are depicted monthly minimum and maximum average temperatures at various boreholes along with initial temperature profiles, numerically obtained based on laboratory conductivity results. Also concerning this system, heat maps of two research boreholes over a monitoring period of about 4 years (with some recording interruptions them during the pandemic period) are analysed. The processing of the large amount of data registered in this system is ongoing through correlation studies, incorporating factors such as: distance to the BHE, effects of facade orientation (solar exposure), and atmospheric temperature (via data from a nearby weather station). An increase in temperature has been observed, especially in the shallower depths, which is consistent with a rise in temperature in the city of Aveiro (both average and extreme) in the years under consideration.

When it comes to shallow geothermal systems, it is also of special relevance to promote the study and quantify the environmental impacts of their construction and operation, using appropriate metrics, in order to adequately assess the potential benefits of these systems. With this purpose, the Life Cycle Assessment (LCA) method, as defined by ISO 14040, which involves the compilation and evaluation of the inputs, outputs, and potential environmental impacts of a product system throughout its life cycle and enables accounting environmental impacts for any product, can be particularly suitable for these studies. It encompasses various life phases, beginning with raw material extraction and production, through operation, and concluding with end-of-life phases (e.g., disposal or landfill). This type of evaluation was carried out for a university building located in northern Portugal by Aljundi (2004), where an integrated analysis of the building energy simulation (BEM) with EnergyPlus tool and that of the installed geothermal system, was conducted based on appropriate soil characterization and local meteorological conditions. The BHE system was integrated in the BEM using the g-function models. The building model was calibrated using monitored temperature data recorded inside two rooms using temperature sensors and the primary energy needs for heating and cooling were assessed and compared with the design values. The effect of varying ground thermal conductivity was analysed in terms of system sizing for different scenarios. The sustainability analysis of the shallow geothermal system was conducted considering environmental and economic aspects using LCA methodology. A sensitivity analysis was performed to show the influence of soil thermal conductivity on BHE system sizing and, therefore, on its life cycle environmental impacts, and comparisons were made for different climatic contexts (different Portuguese cities) where the energy needs differ from that of the base case study. Moreover, the effect of the renewable energy share in electricity production on the environmental

impact of the operation of the system was studied. Overall, this study revealed the efficiency of the system in terms of energy and environmental aspects, with thermal conductivity being a critical aspect in energy simulation and in the quantification of environmental indicators.

The increasing urbanization and climate change will continue to promote the development of innovative solutions for energy and environmental management. The use of soil as a thermal reservoir emerges as a promising alternative to largely meet the heating and cooling needs in large urban centres, promoting decarbonization and improving the quality of life in cities. This utilization should be based on adequate soil knowledge, thus allowing appropriate management of this resource to avoid undesirable consequences, such as significant changes in soil temperature fields, which, besides affecting system performance over time, can have various impacts (from reducing the energy performance, to altering soil mechanical properties and, eventually, interfere with the surrounding biological environment).

5 FINAL REMARKS AND PERSPECTIVES

The relevance and scope of thermal soil study have evolved considerably in recent decades, from understanding the mechanisms of heat transfer, with the proposal of semi-empirical relationships taking into account the multiphase constitution of soil to estimate thermal properties, to significant advances in understanding the phenomenology of its multiphysical behaviour (thermohydromechanical), supported by laboratory tests under non-isothermal conditions, case studies of geotechnical works and structures, and the development of advanced constitutive models, to the issues related to the direct use of superficial geological layers as thermal reservoirs. Challenges stemming from increasing urbanization and climate change will continue to drive innovative solutions for energy management and environmental protection. Proper analysis of these solutions requires a multidisciplinary approach, with planning topics emerging as crucial. In this regard, geospatial mapping of soil thermal properties, the provision of adequate information for the design of each system with increasing discretization at the local and district levels, and the use of specific methodologies to assist in decision-making regarding strategic areas for the systems installation aiming at optimizing their performance, are essential.

It is particularly significant to analyse the temperature field alteration due to the exploitation of shallow geothermal systems at local and district-levels, both in the medium and in the long terms. For this purpose, monitoring and data analysis considering interferences, boundary effects, hydrogeological conditions, and climatic variations, will increasingly allow a better understanding of the possible induced alterations in soil deposits and their causes.

Regarding thermohydromechanical behavior, there is a mature understanding of the subject although doubts persist in some observed trends, both in isotropic stress states and generalized ones. Accounting for these effects must be considered in energy geostructures. Thermoplastic soil behaviour, which includes aspects of thermal compaction and consideration of strain rate in non-isothermal behaviour, should continue to receive attention, both in fundamental and applied research contexts. It is anticipated that the increasing frequency, amplitude and duration of heat waves and of long periods of drought alternated with intense rainfall, enhancing collapse phenomena large deformations and slope stability, is liable to progressively affect the performance of geotechnical structures and infrastructure, and it is essential to model these effects.

For considering these and other aspects, other approaches may be necessary, taking into account partial saturation and discontinuous medium analyses. Collaboration among different areas of knowledge, related to Civil Engineering, Geology, Environmental Engineering, Mechanical Engineering, Climatology and Land Use Planning, is essential for the success of this research. Integrating different perspectives and using advanced computational tools is NECES for the development of accurate and reliable models that allow for the optimization of soil utilization as a geothermal resource. The study of soil thermal behaviour is an ever-evolving research domain that demands thorough consideration in tackling the challenges of contemporary society.

Unearthing the urban future: the evolving role of tunnel and underground structures in modern cities

Déterrer l'avenir urbain: le rôle évolutif des tunnels et des structures souterraines dans les villes modernes

A. Cornaro*
ETH, Amberg Engineering Zurich, Switzerland
**acornaro@ethz.ch*

ABSTRACT: In the pursuit of maintaining and enhancing the livability of our cities, the utilization of both open and subterranean spaces is becoming increasingly crucial. This paper explores the imperative for multidimensional urban planning and infrastructure development, highlighting the rising significance of underground spaces. Addressing the escalating demands for housing, office space, infrastructure, and open areas within urban environments, the author underscores the necessity for strategic allocation of both surface and subsurface resources. International case studies of innovative underground developments are examined, showcasing multifaceted projects that ingeniously leverage subterranean space to meet diverse urban needs. This paper elucidates the pivotal role that tunnel and underground structures will play in shaping the future of modern cities, advocating for a forward-thinking approach to urban planning that embraces the full spectrum of spatial possibilities.

RÉSUMÉ: Dans la quête du maintien et de l'amélioration de la qualité de vie de nos villes, l'utilisation des espaces ouverts et souterrains devient de plus en plus cruciale. Cet article explore l'impératif d'une planification urbaine multidimensionnelle et du développement des infrastructures, en soulignant l'importance croissante des espaces souterrains. Répondant à la demande croissante de logements, d'espaces de bureau, d'infrastructures et d'espaces ouverts dans les environnements urbains, l'auteur souligne la nécessité d'une allocation stratégique des ressources de surface et souterraines. Des études de cas internationales de développements souterrains innovants sont examinées, présentant des projets à multiples facettes qui exploitent ingénieusement l'espace souterrain pour répondre à divers besoins urbains. Cet article élucide le rôle central que les tunnels et les structures souterraines joueront dans l'avenir des villes modernes, en plaidant pour une approche avant-gardiste de la planification urbaine qui embrasse tout le spectre des possibilités spatiales.

Keywords: Underground structures; urban planning.

1 INTRODUCTION

Cities are dynamic ecosystems where space is both scarce and precious. As urban populations surge and demands for housing, office space, infrastructure, and open areas escalate, urban planners face the daunting challenge of accommodating these needs within limited surface areas.

In response, the exploration of subterranean spaces has gained traction, offering a solution to the spatial conundrum. This article navigates through the labyrinth of urban planning, shedding light on the pivotal role that underground spaces play in shaping the future of modern cities

1.1 The necessity for multidimensional urban planning

To comprehend the significance of underground spaces, one must first acknowledge the multidimensional nature of urban planning (Admiraal and Cornaro, 2021).

Han Admiraal and Antonia Cornaro have extensively studied the intricate dynamics of urban spaces, emphasizing the need for holistic approaches that transcend traditional surface-level planning. Urban environments are not merely two-dimensional; they encompass layers of infrastructure, utilities, and potential living, recreational, social, and working spaces that extend beneath the surface. Neglecting this

vertical dimension leads to underutilization of valuable resources and exacerbates urban congestion and environmental strain.

As cities evolve, so must their planning strategies. Traditional urban planning often prioritizes surface developments, neglecting the vast potential that lies beneath. However, as populations burgeon and land becomes scarcer, this approach is no longer tenable. Shana Debrock, an advocate for subterranean urbanism, argues that the future of urban development hinges on embracing the full spectrum of spatial possibilities, including underground spaces (Debrok, 2021).

By adopting a multidimensional perspective, cities can optimize their limited land resources and foster sustainable growth.

1.2 Utilizing underground spaces to meet urban needs

The utilization of underground spaces presents a myriad of opportunities to address the diverse needs of urban populations. From housing and transportation to recreation and commerce, subterranean developments offer versatile solutions that complement surface-level infrastructure. ITACUS, the ITA's committee of Underground Space, dedicated to exploring the potential of underground spaces, emphasizes the importance of reimagining urban landscapes to encompass both horizontal and vertical dimensions.

2 CASE STUDIES

Several case studies from around the globe illustrate the innovative ways in which cities are harnessing underground spaces to alleviate urban pressures. Some examples are outlined below.

2.1 Hong Kong cavern development plan

Hong Kong, a city known for its dense urban fabric, faces significant challenges in meeting the demands for housing and infrastructure. To address this, the Hong Kong government has embarked on ambitious cavern development plans. (Ho, Wong, 2016)

By excavating vast underground caverns beneath the city, Hong Kong aims to create additional space for facilities such as transportation hubs, utilities, and storage. These caverns not only optimize land use but also enhance urban resilience by providing critical infrastructure protected from external threats such as typhoons and land scarcity.

They complement the inner-city urban underground uses and underground pedestrian networks.

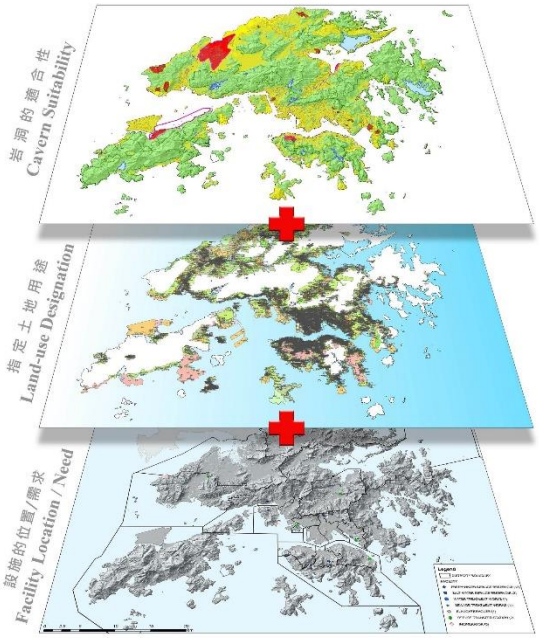

Figure 1. A task under the Study on Long-term Strategy for Cavern Development, CEDD.

2.2 Singapore: creating spaces for growing needs

The Urban Redevelopment Authority (URA) of Singapore emphasizes the significant role of underground spaces in creating a sustainable and resilient city of the future.

It highlights the importance of utilizing underground spaces for various purposes, including infrastructure, utilities, and transportation, to optimize land use and address the challenges of limited surface space in urban environments. By incorporating underground developments into urban planning strategies, Singapore aims to maximize the efficiency and functionality of its cityscape while enhancing the quality of life for its residents.

This underscores the URA's commitment to embracing innovative solutions and leveraging all available spatial possibilities to create a more livable and sustainable urban environment.

Singapore's Jurong Rock Caverns: In Singapore, the Jurong Rock Caverns project exemplifies how subterranean spaces can be leveraged for strategic storage and industrial purposes. Situated beneath Jurong Island, the caverns provide secure storage for liquid hydrocarbons, freeing up valuable surface land for other developments.

This innovative use of underground space not only enhances Singapore's energy security but also demonstrates the potential of subterranean solutions to address pressing urban challenges.

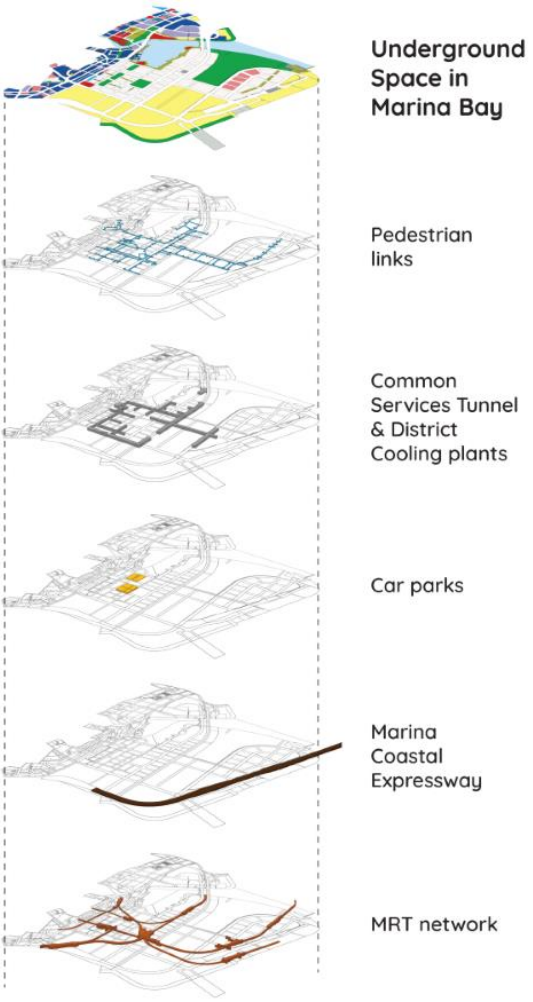

Figure 2. Spatial layering approach, Singapore, URA (2024).

2.3 London's subterranean infrastructure

London, a city with centuries of urban development, is increasingly looking underground to expand its infrastructure network.

From Crossrail, Europe's largest construction project, to the Thames Tideway Tunnel, which aims to alleviate pressure on the city's aging sewer system, London is harnessing subterranean spaces to enhance connectivity and resilience. These projects demonstrate London's commitment to integrated urban planning that encompasses both surface and subsurface realms.

A station schematic of Crossrail can be viewed below in figure 3. The Elizabeth line station at Canary Wharf is situated beneath a five-story mixed-use complex called Crossrail Place, which features a public rooftop garden. The station is so spacious that it could accommodate the entirety of Canary Wharf's iconic skyscraper, One Canada Square, laid horizontally within its confines.

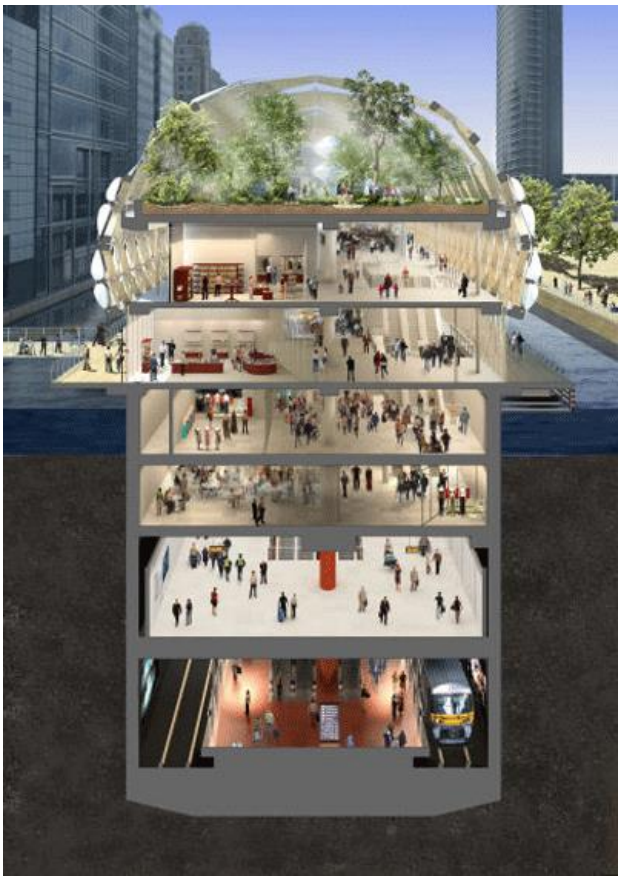

Figure 3. Station schematic of Canary Wharf, Crossrail.

An initiative that was co-launched by ITACUS, the ITA Committee of Underground Space through its National Action Think Deep Programme (NATDP) is the Think Tank *Think Deep UK,* a group of built environment experts committed to creating resilient, sustainable and liveable cities through smart use of underground space. Its mission is (1) to promote an awareness of the value of underground assets and to create a policy framework that can enable their fair use. (2) To inform and guide the general public, decision makers, politicians and professionals how the use of urban underground space can create better cities with socio-economic benefits for society. (3) To encourage thinking deeply when making decisions and planning for the future of our cities.

Such groups and initiatives help improve and broaden public opinion on the topic and are the basis of future policy shaping the future of cities.

2.4 Flanders region Urban Underground Space (UUS) plan

In the Flanders region of Belgium, the Urban Underground Space (UUS) Plan seeks to optimize the use of underground spaces for a variety of purposes, including parking, utilities, and recreational facilities.

By integrating underground developments into urban planning processes, Flanders aims to alleviate

surface congestion and enhance the quality of urban life. This comprehensive approach to underground space management serves as a model for sustainable urban development in densely populated regions.

2.5 Switzerland's national strategy on the underground

Switzerland, known for its engineering prowess, has developed a national strategy to maximize the potential of underground spaces. Recognizing the need for coordinated planning and management, Switzerland's strategy emphasizes the importance of integrating underground developments into broader urban planning frameworks.

From transportation tunnels to underground energy provision to underground research facilities, Switzerland's approach underscores the versatility and resilience of subterranean solutions in shaping the future of urban environments.(Swisstopo, 2023).

3 CHALLENGES AND OPPORTUNITIES

Despite the immense potential of underground spaces, their integration into urban planning poses unique challenges. Technical feasibility, cost considerations, and regulatory frameworks often impede the realization of subterranean projects. Moreover, public perception and safety concerns can hinder public acceptance of underground developments. However, as demonstrated by successful case studies and ongoing research initiatives, these challenges are by far not insurmountable.

The various cited case studies from around the world illustrate innovative approaches to utilizing underground spaces in urban environments and how they can benefit society overall.

4 CONCLUSION

In the pursuit of sustainable urban development, the utilization of underground spaces is no longer a mere novelty but a necessity. As cities grapple with escalating urban pressures, embracing multidimensional planning approaches that encompass both surface and subsurface realms is imperative.

The case studies highlight the diverse approaches cities are taking to address urban pressures and create more sustainable, resilient, and livable urban environments through the strategic use of underground spaces. By harnessing the full spectrum of spatial possibilities, cities can unlock new avenues for growth, innovation, and livability. As Antonia Cornaro and Han Admiraal assert, the future of urbanism lies beneath our feet, waiting to be unearthed (Admiraal and Cornaro, 2016).

Underground and beyond: The road to resilience

Souterrain et au-delà: En route pour la résilience

A.N.P. Lamas*
Amberg Engineering , Brussels, Belgium
**plamas@ambergengineering.com*

ABSTRACT: Cities currently house more than half of the world's population, and by 2050, this number is expected to rise dramatically. With increasing urbanization, cities face significant challenges, including the need for sufficient and appropriate infrastructure, particularly transportation infrastructure. Besides, public owners are taking the environmental impact of their projects more and more seriously, and as a result, both designers and contractors need to tackle this arising concern and find solutions to increase resiliency of their projects. In this context, tunnelling offers an underground alternative to standard surface transport networks , providing new space in saturated areas and opening the door to exploring more resilient and sustainable ways of urbanism. Designing a new path into this transformation will however imply a social mindset change. Advanced construction techniques help minimize surface disturbance and habitat disruption. Real-time monitoring systems together with artificial intelligence and predictive analytics are being used to optimize maintenance schedules and detect potential issues before they escalate. A new construction era begins and possibilities offered by the underground are yet to be rediscovered.

RÉSUMÉ: Plus de la moitié de la population mondiale habite à ce jour dans des villes et on attend cette chiffre d'augmenter énormément d'ici 2050. Avec l'urbanisation croissante, les villes sont confrontées à des défis importants, notamment la nécessité de disposer d'infrastructures suffisantes et appropriées, en particulier dans le domaine des transports. En outre, les institutions publics prennent de plus en plus au sérieux l'impact environnemental de leurs projets et, par conséquent, les concepteurs et les entrepreneurs doivent s'attaquer à cette préoccupation croissante et trouver des solutions pour accroître la résilience de leurs projets. Dans ce contexte, les tunnels offrent une alternative souterraine aux réseaux de transport de surface, fournissant des nouveaux espaces dans les zones saturées et en ouvrant la voie à l'exploration des modes d'urbanisme plus résilients et durables. La conception d'une nouvelle voie vers cette transformation impliquera toutefois une évolution de mentalité à niveau social. Des nouvelles techniques de construction permettent ces jours de minimiser les perturbations de la surface et de la population. Des systèmes de suivi en temps réel, associés à l'intelligence artificielle et à l'analyse prédictive, sont utilisés pour optimiser les plannings de maintenance et détecter les problèmes potentiels avant qu'ils ne s'aggravent. Une nouvelle ère de construction commence et les possibilités offertes par le sous-sol restent à redécouvrir.

Keywords: Tunnel; resilience; innovation , mindset.

1 INTRODUCTION

The development of new infrastructure in today's global context is faced with several challenges, particularly when it comes to ensuring resilience of new infrastructure. In addition, the modern urban environment is characterized by a heavily constrained network, presenting many restrictions for transportation development, such as space limitations, conglomeration of existing structures, surface traffic, and disturbances to the everyday life of the city's residents. Underground infrastructure can be seen as a perfect alternative solution for both of these problems.

This article aims to explore possibilities within the underground space. On one hand, underground infrastructure provides various opportunities for sustainable practices, taking advantage of self-sustaining energy sources through geothermic activation and exploring innovative construction methods to reduce the carbon footprint. On the other hand, it allows for efficient use of surface space, promoting social cohesion and civic engagement.

Regulatory and policy context transformation required to transition to this new way of imagining infrastructure development are also discussed in the following chapters.

2 NEW CHAPTER IN INFRASTRUCTURE DEVELOPMENT

The engineering private sector is just beginning to accept the challenge of participating in this new commitment, enhancing infrastructure resiliency. Environmental considerations are now central to tunnelling projects. The main challenge consists of identifying the hazards that could jeopardize the durability of the project soon enough to be able to confront them.

Once the target has been outpointed, expert collaboration and rigorous study of the case in its context will allow us to seize the opportunity to change the industry pattern and develop our project within a sustainable frame.

Embracing a circular economy approach promotes the reuse, recycling, and repurposing of materials to reduce the overall environmental footprint of the project. Exploring possibilities of the underground space is set to be the new path to ensure liveability in urban environments as we know them.

2.1 New initiatives and criteria assessment

Improving energy efficiency is the key to building resilience. Such a goal can only be achieved in the context of a supporting policy framework. Creating fair green certifications and transparent labelling, incentivizing data-driven design tools, or promoting investments in recycled, reused, and bio-based materials are some of the initiatives that can help promote such a scenario.

Once the framework is constructed, third-party verification of work site processes and emissions shall guarantee sustainability compliance during construction. Regulatory measures regarding the design and conception of the infrastructure will ensure long-term compliance for the remaining infrastructure's lifespan.

2.1.1 Updating sustainability assessment

Every construction project counts with several indicators that can be assessed from a sustainability perspective. Such indicators have traditionally had an importance regarding the general overview of the construction project.

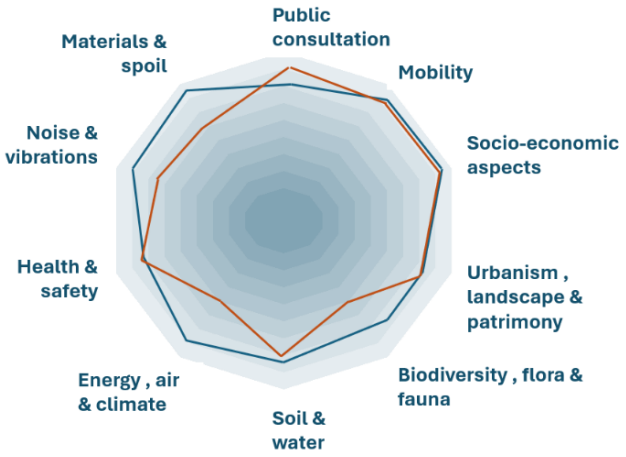

Figure 1. Sustainability indicators relative weight drift between standard (orange) and resilient (blue) metro projects decision-making.

However, since public policies are drifting to adapt to new resilience requirements relative weight or such indicators also ought to be reconsidered, as illustrated in Figure 1.

Standardizing requirements from a policy perspective is essential. To evaluate a project's sustainability performance, it is necessary to define adequate criteria based on the following facts:

- Quantifiable factors;
- Qualitatively ascertainable criteria;
- Regulated framework;
- Resilience requirements for infrastructure included in tender specifications.

2.2 Mindset & policy change

In order to fully implement the initiatives discussed in chapter §2.1, a change in mindset is required to encourage a policy transition. Currently, decision makers in the construction industry are typically manufacturers, owners, and developers. However, we are advocating for a shift in mentality so that governments take on the responsibility of promoting resilience and become the key decision makers when it comes to construction projects. This can be achieved by regulating the construction framework. Once this shift is accomplished, designers will guide policy makers in implementing a new, more resilient approach to construction.

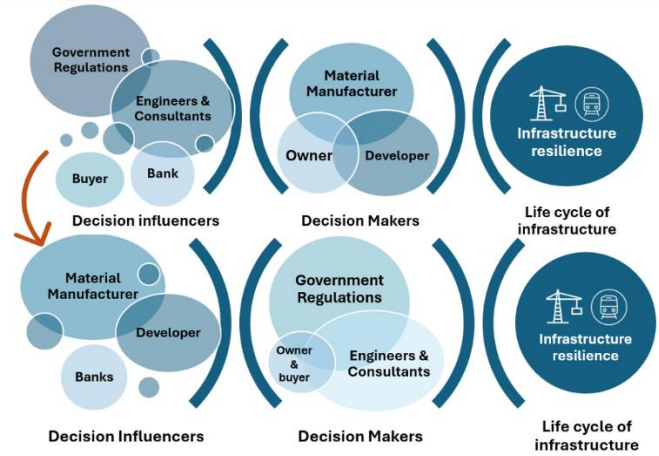

Figure 2. Shift in decision-making intervenors on infrastructure life cycle

In this reinvented scenario, new responsibilities shall be assumed by the designers:

- Design for longer life
- Increase research and education in decarbonisation strategies
- Digitalization of design to ensure optimization from a very early stage of the project (BIM)
- Design based in local materials reuse (ie. muck treatment for concrete production)
- Closed collaboration with manufacturers to enhance the use of circular materials
- Improve management of on-site construction with circular design
- Design for disassembly and re-use when possible (reuse of TBMs and construction facilities)

3 EXPLORING UNDERGROUND POTENTIAL

3.1 Geothermic activation of metro network

Geothermic activation of underground infrastructure is imagined as a shortcut to ensure self-sustainability of new metro networks.

Feasibility studies for geothermic activation of subway projects involve the following steps:

- Identification of the horizontal and vertical alignment of the layout;
- Definition of existing solutions;
- Division of the line into homogeneous sections in geological and hydrogeological terms;
- Application of geothermic abacuses to each homogeneous section identified to evaluate the winter and summer geothermal potential and the total thermal power that can be exchanged with the ground;
- Identification of receptors;
- Assessment of the economic, regulatory and technical framework;
- Definition of the studies to be carried out in the subsequent phases of the project and planning.

Amberg Engineering has explored methodology together with GEOEG for Brussels Metro and also with NGE for L15 Grand Paris.

3.1.1 Grand Paris Ligne 15

In the context of the opportunity study, an assessment of L15O geothermal retaining walls and tunnel potential has been conducted. Results show that a geothermal activation of the line would make it possible to mobilize the following powers below:

Table 1. Table of exchangeable power results for L15O

Season	Tunnel	Stations	Total
Summer	2,57 MWh	0,99 MWh	3,56 MWh
Winter	5,43 MWh	0,82 MWh	6,25MWh

A preliminary analysis of potential energy needs per station was equally drafted. It should be noted that the energy demand for cooling in the anticipated scenario is greater than the demand for heating, due to the permanent need for cooling the technical rooms.

The requirements per station would therefore be:

Table 2. Table of exchangeable power results for L15O

In winter	In summer	All the year
162 kWh / station	376 kWh / station	376 kWh / technical rooms

The conclusion withdrawn is that activation of the retaining walls alone is enough to cover the stations' heating and cooling needs all over the year. The technical rooms could be cooled all year round.

However, the risk of using the system continuously in a single mode (cooling) is to lead to an annual thermal drift with a decrease in thermal performance over time (heat saturation of the ground). A further study on this particular issue was to be pursued.

3.1.2 Metro Nord Brussels

A similar study was conducted on Metro Brussels, including in this case geothermic activation of the station slabs. Results showed that power mobilized would suffice to provide energy for the stations and energy-efficient housing within a 100m radio from the metro stations.

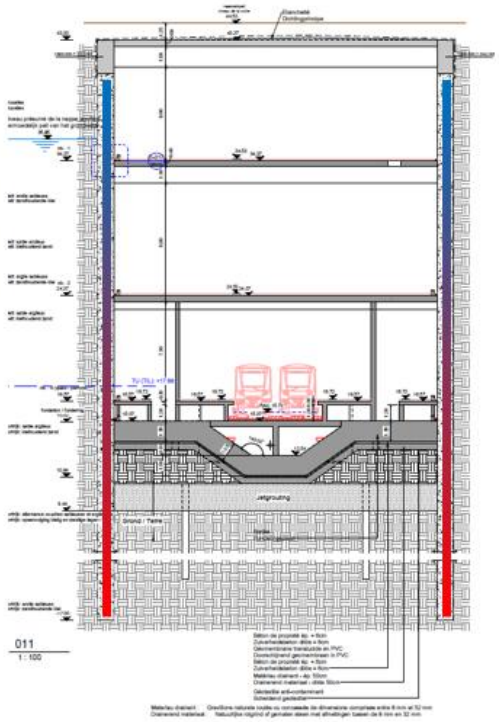

Figure 3. Geothermic activation of Metro Nord Bruxelles station.

3.2 Innovation for resilience

3.2.1 Materials

It is well known that most current construction materials rely on energy-intensive, mineral-based extractive processes which cause deleterious environmental impacts all through the life span of the material. Concrete and cement by themselves are responsible of ~1.5% of global CO2 emissions. Besides, the 'take-make-waste' model still governs current material production practices. This means that most construction materials become waste once their lifespan is completed.

Aiming for decarbonising materials at a global scale in the construction sector imposes a mindset change to unblock resistance, and for that purpose, policymakers must engage actors across the value chain.

Investment on further materials investigation shall be a first priority goal for actors within the material production chain. Recent studies have found that the inclusion of limestone fines in a CEM I and GGBS ternary system improved material efficiency, demonstrating that the limestone fines could be used as a replacement for both the CEM I and GGBS portions of the blend. This results in concrete with both a lower embodied carbon and a reduced use of GGBS, whilst producing an equivalent performance.

Action still needs to be taken by policymakers in order to implement a regulatory framework that can impose new carbon print limitations on construction materials. A restrictive policy change regarding construction materials would trigger increased investment in alternative solutions. In this regard, the UK has just set a European example with the update of the standard BS 8500:2023, which incorporates the use of multi-component cements. This update allows for a reduction in the proportion of Portland cement used for a given volume, thereby reducing the embodied carbon in the concrete produced.

3.2.2 Artificial Intelligence

In recent times, the quest for innovative ways to reduce carbon footprint has led to increased exploration of out-of-the-box thinking. Every effort counts towards achieving the goal of resilience and given the point at which we stand today, conventional approaches may no longer suffice. It is, therefore, imperative to explore creative solutions and rethink our development approach. How can IA help geotechnical engineers in achieving this objective? Some of the possibilities that can be developed through this new powerful tool might be:

- Increasing efficiency through a faster data analysis;
- Reducing material consumption by ensuring a more accurate design ;
- Increasing safety by granting a more controlled construction environment.

Digitalizing the entire project lifecycle will make data-driven decisions easier and faster.

Furthermore, IA , as a data-based tool, will allow us to improve the calibration of geotechnical models by using historical data combined with real-time backanalysis. This methodology will rapidly compare monitoring data (such as topography, inclinometers, piezometers, etc.) with geotechnical information from surveys, which had previously been introduced in a digital twin (numerical models). This cross-check of geotechnical data will provide a more accurate representation of the real soil behaviour.

Relying on such a data platform may allow us to eventually optimise construction projects by reducing geotechnical uncertainties for a more suitable design.

Besides, new machine learning algorithms analyse excavation data in real-time, optimizing tunnelling strategies and minimizing wear on equipment. AI-driven predictive analytics can optimize TBM performance and prevent potential operational disruptions. This ensures not only greater efficiency but also extends the operational lifespan of the machinery.

The integration of machine learning into geotechnical engineering represents a significant challenge but may open a whole world of possibilities regarding efficiency and safety during construction.

Undoubtedly, systematic analysis of the context constraints and requirements, followed by a well-planned implementation of novel strategies like IA, will be key steps for the industry to take towards a more efficient, and therefore more sustainable future in construction.

3.3 Reconsidering underground space

3.3.1 Madrid's reconditioning

M30 road is an urban motorway that with a total length of 32.5km and three lanes per direction, circles the central districts of Madrid.

As it passes through Las Ventas, M30 alignment, dating from the late 70's, had not being conceived underground despite running below the surface level.

However, recently approved urban proposal foresees transitioning this stretch from an Open Cut to a Cut & Cover solution, allowing to create a green recreative area above the current traffic lanes. This measure will not only entail covering M30 roadways with a green refreshing carpet but will also decrease sound disturbances due to heavy traffic in the area.

Besides, the new park will enhance communication between neighbouring districts that where at the moment split apart by the urban motorway, transforming urban fabric perspectives.

Figure 4. Current situation at Las Ventas bridge, Madrid.

Figure 5. Foreseen urban action Las Ventas bridge, Madrid.

Being able to recover a damaged urban framework in such a way that it allows to rebrand a neighbourhoods character, revitalizing its surroundings proves the real impact of exploring new underground opportunities.

This being said , truth is underground works initiatives are too often burdened by high cost estimations expectations, from a policy making perspective. However , mixed solutions such as Cut&Covers might arise great opportunities to relieve urban pressure within rather affordable budgets. Counting on creative technical teams supporting policy decision making should allow to explore alternative ways of reinventing saturated metropolitan areas.

4 CONCLUSIONS

Underground infrastructure innovation and development open up the possibility of exploring the urban fabric in ways that were just not technologically possible years ago.

Imagining the possibilities of creating a self-sufficient underground space and building the tools to explore it and take the most out of it defies the traditional concept of geotechnical and tunnelling engineering as we knew it.

Achieving a better balance between infrastructure development and resilience is nonetheless, a major task. Taking up this challenge has yet become our responsibility as a generation, making the assignment both appealing and demanding. Engaging ourselves as engineers in this urgent request implies committing to the responsibility of changing direction. We have it still in our hands to take action and make it happen.

Underground space: Opportunity or a non sense option?

L'espace souterrain: Opportunité ou option insensée?

P.R. Silva*
Saraiva+Associados, Lisbon, Portugal
**prsilva@msa.com.pt*

ABSTRACT: The growth of the world population and its movement to cities in search of better opportunities will continue to place urban infrastructures and the needs for housing, equipment and services under great pressure. This growing demand, which is expected to continue, poses major challenges to city management. The topic does not end with the issue of available space, but nowadays it is mainly focused on sustainability issues. For example, the costs associated with mobility (time and pollution) and the provision of services (operation and maintenance of urban services) place available space under great scrutiny. For architects, among other professionals, urban planning and design, the design of different uses and buildings, must take in to account the dimension of the lifestyle it provides. Architecture as an art of creating the physical space where human activity takes place has to consider which spaces are best for each use, associating this placement in the territory with a way of life, providing private space and public space in a desirable balance for the development of a plural and happy society. This consideration of spaces for different uses has meant that, over time, the underground space has been used to house some of the activities. This allocation has been variable, but population growth and the need to make the best and most efficient use of available space opens up new perspectives.

RÉSUMÉ: La croissance de la population mondiale et son déplacement vers les villes à la recherche de meilleures opportunités continueront de mettre les infrastructures urbaines et les besoins en logements, équipements et services sous forte pression. Cette demande croissante, qui devrait se poursuivre, pose des défis majeurs à la gestion de la ville. Le sujet ne se limite pas à la question de l'espace disponible, mais il se concentre aujourd'hui principalement sur les questions de durabilité. Par exemple, les coûts associés à la mobilité (temps et pollution) et à la fourniture de services (exploitation et entretien des services urbains) soumettent l'espace disponible à un examen minutieux. Pour les architectes, entre autres professionnels, l'urbanisme et le design, la conception des différents usages et des bâtiments, doivent prendre en compte la dimension du style de vie qu'ils offrent. L'architecture en tant qu'art de créer l'espace physique où se déroule l'activité humaine doit considérer quels espaces sont les meilleurs pour chaque usage, en associant cet emplacement sur le territoire à un mode de vie, en fournissant un espace privé et un espace public dans un équilibre souhaitable pour le développement d'une société plurielle et heureuse. Cette considération des espaces pour différents usages a fait qu'au fil du temps, l'espace souterrain a été utilisé pour abriter certaines activités. Cette répartition a été variable, mais la croissance démographique et la nécessité d'utiliser au mieux et le plus efficacement l'espace disponible ouvrent de nouvelles perspectives.

Keywords: Underground construction; sustainability; lifestyle; architecture.

1 INTRODUCTION

The growth of the world population has caused enormous pressure on cities, the main centers of economic activity and which offer more opportunities for work, quality of life and leisure (Figure 1).

Cities have been the great catalysts for development, with a great concentration of economic activities, namely services, industry and leisure, with the consequent increase in those who want to live there, resulting in a clear need for housing and education, health, culture, among others.

This fact has caused great pressure on land use in areas where there are cities, with enormous environmental impacts and infrastructure costs associated with these expansions.

The cost of expanding construction horizontally, especially with regard to the maintenance and exploitation of urban and transport infrastructures, has put pressure on construction to be carried out vertically in many circumstances, often densifying low-density spaces that are already in place. infrastructure and which are demolished.

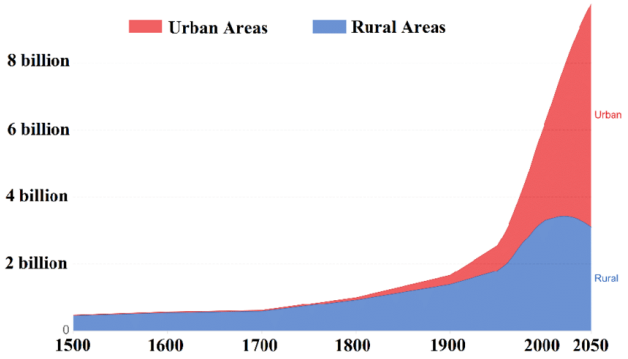

Figure 1. Urban vs Rural areas; Source: Research Gate.

2 OVERVIEW OF UNDERGROUND CITIES

This densification is, from a certain point of view, a sustainable response, maximizing resources, saving infrastructure and also minimizing mobility needs.

The exponential increase in the built space of cities, and the consequent competition between uses, led to the set of urban infrastructures that support their functioning occupying "non-useful" territory, that is, the underground.

Along with the increase in population, the development of economic activity has systematically changed production models, consumption continues to increase as well as emissions.

These new lifestyles have caused profound changes in natural balances and put biodiversity and, above all, the planet's biocapacity under great pressure, which will certainly lead us, if drastic changes are not introduced in the way we use the planet, to a collapse.

The increase in the area occupied by cities and the degradation of the global state of the planet are two facts that are intrinsically linked.

Although architecture and urban design, an activity of architects and which we develop at S+A, cannot in themselves solve this problem, they can, as instruments for creating the physical space where we live, be agents of change, inducing changes in styles of life.

Man has always sought shelter and with the evolution of his needs, he has gone from simple protection from the elements, and defense against predatory animals, to a broader search for comfortable living spaces.

The shelter always had a connection with "under the roof", and in some cases it was even "under the ground".

On the other hand, our desire to be outdoors, with natural light, factors that influence the entire natural environment and in some way our well-being, lead to the outdoor space also being designed.

Over time, the occupation of underground soil has had different reasons, such as Cappadocia in Turkey (Figure 2), Pilsen in the Czech Republic, or Naours in France.

Some of these spaces continue to be incorporated into our activities, especially as tourist attractions that provide "experiences", an aspect that is important to consider in land use competition and that in many circumstances can have major impacts on the functioning of cities.

The search for "shelter", which has become home, continues to be a very relevant factor today and not just due to climatic factors.

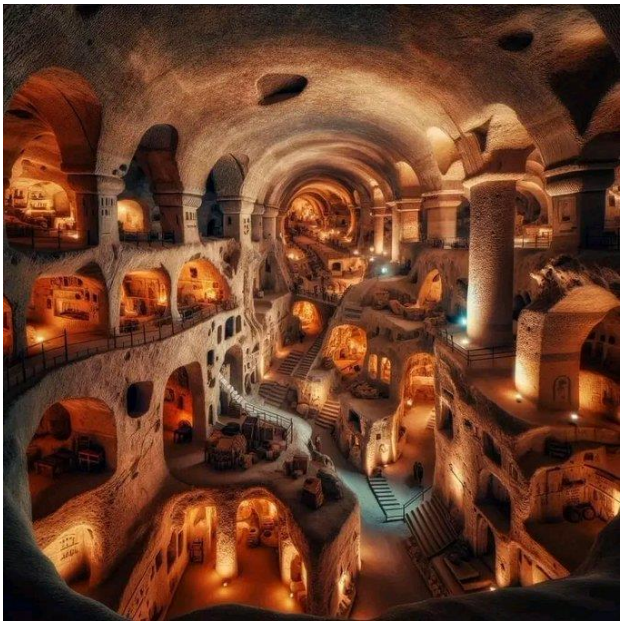

Figure 2. Derinkuyu, Turkey – Underground city; Source: Reddit.

The increase in living conditions was, and continues to be, a challenge, as well as finding new answers to the comfort needs that new lifestyles demand.

Society is evolving and ways of living are changing, looking for new models of organizing spaces, whether built or outdoors, an aspect that has proven to be extremely important for the quality of life required in the days of today.

This factor of the need of free space for everyone to enjoy outdoor living puts even more pressure on the city's land.

Our projects can respond to the most challenging programs, whether through the composition of construction elements or with new design solutions. Throughout our professional practice, we have seen programmatic responses to the most varied challenges, namely new use programs, climate protection, minimization of energy and water consumption,

comfort requirements, spaces adapted to different lifestyles.

These are new responses to the "shelter" that has become "home", in the current conditions of society, and which obviously takes different forms in different geographies.

However, we continue to observe several phenomena that continue to put pressure on the city's spaces and are causing significant changes in built spaces.

3 NON SENSE OPTION?

But in essence, we can summarize the situation as a new "shelter" and protection from the "weather". Shelter in the current context, that is, protected spaces for all the activities that society develops, has different characteristics and responds in many cases to the stimuli of new lifestyles.

In the case of "weather" protection, we are not only talking about effective protection from the weather and the climatic factors of each location, but we must include "sheltering the planet from the weather", that is, actively contributing to reductions in consumption and emissions in all possible components and, at the same time, ensure the increase in biodiversity by freeing up space on the surface to house new green spaces and also not occupying new natural territories with construction.

Underground construction has arisen for various reasons, but initially due to a lack of available space to expand the supply, namely commerce and leisure.

It is also worth noting that in some geographies, planned activities and uses cannot be carried out outdoors for a large part of the year, nor is there natural light. In these cases, why not?

Figure 3. Montreal Underground city; Source: Guide to Underground City.

Even without considering climatic conditions of extreme temperatures or lack of daylight, some of the activities are already, and some always have been, carried out in many enclosed spaces, without natural light, such as theater or cinema, and can clearly be transferred for buried spaces, leaving surface spaces free for housing or office uses, uses where natural light is clearly more valued.

There are already several examples of shopping centers, multifunctional spaces and also plans to expand the city into underground spaces.

We can point to Montreal, Singapore, and Helsinki as examples (Figures 3, 4 and 5).

Figure 4. Singapore Underground plan; Source: Ziptopia.

These are expansions of cities that take advantage of existing structures or that plan new areas for expansion and rehabilitation with very different programs and uses.

These are ambitious examples, which are important to evaluate not only from the perspective of efficiency and soil optimization, which is important and economically very relevant, but fundamental from the perspective of protecting the planet and the quality of life of all inhabitants.

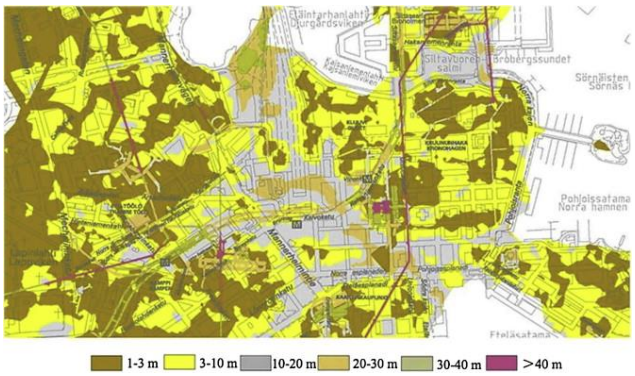

Figure 5. Helsinki Underground plan; Source: Science Direct.

When occupying the underground areas, it will be important to assess under which circumstances the infrastructure will be more efficient in terms of air conditioning or energy consumption.

But also, what uses are appropriate: commerce? hotels? culture? leisure?

It seems clear that some activities that take place in enclosed spaces can be transferred underground, freeing up surface territory, but other aspects, some already described above, must be taken in to account. Especially regarding habitability and the need for each use.

One of the situations that will be important to present in this short note is the case of underground projects that are developed to offer a different "experience" of life.

In recent decades, there has been an increased demand for lifestyles that are very focused on distinctive factors.

The underground has also been the target of proposals for highly spectacular projects, where the challenges are enormous, namely how natural light enters, or what type of infrastructure will need to be installed.

We can point out two cases, one in Mexico City, with the Underground Scraper (instead of skyscrapers) or the recent proposal from NEOM, a KSA PIF, The Aquellum (Figure 6), a vision of a digital underground community on a mountain next to the Gulf of Aqaba.

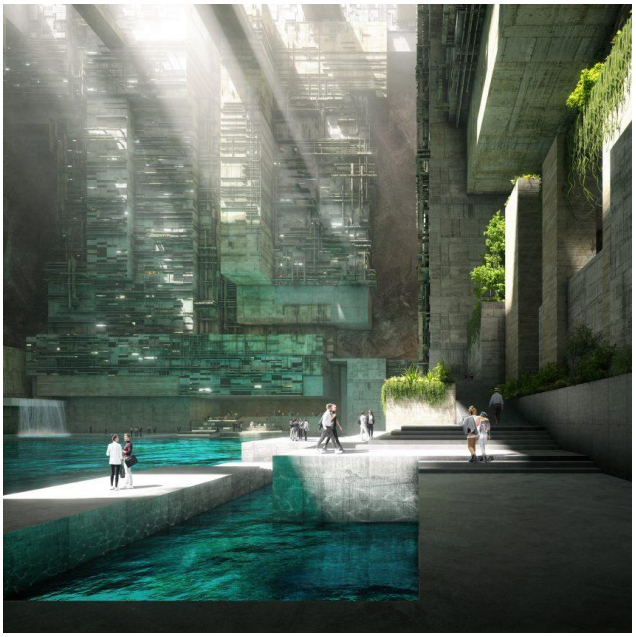

Figure 6. NEOM – Aquellum – Source: NEOM.

4 FINAL REMARKS

are proposals with enormous challenges for all project areas, particularly geotechnical. Not only because of much more construction underground, but because the volume of built elements that will overlap in this space can grow a lot, making the integration of all systems and technical requirements much more demanding.

There are also major challenges to technology, such as how to bring natural light underground?

The world continues to pose challenges to the creators of built space and to all the technical disciplines that contribute to these creations.

The need for shelter from the elements will continue, but now with new ingredients that we have to incorporate into projects, ensuring a unique quality, as should be the objective of each and every construction project.

The Heritage Time Capsule project and the Portuguese geotechnical history

Le projet Heritage Time Capsule et l'histoire géotechnique Portugaise

J. Mateus de Brito*
Consulting Engineer, Ex-TPF/Cenor, Lisbon, Portugal
**jmateusdebrito@gmail.com*

ABSTRACT: Within the scope of the Heritage Time Capsule (HTC) project, launched by the International Society of Soil Mechanics and Geotechnical Engineering (ISSMGE), the Portuguese Geotechnical Society (SPG) has been developing actions related to the History of Geotechnics in Portugal. The objectives of the project, the actions already carried out and the main aspects of the contribution given by SPG are described. The most relevant aspects of the development of geotechnics in Portugal and main large projects in the last 70 years are briefly presented. Main large geotechnical engineering projects underway and those planned are also briefly presented.

RÉSUMÉ: Dans le cadre du projet Héritage Time Capsule (HTC), lancé par la Société Internationale de Mécanique des Sols et d'Ingénierie Géotechnique (ISSMGE), la Société Géotechnique Portugaise (SPG) a développé des actions liées à l'histoire de la géotechnique au Portugal. Les objectifs du projet et les actions déjà réalisées ainsi que les principaux aspects de la contribution apportée par SPG sont décrits. Les aspects les plus importants du développement de la géotechnique au Portugal et les principaux grands projets des 70 dernières années sont brièvement présentées. Les principaux grands projets d'ingénierie géotechnique en cours et ceux prévus pour le futur sont également brièvement présentés.

Keywords: Portuguese geotechnical history; portuguese geotechnical works; Heritage Time Capsule project.

1 PORTUGUESE NATIONAL SOCIETY

SPG was formally created in 1972, although in reality it began in 1951, the year in which the Portuguese Society of Soil Mechanics (SPMS) was created (Nascimento, 1990), developing its activity within the scope of the Soil Mechanics Commission of the Portuguese Engineers' Order (OE), which was led by Professor Manuel Rocha (Figure 1). In 1952, this Commission promoted, a course on Soil Mechanics of great impact on the national technical environment. It was this course that definitively established Soil Mechanics in Portugal.

The Commission of OE became independent in 1960 and joined the ISSMFE in the same year. In 1966, coinciding with the holding in Lisbon of the First International Congress of Rock Mechanics (Figure 1), became part of the International Society of Rock Mechanics - ISRM (SPG, 2021). With this, also in Portugal, rock mechanics was established as an independent discipline, within the scope of geotechnical engineering. At that congress, around 800 people participated and around 250 works were presented, many of exceptional interest. Manuel Rocha was elected President for the period 1966-1970 and the secretariat of ISRM was installed at Laboratório Nacional de Engenharia Civil (LNEC), where it remains until today.

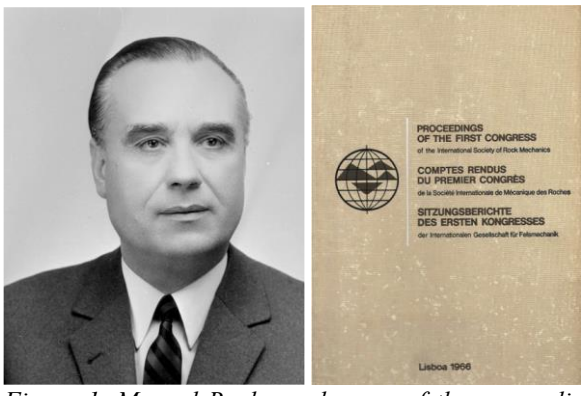

Figure 1. Manuel Rocha and cover of the proceedings of the First International Congress of Rock Mechanics.

Since then, the SPMS became member and represents in Portugal the International Association for Engineering Geology and the Environment - IAEG (1972), the International Tunnelling Association - ITA (1980), and the International Geosynthetics Society - IGS (2001).

SPG launched the first issue of Geotecnia Journal in June-July 1971 (Figure 2), with José Folque as director, and the president of SPMS, Úlpio Nascimento, as editor (Figure 3). The publication of Geotecnia journal has been a regular activity of SPG. Currently, the journal is published by SPG with the collaboration of the Brazilian Association of Soil Mechanics and Geotechnical Engineering (ABMS) and the Spanish Society of Soil Mechanics and Geotechnical Engineering (SEMSIG). The journal is published quarterly.

In 2007, Solos e Rochas Brasilian Journal, that was first released in 1978, acquired the status of an international journal, being, since then, published in english, by ABMS and SPG under the title Soils and Rocks (Figure 2). This journal is published quarterly.

Figure 2. Covers of the first issue of Geotecnia Journal (June-July 1971) and of Volume 30, N. 1 January-April 2007, first issue of Soil and Rocks Journal.

Figure 3. José Folque (left) and Úlpio Nascimento (right).

SPG awards four prizes:

- Manuel Rocha Award, established in 2003, with the aim of rewarding research works at the doctoral level; the prize is awarded every four years;
- SPG Award/Young Geotechnicians Award/José Folque Award, since 1984-1985 biennium, with the aim of encouraging research within the scope of postgraduate activities at master's level;
- Geotecnia Journal Award/Úlpio Nascimento Award, since 1986-1987 biennium, with the aim of reward the article with the greatest technical and scientific interest published in the journal;
- Ricardo Esquível Teixeira Duarte Award, established in 2017, with the aim of distinguishing the authors of design solutions for geotechnical works or projects with a relevant geotechnical component, already completed (every two years).

In 1984 the Manuel Rocha Lecture was established by SPG and the Association of Geotechnicians Former Students of Universidade Nova de Lisboa (UNL). It is held annually at the Calouste Gulbenkian Foundation headquarters, with geotechnical guest speakers of recognized merit, alternately Portuguese and foreign. Forty lectures have already been presented to date.

Manuel Rocha was one of the pioneers of geotechnics in Portugal and he is considered the most illustrious Portuguese geotechnician. He was the driving force behind rock mechanics studies and one of the greatest international researchers in this field. He was director of LNEC between 1954 and 1974, date in which he took up the position of Minister of Public Works.

Under the auspices of SPG, in addition to the First International Congress of Rock Mechanics, the main international conferences held in Portugal were:

- 7th Congress of IAEG, at LNEC (1994);
- 11th Congress of ISRM at LNEC (1996);
- 3rd International Congress of Environmental Geotechnics at LNEC (1998);
- 2nd Internacional Conference of Earthquake Geotechnical Engineering, at LNEC (1999).

It is worth noting that Ricardo Oliveira was elected IAEG Vice-President for Europe in 1986 and IAEG President (1990-1994). It is also worth noting the election of Pedro Sêco e Pinto for ISSMGE Vice-President for Europe (2001-2005) and ISSMGE President (2005-2009).

SPG also collaborates with ABMS in the organization of the Victor de Mello Lecture, that was established in 2008. It takes place every two years, alternating in Portugal and Brazil, and is preferably given during the Luso-Brazilian Geotechnical Congresses. Eight lectures have been presented to date.

2 THE HERITAGE TIME CAPSULE PROJECT

In 2021, ISSMGE launched a project with the objective to collect the main milestones of the contribution of geotechnics to the development of each country at national level and around the world, creating an HTC, and invited the Member Societies to give their contribution. SPG accepted the challenge and considered this to be a unique opportunity to publicize the achievements and current state of Portuguese geotechnical engineering, as well as to foresee and prepare the future, thus filling the existing gap in the systematization of knowledge in these areas. Beyond this first phase, concerning contributions, three more phases have emerged as explained by Pathmanandavel et al (2024) in this European Conference.

3 SPG CONTRIBUTION TO HTC

SPG defined the following objectives for its contribution to the HTC project: (i) disseminate the cultural, scientific and technological heritage, showing what is important in the history of Portuguese geotechnics, thus catalyzing the interest of geotechnicians, especially the youngest, and contributing to eliminating the gap between the industry and academia; (ii) highlight, alongside the development of Portuguese geotechnics, the role of civil engineering and the country's social, economic and political development; (iii) present the most suggestive cases of geotechnical works, which highlight, through the corresponding solutions, the development and characterization of each of the stages of scientific knowledge and construction techniques; iv) highlight successes and show failures of the past.

SPG primarily developed the following topics as the basis of the Portuguese contribution:

- Pillars of Portuguese geotechnics;
- Relevant Portuguese geotechnical works, in the country and abroad;
- History of geotechnics in Portugal.

The following pillars were considered as representative of national geotechnical engineering activity:

- Geotechnical associations, events, and publications: evolution of geotechnical associations, main Portuguese geotechnical events and international geotechnical events that took place in Portugal;
- Geotechnical consultancy companies: history and main achievements of the main consultancy companies of the past and present;
- Geotechnical works contractors: history and main achievements of the main contractors of the past and the present.

For the relevant geotechnical works, the presentation of the information was made in detailed sheets, prepared by the design and construction companies.

For the history of geotechnics in Portugal it was considered that this could not be presented without mentioning civil engineering and social, economic and political development in Portugal and abroad. Therefore, alongside the evolution of geotechnics, it was considered relevant to mention the most striking aspects of the evolution of civil engineering and to introduce some events that determined the development of Portugal and some relevant international references. The geotechnical works, were chosen due to their geological and geotechnical conditions, reflecting relevant and innovative aspects. The history of geotechnics covers the period from the mid-17th century to the beginning of the third decade of the 21st century, having been divided into relevant time periods. A recent paper from the author, related to Portuguese Geotechnical History, was published in Geotecnia Journal (Mateus de Brito, 2024).

The documents produced by SPG are hosted in the websites https://spgeotecnia.pt and https://www.issmge.org/the-society/time-capsule.

4 DEVELOPMENT PATH OF GEOTECHNICAL ENGINEERING IN PORTUGAL (1950-2020)

4.1 1950s. The foundation of LNEC and the beginning of the maturity period of Portuguese engineering

During this decade, the execution of public works had a significant increase in Portugal, namely large hydraulic projects to produce electricity and for irrigation and water supply. The elaboration and execution of plans for these uses were extended to overseas provinces. The implementation of the electrification program was a success, showing significant results in a considerably short period of time. Existing hydroelectric companies played a decisive role. Portuguese concrete dam engineering entered a period of maturity that allowed it to design and build large concrete dams, which marked a remarkable development. Sixteen concrete dams were completed, representing the largest number of these dams built in a decade in Portugal.

In the field of civil engineering research and particularly in geotechnics, a decisive step was taken with the constitution of LNEC at the end of 1946, as part of a movement to create the so-called State Laboratories, which emerged in the post-war period in many European countries, with direct responsibility for promoting research applied to European reconstruction activities (Maranha das Neves, 2008).

In this decade, it is fair to highlight the pioneering role of Facudade de Engenharia da Universidade do Porto (FEUP), in launching the Stability Studies Seminar, that began in April 1952, involving not only structural materials, but also Soil Mechanics. It should also be mentionid, in the 1955/56 academic year, the study plan for the Civil Engineering courses at Instituto Superior Técnico (IST) and FEUP, that began to include a semester-long subject on Soil Mechanics.

Until the end of the 1950s, studies and projects were carried out by public bodies, without specific geotechnical training, based essentially on the experience of the engineers involved, and using national and foreign consultants. The first private engineering consultancy company, Hidrotécnica Portuguesa, was founded in 1957, initially dedicated to the study and design of hydraulic works.

The main drivers of change in the 1950s were:

- Notable increase in the construction of dams for the production of electrical energy;
- Development of an ambitious Alentejo Irrigation Plan;
- Creation of a course in Soil Mechanics at IST and FEUP (1955);
- Creation of the first large consultancy company (1957);
- Construction of Paradela dam (112 m), first rockfill CFRD dam in the country, tallest in the world of its type (1958);
- Launch of Lisbon Metro (ML) with two lines, built from 1955 to 1958.

Of the geotechnical works carried out in this decade stands out, for its symbolism, the Cabril dam (Figure 4), completed in 1954, still the tallest Portuguese dam, that is recognized as having marked the development of the double-curvature vault type dams of its time. The dam has a maximum height of 132 m above the foundation and a crest length of 290 m. It is one of the greatest achievements of national engineering and marked the time as particularly notable for the technical level of Portuguese engineering (Xerez, 1954). It marked the transition between the collaboration given by eminent foreign technicians and the total intervention and responsibility of Portuguese technicians.

4.2 1960s. Emergence of large engineering consultancy companies

In this decade there was an endogenization of technology, which led the national engineering sector to develop capacities to design all types of large works built by Portuguese people, in the country and abroad, resulting in a remarkable period of execution of major engineering works, involving the construction of several sections of highway in the regions of Lisbon and Oporto, vital for the development of the country, and several dams throughout the territory, promoting the development of construction techniques and the growth in the number of specialized engineers, who contributed to the construction of these works in Portugal and later abroad.

In this period, LNEC assumed a fundamental role in Soil Mechanics, Rock Mechanics, and Engineering Geology research, carried out by its technicians.

New design and consultancy companies emerged, such as Coba (1962), Profabril (1963), Hidroprojecto (1966) and Consulmar (1970), all of them integrating geotechnical specialists, who would also play a decisive role in the development of the Portuguese geotechnical market.

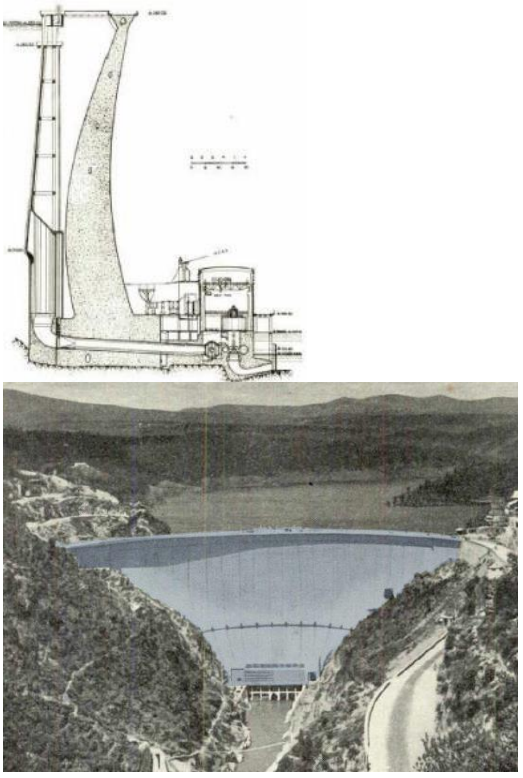

Figure 4. Transversal section and downstream view of Cabril dam, in June 1954 (Xerez, 1954).

With the inauguration of the then-named Ponte Salazar (currently 25 de Abril bridge), on August 6, 1961, connecting Lisbon to the Setúbal peninsula, Portugal got the longest suspension bridge span in Europe. Among the innovations in the construction of this bridge are the foundations of the towers of the two pillars on the river, made up of large concrete blocks with plan dimensions of 40 m x 23 m, built using the so-called open caisson method with air domes, achieving a depth of 79 m at the foundation of the south tower.

The main drivers of change in the 1960s were:

- Industrialization of basic sectors of the Portuguese economy;
- Creation of the LNEC Geotechnical Department (1961);
- Holding of the First ISRM Congress, at LNEC (1966);
- Establishment of Engineering Geology as an autonomous science (mid-1960s);
- Construction of 25 de Abril bridge;
- First sections of highway in Lisbon and Oporto regions;
- Emergence of large engineering consultancy companies;
- Development of diaphragm wall and anchoring technologies and widespread of its use in urban excavations;
- Universal acceptance of the concept of Geotechnics.

The most relevant achievement of the decade was the construction of dry docks of the Lisnave Naval Shipyard in Almada, that opened in 1967 and quickly gained a foothold in shipbuilding and repair, to such an extent that the docking capacity was expanded to receive oil tankers from new generation then planned, with ships up to 1 000 000 ton. With the expansion with dock 13 (Figure 5), the largest dry dock in the world at the time (320 m x 97 m), built between 1969 and 1971, Lisnave became considered one of the best ship repair yards in Europe and an international reference in the sector. The local geotechnical conditions are very favorable, as, at the level of the foundations of the walls and bottom slabs of the dock, there are very dense Miocene sandy clays, whose average permeability coefficient made it possible for the adoption of very economical structural solutions, with drained bottom slabs supported directly on the ground.

4.3 1970s. Democracy and turn to Europe. Start of soil and rock mechanics teaching at universities

Following the revolution of 1974, which established a democratic regime in Portugal, major changes took place in the Portuguese business sector, namely at the construction sector, with some consulting and construction companies going into irreversible decline and others entering a restructuring phase. Most of the economy sectors were nationalized. The independency of African territories under Portuguese administration (Angola, Mozambique, Guinea Bissau, Cape Verde and S. Tomé and Príncipe) took place in 1975, which made most of the technicians who worked there to return to Portugal mainland, contributing to increase the staff of various official bodies, consultants, and contractors.

At the end of the decade, due to the economic growth and following the trend in the previous years in the developed countries, multiplication of large urban excavations started, not only for metro lines or other transportation works, but also for underground car parking of new buildings or under public spaces.

In 1975, specialization courses and, after, postgraduate courses in geotechnics, were created at the newly created UNL. In 1980, master degrees were created at the same university.

The main drivers of change in geotechnics in the 1970s were:

- Development of computers and the advent of the finite element method;
- Creation of Postgraduate Courses in Geotechnics at UNL (1975/76);
- Evolutionary trend towards the construction of embankment dams with zoned profiles with chimney filter;
- Significant increase in the use of soil treatment processes;
- Consolidation of important slopes of railway Lisbon-Oporto in Santarém (1970);
- Pioneer temporary tangent piles with 4 levels of anchors support wall of ML Alameda Station (1974);
- Beginning of the construction of Sines Port, one of the most relevant works of Portuguese engineering (1973).

In this decade the most relevant entreprise was the construction of Cahora Bassa hydroelectic schema, in Mozambique, completed in 1974. It comprises a concrete arch dam, 164 m high, that creates the second largest artificial lake in Southern Africa. The concrete vault dam has appurtenant works designed for a peak flow of 12,600 m^3/s and an underground

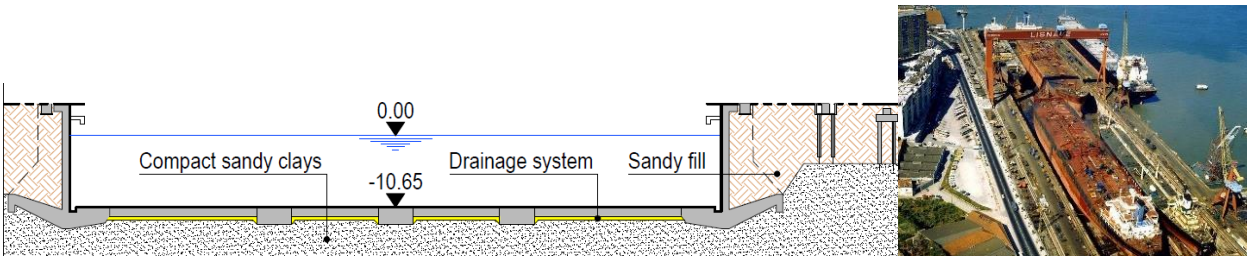

Figure 5. Transversal section and aerial view of Lisnave dock 13.

power plant on the south bank of the Zambezi River with five groups of 415 MW each (Figure 6). The rock mass at the site is made up of granitoid gneiss with excellent mechanical qualities, which, due to the existence of some lamprophyric and gabbric veins, posed some design and execution problems. This dam was a testimony of Portuguese engineering capacity to design the installation of high-power hydroelectric schemas.

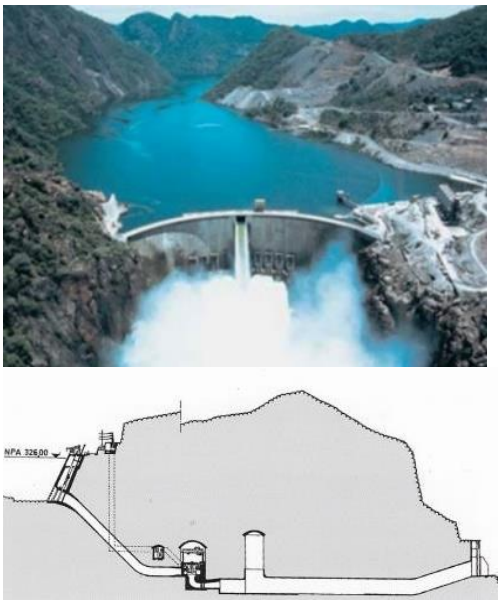

Figure 6. Downstream aerial view of Cabora Bassa Dam at maximum flood discharge and longitudinal section of the power plant and hydraulic circuit (Cruz et al, 2007).

4.4 1980s. Emergence of community funds. Generalized teaching of geotechnics in universities

With the first years of the 80s, the economic cycle reversed itself again and the construction market suffered major impact. The deterioration in demand and the worsening of the economic and financial situation created a situation without parallel since the 1974-75 recession.

In 1985, Portugal joined the European Economic Community (EEC), which would play a fundamental and decisive role in the country's economic development, with an obvious repercussion on the development of geotechnics.

The last years of this decade witnesed the dynamism of civil construction works, namely in the road, airport, river, and maritime areas, which resulted from importing of technologies already widely applied in other countries, but which led to the modernization of the construction industry, development of technological means and training of specialized technicians.

In the decade there was a widespread progress in the teaching of geotechnics at universities and began the creation of teaching teams with adequate geotechnical training and a doctorate degree in the country.

During the 1970s, rockfill, a very abundant material in the country, was not used either in dams or in roads or airports embankments, due to the lack of knowledge on the mechanical behavior of these materials, as well as of adequate construction techniques. So, in the 1980s, LNEC began an ambitious research project on rockfill, which covered the theoretical and experimental aspects of the rockfill mechanics, with the Beliche dam becoming a case study around which all the research was developed. The materials to be used in the dam were tested with equipment designed and built at LNEC. This set of studies contributed to placing Portugal and LNEC in a leading position in the field of rockfill use in various types of infrastructure (Maranha das Neves, 2008).

The main drivers of change in geotechnics in the 1980s were:

- Portugal's accession to the EEC;
- Beginning of the development of the research area in universities;
- Creation of Masters in Soil Mechanics and Engineering Geology;
- Research project on rockfill at LNEC;
- Start of copper production in Somincor mines (1988);
- Development of the nailed wall technique;
- Development of excavation support with diaphragm walls using a hydromill;
- Emergence of major environmental concerns.

The construction of the Beliche dam was completed in 1986. It consists of a zoned

embankment, with well graded schist and greywacke rockfill shells and a clayey core, of weathered schist, upstream and downstream chimney filters with double layers of coarse filter and fine filter (Figure 7). It was the first dam of this type to be built in Portugal. The foundation consists of schist and graywacke.

4.5 1990s. Great public works development

The 1990s were a very intense period of construction in Portugal, largely resulting from the availability of European Community funds within the scope of various development support programs resulting from Portugal's integration into the EEC. The many millions of euros allocated to Portugal were a strong driver of the country's economy, reflected in many areas, especially in road infrastructure, in water

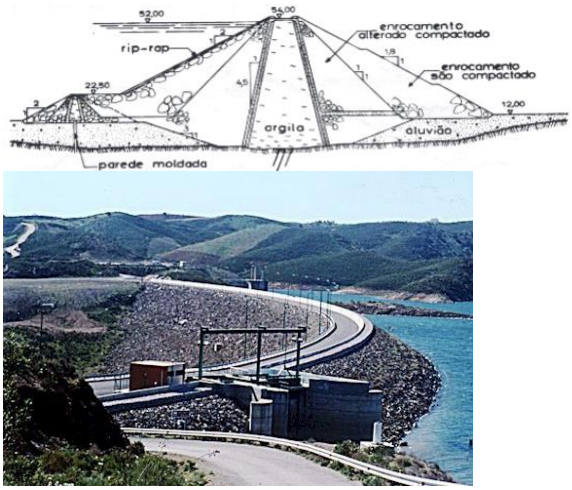

Figure 7. Cross section and vew of Beliche dam.

supply, both for consumption and irrigation, in the production of hydroelectric power and in environmental domain.

In the teaching of geotechnics, the trends of the previous decade were consolidated with a progress in research and significant increase in the number of doctorates reaching an international quality level.

In urban planning, the Expo'98 complex stands out in the northeast zone of Lisbon, with major works being carried out (Figure 8). It is considered one of the largest infrastructure projects at national and even European level. Located in the alluvial zone of the Tagus River, where the muddy alluvium reaches maximum depths of around 25 m, these works constituted a notable engineering achievement, with a strong geotechnical component, whose completion represented an enormous technical challenge.

At Madeira Island a new road network was built over a period of around 15 years, starting in 1989, which greatly improved the connections between Funchal and other main cities on the island. This was the most important investment in the history of Madeira, exceeding 2 000 M€.

The main drivers of change in geotechnics in the 1990s were:

- Publication of the Dam Safety Regulations (1990);
- Development of rockfill dam construction;
- Explosion of Portuguese road construction;
- Construction of long-span road bridges;

Figure 8. Expo'98 aerial view.

- Construction of large-section road tunnels;
- Construction of new ML lines;
- Bologna Declaration (1999).

The most relevant road work carried out in this decade was the Vasco da Gama bridge, over the Tagus River, in Lisbon, inaugurated in 1998. It is one of the largest national infrastructure projects and the second longest bridge in Europe, contributing decisively to the development of national road accessibility, with relevance to the Lisbon metropolitan area. The cost was around 1 000 M€. This road complex comprises a bridge, several viaducts and access roads, totaling 18 200 m, of which 12 340 m are on bridge and viaducts. The bridge and access viaducts cross the Tagus River alluvial valley (Figure 9), which, in this area, reaches a width of more than 12 km and a maximum thickness of around 80 m (Seco e Pinto & Oliveira, 1998). The main bridge, crossing the north channel, is a cable-stayed structure 826 m long and with a free span of 420 m between towers. The towers of the central span, 148 m high, rest on massive headers on 2.2 m diameter bored piles built under large cofferdams.

Another achievement that must be mentioned is the construction of the Al Whada dam, in Morocco, aimed to control flooding, irrigation, water supply and production of hydroelectric energy, located in an high seismic risk area. It is a zoned earth dam with 1 600 m long and with a maximum height above the foundation of 88 m. The volume of excavations was 13,8 Mm^3 and the volume of earthfill was 26.4 Mm^3.

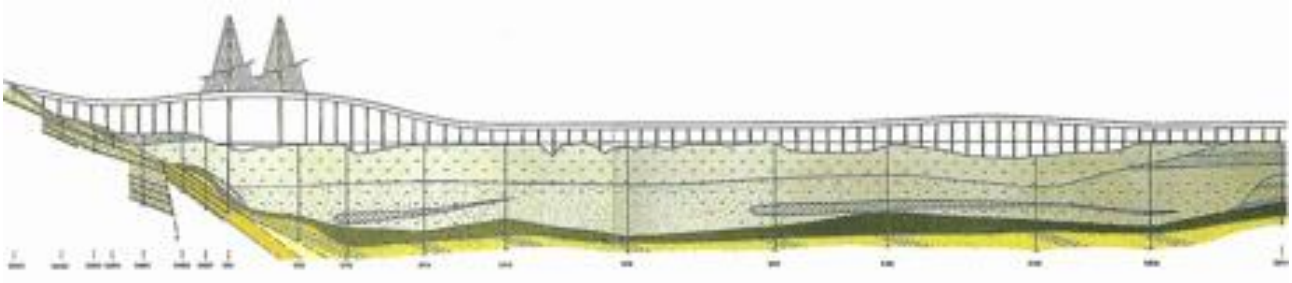

Figure 9. Geologic longitudinal section of west zone of Vasco da Gama bridge (Portuguese Engineers' Order, 2003).

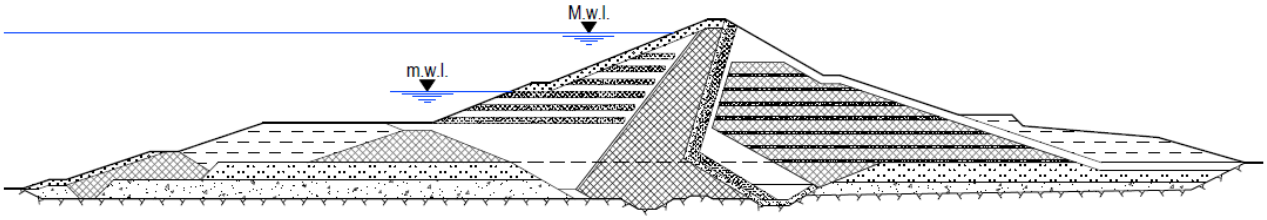

Figure 10. Transversal section of Al Whada dam, Morocco (Mineiro, 1991).

The foundation is constituted by marls interspersed with sandstones, with the riverbed being filled with coarse and fine alluvium (Figure 10).

The design of the dam, the configuration and layout of the spillway, the restitution channel, and the energy dissipation pit, were strongly conditioned by the very adverse geological and geotechnical conditions of the foundation, where the existence of expansive marls interlayered with rigid sandstone banks, dictated the positioning of the dam's main hydraulic works (Mineiro, 1991). It is the second largest dam in Africa, after the Aswan dam, and the largest in Morocco.

4.6 2000s. Increase in the internationalization of Portuguese engineering. Maturity of teaching and research in geotechnics

At the beginning of the century, teaching and research in geotechnics reached maturity. New university campuses or new university buildings were opened at the beginning of the decade, creating better conditions for teaching and research, and strengthening laboratory capacity.

From 2004 onwards the instability of the internal market and the retraction of national investment severely affected the construction and consultancy companies that had to extend their activities abroad.

Only at the end of the decade the government decided to give greater impetus to public works, having granted a significant part of large projects to the private sector, with a strong social impact on the country. Concession groups were created, called Public Private Partnerships (PPP), which developed global projects covering the design, financing, construction, and exploration components, with six PPP sub-concessions being created for highways.

The main drivers of change in geotechnics in the 2000s were:

- Significant progress in research in geotechnics applied to civil engineering in the field of theory, materials characterization and innovation of construction technologies;
- Large volume of highway construction throughout the Continent and Madeira Island, which included the construction of numerous bridges, tunnels, embankment and slope stabilization works;
- Expansion of ML and beginning of construction of Oporto subway (MP);
- Strong decline in investment since 2004, which severely affected companies in the consultancy sector;
- Increase in work carried out by Portuguese design companies to external markets.

Of the ML works, it is worth highlighting the completion, in 2007, of the Terreiro do Paço Station, adjacent to Tagus River. The station structure corresponds to a large reinforced concrete box, built from the ground surface, 140 m long and 24 m width in the wide zone (Figure 11). The soils are predominantly clayey-silty alluvium, ranging from very soft silt to sand with a very significant predominance of clean sand at the base of the alluvium. Underlying the alluvium, slightly below the base of the station bottom slab, occur Miocene formations, composed of very stiff clays. The retaining structures consist of alternated reinforced concrete and bentonite-cement piles 1,50 m in diameter. For the temporary shoring system, five levels of pairs of horizontal struts were used, between the longitudinal faces of the retaining structures, consisting of tubular steel profiles (ϕ711 mm) with an

average horizontal spacing of 3.5 m. The struts were heavily prestressed during installation, with a uniform prestress of 3 500 kN per strut, introduced by 4 hydraulic jacks. This system was complemented, in the wide area of the station, with a 3 m thick jet grouting slab, between the depths of 18 and 21 m placed between the existing tunnel, previously filled with poor concrete, and the retaining structures. The excavation was carried out in 5 phases, until reaching a depth of 26.5 m (Matos Fernandes, 2010, Mateus de Brito, 2020).

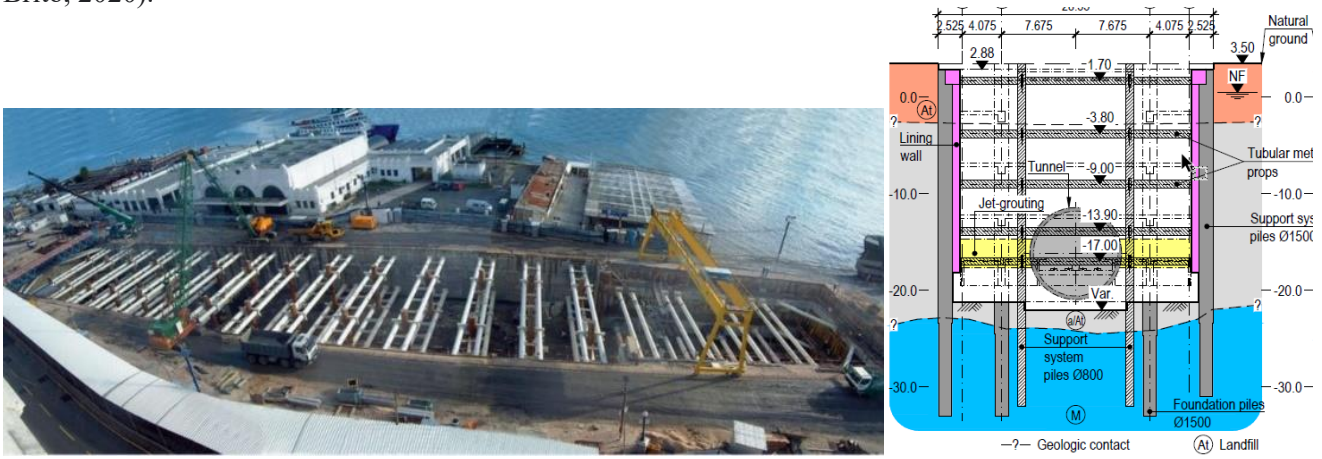

Figure 11. View of Terreiro do Paço Station during construction and cross section of the wide area of the station after completion of the last excavation phase (Mateus de Brito & Matos Fernandes, 2014).

Regarding university education, there were serious difficulties that affected the quality of geotechnical training and led to a reduction in the number of civil engineering students with this training, as well as the teaching staff necessary to provide it. Between 2010 and 2014, there was an abrupt reduction of the number of students placed in civil engineering courses, because of the crisis. After 2015 the number stabilized at around 400 students, about half the number of students placed in the precedent decade. Although there has been a tendency towards an increase in interest in civil engineering training, it appears that the number of students placed in universities will not guarantee an adequate response to the needs and the challenges that the country is currently going through.

The main drivers of change in geotechnics in the 2010s were:

- Significant reduction in public investment;
- Search for consultancy and construction companies to increase their activity abroad;
- Completion of important geotechnical works abroad, designed and built by Portuguese engineering companies;
- Increase in the number of PhDs in geotechnics in Portuguese universities;
- Significant reduction in the number of students in civil engineering;
- Entry into force of Eurocodes (2019);
- Power reinforcements in existing dams; the most important (732 MW) was in Venda Nova dam (2017);
- Conclusion of important new hydroelectric dams.

4.7 2010s. Retraction of public investment

As a result of the financial crisis that began in 2008, there was a significant retraction in public investment from 2010 onwards, which led the government to suspend some infrastructure projects, with consultancy and construction companies being forced to increase its activity in foreign markets in Africa, Asia, and Latin America, namely in Angola, Mozambique, Algeria, and Brazil.

In 2018 the Place des Martyres Station was inaugurated, the most important underground station on the Algiers metro, located at a square with the same name, in the central area of the city, at the base of the Kasbah and near Algiers' harbor. Highly important archaeological findings located in the whole square area rendered the initial excavation cut and cover method impracticable and led to the development of an alternative solution consisting of an underground excavation. It comprises a gallery with unusual large dimensions, with a maximum span of 26 m, height of 19 m, and maximum depth of 35 m, corresponding to an excavation cross section of 397 m^2 and a length of 144 m (Figure 12). Most of the underground works were done in moderately to slightly weathered sericitic schist. In the area, an alluvial layer and landfills were identified with a significant thickness, about 7 m and groundwater level located in the base of the fill layers with in-depth water percolation in the most fractured zones of the rock mass (Conceição et al, 2012).

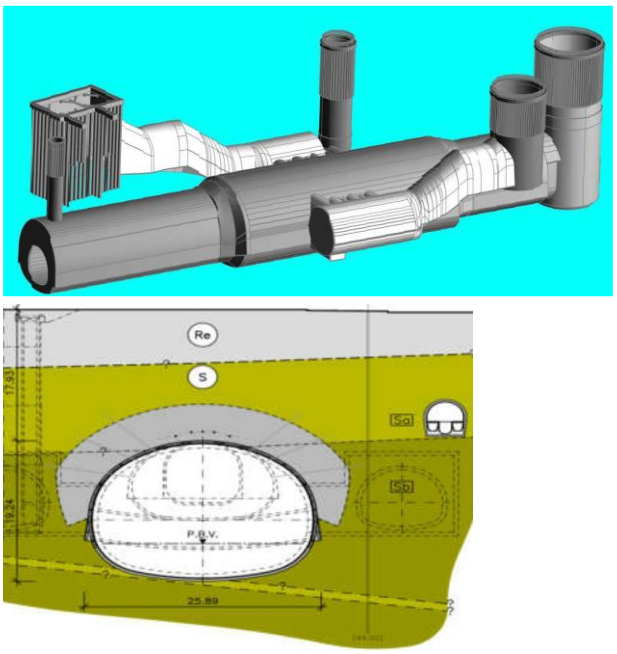

Figure 12. 3D view and cross section of the Place des Martyres Station in Alger (Conceição et al, 2012).

4.8 2020s. Large public investment in railways and renewable energies

In the beginning of this decade some important achievements were completed, and others are ongoing. Most of these achievements are financed by the Recovery and Resilience Plan (2021-2028), integrated at NextGenerationEU, that is the EU's 800 000 M€ temporary recovery instrument to support the economic recovery from the coronavirus pandemic and build a greener, more digital and more resilient future.

One of the largest initiatives in the history of Portuguese hydroelectric energy sector, the Alto Tâmega Electric Production System, was completed in 2023, with an investment of more than 1 500 M€. It is a complex formed by three dams and three hydroelectric plants: Alto Tâmega, Daivões and Gouvães. It stands out for its great reversibility capacity, with a total installed power of 1 158 MW, of which 880 MW are reversible. The Alto Tâmega dam reservoir has a total area of 466 ha for a storage volume of 56.2 Mm^3. The plant has two groups installed with a total power of 160 MW. It is a double-curved vault with a height of 104.5 m, a crest length of 335 m and 220 000 m^3 of concrete volume. It is founded on a phyllitic-grauvachic formation, made up of mica schists with interstratifications of dark carbonaceous schists, with stiffness at the bottom of the valley of 23 to 30 GPa and on the slopes of 7 to 22 GPa (Figure 13).

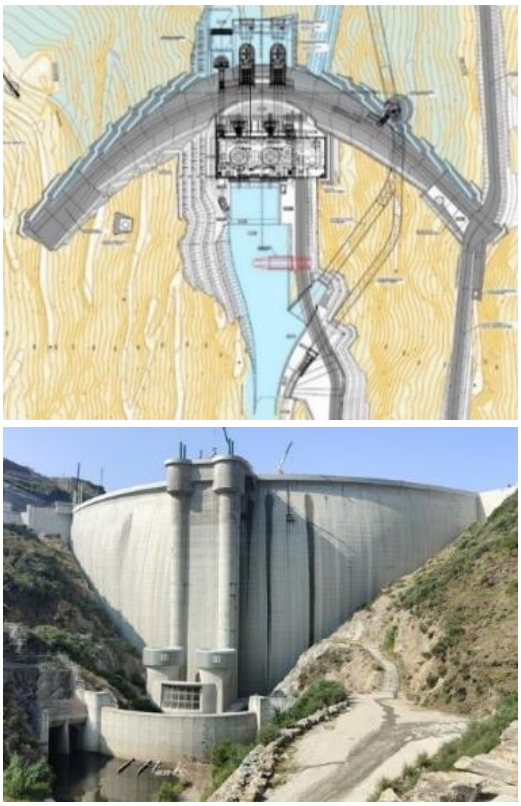

Figure 13. Plan and upstream view of Alto Tâmega dam.

Concerning railway lines, is planned in this decade, a global investment of 2 700 M€ both for the construction of new railway lines, covering a length of 214 km, and for the modernization of existing lines, covering around 900 km. In 2024, the first phase of the railway line between Évora and Elvas was completed, integrated into the future Southern International Corridor, linking Sines to Elvas near the Spanish border. This new section, with 80 km, is the first high-speed connection in Portugal, for passengers and goods, with an investment of 442 M€.

This new railway platform will constitute the largest railway line built in over a century in Portugal and is one of the largest railway works carried out in recent years. It is the first new railway infrastructure built to meet the criteria to be considered a high-speed line, having a maximum circulation speed equal to or greater than 250 km/h, for passengers, and 120 km/h, for goods. It was built on a single electrified track ballasted in Iberian gauge (1,668 m), but on a platform for double track and with the installation of multipurpose sleepers, to facilitate a future migration to European gauge (1,435 m) (Figure 14). It has around 30 bridges and viaducts and 89 km of new rail, resulting in an excavation volume of 7.1 Mm^3 and of earthfills of 5.9 Mm^3.

Figure 14. New HSRL linking Évora to Elvas.

In mid-2024 the first section of the new Lisbon-Oporto high speed railway line will be awarded, covering a length of 290 km. It has a design speed of 300 km/h and a journey time of 1h15. It will be carried out in 3 phases. Phase 1, that comprises the section between Oporto and Soure, is an investment of around 3 000 M€ and is expected to be concluded in 2028. Phase 2, between Soure and Carregado, has an estimated investment of 1 900 M€ and should be completed by 2030. Phase 3, between Carregado and Lisbon, has a small impact on travel time, so it should only be built later (see Figure 21). The first route corresponds to 71 km between Oporto and Oiã, including the construction of a new road-rail bridge, with two decks, over the Douro River, a new underground station in Santo Ovídio (Gaia), a twin-tube tunnel of around 6 km, that ran underground in the municipality of Gaia, five single-tube tunnels, as well as 15 double-track bridges and two single-track bridges.

Also ML will make important investments in this decade. The extension of the Yellow and Green Lines, already under construction, is an important upgrade to ML network with 2 km of track and 2 new stations. By creating a new connection between two existing lines, this project will form a circle line which will enhance the usability of public transportation services in the city centre (Figure 15). Construction works started in 2021 and passenger services are planned to start in 2025. The total cost is 331.4 M€.

Another important ML project, which began in 2024 and will end in 2027, is the expansion of the Red Line between S. Sebastião and Alcântara serving the western part of the city of Lisbon (Figure 15). It will have 4 new stations and around 4 km of track. The total cost is 405.4 M€.

The ML network will continue to expand in this decade, through a light surface metro system, which will serve the municipalities of Loures and Odivelas, with the connection to the rest of the network made through an interface in the existing Odivelas station, on the Yellow Line. It is called the Violet Line and will have a total of 17 stations and is approximately 13 km long, predominantly on the surface (8.6 km), but also with sections in trenches (0.4 km), viaducts (0.4 km) and tunnels (four tunnels with a total length of 3.7 km) as well as 3 underground stations and 2 trench stations (Figure 15). The project represents an investment of 527.3 M€, and the work should be completed in 2028.

Figure 15. Future Lisbon Metro network.

With regard to MP, the six lines in operation will be upgraded by the end of 2024 with the Pink Line (Casa da Música-São Bento), and the extension of the Yellow Line (Santo Ovídio-Vila d'Este), whose construction began in 2021 (Figure 16). The Pink Line extension is in tunnel through the central axis of the city of Oporto, with an approximate length of 3.1 km, and includes the construction of 4 new stations. The cost is 333 M€. It will improve access to central areas of the city with important business, residential and health facilities. The extension of Yellow Line has a length of about 3,15 km and 3 stations.

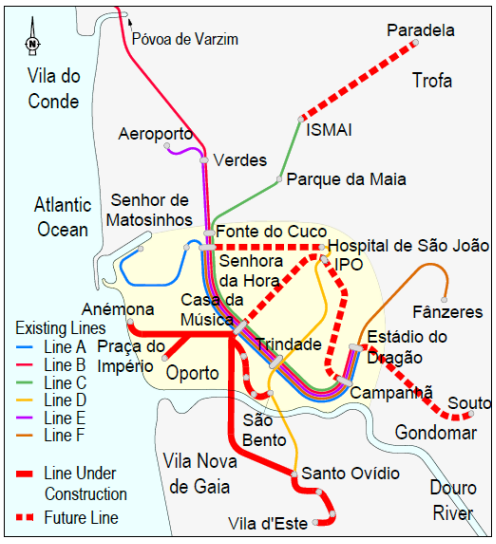

Figure 16. Future Oporto Metro network.

Another line, the Rubi Line of MP, whose construction began in the first half of 2024, will connect Casa da Música and Santo Ovídio (Figure 16) with a length of 6.3 km, including 8 stations and 2 tunnels. It includes the construction of a new crossing over the Douro River, the Ferreirinha bridge (Figure 17). The construction of this new line costs 435 M€.

MP will have in the future four more new lines, planned to be built by 2030. These lines will have a total length of 37 km and 38 stations, with a cost of around 1 000 M€ (Figure 16).

Figure 17. Porto Metro network. 3D view of Ferreirinha bridge.

The other very important transport infrastructure, planned to start in 2024, is the new Lisbon International Airport. It will be the biggest public project since the Vasco de Gama bridge and will put an end to a discussion that has been going on since the end of the 1960s. This airport has great probability to be located at Alcochete. In the first phase, planned to be concluded in 2030, the solution will involve a dual airport, with the current Lisbon airport. The new airport will have only one runway with a cost of 3 200 M€. Figure 18 shows the location foreseen for the new airport and the new highway and railway accesses.

For highway and railway accesses to the airport, is necessary to build a third crossing over the Tagus River, between Chelas (Lisbon) and Barreiro (Setúbal), that should be completed by the end of 2030 (Figure 18). The crossing will have a length of 13 km and the bridge will have a length of 7 200 m. The deck of the bridge will have two lanes for high-speed railway, two for conventional railway, and two side lanes with three lanes each for road traffic. The estimated cost in 2008 was around 1 800 M€.

The Lisbon General Drainage Plan, whose construction began in 2019 and is expected to be completed in 2030, is intended to significantly reduce flooding in critical locations of Lisbon, and the consequent social and economic costs, preparing the city for extreme events caused by climate change. The work includes tunnels between Monsanto and Santa Apolónia (4.6 km) and between Chelas and Beato (1 km) with an internal diameter of 5.5 m. The tunnels are being executed by a tunneling boring machine that has around 130 m long, 6.41 m

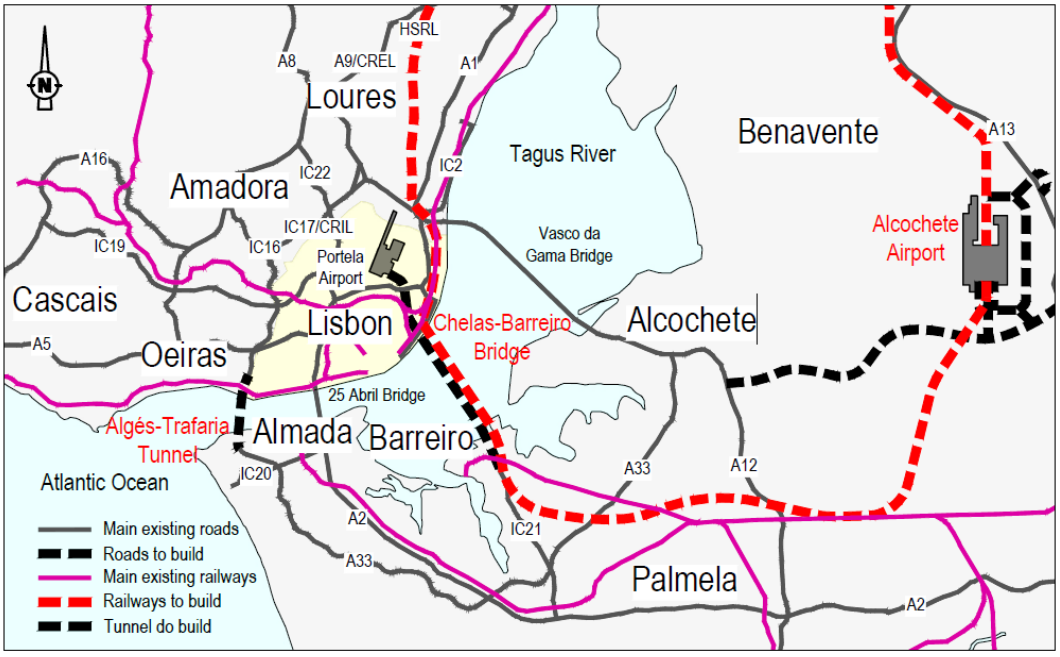

Figure 18. Location of future Alcochete airport and road and raiway accessabilities.

Figure 19. View of the cutting head of TBM and north portal of Monsanto-Santa Apolónia tunnel.

external diameter and a cutting head that weighs 70 ton, and which will advance around 10 m per day (Figure 19).

The Port of Sines has an important volume of containerized cargo movement. In 2022, Sines Terminal XXI had an additional 204 m of mooring quay, corresponding to Phase 3A (see Figure 23). In 2023, an increase in the embankment area (Phase 3B) was built, providing 1 150 m of docks, which allows it to simultaneously operate three mega-carriers of 330 m each. By 2025, additional quays and embankments will be built, and the same will happen by 2027 (Figure 23). Lastly, Terminal XXI will have a 1 950 m quay front, 60 ha of embankments and 19 super post Panamax quay gantries, suitable for simultaneously operating four of the largest ships currently in commercial operation, measuring 400 m in length overall. Capacity will then be 4.1 MTEU/year (TEU=20-foot containers), almost double the 2.3 MTEU in 2021.

The adopted quay solution consists of a reinforced concrete beam slab, over five alignments of piles. The piles are made of reinforced concrete with metallic pipe formwork, with a length of about 25 m, a penetration into the rocky substrate of 4.00 m, and a 1.30 m diameter. For the execution of the piles was used an equipment positioned on vessels (Figure 20).

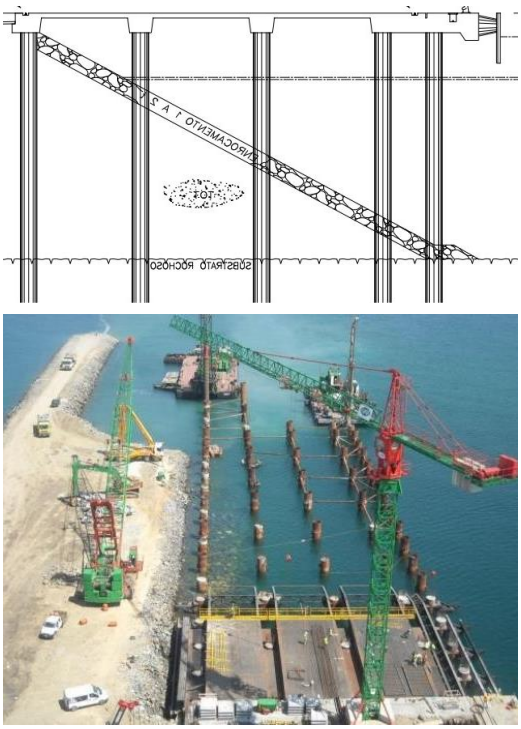

Figure 20. Transversal section ot the adopted solution for the quay and view of piles execution of the phase 2 of Terminal XXI (Linhares, 2012).

5 FUTURE MAIN GEOTECHNICAL ENGINEERING PROJECTS IN PORTUGAL

The main projects with a significant geotechnical component that are expected to be carried out in the decades ahead will be mainly in the areas of transport infrastructure (mainly railways, maritime and port), energy production (reversibility of existing dams, eolic onshore and offshore, geothermal, lithium mining explorations), environmental industry (soil decontamination) and those resulting from climate change resilience projects (protection and support works in coastal and underwater areas, stabilization of landslides and drainage works to control floods).

In the future, it is expected that the most relevant achievement will be the extensions of the HSRL. Firstly Lisbon-Oporto will extend to Vigo and another line will be built to Badajoz, which would allow the connection between Lisbon and Madrid in 3 hours. Later, 2 new lines are expected to be constructed: Aveiro-Salamanca and Évora-Faro-Seville (Figure 21).

Figure 21. Future HSRL network.

By the middle of the century probably the fourth Tagus crossing will link Algés to Trafaria and will close the Lisbon's outer circular roadway (Figure 18).

Due to safety, environmental and cost reasons the TBM tunnel is the more favorable solution. The tunnel will cross the alluvium formations and will have 5 km long with an inner diameter of 14,20 m, that allow two traffic galleries with three lanes each (Pompeu-Santos, 2022).

Another future relevant work will be the new Vasco da Gama container terminal (Figure 23), whose project foresees an installed capacity of around 3.5 MTEU, with a 1 375 m quay front, allowing simultaneous operation of three additional ships with 400 m long. It will involve an investment of around 640 M€. This terminal is fundamental for the expansion of the port of Sines and will allow it to be on par with large European ports, such as Rotterdam (Netherlands) and Antwerp (Belgium).

Portugal is one of the most promising European countries where lithium resources exist with high potential for use and could thus make an important contribution to the development and expansion of new non-polluting technologies. Therefore, the implementation of the exploration of lithium mines in the country is a project of high national, European, and global interest, contributing to meet the enormous demand for this metal in which Europe is lacking and dependent on other countries.

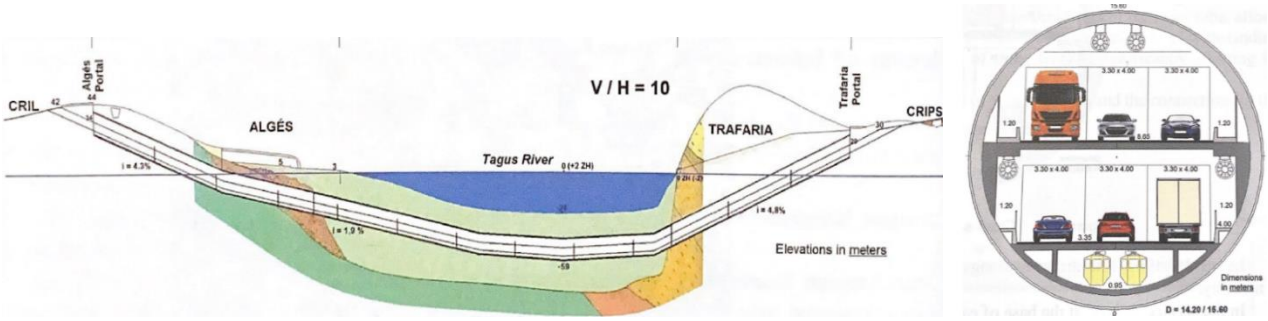

Figure 22. Longitudinal section of the proposed TBM tunnel for Algés-Trafaria crossing. Lay-out of traffic galleries of the tunnel with three lanes each (Pompeu-Santos,2022).

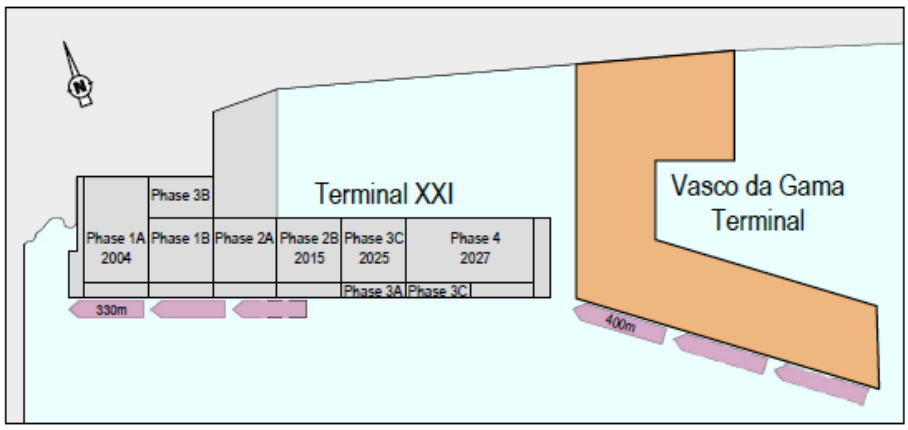

Figure 23. Construction phasing of Terminal XX1 and future Vasco da Gama Terminal.

6 CLOSING FINAL REMARKS

The challenge launched by ISSMGE, through the HTC project, was a unique opportunity to publicize the main achievements and the current state of Portuguese geotechnical engineering. Reflection work was carried out by SPG on the development trajectory of national geotechnics over the last 100 years, from the first steps taken in 1920s, through the period of the 1950s/1960s, in which was created a geotechnical community in the country, until the first years of the 2020s.

Over the last 100 years, Portugal has progressed from an underdeveloped country to a country that today has almost all the characteristics of developed countries. Therefore, to make the history of the development of geotechnics, it was necessary to succinctly address the role of civil engineering, from which geotechnical engineering emanates, in the social, economic, and political development of the country. The projects included in this paper are indicative of the infrastructure works that took place in Portugal which are characterized by having conditioning geological conditions and relevant geotechnical features, resulting in innovative aspects of design and execution, which are certainly a reference for the practice of geotechnical engineering. For these projects, that marked their time, Portuguese geotechnical engineers provided important to crucial input for the design and construction.

For geotechnical related activities we need more individuals with appropriate qualification and experience. The world is changing very fast and we have to renovate the geotechnical competences and to create new disciplines and new approaches. In Portugal we have an excellent level of knowledge and qualifications among young people who attend our engineering universities, but we need to significantly increase the number of candidates for civil engineering courses to increase significantly to guarantee an adequate response to the needs of our society and the fulfillment of the challenges that the country will experience. We have to make geotechnical engineering more attractive for young people.

ABSTRACT: The ISSMGE Heritage Time Capsule (HTC) project will launch key initiatives in 2024 to actively engage with the individual members of the International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE). A significant initiative is the design and launch of a new website, dedicated for the HTC project to present, online, in a useful and engaging way, the diverse contributions made to the HTC. These contributions are from ISSMGE Member Societies, Past Presidents, Technical Committees, Corporate Associates, Key Persons, and other Board Level Representatives, and include video recordings, commented slide presentations, text documents and articles. Furthermore, this paper describes the HTC discoverer program, where individual members can provide their reports on HTC contribution(s) of their choice, for review and hosting on the HTC website. Plans for HTC discovery sessions in 2024 on areas of specific interest to ISSMGE regions are also included in the paper. The focus of this paper is the need and opportunity for discovery, the planned discovery process, and the anticipated outcomes of the discovery phase. The discovery phase bridges the contributions received from 2022 to 2024, to the display and sealing of a physical time capsule in 2026 at the 21st ICSMGE in Vienna, Austria, and the final phase of the HTC project reflecting on the needs of geotechnical engineering in the next 100 years.

RÉSUMÉ: Le projet ISSMGE Heritage Time Capsule (HTC) lancera des initiatives clés en 2024 pour s'engager activement avec les membres individuels de l'ISSMGE. Une initiative importante est la conception et le lancement d'un nouveau site web, dédié au projet HTC, pour présenter en ligne, de manière utile et attrayante, les diverses contributions apportées à la HTC. Ces contributions proviennent des sociétés membres de l'ISSMGE, des anciens présidents, des comités techniques, des entreprises associées, des personnes clés et d'autres représentants du conseil d'administration, et comprennent des enregistrements vidéo, des présentations de diapositives commentées, des documents textuels et des articles. En outre, ce document décrit le programme de découverte HTC, dans le cadre duquel les membres individuels peuvent fournir leurs rapports sur les contributions HTC de leur choix, qui seront examinés et déposés sur le site web HTC. Les plans pour les sessions de découverte HTC en 2024 sur des domaines d'intérêt spécifique pour les régions ISSMGE sont également inclus dans le document. Le présent document met l'accent sur la nécessité et l'opportunité de la découverte, sur le processus de découverte prévu et sur les résultats escomptés de la phase de découverte. La phase de découverte fait le lien entre les contributions reçues entre 2022 et 2024, l'exposition et le scellement d'une capsule temporelle physique en 2026 lors de la 21e édition de l'ICSMGE à Vienne, en Autriche, et la phase finale du projet HTC qui réfléchit aux besoins de l'ingénierie géotechnique au cours des 100 prochaines années.

Keywords: Time capsule; ISSMGE; geotechnical engineering; individual members; discoverer program.

1 INTRODUCTION

Prompted by the approach of the centenary in 2036 of the 1st International Conference on Soil Mechanics and Foundation Engineering held at Harvard University, the first author, initiated a conversation in October 2019 with the ISSMGE Board (2017-2022) about the desirability of a time capsule project for the ISSMGE. In March 2020, the ISSMGE Board approved the formation of a 16-person committee, led by the first author, to proceed with a scoping study.

Generally, the intent is for the contents of a time capsule to be closed then opened and viewed (i.e., discovered) in say, 100 years or a longer period. Therefore, understandably, the main questions raised by those outside the Heritage Time Capsule (HTC) team at the beginning of this project were: How long should the time capsule be kept sealed? How will it be protected over that time? What technologies need to be incorporated to enable future generations to understand its contents? The HTC design team considered however that there were other aspects of the time capsule that needed to be first addressed.

Indeed, it rapidly became clear that there was not a common understanding of the material to be placed in the time capsule. Across geographies, there is a significant diversity of knowledge and practice, and in application of technology, for instance there is the often-quoted aspect of increasing distance with time between theory and practice in geotechnical engineering. In addition to all this, "geotechnical engineering challenges to meet current and emerging needs of society", this conference's slogan, suggests there is unlikely to be a universal understanding and acceptance of what needs to be placed in a time capsule.

The HTC team was excited by the possible benefits of a visible and accessible fusion of material from disparate sources to the advancement of geotechnical engineering. It was essential therefore that as many people as possible, at all levels of the ISSMGE community, participate and contribute to the time capsule, for the contents in the time capsule to be a reasonable reflection of geotechnical practice globally. Capturing diversity in an effective and transparent manner was paramount. Technology enabled the creation of a webpage platform within the ISSMGE website, to hold and host information and make it widely accessible. Figure 1 presents an extract from one such Member Society contribution.

The HTC team soon realised a few further steps were required to convert information into knowledge and collective insight. Four clearly defined and separate phases have emerged, these being

- Phase 1 - Contributions
- Phase 2 - Discovery
- Phase 3 - Time Capsule
- Phase 4 - 100 years on

In 2024, the HTC projet is transitioning from Phase 1 - Contributions to Phase 2 - Discovery, and this is the opportunity for ISSMGE individual members to make a mark in the HTC project.

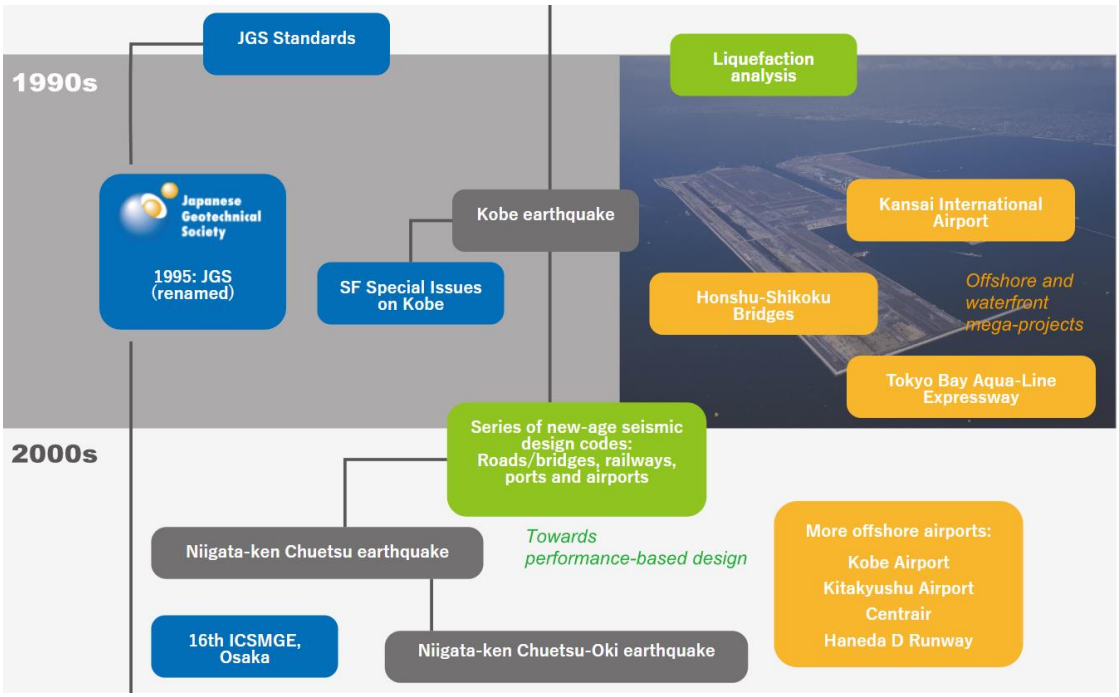

Figure 1. An extract of contribution in the form of a dynamic HTML format for browsing on screen, Japanese Geotechnical Society.

2 HTC PROJECT OVERVIEW

The idea of the time capsule is not new in the ISSMGE, and a physical object (in the form of a blue barrel) to be filled with contents, made its public appearance in 2013 at the quadrennial ISSMGE conference (18th ICSMGE in Paris). Jean-Louis Briaud (President 2009 - 2013) noted in his 45th Progress Report (2013) the following in relation to the time capsule, "*While the final decision is still in the air, here is what we have in mind. Each society would have the opportunity to place one small item in a barrel size container which would be the time capsule. This time capsule would be kept in a secure place and opened in 150 years* ". It is fitting that the curent President Marc Ballouz, who as Chair of the ISSMGE Public Relations Committee (2009 - 2013), championed the idea of a time capsule, is now acting with the ISSMGE Board, to direct the HTC team to bring to a successful conclusion a vision aired over a decade ago. A conclusion that would not have been possible without the leadership of President Charles Ng between 2017 and 2022 (see Figure 2).

Figure 2. Passing of the Presidential Gavel at the 20th ICSMGE, Sydney, Australia. (from ISSMGE Website).

Table 1 shows how in 2020, the HTC design team started work on creating an online repository (virtual time capsule) for the 21,000 or so individual members of the ISSMGE to access and get to know where geotechnical engineering's origins were, what and who guided its development, and the paths followed in

Table 1. Project progress overview & timeline.

Year	Project progress and timeline
2020	• Scoping of the project by a 16-person project committee, and formation of a design team • Work started on creating an online repository (virtual time capsule), hosted in the ISSMGE website, (https://www.issmge.org/), under the Society tab
2021	• Communications sent to and followed by online meetings with Member Societies, Technical Committees, Past Presidents, and Corporate Associates
2022	• Contributions received in the lead up to and following the 20th ICSMGE, Sydney • Launch of the time capsule project in a plenary session at the 20th ICSMGE, Sydney • Renaming of the project to Heritage Time Capsule (HTC)
2023	• A project update was provided in "ISSMGE Heritage Time Capsule – 3 Years on" (2023) • Construction started on the dedicated website for HTC, under a subdomain of issmge.org • Contributions added from ISSMGE Bulletin archives • HTC sessions held in Asia (17th ARC, Astana, Kazakhstan) and Australasia (14th ANZ, Cairns, Australia)
2024 (plan)	• Young Member Presidential Group (YMPG) help to prepare an initial stock of discoverer reports • Dedicated HTC website launch scheduled for the HTC session in GeoShanghai 2024 conference (Shanghai, China), at the end of May • Discoverer program to be announced, post launch of the dedicated HTC website • HTC sessions to be held in Africa, Europe and South America, and HTC follow up sessions to be held in Asia, and Australasia
2025 (plan)	• Work to be undertaken on the physical time capsule (Phase 3), and Phase 4 - 100 years on • Further HTC follow up sessions to be held
2026 (plan)	• Unveiling and sealing of the physical time capsule at the 21st ICSMGE in Vienna, Austria • Presenting the results of the HTC sessions on region specific issues

the various regions of the world, pitfalls and successes, and the philosophies in practice in many of its technical subdisciplines. Table 1 also shows progress from the start of the project and the planned timeline to the next quadrennial international conference in 2026 (21st ICSMGE in Vienna, Austria). The HTC project logo, developed in 2021, highlights the importance of the past, present and future in the HTC project (Figure 3).

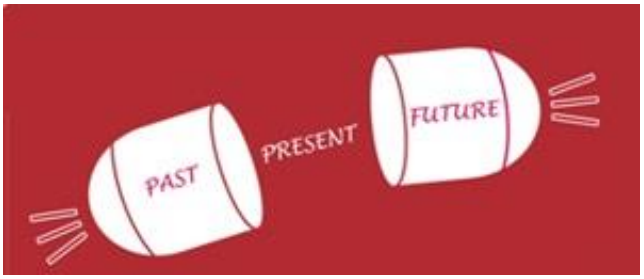

Figure 3. The HTC project logo.

The first step in this journey, Phase 1 - Contributions, started in the lead up to the 20th ICSMGE (Sydney, 2022). Contributions were invited from those related to the ISSMGE, including Member Societies, Technical Committees, Corporate Associates, Past Presidents & Key Persons, Vice Presidents, and Board level Committees. The material received includes video recordings, commented slide presentations, text documents and articles, all held online. Contributions on behalf of some of the past presidents were made by nominated champions. Table 2 shows the status of responses (as of February 2024).

Received material are presently hosted in the ISSMGE website, (https://www.issmge.org/the-society/time-capsule), and will be moved in 2024 to a dedicated website under a subdomain of issmge.org.

Table 2. Status of responses as of February 2024.

ISSMGE Category	Responses held from	Comments
Past Presidents	12 no.	
Member Societies (MSs)	56 no.	Further submissions in 2024 are invited from MSs, TCs, and CAs. These can be new or additions / amendments to existing material.
Technical Committees (TCs)	18 no.	
Corporate Associates (CAs)	5 no.	

Phase 2 - Discovery, is a pivotal element of the HTC project, in which the opportunity is provided for ISSMGE individual members to shine a spotlight on the HTC contribution(s) of their choice, and earn their individual place as discoverers in the HTC website. Also in Phase 2, there are the HTC discovery sessions, hosted at the ISSMGE Regional Conferences, and follow up HTC sessions held under the auspices of Member Societies, to address region-specific issues.

HTC sessions are planned to be held at the 2024 ISSMGE Regional Conferences, being, the European XVIII ECSMGE (Lisbon, Portugal), the African 18th ARCSMGE (Algiers, Algeria) and the Panamerican XVII PCSMGE (La Serena, Chile). Further, in 2024, follow up HTC sessions are planned, for the Asia region at GeoShanghai 2024 (Shanghai, China), and for the Australasia region, at local events of the Australian Geomechanics Society (AGS) and the New Zealand Geotechnical Society (NZGS). ISSMGE individual members are encouraged to participate and contribute at these HTC sessions.

The ISSMGE Board has also set the HTC team the challenging task of what to place in long term storage in a physical time capsule, for the benefit of geotechnical engineers many generations hence. This is tackled in Phase 3 - Time Capsule, with the physical time capsule to be unveiled (and sealed) at the 21st ICSMGE to be held in Vienna, 2026.

Throughout all this, the HTC team had in mind, what is the practical value, now and for the immediate future, for the geotechnical community? In Phase 4 of the project, 100 years on, with the benefit of experience and knowledge from Phases 1, 2 and 3, the ISSMGE global cohort will be further engaged to examine how we think and act as a community of practice, and the need to recalibrate ourselves.

While 100 years might seem a very long time to look ahead, we do have the benefit of records of what has happened in geotechnical engineering over the past 100 years, aided in some small way by the work of the HTC project. Furthermore, in practice, there should be no issue with teams of individual members who wish to work on shorter time periods (e.g. 20 years, 50 years). Projection and imagining into the future can prompt us to consider what other fields of engineering and other related fields (e.g. project management) are working on, and accepting what we now hold to be essential and or important may not necessarily be that way in the future.

3 HTC WEBSITE DESIGN & ARCHITECTURE

The dedicated HTC website, under a subdomain of issmge.org, is scheduled for launch at the HTC session in GeoShanghai 2024 conference (Shanghai, China) at the end of May. This website aims to present different types of material to the visitor in a useful and engaging way. Of particular note is the contributions section that displays a gallery of about 30 randomly selected

contributions. Each time the home page loads, different contributions appear in a different order. Visitors are also provided with the option to navigate through the different types of contributions through button links at the top of the gallery. The home page also contains a prominent search form, where contributions can be searched based on keywords. Results are returned based on title, content, specifically assigned tags and categories.

The top row of the home page displays the upcoming HTC sessions in the ISSMGE regions of Africa, Asia, Australasia, Europe, North America and South America. The top bar of the HTC Website contains the main content structure navigation options of the website, which are: *What is the HTC?*, *Contributions*, *Discovery*, *News*, *Contact*, and *Search* tabs. In the coming months, two additional tabs will be shown, being *Time Capsule*, and *100 years on*. These relate respectively to the display and sealing of a physical time capsule in 2026 at the 21st ICSMGE in Vienna, Austria, and the final phase of the HTC project reflecting on the needs of geotechnical engineering in the next 100 years.

The home page also features prominently discoverers' reports and items relating to the HTC, and blogs submitted by individuals. Scrolling features are enabled, to facilitate quick access to reports, news items and blogs. Furthermore social sharing buttons have been added so users can share contributions and discoverer reports on social media.

4 THE DISCOVERER PROGRAM

An essential requirement for the discovery process is the engagement of the individual members. As mentioned before, engagement by as many of the individual members of the ISSMGE is a much-desired aim of the HTC team. Hence, considerable attention was paid to the development and launch of a HTC discoverer program.

At the time of the launch of the ISSMGE Time Capsule project at the Sydney international conference in 2022, four individual members tested the initial discoverer concept, and their discoverer reports now form part of the HTC project. These discoverer reports are presently hosted in the ISSMGE website, (https://www.issmge.org/the-society/time-capsule). Table 3 shows the names the four early discoverers, the Member Societies they are affiliated with, and the HTC contributions that were the subject of their discoveries. Dr Peter Day, Chair of the ISSMGE Corporate Associates Presidential Group (CAPG), provided valuable help by reviewing the early discoverer reports, and suggesting ways in which future requests for discoverer reports could be framed.

Table 3. Early discoverers.

Name, Member Society	Reported Contributions
Asal Bidarmaghz, Australian Geomechanics Society	• Austrian Geotechnical Society • French Committee for Soil Mechanics and Geotechnics • TC103 on Numerical Methods in Geomechanics
Choo Siung Chung, Malaysian Geotechnical Society	• Le Comité Français de Mécanique des Sols et de Géotechnique • Hellenic Society of Soil Mechanics and Geotechnical Engineering • Canadian Geotechnical Society
Monica Löfman, Finnish Geotechnical Society	• Macedonian Association for Geotechnics • TC101 Laboratory Testing
Sonia H. M. Marques, Sociedade Portuguesa de Geotecnia	• Sociedad Colombiana de Geotecnia • Canadian Geotechnical Society • TC304 Risk

The HTC Team has now sought the assistance of the Young Member Presidential Group (YMPG) Core Team (Figure 4), to create additional discoverer reports prior to the launch of the HTC website. YMPG carries out activities that help ISSMGE engage with the next generation of geotechnical engineers. These activities are aimed at encouraging collaboration and communication among young members. YMPG has liaison members in over 40 of the 90 Member Societies, and over 1,100 corresponding members.

Two of the Core Team members, Bridget Lokoe and Judy Eid, are leading the work of coordinating the preparation of discoverer reports by members of the YMPG liaison.

Figure 4. Members of the YMPG Core Team 2022-2024.

The HTC team expects the uploading to the website of the discoverer reports created by the YMPG liaisons to inspire the individual members of the ISSMGE to create a larger number of discoverer reports. These discoverer reports will be uploaded for display on the HTC website, and for sharing on social media. The HTC team believes the creation and sharing of many discoverer reports, in all regions of the ISSMGE, will both increase awareness of the HTC website, as well as help to increase the visibility of the geotechnical engineering profession and its contribution to the wellbeing and security of society.

Multiple discoverers can make discoveries of any one particular HTC material (or part thereof), as long as the work of the discoverer reports is unique. Discoverer reports may also be prepared by small teams or groups of individual members, provided a lead discoverer is appointed for the contribution. Figure 5 outlines the steps applicable to the discoverer reports.

Invitation to the ISSMGE individual members to submit discoverer reports will be announced in 2024, post launch of the dedicated HTC website at the GeoShanghai 2024 conference, at the end of May.

Each discoverer will prepare a brief report for storing and sharing on the HTC website. The emphasis of the report is to shine a spotlight on the chosen HTC contribution(s) or parts thereof and bring the HTC contributions to the reader's attention. The discoverer's report can be a brief note, video, audio, or other forms able to be stored and displayed online. Following are the nominal guidelines in terms of length, and while brevity is valued, greater lengths will be considered on their merit.

- Word document - up to 1,000 words,
- Video - up to 3 min length
- PowerPoint presentation - up to 8 slides

A discoverer is required to be an individual member of the ISSMGE. The discoverer's report should:

- State, in the beginning, the Member Society the discoverer is affiliated with,
- Identify, in the beginning, which HTC contributions i.e. Member Societies, Technical Committees, Past Presidents, etc., that are selected for the discoverer report,
- Be complete and self-contained, and presented in a suitable fashion for review,
- Carefully identify which parts of the discoverer report are drawn from the HTC contributions, and what parts are their own insights, thoughts and comments, and,
- Not include material external to the HTC contributions that may be subject to copyright or other restrictions from publication.

Figure 5. Steps applicable to discoverer reports.

5 HTC DISCOVERY SESSIONS

The discovery sessions are organised along regional lines, reflecting the makeup of the ISSMGE Board. The regional Vice Presidents are representatives of their region; hence they can act on behalf of their Member Societies and guide them along a theme that is most reflective of the present needs of the regions.

Thus, Australasia region's theme is geo-education, reflecting the interest in the region on the operation of systems and mechanisms (including university education) that can have an impact on geotechnical engineering capability and capacity to respond to current and future needs. Figure 6 provides an illustrative overview of the HTC sessions carried out and planned for the Australasia region.

In Asia, the HTC project has provided the opportunity to discuss measures that can be undertaken to increase collaboration between Member Societies, both across the region, as well with Member Societies in the other regions. The HTC themes for Africa, Europe and North and South America regions are at various stages of development. The HTC Africa team, with representatives from six Member Societies, and liaising with the other Member Societies in the African region, is working on the launch of a 1-hour plenary HTC session at the 18th ARCSMGE, Algiers, Algeria.

The following individual members are leading the development of regional HTC sessions:

- Africa - Akua Asantewaa Akosah-Yentumi
- Asia - Mingliang Zhou
- Australasia - Golnaz Alipour
- Europe - Pedro Pinto, ISSMGE past President (2005 - 2009)
- Pan-American - Hugo Acosta Martinez

HTC discovery sessions provide for leadership opportunities for the emerging cohort of individual members to challenge established wisdom, and in turn obtain increased knowledge about the ISSMGE and the current and diverse conditions that are in operation in their region. As much as possible, the HTC sessions are to be reported, either in the ISSMGE Bulletin or in a relevant Journal(s) of the region. The HTC session on geo-education at the ANZ2023, Cairns, Australia last year has been comprehensively reported in the paper, "ISSMGE HTC project session at 14th ANZ conference on geomechanics" (2023).

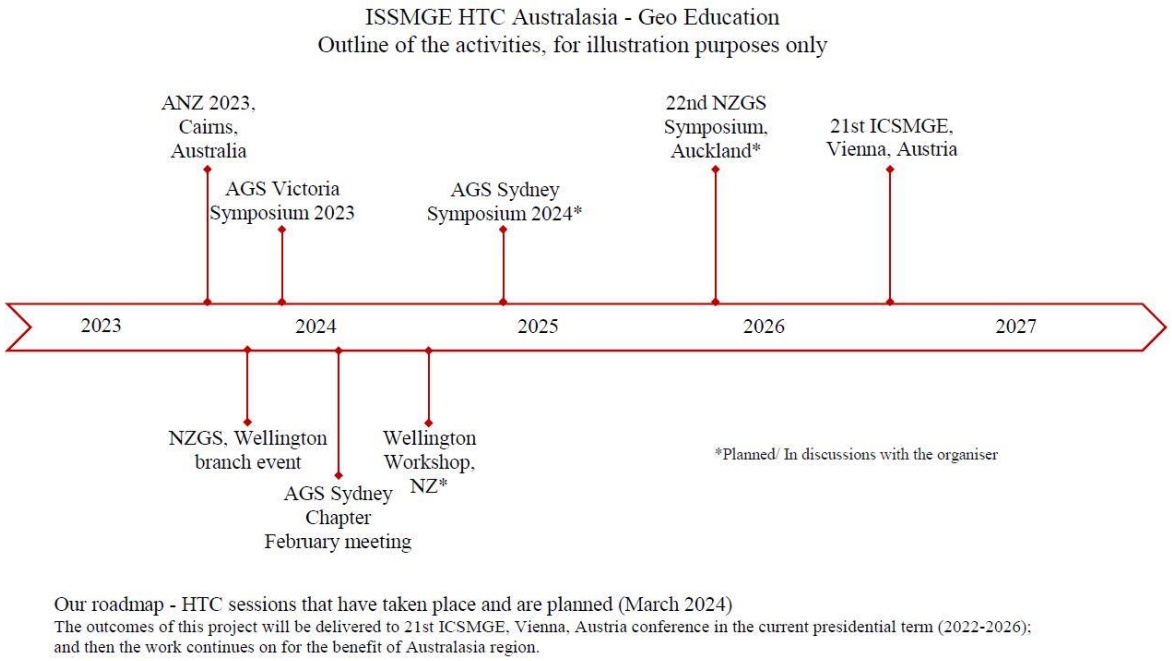

Figure 6. Geo-Education Australasia road map, updated March 2024 (from HTC Australasia team).

6 THE OUTCOMES OF DISCOVERY

The discovery phase is designed as a pivotal point in the HTC project, providing input to the subsequent two phases, Phase 3 - Time Capsule and Phase 4 - 100 years on. If, as the HTC team hopes, sufficiently large numbers of individual members become engaged in the discovery process, either as discoverers or as participants in the HTC discovery sessions, or both, there is an increased likelihood of a more widely shared understanding of the HTC project and a perspective of geotechnical engineering that is more aware and understanding of the diversity in geotechnical engineering among the individual members. Thus, the ground would have been well prepared for in-depth and informed discussions in 2025 and 2026 about what aspects of our current and past practice we want to share with generations hence in the time capsule (Phase 3).

Additionally, those individual members involved and engaged in Phases 1 and 2 may be able to better represent at all levels, and across geographies, thoughts and aspirations about the future of geotechnical engineering, and what the profession might or should look like in 100 years on (Phase 4). Figure 7 points to a possible future imagined.

Imagine the next 100 years

In 'discovering' contributions made, the HTC team has been very much impressed and moved by the wholehearted dedication of so many of our individual members at all levels in collaborating and contributing to the advancement of the geotechnical engineering community and profession. ISSMGE has played a vital role in leading and encouraging this work.

The HTC team could imagine, aided by the outcomes of the work of the HTC project, and led by the ISSMGE, there could be an interest by many in the geotechnical community, in charting out a path or paths for the overall advancement of geotechnical engineering in the successive decades to come, not only in the various technical streams, but also in terms of benefit to society, such as disaster mitigation, climate change, energy, reuse, productivity and the various challenges that cities and less populated areas face. Such forward planning may help increase the visibility of geotechnical engineering in society, and help achieve earlier and more effective feedback loops of our activities.

Figure 7. A possible future imagined.

7 CONCLUSIONS

The paper has illustrated the initiatives launched to create an ISSMGE Heritage Time Capsule (HTC) that aim to actively engage with the Member Societies and individual members of the ISSMGE. Among these are the design and the scheduled launch of a new dedicated website, under a subdomain of issmge.org, at the HTC session at GeoShanghai 2024 conference (Shanghai, China), at the end of May, and the engagement of individual members for discovery, bridging the contributions received, to the display and sealing of a physical time capsule at the 21st ICSMGE in Vienna and to the final phase of the HTC project, reflecting on the needs of geotechnical engineering in the next 100 years.

The success of the HTC project, and achieving its important aspirations now largely depends on what individual members can and should do in respect of the HTC project. A reasonably broad and deep working space has been provided by the HTC project for the individual members of the ISSMGE to feel that they all are included in this project and that they can contribute to their own level of interest.

An action taken to become a discoverer can provide benefits to the individual in terms of knowledge gained through studying HTC contributions, and individual profile recognised through hosting of the discoverer report in the HTC website and the potential to share the discoverer reports on social media. The results of the discovery sessions across the six regions of the ISSMGE have the possibility to create clarity of action plan for future for the geotechnical community, and to help improve effectiveness of geotechnical engineering for future generations.

Let's imagine, together, the coming 100 years.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the Presidents and the ISSMGE Boards of 2017-2022 and 2022- 2026, for their approval and support for this project. We thank immediate past President Charles Ng for his support for the time capsule project, and to President Marc Ballouz for his insight that a dedicated website was required the HTC project, and his vision for a physical time capsule to be opened in 100 years.

The authors are also very grateful for the Member Societies, Technical Committees, Corporate Associates, Past Presidents and Key persons, Champions for Past Presidents, Vice Presidents, and Board level Committees for their commitment to the project and for their contributions. Special thanks are due to Pedro Pinto, Roger Frank, Harry Poulos, Peter Day and Pierre Delage, who have provided their valuable time helping the HTC team with this project.

We thank the four early discoverers for their willingness to trial the discoverer program. The Young Members Presidential Group (YMPG) has been invaluable in helping to carry out many key actions of the HTC project. The ISSMGE IT team (ARGO – E Group) led by Kostis Tsantilas, has demonstrated that they are highly committed to making viewer experience a priority in the development of the time capsule webpage, and now the design and construction of the dedicated HTC website, and we thank them for their great support.

Finally, the authors thank all the members of the HTC team who are working hard on many fronts and actions to advance the HTC project, and we highly value their inputs and comments on this paper at its various stages of preparation.

Incorporating site variability into LRFD design of piles

Intégration de la variabilité du site dans la conception LRFD des pieux

ABSTRACT: The properties of geotechnical materials are inherently variable due to many uncertainty sources including spatial variability, measurement error, statistical error, and model bias. This study focused on evaluating the site variability from cone penetration tests (CPT), and its implementation into the Load and Resistance Factor Design (LRFD) of pile foundations. For this purpose, data from six project sites with multi CPT tests performed at different locations were collected. The spatial variability of CPT data for each site was evaluated using the semi-variogram. The coefficient of variation due to spatial variability ($COV_{R,spatial}$) was determined for each site. The total coefficient of variation ($COV_{R,total}$) for each site was then estimated from $COV_{R,}$spatial and the method coefficient of variation ($COV_{R,method}$), which were then used to calibrate the resistance factors ($\phi_{spatial}$, ϕ_{total}) for application to LRFD design of piles. The results of this study demonstrated the significance of incorporating site variability into LRFD design of piles. For sites with lower site variability than the design method (i.e., $COV_{R,spatial} < COV_{R,method}$), the value of the $COV_{R,total}$ will be decreased, and hence the resistance factors ($\phi_{spatial}$ or ϕ_{total}) will be increased (credit), and vice versa.

RÉSUMÉ: Les propriétés des matériaux géotechniques sont intrinsèquement variables en raison de nombreuses sources d'incertitude, notamment la variabilité spatiale, l'erreur de mesure, l'erreur statistique et le biais du modèle. Cette étude s'est concentrée sur l'évaluation de la variabilité du site à partir des essais de pénétration du cône (CPT) et sur sa mise en œuvre dans la conception des facteurs de charge et de résistance (LRFD) des fondations sur pieux. À cette fin, des données provenant de six sites de projet avec des tests multi-CPT effectués à différents endroits ont été collectées. La variabilité spatiale des données CPT pour chaque site a été évaluée à l'aide du semi-variogramme. Le coefficient de variation dû à la variabilité spatiale ($COV_{R,spatial}$) a été déterminé pour chaque site. Le coefficient de variation total ($COV_{R,\ total}$) pour chaque site a ensuite été estimé à partir du COV_R, spatial et du coefficient de variation de la méthode ($COV_{R,\ méthode}$), qui ont ensuite été utilisés pour calibrer les facteurs de résistance ($\phi_{spatial}$, ϕ_{total}) pour application au LRFD conception de pieux. Les résultats de cette étude ont démontré l'importance d'intégrer la variabilité du site dans la conception des pieux LRFD. Pour les sites avec une variabilité de site inférieure à celle de la méthode de conception (c.-à-d. $COV_{R,spatial} < COV_{R,méthode}$), la valeur du $COV_{R,total}$ sera diminuée et, par conséquent, les facteurs de résistance ($\phi_{spatial}$ ou ϕ_{total}) seront augmentés (crédit), et vice versa.

Keywords: Site variability; pile foundation; CPT; resistance factor.

1 INTRODUCTION

All natural soil deposits are highly variable in their properties and are rarely homogeneous. These properties vary inherently from point to point horizontally and vertically due to several reasons including the depositional environment, the degree of weathering, and the physical environment (Elkateb et al. 2003, Lumb 1974). Variability of geotechnical soil properties is a complex phenomenon that results from many disparate sources of uncertainties. The four primary sources of geotechnical uncertainty that affect the soil behavior are the spatial variability of soil deposit, the random measurement errors, statistical error, and the model bias.

Lacasse and Nadim (1996) showed that the geotechnical parameters had variability in both horizontal and vertical directions with a greater inclination to be similar to the closely neighboring. McVay et al. (2009) conducted a study to evaluate the resistance factors (ϕ) for the Load and Resistance Factor Design (LRFD) of piles that incorporates the effect the spatial variability of local soil strength. Faraone (2014) presented a methodology that incorporates the framework of reliability-based design, while accounting for the site specific spatial variability, which is applicable to several deep foundation design practices (like pile foundations).

2 EVALUATING AND INCORPORATING SITE VARIABILITY INTO LRFD

In order to define the spatial variability from the measured data, it requires engineers to determine the correlation between data pairs that are separated by different distances using different parameters. One of the main parameters that is used to measure the site variability is known as the semi-variogram, γ(h), which can be defined as the distance range, a, that defines the end of correlation between data pairs as:

$$\gamma(h)=\frac{1}{2n_h}\sum (q_i - q_j)^2 \quad (1)$$

where q_i and q_j are data pairings (separated by distance h), and n_h is total number of data pairs.

Several theoretical models are available to predict the spatial covariance function, such as spherical, exponential, Gaussian, and circular. The most widely used amongst these models is the spherical model.

The ranges obtained from semi-variogram analyses are used to determine the reduction factor, α (McVay et al., 2009), which will be applied to calculate the spatial coefficient of variation $COV_{R,spacial}$ as a function of the coefficient of variation, COV_q, of the field measurements and/or laboratory results (e.g., CPT_{-qt}, SPT-N, S_u) using the following equation:

$$COV_{R,spatial} = \sqrt{\alpha}\, COV_q \quad (2)$$

For application to pile foundation design, the generalized expression for COV_R can be given as follows (McVay et al. 2009):

$$COV_{R,\,spatial} = \frac{\sigma_R}{R_n} = \frac{\sqrt{\pi^2 D^2 \sum_{j=1}^{n_L} L_{Lj}^2 \alpha_{Lj} \sigma_{Lj}^2 + \sigma_{EB}^2}}{\pi D \sum_{j=1}^{n_L} L_{Lj} m_{Lj} + m_{EB}} \quad (3)$$

where D is diameter of pile; L_{Lj} are length intervals of shaft; m_{Lj} are expected values of fs_{Lj} in each layer; m_{EB} is expected value of end bearing resistance; α_{Lj} is α for each layer calculated following McVay et al. (2009) approach; σ_{Lj2} is the variance in q for each layer; and σ_{EB2} is the variance in end bearing resistance.

In equation 3, the reduction factor, α is a function of (L/a_v, D/a_h), where a_v and a_h are the correlation ranges in both the vertical and horizontal directions, respectively; and L and D are the pile length and pile diameter, respectively.

Once the value of COV_R is defined, the resistance factor, ϕ, for pile design according to LRFD method can be calculated using the following modified first order second moment method (MFOSM) calibration equation proposed by McVay et al. (2009):

$$\phi = \frac{\lambda_R\left(\gamma_D \frac{Q_D}{Q_L} + \gamma_L\right)\sqrt{\frac{1+COV_Q^2}{1+COV_R^2}}}{\left(\lambda_{QD}\frac{Q_D}{Q_L} + \lambda_{QL}\right)\exp\left(\beta_T\sqrt{\ln\left(1+COV_R^2\right)\left(1+COV_Q^2\right)}\right)} \quad (4)$$

where λ_R is the resistance bias factor; Q_D and Q_L are the dead load and live load, respectively; β_T is the target reliability index; γ_D and γ_L are the load factors for dead load and live load, respectively; λ_{QD} and λ_{QL} are the load bias factors (mean ratio of measured over predicted value) for the dead load and live load, respectively. COV_{QD} and COV_{QL} are the coefficient of variation values for the dead load and live load, respectively. The Q_D/Q_L is the dead load to live load ratio, which is assumed to be 3 in this study.

The value of resistance bias factor, λ_R, is calculated as:

$$\lambda_R = \frac{\sum \lambda_{Ri}}{N} \quad (5)$$

where λ_{Ri} is the resistance bias factor for each site and N is the number of sites.

The coefficient of variation of the random loads, COV_Q, was introduced by McVay et al. (2009) using the following equation:

$$COV_Q = \sqrt{\frac{\frac{Q_D^2}{Q_L^2}\lambda_{QD}^2 COV_{QD}^2 + \lambda_{QL}^2 COV_{QL}^2}{\frac{Q_D^2}{Q_L^2}\lambda_{QD}^2 + 2\frac{Q_D}{Q_L}\lambda_{QD}\lambda_{QL} + \lambda_{QL}^2}} \quad (6)$$

where COV_{QD} and COV_{QL} are the coefficient of variation values for the dead load and live load, respectively.

2.1 Description of CPT Sites and subsurface soil characterization

Six sites in Louisiana with many CPT tests performed at each site were used to evaluate the effect of site variability on LRFD design of piles. These sites are: Metairie site with 14 CPT tests performed at different locations down to 36.6 m; Accelerated Loading Facility (ALF) site with 10 CPT tests performed at different locations down to 15.2 m; Bayou Lacassine site with 10 CPT tests performed at different locations down to 22.9 m; US90 & LA85 site with 22 CPT tests performed at different locations down to 27.4 m; Hammond site with 7 CPT tests performed at different locations; and LA1 site with 22 CPT tests performed at different locations down to 22.9 m. Figure 1 presents the CPT locations for LA 1 site.

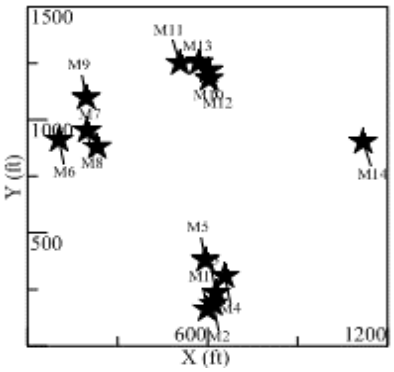

Figure 1. Plan view of CPT locations for Metairie site.

The subsurface soil conditions for the six sites were characterized using the results of CPT tests, as well as, the soil borings and associated laboratory tests. As an example, the profile of soil type for Metairie site, results of SPT tests and undrained shear strength, S_u, and the profiles of average corrected tip resistance per foot, for all the CPTs, are presented in Figure 2.

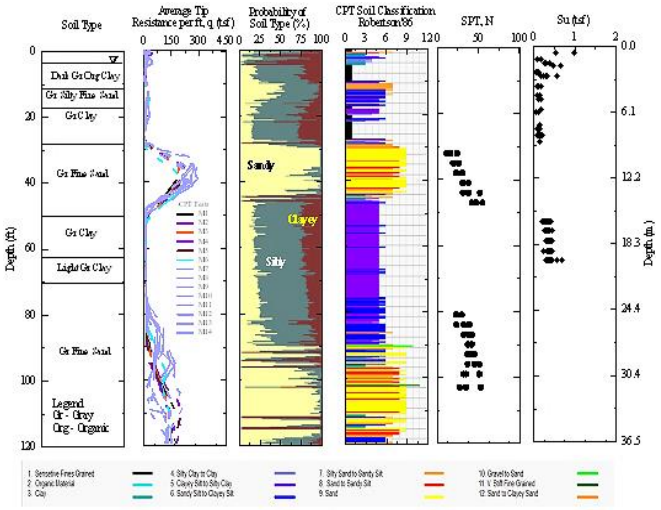

Figure 2. Soil boring and CPT soil classification at Metairie site.

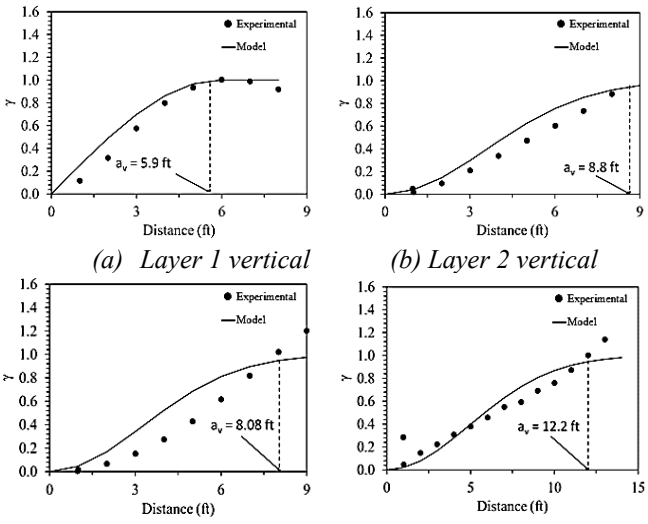
The coefficient of variation (COV) of the corrected cone tip resistance, q_t, was calculated for each site. The profiles of CPT tests were used to classify the subsurface soil using the probabilistic region "soil behavior" estimation method (Zhang and Tumay 1999) as shown in Figure 2. In addition, the CPT soil classification proposed by Robertson (1990) was adopted in this study to define the soil layering. For Metairie site, six soil layers were identified for analysis: 0.0 - 8.5 m, 8.5 - 12.2 m, 12.2 - 15.2 m, 15.2 - 23.8 m, 23.8 - 33.8 m, and 33.8 - 36.6 m.

3 RESULTS AND ANALYSES

3.1 Site variability from CPT data and LCPC Pile-CPT method

To investigate the site variability from CPT data and its effect on the LRFD design of piles using the LCPC pile-CPT design method, the CPT data (q_t) collected from the six project sites was evaluated separately per site. In order to investigate the effect of site variability for each site using the geo-statistics tools, all the collected data for each site should be first transferred to stationary data without any trend, which is necessary to perform the semi-variogram analyses. Data transformation from nonstationary to stationary data was performed for all six sites.

Experimental variogram analyses were performed using the JeoStat software for each soil layer of the six sites. The resulted experimental semi-variograms for four soil layers at Metairie site are presented in Figure 3. Variability analyses for this site were done in the vertical direction only, and the horizontal semi-variograms were not included due to long spacing between the CPT points. The spherical model was adopted here to fit the model's semi-variogram with the experimental semi-variogram data to define the vertical correlation range, a_v, for each soil layer.



(a) Layer 1 vertical *(b) Layer 2 vertical*

(c) Layer 3 vertical *(d) Layer 4 vertical*

Figure 3. The experimental and spherical semi-variogram models for four soil layers at Metairie site.

The statistical data and the correlation length values, a_v, determined by the semi-variograms were used to calculate the LRFD resistance factors, ϕ, for the six sites as shown in Table 1. Equation (3) was used to evaluate $COV_{R,spatial}$, while equation (6) was used to calculate COV_Q. The layer's mean, m, and standard deviation, σ, were calculated from the CPT- q_t data

(using the JeoStat software). The resistance factor considering spatial variability, $\phi_{spatial}$, for each site was then evaluated using equation (4). Following the procedure proposed by Elkateb et al. (2003), the values of $COV_{R,spatial}$ for Metairie, ALF, Bayou Lacassine, US90 & LA85, Hammond, and LA1 sites were calculated as 0.20, 0.11, 0.08, 0.09, 0.16 and 0.10, respectively. The corresponding LRFD resistance factors based on spatial variability, $\phi_{spatial}$, are 0.77, 0.93, 0.98, 0.95, 0.85 and 0.95 for Metairie, ALF, Bayou Lacassine, US90 & LA85, Hammond, and LA1 sites, respectively. These resistance factors were calculated using the $COV_{R,spatial}$ only. The LRFD resistance factors was also calculated using the design method resistance coefficient of variation, $COV_{R,method}$, which is equal to 0.31 for LCPC pile-CPT design method (Amirmojahedi and Abu-Farsakh, 2019). The corresponding method's resistance factor, ϕ_{method}, for LCPC design method equals 0.61 based on Amirmojahedi and Abu-Farsakh (2019) study, which is the same for all sites. In evaluating ϕ_{method}, no consideration was given to site variability, although variability between the different sites in Louisiana were indirectly included in the calibration of ϕ_{method}. In this study, the authors recommend to incorporate both the $COV_{R,spatial}$ and the $COV_{R,method}$ in the LRFD calibration of resistance factor, ϕ_{total}, using the following proposed equation:

$$COV_{R,total} = \frac{c1 \times COV_{R,spatial} + c2 \times COV_{R,method}}{c1+c2} \quad (7)$$

where c1 and c2 are weighted coefficients for the spatial site variability and design method variability, respectively, which can be evaluated based on engineering judgment of the specific site variability. In this study, the authors assumed c1 = c2 = 0.5, since both variabilities are of close importance.

Table 1. Calibrated resistance factors, ϕ, for LCPC Pile-CPT design method.

Parameters	Metairie	ALF	BL	US90	Hammond	LA1
$COV_{R,spatial}$	0.20	0.11	0.08	0.09	0.16	0.1
$COV_{R,method}$ (LCPC)	0.31					
$COV_{R,total}$	0.255	0.21	0.195	0.20	0.235	0.205
COV_Q^2	0.011					
$\phi_{spatial}$	0.76	0.91	0.96	0.94	0.83	0.93
ϕ_{method} (LCPC)	0.61					
ϕ_{total}	0.67	0.74	0.77	0.76	0.70	0.75

Table 1 presents the $COV_{R,spatial}$, $COV_{R,total}$ and ϕ_{total} for different sites. It can be seen that the values of ϕ_{total} are different for the different sites, basically based on the variability on the $COV_{R,spatial}$ of the site. The relatively high site variability of Metairie site resulted on lower resistance factor, ϕ_{total} = 0.67, than the other sites; while the low site variability of Bayou Lacassine site resulted on higher resistance factor, ϕ_{total} = 0.77, than the other sites.

4 CONCLUSIONS

This study investigated the effect of site variability on the geotechnical properties from site exploration, and its implementation into LRFD design of pile foundations. Based on the findings of this study, the following conclusions can be made:

- Spatial site variability can be evaluated from site exploration involved multi CPT tests performed at different locations within the same site.
- The effect of site variability can be implemented into LRFD design of pile foundations through evaluating the spatial and total coefficients of variation ($COV_{R,spatial}$, $COV_{R,total}$) of the site using the semi-variogram approach, which can be used to calibrate the resistance factor ($\phi_{spatial}$ or ϕ_{total}) for the specific site using Equation (4).
- The values of $COV_{R,spatial}$ for all six sites are lower than $COV_{R,method}$. In $COV_{R,method}$, no consideration is given to the specific site variability, although variability between different sites in Louisiana were indirectly included in the LCPC method.
- For sites with lower site variability than the variability of design method (i.e., $COV_{R,spatial} < COV_{R,method}$), the total coefficient of variation ($COV_{R,total}$) decreases and the corresponding resistance factor ($\phi_{spatial}$ or ϕ_{total}) increases, and vice versa; hence giving a credit to low variability sites as compared to high variability sites in terms of increasing either $\phi_{spatial}$ or ϕ_{total}, for use in the design of pile foundations.

ABSTRACT: This paper evaluates the performance of several empirical geosynthetic-reinforced pile-supported (GRPS) embankment design methods, which include the BS8006, Nordic, EBGEO, FHWA, and CUR226 methods. Assessment of these GRPS design methods was performed using three field case studies using four criteria: the efficacy, stress concentration ratio, maximum differential settlement, and maximum reinforcement. The results show that the performance of GRPS design methods varies from case to case and depends on the criterion considered. For efficacy criterion, the field measurements are closer to Nordic and EBGEO than the other methods. For SCR criterion, the field measurements are closer to BS8006 than the other methods, and to finite element models (FEM) in two cases. However, for the maximum tension and differential settlements criteria, the field measurements are much closer to CUR226, EBGEO, and FEMs.

RÉSUMÉ: Cet article évalue les performances de plusieurs méthodes empiriques de conception de remblai sur pieux renforcés de géosynthétiques (GRPS), notamment les méthodes BS8006, Nordic, EBGEO, FHWA et CUR226. L'évaluation de ces méthodes de conception GRPS a été réalisée à l'aide de trois études de cas sur le terrain en utilisant quatre critères: l'efficacité, le rapport de concentration des contraintes, le tassement différentiel maximal et le renforcement maximal. Les résultats montrent que les performances des méthodes de conception GRPS varient d'un cas à l'autre et dépendent du critère considéré. Pour le critère d'efficacité, les mesures de terrain sont plus proches de Nordic et EBGEO que des autres méthodes. Pour le critère SCR, les mesures de terrain sont plus proches de la BS8006 que des autres méthodes, et des modèles éléments finis (FEM) dans deux cas. Cependant, pour les critères de tension maximale et de tassements différentiels, les mesures sur le terrain sont beaucoup plus proches de CUR226, EBGEO et FEM.

Keywords: Geosynthetics; load transfer platform; piles; embankments.

1 INTRODUCTION

The construction of road embankments on soft soils often faces potential challenges such as bearing capacity failure, slope failure, lateral sliding, and excessive differential settlement. An effective solution is to use geosynthetic-reinforced pile-supported (GRPS) embankments. The inclusion of a load transfer platform (LTP) allows for effective redistribution of stresses onto the pile caps, which leads to smaller differential settlement. The load transfer from embankment load to pile caps takes place due to three factors: soil arching, development of geosynthetic tension, and soil-geosynthetics interaction. To fully understand the mechanisms of GRPS embankments, many studies had been carried out including full-scale field testing (e.g., Lu et al., 2020), experimental studies (e.g., Rue et al., 2016), and theoretical analyses (e.g., McGuire et al., 2020).

Several analytical methods were developed in literature to evaluate the vertical load distribution on the pile caps and soft soil surface in GRPS embankments. Hewlett and Randolph (1988) developed a semi-spherical arching model to characterize the load transfer mechanism based on 3D model tests. However, this method does not consider the effect of geosynthetic reinforcement. Low et al. (1994) improved the Hewlett and Randolph method by including the body force in a plain-strain differential equation. The BS8006 (2010) design method used the Hewlett and Randolph (1988) method to calculate the vertical load distribution. The EBGEO (2011) adopted Kempfert method (2004), which is based on laboratory modeling of piled-embankment systems. Combining

the EBGEO (2011) and Hewlett and Randolph (1988) methods and based on laboratory observations, Van Eekelen et al. (2013) proposed a new model with concentric arches and hemispheres for analyzing the arching effect. Lee et al. (2020) proposed an inverse-triangular shape distribution for the vertical load on top of soft soil and a uniform distribution for stiff soil, which is compatible with Van Eekelen's concentric arches model. Filz and Smith (2006) derived the vertical stress distribution on embankment based on the generalized form of Terzaghi's method. Filz et al. (2019) added the following refinements to Terzaghi's method: limiting vertical shearing of embankment to the part of the embankment below the critical height, separating the embankment into two layers based on the location of the LTP, and considering different piles arrangements. The Filz and Smith (2006) method has been adopted in the FHWA.

2 BRIEF REVIEW OF DESIGN METHODS

In this study, five design methods were selected for comparison and evaluation using field measurements. These methods include the British method (BS8006), German method (EBGEO), Nordic method (NGG 2005), Netherland CUR226 (2016) method (2016), and FHWA method (Schaefer et al., 2017).

The main assumptions in British (BS8006) method are that the soil arching between two adjacent piles is developed in a hemispherical shape, and the soil failure occurs either at the crown of the arch or at the pile cap, as shown in Figure 1. Several equations are proposed to calculate the arching efficacy, maximum tension in geosynthetics, and maximum differential settlement between the mid-span of two piles and pile cap. The BS8006 method recommends a maximum strain of 6% for design.

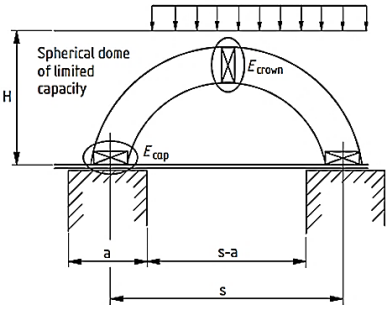

Figure 1. Arching mechanism and critical failure locations for BS8006 method (2016).

In German EBGEO method, the multi-arching theory is used as shown in Figure 2. The model is based on the lower bound theorem of plasticity as well as experimental observations of stress directions in the arch. The subsoil support is considered when determining the reinforcement tension. The vertical stresses on the pile cap and subgrade soil are assumed to be uniformly distributed. The membrane theory is used to calculate the tensile force in geosynthetic reinforcement. The maximum strain can be estimated using design charts provided in the EBGEO design code. No equation provided to estimate the differential settlement between the pile cap and mid-span of subgrade soil in this method. Hence the BS8006 equation is used to calculate the differential settlement.

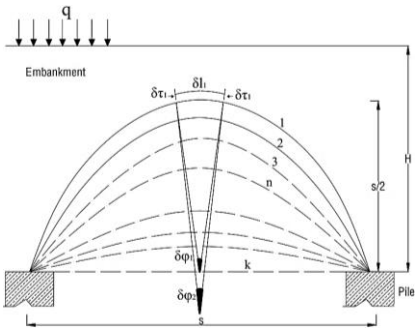

Figure 2. Multi-arching theory by Kempfert et al. (2004).

In CUR226 method, a concentric arches model are adopted for GRPS embankments (Kempfert et al., 2004) based on observations of stress formation and distribution in laboratory testing. The concentric-arch model is solved using the limit equilibrium approach. A schematic drawing of the concentric arches model is shown in Figure 3. The vertical load is divided into three parts: load on pile cap, load on geosynthetic square area, and load on geosynthetic strips generated from 2D arches. A relationship equation was proposed between the three components. Once the vertical stress distribution is determined, the reinforcement tension can be calculated. The distribution of vertical load along the geosynthetic layers can be assumed either uniform or inverse triangular.

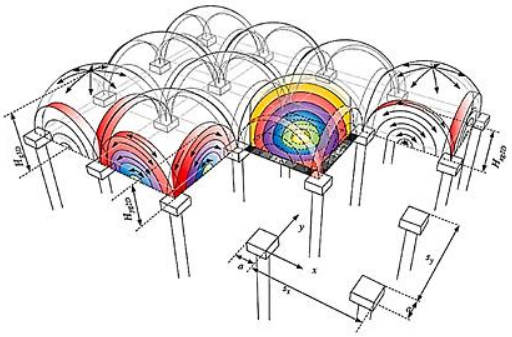

Figure 3. Concentric arches by Van Eekelen et al. (2013).

In FHWA design method, the pile type, spacing, diameter, and length will be first determined based on service limit state and ultimate limit state. An equation is provided to calculate the critical height of embankment, which is important to determine the

stress distribution. The method adopts the load-displacement compatibility method proposed by Filz and Smith (2006) to estimate the vertical load on top of pile cap and geosynthetics. The vertical load is divided into four components: average vertical stress acting down on top of geosynthetics in the area underlain by pile, average vertical stress acting down on top of geosynthetics in the area underlain by soil, average vertical stress acting on bottom of geosynthetics in the area underlain by pile, and average vertical stress acting on bottom of geosynthetics in the area underlain by soil. The vertical equilibrium of system is then satisfied.

In Nordic design method (NGG 2005), the load carried by reinforcement will be first calculated based on the assumption of a soil wedge. By assuming the vertical stress on top of subgrade is uniform, the vertical stress can then be calculated. An equation is proposed to calculate the tension in reinforcements. The maximum differential settlement is calculated using the same equation in BS8006 method.

3 FINITE ELEMENT MODEL (FEM)

A 2D and 3D FEMs were developed for GRPS embankments using PLAXIS2D & 3D softwares. The Mohr-Coulomb (MC) model was used for cohesionless soil layers and embankment fill, and the modified Cam Clay model was used for cohesive soils. The granular material in LTP was modeled using the Hardening Soil model. The piles were simulated using linear elastic model. In this study, the equivalent stiffness method was adopted to simulate the piles in the 2D FE model, in which pile spacing and diameter remain unchanged while the piles' stiffness and permeability of surrounding soil are adjusted. The interface between geosynthetics and geomaterials, and between piles and surrounding soils were modeled using interface elements and MC frictional model.

Four criteria were adopted in this study to evaluate the performance of GRPS embankments: efficacy, stress concentration ratio, maximum differential settlement, and maximum tension in geosynthetic reinforcement. Definition of these criteria can be found in Izadifar et al. (2023).

4 EVALUATING OF DESIGN METHODS

The five GRPS embankment design methods were evaluated using three case studies and the results of FE analysis. The first case study was presented by Liu et al. (2007) for the 18 ft. high GRPS embankment located in Shanghai, China. The second case was conducted by Briançon and Simon (2012) on a 16 ft. high full-scale experiment within the French national research project located northeast Paris. The third case was presented by Huang et al. (2009) for a 5.9 ft. height GRPS embankment constructed in northeast of Helsinki, Finland.

Figure 4 presents the comparison between the field measurements, FE results, and estimations from the GRPS design methods based on the four different criteria.

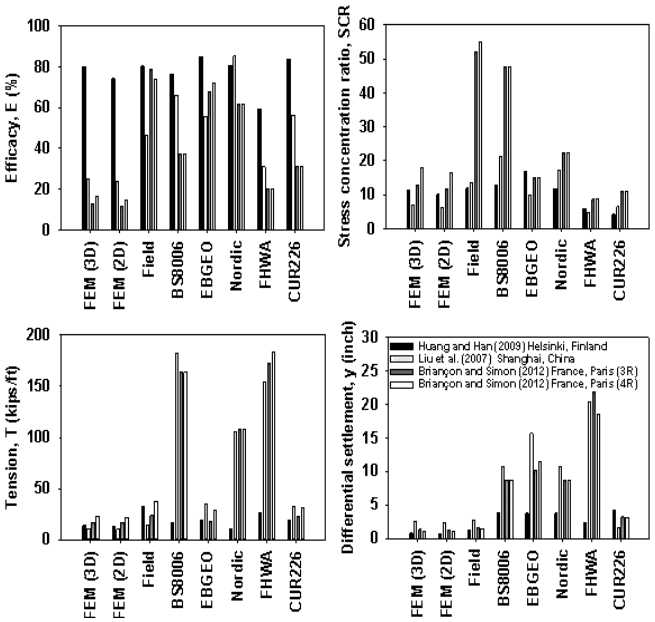

Figure 4. Performance evaluation of GRPS design methods based on field measurements.

It can be seen that the performance of each GRPS design method varies for different case studies and different criteria. In general, all the design methods tend to overestimate the four design criteria, sometimes by a very large amount. For example, the BS8006, Nordic, and CUR226 methods overestimate the tension by about 10, 6, and 2 times, respectively, for the Shanghai case. On the contrary, the FE results provide close agreement with the field measurements in most scenarios except for the efficacy and SCR values of the Paris case. Comparing the 2D and 3D FE results showed that the 3D provides closer results to field measurements. However, the difference between the 2D and 3D for the different criteria are low.

For the GRPS design methods, however, the accuracy of each design method is highly dependent on the case study and the criterion of interest. For efficacy criterion, the field measurements are closer to Nordic and EBGEO than the other methods. For SCR criterion, the field measurements are closer to BS8006 than the other methods, and to FEM in two cases. However, for the maximum tension and differential settlements criteria, the field measurements are much closer to CUR226, EBGEO, and FEMs.

5 CONCLUSIONS

- The performance of GRPS design methods varies from case to case and depends on the criterion considered due to assumed arching model.
- The 2D and 3D FEMs provide close agreement with field measurements in most scenarios except for the efficacy and SCR values of the Paris case.
- For efficacy criterion, the field measurements are closer to Nordic and EBGEO than the other methods.
- For SCR criterion, the field measurements are closer to BS8006 than the other methods, and to FEM in two cases.
- For the maximum tension and differential settlements criteria, the field measurements are much closer to CUR226, EBGEO, and FEMs.

Development of CPT-V_s correlations for soft quaternary clays of Szeged city Hungary

Développement de corrélations CPT-V_s pour les argiles molles du quaternaire ville de Szeged Hongrie

ABSTRACT: The role of small-strain parameters of soils in contemporary engineering geology is significant. Empirical correlations for shear-wave velocity (V_s) at Szeged city in the Southern Great Plain region of Hungary were assessed using research measurements of seismic piezocone test (SCPTu) and multichannel analysis of surface waves (MASW) results that were collected. In general, numerous existing cone penetration tests (CPT) -V_s or CPTu-V_s correlations for soils have been examined. Five indices were used in the assessment, including the ratio of the estimated to measured V_s values, the root mean square error (RMSE), the ranking index (RI), the ranking distance (RD), and the Variable Coefficient (CVK). Afterward, new empirical correlations for Szeged were formulated, and their performance was evaluated by comparing the predicted and measured values of V_s. This correlation offers a method to estimate V_s (shear wave velocity) from CPT data tailored to Szeged city's clay-like dilative soils, as per the Robertson 2016 chart. This recommendation constitutes a valuable contribution to the practice of geologists and engineers not only in Szeged city but also in other similar depositional environments in Hungary.

RÉSUMÉ: Les paramètres de faible déformation des sols jouent un rôle crucial en géologie technique contemporaine. À Szeged, dans la région sud de la Grande Plaine de Hongrie, des corrélations empiriques pour la vitesse des ondes de cisaillement (V_s) ont été évaluées à partir de mesures de tests sismiques au piézocône (SCPTu) et d'une analyse multicanal des ondes de surface (MASW). Les nouvelles corrélations formulées pour Szeged offrent une méthode précise pour estimer V_s à partir des données CPT, adaptées aux sols dilatés argileux de la région, en se conformant au graphique Robertson 2016. Cette recommandation est une contribution précieuse pour les géologues et ingénieurs, tant à Szeged que dans d'autres environnements similaires en Hongrie.

Keywords: In situ testing; shear wave velocity; cone penetration test; empirical correlation.

1 INTRODUCTION

V_s is a measure of the speed at which shear waves propagate through a soil medium. It is typically expressed in meters per second (m/s) or kilometers per second (km/s). The shear wave velocity is directly related to the shear modulus (G_{max}) of the soil, which is a measure of its stiffness or resistance to deformation under shear stress (Steve Kramer 1996).

To obtain V_s measurements, both in situ and laboratory tests can be performed. In situ tests involve the use of specialized equipment to generate and measure seismic waves directly in the ground. Common in situ tests for V_s measurement include the seismic cone penetration test (SCPT), seismic refraction, and downhole testing.

This paper seeks to identify the best empirical correlations for estimating shear wave velocity in different soil types in Szeged city Figure 1. using data from the Cone Penetration Test. Reliable data will be collected from reputable ground investigation firms. By applying empirical correlations, shear wave velocity will be calculated, and statistical and graphical analyses will be performed to compare the calculated and measured values.

These analyses will guide us in determining the most accurate correlations for each soil type. The study outcomes will yield valuable insights for estimating shear wave velocity in different Hungarian soils in Szeged city.

A comprehensive understanding of the soil behavior and its variability with depth is crucial for

reliable- seismic hazard assessment and design of resilient structures.

Figure 1. Map of Szeged city Hungary.

2 SITE DESCRIPTION AND DATA SOURCES

Situated in the Pannonian Basin above the Algyő High, the city of Szeged showcases sedimentary formations from the Neogene and Quaternary periods. The Neogene period (gyalog L. 2016) left behind marine sediments, while the Quaternary period witnessed the influence of glacial and alluvial deposits that have shaped the landscape.

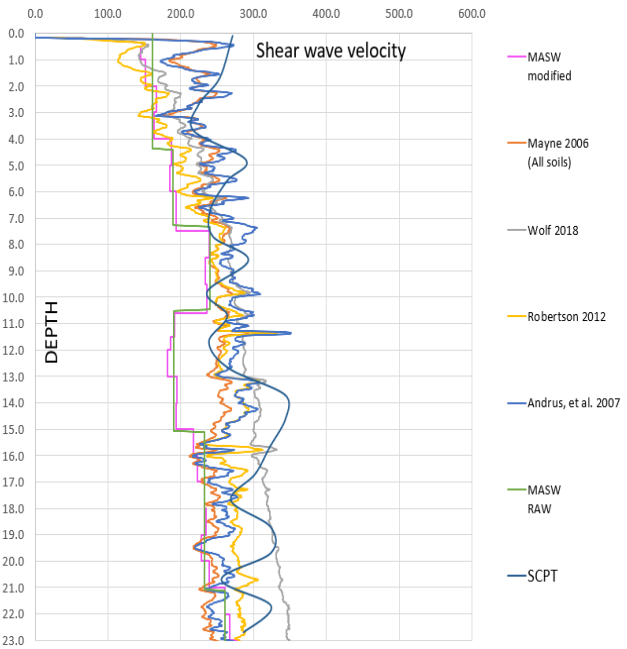

Figure 2. Seismic data (MASW&SCPT) measured in Szeged city.

The first step involves collecting site data including cone penetration tests (CPTs), seismic measurements (MASW or SCPT), and boreholes. Mapping helps identify relevant CPTs for assessment. Two MASW and one SCPT measurements, along with eleven CPTu measurements, were chosen for the study.

Considering that MASW data typically provides average shear wave velocities for a zone spanning several meters, whereas CPTu soundings offer data points at much finer intervals (typically every 1-2 cm), methods for alignment and averaging are employed. This may involve averaging CPTu data points across the depth intervals covered by MASW measurements or averaging MASW readings themselves Figure 2. Furthermore, integrating MASW and CPTu data is pursued to obtain a comprehensive understanding of subsurface conditions. MASW data offers insights into the overall shear wave velocity profile, while CPTu data provides detailed information on soil properties and stratigraphy at specific depths.

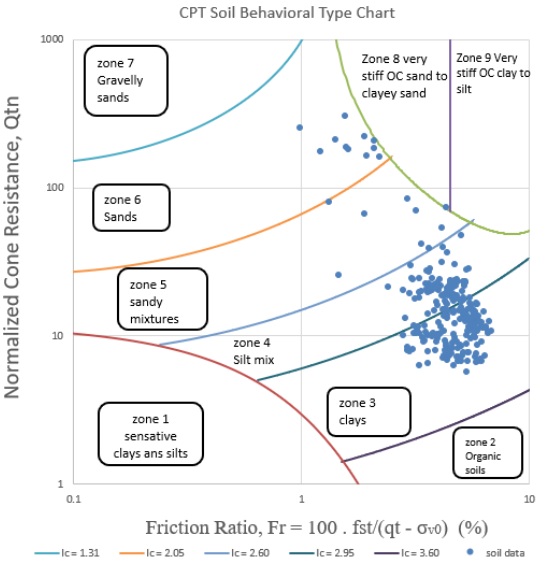

Figure 3. Soil Behavioural Type (SBT_n) Chart (Robertson 2009) for normalized Cone Penetration Test (CPT) results.

The soils collected in this study primarily demonstrate clay-like behavior meaning They possess high plasticity, low permeability, and are prone to volume changes known as shrinkage and swelling in response to moisture fluctuations. they exhibit high cohesion and low shear strength, rendering them susceptible to deformations and stability concerns, and as depicted in Robertson's (2009) soil behavioral type (SBT) chart Figure 3.

Over 40 V_s-CPT correlations were assessed for this study Table 1 Figure 2 displays the primary correlations that were evaluated.

Table 1. Previously suggested correlations between Vs and CPT or CPTU data for various soil classifications.

Correlations		Soil	Notes
(Mayne 2006)	$V_S = 118.8\ log\ f_s + 18.5$	Sands, clays, and organic plastic clays	fs is the sleeve friction in kPa
(Andrus, et al. 2007)	$V_S = 2.62 \cdot {q_t}^{0.395} \cdot {I_c}^{0.912} \cdot z^{0.124} \cdot SF^a$	Combined Holocene–Pleistocene soils	SF is a scaling factor that depends on soil deposit age, a = 0.88–0.92 for Holocene-age sites, z is depth in m a = 1.11–1.12 for Pleistocene sites
(Wolf 2018)	$V_S = 11.97 \cdot {q_t}^{0.262} \cdot {I_c}^{0.709} \cdot z^{0.107}$	All soils	q_t is the total cone tip resistance, I_c is the soil behavior type categorization index
(Cai, Puppala and Liu 2014)	$V_S = 7.954 \cdot {q_t}^{0.403}$	Soft clays	R^2 value of 0.631.
(Robertson and Cabal 2012)	$V_{S1} = (10^{0.55Ic+1.68} \cdot q_{c1N})^{0.5}$	All soils	q_{c1N} Truly normalized (i.e. dimensionless) cone penetration resistance corrected for overburden stress.

3 METHODOLOGY

In the assessment of correlations, the Root Mean Square Error (RMSE) Eq.1 is commonly used to measure the accuracy by comparing predicted values from the correlation with the actual measured values. The correlation with the lowest RMSE value is considered the most effective in providing accurate predictions. Consequently, RMSE serves as a valuable tool in identifying correlations that offer precise estimations for the studied outcome variable (Ziegler 2016) (Kuhn and Johnson 2013):

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^{N} (V_{s,measured} - V_{s,calculated})^2} \quad (1)$$

To achieve this optimization, the RMSE was minimized by adjusting the multipliers (factors) of the input parameters for each correlation tested. Robertson 2012& Wolf 2018 (All soils) correlation were selected as the model equation to generate the proposed correlations:

$$V_S = (\sigma v`/P_a)^{0.25} \cdot (10^{a\,Ic+b} \cdot q_{c1N})^c \quad (2)$$

$$V_S = a \cdot {q_t}^b \cdot {I_c}^c \cdot z^d \quad (3)$$

Where P_a is the atmospheric pressure, and q_{c1N} the Truly normalized cone tip resistance, truly normalized (i.e., dimensionless) cone penetration resistance corrected for overburden stress (qc1N) and I_c (soil behavior type index) parameters in these correlations contributes to a better prediction of vs and help reflects the geological site characteristics in reality.

4 RESULTS

Through the optimization process, notable improvements were obtained in the model equation for the studied categories.

All soils: based on the (253) data pairs the recommended best-fit equation for predicting vs in m/s is:

$$V_S = (\sigma v`/P_a)^{0.25} \cdot (10^{0.398Ic+3.65} \cdot q_{c1N})^{0.387} \quad (4)$$

$$V_S = 3.94 \cdot {q_t}^{0.397} \cdot {I_c}^{0.827} \cdot z^{0.066} \quad (5)$$

Where σv` is the effective overburden stress, Figure 4 shows the proposed correlation (eq.4) for all soils compared to the original one, most of the predicted values of V_s are within 20% of the measured V_s, and noticeable improvement in RMSE.

Quaternary -Age Soils: Based on the quaternary data pairs, the recommended best-fit equation for predicting V_s in m/s is:

$$V_S = (\sigma v`/P_a)^{0.25} \cdot (10^{0.372Ic+4.08} \cdot q_{c1N})^{0.368} \quad (6)$$

Tertiary-Age soils: For predicting V_s in m/s, the recommended equation in case any tertiary soils found in higher depths is:

$$V_S = (\sigma v`/P_a)^{0.25} \cdot (10^{0.545Ic+2.1} \cdot q_{c1N})^{0.47} \quad (7)$$

In the scatter plots, Figure 5 illustrate the performance of the proposed Equation 4. The arrangement of these data points reflects the level of agreement or correlation between the estimated and

measured values. The data points tend to cluster closely around a straight line, suggesting a more accurate estimation of Vs. However, it is expected to observe some scattering due to measurement errors and inherent variability in soil properties.

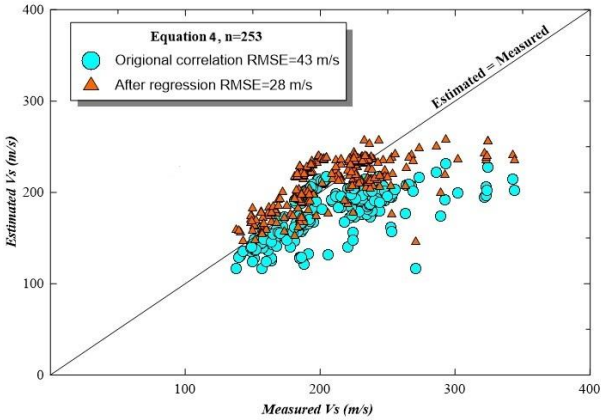

Figure 4 The proposed correlation (eq.4) for all soils compared to the original one.

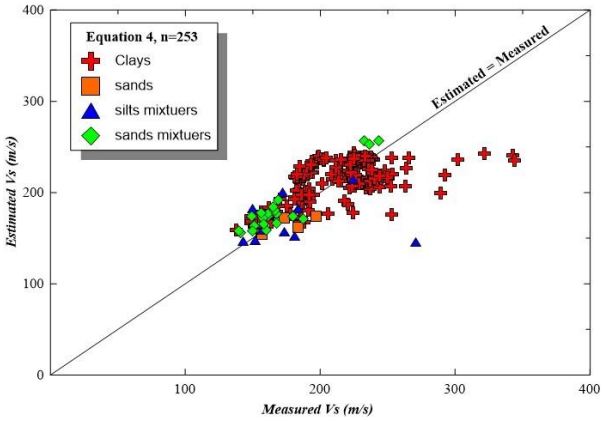

Figure 5. The proposed correlation (eq.4) for all data points showing all 4 soil types.

5 CONCLUSION AND RECOMMENDATION

In a comprehensive study conducted in Szeged city, correlations between shear wave velocity (V_s) and cone penetration test (CPT) results were investigated. Reliable Data were collected, resulting in 253 data pairs. Statistical analysis was performed using key parameters (K and RMSE) to identify suitable correlations for Szeged city soil types.

The study found that correlations proposed by (Robertson and Cabal 2012) and (Wolf 2018) provided accurate predictions for shear wave velocity across different soil categories. The derived equation also performed well. For Quaternary and tertiary age soils, Robertson (2012) and Wolf Akos (2018) correlations were recommended.

The findings emphasize the need for region-specific correlations due to the influence of soil formation and geological settings. It is crucial to involve expert engineers and conduct site-specific testing, as there is no direct relationship between CPT and Vs. Caution should be exercised when using empirical correlations, considering available data, uncertainties, and applying them within calibrated conditions.

ABSTRACT: The physical nonlinearity of soil deformation distinguishes it from the deformation of structural materials, as the stiffness characteristics of soil depend on the stress-strain state. Therefore, determining the mechanical parameters of soils requires considering the in-situ stress conditions. This article presents an in-situ method for determining these parameters for a phenomenological physically nonlinear soil model. The method also allows for determining the characteristics of an elastic-plastic model with the Coulomb flow condition. The use of this method for designing foundations on non-rocky soils (sand, clay) can significantly reduce costs while ensuring reliability. The method is based on special procedures for solving inverse nonlinear problems through numerical simulation of soil deformation under static loading. It also takes into account the geometric nonlinear factor of comparability of one-dimensional and angular deformations in non-rocky soils. The core idea of the method is to minimize the deviations between actual soil deformations from in-situ tests and numerically simulated deformations using a verified physically nonlinear soil model. The application of this method in the design of a spread-slab foundation for a high-rise residential building in Ekaterinburg (Russia) resulted in a one million USA dollars cost reduction while maintaining the necessary foundation reliability. This was achieved by using a physical and mathematical soil model that accurately represents the nonlinear deformation behavior of the soil and incorporates the actual values of soil mechanical parameters. The article includes the algorithm of the method and provides examples of its practical application in the design of real projects.

RÉSUMÉ: La non-linéarité physique de la déformation du sol la distingue de la déformation des matériaux structurels, car les caractéristiques de rigidité du sol dépendent de l'état de contrainte et de déformation. Par conséquent, la détermination des paramètres mécaniques des sols nécessite la prise en compte des conditions de contrainte in situ. Cet article présente une méthode in situ pour déterminer ces paramètres pour un modèle phénoménologique de sol physiquement non linéaire. La méthode permet également de déterminer les caractéristiques d'un modèle élastique-plastique avec la condition d'écoulement de Coulomb. L'utilisation de cette méthode pour la conception de fondations sur des sols non rocheux (sable, argile) peut réduire considérablement les coûts tout en garantissant la fiabilité. La méthode est basée sur des procédures spéciales de résolution de problèmes non linéaires inverses par simulation numérique de la déformation du sol sous charge statique. Elle prend également en compte le facteur géométrique non linéaire de comparabilité des déformations unidimensionnelles et angulaires dans les sols non rocheux. L'idée centrale de la méthode est de minimiser les écarts entre les déformations réelles du sol provenant d'essais in situ et les déformations simulées numériquement à l'aide d'un modèle de sol physiquement non linéaire vérifié. L'application de cette méthode à la conception d'une fondation à dalle étalée pour un immeuble résidentiel de grande hauteur à Ekaterinbourg (Russie) a permis de réduire les coûts d'un million de dollars américains tout en maintenant la fiabilité nécessaire de la fondation. Ce résultat a été obtenu grâce à l'utilisation d'un modèle physique et mathématique du sol qui a permis d'obtenir des résultats précis.

Keywords: Soil; non-linearity; characteristics; method; practical use.

1 INTRODUCTION

Soil base is a basic, often the most pliable, load-bearing element of the building. Not being, as a rule, constructive element of the building (except maybe artificially created reinforced soil massifs (geomassifs) soil base takes on entire load from building, affecting operational and strength parameters of the building. This situation certainly determining the mechanical parameters of a physically nonlinear soil from in-situ tests because laboratory tests for these purposes are complex and on various reasons their results are unreliable. In the 1940s Russian scientist Botkin experimentally determinated and investigated physically nonlinear type of deformation of non-rocky soils (clays and sands) (Botkin, 1940); later this feature of nonrocky soils was confirmed by other geotechnicians (Alekhin, 2015, 2022), (Malyshev, 1994). (Mirsayapov, 2011), (Lushnikov, 2019), (Zhussupbekov, 2023). Currently researches on various aspects of this fundamental reality are being actively and successfully developed. One of the most important aspect is development of the methods for determining design parameters of nonlinear soil models from in-situ test data including geometric nonlinearity as well as soil rheological properties. If the question of geometric nonlinearity, which importance for soil deformation has not yet been fully elucidated, is solved rather simply, mainly by a small adjustment of formulas for relative strains, while very complex but important investigations of rheological properties simultaneously with physical nonlinearity are now carried out at number of laboratories: perhaps an effective in-situ method will allow for rheological theory to be corrected taking into account initial stress state in soils; perhaps an application of this method will also may help to assess more accurately geometric nonlinearity influence, for example, at designing neighbouring buildings. Thus, the validity to solve problem of using in-situ test data was predetermined both by unique physical properties of non-rocky soil itself as specific kind of solid medium with specific internal bonds and by the presence of the initial stress state of the soil (both of them are inevitably destroyed when taking soil samples). To solve this problem reliable authentic for soil deformation the soil physical-mathematical model with complex nonlinear dependencies is needed. At present Botkin's model is the only systematically and consistently verified model, including its practical application. Moreover, for nowadays this is the only soil model with complex nonlinear dependencies for which it was possible to develop a convenient method for determining true values of design mechanical parameters from in-situ test data that much increase reliability and accuracy of geotechnical design (Bodkin, 1940). General principles of the proposed method, particular in solving the revers unstable problems can be applied for determining mechanical parameters of other types of physically nonlinear models. Below algorithm for the determination of mechanical parameters of physically nonlinear soil model in relation to the Botkin's model is presented. As for the way of derivation of constitutive relations for the Botkin's model as well as the formula of less general physically linear Young-Hook's model, they are referred to the, so called, phenomenological form obtained as a result of approximation of data of actual and presentable in general parameters of the stress-strain state (SSS) of mechanical tests on deformation. Phenomenological difference between physically linear and physically nonlinear (Botkin, 1994) deformation types of a solid medium is shown at Figure 1: this figure graphically and with the help of formulas explains the fundamental difference between the deformation of artificial (essentially manmade) materials with dense and strong, and therefore most often elastic bonds between particles (structural materials) and the deformation of naturally formed solid medium with movable in that or in some other degree connections between their particles (non-rocky soils). Naturally such a great fundamental difference in the deformation of two types of solid substance could be ignored by scientists.

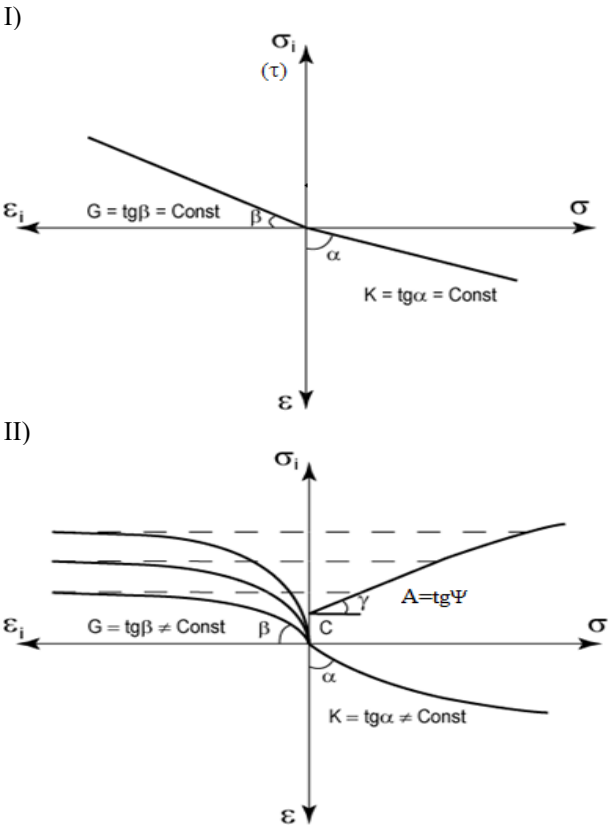

Figure 1. Types of deformation.

I) physically linear type of deformation (solid materials and rocks) II): physically nonlinear type of deformation (non-rocky soils: sands and clays); K and G – bulk modulus and shear modulus respectively; σ and ε – first invariants of the stress and strain tensors (bulk deformation); σ_i and ε_i – second invariants of the stress and strain deviators shape deformation).

Type I Inauthentic for the soil (phisically linear) [First investigator R. Hooke, 17-th century]

Type II Authentic for the soil (phisically nonlinear) [First investigator – A. Botkin, 20-th century]

I) Characteristics of Rigidity: E = const; ν = const → K = E/(1-2ν) = const; G = 0.5E/(1+ν) = const

II) Characteristics of Rigidity: $K = \sigma^{1-\alpha}/A_0 \neq$ const; $G = (\sigma_u - \sigma_i)/B = (A\sigma + C)/(B + \varepsilon_i) \neq$const ($\sigma_u = A\sigma+C$ – Soil strength condition according Mises and Botkin) → $E3KG/(K+ G) \neq$ const; $\nu= 0.5(K-2G)/(K+G) \neq$ const

2 METHODOLOGY

From the formulas shown in the Figure1 it follows that in contrast to the invariance of Young's modulus E with respect to the stress-strain state (SSS) for structural materials and rocks (I type of deformation) for non-rocky soils (II type of deformation) this value under called "modulus of deformation" is different at different points of soil base since form and magnitude of the reactive forces produced in the soil mass by external load are complex (see, for example, Figure 2).

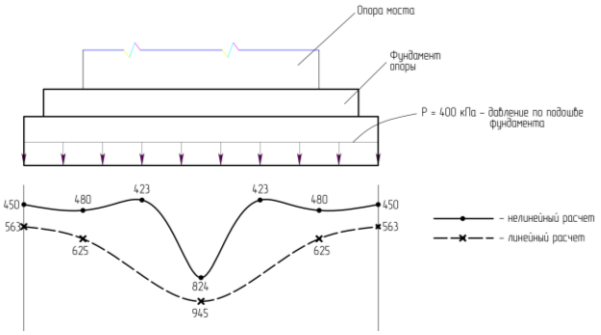

Figure 2. Distribution of reactive forces under foundation.

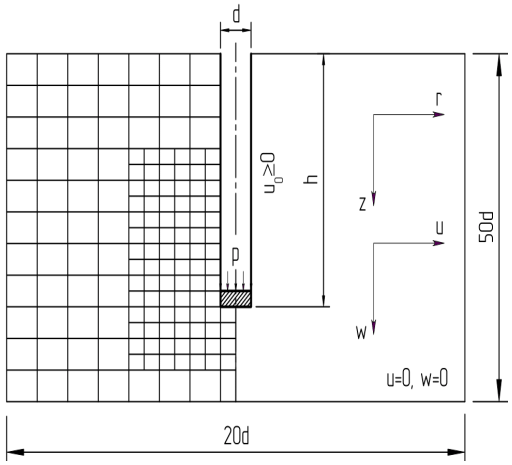
Thus, the value E (modulus of deformation) is physical and mathematical analogue of the Young's modulus from phenomenological Hooke's theory-model), and cannot be technologically acceptable stiffness characteristic (or parameter) for non-rocky soils because it cannot be determined at each point of soil base for a spatial assessment of its stiffness. However, when using the nonlinear phenomenological Botkin's theory-model in design the problem of determining real stiffness of soil base at each point is easily solved. To do this it is necessary to obtain from in-situ tests data meanings of mechanical parameters of Botkin's soil model (A, B, C, A_0, α), which along with meanings of stress-strain parameters (σ and ε_i) determine values of non-rocky soil stiffness characteristics (K and G) that should be used in design. The algorithm for determining actual (with index «f» of parameters A_f, B_f, C_f, $A_{f\,0}$, α_f) is given below: index «m» denotes numerically simulated values, for example, settlements at i-th load stage S_{mi}, while stage S_{fi} are corresponding values from in-situ test data.

Set of required parameters: $z_k = \{A_f, B_f, C_f, A_{0f}\, \alpha_f\}$.

a)



b)

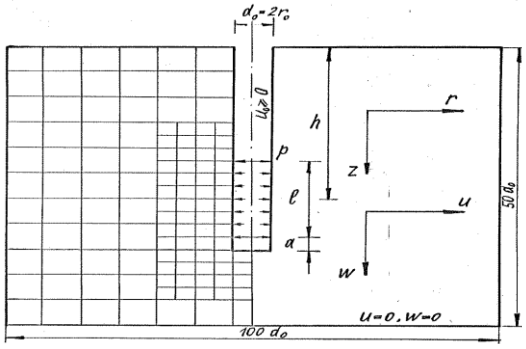


Figure 3. Test type, a) Rigid circle plate; b) Radial pressuremeter.

Algorithm for determining actual values of soil mechanical parameters:

1. Determination of the parameter

$$B_f = \frac{B_m \sum S_{fi}}{S_m} \qquad (1)$$

(formula is obtained from linear dependence of soil settlement on parameter B (Alekhin, 2015, 2022), with use of Least squares method for statistical processing of relationships between experimental results and corresponding results of numerical modeling):

$$S = \sqrt{3}B/2 \int_0^1 y_z d_z \qquad (2)$$

2. Determination of the parameter A_f by search method through frictional angle parameter φ with its technically sensitive step 1^0 using formula of (Malyshev,1994):

$$A = \frac{\sqrt{2(3+\mu^2)\sin\varphi}}{3+\mu\sin\varphi} \quad (3)$$

3. Determination of the parameter C_f by Tikhonov's procedure (Malyshev,1994) (Zhusupbekov, 2023) for solving unstable inverse problems, the essence of which consists in minimizing the deviation between actual physical measurements of any parameter (for example, soil settlements S_{fi}) and their numerically simulated values S_{mi} with using stable direct solution and verified physical and mathematical soil model:

$$min\sum\left(S_{fi} - S_{mi}\right)^2 \quad (4)$$

Also were used program ALEXANDER (Alekhin, 2015) to solve the direct boundary value stable problems and program FLEXIPLEX (Alekhin A. 2022) to search the global minimum of function (4);

4. Determination of the parameter α_f by Tikhonov's procedure with programs ALEXANDER and FLEXIPLEX;

5. Determination of the parameter A_{0f} by Tikhonov's procedure with programs ALEXANDER (Alekhin, 2015), (Zhussupbekov, Sarsembayeva and Alibekova, 2023) and FLEXIPLEX

For determining parameters A_{0f} and α_f can be used programm FLEXIPLEX for search global minimum on two parameters.

In the case of using an elastic-plastic soil model, for example with a limiting surface determined by the soil strength criterion according to Coulomb-Mohr version, the actual values of limiting surface parameters can be obtained from Malyshev relations (Malyshev,1994): (Formula 3,5)

$$C = \frac{\sqrt{2(3+\mu^2)\cos\varphi}}{3+\mu\sin\varphi}\, c \quad (5)$$

Where φ and c are soil strength parameters on Coulomb's version of soil strength, μ – Lode parameter. These formulas made it possible to use the simplest minimization procedure with single result being obtained by looking over different values of angle φ.

3 CONCLUSION

Using physically nonlinear Botkin's model several geotechnical objects were designed and built in Ekaterinburg, namely: strip foundations of 6-storey neighboring buildings instead of pile foundations, retaining wall close to 9-storey building and spread-slab foundation of 35-storey high-rise building (see Figure 4a and Figure 4b). In all these cases Botkin's soil model with design parameters values from in-situ test data were used for design of foundations. At all cases the cost of geotechnical constrictions was about $1 million less than the cost in original project on the base of Hooke's linear theory and with significant increase in reliability of the design solution on the base of true soil model: for example, in the case of 35-storey high-rise building, on eluvial hard silty-argillaceous loam and sandy loam, actual settlements differ from design one for about 25%, that is, discrepancy coincides with discrepancy due to replacing in design real soil by ideal continuous medium.

ABSTRACT: The study of the bearing capacity of shallow foundation on rock mass is a topic that still have many parts to be studied, due to the particularities of each rock mass (discontinuities, anisotropy...). The present paper presents how the discontinuities, even being distanced from the foundation, affect the ultimate load and the failure mode. It is highlight that the definition the failure type is very important to limit the area of influence of each foundation, checking that it does not destabilize other nearby structures. According to the numerical calculations, it is estimated that in cases of circular footings the size of the breaking wedge is much smaller, than in the cases of strip foundation. In the laboratory, initially several tests are carried out to characterize the material; subsequently, three tests are performed that simulate superficial footings on rock mass with a horizontal discontinuity (at the block bottom). Different geometric configurations (block size and footing width) and boundary condition (in one case the bottom of the block is free to move and in the others are fixed) are adopted in order to see how the ultimate load and the form of failure change. It is observed that the ultimate load is highly influenced by the presence and the resistance of discontinuities, also that the failure mode changes in function of the boundary conditions. The results obtained in laboratory tests are also compared with the analytical solution for shallow foundation on anisotropic discontinuous rock mass. The laboratory tests were performed in sandstone, from Burgos, Spain.

RÉSUMÉ: La capacité portante des fondations superficielles sur massif rocheux est un sujet qui comporte encore de nombreuses parties à étudier, en raison des particularités de chaque massif rocheux (discontinuités, anisotropie...). Le présent article analyse comment la présence de discontinuités, même si elles sont éloignées de la fondation, modifie la charge ultime et le mode de rupture. Il est important de souligner que définir le type de rupture est très important pour limiter la zone d'influence de chaque fondation, en vérifiant qu'elle ne déstabilise pas les autres structures. Selon les calculs numériques, on estime que dans le cas de fondations circulaires, la taille du coin de rupture est beaucoup plus petite que dans le cas de fondations filantes. En laboratoire, plusieurs tests sont réalisés dans un premier temps pour caractériser le matériau; ensuite, trois essais sont réalisés qui simulent des semelles superficielles sur un massif rocheux présentant une discontinuité horizontale (le fond du bloc). Différentes configurations géométriques (taille des blocs et largeur des fondations superficielles) et conditions limites (dans un cas le bas du bloc est libre de mouvement et dans les autres il est fixe) sont adoptées afin de voir comment la charge ultime et la forme de rupture changent. On observe que la charge ultime est très influencée par la présence et la résistance des discontinuités, et que le mode de rupture change en fonction des conditions limites. Les résultats obtenus lors des tests en laboratoire sont également comparés à la solution analytique pour fondation superficielle sur massif rocheux discontinu anisotrope. Les tests en laboratoire ont été réalisés dans du grès provenant de Burgos, en Espagne.

Keywords: Circular footing; laboratory model test; rock mass; failure mechanism; splitting.

1 INTRODUCTION

The analytical solution for a shallow foundation on rock mass (Serrano et al., 2000), just as the classic failure wedges (Terzaghi, 1943, Prandtl, 1920) are developed considering strip footing. More recently, some numerical studies analyzed the bearing capacity and the failure wedge of circular footing.

Clausen (2013) proposed a series of charts with a coefficient, that multiplied by the uniaxial compressive strength for intact rock mass (UCS), allows an estimation of the bearing capacity of a circular footing.

Melentijevic et al. (2019) compared the wedge obtained with plane-strain and axisymmetric conditions, simulating a strip and a circular footing. According to the results, the area affected by the failure wedge in the case of circular footing is much less than in the case of strip foundation.

Alencar et al. (2019) developed a shape coefficient that allows conversion of the bearing capacity obtained by the analytical solution (Serrano et al., 2000) strip foundation in the value of the bearing capacity for a circular footing. This coefficient also can be used with the analytical solution proposed by Serrano et al. (2016) for shallow foundation on anisotropic discontinuous rock mass.

In the present paper, an experimental study is carried out, trying to simulate a shallow foundation on rock mass. The failure load and mechanism obtained are analyzed. With rock mass, no similar study was found. However, with soils some experiments have been performed like Chi and Lin (2020) who studied the bearing capacity of footing on one or two-layered soil; Hassani et al. (2023) analyzed the behavior of strip foundations with inclined loading on a soil-reinforced with geogrid.

2 CHARACTERIZATION AND METHODOLOGY

The studied rock was a Lower Cretaceous (Weald facies) medium grain quartzarenite from Burgos, Spain. This rock shows beige tone with veining in form of pinkish and orange stains. Table 1 presents a summary of the parameters obtained in the laboratory test carried out.

The sandstone used in the laboratory test shows a transversely isotropic foliation, so as that the anisotropy does not interfere with the results all samples were taken perpendicular to the Z direction.

Table 1. Sandstone properties obtained in laboratory tests.

Sandstone properties		Number of test	Values	
			Avg	SD**
Density (kg/m^3)		10	2133	30
Direct tensile strength (MPa)*		11	0.57	0.17
Uniaxial compression strength (MPa)*		7	22.1	1.0
Young's modulus (GPa)*		7	1.8	0.2
Poisson's Ratio		7	0.21	0.06
P-wave velocity (m/s)	X (β = 90º)	10	1563	187
	Y (β = 90º)	10	1672	213
	Z (β = 0º)	10	1362	202

** Perpendicular to Z direction.*
*** Standard deviation*

The blocks are from outcrops in the surface and show a GSI that can be considered equal to 100. The typical value of the parameter m_i for sandstone is 19 (Hoek et al., 1998).

In order to simulate different foundation configurations 3 blocks were tested varying the boundary conditions (Table 2 and Figure 1). In all cases the foundation is located in the center of the block; laterals boundaries are free, none lateral confinement was applied; to simulated an infinite block the base of block 2 was glued on fine steel plate, and the base of block 3 was glued on perfect rigid steel plate. The blocks were attached in the plates using the same glue applied in the direct tensile test (epoxy adhesive EA 9483).

Table 2. Blocks geometry.

Block	Dimension (cm)	Foundation diameter (*B*) (cm)	Base condition
1	15x15x15	3.8	Free
2	20x20x20	3.8	Fix*
3	20x20x20	2.0	Fix

** The block broke when it was detached from the support.*

3 RESULTS AND COMMENTS

In the case of block 1, all boundaries were free to move, and the failure load was 84.1 MPa. Before the failure in the lateral surface vertical cracks appeared. The block is broken into three parts, more the splitting wedge (Figure 2).

Block 2 was glued in a thin plate, being the ultimate load 100.6 MPa. The failure occurred in a fragile way; one-half of the block detached from the plate - breaking the block into two parts and the splitting wedge (Figure 3).

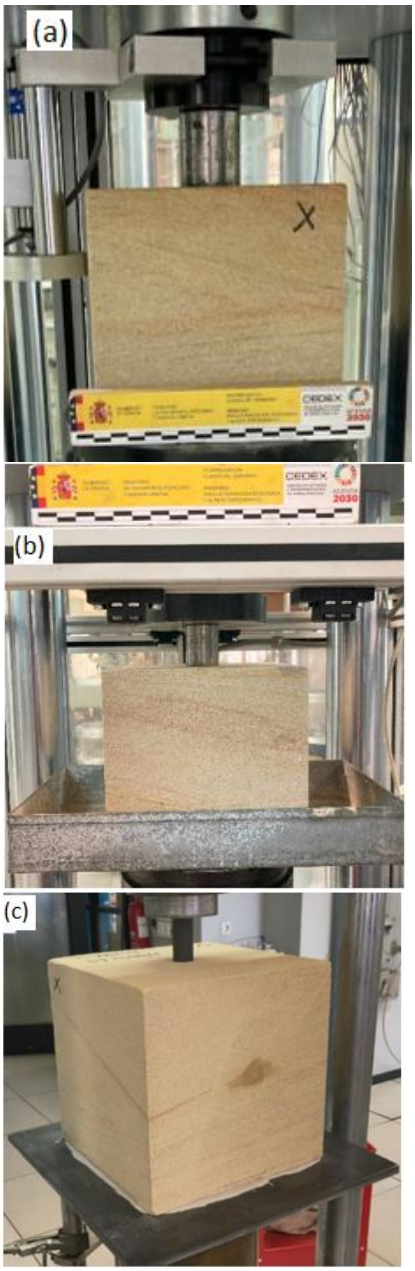

Figure 1. Blocks: (a) 1; (b) 2; (c) 3.

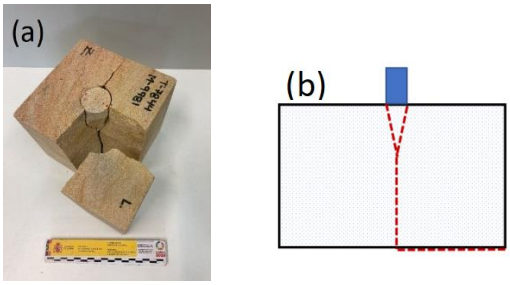

Figure 2. Block 1. (a) After failure. (b) Failure scheme.

The block 3 was attached in a perfect rigid steel plate (1 cm of thickness), the failure load was 185.0 MPa. In that case, as the block could not be detached from the plate, a horizontal and a vertical crack was formed, breaking the block into two parts; in a certain way detaching it from the plate (Figure 4).

Figure 3. Block 2 after failure.

Figure 4. Block 3 after failure.

According to the method proposed by Clausen (2013) - for circular footing, without influence of the boundary conditions and assuming that the rock mass is homogeneous and isotropic - the bearing capacity of the rock in this study is about 475 MPa, once the GSI is 100, $m_i = 19$ and UCS = 22.1 MPa.

Using the analytical solution for anisotropic discontinuous rock mass (Serrano et al., 2016) jointly with the shape coefficient proposed by Alencar et al. (2019), it can be estimated the bearing capacity considering a horizontal discontinuity. The horizontal discontinuity represents the bottom of the blocks in the laboratory test. How can be observed in the results shows in Table 3 the values obtained in laboratory test are of the same order of magnitude as to estimate by the theory that is dependent on the discontinuity strength; remarking the influence of the discontinuities in the failure load.

Table 3. Bearing capacity estimated by Serrano et al. (2016) jointly with the coefficient proposed by Alencar et al. (2019).

Boundary condition		**Bearing Capacity (MPa)**
Internal friction angle of the discontinuity	10º	50
	20º	77
	30º	106
Without discontinuity		402

However, the theoretical solution implies the worse location of the horizontal discontinuity, while in the laboratory test it is between 4 and 10 times the width of the foundation. The great difference with the analytical solution in isotropic rock mass highlights the influence of the discontinuity resistance; while the different location of the lower contour in relation to the dimension of the experimental footing clearly indicates that the position is influential much more than expected, even at 10 the width of the foundation.

4 CONCLUSION

As expected in a case with high GSI, the ultimate bearing load is much higher than the UCS. However, it is important to highlight that although the spacing between the discontinuities (simulated) is much greater than the size of the foundation, still influences the failure load. Being the failure load obtained much less than estimated using the Clausen (2013) method or Serrano et al. (2000) that do not consider the presence of a discontinuity.

However, the results obtained in the experimental test are coherent to estimate using the method proposed by Serrano et al. (2016) for anisotropic discontinuous rock mass, jointly with the coefficient proposed by Alencar et al. (2019).

It was observed, that without lateral confinement, it is very difficult to achieve the formation of the theoretical failure wedges, occurring in the three cases the splitting.

As future work, this study can be extended by performing more tests with different geometric configurations - with the aim of knowing how the presence of a discontinuity, even distanced from the foundation, changes the ultimate bearing capacity and the manner of the failure.

ACKNOWLEDGEMENTS

The research described in this paper was financially supported by the European Union-NextGenerationEU - UP2021-035.

It has also been partially funded by the project “Neural networks and optimization techniques for the safe design and maintenance of transportation infrastructures: geotechnics of volcanic rocks and slope stability, IA-PYROSLOPE (PID2022-139202OB-I00)” of the Ministry of Education and Science.

The cooperation between the University of Porto and the Tecnical University of Madrid (UPM) is supported by the mobility program of the Universidad Politécnica de Madrid collaboration with Banco Santander (VMOVILIDAD23RAGA).

ABSTRACT: The behavior and design of piled embankments constructed on soft soils are significantly influenced by soil arching, characterized by the redistribution of stresses between the yielding mass and the surrounding nonyielding soil. On the other hand, lateral spreading action within the embankment acts as an important factor in the load distribution mechanism. Considering the lateral deformations and principal stress directions, this study investigated arching evolution in CPS and GRPS embankments under self-weight using FEM analyses in 2D and 3D. A series of numerical models were employed to examine the impact of geometry parameters such as embankment height and center-to-center pile spacing on arching evolution. The lateral earth pressure coefficients and horizontal deformations inside the fill were observed to understand the arching mechanism and pile efficacy.

RÉSUMÉ: Le comportement et la conception des remblais sur pieux construits sur des sols mous sont significativement influencés par l'effet de voûte du sol, caractérisé par la redistribution des contraintes entre la masse déformable et le sol non déformable environnant. D'autre part, l'action de propagation latérale à l'intérieur du remblai constitue un facteur important dans le mécanisme de distribution des charges. En tenant compte des déformations latérales et des directions des contraintes principales, cette étude a examiné l'évolution de l'effet de voûte dans les remblais en CPS et GRPS sous l'effet de leur propre poids, en utilisant des analyses par la méthode des éléments finis en 2D et 3D. Une série de modèles numériques a été utilisée pour examiner l'impact de paramètres géométriques tels que la hauteur du remblai et l'espacement entre les pieux centre-à-centre sur l'évolution de l'effet de voûte. Les coefficients de pression latérale du sol et les déformations horizontales à l'intérieur du remblai ont été observés afin de comprendre le mécanisme de voûte et l'efficacité des pieux.

Keywords: Soil arching; CPS and GRPS embankments; lateral earth pressure coefficient; principal stress directions; Geogrid.

1 INTRODUCTION

Modern societies depend exceedingly on transportation systems, which cover extensive distances and demand specific considerations in their design. In geotechnical engineering, the interaction between soil and structures is an important aspect when designing transportation infrastructure like embankments, tunnels, and pipelines.

Embankments, frequently constructed in lowland areas with soft and alluvial soils, are particularly prone to significant settlements and deformations. Overcoming these challenges typically involves employing two common approaches. The first approach utilizes controlled stage construction techniques (Indraratna et al., 2005; Oztoprak and Cinicioğlu, 2005; Oser and Cinicioglu, 2017). The second method involves embedding piles into the ground beneath the embankment (Han and Gabr, 2002; Kelesoglu and Cinicioğlu, 2010). The latter approach is known for promoting soil arching, a phenomenon that has received increasing academic attention in recent years.

The economic and optimal use of piles beneath embankments to enhance soil arching has been investigated in numerous studies. However, the stability and durability of the load transfer mechanism resulting from arching are still subjects of ongoing

research, necessitating further investigation (Van Eekelen et al., 2013).

Embankments that are supported by high modulus columns (piles) are commonly known as "conventional pile-supported (CPS) embankments." Compared to the traditional staged construction method, CPS embankments are more efficient by significantly reducing expected settlement and shortening the construction period (Mesri et al., 1994; Fagundes et al., 2017). Moreover, CPS embankments can effectively prevent local failure and deformations (Van Eekelen et al., 2020).

The arching mechanism plays a crucial role in governing the CPS embankments' behavior, controlling the stress distribution between the soil and structural elements with different rigidities. Soil arching occurs due to the relative displacement of piles and soil.

Geosynthetic-reinforced pile-supported (GRPS) embankments were developed as an improvement to the CPS embankments (Van Eekelen and Han, 2020; Van Eekelen et al., 2020). Geosynthetic reinforcements create resistance to the lateral spreading of the fill. Geosynthetic reinforcements are laid in the granular fill as a load transfer platform on top of the piles. Thus, geosynthetic reinforcements support the arching mechanism in the soil by providing more efficient and stable load transfer to the piles. Likewise, when the GRPS embankments are preferred, the need for large pile caps is reduced, and the pile spacing can be increased (Van Eekelen et al., 2013; Van Eekelen et al., 2020).

In the CPS embankments, arching is the only mechanism that reduces the share of the fill load borne by the subsoil between the piles. However, in GRPS embankments, the loads from the fill located under the arched zone are transferred to the piles through geosynthetic reinforcement (Van Eekelen and Han, 2020).

Following the model proposed by Hewlett and Randolph (1988), the lateral earth pressure coefficient (K) in the arched zone between two piles can be classified into three states. These K values represent the active, passive, and at-rest conditions for points on the pile, under the arch crown, and above the arch, respectively. Observing how K values change both horizontally and vertically within the fill could be used as an indication of the arching evolution.

This study analyzes the potential relationships between the pile spacing, presence of geogrid reinforcement, embankment height, lateral fill displacement, piles' deflection, lateral earth pressure coefficient values, and arching evolution through 2D and 3D Finite Element analyses. Eighteen Plaxis 2D and three 3D model tests for various embankment heights and pile spacings were conducted for this purpose, and the results are presented in this paper.

2 MAIN FEATURES OF THE PARAMETRICAL ANALYSES

The conventional pile-supported (CPS) embankments under self-weight in a plane strain 2D and 3D conditions were modeled using the finite element method (FEM) based software Plaxis. The soil profile of Stanstead Abbots (Willow Plantation or Harlow) was selected as a well-documented case history to represent the soft ground over which the embankment will be constructed (Oztoprak and Cinicioglu, 2007; Hird et al., 1995). The soil stratigraphy and geotechnical properties of Stanstead Abbotts are presented in Figure 1 and Table 1, respectively. The groundwater table is located at a depth of 1.5 m beneath the ground surface. To focus on the arching behavior, the embankment's shoulder slopes were defined as 1:3 (V: H) to prevent potential slope instability.

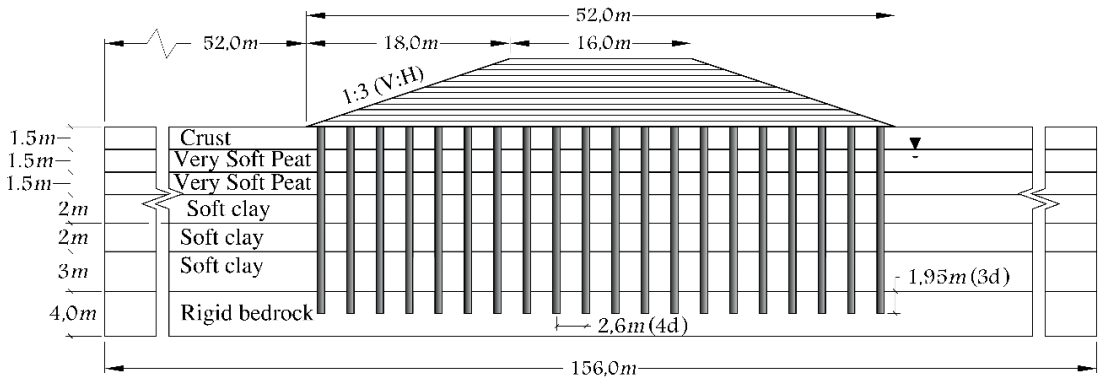

Figure 1. Studied embankment model.

Table 1. Material parameters for the piled embankment.

Material	Soil Model	Unit weight		Poisson's ratio	Permeability	Void ratio	Adopted from Hird et al., 1993

The behavior of the soft ground beneath the embankment was modeled using the soft soil model with undrained loading stages followed by the consolidation stages in between.

Three different heights (6, 8, and 10m) were considered to analyze the behavior of the GRPS and CPS piled embankments resting on the considered soil profile. The staged construction technique was adopted, and layer placement thicknesses were chosen as 0.5m each. After completion of fill construction, excess pore water pressure was allowed to dissipate during the final consolidation phase.

A reduction factor (R_{inter}) of $2/3\phi$ was applied to the shear strength parameter of the soil surrounding the piles. The soil profile ends with a bedrock layer at the bottom. Piles of 13.45 meters were embedded for a depth of 3d into the bedrock. The pile diameters (d) were taken as 0.65m across all models. The center-to-center spacing of the piles varied as 4d, 5d, and 6d. Also, three CPS models with a pile spacing of 5d and the rectangular pile arrangement were analyzed in 3D.

The CPS 2D FEM models were analyzed after being reinforced with two layers of geogrid located at 0.35m and 0.7m over the pile heads. The geogrid layer is defined as an elastic material with isotropic properties and a stiffness (EA) equal to 1500 kN/m.

3 RESULTS

Figure 2 displays the variation in K values against the fill height through a vertical cross-section from the top to the bottom of the fill centerline for GRPS and CPS models. There are two main ranges for the K value along the cross-section: compression ($K_p<K<K_0$) and relaxation ($K_a<K<K_0$) zones.

The compression zone is a key indicator of arching and mobilized shear strength. The thickness of the compression region increases with the increase of pile spacing. However, the strongest part of the formed arches is located where the K value is closest to K_p = 3, indicating the greatest compression of the soil grains.

The lateral spreading of the embankment from the centerline towards the toes leads to the formation of a region with the K value ranging from K_a to K_0 (relaxation zone). Inspecting the thickness of the relaxation zone in the GRPS models with geogrid shows that the thickness is smaller for the geogrid-reinforced models compared to the models with no geogrid. This observation supports the idea that the lateral spreading of the embankment could be the reason for the formation of the relaxation zone. The presence of the geogrid layers limits the horizontal deformation, and as a result, the thickness of the relaxation zone will be reduced, too. It means that the thickness or height of the passive zone would also be greater for the GRPS models.

Previous studies using trapdoor models or specific embankment sections have shown that, due to the rigidity of the side walls or boundaries, the K values through the same vertical cross-section start from K_0 and reach K_p in the arching zone (Meena et al., 2020). This behavior is due to the limited horizontal deformation of soil in models with rigid side boundaries. In contrast, modeling the full-size embankment allows for lateral spreading of the fill from the centerline towards the sides, resulting in the formation of the active zone under the crest.

Figure 3 illustrates the lateral earth pressure values (K) variation along a vertical cross-section (at the centerline) in the 6m high embankment with the pile

spacings of 4d, 5d, and 6d. Also, in the left part of Figure 3, the principal stress direction is shown through the half-body of the fill. The rotation of the principal stresses is an indication of arching.

For the GRPS models, the arch height, which was calculated based on the direction of the principal stresses, is as follows: for all fill heights with the 4d pile spacing, the arch height is 1.9m. In models with the 5d and 6d pile spacing, the arch height range is 2.45m- 2.25m and 3.m-2.65m for the fill heights of 4m, 5m, and 6m, respectively.

In the case of CPS models, for all fill heights with the 4d pile spacing, the arch height is 1.7m. In models with the 5d pile spacing, the arch height range is 2.3m-1.85m and 2.7m-2.4m for the fill heights of 4m, 5m, and 6m, respectively. It is obvious that in both GRPS and CPS models with a pile spacing of 4d, the arch height is not sensitive to changes in fill height.

It should be noted that arch heights are always smaller than the compression zone thickness. The results indicated that, for both CPS and GRPS models, only a K value greater than 0.95 leads to the formation of an arch within the compression zone.

Figure 4 presents the difference between the pile head deflection for the GRPS and CPS embankments with 6, 8, and 10 m heights and different pile spacings of 4d, 5d, and 6d. It could be seen that there is a considerable difference between the maximum pile deflection of GRPS and CPS models. The difference between the deflection of the CPS and GRPS embankment models is more prominent when the center-to-center spacing between the piles increases from 4d (2.6m) to 6d (3.9m).

The horizontal deformation of the 10mH-6d GRPS and CPS embankment models at the bottom of the fill is demonstrated in Figure 5. The maximum horizontal displacement for the CPS model is 15.6cm at 18 m from the centerline, and the value decreases to 11.67cm at 21m for the GRPS model.

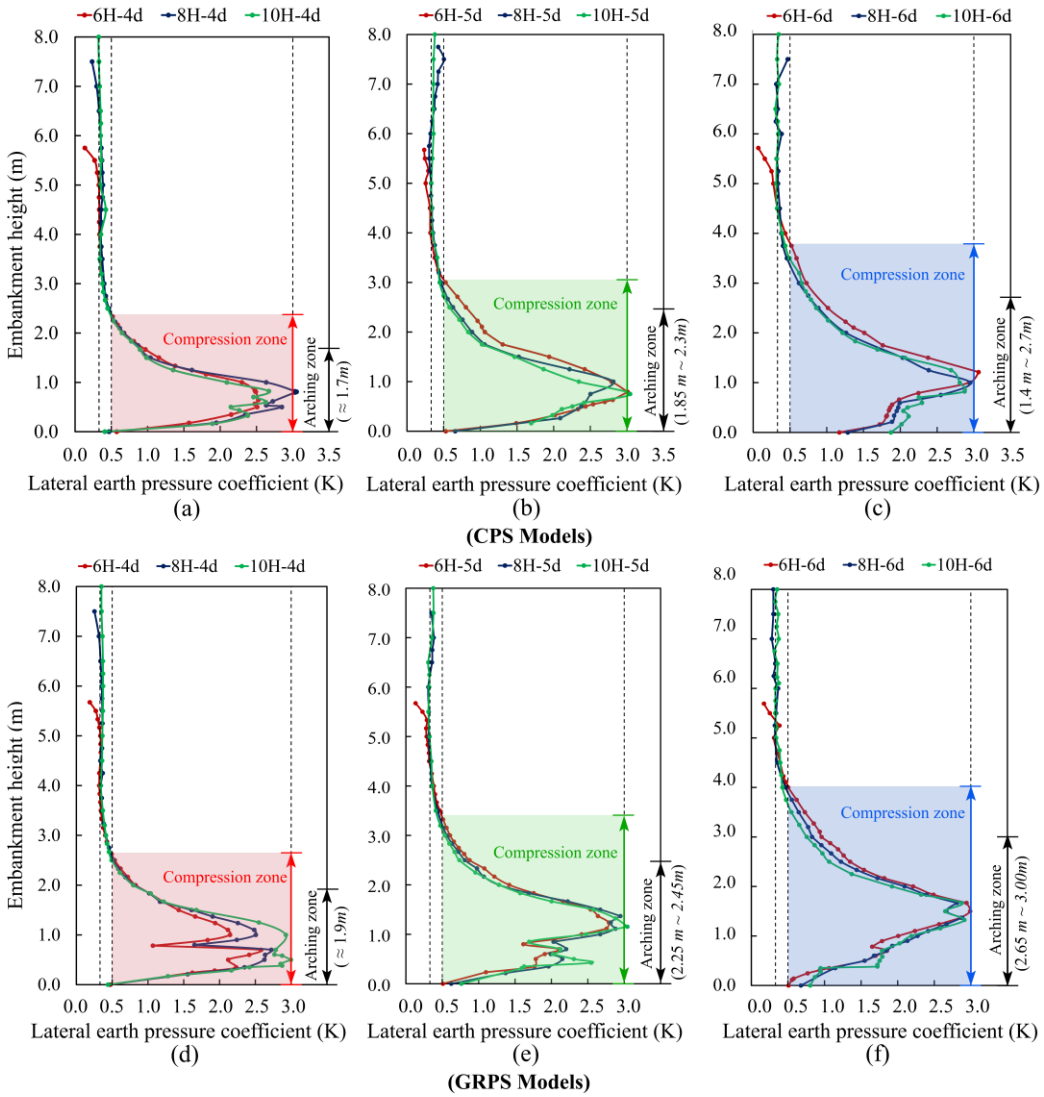

Figure 2. Lateral earth pressure at the vertical centerline of CPS and GRPS embankments.

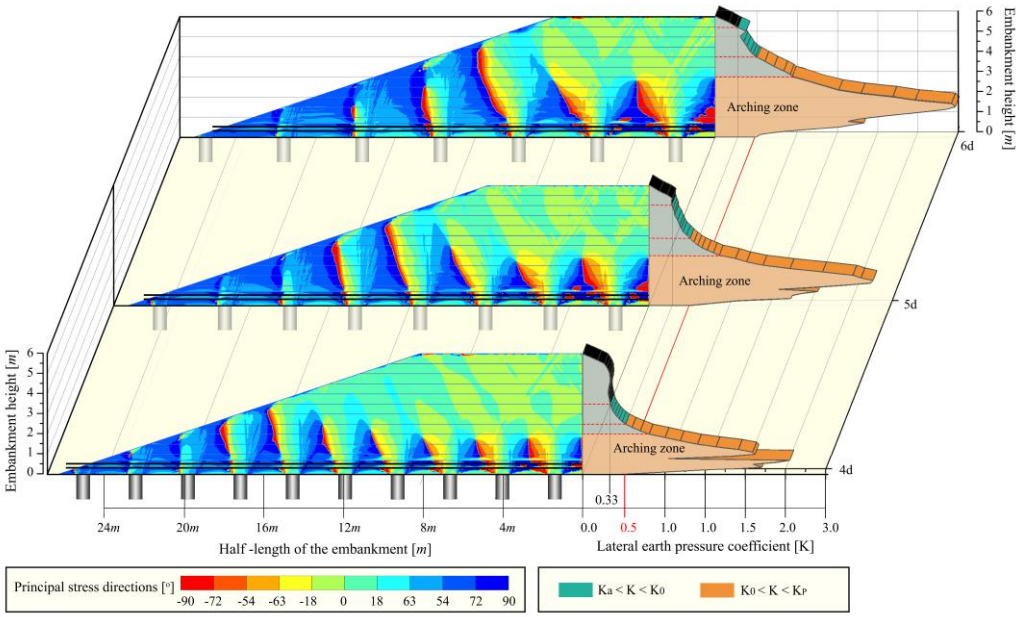

Figure 3. Relationship between principal stress directions and K values for 6m high embankment.

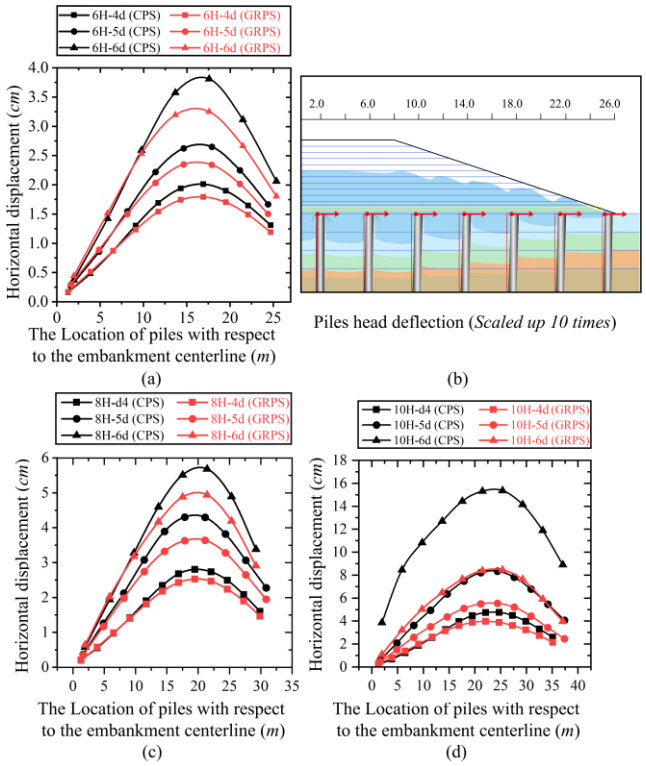

Figure 4. Piles' head deflection for CPS and GRPS models.

Figure 6 shows the pile efficacy (E) for all CPS and GRPS models versus the height of the embankment (H) and center-to-center pile spacing (s). Pile efficacy can be defined as the ratio of the loads carried by the piles to the total load of the embankment calculated as $E = P/s\gamma H$ (P is the total load carried by the pile). It is obvious that the pile efficacy for the geogrid-reinforced models improves in comparison with the models with no geogrid. For example, for the 4d pile spacing in all heights, there is an almost 10% improvement in the pile efficacy values. Moreover, the efficacy of 3D models with 5d pile spacing is greater than that of GRPS and CPS 2D models' efficacy. In the case of 3D models, the efficacy is raised by increasing the fill height. The results for GRPS models showed that the efficacy increases with a decrease in pile spacing.

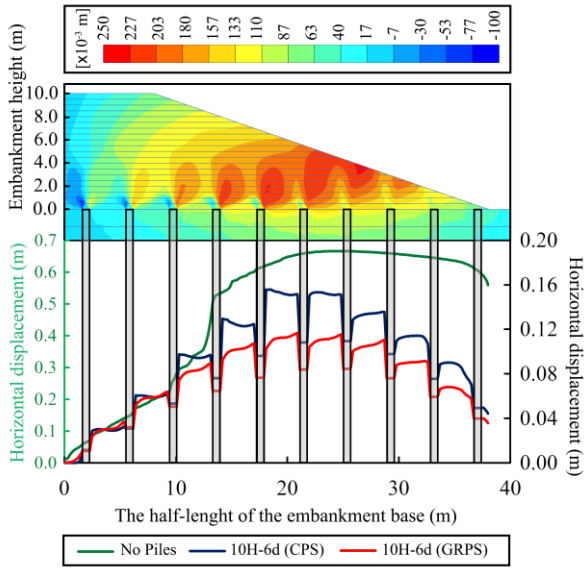

Figure 5. Horizontal displacement of GRPS and CPS embankments' base for 10mH-6d model versus non-piled embankment.

4 CONCLUSIONS

The effects of varying parameters, such as pile spacing and embankment height, on the arching evolution were studied through numerical analysis of CPS and GRPS

embankment models. The study yields the following conclusions:

The use of geogrid reinforcement decreased the piles' deflection and the horizontal displacement of the embankment.

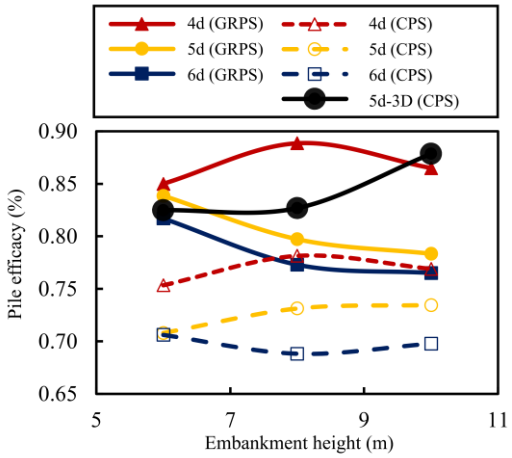

Figure 6. Pile efficacy of GRPS and CPS models.

Geogrid reinforcement increased the thickness of the compression zone and improved the load transfer mechanism to piles. For both CPS and GRPS models, only a K value greater than 0.95 leads to the formation of an arch within the compression zone.

The efficacy of CPS and GRPS increases with a decrease in pile spacing.

ABSTRACT: The expansion of construction projects in seismic regions with poor soil conditions and the vast legal and financial implications of faulty geotechnical information have led stakeholders to call for faster, cheaper and more reliable characterization of geomaterials under dynamic conditions. A popular approach to dynamic testing of geomaterials involves piezoelectric transducers called bender elements. Despite their widespread use, bender element measurements are still hampered by considerable uncertainty in the interpretation of the output signal. Aspects such as wave directivity, apparatus-induced size effects, and boundary reflectivity are still poorly understood and accounted for. This communication presents a modified Rowe cell apparatus, designed to obtain experimental data to better understand these effects. Besides offering all advantages of a conventional Rowe cell (controllable state conditions, hydraulic loading), the device is fitted with bender elements, and features a larger diameter (200mm), adjustable height (20-100mm) and controllable boundary conditions (rigid, semi-rigid or flexible). The cell offers eight insertion slots where bender elements can be housed with distinct orientations. The bender elements operate in echo mode as the insertion slots are located on the same side of the sample. A reliability study of the new Rowe cell is presented, along with some illustrative examples of its potential use.

RÉSUMÉ: L'expansion des projets de construction dans des régions sismiques présentant des sols de mauvaise qualité et les vastes implications juridiques et financières d'informations géotechniques erronées ont conduit les parties concernées à appeler à une caractérisation plus rapide, moins coûteuse et plus fiable des géomatériaux dans des conditions dynamiques. Une approche populaire de l'essai dynamique des géomatériaux fait appel à des capteurs piézoélectriques appelés «bender elements». Malgré leur utilisation répandue, les mesures par des capteurs piézoélectriques sont encore pénalisées par une incertitude considérable dans l'interprétation du signal de sortie. Des aspects tels que la trajectoire des ondes, les effets de taille induits par les appareils et la réflectivité aux limites sont encore méconnus et pris en compte.Cette communication présente une nouvelle cellule Rowe, conçu pour obtenir des données expérimentales permettant de mieux comprendre ces effets. Outre les avantages d'une cellule Rowe conventionnelle (conditions d'état contrôlées, chargement hydraulique), l'appareil est équipé de capteurs piézoélectriques et présente un plus grand diamètre (200 mm), une hauteur réglable (20-100 mm) et des conditions aux limites contrôlées (rigide, semi-rigide ou flexible). La cellule offre huit emplacements d'insertion dans lesquels des capteurs piézoélectriques peuvent être logés avec des orientations particulières. Les capteurs piézoélectriques fonctionnent en mode écho car les emplacements d'insertion sont situées du même côté de l'échantillon. Une étude de fiabilité de la nouvelle cellule Rowe est présentée, accompagnée de quelques exemples illustrant son utilisation potentielle.

Keywords: Small strain shear modulus; bender element; modified Rowe cell; dynamic interface.

1 INTRODUCTION

Bender elements (BEs) are piezoelectric transducers used for the experimental identification of small strain shear moduli (G_0) of geomaterials. A typical BE setup consists of two BEs: a transmitter that is excited by a voltage (input signal) and vibrates laterally to generate a shear wave, and a receiver that reads the arrival of that wave at another point of the geomaterial (output signal). The travelling time of the shear wave gives its velocity, from which the shear modulus can be obtained. Despite their widespread use, the precision, reproducibility, and robustness of G_0 measurements obtained with BEs are still largely open to debate. The main questions are related to the identification of wave travel time, for which a variety of time and frequency domain techniques exist, but no clear consensus has emerged (e.g. Arroyo et al. 2010, Yang & Gu, 2013).

A key component of BE test uncertainty is model error (Arroyo et al. 2006). The elastodynamic model underlying most current interpretation methods is that of a plane wave propagating between source and receiver. Using this simple model, a variety of relevant wave-propagation phenomena like near-field effects (Lee & Santamarina, 2005), sample boundary effects (Moldovan & Correia, 2021) or particle scattering (Yang & Gu, 2013) become noise. Those noises are strongly dependent on the source-to-receiver distance, sample dimensions, or particle diameter.

A modified Rowe cell fitted with multi-directional BEs was designed and manufactured to better understand such issues. As opposed to oedometers, Rowe cells offer drainage control, measure the pore water pressure, and are less prone to environmental perturbations as they use hydraulic loading systems. An adaptation of a Rowe cell to allow for the insertion of BEs was reported by Ngoc et al (2019). The benders were installed in the tip-to-tip configuration, which hinders some of the mechanical systems of the cell, like the pressurized membrane at the top of the sample. In the present work, the transmitter and receiver BEs are installed only in the bottom pedestal of the apparatus and measure the rebounds of the wave from the top boundary. The top platen can be rigid or flexible. The rebound measurement is a relatively new concept in BE experiments and proven particularly convenient in the context of Rowe measurements. The following sections present a brief description of the modified Rowe cell and its measurements.

2 DESIGN AND CONSTRUCTION

The prototype design is based on a conventional Rowe cell, modified to enable the flexible definition of the sample's geometry, fitting of BEs, and multiple types of boundary conditions. The diameter of the sample is set to 200 mm and its height can be varied between 40 and 200 mm. A drainage line enables the pore water pressure measurement. Additionally, a displacement transducer (LVDT) is incorporated for the accurate measurement of the vertical strain (Figure 1).

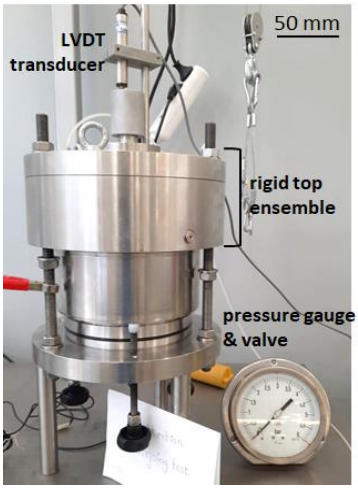

Figure 1. General view of the modified Rowe cell.

The bottom pedestal is designed to hold up to eight BEs in different positions. These were selected using numerical models (Moldovan & Cismasiu 2018) to enable both off-centre and off-plane locations of the BEs (Figure 2). The distance between a transmitter inserted in the center of the pedestal, and the receiver ranges between 30 mm (B4) and 70 mm (B1) with 10 mm increments. Slot C4 is an exception, its distance to the transmitter being $30\sqrt{2}$ mm.

The installation and removal of the BEs from the pedestal are simplified by specially designed bender capsules and screws. On the internal walls of the slots, O-rings are inserted, to fix the BEs and stop leakage when a test is performed on a saturated sample. The slots that are not hosting BEs are filled with metallic plugs.

Transmitter and receiver BEs may be installed in the same plane or out of plane. The coplanar setup is aimed at minimizing the content of compression waves in the output signal. Conversely, the non-coplanar setup is aimed at accommodating both (direct) compression waves and (reflected) shear waves in the same output signal.

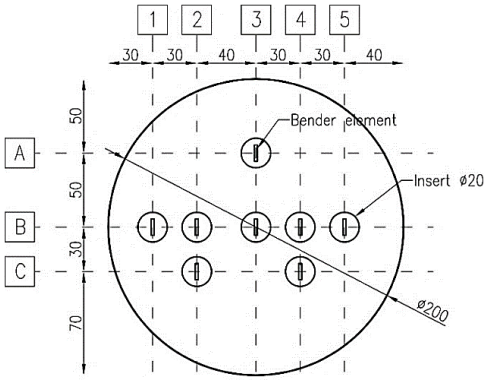

Figure 2. Insertion slots of BEs in the bottom pedestal.

On the opposite side of the sample, various boundary conditions may be applied, including rigid (steel, aluminum, plexiglass) or fluid-pressurized flexible membrane. The rigid setups (Figure 3) are designed to maximize boundary reflections, enabling the best possible echo reading of the shear wave signal for the correct assessment of G0. The rigid plates are actuated by a piston capable of applying up to 70 MPa of pressure to the geomaterial.

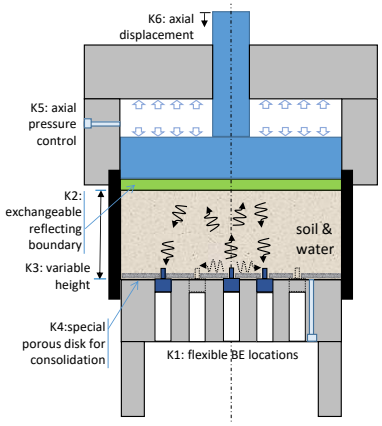

Figure 3. Rigid top boundary configuration.

The flexible setup (Figure 4) uses a pressurized membrane to apply the confining pressure to the geomaterial. The setup is designed to replicate the flexible boundary conditions that occur in triaxial pressure chambers, enabling the quantification of the wave energy that is lost at the sample-apparatus interface. As opposed to the rigid setup, the objective of flexible setups is to maximize the energy radiated from the sample (boundary losses).

3 RELIABILITY AND VALIDATION

An extensive set of experiments was performed to validate the BE results obtained with the new Rowe cell against other results available in the literature, and to assess their reproducibility (consistency of repeated measurements).

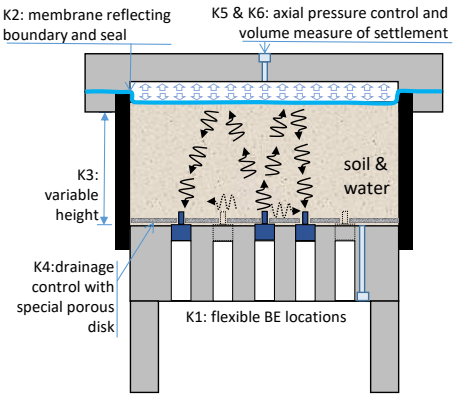

Figure 4. Flexible top boundary configuration.

The experiments were conducted on dry samples of the Toyoura sand benchmark (Yamashita et al., 2009) and performed using a sample height of 60 mm. Toyoura sand is rounded and uniformly graded, with almost no particles with a diameter below 75 µm (Sieve No. 200). The sand has a mean particle diameter D_{50} of 0.15 mm and a uniformity coefficient C_u of 1.43. One BE receiver was used, located 30 mm away from the transmitter BE in a non-coplanar setup (Figure 5). The experiment is conducted using a rigid boundary. The applied vertical pressure is 200kPa. While various void ratios were tested, the results presented below were obtained for e=0.85.

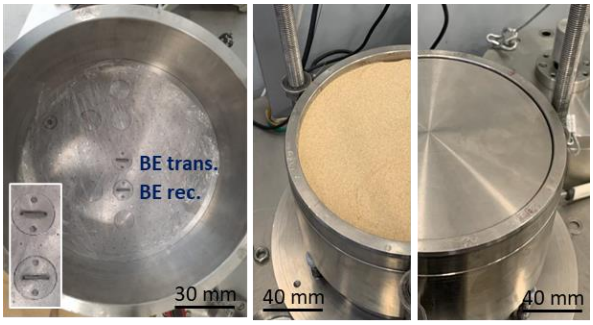

Figure 5. BEs, sample preparation, and rigid top platen.

To assess the reliability of the G_0 measurements in the echo mode, the tests were repeated 10 times in full, i.e. the sample was removed from the modified Rowe cell, dried and set up again. The correlations between the output signals obtained on these tests varied between 0.762 and 0.997, with most results above 0.850, indicating strong correlation. The error bands of the output signals for all experiments are presented in Figure 6. The signals obtained in the 10 experiments are consistent until the arrival of the shear waves and less so after that, as the higher attenuation and complexity affecting reflection patterns compromise the consistency of the plots. The validation of the modified Rowe cell measurements is based on the comparison of the shear moduli obtained with six interpretation techniques (first break, first bump, zero-

crossing, peak-to-peak, cross-correlation, and cross-spectrum) and for three void ratios, with those reported by an international parallel test (Yamashita, et al. 2009). The average shear moduli obtained in the modified Rowe cell on 10 repeated experiments are around the median values of the shear moduli reported by the parallel test (Figure 7), indicating that the measurements are consistent with established practice.

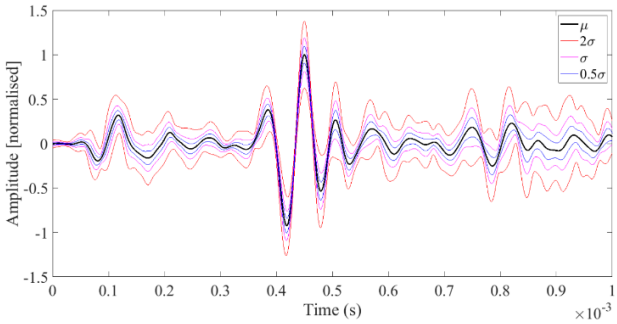

Figure 6. Average and error bands of output signals.

The results are relatively compact, with standard deviations below 4% of the average value, which means that approximately 95% of the readings are anticipated to fall within 8% of the average value.

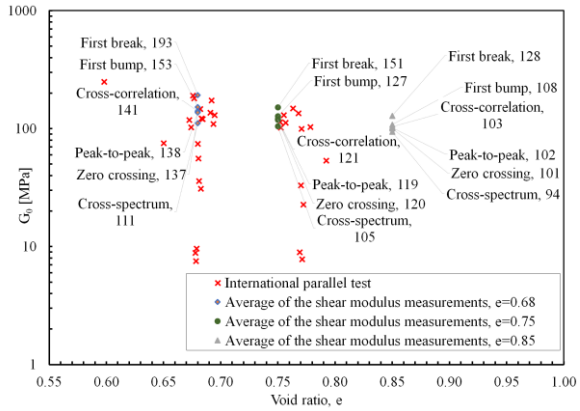

Figure 7. Shear moduli obtained with the modified Rowe cell (using rigid top boundary), in the context of the international parallel test.

4 CONCLUSIONS

A new, modified Rowe cell with flexible geometry was designed to be fitted with BEs. The BE locations and orientations are flexible, enabling the observation of multiple shear and compression waves with a single receiver. Besides offering the same level of control as a regular Rowe cell, the new device can be fitted with different boundary conditions on the plate with no BEs. Rigid boundary conditions can be used to maximize the wave reflections and support a clear reading of the shear modulus in the echo mode, while flexible boundaries can be used to assess boundary losses in conditions similar to those in the triaxial test. The readings obtained with the new device are robust and match those reported in literature benchmarks.

RESUME: Cet article s'inscrit dans le cadre du projet national français ASIRI+ (2019 - 2024) qui est une extension du projet ASIRI (2005-2012) et qui vise à fournir des recommandations pour la conception d'un renforcement par inclusions rigides. Le premier objectif de l'article est d'améliorer les méthodes analytiques d'ASIRI (2012) pour la conception de plateformes de transfert de charge dans le cas des semelles sur inclusions rigides, en utilisant des calculs par éléments finis en 3D. Le deuxième objectif est de comparer différentes méthodes de dimensionnement de renforcement par géosynthétiques afin de développer et de valider un modèle analytique. Trois méthodes sont étudiées: la méthode Concentric Arches (CA), une méthode d'éléments discrets en 3D (DEM), et un modèle biphasique simplifié (Taspie+).

ABSTRACT: This article is part of the French national project ASIRI+ (2019 - 2024), an extension of the ASIRI project (2005-2012), aiming to provide recommendations for the design of a soil reinforced by rigid inclusions. The first objective of the article is to improve the analytical methods of ASIRI (2012) for the design of load transfer platforms in the case of shallow foundations on rigid inclusions, using 3D finite element calculations. The second objective is to compare different methods for the design of geosynthetic reinforcement in order to develop and validate an analytical design model. Three methods are studied: the concentric arches method (CA), a 3D discrete element method (DEM), and a simplified biphasic model (Taspie+).

Keywords: Geosynthetics; rigid inclusions; concentric arches; load transfer platforms; shallow foundations.

1 INTRODUCTION

Le renforcement par inclusions rigides est un procédé qui s'est largement répandu en France ces trente dernières années. Les recommandations ASIRI (2012) ont détaillé des méthodes simplifiées pour la définition de la charge limite pouvant être reprise par le matelas de répartition. Ces méthodes sont largement éprouvées pour la définition de la charge limite lorsque le mécanisme de poinçonnement du matelas peut se développer « librement » (calculs en zone courante pour une maille infinie avec une épaisseur de matelas et un entraxe entre les inclusions suffisant). En revanche, les méthodes proposées peuvent s'avérer conservatives dans le cas particulier des semelles sur inclusions et dans le cas des remblais ne permettent pas d'évaluer le transfert de charge dans le matelas en présence des géosynthétiques.

Cet article a pour objectif de définir quelques pistes d'amélioration des méthodes simplifiées afin de d'évaluer le transfert de charge dans le cas d'un matelas de répartition, avec ou sans géosynthétiques, sous une semelle (§2) ou sous un remblai (§3).

2 SEMELLE SUR INCLUSIONS RIGIDES

2.1 Règles simplifiées d'ASIRI

Suivant les règles ASIRI (2012), la contrainte limite de poinçonnement dans le matelas $q_p^+(P)$ est déterminée en partie courante suivant le mécanisme de Prandtl à partir de la formule ci-dessous (avec q_s^+ la contrainte dans le sol à la base du matelas à la rupture et N_q facteur de portance) ; la contribution du poids et de la cohésion sont négligés:

$$q_p^+(P) = N_q q_s^+ \qquad (1)$$

La formule ci-dessous suppose implicitement un développement « libre » d'un mécanisme de poinçonnement au sein du matelas (épaisseur et entraxe suffisants). Dans le cas d'une semelle sur IR, la résistance au poinçonnement du matelas peut être affectée défavorablement par l'effet de bord (Figure 1).

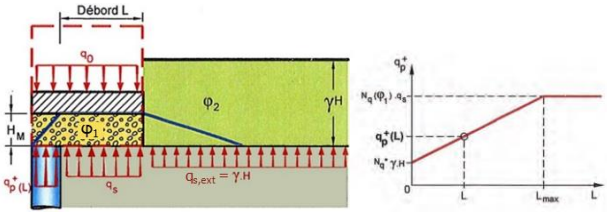

Figure 1. Prise en compte du débord L [ASIRI, 2012].

ASIRI (2012) propose une approche simplifiée consistant à interpoler entre la contrainte de référence $q_p^+(P)$ correspondant au débord L_{max} (obtenue avec un facteur de portance N_q de l'ordre de 30 à 50) et la contrainte $q_p^+(0)$ correspondant à un débord nul (obtenue avec une borne inférieure du facteur de portance noté N_q^*, de l'ordre de 10 à 30). La contrainte résultante notée $q_p^+(L)$ est définie comme suit:

$$q_p^+(L) = q_p^+(0) + \frac{L}{L_{max}}\left(q_p^+(P) - q_p^+(0)\right) \qquad (2)$$

avec : $q_p^+(0) = N_q^* q_{s,ext}$

L_{max} : largeur du mécanisme de Prandtl.

Cette approche est complétée par des règles empiriques pour prendre en compte la position des inclusions dans la semelle. En particulier, pour une inclusion située dans le coin on a:

$$q_{p,a}^+ = \frac{7}{12} q_p^+(P) + \frac{5}{12} q_p^+(L) \qquad (3)$$

Enfin, à titre de comparaison, on peut définir un facteur de portance équivalent avec effet de bord noté « $N_{q,eq}$ » en posant : $N_{q,eq} = q_{p,a}^+ / q_s$ où q_s est défini tel que $q_0^* = \alpha \times q_{p,a}^+ + (1-\alpha) \times q_s$, α étant le taux de substitution et q_0* la contrainte moyenne à la base du matelas. Afin d'illustrer la démarche, on étudie le cas d'une semelle carrée sur quatre inclusions de diamètre B suivant les données du Tableau 1. Le Tableau 2 présente les résultats obtenus pour L = 0,6 m, q_0^* = 100 kPa.

Tableau 1. Paramètres de calcul.

$B_{semelle}$ [m]	B [m]	φ_1 [°]	φ_2 [°]	α [%]	$q_{s,ext}$ [kPa]
2,21	0,34	38	30	7,4	10

Tableau 2. Résultats – ASIRI (2012).

N_q [-]	N_q* [-]	L_{max} [m]	$q_p^+(0)$ [kPa]	$q_p^+(P)$ [kPa]	$q_p^+(L)$ [kPa]	$q_{p,a}^+$ [kPa]	$N_{q,eq}$ [-]
49	26	2,4	260	1084	465	826	19

2.2 Comparaison à un traitement numérique en éléments finis 3D

Le facteur $N_{q,eq}$ obtenu avec les règles simplifiées ASIRI (2012) est comparé à celui obtenu via un modèle aux éléments finis 3D. On reprend la configuration décrite dans le Tableau 1 et on étudie un quart de modèle par symétrie (voir Figure 2). Une étude paramétrique est réalisée en faisant varier le rapport entre le débord L et le diamètre de l'inclusion B ($0 \le L/B \le 1{,}75$), le rapport entre la hauteur H du matelas et B (H/B = 1,5 et H/B = 1,0) et le rapport des contraintes de confinement à l'extérieur et l'intérieur de la semelle ($q_{s,ext}/q_s$ = 0,25, $q_{s,ext}/q_s$ = 0,33 et $q_{s,ext}/q_s$ = 0,50).

La rupture du matelas est supposée atteinte pour un déplacement imposé u_z fonction du diamètre B de l'inclusion (avec u_z = B/10 et u_z = B/5). On définit ainsi le facteur de portance équivalent $N_{q,eq} = q_p^{max}/q_s$ avec q_p^{max} la contrainte de rupture et q_s la contrainte verticale sous le matelas à l'intérieur de la semelle.

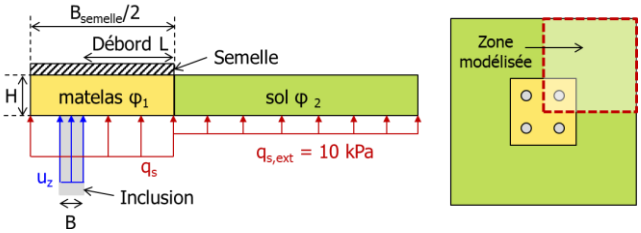

Figure 2. Modèle 3D (coupe et vue en plan).

La Figure 3 et la Figure 4 présentent l'évolution de $N_{q,eq}$ en fonction de L/B comparé aux résultats obtenus avec les méthodes analytiques ASIRI (2012).

On peut voir que le facteur de portance équivalent obtenu est 1,5 à 4 fois supérieur au facteur ASIRI avec effets de bord et dans certains cas dépasse le facteur de portance ASIRI sans effets de bord (N_q =49 pour φ_1 = 38°).

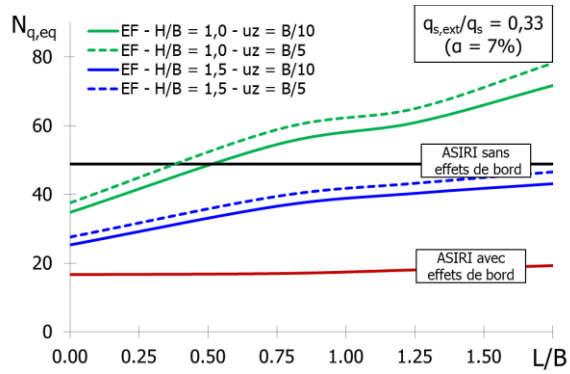

Figure 3. Facteur de portance équivalent fonction de L/B pour différentes valeurs de H/B ($q_{s,ext}/q_s$ fixé = 0,33).

La Figure 3 montre que plus le rapport H/B est faible plus $N_{q,eq}$ est élevé ce qui traduit l'effet bénéfique lié à la présence de la semelle qui bloque le développement du mécanisme de rupture. On peut voir également que la pente des courbes est plus élevée pour H/B =1 que pour H/B =1,5.

La Figure 4 montre que l'augmentation de q_s a pour effet d'augmenter l'ordonnée à l'origine des courbes en conservant la même pente qui est fonction du rapport H/B. Enfin, on note que le critère de rupture imposée (u_z = B/10 ou u_z = B/5) a un faible un impact sur les résultats.

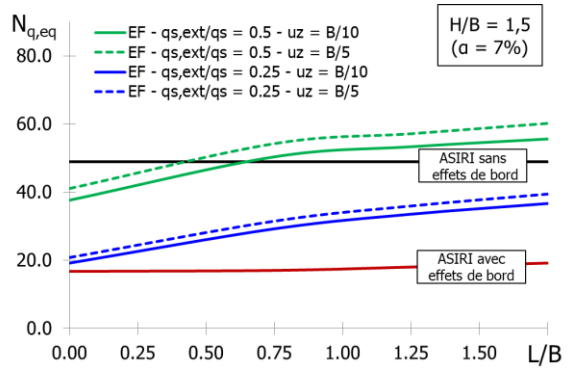

Figure 4. Facteur de portance équivalent fonction de L/B pour différentes valeurs de $q_{s,ext}/q_s$ (H/B fixé = 1,5)

3 REMBLAI SUR INCLUSIONS RIGIDES AVEC MATELAS RENFORCE OU ON PAR GEOSYNTHETIQUES

3.1 Description des méthodes

3.1.1 Méthode DEM

L'étude menée avec la méthode DEM (Tran et al., 2019 et Tran et al., 2021) est utilisée comme point de comparaison pour évaluer les méthodes analytiques en présence de géosynthétiques.

Dans la méthode des éléments discrets 3D (DEM) des particules élémentaires sont utilisées pour simuler la microstructure des matériaux granulaires, et une méthode couplée éléments discrets - éléments finis (DEM - FEM) permet de décrire le comportement du géosynthétique et son interaction avec le matériau granulaire.

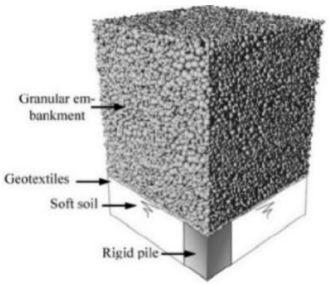

Figure 5. Méthode DEM [Villard et al., 2024].

3.1.2 Arches concentriques (CA)

La méthode arches concentriques (CA) décrite Figure 6, est une méthode de conception de renforcement par géosynthétiques développé par S. Van Eekelen qui est couramment utilisée, et présentée dans le CUR 226 néerlandais (2016). Cette méthode de dimensionnement se base sur un calcul en deux étapes. La première étape permet de définir la part de charge transmise par effet de cisaillement (A, B et C) et la deuxième étape décrit le comportement (force de traction et déformation maximum) du géosynthétique sous la charge résiduelle (B+C).

Une feuille de calcul a été développée par S. Van Eekelen afin de faciliter le calcul de ces deux étapes. Celle-ci a été utilisée afin de comparer les différentes méthodes.

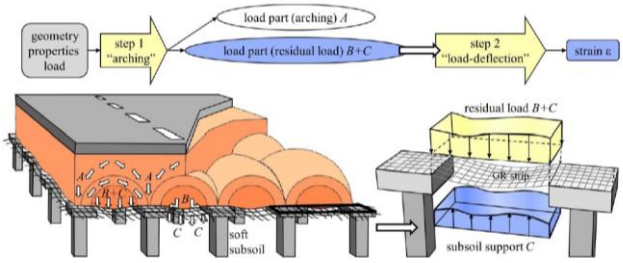

Figure 6. Méthode CA [Van Eekelen, 2016].

3.1.3 Modèle Taspie+

Le modèle Taspie+ (Cuira & Simon, 2009) est un modèle biphasique simplifié suivant les règles d'ASIRI qui a pour objet l'étude d'une cellule élémentaire centrée sur une inclusion soumise à un chargement vertical (voir Figure 7). La prise en compte des géosynthétiques est réalisée en ajoutant dans les équations du modèle, à la hauteur du géosynthétique, la relation entre le déplacement de ce dernier et la charge qu'il peut transférer à ses extrémités.

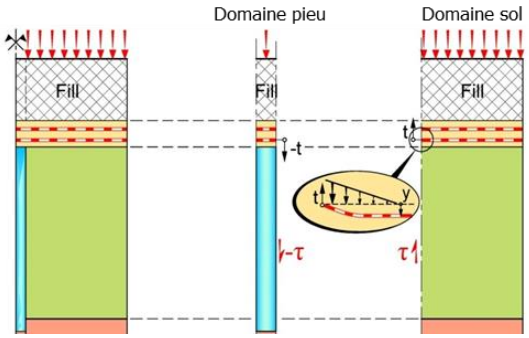

Figure 7. Modèle Taspie+ [Simon et al., 2014].

Cette relation est déduite du comportement des bandes reliant les têtes d'inclusion, selon les côtés des mailles. Ces bandes sont supposées soumises à une pression différentielle p distribuée selon un profil triangulaire inverse (voir Figure 8). L'équilibre élastique de la bande est étudié en grandes déformations (avec prise en compte des effets de second ordre) et sa résolution permet d'établir une relation non linéaire directe entre la pression p et la flèche Δy qui en résulte.

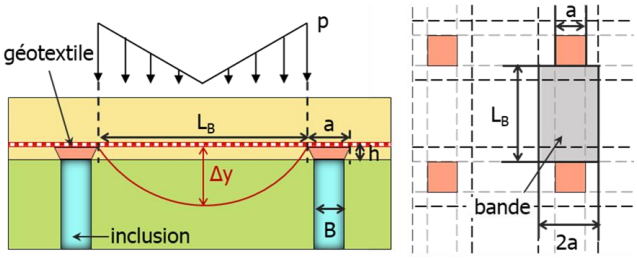

Figure 8. Bande soumise à un profil triangulaire inverse.

3.2 Comparaisons

3.2.1 Configurations étudiées

On reprend les configurations de l'étude DEM servant de référence (Tran et al., 2021), soit :

- Inclusions carrées de 0,6 m de côté ;
- Maille carrée de 3,0 m x 3,0 m ;
- Trois hauteurs de matelas : H = 0,75 m, H = 1,5 m et H = 3 m ;
- Géosynthétique bidirectionnel de raideur J = 3000 kN/m.

Différentes valeurs du module du sol entourant les inclusions sont étudiées, comprises entre 0,01 à 1 MPa.

Pour le matelas, deux densités enveloppes et compatibles avec les caractéristiques microscopiques du modèle DEM sont étudiées, voir Tableau 3. Ces dernières sont utilisées directement dans la méthode CA en considérant l'angle de frottement résiduel. L'utilisation du modèle Taspie+ nécessite la définition préalable du module de déformation du matelas compatible avec les paramètres microscopiques et macroscopiques du modèle DEM. On se base pour cela sur les simulations numériques d'essais triaxiaux effectuées sur des échantillons de matelas en utilisant le modèle DEM (Tran et al., 2019), afin de calibrer une loi contrainte-déformation. Cette démarche a permis de déterminer un module du matelas en fonction de la contrainte verticale σ'_v comme suit (voir Tableau 4):

$$E_{50} = E_{50}^{ref} \left(\frac{\sigma'_v}{p_{ref}}\right)^m \quad (4)$$

Tableau 3. Paramètres macroscopiques matelas- DEM/CA

Densité	φ'_{pic} [°]	$\varphi'_{res.}$ [°]	γ_d [kN/m^3]
Lâche	34	26	14.40
Dense	46	26	16.20

Tableau 4. Paramètres matelas –Taspie+.

Densité	$E_{50,ref}$ [MN/m^2]	p_{ref} [kPa]	ν [-]	m [-]	γ_d [kN/m^3]
Lâche	2,10	100	0,3	0,24	14.40
Dense	3,50	100	0,3	0,15	16.20

3.2.2 Efficacité sans géosynthétiques

L'efficacité est définie comme le rapport de l'effort en tête des inclusions rigides sur l'effort total de la maille. La Figure 9 présente l'efficacité sans prise en compte les géosynthétiques pour les modèles DEM et Taspie+. Pour les deux modèles, on observe une augmentation de l'efficacité lorsque le module du sol diminue. Avec le modèle DEM, on atteint un pic au-delà duquel le matelas plastifie, entraînant une diminution de l'efficacité. En revanche, avec le modèle Taspie+, ce pic n'est pas visible, car le matelas se comporte de manière élastique. Des vérifications de non-poinçonnement du matelas sont effectuées ultérieurement, conformément aux considérations décrites dans le §2.

De plus, on peut noter que dans le cas d'un matelas lâche, les courbes sont comparables pour des modules de sol supérieurs à 0,2 MPa, avant la rupture du matelas. En revanche, dans le cas d'un matelas dense, le modèle Taspie+ sous-estime l'efficacité. Cette observation s'explique par le fait que dans le modèle Taspie+, le transfert des charges au niveau du matelas s'effectue par cisaillement vertical, plafonné à $k\tan\delta \times \sigma'_v$. Le facteur $k\tan\delta$ est un paramètre empirique qui représente le produit d'un frottement $\tan\delta$ par un coefficient de butée k (tel que $\sigma'_N = k\,\sigma'_v$). Dans la pratique, le facteur $k\tan\delta$ est plafonné forfaitairement à 1 indépendamment de la densité du matelas. Les comparaisons avec la méthode DEM inciteraient ici à adapter la valeur de $k\tan\delta$ à la densité du matelas.

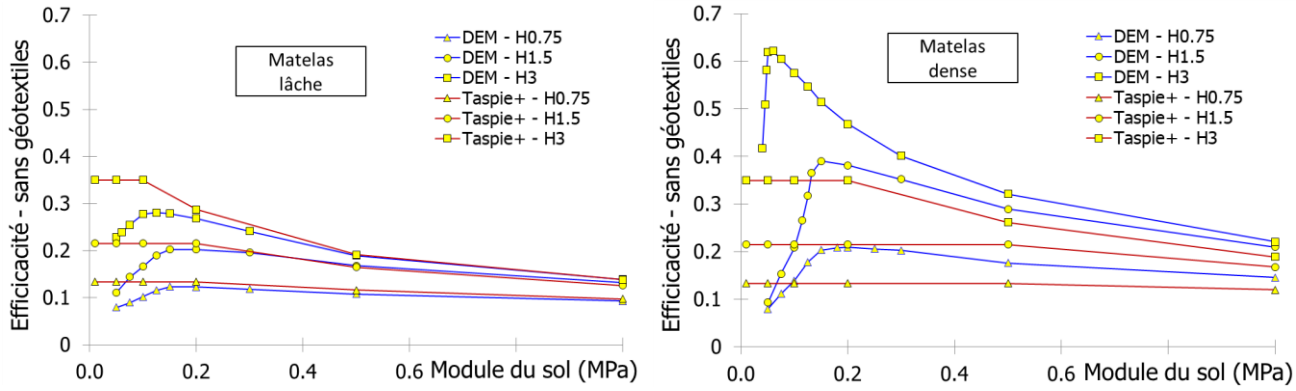

Figure 9. Comparaison DEM/Taspie – Efficacité sans géosynthétiques.

3.2.3 Efficacité avec géosynthétiques

La Figure 11 et la Figure 12 présentent la comparaison, entre les différentes méthodes, de l'efficacité avec prise en compte des géosynthétiques.

Les résultats obtenus avec Taspie+ montrent une évolution similaire à ceux obtenus par la méthode DEM. Pour les matelas de type lâche, l'accord est satisfaisant. En revanche, pour les matelas de type dense les résultats se placent du côté de la sécurité. L'adaptation de la distribution de la pression différentielle selon un profil triangulaire inverse s'appliquant seulement à une fraction de la demi-maille (profil tronqué) pourrait conduire à un meilleur accord pour des matelas denses (Figure 10). En effet, à résultante de pression p constante, ceci a pour conséquence de diminuer la flèche Δy du géosynthétique et donc de rigidifier l'ensemble (avec une traction associée dans le géosynthétique également plus faible). La mise en place d'un profil de ce type est en accord avec les observations réalisées dans les modèles DEM qui montrent que la distribution de la pression suit une fonction polynomiale du troisième degré (Villard et al., 2024). Cette fonction peut être simplifiée suivant le profil Figure 10.

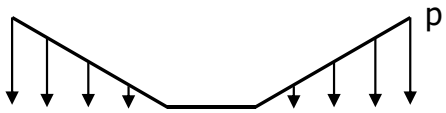

Figure 10. Profil triangulaire inverse « tronqué ».

Les résultats obtenus avec la méthode CA montrent que celle-ci surestime la part de charge A, donc l'efficacité, pour les matelas de type lâche et sous-estime légèrement l'efficacité dans le cas des matelas denses de forte hauteur (H = 1,5 m et H = 3,0 m). Mais pour le cas H = 0,75 m l'accord est satisfaisant.

3.2.4 Tassements en surface avec géosynthétiques

La Figure 13 présente le tassement en surface avec prise en compte des géosynthétiques pour le modèle DEM et le modèle Taspie+. Les résultats sont comparables entre les deux modèles. Pour les matelas de type dense, les tassements sont surestimés avec la méthode Taspie+ ce qui corrobore les observations réalisées sur l'efficacité du report de charge §3.2.3. Pour les matelas de type mou les résultats sont comparables, excepté pour des fortes épaisseurs de matelas où le calcul Taspie+ semble sous-estimer les tassements.

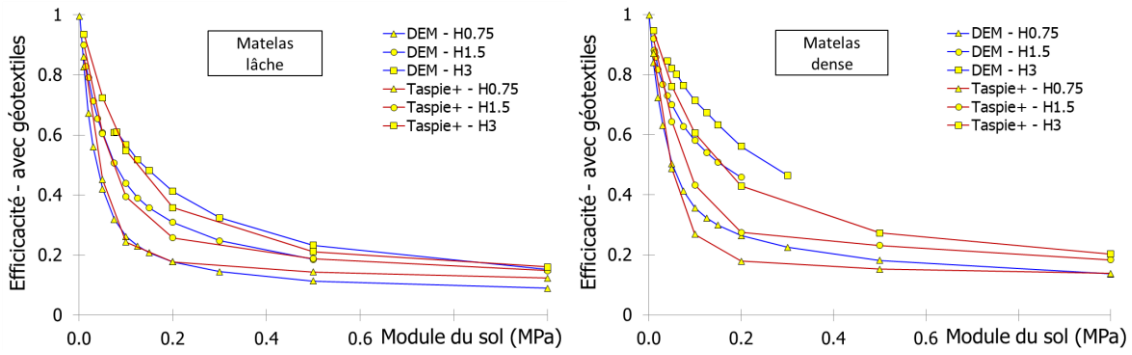

Figure 11. Comparaison DEM/Taspie – Efficacité.

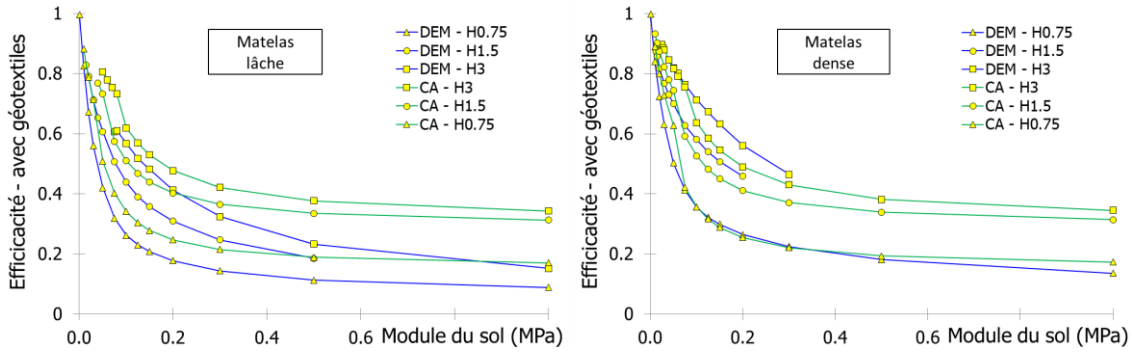

Figure 12. Comparaison DEM/CA – Efficacité.

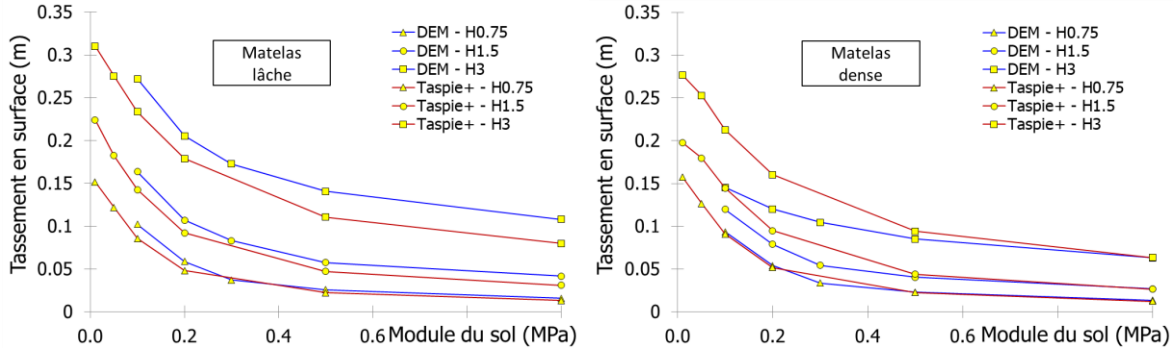

Figure 13. Comparaison DEM/Taspie – Tassements.

4 CONCLUSIONS

Pour le cas d'une semelle sur inclusions, les résultats montrent que les règles ASIRI (2012) sous-estiment la charge limite d'un facteur variant entre 1,5 et 3. Des abaques basés sur des calculs numériques peuvent être proposés pour la nouvelle version des recommandations qui sera éditée à la fin du projet ASIRI+.

Pour le cas d'un remblai sur inclusions, les comparaisons entre les modèles DEM et Taspie+ ont montré que les résultats obtenus évoluent de manière comparable en termes d'efficacité et de tassements. Pour les matelas de type lâche l'accord est bon. Pour les matelas de type dense les résultats se placent du côté de la sécurité. Une amélioration du modèle Taspie+ pourrait consister à adapter, selon la densité du matelas, la valeur du frottement limite $k\tan\delta \times \sigma'v$ ainsi que la distribution de la pression différentielle (suivant un profil triangulaire inverse tronqué). Néanmoins, en pratique, l'utilisation d'un profil non tronqué s'avère sécuritaire pour le dimensionnement. En ce qui concerne les comparaisons entre les modèles CA et DEM, la méthode CA n'a pas montré une bonne cohérence des résultats d'efficacité avec la méthode DEM dans le cas d'un sol lâche. Cependant, elle montre un bon calage avec le type de sol dense, plus particulièrement pour un remblai de hauteur 0,75m, et se place du côté de la sécurité pour les deux autres hauteurs de remblai.

Prediction of uplift and compression bearing capacity of screw piles in saturated sand

Prévision de la capacité de charge en compression et en soulèvement des pieux vissés dans le sable saturé

Aalborg University, Aalborg, Denmark

**dka@build.aau.dk*

ABSTRACT: Accurate determination of bearing capacity for screw piles remains an unresolved challenge. Previous research has predominantly concentrated on uplift capacity equations for helical anchors, with limited focus on compression capacity. This study aims to assess and adapt existing methodologies for determining the bearing capacity of screw piles, accounting for the distinct geometrical features, and applying them to both uplift and compression capacities. Additionally, Cone Penetration Test (CPT)-based methods are investigated for their applicability in this context. The research methodology entails reviewing current bearing capacity determination methods, modifying them to accommodate the unique screw pile geometry, and analysing CPT-based approaches. Static load tests are conducted at Aalborg University's laboratory to obtain reference static bearing capacities. Comparisons are drawn between the outcomes of the adapted earth pressure theory-based and CPT-based methods and the lab-obtained static bearing capacities. The results indicate that the existing framework is inadequate and unreliable for determining the uplift and compression bearing capacity of the screw piles investigated. The study highlights the necessity for further research and development of novel methodologies to enhance the accuracy of screw pile bearing capacity predictions.

RÉSUMÉ: La détermination précise de la capacité portante des pieux vissés reste un défi non résolu. Les recherches antérieures se sont principalement concentrées sur les équations de capacité de soulèvement pour les ancrages hélicoïdaux, avec une attention limitée à la capacité de compression. Cette étude vise à évaluer et à adapter les méthodologies existantes pour déterminer la capacité portante des pieux vissés, en tenant compte des caractéristiques géométriques distinctes, et à les appliquer aux capacités de soulèvement et de compression. En outre, les méthodes basées sur le test de pénétration du cône (CPT) sont étudiées pour leur applicabilité dans ce contexte. La méthodologie de recherche comprend l'examen des méthodes actuelles de détermination de la capacité portante, leur modification pour tenir compte de la géométrie unique des pieux vissés, et l'analyse des approches basées sur le CPT. Des essais de charge statique sont effectués au laboratoire de l'Université d'Aalborg pour obtenir des capacités portantes statiques de référence. Des comparaisons sont établies entre les résultats des méthodes adaptées basées sur la théorie de la pression des terres et basées sur les CPT, et les capacités de charge statique obtenues en laboratoire. Les résultats indiquent que le cadre existant est inadéquat et peu fiable pour déterminer la capacité portante de soulèvement et de compression des pieux vissés étudiés. L'étude souligne la nécessité de poursuivre les recherches et de développer de nouvelles méthodologies pour améliorer la précision des prévisions de capacité portante des pieux vissés.

Keywords: Screw piles; analytical methods; CPT-based methods; experiments.

1 INTRODUCTION

Screw piles have historically been used for sustaining tension loads with minimal focus on the compressive bearing capacity. To introduce screw piles into the housing market, it is a necessity to study their behaviour under compressive loading. Screw piles are steel piles with different configurations with varying diameters of hollow, tubular shaft and thread sizes. The screw piles studied in this paper are illustrated in Figure 1. The threads are welded on with a constant pitch. Furthermore, the threads are continuous and therefore a special case of previously studied helical piles (Das and Shukla, 2013). The study of bearing capacities in this paper is based on experiments performed at Aalborg University 'Sand Box' with the dimensions of 4.4 x 2.5 x 3.2 meters and a hydraulic multi-purpose robot.

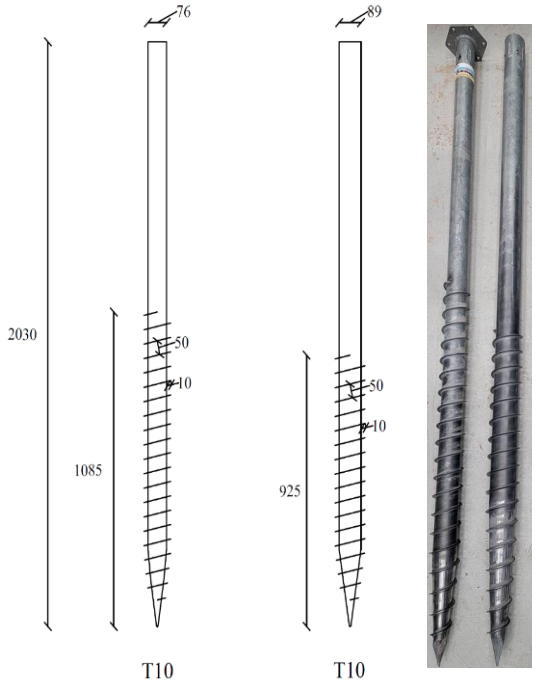

Figure 1. Screw piles used at Aalborg University with geometries in [mm] on the left.

2 EXPERIMENTS

The experimental procedure is separated into different steps which are described in the following subsections. The experiments are carried out in saturated silica sand where Aalborg Sand No. 1 is used with parameters listed in (Nielsen and Nielsen, 2018).

2.1 Soil preparation

For testing the soil in the 'Sand Box' the soil must be able to be returned to initial conditions, this is achieved by liquefaction using pumps to generate a water gradient sufficient to subdue the generated stresses through compaction of the soil. Subsequently the soil is vibrated in a pattern to achieve uniform soil conditions which is ensured by performing small cone penetration tests (CPT's) and to minimize the boundary effects which arise from vibrating the soil.

2.2 Cone penetration test

To verify the uniformity of the soil conditions, before performing the installation and testing of the screw piles, six CPT's are conducted at six different positions in the 'Sand Box'.

2.3 Installation

The installation is controlled to ensure reliable and reproducible results. Furthermore, to minimize soil disturbance the screw pile is installed with a rate of one pitch per rotation which equivalently was used in previous studies of screw piles (Ghaly and Hanna, 1991).

2.4 Static load testing

The method for determining bearing capacities is carried out using a displacement-controlled static load test performed with a hydraulic piston.

2.4.1 Tensile load test

The pile is subjected to a tensile load, during the test load and displacements are measured. Failure during the tensile load test is determined as the point at which a sudden drop in the exerted tensile load occurs. This is equivalent to the maximum tensile load during the test.

2.4.2 Compression load test

The compression load test is started, and the load and displacement are measured, the displacement-controlled test is loaded until 100 mm with unloading at 50 mm. The compressive bearing capacity is determined at 50 mm and D/10 of displacement based on experience from load-displacement curves.

2.5 Extent of experiments

In this paper, the results of 6 tensile tests and 28 compressive tests are studied. Two different pile configurations are illustrated in Figure 1 and the geometrical sizes are given in Table 1.

Table 1. Geometrical sizes of studied screw piles.

Pile Name	Diameter [mm]	Thread size [mm]	Pitch [mm]
D76T10	76	10	50
D89T10	89	10	50

The tests were carried out in different relative densities varying from 41% to 97%.

3 METHODS

Different methods for determining the uplift and compressive static bearing capacities are investigated and adapted to the geometry of the screw piles shown in Figure 1. The bearing capacities are studied by two solution approaches, both analytical methods and CPT-based methods.

3.1 Analytical methods

In this paper, two analytical methods are investigated. Firstly, the Mitsch and Clemence method (M&C method) is studied which is based on the failure

mechanism of cylindrical shear (Mitsch and Clemence, 1985). Originally this method was developed for predicting the uplift capacity of helical anchors however, it is modified to account for compressive loading by introducing the bearing capacity factor instead of the uplift capacity factor (Mohajerani, Bosnjak and Bromwich, 2016). The other analytical method studied is a further development of the Mitsch and Clemence cylindrical shear method where Perko's method is derived from soil pressures and static solution, unlike Mitsch and Clemence theory, which is based on failure lines and a kinematic solution (Perko, 2009). The main factors studied by Mitsch and Clemence are the coefficient of lateral earth pressure and friction angle, where Perko's method is more focused on the ultimate bearing pressure and soil shear strength (Perko, 2009) (Mitsch and Clemence, 1985).

3.2 CPT-based methods

Similarly, to analytical methods, different CPT-based methods have been studied. In this paper, four different methods have been investigated. Firstly, the LCPC method which is calibrated for drilled, driven, and cast screw piles which are reliable for complex layered soils. However, this is not considered as a stand-alone method consequently supplementary for analytical methods (Perko, 2009). Secondly, the ICP-05 method which is developed for large-diameter driven tubular piles in very dense sands, is common in offshore structures. The failure is studied as local shear failure using the Coulomb criterion (Jardine, Merritt and Schroeder, 2015). The NGI-05 method is developed for driven piles in sandy soils and uses empirical factors to determine the ultimate skin friction. Furthermore, a triangular distribution of soil pressures with depth, and homogeneous soil deposits is assumed (Clausen, Aas and Karlsrud, 2005). The last CPT-based method studied is the UWA-05 method which similarly to the other methods are developed for driven piles. However, the UWA-05 method is based on siliceous sands and the pile having a large diameter (Lehane, Schneider and Xu, 2007).

3.3 Adaptations

The adaptations of the methods are mainly based on geometrical differences. The LCPC method is similarly to the analytical methods adapted primarily to the geometrical part. However, the other CPT-based methods do not have the same degrees of freedom and thereby the geometrical difference is not capable of being captured. Furthermore, the CPT-based methods are developed for driven piles which differs significantly from the installation procedure of the screw piles studied in this paper and therefor is suspected to yield unfavourable results. Thereby the screw piles are assumed to be tubular and hollow piles for the CPT-based methods.

4 RESULTS

Based on the adaptation of the analytical and CPT-based methods the uplift and compressive static bearing capacities are determined. To quantify the precision of these models a percentage level of exceedance (PLE) has been chosen to represent the credibility of the studied methods, which is determined by Equation (1).

$$PLE = \left(\frac{Q_{theory} - Q_{measured}}{Q_{measured}}\right) \cdot 100 \qquad (1)$$

where Q_{theory} (kN) is the calculated bearing capacity based on the methods, $Q_{measured}$ is the measured bearing capacity that is derived from the static tests. Based on all the experiments the percentage level of exceedance has been calculated and shown in Figure 2 for tensile bearing capacity and Figure 3 for compressive bearing capacity.

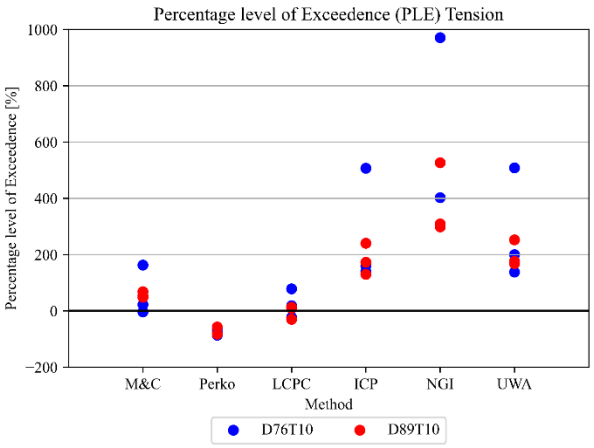

Figure 2. Percentage level of exceedance from tensile tests. Red indicates the results for the D89T10 pile, and blue indicates the results for the D76T10 pile.

5 CONCLUSION

Based on the results shown in Figure 2 and 3 it can be concluded that the current framework is inadequate for reliably predicting the bearing capacity of the screw pile configurations studied at Aalborg University. In compression, the variation in predictions is significant, which indicates the reliability of the results is low however, the Perko method indicates the lowest deviation of results, which is indicative that it consistently predicts wrong. For tensile bearing

capacities, it is shown that most of the CPT-based methods overpredict the uplift capacity significantly, whereas the NGI-05 method, in the worst case, has a percentage level of exceedance of 970%. However, the Perko method shows relatively low scatter, which indicates that this is the most consistent method for both uplift and compression. Furthermore, most methods underpredicts the compressive bearing capacity and over predicts the uplift bearing capacity. In conclusion the current framework is not sufficient to determine the bearing capacities of the screw piles used at Aalborg University and thereby, further adaptations or developments are required.

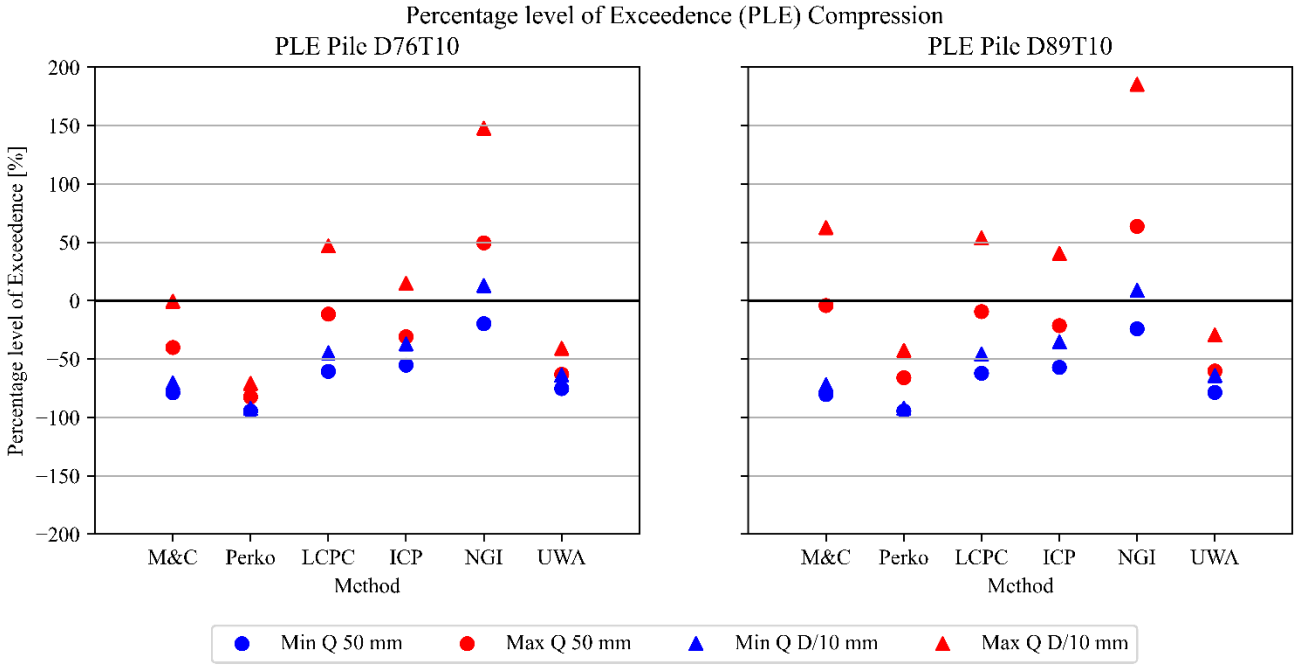

Figure 3. Percentage level of exceedance from compression tests. Red indicates the maximum value of PLE and blue indicates the minimum value of PLE. Triangles and circles indicate the two different definitions of failure at D/10 mm and 50 mm respectively.

Evaluating the reliability of existing methods for predicting installation torque of screw piles in saturated sand: A comparative study

Évaluation de la fiabilité des méthodes existantes pour prédire le couple d'installation des pieux à vis dans le sable saturé: Une étude comparative

ABSTRACT: Screw piles have been the subject of extensive research, with various methodologies proposed to predict installation torque from earth pressure theory-based and Cone Penetration Test (CPT)-based perspectives. Accurate prediction of installation torque is crucial for determining the required equipment, assessing the suitability of screw piles as a foundation solution, and ensuring that the pile material does not yield under the installation torque necessary for a specific installation depth. This study aims to modify existing methods and adapt them to the unique geometry of the screw piles investigated at Aalborg University. The methodologies compared in this study are based on experiments in saturated sand carried out at the laboratories at Aalborg University. The results indicate that earth pressure theory-based approaches provide more consistent outcomes, while CPT-based methods exhibit greater scatter. Consequently, it is concluded that current methods for predicting installation torque are unreliable, necessitating further research.

RÉSUMÉ: Les pieux vissés ont fait l'objet de recherches approfondies, avec diverses méthodologies proposées pour prédire le couple d'installation à partir de la théorie de la pression terrestre et de l'essai de pénétration au cône (CPT). Une prédiction précise du couple d'installation est cruciale pour déterminer l'équipement nécessaire, évaluer l'adéquation des pieux vissés en tant que solution de fondation et s'assurer que le matériau du pieu ne cède pas sous le couple d'installation nécessaire pour une profondeur d'installation spécifique. Cette étude vise à modifier les méthodes existantes et à les adapter à la géométrie unique des pieux vissés étudiés à l'Université d'Aalborg. Les méthodologies comparées dans cette étude sont basées sur des expériences dans du sable saturé réalisées dans les laboratoires de l'Université d'Aalborg. Les résultats indiquent que les approches basées sur la théorie de la pression des terres fournissent des résultats plus cohérents, tandis que les méthodes basées sur les CPT présentent une plus grande dispersion. Par conséquent, il est conclu que les méthodes actuelles de prévision du couple d'installation ne sont pas fiables et qu'il est nécessaire de poursuivre les recherches.

Keywords: Screw piles; earth pressure; CPT; experiments.

1 INTRODUCTION

The common practice for installing piles in soil, is driving piles or bored piles however, for screw piles the installation procedure is different since it is being inserted into the ground by rotation and in some cases exerted an axial force. Due to the difference in installation methods, it is essential to understand the effects of rotating the pile down into the soil and how to minimize the soil disturbance during installation. Here (Ghaly and Hanna, 1991) suggested an installation rate of one pitch per rotation, which is an indication of the influence of the pile geometry on the disturbance of the soil. This effect is similar to that experienced through boring holes.

Prediction of installation torque is a necessity for ensuring a safe and reliable installation of screw piles in different soil conditions. This paper seeks to compare existing methods for predicting the installation torque based on full-scale laboratory testing in the 'Sand Box' at Aalborg University. The test setup is 4.4 x 2.5 meters and 3.2 meters in depth.

2 EXPERIMENTS

The full-scale laboratory test conducted in this study is performed on six different pile geometries, where a principle sketch is illustrated in Figure 1.

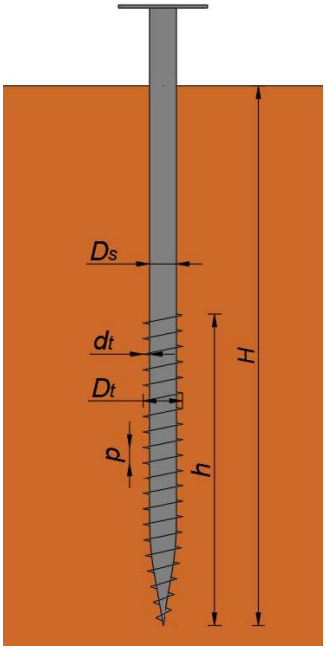

Figure 1. Principle sketch of screw piles used at Aalborg University.

For all piles, the installation depth, *H*, is kept constant at 1.7 meters and the pitch, *p*, for all pile configurations are the same, 50 millimetres and the thickness, *t*, of the steel is 5 millimetres and finally, the threaded length, *h,* is 1 meter. The geometrical sizes of the screw piles are listed in Table 1. The naming of the piles is based on the diameter, D, and the thread size, T.

Table 1. Geometrical sizes of studied screw piles.

Pile Name	D_s [mm]	d_t [mm]	D_t [mm]
D76T10	76	10	96
D76T20	76	20	116
D89T10	89	10	109
D89T20	89	20	129
D115T20	115	20	155
D140T20	140	20	180

2.1 Preparation of the Sand Box

Before installation of the screw piles, the test set-up must be prepared for desired soil state. This is carried out by liquefying the soil and reverting it back to the loosest state, which subsequently is vibrated to the desired soil state. The vibration of the saturated sand is carried out in a manner to minimise boundary effects and obtaining relative densities of approximately 50%, 70% and 85%. The soil state is investigated with small cone penetration tests (CPTs), where six CPTs, at different locations in the Sand Box, are performed to study the uniformity of the prepared saturated sand.

2.2 Installation

The screw piles are installed at the desired positions by applying torque with a steady rate of one pitch per rotation minimising the soil disturbance (Ghaly and Hanna, 1991). During installation, the installation torque and depth are measured with a torque measurement device and LiDAR measurements. The output of the installation is an installation curve, which is illustrated in Figure 2 for a D89T10 pile.

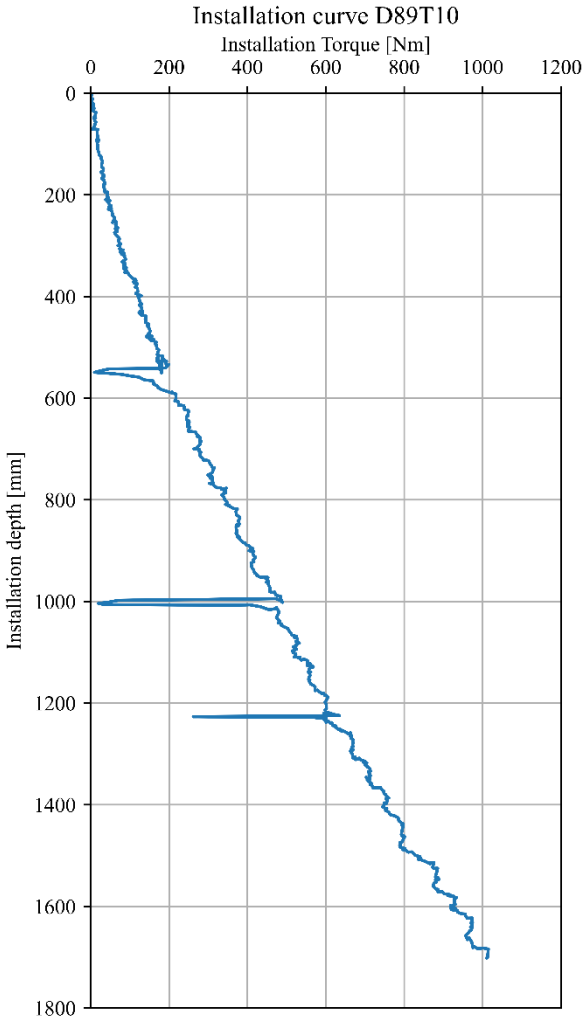

Figure 2. Example of installation curve of a D89T10 pile.

The installation torque, which is determined from the installation curve, is taken as the mean torque over the last rotation, which alleviates some of the uncertainty associated with the measurement, such as observing a spike in the torque.

2.3 Extend of experiments

In this paper, a sample size of 64 piles is studied however, some are regarded as outliers and thereby neglected when evaluating the studied methods. Three piles were omitted due to the following reasons:

- Unexpected low torque measurements, the measuring device failed.
- Abrupt change in installation speed and, thereby greater disturbance of soil

Thereby, the sample size was reduced to 61 piles.

3 METHODS

Predicting the installation torque is evaluated based on different methods where two different approaches are studied, earth pressure-based methods and CPT-based methods, respectively. The older methods were based on earth pressure theory, whereas newer studies have been based on CPT measurements. The following methods have been adapted in accordance with the screw pile geometries illustrated in Figure 1 and listed in Table 1.

3.1 Earth pressure-based methods

Two earth pressure-based methods are investigated. The original approach defined by Ghaly and Hanna was based on a single-pitch helical pile and is a summation of resisting torque contributions from the earth pressure which occur during installation (Ghaly and Hanna, 1991). Later the Ghaly and Hanna method was modified by Sakr with the same considerations with respect to torque contributions of earth pressures occurring during installation (Sakr, 2015). The difference between the two methods lies in the stress analysis where Ghaly and Hanna use total stresses and Sakr studies effective stresses.

3.2 CPT-based methods

Newer approaches are based on utilization of CPT measurements where three different CPT-based methods are studied in this paper. Tsuha and Aoki proposed a model for deep helical piles in sand based on the assumption that the installation torque consists of a resisting moment acting on each helix in conjunction with a moment acting on the shaft (Tsuha and Aoki, 2010). Further development of Tsuha and Aoki's method was done by Gavin who correlated both contributions of the installation torque to CPT measurements and thereby it will be the Gavin method which will be evaluated (Gavin et al., 2013). The prediction of installation torque was further investigated by Al-Baghadi. Initially, the method was modelled for straight shafted piles with two contributions to the installation torque from the shaft and the base of the pile. Later the model was expanded to govern single helix piles with an additional contribution from the helix (Al-Baghadi et al., 2017). Lastly Davidson altered some of the contributions from (Al-Baghadi et al., 2017) and introduced an additional contribution from a helix angle (Davidson et al., 2018).

3.3 Adaptations

The adaptations of the methods are mainly based on geometrical differences since they were developed for single helix piles, thereby the contribution from each helix is summed excluding the first and last helix which will have contributions from the base and leading edge.

4 RESULTS

Based on the adaptation of the earth pressure and CPT-based methods installation torque is calculated. The predicted installation torque based on the described methods is compared to the measured torque. To evaluate the method's accuracy and reliability the predicted torque is plotted against the measured torque and results for all the methods are illustrated in Figure 3. Here it is shown the method proposed by Gavin significantly overpredicts the installation torque and shows great scatter at higher values of the installation torque. For quantifying the reliability and accuracy of the methods linear regression has been performed on all methods with the intersection being zero due to no torque should be predicted when no installation torque is being measured the results of the linear regression are listed in Table 2.

Table 2. Results of linear regression for all methods.

Method	Regression fit slope	R^2
Ghaly and Hanna	0.607	0.946
Sakr	2.567	0.898
Gavin	8.998	0.887
Al-Baghadi	1.809	0.882
Davidson	2.052	0.883

For an ideal fit, the regression fit slope should be equal to 1 which indicates that the methods predict the experimental measurements. The Ghaly and Hanna method has the highest R^2-value which stipulates that the reliability of the earth pressure-based method is a more consistent predictor of the installation torque for the screw piles studied at Aalborg University. Generally, the earth pressure-based methods indicate that they are more consistent in comparison to the CPT-based methods.

To compare and evaluate the two different methodologies one method has been chosen to represent the different approaches. For the earth

pressure-based methods, Ghaly and Hanna are chosen due to the higher R^2-value however, the slope is below 1 which indicates that it underpredicts the installation torque. Contrary to the earth pressure-based method the CPT-based methods overpredicts the installation torque since all slopes are above one, the chosen representative method for CPT-based methods is Davidson. The two representative methods are illustrated in Figure 4 where the regression line and ideal line are added Here it becomes apparent that the Ghaly and Hanna method is the most accurate and consistent method. This is attributed to the theoretical approach from the earth pressure theory and is furthermore, better at predicting installation torque at greater torque measurements where Davidson method shows greater scatter which is further indicated by the lower R^2-value.

5 CONCLUSION

Based on the results depicted in Figure 3-4 and the results from the linear regression listed in Table 2 it can be concluded that existing methods accuracy of predicting the installation torque is inadequate, however, the method shows consistent results which is indicated by the R^2-value. Thereby, the reliability in terms of consistency of existing methods are acceptable. Regarding the overall reliability of existing methods further studies are necessary to achieve a sufficient and adequate method for predicting installation torque for the screw piles studied at Aalborg University.

ABSTRACT: Settlements in soils occur due to changes in effective stress (instant settlements) and creep in time during and after application of the effective stress changes (delayed settlements). In soft clays, the delayed settlement can be significant and must be accounted for. This paper presents a settlement analysis method that accounts for both instant and delayed components. Relations between accumulated creep strain, apparent age of the soil layer and the pre-consolidation stress due to creep are established as 1-D Intrinsic Compression Curves (1-D ICC). The paper describes the parameters used with the 1-D ICC method and how they can be determined from the constant rate of strain (CRS) oedometer tests including a creep phase. The construction and the use of 1-D ICC method to model the settlement development with time during and after consolidation process are also presented.

RÉSUMÉ: Les tassements du sol se produisent en raison de changements dans la contrainte effective (tassements instantanées) et de fluage, en temps, pendant et après l'application des changements de contrainte effective (tassements retardés). Dans les argiles molles, les tassements retardés peuvent être importants et doivent être pris en compte. L'article présente une méthode d'analyse des tassements qui prend en compte à la fois les composantes instantanées et retardés. Les relations entre la déformation de fluage accumulée, l'âge apparent de la couche de sol et la contrainte apparente de pré-consolidation due au fluage sont établies sous forme de Courbes de Compression Intrinsèques en problème monodimensionnel, CCI 1-D. L'article décrit les paramètres utilisés avec la méthode CCI 1-D et comment la méthode peuvent être utilisée pour modéliser le développement des tassements dans le temps.

Keywords: Oedometer tests; instant and delayed strains; embankment settlements.

1 INTRODUCTION

Bjerrum (1967) postulated the concept of instant, $\Delta\varepsilon_i$, and delayed, $\Delta\varepsilon_d$, compression strain due an increase in effective vertical stress, $\Delta\sigma'_v$, and due to creep in a period, Δt, under constant effective stress, respectively, Figure 1.

Based on results from oedometer tests conducted with different periods of time to creep under constant effective stress after consolidation, Bjerrum postulated that lines with equal creep rate, isotaches, are parallel with the Instant 1-D compression line, Figure 2.

The isotache concept and the insight into the creep behaviour of soils have been accumulated in time over many decennia (Den Haan, 2007).

The aim of the paper is to present a simplified method for calculating settlements of soft clays accounting for instant and delayed (creep) compression strains.

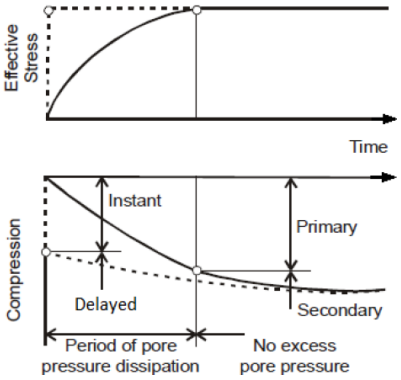

Figure 1. Instant and delayed compression (Bjerrum, 1967).

The method is based on a simplified formulation of tangent creep resistance as a function of apparent age and on an intrinsic compression curve of accumulated delayed strain, ε_c, vs. age of the clay deposit, t_a.

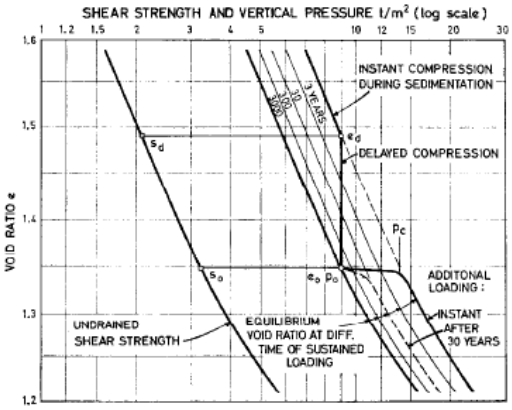

Figure 2. e-log σ'_v diagram showing isotaches (Bjerrum, 1967).

2 INSTANT AND DELAYED COMPRESSION STRAINS

The calculation of compression strains (settlements) due to an increase in effective stress from σ'_1 to $\sigma'_2 = \sigma'_1 + \Delta\sigma'$ in a period of time from t_1 to $t_2 = t_1 + \Delta t$ can be performed separately for instant and creep part, if the stress and time increments, $\Delta\sigma'$ and Δt are small enough to neglect the parameter variation with stress and time.

The delayed (creep) strain increment due to a time interval from t_1 to t_2 can be expressed as:

$$\Delta\varepsilon_{del} = \mu^* \cdot ln\left(\frac{t_2}{t_1}\right) = \frac{1}{r_s} \cdot ln\left(\frac{t_2}{t_1}\right) = \frac{C_\alpha}{(1+e_o)} log\left(\frac{t_2}{t_1}\right) \quad (1)$$

where e_o is the void ratio, and μ^*, r_s, and C_α are tangent creep parameters (for a time interval, Δt_a, from $t_1 = t_a$ to $t_2 = t_a + \Delta t_a$).

The increment of instant strain due to an increment of effective stress from σ'_1 to σ'_2 is calculated as: for $\sigma'_1 < p'_c < \sigma'_2$:

$$\Delta\varepsilon_{inst} = \kappa'^* \cdot ln\left(\frac{p'_c}{\sigma'_1}\right) + \lambda^* \cdot ln\left(\frac{\sigma'_2}{p'_c}\right) \quad (2)$$

The parameters $\kappa'^* = \frac{C'_s}{(1+e_o)\ln 10} = \frac{1}{m'_{OC}}$ refer to instant (without creep) compression within the over consolidation (OC) stress range in contrast to $\kappa^* = \frac{C_s}{(1+e_o)\ln 10} = \frac{1}{m_{OC}}$ which refer to total, instant including creep compression (as measured in oedometer tests) in the same, OC range.

By equating creep strain with plastic strain in normal consolidation range, (Leroueil et al., 1985), found that the ratio of the effective stresses, σ'_1 and σ'_2, at the same strain, measured in two oedometer tests with the same soil and initial state performed with two different strain rates, $\dot{\varepsilon}_1$ *and* $\dot{\varepsilon}_2$, are related by:

$$\frac{\sigma'_1}{\sigma'_2} = \left(\frac{\dot{\varepsilon}_2}{\dot{\varepsilon}_1}\right)^B, \; B = \frac{C_\alpha}{C_c} = \frac{\mu^*}{\lambda^*} = \frac{m_{NC}}{r_s} \cdot \quad (3)$$

Consequently, in the NC range, the rate parameter, B, is related to C_α and C_c as given in Eq. (3), and is found to depend on the type of clay (Mesri and Godlewski, 1977; Leroueil et al., 1985). The Eq. (3) is based on Janbu's definition of constrained modulus in NC range (Janbu, 1963), where σ'_r is the reference stress.

Following the Eq. (3), a relation can be obtained between creep and compression parameters in NC range:

$$\mu^*_{NC} = \frac{B}{M/\sigma'} = \frac{B}{m_{NC}} \quad (4)$$

in which M is the compression tangent constrained modulus and σ' is the applied effective stress in NC range.

Laboratory tests show that the isotaches corresponding to a constant ratio t_{ai}/t_{ai-1} are not equidistant but are narrower as the apparent age increases and, consequently, that the creep rate decays more than linear with log of time, Figure 3.

Figure 3a presents the results from special compression tests with four 125 mm long, sub-elements connected in series by (Mesri and Feng, 1986 and Mesri et al., 1995). Leroueil et al. (1986) and Leroueil and Marques (1996) reinterpreted the results to define the compression curves of each sub-element subjected to consolidation under a pressure increment from 97 to 138 kPa, followed by creep phase at constant stress of 138 kPa. Also drawn on the figure is a fictitious isotaches assuming B= 0.03 for St-Hilaire

clay. The set of isotaches coincides very well with the observed behaviour. The blue points in Figure 3b are constructed as follows. The void ratio at the intersection between an isotache and the vertical line corresponding to constant stress of 138 kPa in Figure 3a is plotted against the strain rate of this isotache (the lower horizontal axis). The plot e vs. strain rate shows that the isotaches are not equidistant (Δe from 10^{-8} to 10^{-9} min^{-1} is less than Δe from 10^{-5} to 10^{-6} min^{-1}).

In our opinion the compression curves of the four sub-elements in Figure 3 include both instant and delayed compression strains (Hypothesis B). The monitored strain rates match the set of isotaches and prove that the clay behaviour is strain rate dependent during primary consolidation.

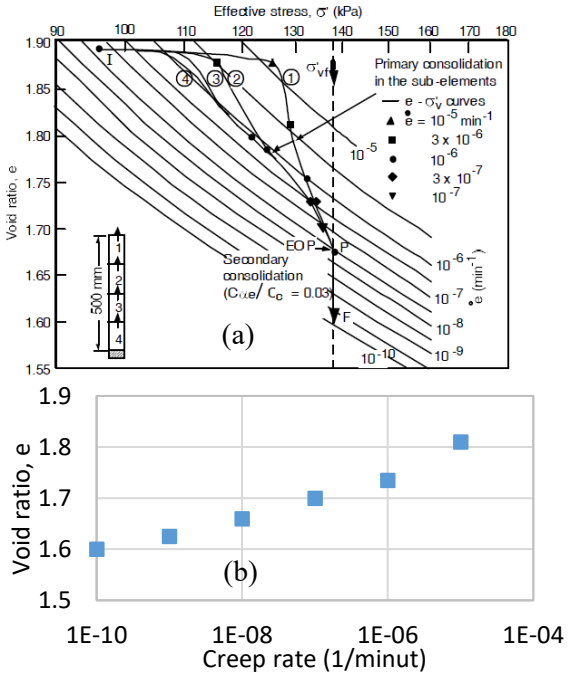

Figure 3. a) Consolidation of Saint-Hilaire clay; from Mesri et al. (1995); from Leroueil (2006) b) Void ratio versus creep rate from the data in figure (a).

Further arguments for hypothesis B may be found in Degago et al. (2011).

The results shown in Figure 3a are used to obtain a picture of distance between two consecutive isotaches in log scale as a function of creep rate. As the isotaches represent lines of equal creep rate and, at the same time, lines of equal creep time, the relation between creep rate and time is found from the definition of creep rate:

$$\dot{\varepsilon}_c = \frac{\mu^*}{t} \qquad (5)$$

If creep parameter, μ*, is independent on time, the isotaches are equidistant. The blue point curve, constructed as void ratio distance between two consecutive log cycle creep rates (10^{-5} 1/min, 10^{-6} 1/min, and so on) at stress 138 kPa, shows, however, that the isotaches are not equidistant, indicating a non-linear creep parameter.

The non-linearity of creep parameter has been discussed by many researchers, e.g., (Watabe et al., 2012, Karim and Lo, 2020, Yuan et al., 2015), (Vergote et al., 2021). Based on several CRS oedometer tests including creep phases under constant stress, the following expression is proposed for creep parameter as a function of time:

$$\mu^* = \frac{\mu^*_{NC}}{[1+\alpha \cdot ln\left(\frac{t}{t_{inst}}\right)]} \qquad (6)$$

where α is empirical factor determined experimentally. t_{inst} is the time corresponding to virgin (instant) compression line along which only instant strains are developed as a function of applied effective stress (no creep strains.) A value of 1 second is assumed for t_{inst}.

Using Eqs. (5) and (6) we obtain the differential equation for the accumulated creep strain rate at the time t:

$$d\varepsilon_c = \mu^* \cdot \frac{dt}{t} = \frac{dx}{r_{sNC} \cdot x \cdot [1+\alpha \cdot ln(x)]} \qquad (7)$$

with $x = t/t_{inst}$. The differential equation (7) is integrated to obtain the accumulated creep strain at age, t_a, under constant effective stress, p'_0:

$$\varepsilon_c = \frac{1}{D} ln\,[1 + \alpha \cdot ln\,(\frac{t_a}{t_{inst}}] \qquad (8)$$

where $D = r_{sNC} \cdot \alpha$

From Eq. (8) we can obtain a relation between the apparent age, t_a, and the accumulated creep strain, ε_c, as:

$$t_a = t_{inst} \cdot exp\,\{\frac{1}{\alpha} \cdot [exp(D \cdot \varepsilon_c) - 1]\} \qquad (9)$$

If accumulated creep strain is equated to plastic strain, the intrinsic relation between over-consolidation ratio and age is obtained as:

$$\frac{p'_c}{p'_o} = [1 + \alpha \cdot ln\left(\frac{t_a}{t_{inst}}\right)]^A \qquad (10)$$

with $A = \frac{1}{D \cdot (\lambda^* - \kappa'^*)}$.

The pre-consolidation pressure, p'_c, is defined by the intersection between unloading-reloading line (with slope κ'^*) from p'_0, ε_0 and instant compression line (slope λ^*) in contrast to the apparent, oedometer pre-consolidation stress, p'_{ca}, defined at the intersection between unloading-reloading line (slope

κ^*, without delayed strains) from p'_0, ε_0 and oedometer isotach (slope λ^*), as seen in Figure 4.

To verify the validity of the proposed formulation for creep parameter, an attempt is made to model experimental results of normalized pre-consolidation (p'_{ca}/p'_{c0}) where p'_{c0} is the apparent pre-consolidation stress at a strain rate of 10^{-7} 1/s, as a function of creep rate, Figure 5. The blue line depicts the relationship predicted based on Eq.(6). As seen from Figure 5, the agreement of prediction to measurements is encouraging. Similar good agreement is shown in Figure 6 for Osaka Bay clays.

Experimental results show also that r_s is low when creep is measured at effective stress, $\sigma' \geq p'_{ca}$, and r_s increases gradually as the ratio σ'/p'_{ca} decreases, (e.g., Christensen, 1985). This is since the age of the clay and, consequently, r_s, increases as σ'/p'_{ca} decreases.

Using the proposed formulation of creep parameter, Eq.(6), and combining Eqs.(8)-(10), the relation between μ^* (or r_s) and σ'/p'_{ca} is obtained as follows:

$$\mu^* = \frac{1}{r_s} = \mu^*_{NC} \cdot \left(\frac{\sigma'}{p'_{ca}}\right)^{1/A} \qquad (11)$$

The results of creep oedometer tests on Bangkok clay, showing measured r_s vs. σ'/p'_{ca} and the relation predicted by Eq. (11) are shown in Figure 7.

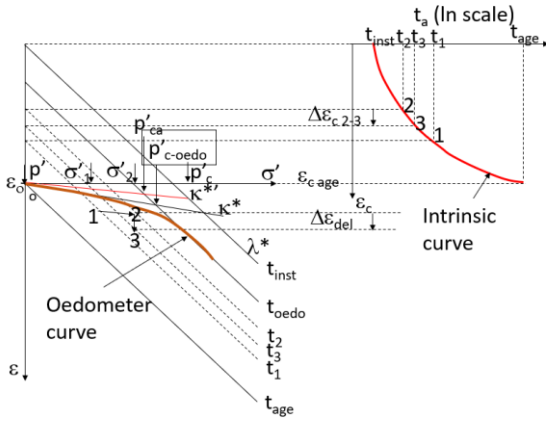

Figure 4. Intrinsic creep strain curve: ε_c vs. ln (t_a).

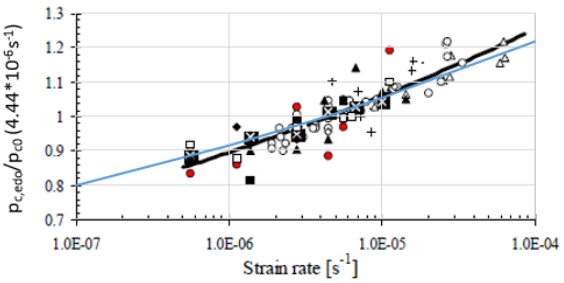

Figure 5. Normalized pre-consolidation vs. strain rate at a strain of 10% for finish clays, from (Leroueil et al., 1985). Blue line prediction uses Eq.(6) and α=0.005, λ=0.35, k*'=0.002 and r_{sNC}=44.*

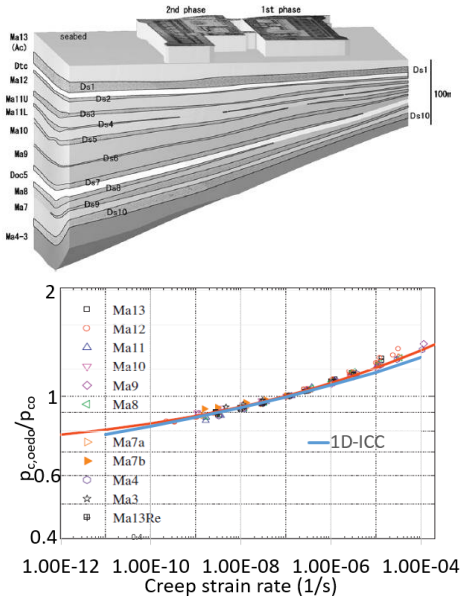

Figure 6. a. Stratigraphy model of Kansay International Airport; b. p'_{ca}/p'_{c0}-log $\dot{\varepsilon}_c$ relationship for clays at Osaka Bay (red curve – proposed trend line, (Watabe et al., 2012), blue curve predicted by Eq. (6)). ($\alpha = 0.1$; $\lambda^* = 0.3$; $\kappa^{*\prime} = 0.002$; $r_{sNC} = 47$).

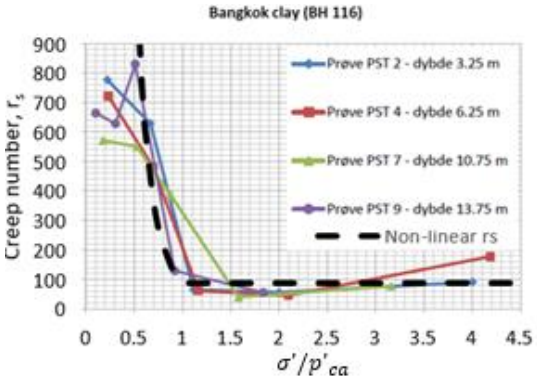

Figure 7. Variation of r_s with σ'/p'_{ca} (Athanasiu, 2012).

3 SOFT CLAY BEHAVIOR UNDER LOADING AND INTRINSIC CURVES

Experimental results reveal that creep rate decreases with time (Figure 3 and Figure 7) and that stress-strain curves obtained in oedometer tests depend on the rate of strain at which the test is performed (Figure 5 and Figure 6)

The accumulated creep strain during consolidation in geological time can be described by an intrinsic relation (1-D Intrinsic Compression Curve) between accumulated creep strain and apparent age of the deposit, ε_c vs. t_a, Eq. (8) as shown in Figure 4.

The 1-D ICC is the "fingerprint" of the creep geological history of the clay deposit.

The strain changes due to changes in stress and time can be calculated using the frame of 1-D ICC as follows.

Let the point 1 in Figure 4 describe the stress-strain-age (σ'_1, ε_{c1}, p'_{c1} and t_1) conditions before a new load change is applied. If the effective stress is increased from σ'_1 to σ'_2, the apparent age will be changed from t_1 to $t_2 < t_1$ (the clay becomes "younger" and with a lower accumulated creep strain). The increment of instant strain, $\Delta\varepsilon_{inst}$, is calculated using Eq.(2).

The preconsolidation stress remains unchanged, $p'_{c2} = p'_{c1}$ if $\sigma'_2 < p'_{c1}$ but must be updated, $p'_{c2} = \sigma'_2$ if $\sigma'_2 > p'_{c1}$.

The accumulated creep strain, is then calculated as plastic strain:

$$\varepsilon_{c,2} = (\lambda^* - \kappa'^*) \cdot \frac{p'_{c,2}}{\sigma'_2} \qquad (12)$$

and the apparent age t_2 is calculated using Eq.(9). Let the time required by consolidation process to increase effective stress from σ'_1 to σ'_2 be Δt . The change in delayed strain due to Δt is equal to the increase in intrinsic accumulated strain from ε_{c2} to ε_{c3} where ε_{c3} corresponds to the apparent age in point 3 ($t_3 = t_2 + \Delta t$) and can be calculated using Eq.(8). The change in delayed strain is then calculated as:

$$\Delta\varepsilon_{del} = \varepsilon_{c,3} - \varepsilon_{c,2} \qquad (13)$$

The pre-consolidation stress at point 3 must now be updated due to age changing to t_3 using Eq.(9) to obtain p'_{c3}/σ'_3, ($\sigma'_3 = \sigma'_2$) as a function of t_3.

The procedure described above can be repeated for all steps of a consolidation process, where in each step the stress-strain-age state of point 1 is updated from the stage at point 3 in previous step.

4 CALIBRATION OF PARAMETERS USING THE CREEP PART OF OEDOMETER TEST

During the creep part of the oedometer test the effective stress is, theoretically, kept constant. Care must be taken to align the measured time, t_m, with the apparent age time, t_a: at the start of the creep test, t_a is equal to t_{oedo}, Figure 8.

The calibration requires two sets of simple iterations, one for compression indices, (λ* or m_{NC}, κ* and κ*') and one for creep parameters (B or r_{sNC} and α). The accuracy of the geological age of a clay deposit depends on how well the geological history of the deposit is known. In addition, it is assumed that pre-consolidation pressure is induced exclusively by creep, i.e., the clay is NC, aged clay.

The comparison between measured and computed accumulated strains are shown in Figure 9.

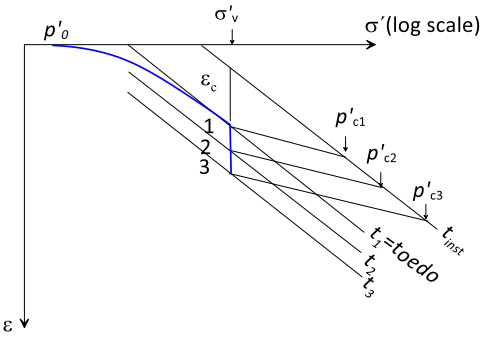

Figure 8. Creep test part starts on t_{oedo} line.

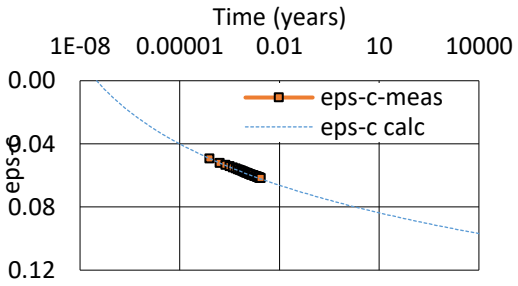

Figure 9. Comparison of measured and computed creep strains during creep part of the test.

5 BACK-CALCULATION OF OEDOMETER TEST

Next the calibration of 1-D ICC method is illsustrated using incremental oedometer loading (IL) test results of samples taken from the well-known Väsby test fill, Sweden.

The Väsby test fill (Chang, 1981), consists soft sediments of glacial and post-glacial origin.

Figure 10 presents the results of incremental loading (IL) oedometer test on sample taken with 200 mm Laval sampler from 4.2 m depth (Leroueil et al., 1985, Degago and Grimstad, 2016).

The consolidation and creep settlement parameters resulted from matching the oedometer curve with the back-calculated curve in Figure 10, are presented in Table 1.

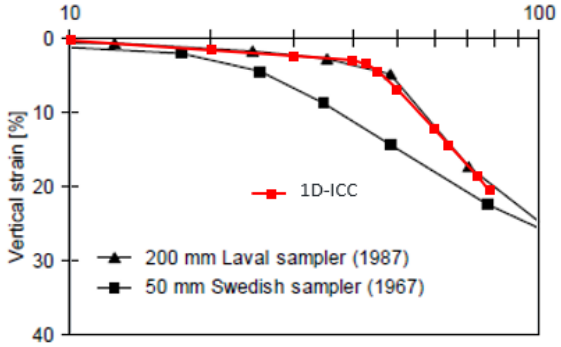

Figure 10. Calibration of incremental oedometer test results on samples taken at 4.2 m from Väsby field depth using two different samplers, data from (Leroueil and Kabbaj, 1987).

Table 1. Calibrated parameters.

Parameter	Units	Value
κ^*	-	0.1
λ^*	-	0.3
κ'^*	-	0.02
B	-	0.06
α	-	0.06
t_{age}	years	1000
p'_{ca}	kPa	44.9
$p'_{c\text{-}oedo}$	kPa	50
p'_0	kPa	30

6 CONCLUSIONS

A time resistance formulation is proposed to describe the variation of creep parameter, μ^*, with apparent age of a clay sediment.

Experimental results are compared to those predicted by the proposed formulation and the comparison shows fair good agreement.

The paper defines an intrinsic compression curve of accumulated creep strain of a clay layer effectively supporting the overburden pressure throughout the age of the deposit. This is used as a framework to calculate instant and delayed strains caused by steps of effective stress and time increments.

ACKNOWLEDGEMENTS

The authors are indebted to their colleagues, particularly to Anders Bye and Joar Spencer Gloppestad for fruitfull discussions regarding the consequences of delayed strains on settlements of offshore structures.

The contribution from workshops organized at Norwegian University of Science and Technology, NTNU, on creep settlements are also gratefully aknowledged.

ABSTRACT: In the context of the French National Project ASIRI+, the behaviour of rigid inclusion systems with thin platforms has been studied using physical centrifuge models. These systems are particularly useful in cases of road construction on soft soil subjected to significant settlement, or for studying the behaviour of rigid inclusion systems during construction phases. However, these systems differ from classic reinforcement systems with rigid inclusions due to the specificity of the loading. Indeed, on linear infrastructure or circulating platforms, the loadings are limited to small areas, potentially loading only one inclusion at a time and failing to generate a beneficial arching effect. Moreover, these loadings are usually moving over time, which modify load transfer and repartition in the rigid inclusions. To complement the centrifuge model study, we propose a numerical study in this paper to compare results and help analyse the behaviour of these systems. We first discuss the model fitting on the centrifuge results, followed by a parametric study to analyse the effect of key parameters on load transfer and failure mechanisms. Lastly, we developed a model representing the behaviour of these structures under mobile loading. This allowed us to study the evolution of the load transfer mechanism and the elastic-plastic behaviour of the load transfer platform under several loading cycles.

RÉSUMÉ: Dans le cadre du Projet National ASIRI+ (France), le comportement d'un système de renforcement de sol par inclusion rides avec une plateforme de transfert de charge mince a été étudié à l'aide d'un modèle réduit centrifugé. De tels systèmes de renforcement de sol sont particulièrement intéressants pour la construction de routes sur des sols meubles subissant d'importants tassements ou pour l'étude des phases de construction. Cependant, de tels systèmes diffèrent des systèmes classiques de renforcement par inclusion rigide par la spécificité de leur chargement. En effet, sur les infrastructures linéaires ou les plateformes de circulation, les charges sont limitées à des zones restreintes, et ne sollicitent parfois qu'une seule inclusion en même temps, ne créant pas les effets d'arche de report de charge. De plus, ces charges sont généralement mobiles, ce qui modifie la répartition des charges dans les inclusions. Pour compléter l'étude sur modèle réduit centrifugé, il est proposé une étude numérique dans le but de confronter les résultats et d'analyser le comportement du système. Ainsi, dans cet article est présenté le travail de calage du modèle numérique sur les résultats expérimentaux, puis une étude paramétrique sur quelques paramètres clés dans le but d'analyser leurs influences sur les mécanismes de report de charge et de rupture. Enfin, un modèle représentant le comportement de la structure soumise à un chargement mobile est présenté. Il permet d'étudier la variation des effets de transfert de charge et le comportement élastoplastique de la plateforme sous l'influence de plusieurs cycles de chargement.

Keywords: Rigid inclusions; numerical modelling; mobile loading.

1 INTRODUCTION

The rigid inclusion system aims to create a composite soil by including a network of rigid elements (similar to micro-piles) inside the soft soil layer. Such systems are created in order to support buildings and construction in areas of soft soil that are subject to potential high settlement (ASIRI, 2012). In the process, a Load Transfer Platform (LTP) is constructed on top of the composite soil with a granular material. The behaviour of such a system results in an unequal sharing of the surface load between the soil and rigid inclusions. Indeed, the differential settlement between the soft soils and the rigid inclusions creates specific force chains between the granular elements, focusing the load on the rigid inclusions. This effect is known as the arching effect and can be represented in Figure 1.

In 2019, the French National Project was launched with the aim of developing rigid inclusion systems

and improving the comprehension of their behaviour. Among the project's works, we focus here on the understanding of rigid inclusion systems under mobile load solicitation. Indeed, the rigid inclusion reinforcement process can be used for circulation platform reinforcement, for example. In such cases, the loads are constituted by trucks or machinery. These conditions might also occur during the construction stage (compaction of the load transfer platform). Therefore, the loads are restricted to a small area and are not always on top of an inclusion or covering several inclusions. Such loading cases do not correspond to classical rigid inclusion cases and cannot generate an arching effect.

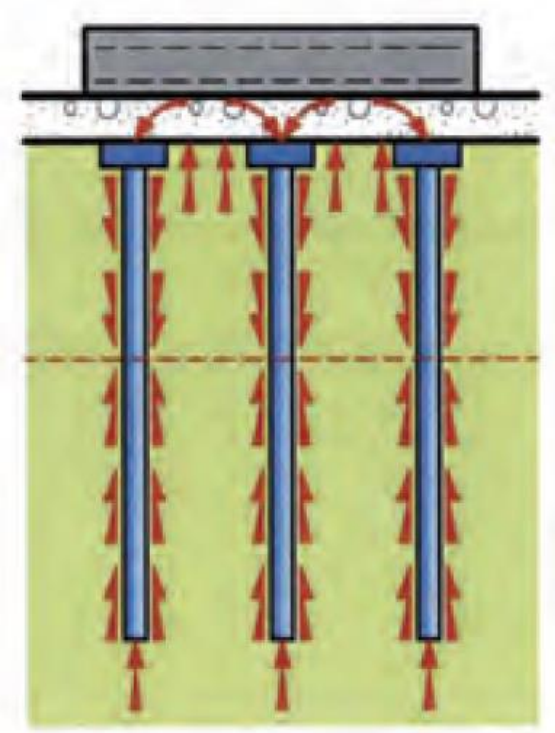

Figure 1. Behaviour of rigid inclusion system (ASIRI, 2012)

2 CENTRIFUGE AND NUMERICAL MODELING

In order to address such loading cases, several models have been studied using a centrifuge test device at the University Gustave Eiffel in Nantes (Corte 1984). The test program consisted of 15 test configurations. A slab was loaded on top of a soil model reinforced by rigid inclusions (Dubreucq et al., 2023). We focus here on two of these configurations: one where the slab was placed on top of an inclusion, and one where the slab was placed between two inclusions (see Figure 2 and Table 1)

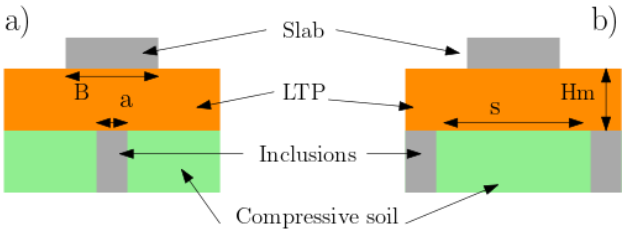

Figure 2. Studied cases a) and b).

Table 1. Model size parameters at prototype scale.

S	a	B	Hm
100 cm	10 cm	30 cm	60 cm

The numerical model is built using the FEM software CESAR LCPC (Humber et al. 2005) at prototype scale. The model is not representative of realistic dimensions, but is designed to explore and understand the behaviour of the system. The model is represented in 2D, with aluminium slab and inclusion. The compressive soil is modelled by expanded polystyrene as it represents an equivalent soil. The LTP is modelled by dense Hostun sand.

The numerical model was built according to the presented geometry. The material parameters were selected as follows: linear elastic for the aluminium elements, perfectly plastic Mohr-Coulomb for the LTP, and hardening Von Mises model for the equivalent soft soil. The parameters of the models were fitted on two preliminary tests of slab only on sand and only on soft soil. The parameters are listed in table 2, and fitting results are presented in Figure 3.

Table 2. Models parameters.

	Aluminium	Sand	Soft soil
$\boldsymbol{\rho}$	2700 kg/m^3	1650 kg/m^3	15 kg/m^3
$\boldsymbol{E}$	62 GPa	5	0.8MPa
$\boldsymbol{\nu}$	0.24	0.25	0.01
$\boldsymbol{\phi}$	-	36°	-
$\boldsymbol{c}$	-	3 kPa	-
$\boldsymbol{\psi}$	-	23°	-
$\boldsymbol{K_{VM}}$	-	-	30 kPa
$\boldsymbol{H_{VM}}$	-	-	230 kPa/def

Based on the initial models, a second model was built with a mobile load. It represents a rolling load placed on top of the LTP and displaced from one side to another for multiple loading cycles. The mobile load is set to represent a service load at a fraction of the ultimate load determined from previous computations.

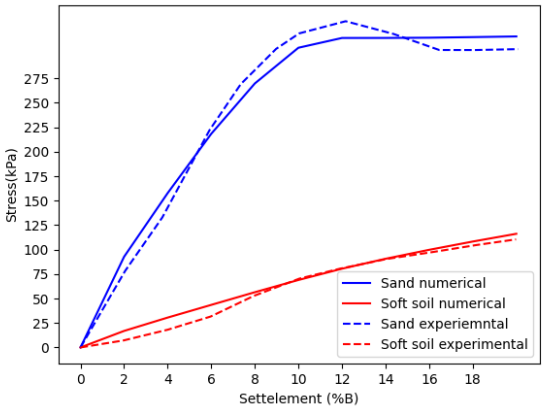

Figure 3. Results of fitting models.

3 RESULTS OF NUMERIALC MODELS

The results of experimental models are not presented in detail in this work.

3.1 First models

The results of models a) and b) are presented in Figures 4 and 5.

Figure 4 presents the shearing band pattern computed for both models. The patterns are the same as those obtained with experimental models.

Figure 5 presents the load-displacement results for both models and both experimental and numerical models. We observe a very good agreement between numerical and experimental results. Moreover, we can observe that the overall behaviour of the system is similar regardless of the position of the slab. We have confirmed this observation with complementary studies with intermediate positions of the slab (not presented here).

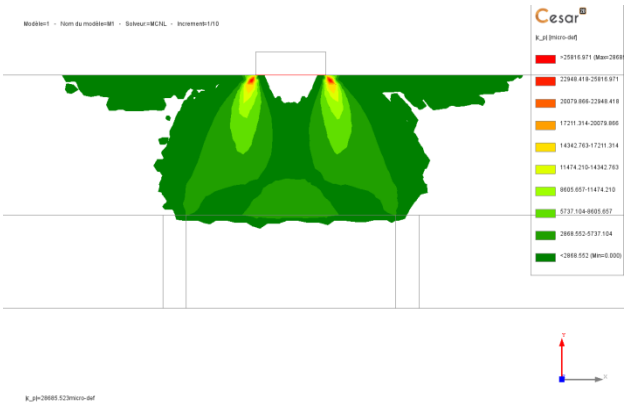

Figure 4. Shearing band patterns on cases b).

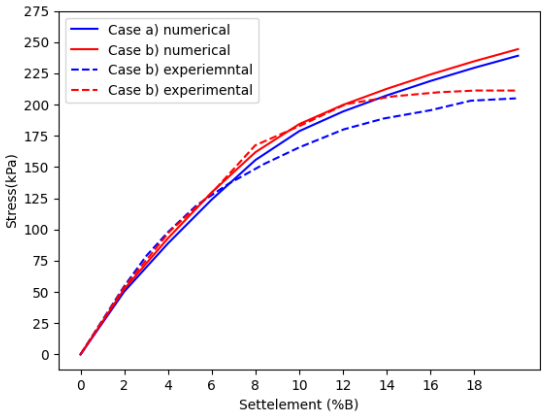

Figure 5. Results for case a) and b).

3.2 Mobile load models

Some results of the mobile loading models are shown on Figure 6. These figures represent the vertical stress at the interface between LTP and composite soil. This figure clearly shows that the arching effect causes the stress to be much more important on top of the inclusion. The weight load of the LTP is focused on the inclusion, and the soft soil is less loaded. However, after the first loading cycle, we observe that the arching effect was destroyed by the mobile loading. Indeed, the load on top of the inclusion is almost null and the load is now sheared onto the top of the soft soil.

This phenomenon can be explained as the mobile loading is not wide enough to transfer its load to the inclusion regardless of its position. Therefore, while between two inclusions, it generates plastic strain, forcing the mechanical interaction between the LTP and soft soil. Mechanically, this results in an unloading of the inclusions.

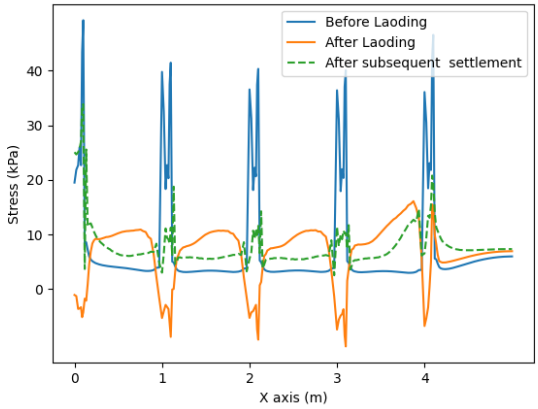

Figure 6. Vertical stress on surface between LTP and composite soil.

3.3 Subsequent settlement

As this phenomenon could be damaging to the arching effect and final behavior of the system, we studied the effect of subsequent settlement. Indeed, we postulate that such behavior will mostly occur during the construction phase of the LTP compaction. Moreover, as it overloads the soft soil, this phenomenon will result in subsequent and continuous settlement of the soft soil, regenerating the arching effect.

This hypothesis was tested by imposing a second settlement phase after the loading cycles. This results in the development of a new arching effect, as shown in Figure 6.

4 CONCLUSION

In this paper, we have presented part of the numerical work prepared in parallel with experimental modelling conducted in the scope of the French National Project ASIRI+. The goal of this work is to model and observe the behaviour of a rigid inclusion system subjected to small slab loading and mobile loading, with a thin load transfer platform. In such cases, the arching effect will not appear as the loading zone is too small to interact with more than one inclusion. Therefore, the resistance of the system should be studied with care. We present numerical modelling which shows good agreement with the experimental results and promising potential. In a second model, we expose the behaviour of a similar system subjected to mobile loading. The mobile loading applied on the LTP disturbs the chain forces in the granular layer and disrupts the pre-existing arching effect in the LTP, which may have an influence on the final behaviour of the system. However, subsequent settlement may regenerate the arching effect.

ACKNOWLEDGEMENTS

The work presented in this article is based on the master thesis of Nizar Ouchten. It is part of the French National Project ASIRI+, and is self-funded by the University Gustave Eiffel.

ABSTRACT: A series of static penetration tests of trapezoidal walls in dense Fontainebleau sand were performed in the geotechnical centrifuge at Gustave Eiffel University. The models of wall with three different shapes (straight profile with thickness D=16mm, 0.75 degree and 1.5 degree of taper angle) but with the same volume were used. The soil mass was instrumented with five stress cells located at two levels at 2D, 4D and 6D distance from the wall axis to follow the stress state changes during the model penetration. Moreover, three pressure sensors were integrated on the model surface to track the changes of normal stress during the continuous penetration of the wall. Thus for the three walls of different geometry the evolution of the following variables is considered during monotonic penetration of the wall: 1) total vertical force; 2) horizontal stresses in the soil mass; 3) normal stresses on the wall surface.

RÉSUMÉ: Une série de pénétrations statiques d'une paroi dans du sable de Fontainebleau dense est effectuée dans la centrifugeuse géotechnique de l'Université Gustave Eiffel. Le volume de chaque paroi est identique mais leur profile varie: rectangle d'épaisseur D=16mm ou trapèze d'angle 0.75° ou 1.5°. Pour suivre l'évolution des contraintes pendant le fonçage continu du modèle, le massif du sol est instrumenté: cinq capteurs de contrainte distribués à deux niveaux à la distance de 2D, 4D et 6D de l'axe de paroi. Trois capteurs de contrainte sont de plus intégrés dans la paroi afin de mesurer la contrainte normale lors du fonçage de la paroi, dont l'effort vertical de fonçage est enregistré. Ainsi pour les 3 géométries, on compare pendant le fonçage, l'évolution: 1) des efforts de fonçage; 2) des contraintes horizontales dans le massif; 3) des contraintes normales à la paroi.

Keywords: Installation effects; dense sand; pushed-in piles.

1 INTRODUCTION

The installation of displacement piles induces significant changes of displacement, strain, and stress fields in the surrounding soil. These effects are considered in the physical modelling of tapered piles/trapezoidal walls in centrifuge in the present study. The testing program includes the installation of pushed-in continuous walls with observation of displacement patterns and stress evolution in the vicinity of the model. In addition, the tapered piles are installed in-flight by driving and pushed-in mode to evaluate their bearing capacity. Some studies on interface friction are also planned within this project (Foray et al., 1998; Bałachowski, 2006). This paper focuses on the installation of tapered walls with stress evolution in the soil mass and on the model surface.

Tapered piles are characterized by a gradually decreasing cross section with depth. Timber piles are traditional examples of such structures (Christin et al., 2013). Nowadays, concrete precast or cast-in place piles (Khan et al., 2008; Lee et al., 2009), steel or composite tapered piles are also applied (Sakr et al., 2004). They can be also used for densification of sandy subsoil (Zil'berberg & Sherstnev, 1990; Stuedlein et al., 2016).

2 PHYSICAL MODEL SETUP

In the range of Geolab (2021) European project, a series of centrifuge tests was performed at Gustave Eiffel University (Nantes, France) in the GERS-CG lab (Gers-CG, 2023). This geo-centrifuge (Thorel, 2022) has a radius of 5.5m and a total mass of 2tons can be embarked in the swinging basket.

2.1 Soil mass preparation and instrumentation

Prior to each test, the homogeneous soil mass was prepared using sand raining technique to achieve designed relative density 0.68 and the dry bulk density of 1620 kg/m^3 measured with boxes disposed at the bottom of the container. Uniform Fontainebleau quartz

sand (NE34) with d_{50}=0.206 mm was used with parameters described in (Andria-Ntoanina et al., 2010; Beroya-Eitner et al., 2022). The container with a transparent glass (Figure 1) and inside dimensions of 800×450 mm enables visual observation of soil behaviour during wall installation.

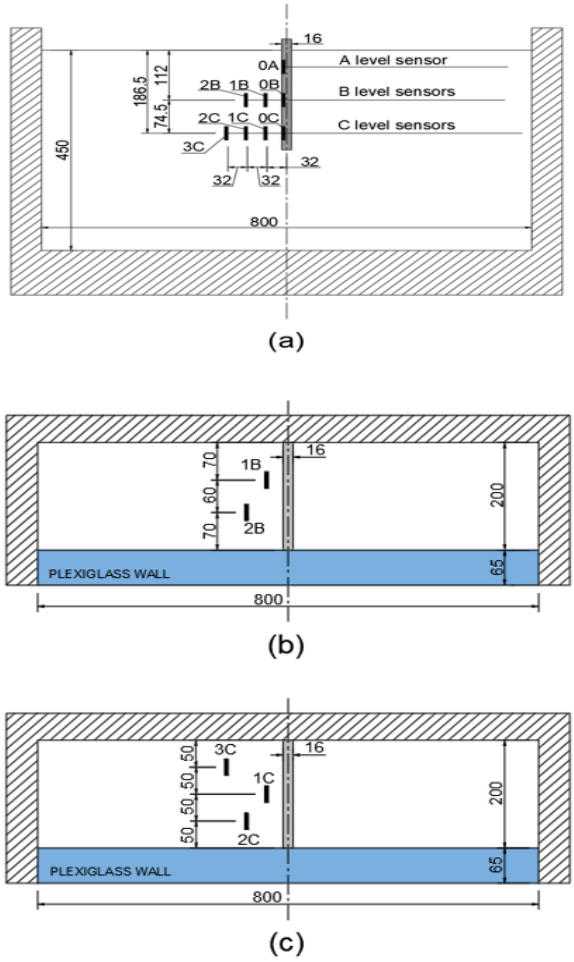

Figure 1. Centrifuge model setup and soil instrumentation: (a) vertical cross-section, (b) B level horizontal cross-section, (c) C level horizontal cross-section. (All dimensions in [mm]).

Kyowa small-sized soil pressure transducers having an outer diameter of 30 mm and a pressure-sensing surface diameter of 23 mm were used. Five sensors where placed in the soil mass at two levels (Figure 1b, 1c). Additional three sensors were fixed on the model surface (Figure 2). All transducers were calibrated in centrifuge under loading-unloading cycles induced by the increased gravity.

2.2 Model walls

Three model walls were used: straight wall (denoted as 'S') with 0° taper angle, tapered wall with 0.75° taper angle (denoted as 'T1') and wall with 1.5° taper angle (denoted as 'T2'), see Figure 2a-c. Each model was equipped with three normal stress sensors fixed on its surface (Figure 2d). The model wall was fitted to the container width of 20 cm to reduce any gap in the contact wall-glass. At final embedment only a few sand grains were trapped between the model and transparent wall.

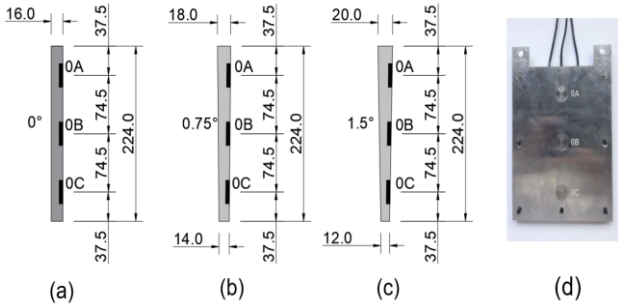

Figure 2. Instrumented models with a taper angle of: (a) 0° (standard S wall), (b) 0.75° (T1), (c) 1.5° (T2) and (d) model wall – front view.

2.3 Test execution

Three monotonic pushed-in tests with tapered walls were completed on single series. The centrifuge operated at an acceleration level of 25g. In each test, the wall was pushed into the subsoil with 0.1 mm/s rate to the depth of 224 mm, which gives the wall slenderness 14.

3 RESULTS

3.1 Total force mobilization

The mobilization of axial force during wall installation is given (Figure 3) for each wall type. It can be noticed that the total force required for monotonic installation of the wall was slightly lower for the models with higher taper angles compared to the straight profile. At final embedment the penetration force for T2 (respectively T1) constitutes only about 0.75 (resp. 0.9) of corresponding axial force for straight wall.

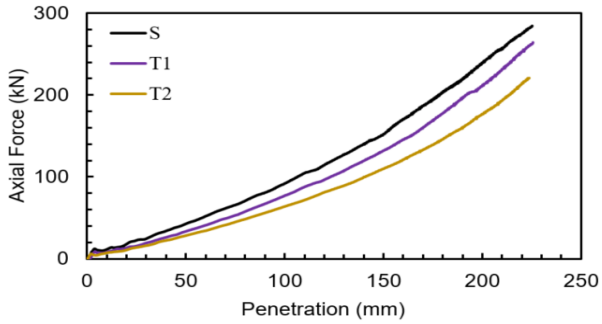

Figure 3. Axial force mobilized during wall installation (model scale).

3.2 Horizontal stress in the soil mass

The horizontal stress development (at fixed altitude) in the soil mass during installation of the wall is shown in Figure 4. A distinct peak in horizontal stress was observed in the soil mass just before the wall base has passed the level of the stress cell. This tendency can be noticed for the sensors in upper (B) and lower (C) levels. Once the wall base has moved below the position of the stress cells, a continuous decrease in normal stress was observed for the straight wall model. In contrast for tapered models the stress cells at the upper level exhibit further slight re-mobilization of horizontal stress, especially for the wall with higher taper angle. The maximum value of horizontal stress gradually decreases with distance from the wall. For the stress sensors placed at a given distance to the wall the highest maximum horizontal stress is noticed for the straight wall.

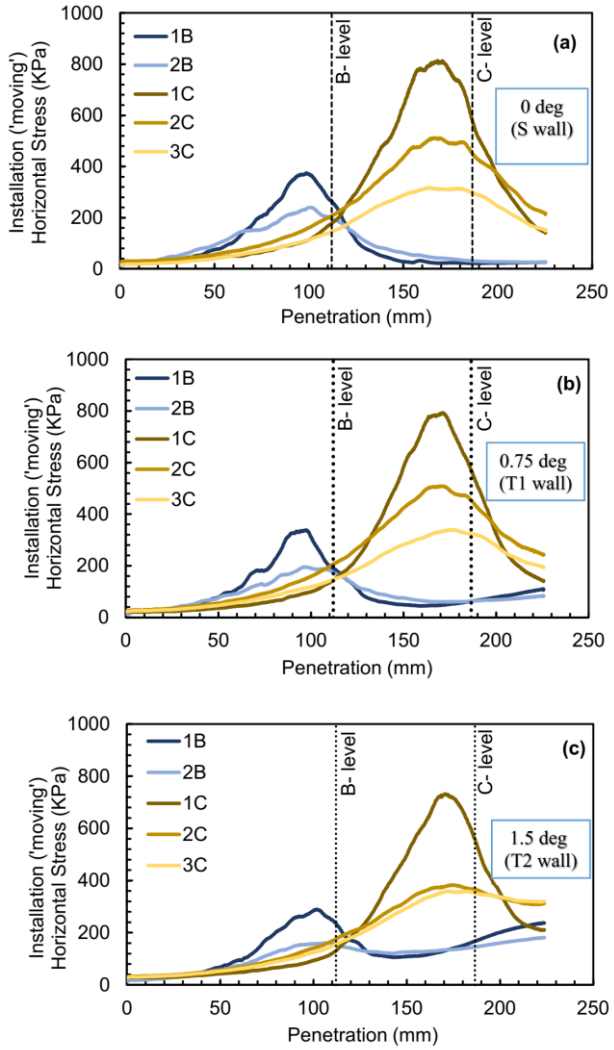

Figure 4. Stress distribution in the soil mass during wall installation (a) standard (S), (b) tapered (T1), and (c) tapered (T2).

3.3 Normal stress at the wall interface

The mobilization of normal stress at three positions (moving downwards) during tapered wall pushed-in is given in Figure 5. The observed maximum normal stress on the wall increases with the taper angle. At final stage of penetration, a sharp increase of normal stress is observed near the base due to mobilization of base resistance. One should also notice that the normal stress sensors on the tapered wall capture not only horizontal stress component but the vertical one as well. The latter can considerably influence the recorded values especially in case of the stress cell located in the vicinity of the base.

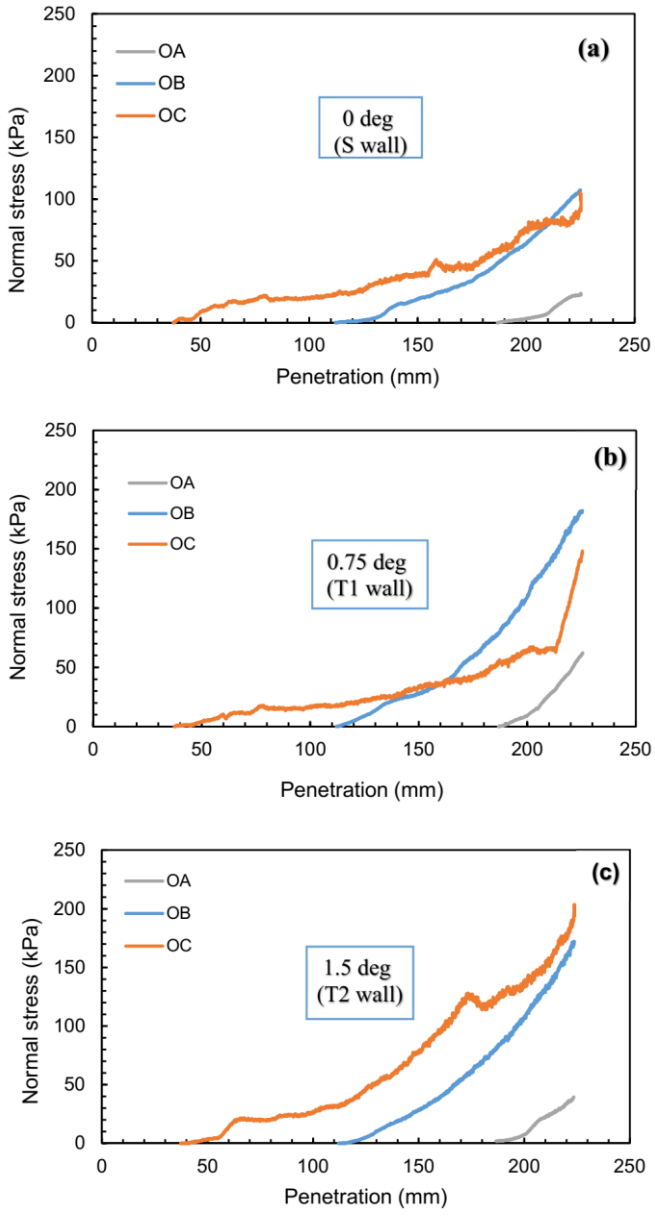

Figure 5. Normal stress mobilization on the wall during installation (a) standard (S), (b) tapered (T1), and (c) tapered (T2).

4 CONCLUSIONS

The installation of the continuous wall induces modifications in horizontal stress in the soil mass, normal stress at the model interface, and reduced axial force necessary for the penetration of tapered walls. The lateral stress modification in the vicinity of models is a function of taper angle. While the highest level of horizontal stress in the soil mass is observed for the straight wall, the normal stress on the wall surface is the largest for the model with the highest taper angle. The maximum horizontal stress in the soil mass for T1 and T2 wall is about 0.95 and 0.8 of the corresponding stress for the straight wall. However, at the end of installation both horizontal and normal stresses are significantly higher for tapered walls than for the standard one. The resulting installation effort is the lowest for T2 wall as higher shaft friction of tapered walls does not compensate the lower contribution of the wall base. The test results on walls can be qualitatively applied to describe the behaviour of tapered pile models.

Effects of non-linear response of shallow foundations on transmission tower serviceability

Effets de la réponse non linéaire des fondations superficielles sur l'aptitude au service des pylônes de transmission

ABSTRACT: Electrical transmission tower design has been a key global topic driving the development of reliability analysis of foundations since the 1980s. Many reliability-based ultimate limit state design methods for shallow foundations can be traced to seminal work conducted in the 1980s by EPRI. However, current design simplifies the foundation behaviour to be equivalent to a perfectly pinned or fixed point which does not allow proper consideration of serviceability conditions. This paper presents a simplified assessment of the soil-structure interaction of a transmission tower to better understand the effect of the non-linear behaviour of the foundation on the structural response and elucidate whether it is relevant.

RÉSUMÉ: Depuis les années 1980, la conception des pylônes de transmission électrique est un sujet mondial clé qui a conduit au développement de l'analyse de fiabilité des fondations. De nombreuses méthodes de conception de l'état limite ultime basées sur la fiabilité pour les fondations peu profondes peuvent être attribuées aux travaux fondamentaux menés dans les années 1980 par l'EPRI. Cependant, la conception actuelle simplifie le comportement de la fondation pour qu'il soit équivalent à un point parfaitement chevillé ou fixe, ce qui ne permet pas de prendre correctement en compte les conditions de service. Cet article présente une évaluation simplifiée de l'interaction sol-structure d'une tour de transmission afin de mieux comprendre l'effet du comportement non linéaire de la fondation sur la réponse structurelle et d'élucider si elle est pertinente.

Keywords: Foundation; transmission line; non-linear; serviceability.

1 INTRODUCTION

The determination of serviceability limit states in foundation design depends on the intended purpose of the structure being supported. This limit state may not reflect an intrinsic limit of the foundation itself, but rather a situation for which the foundation movement hinders the ability of the superstructure to deliver the desired service. The same foundation, subjected to similar levels of loading, may have different serviceability limit states depending on it being used to support a building, bridge, or other structure. Even within similar transmission structures, the same foundation can have different serviceability limits.

Currently, transmission tower design guidelines in Canada and the U.S. do not recommend specific serviceability limits for the design of foundations or transmission towers. However, standards from other countries address this issue. For example, the Chinese standard DL/T741-2001 (NDRC 2001) specifies limits for tolerable levels of inclination for pole towers. It also specifies limits at which corrective measures should be taken. Majcherczyk and Niedbalski (2017) indicate that a similar standard exists in Poland. BN-90/9056-01 specifies that the deviation from the vertical of the transmission pylon peak, standing without conductors, is H/300, where H is the height of the structure.

The analysis of the response of transmission towers to wind loads, whether in scaled models, finite element models or considering field conditions, is usually limited to the structure itself. However, few authors have investigated the behaviour of the foundations. (Savory et.al. 1998, 2008) measured the force applied in the foundations by placing strain gages in all the tower feet directly above the foundation. The structure was a 44 m tall transmission tower located in Dorset (England) between 1995 and 1999. Along with the strains, the wind speed at 10 m height was also recorded. The results showed that foundation load is proportional to the square of the wind speed, with measured loads below ultimate limit state loads specified by code, with a code overprediction of 14%.

Structural analysis of transmission towers subjected to wind loads does not consider the

foundation stiffness and displacement. This omission can have significant consequences given the non-linear behaviour of the structure. This paper uses a simplified foundation model and assesses the effect on the structural response compared to the typical fixed supports. The objective is to better understand how to define a serviceability limit state for the foundations.

2 METHODOLOGY

2.1 Wind load

The wind load is modelled based on the combination of a mean wind speed and a turbulent wind component. For synoptic winds, the mean wind speed is considered constant at any given height. Variation with height is controlled by a power law wind profile with an exponential coefficient of 1/7, with the wind speed at 10 m height above the ground surface used as a reference value. The turbulent flow around the mean wind speed is modelled as a Gaussian random process based on the Kaimal spectrum and the Davenport coherence model (Simiu and Scanlan 1996), and simulated using the spectral representation method (SRM) (Shinozuka and Jan 1972). The wind speed is transformed into loads following CSA 60826-10 (2019) guidelines.

In this study, a 46.9 m tall transmission tower with adjacent spans of cables is considered. The investigation is carried out based on a location in Ottawa (Canada), and the corresponding 10-minute mean wind speed at 10 m height with a return period of 10, 25, 100 and 500 years equals 22.81, 24.07, 25.94 and 28.09 m/s respectively, which is adopted to generate the wind speed field for later analysis.

2.2 Structural model

A finite element model of the structure developed in ANSYS Multiphysics 18.0 (ANSYS 2014) was used for the analysis. The model was employed by (Mara and Hong 2013) considering rigid foundations. Each tower member is modelled using three 2-node BEAM188 beam elements, with 6 degrees of freedom at each node. The material nonlinearity in the tower member is included by using a bilinear hysteretic model. Each span of cables consists of 2 conduct lines and 1 ground line with a span length of 488 m. Each cable within a span is modelled using thirty 2-node link elements with only axial loading capacity. The ends of the tower-line system are connected to springs that represent the stiffness of the remote towers and cables. The details of the geometric variables and material properties of the tower and cables can be found in Yang and Hong (2016). The structural model includes the effects of the geometric non-linearity using a large-deformation analysis.

2.3 Reaction loads

Figure 1 shows the vertical, longitudinal, and horizontal components of the reaction loads in the foundations of the lattice transmission tower for the 500-year event. The reactions include the effects of the dead load (45 kN), which accounts for the offset between the uplift and compression directions. The main effect of the wind load relates to the axial components required to balance the overturning moment, with the mean value of the horizontal components being less than 10%.

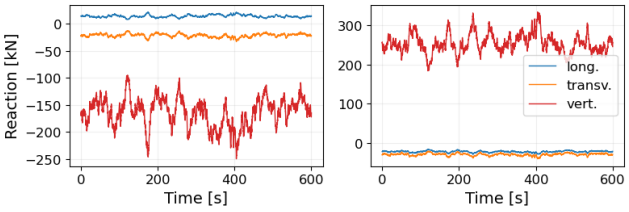

Figure 1. Transmission tower reactions to the 500-year event.

Table 1 shows the temporal mean value and standard deviation of the reaction loads due to the wind alone for different return periods (TR). The horizontal component is generally below 10% of the vertical components, with the significance reducing as the return period increases. It can also be seen that the variation around the mean value, indicated by the standard deviation, is relatively constrained as well.

Table 1. Reaction load mean (standard deviations) in kN.

TR [yr]	Vertical	Long.	Trans.
10	138.2 (17.0)	12.1 (1.5)	16.7 (2.1)
25	153.9 (19.0)	13.5 (1.7)	18.6 (2.3)
100	178.7 (22.4)	15.8 (2.0)	21.6 (2.7)
500	209.5 (26.6)	18.5 (2.4)	25.4 (3.2)

2.4 Foundation design

Following the ASCE (2020) guidelines, foundations were designed for the 100-year event. Uplift capacity was computed using the Meyerhof and Adams (1968) method with a safety factor of 1.5 in a uniform stratigraphy with a loose Hostun sand. The required design parameters are provided by Schanz et al. (1999): friction angle at failure $\varphi_p = 34º$, dilatancy angle at failure $\psi_p = 0º$, a reference stiffness modulus $E_{50}^{ref} = 20\,MPa$, a stress dependency power $m = 0.65$, an unloading reloading Poisson ratio $\nu_{ur} = 0.2$, a reference Young modulus for unloading and

reloading $E_{ur}^{ref}/E_{50}^{ref} = 3.0$. A unit weight $\gamma_s = 19\,kN/m^3$ is adopted. The IEC 60826 (2003) and CIGRE (2002) design guidelines are concerned only with the ultimate limit state, and thus, do not consider the foundation stiffness or force-displacement behaviour. Two circular chimney shallow foundation designs are adopted, a "deep" foundation with an embedment depth (D) of 2.00 m and a width (B) of 0.75 m, and a "shallow" foundation with D of 1.25 m and B 1.75 m. In both cases, foundation and column thicknesses of 30 cm were adopted. According to current design guidelines, these foundations are equivalent to each other (with a safety factor slightly above 1.5).

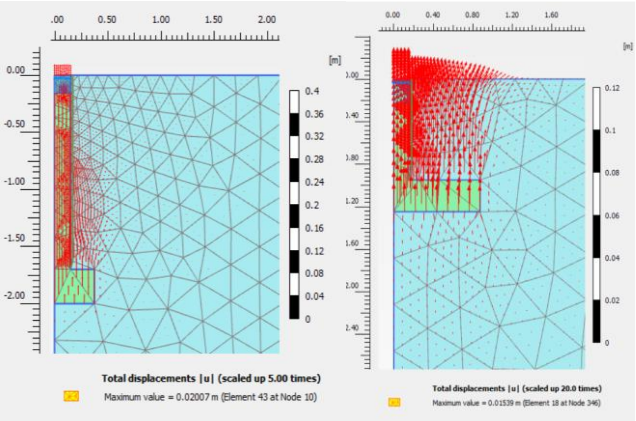

Figure 2. Displacement field at pull-out failure for the "deep" (left) and "shallow" (right) foundations.

2.5 Load tests

Axisymmetric PLAXIS (Bentley 2020) finite element models of the foundations were developed to analyse the response when subjected to different levels of excitation. The Hostun sand is modelled using the Hardening Soil model, an associated elasto-plastic model that combines the Mohr-Coulomb failure surface with an elliptical cap and has a stress-dependent stiffness that distinguish between virgin and un/reloading. Concrete is modelled as an elastic material. Interface elements were included between the column and the soil, so no shear transfer took place. The models were loaded statically first to the dead load level, and then subjected to load cycles corresponding to the 100/500-year events, to determine the foundation stiffness. This stiffness is then used in the structural model to determine the transmission tower responses. Figure 2 shows the displacement (velocity vector) field at pull-out failure for the two foundations with D/B of 2.7 and 0.7 respectively. A clear difference in the behaviour can be seen, where the deep foundation mechanism is far more localized around the foundation (base/column), whereas the shallow foundation mechanism extends to the free surface with an apparently outward-curving edge (related to the angle of dilation of the sand).

3 RESULTS

3.1 Soil-structure interaction

Figure 3 show the response of the foundations when subjected to loads alternating between pull-out and compression cycles corresponding to repeated 100 (blue) and 500-year (red) design storms. The design loads, corresponding to the 100-year event, are shown as dashed grey lines. A clear difference in the behaviour of both foundations is seen. Wide hysteresis loops with increasing permanent deformations characterize the response of the "deep" foundation, while very narrow hysteresis loops are seen for the "shallow" foundation. This is due to the failure mechanisms observed in Figure 2 and reflected in the pull-out and compression test also shown in Figure 3. A common feature of both foundations is that the initial loading is always less stiff than the unload-reload behaviour. This can be in part explained by the high $E_{ur}^{ref}/E_{50}^{ref} = 3.0$ used for the Hostun sand.

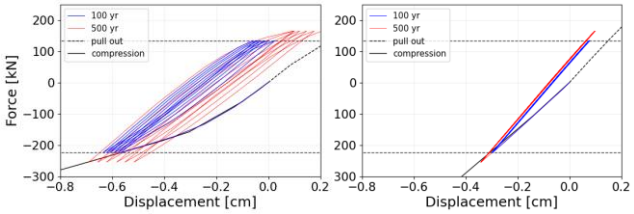

Figure 3. D/B of 2.7 (left) and 0.7 (right) foundations subjected to 100 and 500-year events.

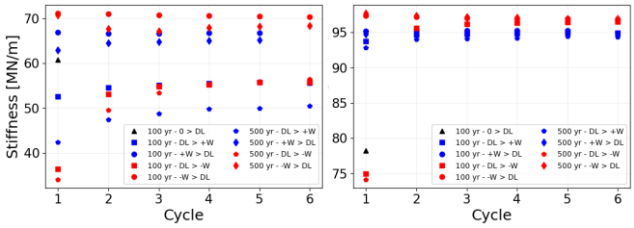

Figure 4. D/B of 2.7 (left) and 0.7 (right) foundations secant stiffness for 100-year and 500-year events.

The hysteresis loops in Figure 3 are transformed into a secant stiffness to represent loading or unloading behaviour, in the compressive and pull-out directions. The resulting secant stiffnesses are presented in Figure 4. After the first load cycle, the stiffness stabilizes. The "shallow" foundation has a more uniform stiffness across load levels (100 or 500-year) for loading or unloading. The latter is reflected in the narrower hysteresis loops shown in Figure 3. The deep foundation exhibits a markedly different behaviour under loading or unloading, with a stiffer unloading,

explained by the wider hysteresis loops. Interestingly, whether the loading is in the compressive or pull-out direction, there is no significant change in stiffness. Based on the results, a 60 MN/m stiffness is used for the "deep" case & 95 MN/m for the "shallow" case in the structural model.

Table 2. Transmission tower peak displacements [m].

TR [yr]	Fixed	Deep	Shallow
10	0.1379	0.1760	0.1616
25	0.1543	0.1969	0.1808
100	0.1804	0.2303	0.2113
500	0.2131	0.2723	0.2496

Table 3. Natural frequencies [Hz].

Mode	Fixed	Deep	Shallow
Transverse	1.155	1.033	1.074
Longitudinal	1.219	1.074	1.121
Vertical	1.555	1.555	1.555

The effect of the foundation stiffness can be seen in the transverse and longitudinal natural frequencies of the structure. As Table 3 shows, the vertical stiffness of the foundation affects the overall horizontal stiffness of the structure, with a more flexible foundation inducing a more flexible (lower natural frequency) structure. Therefore, models that consider fixed foundations tend to over-estimate the stiffness and natural frequency of the structure.

4 CONCLUSIONS

It is well-known from theoretical approaches that foundation geometry affects stiffness and non-linear behaviour under repeated load cycles. However, the absence of a proper quantification precluded the estimation of its significance in terms of the SLS. Our analysis has shown that it plays a crucial role in the response of transmission towers to wind loads. This has so far been ignored by design standards. The comparison of different foundation geometries (that from a design point of view are equivalent) shows that the dissimilar responses can affect the SLS and the long-term response after many load-cycles associated with significant weather events. Thus, the structural serviceability cannot be effectively studied without the foundation component, and the foundation serviceability limit is a function of its stiffness and non-linear response to load cycles. This preliminary numerical analysis demonstrates the problem. Further calibration using model testing in a centrifuge and available full-scale test results is required to refine the design approach to be calibrated.

Automating stability analysis using BIM-FEA-Integration

L'automation d'analyse de la stabilité employant l'intégration du BIM envers la FEA

J. Beck*, H. Jürgens, S. Henke
Helmut-Schmidt-University, Hamburg, Germany
**beckjo@hsu-hh.de*

ABSTRACT: This paper examines chances and frontiers of BIM-to-FEA integration for geotechnical projects using a real-world excavation pit project underscoring its practical applicability. A BIM model is first created, which includes the urban context, the subsoil, the excavation pit, and the building to be erected. Elements relevant to the numerical model are identified, pre-processed and transferred to the FEA software leveraging an interactive automation routine. After the calculations and stability analysis, the results are back-transferred to the BIM model, which triggers an update routine for geometries and properties of the BIM model's objects enabled by their parametric definition. It is demonstrated that 2D numerical models can be derived from a complex BIM model. Strict adherence to the model structure and the establishment of appropriate modelling rules are prerequisites for this. The approach allows real-time interaction between BIM and FEA with automatic compliance of the stability. The developed automation process shows potential for efficiency gains, particularly in variational analyses and supports version control and data consistency.

RÉSUMÉ: Ce papier étudie les opportunités et les frontières pour l'intégration du BIM envers la FEM dans les projets géotechniques, en utilisant une fouille réelle, ce qui souligne l'applicabilité pratique. En premier lieu, une modèle BIM est créé, qui inclut le contexte urbain, le sous-sol, la fouille et le bâtiment à construire. Les éléments qui sont nécessaires au modèle numérique sont identifiés, prétraités et transférés au logiciel de FEM pour être tirés d'une routine de l'automation interactive. Après avoir effectué les calculs et l'analyse de la stabilité, les résultats sont transférés de retour au modèle BIM, que déclenché la routine de mise à jour pour les géométries et les attributs des objets du modèle BIM, causée par leurs définitions paramétriques. Il est démontré que les modèles numériques bidimensionnels peuvent être dérivés d'un modèle BIM complexe. L'adhérence élevée à la structure du modèle et l'établissement des règles appropriées pour la modélisation sont un prérequis pour ceci. L'approche permet d'interagir de temps réel entre le BIM et la FEM avec la conformité automatique de la stabilité. Le process d'automation qui est développé dans ce papier permet aux les gains efficients, notamment pour l'analyse variationnelle, et avalise le contrôle de version et la consistance de data.

Keywords: BIM; FEA; automation; integration; analysis.

1 INTRODUCTION

Building Information Modelling (BIM) exerts significant influence on the digitization of the AEC sector. Its model and data centric approach is increasingly adopted in geotechnical projects. In current practice, geotechnical design analysis is usually performed in separate, disconnected models. BIM models as well as analysis models frequently change during early project stages due to information gain and design changes. Such changes in one domain could potentially affect the validity of other domains models. After each change, the validity should be checked and evaluated. Due to the data isolation in the traditional process of design analysis, the evaluation and adjustments have to be done manually, which is flexible, but laborious and error prone.

To address these shortcomings a fully automated workflow integrating BIM and Finite Element Analysis (FEA) for stability analysis is proposed.

2 METHODOLOGY

The proposed process consists of the following steps: (I) Create a highly parametric BIM model, (II) extract and evaluate parameters needed for design analysis from the BIM model, (III) create two-dimensional (2D) FE model and calculate, (IV) dimensional optimisation, here using the Differential Evolution Algorithm (V) update BIM models using calculation results. Between each step, a version-controlled JSON-file is created, which is then used to trigger the next step and to evaluate, if a modification in one model affects the other one.

The implementation uses *Seequent Leapfrog Works, Autodesk Revit* and *Robert McNeel & Associates Rhino.Inside* for creating and managing the BIM models and *Bentley PLAXIS 2D (Version 2023-2)* for the numerical analysis. A python-webserver is used for data processing and transferring.

The developed process is validated and evaluated using a slightly adapted real world case study. The investigated excavation pit is located in an urban area in northern Germany and has been numerically investigated in (Jürgens & Henke, 2022). The therein listed numerical parameters are also used in the present study.

3 IMPLEMENTATION AND CASE STUDY

3.1 Parametric BIM models

In parametric modelling, in contrast to direct modelling, geometries are described by parameters and constraints. Editing such parameters results in an accordingly updated geometry. BIM authoring tools usually differ between components and a project layer, whereby the components tend to be more parametric.

The model granularity and the parametric logic needs to be set up in a way, that the results from the numerical calculation can update the BIM model. For example, if a calculation objective is to optimize the length of each diaphragm wall lamella, the lamellas need to be modelled individually and their geometric extents shall be driven by a corresponding length parameter.

The BIM models for the present case study are introduced in (Beck & Henke, 2023b) and are further developed for this contribution. Figure 1 shows a 3D view of selected coordinated BIM models.

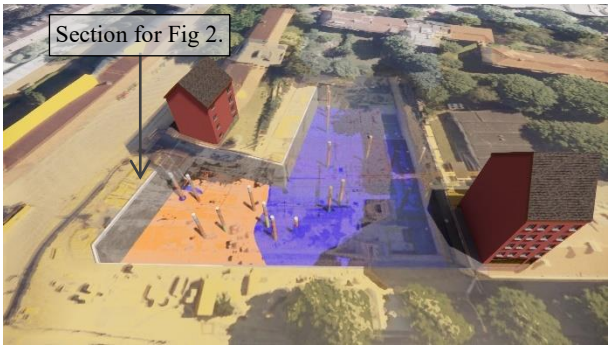

Figure 1. 3D view of coordinated BIM models.

3.2 Data extraction and evaluation

The derivation of the plain strain 2D FE model follows the approach introduced in (Beck & Henke, 2023a). Given the problem definition, which is the stability analysis of a diaphragm wall here, the BIM models and other data sources are queried for relevant content. It is differentiated between elements, that are represented in the numerical model by one-dimensional elements (anchors, wall, etc.) and two-dimensional elements (soils) as well as boundary conditions and material properties. This is made possible by the underpinned semantic model and a rule-based system that evaluates how each element is represented in the FE domain. This approach allows the integration of additional expert knowledge with little effort.

In the following, selected major steps in the developed process are outlined. Whilst many optional parameters can be set, the necessary inputs for the automation are location and type of analysis to conduct. A plane cutting the diaphragm wall perpendicularly at the point to be calculated is created. The resulting polylines of this plane's intersection with the 3D meshes that represent the soil volumes in the BIM model require further processing, as they cannot be directly used for meshing due to tiny segments and angles as well as small gaps between adjacent polylines. Besides that, they do not consider the construction sequence and the limited model area in the numerical domain. To address this issue, Boolean operations and topologically aware simplification techniques are applied as described in (Beck & Henke, 2023a). Figure 2 a) shows an exemplary cross-section through the subsoil model and the diaphragm wall with projected anchors. The width of the section used for the numerical analysis is 90 m, the depth is 50 m. Before the simplification, 19 closed polylines with 4983 control points are present in this area, of which 2593 are unique, meaning no other point is at that location. These polylines are not suited for mesh creation, due to small segments, small angles and little gaps between adjacent regions. After simplification, 17 polylines with 108 points (38 unique) remain. These can be then be used for mesh creation, see Figure 2 b). Multiple evaluation metrices and simplification algorithms ensure good mesh quality. The displayed mesh quality is calculated as ratio of the radius of outer to inner circle of a triangle, normalized to an equilateral triangle resulting in a minimal value of 0.19. The information for material creation in the 2D model is collected from the derived object and adjacent objects in the BIM model, e.g. for calculating anchor distance, as well as from external data sources where geometrical and non-geometrical information are considered. Throughout the whole process the relationships between the objects in the BIM model and its derived counterparts in the numerical model are maintained.

All information required for creating the numerical model is merged in one structured, human- and

machine-readable text file using the JSON-format. This file is updated periodically and after certain events and is version controlled. If changes are found and a calculation in this scope already exists, the calculation is not compliant with the BIM model anymore and has to be recalculated. This information is displayed in a project dashboard, where all calculations are listed and managed. Depending on the number of numerical simulations and their computation times it might not be sensible to trigger a recalculation on changes instantly. The proposed procedure allows to evaluate changes prior to recalculation, so if only minor changes occur, a recalculation can be omitted. The file and the update scripts are designed to minimize the effort in recalculations, e.g. if no discretized geometry is changed, no meshing procedure is conducted.

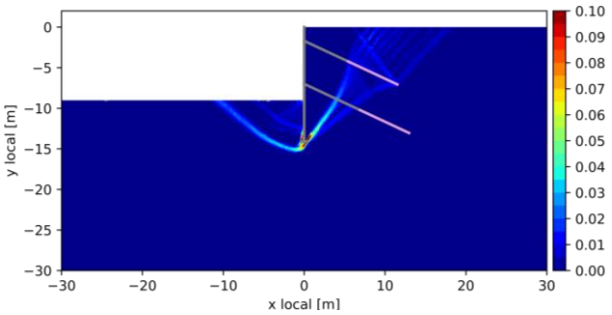

Figure 2. Processing and calculation of an exemplary cross-section

3.3 FE model creation and stability analysis

The named JSON-data is used to trigger the model creation routines which utilize the API provided by the used numerical software. The model creation follows these main steps: (I) Create materials, (II) create geometries, (III) assign materials to the geometry, (IV) generate mesh, (V) create construction sequence via calculation phases, (VI) assign hydraulic / thermal flow conditions. After the model has been created and calculated, strength reduction method for the surrounded soil is conducted and the resulted Factor of Safety (FoS) is stored. The implementation allows for real time interaction between the used programs, for example if the wall thickness needs to be adjusted, the corresponding parameter can be set in the BIM authoring tool and the corresponding parameters in the numerical model are updated immediately.

The soil parameters for the numerical model were realistically determined within the context of an inverse parameter calibration based on inclinometer measurements (Jürgens & Henke, 2022). As a constitutive model, the Hardening Soil Small model is employed, considering hardening plasticity and small strain stiffness. The information on the material parameters used for the soils, the diaphragm wall and the tie-back can be found in (Jürgens & Henke, 2022). The dimensions of the structures for the investigated excavation pit are based on preceding calculations using the limit equilibrium method (LEM) using BLUM's method. Due to the advantages of FEA compared to LEM, such as near-realistic constitutive models and soil-structure interaction behavior, system reserves are probably available. Therefore, the stochastic optimization algorithm, Differential Evolution (DE), originally proposed by (Storn & Price, 1997), is used. The statically required embedment depth t, the free anchor length of the two tiebacks l_{free} and the diaphragm wall width d_{wall} are optimized by creating a population with $n = 4$ adjustable parameters that is iteratively improved on the basis of evolutionary processes. Minimizing the FoS as a result of the strength reduction method serves as the objective function for DE. Therefore, it has to be noted, that this procedure does not find an economic solution. For the optimization process, the dimension of vectors used in DE D is set to 5, from which the population size $m = D \cdot n = 5 \cdot 4 = 20$ is calculated. The implementation of DE for the numerical model is done using the *scipy* library with Python.

Figure 2 c) displays the results of the strength reduction method for the optimized condition in the form of incremental strains for the section highlighted in Figure 1. After a total of 320 calculations, respectively 16 iterations, the following optimized

parameters for the dimension of the excavation pit wall are obtained $t_{\mathrm{DE}} = 4.17$ m, $l_{\mathrm{free,top,DE}} = 8.40$ m, $l_{\mathrm{free,bottom,DE}} = 8.24$ m, $d_{\mathrm{wall,DE}} = 0.69$ m with an minimized Factor of Safety $FoS = 1.18$. Table 1 compares this solution with the initial configuration and indicates optimization potential; see Section 4 for a discussion of practical applicability.

Table 1. Parameters before and after optimization.

	Before Optimization	**After Optimization**
t [m]	6.70	4.17
$l_{\mathrm{free,top}}$ [m]	9.60	8.40
$l_{\mathrm{free,bottom}}$ [m]	10.40	8.24
d_{wall} [m]	0.60	0.69
FoS [-]	1.66	1.18

3.4 Update of BIM models

A routine to analyse the calculation results is triggered, when a new version of the output files created by the numerical software is saved. In addition to default ones, results based on the problem definition are parsed and stored in a separate JSON-file. This file is also version controlled as descried above. If changes are detected, a routine updating the BIM models starts.

In the present case study, the main optimized parameters, that are transferred back to the BIM model, are the anchor lengths as well as the width and the embedment depth of the diaphragm wall. As the corresponding BIM objects are modelled parametrically, only the belonging parameters need to be set and the geometries and derived evaluations update automatically. It is also documented how a parameter is set – either as a result from a changed calculation or another way, e.g. manually. As a result, a re-calculation of the model directly after it has been calculated is avoided. Additional results, such as the FoS, displacements and moment distributions can be set directly assigned to BIM models or by reference, which is preferable for bigger datasets.

4 CONCLUSION AND OUTLOOK

A conceptual BIM-FEA-Integration framework based on commonly used software tools was introduced. It allows for fully automated derivation of 2D-FE models, their calculation and the update of the parametric BIM models based on simulation results and dimensional optimization. The consistency between the numerical models with the BIM models is continuously verified, which is enabled by version-controlled text files that are used to transfer data between process sections. The conducted case study shows that the developed procedure is robust and that complex site conditions can be adequately considered. The conducted stability analysis using strength reduction method proved suitable as a possible method for optimizing design relevant geometric parameters. The used geometry evaluation metrics and simplification techniques and metrices are going to be published separately.

Future endeavors shall strive to more standardization which is supposed to increase efficiency gains and reduce entry thresholds for practitioners. Investigations on the suitability of different optimization techniques and objectives and considering more parameters are also promising to increase the practical applicability. If a single objective optimization technique is applied for real world problems, it is feasible to use an economic evaluation as the objective function instead of the FoS and use the FoS as a constraint.

Micropile bearing capacity analysis using fiber optic technology

Analyse de la capacité portante des micropieux en utilisant la technologie de la fibre optique

ABSTRACT: This paper discusses the bearing capacity of micropiles and the performance of shortening pile measurement using fiber optic technology. Results from a static pile load test on a micropile are presented, along with an analysis of the shortening of the pile shaft based on data obtained from fiber optic measurements. An optical fiber, placed at the center of the micropile, was used to measure deformations along the entire length of the pile. The test involved a 6-meter-long micropile and was conducted until failure. Successive load stages enabled the analysis of the behavior of the entire micropile shaft under load. The ground conditions facilitated the interaction of the pile side with the soil from the surface. The test was conducted on a micropile using rock bolting technology with ARCO steel pipes, which serve as the reinforcement of the micropile. A fiber optic sensor was placed inside the pipe (bar).

RÉSUMÉ: Cet article traite de la capacité portante des micropieux et de la performance de la mesure du raccourcissement des pieux en utilisant la technologie de la fibre optique. Les résultats d'un essai de charge statique sur un micropieu sont présentés, accompagnés d'une analyse du raccourcissement du fût du pieu basée sur les données obtenues par des mesures à fibre optique. Une fibre optique, placée au centre du micropieu, a été utilisée pour mesurer les déformations sur toute la longueur du pieu. L'essai a impliqué un micropieu de 6 mètres de long et a été mené jusqu'à la rupture. Les étapes de charge successives ont permis d'analyser le comportement de l'ensemble du fût du micropieu sous charge. Les conditions du sol ont facilité l'interaction du côté du pieu avec le sol depuis la surface. L'essai a été réalisé sur un micropieu utilisant la technologie de boulonnage de roche avec des tuyaux en acier ARCO, qui servent de renforcement au micropieu. Un capteur à fibre optique a été placé à l'intérieur du tuyau (barre).

Keywords: Mikropile; distributed fiber optic sensing; geotechnical load tests; soil mechanics.

1 INTRODUCTION

The primary characteristic of the micropile installation technique is its effectiveness in high-resistance soils, including rocky terrains, as well as in areas with limited overhead space and uneven surfaces (FHWA, 2005). In this context, tip resistance is often overlooked, with a predominant emphasis on load transfer through skin friction (Allen et al., 2004). Choi & Cho (2010) observed that the injection of neat cement grout can potentially enhance the load capacity of micropiles by over 100% in both soil and rock environments.

For the tested micropile, the ARCO steel pipe anchoring technology was employed. The advantage of this method lies in the integration of corrugated pipes with the ground through a mixture of grout and sand, similar to the reinforcement in concrete structures, thereby ensuring protection against external factors.

Additionally, some researchers (Finno et al., 2002; Holman & Barkauskas, 2007) have highlighted the potential for relative displacement between the steel casing and the neat cement grout. However, the use of stronger grouts and corrugated pipes, as in this study, can mitigate this issue. Żarkiewicz (2023) observed a significant impact of the simultaneous mobilization of skin resistance and resistance under the pile base near its base in his studies, which may also be relevant for loaded micropiles. While the application of micropiles in various solutions is not novel, their comprehensive examination and analysis, particularly in terms of interaction with the ground, are relatively scarce, similar to the situation with the larger market for

standard piles, where despite greater accessibility, research is also limited.

In recent years, the use of distributed fiber optic monitoring systems has significantly increased in geotechnical applications. These systems provide the advantage of offering distributed strain and temperature measurements with high accuracy along the entire length of the structure, without any data gaps (Monsberger 2020). Ouyang (2015) and Schilder (2013) have utilized fiber optic instrumentation to monitor load tests, focusing respectively on a large diameter pile in London and on reinforced concrete piles. Esmaeili (2013) presented a case study on the use of micropiles for reinforcing high railway embankments, while Glisic (2002) discussed the application of fiber optic sensors in monitoring pile behavior during axial compression, pullout, and flexure tests.

The primary objective of this study is to introduce a fiber-optic approach to micropiles, to assess their performance in sand-fine gravel soil, and subsequently to determine the causes of the loss of bearing capacity of the tested micropile. Figure 1 presents the schematic and a view of the conducted load test.

2 EXPERIMENTAL SETUP

The micropile used in this study is a result of employing self-drilling anchors, with a diameter of approximately 16 cm and a length of 6 meters. It is drilled by rotation using an R51 steel pipe equipped with a disposable drill bit tip. This pipe is inserted using a drilling machine specifically designed for this task. The choice of drilling fluid, either water-cement or water, depends on the soil type. Upon completion of the drilling process, a substantial injection of water-cement mixture is conducted. The bar, serving as the reinforcement for the perforated micropile, eliminates the need for additional reinforcement insertion. The continuous threading ensures excellent adhesion of the cement mortar.

In addition to the previously described setup, a linear fiber-optic strain sensor, EpsilonRebar, supplied by shmsystem.pl, was installed inside the micropile's steel pipe reinforcement.

The use of a pure water-cement grout facilitated the easy installation of the sensor within the central part of the micropile. EpsilonRebar is capable of providing accurate strain and crack measurements over its entire length.

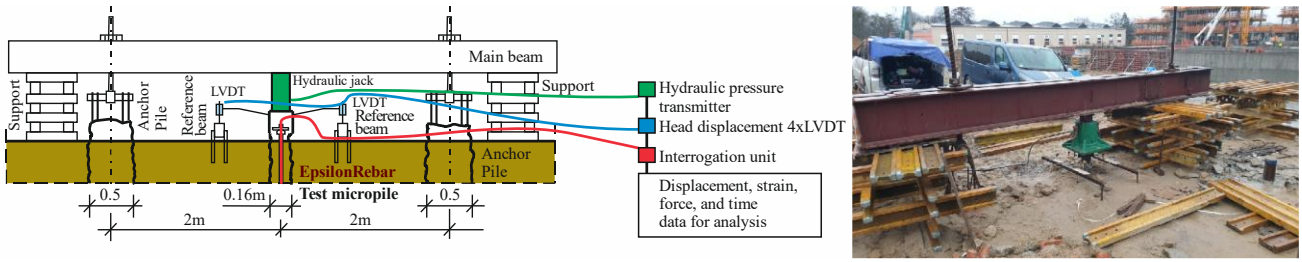

Figure 1. Schematic of the load test and photograph of the test setup.

It is designed as a composite rebar, available in any diameter, with a standard diameter of Ø5 mm. This sensor is suitable for direct embedding into newly-designed structures (such as concrete or soil) or for installation within existing structures (for example, inside grooves in concrete or on the surface of pipelines).

EpsilonRebar's resistance to mechanical loads and environmental conditions makes it ideal for in-situ applications in construction sites or existing infrastructure. The sensor's specifications include a strain measurement resolution of 1.0 με, a strain measurement range of ±2 %, an operating temperature range from -20 to +100 °C, and it is made of glass fiber and epoxide. The sensor utilizes scattering techniques such as Rayleigh, Brillouin, or Raman for its measurements.

3 RESULTS AND ANALYSES

The load test was conducted according to the scheme presented in Figure 2.

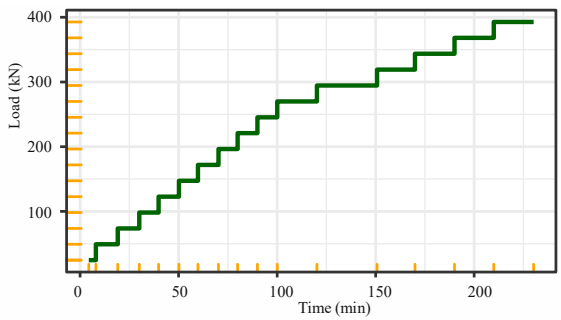

Figure 2. Variation of load over time (hydraulic pressure change of 0.5 MPa).

The study was carried out in 17 stages of loading, with the assumption that the test would continue until

the micropile failed. During the test, efforts were made to maintain the condition that the transition to the next loading stage would occur when, after 10 minutes, the average settlement recorded by the displacement sensors at the micropile head was less than 0.05 mm. After 100 minutes, particularly beyond the applied force of 270 kN, stabilization occurred over a period longer than 10 minutes for each load stage.

The displacement of the micropile head is presented in Figure 3 for successive loading stages. The last six stages required stabilization periods longer than 10 minutes. In the final stage, the micropile failed.

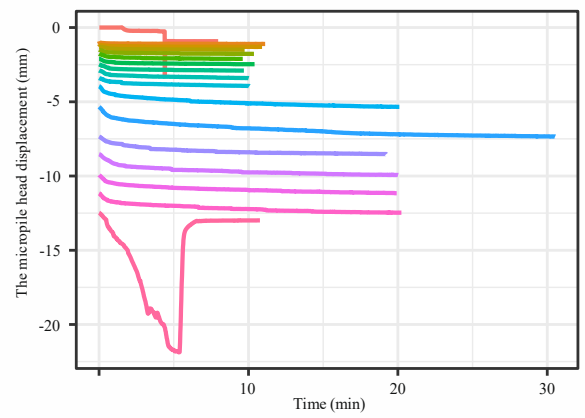

Figure 3. The displacement of the micropile head.

This figure (Figure 4) illustrates the continuous displacement of the micropile head, plotted against the backdrop of the total shaft shortening over time.

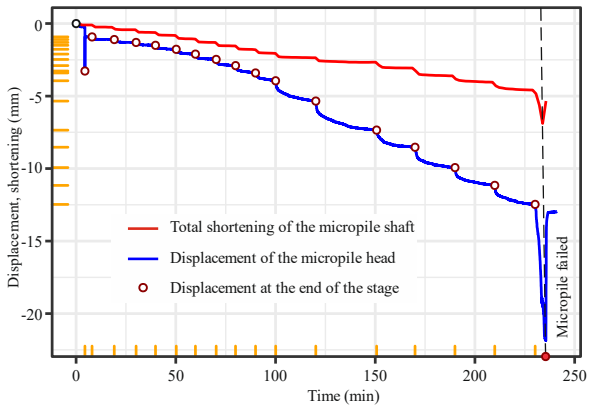

Figure 4. Continuous displacement of the micropile head with total shaft shortening over time and end-of-stage head displacements.

Additionally, it highlights the final displacements of the micropile head at the end of each loading stage, providing a comprehensive view of the micropile's behavior under progressive loading conditions.

Next figure (Figure 5) depicts the correlation between the shortening of the micropile shaft and its depth along the entire length of the micropile, as measured by the high-precision fiber-optic sensor EpsilonRebar. The results, showcasing measurements with an accuracy of 1 cm, are presented for the first ten loading stages, during which the micropile quickly stabilized under the applied load. This detailed analysis illustrates the variations in shaft shortening with depth at each stage, providing crucial insights into the initial structural behavior of the micropile under varying loading conditions.

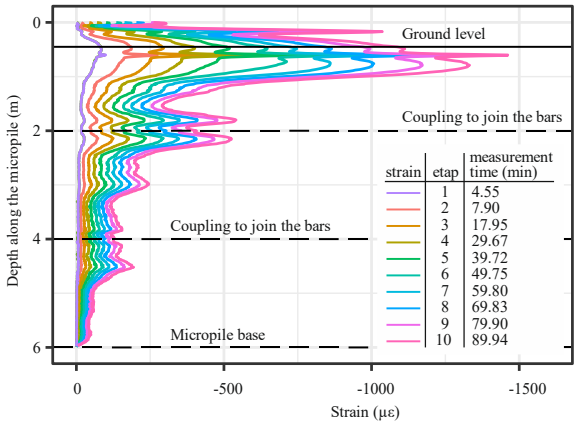

Figure 5. Relationship between the micropile shaft shortening and depth for the first ten loading stages.

Continuing the analysis, the subsequent Figure 6 extends our understanding to the later phases of the load testing.

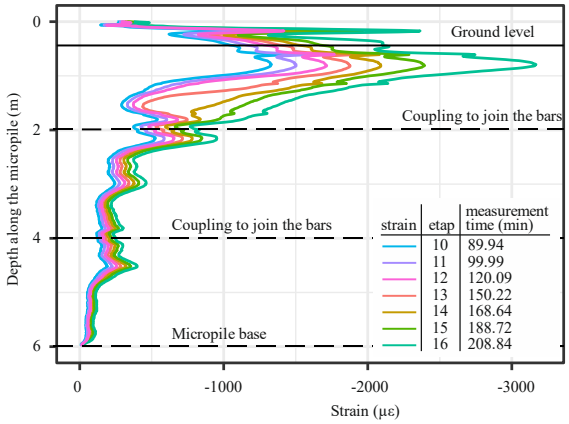

Figure 6. Relationship between the micropile shaft shortening and depth for the next six loading stages.

In this chart (Figure 6), the horizontal axis has been rescaled to twice its original size for clarity. It presents the behavior of the micropile during the following six stages of loading, further elucidating the structural response under increased stress.

The last chart, Figure 7, illustrates the final 5 minutes of the test, during which the micropile shaft failed, rather than a loss of bearing capacity in the soil substrate. This crucial phase highlights the structural

limits of the micropile under extreme loading conditions. The determination of the shaft's failure was made possible through the use of a fiber-optic sensor, which unequivocally allowed for the assessment of the nature of the damage.

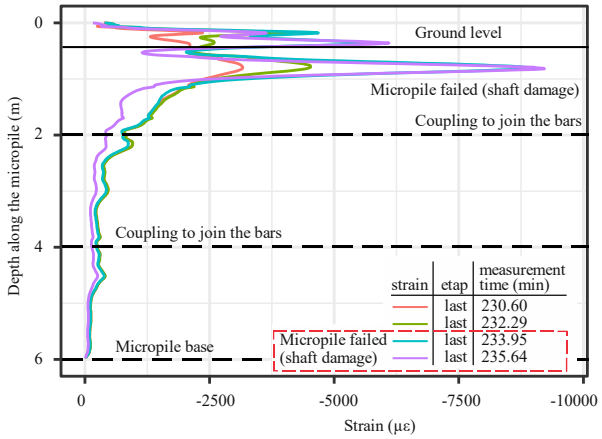

Figure 7. The final 5 minutes leading to micropile shaft failure.

4 CONCLUSIONS AND ACKNOWLEDGEMENTS

This project was an intriguing endeavor that served as a test of our capabilities and prepared us for significantly larger tasks. It required the coordination of numerous variables within a constrained timeframe. Breaking away from conventional solutions and adopting an unconventional approach allowed for the application of one of the most interesting solutions currently available for monitoring piles along their entire length. This solution is not only simple to install but also provides a vast amount of data for analysis. Future plans include correlating the obtained results with theoretical and semi-empirical analyses of the micropile-soil interaction. Further field studies of this nature are also planned.

The project, which involves the micropile tests at the designated test site, is funded privately as part of a collaborative initiative aimed at employing micropiles in regional investments.

ABSTRACT: The design of geotechnical structures requires an accurate assessment of the strain moduli of the grounds. Experience shows that these depend on the range of strain considered. In particular, for dynamic problems (e.g. vibrations induced by the excavation of a tunnel), the maximum shear modulus G_{max} has to be estimated. To contribute to this topic, the results of surface wave measurements under ambient noise (H/V method), cross-hole tests, resonant column tests and pressuremeters tests performed in various clay and marl formations in the Paris subsoil are presented. The analysis concerns the relationship between these different types of measurements and their comparison with data in the literature.

RÉSUMÉ: La conception des ouvrages géotechniques nécessite une évaluation précise des modules de déformation des terrains. L'expérience montre que ceux-ci dépendent de la gamme de déformation considérée. En particulier, pour les problèmes dynamiques (par exemple les vibrations induites par le creusement d'un tunnel), le module de cisaillement maximal G_{max} doit être estimé. Pour contribuer à cette problématique, les résultats de mesures d'ondes de surface sous bruit ambiant (méthode H/V), d'essais cross-hole, d'essais à la colonne résonnante et d'essais pressiométriques réalisés dans différentes formations argileuses et marneuses du sous-sol parisien sont présentés. L'analyse porte sur la relation entre ces différents types de mesures et leur comparaison avec les données de la littérature.

Keywords: Shear modulus; strain level; in-situ wave velocities; resonant column.

1 INTRODUCTION

In geotechnical engineering, predicting the movements of a soil subjected to external mechanical action requires knowledge of its stiffness. However, it is well known that the soil stiffness is not intrinsic to the material. Under a given stress condition (e.g. a fixed mean pressure), soils and weak rocks have a stiffness that decreases as the amplitude of their strain increases. In parallel, numerous experimental observations from laboratory tests have shown that the stiffness of these materials changes very little for strain levels below 10^{-5} (*e.g.* Clayton and Heymman, 2001; Vardanega and Bolton, 2013). For these very low strain levels, it is therefore possible to define a reference shear modulus (G_{max}). Knowledge of G_{max}, combined with data quantifying the degradation of the shear modulus G as a function of strain, is then required to predict ground displacements in geotechnical design.

In practice, there are several experimental methods for determining G_{max} (*e.g.* Atkinson, 2000; Clayton, 2011). On the one hand, in situ geophysical methods are based on the measurement of the propagation velocity of surface or volume seismic waves. For these methods, the value of G_{max} is generally derived from the measurement of the shear wave velocity (V_s) in the ground, using the relationship $G_{max} = \rho.V_s^2$ (with ρ the soil mass density). On the other hand, laboratory methods performed on cored or reconstituted soil samples placed in a triaxial cell are based either on the measurement of the shear wave propagation velocity (bender element testing) or on the measurement of the local or global strain of the sample under controlled mechanical stress (resonant column). It should be noted that cross-analyses of results obtained by these

different methods tend to show that G_{max} values measured in situ are generally higher than those measured in the laboratory (*e.g.* Stokoe et *al.*, 1994).

Although laboratory methods have the disadvantage of using small soil samples that may have been disturbed during drilling and sampling, they have allowed us to demonstrate the influence of various parameters on G_{max}. On the basis of these laboratory tests, several authors have shown the dependence of G_{max} to various parameters as the mean effective pressure (p'), the void index (e), the degree of consolidation (OCR), the plastic index (PI) or the loading path. Several semi-empirical formulations relating G_{max} to these different parameters have been proposed (*e.g.* Hardin and Black, 1968; Hardin and Blandford, 1989; Viggiani and Atkinson, 1995).

Laboratory tests (resonant column, precision triaxial test) also have the great advantage of allowing the reduction in secant shear modulus G as a function of strain (γ) to be quantified over a relatively wide range of strains (*e.g.* from 10^{-5} to 10^{-2} for the resonant column). Thus, by considering a hyperbolic relationship between shear stress and strain (e.g. Duncan and Chang, 1970), several authors (e.g. Hardin and Drnevich, 1972; Vucetic and Dobry, 1991; Santos and Gomes Correia, 2001; Darendeli, 2001) have shown that it is possible to express the reduction in material stiffness as a function of strain in terms of a hyperbolic relationship between G/G_{max} and γ/γ_r of the following general form:

$$\frac{G}{G_{max}} = \frac{1}{1+(\gamma/\gamma_r)^{\alpha}} \qquad (1)$$

where γ_r represents the reference shear strain and α is referred to the curvature parameter.

The aim of this paper is to contribute to this problem by taking advantage of a major measurement campaign carried out as part of the E-Pilot research project, dedicated to the study of vibrations induced by tunnel boring machines. Pressuremeter tests, cross-hole tests, surface wave measurements under ambient noise (H/V method) and resonant column tests were carried out in various clay and marl formations in the Paris subsoil. The analysis concerns the relationship between these different types of measurements and their comparison with data in the literature.

2 EXPERIMENTAL SITE DESCRIPTION

2.1 Geological context

The study site is located in the city of Wissous, in the southern suburbs of Paris. It is located on a plateau (Orly plateau) with a succession of subhorizontal clay-limestone and marl formations.

A T6-116 survey (116 mm diameter double tube core barrel), 39.5 m deep, referenced SC08198, was drilled on site in December 2022. This hole revealed the stratigraphic succession described in Figure 1 with, from bottom to top, the Masses and marls of gypsum (Lower Ludian, -38 My), the Suproagypseous marls of Argenteuil and Pantin, the Green clays, the Brie and Sannois limestones, and the quaternary plateau silts.

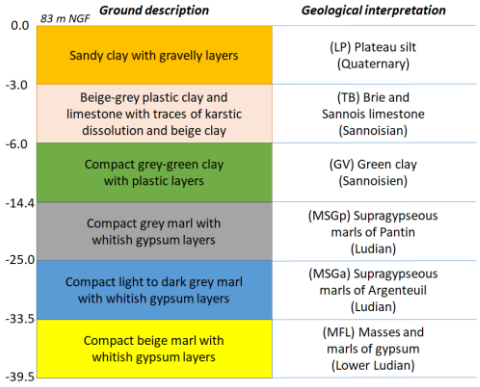

Figure 1. Geological profile (scale not observed). 83 NGF correspond to the surface of the work site.

2.2 Geotechnical characteristics

Table 1 summarises the main state parameters of these different formations: wet mass density ρ, dry mass density ρ_d, water content w, voids index e, degree of saturation Sr, blue-value VBS, plasticity index PI, fine content FC and over-consolidation ratio OCR.

Table 1. Geotechnical characteristics of the grounds.

	LP	TB	GV	MSGp	MSGa	MFL
State parameters						
ρ (kg/m³)	1980	1990	1950	1930	1980	1810
ρ_d (kg/m³)	1660	1640	1560	1530	1600	1380
w (%)	20	21	25	26	23	31
e (-)	0.58	0.61	0.70	0.73	0.65	0.92
Sr (%)	--	93	97	97	97	92
VBS (-)	3	2	6	2	5	3
PI (-)	12	19	33	28	37	45
OCR (-)	1	1	2	1	1.5	1
FC (%)	80	56	97	86	97	87
Mechanical parameters						
E_M (MPa)	8	23	13	43	45	180
p_l^* (MPa)	0.8	2.1	1.1	3.2	3.1	5.8
c' (kPa)	5	15	20	30	30	60
φ' (°)	28	32	15	25	20	35

These were measured in the laboratory on samples taken from the aforementioned core hole, and consolidated by other measurements taken from other surveys carried out in the same geological context.

Pressiometric caracteristics (geometrical means of Ménard moduli E_M and limit pressure p_l^*) and plastic parameters (effective cohesion c' and friction angle φ') are also given in Table 1. These values are deducted of all the tests made for the construction of line 18 metro on the Orly plateau. Note in particular that these values are consistent with the results of the two pressiometric boreholes made in the study site.

3 MEASUREMENTS OF V_S PERFORMED

Three types of measurements of the shear wave velocities V_s have been performed on the study site to assess the maximum shear modulus G_{max}: in-situ cross-hole test, in-situ ambient noise measurements (H/V method), laboratory tests on resonant column apparatus.

3.1 Cross-hole measurements

Measurements of shear wave velocity V_s were carried out between two boreholes 12 m apart, 80 mm in diameter, lined with PVC pipe and sealed to the ground. The signals obtained were of good quality and interpreted in accordance with ASTM D4428.

Significant contrasts appear between the different layers of soil, with little dispersion by layer. The geometric means of V_s by layers are: 353 m/s in LP, 448 m/s in TB, 200 m/s in GV, 423 m/s in MSGp and 471 m/s in MSGa.

It should be noted that the measurements taken beyond a depth of 26 m correspond to oblique paths between the transmitter (maintained at a depth of 26 m) and the receiver of variable depth. The wave speeds measured in the MFL formation are therefore underestimated. The corrected value considering the oblique path is equal to 750 m/s.

3.2 Ambient noise measurements (H/V)

The H/V method is a geophysical method used to analyse the structure of the subsurface. Its primary purpose is to investigate parameters such as the depth to bedrock then, through inversion processes, the shear wave velocity of soil layers. This method entails the comparison of the amplitude of horizontal ground motion (H) with the amplitude of vertical ground motion (V) across various frequencies. During in-situ monitoring, five 3D geophones (TROMINO from the Moho brand) are positioned at 10-meter intervals on the ground surface. These geophones feature three highly sensitive orthogonal acquisition channels with high resolution and a precision of 10^{-7} mm/s. Placed on the natural surface of the ground, 3 m above the worksite platform, measurements were conducted for 30 minutes under ambient noise, without specific mechanical excitation. Considering the superficial layer's depth 6 m (cross hole test), calculations were performed for a frequency range of 0.5-20 Hz.

H/V curves are calculated simultaneously from all sensors using Geopsy software (Figure 2a) and from each sensor using Grilla software (example of one sensor is given in Figure 2b). These profiles are almost identical, showing a similar response of all the sensors.

Classifying H/V peaks as of geological or non-geological origin involves examining the corresponding spectra. A geological peak is characterized by a maximum in the X and Y directions (blue and green) and a minimum in the Z direction (pink), forming an eye shape (Figure 2c). Consequently, based on this criterion, three peaks of stratigraphic origin are identified: $f_3(2.1Hz)$, $f_2(8\ Hz)$ and $f_1(14\ Hz)$.

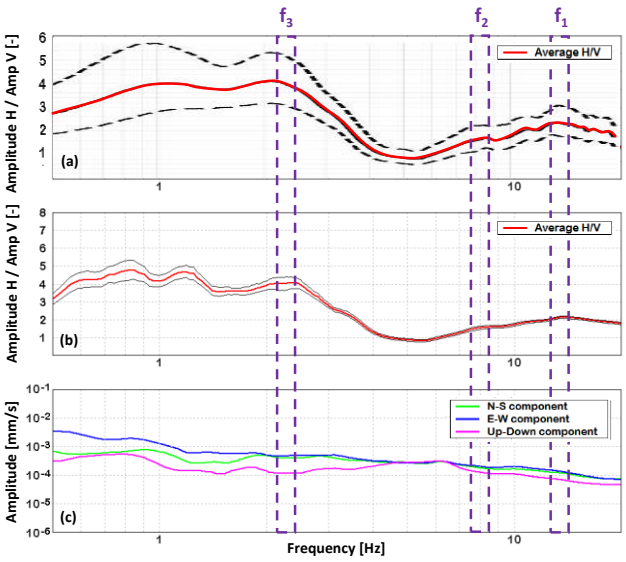

Figure 2. Visualization of (a) Global spectrum amplitude ratio H/V across all sensors, (b) Individual spectrum amplitude ratio H/V from a single sensor, and (c) Spectrum amplitude by direction from the single sensor.

Based on these three peaks, the first three geological layers can be identified. Constraints are required in the inversion process of H/V peaks, either on depth or shear wave velocity. For the upper layer, a depth constraint is specified as $H_1 = 6$ m. Although the resonance equation layer $\frac{V_S}{4H} = f$ cannot be applied in multilayer scenarios, it can serve as a preliminary approximation. Consequently, the shear wave velocity V_S of the resonating layer is estimated as $V_{s1} \approx 4\,H_1\,f_1 \approx 4 \times\ 6\ \text{m} \times 14\ \text{Hz}\ \approx\ 340\ \text{m/s}$.

The second layer, characterized by the frequency $f_2(8\,Hz)$, underwent analysis using a trial-and-error method in Grilla software to achieve the best fit of the H/V Spectral Ratio at this specific frequency. This analysis shows the existence of a layer with a shear wave velocity V_{s2}= 450 m/s situated at depths between 6 and 9 m below the worksite platform (77 to 80 m NGF). Similarly, the third layer, identified with a shear wave velocity V_{s3} of 130 m/s (Figure 4), is located at depths between 6 and 12 m (71 to 77 m NGF).

3.3 Fixed-base resonant column measurements

Five resonant column tests were carried out in the laboratory, one in each of the present layers, with the exception of the LP. These tests, conducted in accordance with ASTM-D4015-15, were carried out on specimens 50 mm in diameter and 100 mm high, loaded in torsion.

The samples, which were nearly saturated in their natural state, were resaturated by applying an internal back-pressure. The Biot coefficients obtained were greater than 0.93. The tests were carried out at confining pressures equal to the geostatic mean effective stress at the depth of each sample.

The shear wave velocities measured for each test, in function of the distortion are presented in Figure 3.

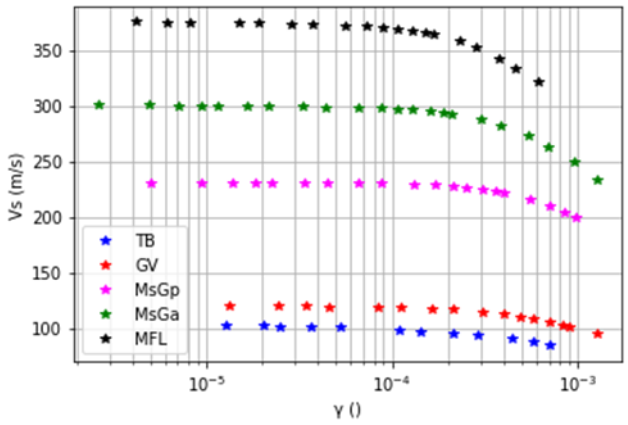

Figure 3. Results of the resonant column tests.

4 CROSS ANALYSIS OF THE MEASUREMENTS OF G_{MAX}

Figure 4 summarises the shear wave velocities measured on cross-hole tests, resonant column tests (values for a distortion of 10^{-5}) and estimated by H/V approach.

Firstly, Figure 4 illustrates that employing measurements under ambient noise using the H/V approach enables estimation of shear wave properties up to a depth of approximately 15 m. It is crucial to note that achieving these results relies on the engineer possessing prior knowledge of local stratigraphy. This understanding is essential to initiate the trial-and-error approach with certain constraints, such as the layer thickness in our case.

Figure 4 shows a good agreement between the Vs measured in situ using the cross-hole tests and those derived from the H/V method, particularly for the top two layers. It illustrates also that the V_s measured at the laboratory scale (resonant column tests) are 1.5 to 4 times lower than in-situ (cross-hole tests).

The maximum shear moduli ($G_{max} = \rho.V_s^2$) calculated in each layer by the two methods are summarised in Table 2. In this table, the geometric means of the V_s measured per layer presented in Figure 3 are used, together with the wet densities given in Table 1. The large difference between the V_s values obtained from the different types of measurements is further increased by squaring them.

Table 2. G_{max} deduced from shear wave velocities.

G_{max} (MPa)	LP	TB	GV	MSGp	MSGa	MFL
Measurements						
Resonant Column	-	22	29	105	182	260
Cross Hole	248	425	78	352	404	1018
Estimation by empirical formula						
Carlton & Pestana (2016) $G_{max\text{-}lab}$	--	110	170	184	289	163
Reiffsteck et al. (2022) $G_{max\text{-}insitu}$	96	340	93	452	474	867

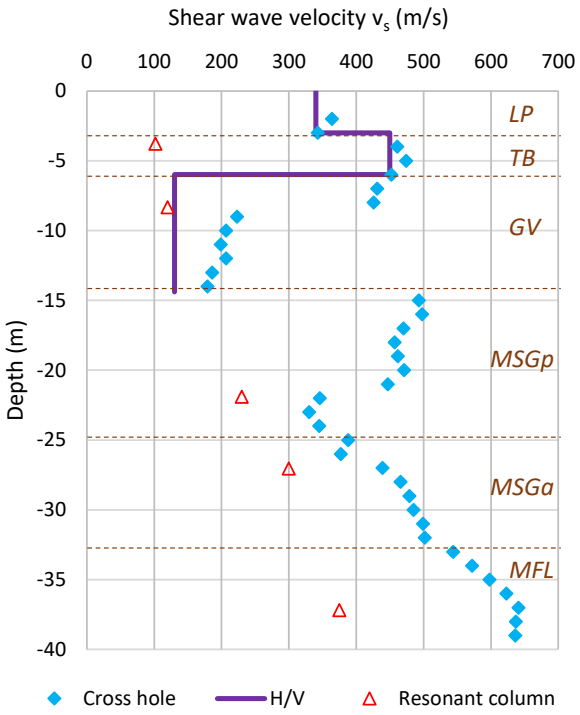

Figure 4. Shear wave velocities measurements.

To go deeper on comparison between in-situ and laboratory shear moduli, the summary provided by Carlton & Pestana (2016), which includes the large-scale test campaign carried out in the USA in the 1990s as part of the ROSRINE project, is used. All the experimental results considered by the authors are shown in blue in Figure 5. These points mixed tests on 331 different soils (sands or clays of different countries), reconstituted or "undisturbed". Our measurements are added in red on this figure.

According to this summary, the moduli measured in the laboratory are lower than those measured in situ (cross-hole). However, the difference observed here appears to be very large, particularly for TB and MFL. The low moduli measured in the laboratory are probably related to sample disturbance during coring or sample preparation (Stokoe *et al*. (1994), cited by Cami (2017)).

By calibration on 1680 laboratory measurements, Carlton & Pestana (2016) propose an estimate of the laboratory measured shear moduli $G_{max,lab}$ as a function of the void index e, the average effective stress p', the over-consolidation ratio OCR, the plasticity index PI and the fine content FC of the soil. In the case of fine soils (FC > 30%), this equation applies:

$$G_{max,lab}(\text{MPa}) = 0.1 * 790.2 * e^{-1.309} * p'^{0.465} * OCR^{2.022*(IP/100)^{1.933}} * (FC/100 + 1)^{-0.124} \quad (2)$$

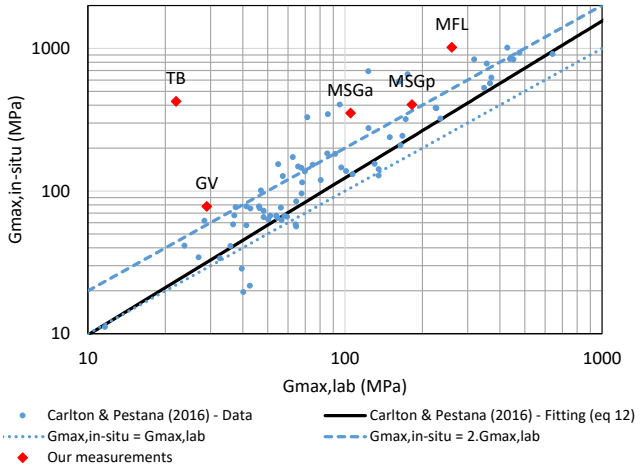

Figure 5. Ratio between the shear moduli measured in-situ and in laboratory.

The moduli measured (Table 2) appear to be 3 to 5 times lower than estimated in the TB and GV. As a result, it seems that the resonance column tests carried out on the most superficial are not very representative of the real shear strain moduli. However, the samples taken appeared to be little disturbed. Multiply systematically the type of tests and consolidate their consistency with empirical expressions would therefore appear to be a good principle to adopt in projects.

Pressuremeter tests were also carried out on the site studied. The pressuremeter moduli measured E_M are summarised in Table 1. These moduli correspond to large distortion ranges (10^{-2} to 10^{-1}), greater than those discussed previously. However, Reiffsteck et *al* (2022) proposed a correlation between G_{max} and E_M on the basis of 750 couples of [E_M; V_s] deduced from 26 different sites (Equation 3):

$$G_{max} = \rho . V_s^2 = \rho . (a . E_M{}^b)^2 \quad (3)$$

where the coefficients (a; b) depend on the type of soil. For clays (LP and GV formations can be considered belong to this category here), this pair is (a = 98; b = 0.29). For marls (TB, MSGa, MSGp, MFL), the values are (189; 0.25).

The calculated moduli are summarised in Table 2. They appear to be in fairly good agreement with the results of the cross-hole test, which supports the expression proposed by Reiffsteck et *al* (2022).

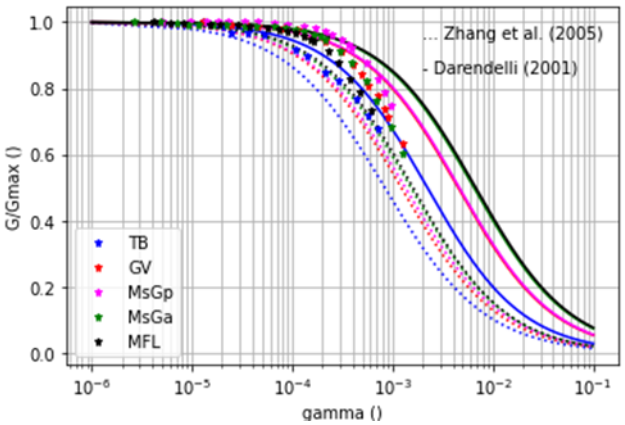

Figure 6. Decrease of the normalised shear modulus with the shear strain magnitude.

5 EVOLUTION OF THE SHEAR MODULUS WITH SHEAR STRAIN

The resonant column tests carried out enable the evolution of the shear modulus with the amplitude of the distortion to be quantified. The curves obtained of normalised shear modulus G/G_{max} are shown in Figure 6 (colored stars). Normalized shear modulus is the current shear modulus G divided by G_{max} obtained in laboratory with a resonant column apparatus.

Experimental results are compared to empirical relationships (solid and dotted lines) that have been proposed in the literature for clay, under the Eq. 1.

Darendeli (2001) and Zhang et *al.* (2005) proposes the expression of γ_r and α given in Eq. 5 and 6

respectively, where p' is the confining pressure and Pa the atmospheric pressure:

$$\alpha = 0{,}919 \qquad (5)$$
$$\gamma_r = \left(0.0352 + 0.00101\, I_p . OCR^{0.325}\right). p'^{0.348}$$

$$\alpha = 0.0021\, PI + 0.834 \quad ; \quad \gamma_r = \left(0.0749 + 0.0011\, I_p\right). \left(p'/Pa\right)^{0.316 \exp\left(-0.0142\, I_p\right)} \qquad (6)$$

These curves are presented in Figure 6: markers and lines in blue correspond to TB, in red to GV, in pink to MsGp, in green to MsGa and in black to MFL. These two types of empirical relationship frame the measured curves.

6 CONCLUSIONS

Analysis of the different methods of measuring G_{max} in the laboratory and *in situ*, and comparison with the literature, mainly show that:

- the cross-hole tests provide reference values for G_{max} to evaluate the vibratory phenomena associated with TBM excavation because they affect a volume of soil representative of the problem studied;
- the H/V method under ambient noise allows to recover V_s values close to those measured by the cross-hole tests, on condition to have a prior knowledge of the stratigraphy in order to constrain the inversion process;
- laboratory measurements using a resonance column give G_{max} values 2 to 4 times lower than those measured in situ (cross hole), in line with observations in the literature;
- the decrease of the normalised modulus G/G_{max} with the distortion observed in the laboratory appears to be little affected by any disturbance of the sample due to the sampling.

ACKNOWLEDGEMENTS

The authors thank the Société du Grand Paris, Arcadis, Vinci Construction and Me2i for the data acquisition, C. Gaillard (CETU), H. Calissano, L. Batilliot and M. Vanwolleghem (Cerema) for their contributions to this study, and French national research agency (ANR) in the project E-PILOT (ANR-21-CE22-0011).

Settlement analysis for a nuclear plant design

Etude de tassement pour le design d'une centrale nucléaire

ABSTRACT: Nuclear plants are very heavy and sensitive structures, therefore very interesting to study in geotechnics. When the site contains soft soil layers, settlements can be significant, and foundation adaptation may be required. Since standard methods are not fit for such high displacements and low tolerances, sophisticated settlement studies are carried out to ensure feasibility. First, adequate geotechnical soil investigations have to be carried out in order to evaluate soil behavior and particularly to estimate their stiffnesses accurately. Once in-situ and laboratory tests have been cross-analysed, soil moduli are derived for the correct range of strains. For new projects on existing sites, the choice of soil moduli is often guided by a back analysis carried out on the nearby operating plant. The complexity might lead to build a 3D model to assess the settlements, taking into account various elements (dewatering, sequence of construction, different backfill areas, etc.). Both drained and undrained (with consolidation) situations are considered. Non-linear behaviour is also assessed for sensitivity calculations. The results are to be used in the different aspects of the design with regards to the tolerances (raft design, thresholds against flooding levels, joints between buildings, pipe displacements, etc.). The article presents the calibration of the settlement model using in-situ data as well as the back-experience from the monitoring on the current plant nearby and give an overview for the use of the results.

RÉSUMÉ: Les centrales nucléaires sont des infrastructures sensibles apportant une charge importante au sol, ce qui rend leur étude géotechnique très intéressante. Lorsque le sol est compressible, les tassements peuvent être significatifs et les systèmes de fondations doivent être adaptées en conséquence. Ainsi, des études de tassements détaillées sont menées afin d'assurer la faisabilité de construction de tels ouvrages. Tout d'abord, des investigations géotechniques sont réalisées afin d'établir un modèle géotechnique. Pour cela, une analyse croisée est réalisée entre les essais de laboratoire et les reconnaissances in-situ. Les modules de sol sont ensuite adaptés aux gammes de déformations apportées par le projet. Pour les nouveaux projets sur les sites existants, le choix des modules est également conditionné par une analyse en retour des déplacements de la centrale en activité. Dans le cadre de notre étude, un modèle 3D a été réalisé afin d'estimer les tassements sous un projet de centrale nucléaire. Des comportements linéaires et non linéaires ont été considérés avec des calculs drainés et en consolidation. Les résultats peuvent être utilisés pour différents éléments de design (radier, joints entre galeries ou bâtiments, etc.) en prenant en considération les tolérances adéquates pour traduire la variabilité des terrains et du phasage de construction par exemple.

Keywords: Settlement analysis; nuclear plant; finite elements analysis.

1 INTRODUCTION

A nuclear plant as built in the 20th century weights several hundred thousand tons, inducing average stresses under the rafts of 200 to 500 kPa. New models in current projects around the world are more powerful, have more features, therefore get larger and heavier (exceeding half a million tons, and inducing average stresses up to 700 kPa). Before the construction of a new nuclear plant, a settlement study is thus essential to ensure an adequate design.

A geotechnical soil model has to be built based on in-situ investigations and laboratory tests. Depending on the soil and the loads expected to be brought by the project, geotechnical moduli have to be adapted to fit the range of strains the soil will experience. In our study, the fitting is based on the back-experience from the monitoring on the current plant nearby, with a nonlinear elastic model derived from pressuremeter data as developped in the ARSCOP project (Hoang et al. 2020). This model already allowed the reproduction of many sets of settlement data: nuclear power plants, high-rise towers in the district of La Défense (Paris, France) and pre-loading embankments at Calais, France.

In our study, two different geotechnical models have been built: one to validate the soil moduli under the existing power plant, and a second one for the new plant, based on the first model but with a strain adaptation because of the greater loads of the future buildings (therefore inducing more strain).

2 SETTLEMENT STUDY FOR THE EXISTING NUCLEAR PLANT

In our study, the geotechnical model has been built with the analysis of the extensive in-situ and laboraty tests and an adaption to strains ranges.

2.1 Nonlinear elastic model from pressuremeter

In the framework of the French national project ARSCOP devoted to the development of the pressuremeter test, a total review of the settlement calculation has been initiated. The aim of this project is to develop a unified calculation approach of shallow foundations and rafts settlements.

In this framework, in order to have a good estimate of settlement under spread foundations, a calculation method has been developed to combine the variation of the deformation modulus according to the strain range and take advantage of short calculation time of analytical methods. This method is based on decay curves, allowing moduli to vary according to the strain range. The aim is to provide the load-settlement curve of any spread foundation up to a load close to 50% of its bearing capacity. For higher loads, the time effects should be considered, and the elasticity theory is not appropriate. The deformation modulus is assessed by considering Menard pressuremeter modulus (Ménard and Rousseau, 1962) for high strain level (10^{-2} to 10^{-1}).

The ground under the spread foundation is divided into various sublayers where E can vary according to the strain level:

$$\frac{E}{E_M} = k(\varepsilon) = \frac{k_0}{1 + \varepsilon/\varepsilon_0}$$

where E_M is the Menard pressuremeter modulus and k_0 and ε_0 depending on the soil type from the Ménard α parameter, as described in (Hoang et al. 2020):

- Type 1: sands and gravels (α=1/3) k_0=6,67 and ε_0=0,005
- Type 2: dense sands and gravels (α=1/2), k_0=4,5 and ε_0=0,008
- Type 3: overconsolidated clays (α=2/3), k_0=3,20 and ε_0=0,014

2.2 Geotechnical model

The existing nuclear plant has been monitored with displacement sensors, during both construction and operation of the buildings. It is a very good way to evaluate repartition of settlements in different soil layers to calibrate the geotechnical model and check its consistency.

Predictive calculations at the time gave greater settlements than the observations show. The available documents suggest that strain corrections were not properly applied and might have led to this overestimation. ARSCOP curves have been used to calibrate soil moduli for the current plant with regards to the calculated strain range. Pressuremeter modulus can be used directly with a non-linear elastic model to match the measurements. Corrected moduli were 3 or 4 higher than E_M, depending on the soil type.

The modulus obtained for each layer shows a relative homogeneity, therefore a linear elastic soil model with one single equivalent modulus per layer is deemed sufficient in our study (Figure 1).

2.3 Modelization

An axisymetrical Plaxis 2D model has been implemented with the calibrated soil moduli. A realistic construction sequence has been set, including excavations, dewatering, backfilling, and loading of the buildings. Drained and undrained behaviors have been computed for 2 soil laws: an elastic and Hardening Soil Model (HSM).

Drained behavior has been firstly implemented to assess the maximum settlement. Undrained

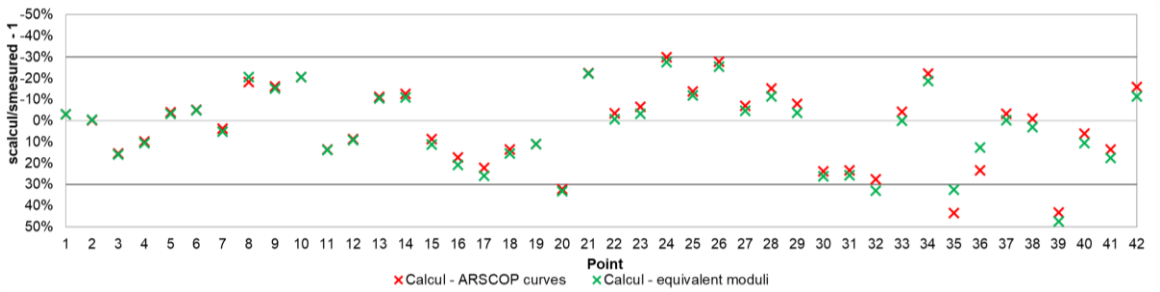

Figure 1. Comparison of measured and back-calculated settlement for the current plant (the ordinate is the discrepancy between calculation and observation, the x-axis represents the various monitoring points all over the existing plant).

calculation was considered to evaluate the impact of the excess pore pressure in deep layers, due to the additional building loads. During the loading, an insignificant increase of excess pore is observed under the plant and dissipated at the end of construction (Figure 2). Therefore, drained and undrained simulations get similar settlement during the loading, and then equal settlements at the end (no more excess pore pressure). After the construction, settlement observations showed no evolution, which correlates with the absence of consolidation or creep of any kind. Excess pore pressure calculations were therefore consistent with settlement observations.

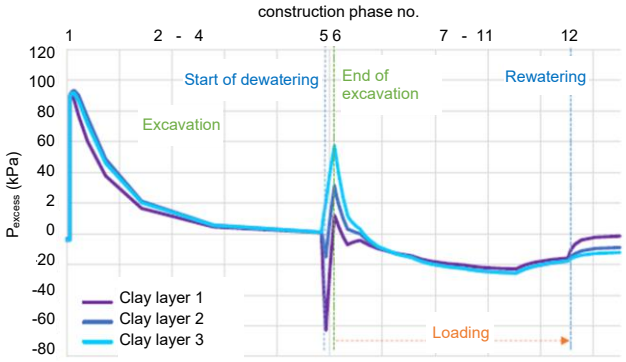

Figure 2. Estimation of the generation of excess pore pressure in deeper layers under the existing nuclear plant.

Linear and HSM calculations were done, both for the drained and undrained cases, to evaluate if there were discrepancies that would invalidate the previous estimation that a linear model with a single modulus for each layer was sufficient to accurately reproduce the expected settlements (as long as it is carefully calibrated). Settlement results are similar and consistent with observations (Figure 3). It does not however mean that the additional loads only solicited the soil in the elastic domain (small deformations) since the choice of the moduli has been made with (secant moduli). The computed strains are also within the estimated range, ensuring consistency of the calculation.

The geotechnical model for the existing plant is therefore validated since calculations and observations give similar results. Moduli can be used with a reassessment for the adequate strain ranges for the future nuclear plant.

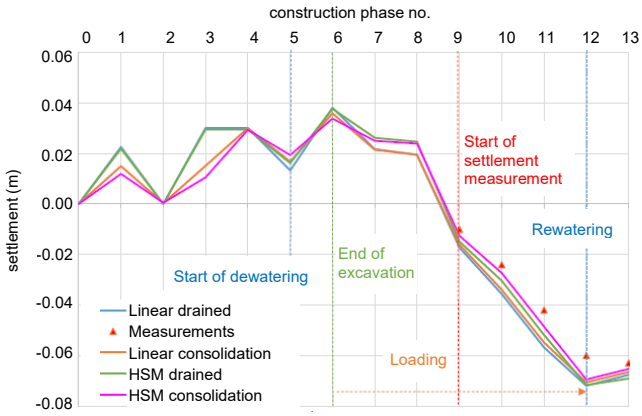

Figure 3. Comparison between settlement calculations and observations for the existing nuclear plant.

3 SETTLEMENT STUDY FOR THE NEW NUCLEAR PLANT

3.1 Geotechnical model

The same process is considered for the new plant to be built nearby (with a stratigraphy not significantly different) using the same pressuremeter modulus, and approximately 50% higher loads induced on the soil. Therefore, degradation is applied on soil moduli with the adequate range of strain.

Moduli for the new nuclear plant are approximately 20% smaller than the corrected moduli used for the existing nuclear plant, resulting in stronger degradations (

Figure 4).

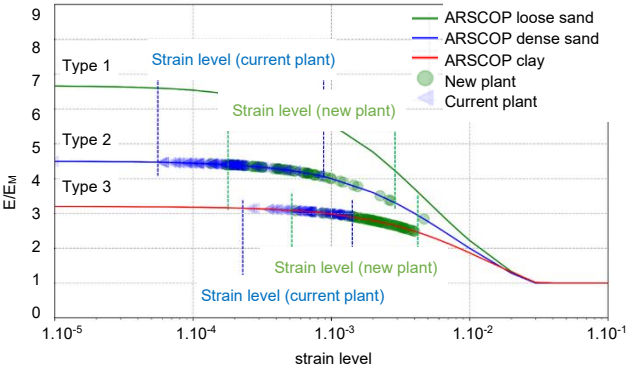

Figure 4. Variation of modulus with strain levels on the current and new plants – ARSCOP curves.

3.2 Modelization

Once soil moduli have been calibrated, a Plaxis 3D model has been built to evaluate the plant settlements (Figure 5). Most of the buildings were implemented as rigid elements except for the bigger and heavier ones - to assess raft deformations.

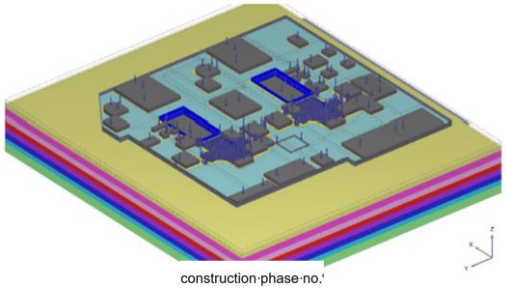

Figure 5. Plaxis 3D model for the future nuclear plant.

The same type of calculations as for the existing nuclear plant have been implemented: linear and HSM soil laws for drained and undrained behaviors.

The consolidation calculation shows greater excess pore pressure during construction (Figure 6 phases 14 to 21 - 200 kPa, compared to Figure 2 phases 6 to 11 - 20 kPa on the existing plant). It is due to the greater loads. It explains that the undrained model (orange line in Figure 7) induces less settlement than the drained model (blue line in Figure 7): excess pore pressure is significant during loading and does not allow immediate settlement.

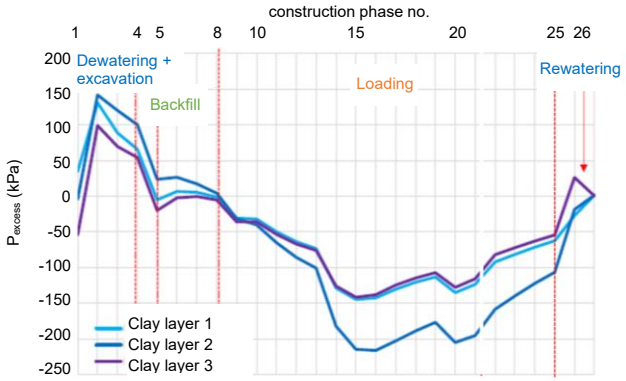

Figure 6. Estimation of the generation of excess pore pressure in deeper layers under the future nuclear plant.

However, excess pore pressures are dissipated at the end of the loading because the construction time is longer than it was for the existing nuclear plant. Therefore, drained and undrained calculation give similar final settlement (Figure 7).

Linear and HSM (drained and undrained) calculations were also done to evaluate if there were any nonlinear behavior in soil layers. Both soil laws give similar final settlement results (Figure 7), demonstrating that the soil still globally works in the estimated strain ranges.

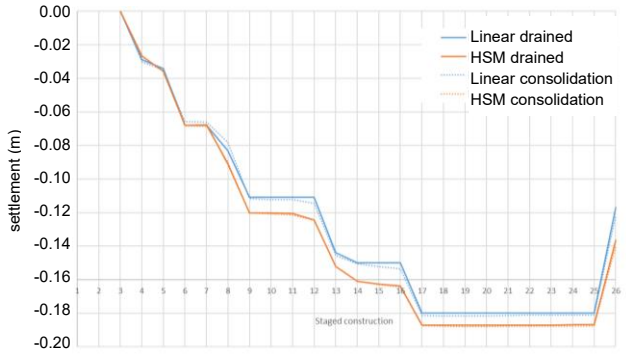

Figure 7. Comparison between linear and HSM calculation – settlement of HR centre.

The difference between phases 25 and 26 (corresponding to the rewatering at the end of the earthworks) lies in the way the reloading modulus is estimated in both behavior laws (all the calibration is done on first loading moduli).

The 3D-settlement model allows to extract the settlement at any point and any phase. It is then possible to evaluate differential settlements along structures like the various embedded galleries (example in Figure 8). Those are essential for calibrating adequate rebars and joints.

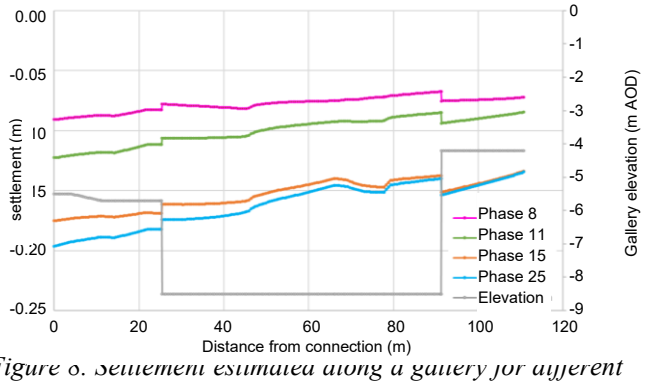

Figure 8. Settlement estimated along a gallery for different phases against its elevation profile (in grey).

4 CONCLUSION

An adapted geotechnical model is essential to predict and understand settlement under buildings. In order to evaluate the settlement of a future nuclear plant and give adequate settlement values for the design, detailled settlement studies are done. They are based on a geotechnical model calibrated on extensive in-situ and laboratory tests data. Depending on the range of strains, the moduli can be corrected with ARCSCOP cuves. It has been tested and compared with existing plant monitoring data on the same site. Settlement observations and calculations are consistant thanks to the calibration done on the moduli. For the future project, since the loads are greater, the moduli should however be adapted with the strains. It can lead to realistic settlement values for the future design.

A critical review of field testing of helical steel piles

Un examen critique des essais sur le terrain de pieux hélicoïdaux

ABSTRACT: In this paper, an initial appraisal of the existing body of knowledge contained in the records of full-scale axial maintained load tests on helical steel piles (HSP) is presented. There are numerous case studies on full-scale testing of HSP which cover a variety of configurations (no. helices, helix spacing, depth of installation, etc.), ground conditions, testing procedures and definitions of failure. This data base is being critically reviewed by the authors and in this paper, the procedures employed in the review are outlined and illustrated through a selection of the case studies. The review involved examining the time-displacement and time-load data (when available), to confirm the reliability of the test stages from a given test and then applying a uniform failure condition across all studies. It is shown that the short loading stage durations employed in most studies (so-called quick test) and not imposing a creep criterion, especially in the latter stages of the test, means that the ultimate capacity is often overstated. This revised and updated database will be used to critically appraise resistance calculation methods used in practice and develop reliability-based design procedures for HSP that are compatible with Eurocode 7.

RÉSUMÉ: Dans cet article, une première évaluation de l'ensemble des connaissances contenues dans les enregistrements d'essais de charge axiale maintenue à grande échelle sur des pieux en acier hélicoïdaux (HSP) est présentée. Il existe de nombreuses études de cas sur les essais à grande échelle de HSP qui couvrent une variété de configurations (nombre d'hélices, espacement des hélices, profondeur d'installation, etc.), conditions de terrain, procédures d'essai et définitions de défaillance. Cette base de données est en cours d'examen critique par les auteurs et dans cet article, les procédures employées dans l'examen sont décrites et illustrées à travers une sélection d'études de cas. L'examen impliquait d'examiner les données de déplacement temporel et de charge temporelle (lorsqu'elles étaient disponibles), afin de confirmer la fiabilité des étapes de test à partir d'un test donné, puis d'appliquer une condition de défaillance uniforme dans toutes les études. Il est montré que les courtes durées d'étapes de chargement employées dans la plupart des études (essai dit rapide) et n'imposant pas de critère de fluage, en particulier dans les dernières étapes de l'essai, font que la capacité ultime est souvent surestimée. Cette base de données révisée et mise à jour sera utilisée pour évaluer de manière critique les méthodes de calcul de résistance utilisées dans la pratique et développer des procédures de conception basées sur la fiabilité pour les HSP qui sont compatibles avec l'Eurocode 7.

Keywords: Helical piles; field tests; design; safety.

1 INTRODUCTION

Helical steel piles (HSP) in various configurations have been used since the 19th century when Mitchell (1848) proposed their use in providing secure ship mooring and for the foundations of near-shore structures such as lighthouses and piers. For this study, HSP are considered to be a foundation element comprising a central, small diameter shaft of variable length with one or more sections of helix located at intervals along the shaft, from the tip. The helices may have differing diameter but typically are 3 to 5 times the diameter of the shaft and spaced 3 helix diameters apart. This latter ensures a so-called individual helix failure mechanism (Perko, 2009) by minimising interference between the respective failure mechanisms.

Since the 1960s and more-so, the 1980s until the present day, there has been an effort to provide a greater scientific understanding of the mechanisms of load-transfer of HSP, and how e.g. the ultimate resistance might vary from experience and design methods drawn from conventional piles. In reviewing these studies, it became apparent that while testing procedures were broadly similar, i.e. use the so-called "quick test", ASTM (2020): a) often load control was poor and not held within acceptable tolerances of the target value, b) it is not reported if the ASTM

recommended consideration of creep was made, to ensure the final load step(s) were stable, and c) a variety of definitions of failure have been employed including maximum attained load or the load associated with a settlement of 10%D, amongst others. It was felt that the former could lead to overstatement of pile resistance, while the latter makes the comparison of results between themselves and in relation to analytical calculation methods, and assessment of their reliability rather difficult. Therefore, it was decided to revisit the body-of-knowledge associated with HSP load testing that is available in the literature. In the following, the methodology adopted in reviewing the HSP database is outlined, along with some examples of its application to selected case studies and how the updating of the database will proceed.

2 METHODOLOGY

In order to uniformize the results of the various HSP load testing studies; first, where possible, the stability of the loading increments and the stability of the settlement versus time were assessed to ensure that each load stage was stable and secondly, a consistent definition for the ultimate resistance of each HSP was applied.

Loading stability was assessed visually for the most part. Figure 1 illustrates poor load control where variations of 20 to 50 kN (3 to 5% of the applied load) occurred. Typically, for the load range of this test, the limit on load variation would be 5 kN (<1 %), ICE (2007). When the load drops off in this manner there is no reliable definition of the load being maintained in a particular load stage, and e.g., the displacement rate will be artificially slowed by the reducing load.

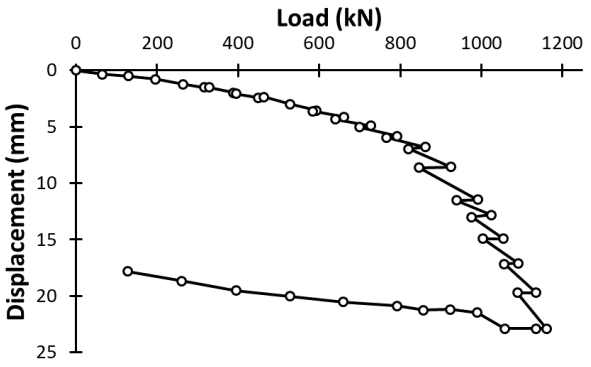

Figure 1. Example of poor load control, from Tappenden (2007).

A simplified version of the approach suggested by England (1992) has been implemented to assess the settlement vs. time, with the time-displacement data fitted with a simgle hyperbolic function to extrapolate and assess whether the recorded settlement was likely to have reached a stable (asymtotic) value at infinite-time. Eqtn. 1 describes this function (shown schematically in Figure 2(a)), where t is the elapsed time during the load stage and s, the increment in displacement in the same period while m and c are the slope and intercept values. The inverse of m, yields the asymptotic value for the displacement as t → ∞.

$$\frac{t}{s} = m.t + c \qquad (1)$$

Likewise, following Fleming (1992) but again using a single hyperbolic function, as per Chin (1972), the load-displacement response was extrapolated and used to derive the ultimate resistance. Only data from stable load stages as defined above, was taken forward into this stage. A single function was used on the basis that most of the load resistance derives from the helix(es) and it was also assumed that the elastic shortening on most HSP would be only a few-mm and could be ignored. Eqtn. 2 describes the hyperbolic function used to extrapolate the load-displacement response where N is the applied load and the other parameters were defined for Eqtn. 1 (Figure 2(a)).

$$\frac{s}{N} = m.s + c \qquad (2)$$

In this case, the inverse of m, yields the asymptotic value for the load, R_∞ as s → ∞.

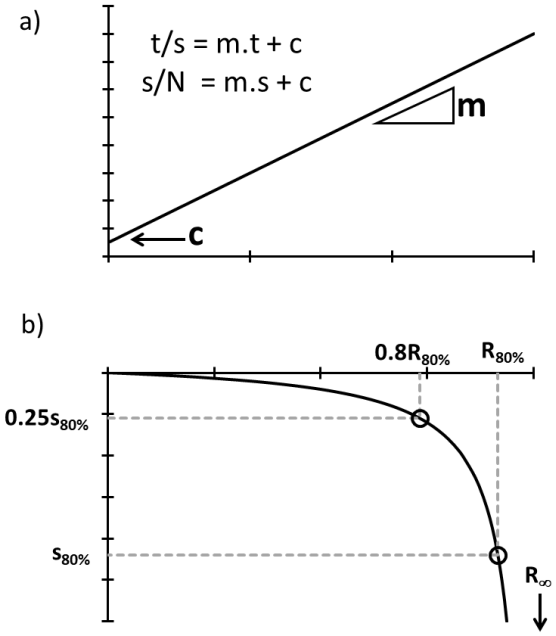

Figure 2. Schematic representation of hyperbolic functions (Equations 1 & 2) and Brinch-Hansen 80% failure criteria.

After some deliberation over the various failure criteria that have been proposed, e.g., as outlined in Fellenius (1980), it was decided that two values would be derived to represent the ultimate resistance, $R_{u,m}$: one based on Brinch-Hansen's 80% criterion (see Fgure 2(b)) which defines the ultimate resistance, $R_{80\%}$ as the load that gives four times the displacement generated by a load at $0.8R_{80\%}$ (Fellenius, 1980) and the asymtotic load obtained from Eqtn. 2. The ratio of $R_{80\%}$ to R_{∞} is about 90±2 %. It is considered that $R_{80\%}$ ensures that a more uniform and comparable state of mobilisation (approching a plunging failure) between case staudies and would be used for the assessment of design methodologies, while R_{∞} will be used in the assessment of analytical calculation models which imply full mobilisation of the pile resistance.

Rather than using the test data directly, Eqtn. 2 was used to derive $R_{80\%}$ and its associated setttlement, $s_{80\%}$ using Eqtns 3 and 4 (see Appendix 1),

$$R_{80\%} = {}^{11}/_{12\mathrm{m}} \qquad (3)$$

$$s_{80\%} = {}^{11c}/_{m} \qquad (4)$$

In some case studies, the test piles were provided with internal sensors, to allow the load-transfer from the pile to the ground to be assessed. Where available, this data has been reassessed and equivalent values for associated resistance parameters (α^* and β^* along the shaft and inter-helix cylinder) and end-bearing capacity factors, N_c^* or N_q^* as appropriate for total and effective stress analysis, were determined. These values are then to be used for comparison with values from analytical solutions. This aspect of the test database will not be discussed here.

3 CRITIQUE OF CASE STUDIES

3.1 Time-extrapolation

The method described above is illustrated here based on the results for tests on HSP in clay reported by Zhang (1999). The compression test shown here was undertaken on a 5.18 m long pile with a 219 mm diam. shaft and 3 no., 356 mm diam. helices, spaced at 1.5 helix diameters. Eleven stages of loading were applied and within each stage, the loads generally varied by less than about ±2 kN (1%).

This is one of the few cases where the author states that creep was considered. However, it is apparent that whatever consideration was made, creep rates were very high from early on when compared to e.g., the 0.25 mm/hr limit referenced by ASTM (2020) or the 0.1 mm/20 min in ISO (2018), for maintained load testing, Figure 3.

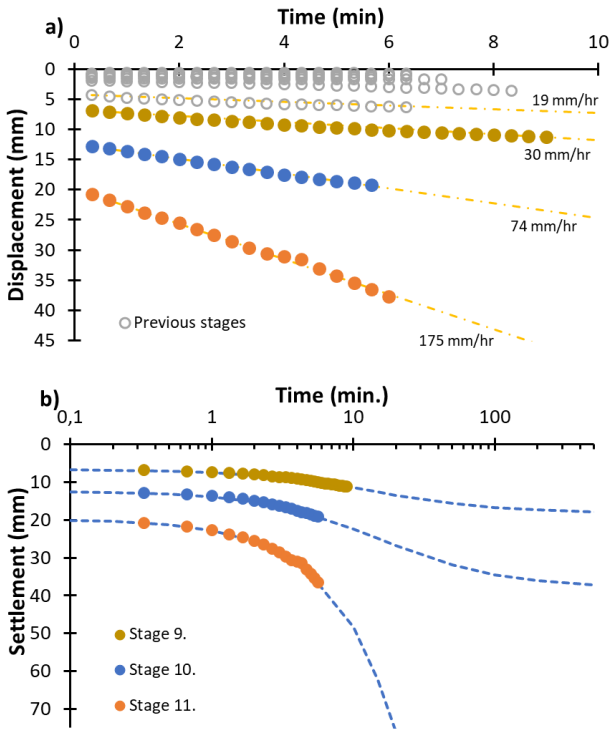

Figure 3. Time extrapolation of load test settlement data.

In Figure 3(a), the settlement rates for the last three stages are examined in more detail. Settlement rates towards the end of each, were in excess of 20 mm/hr. The time-extrapolation of the data from each stage is shown in Figure 3(b) where it can be seen that Stages 9 and 10 are predicted to reach a stable value at ∞-time, while Stage 11 is heading towards a plunging failure. In this example, the stage durations were systematically less than 10 minutes and therefore there is some uncertainty in the extrapolation to ∞-time, especially in the latter stages of the test. It is recommended that loading stages should last at least 30 minutes and/or until the creep rate is less than 0.1 mm/20 min. to increase data reliability.

3.2 Interpretation of ultimate load resistance

In the same example, based on the above, the last stage of the test was deemed to be unstable and therefore should not be considered, i.e., failure occurs at a load between that in Stages 10 and 11 (172 – 177 kN). The failure load reported by Zhang was 180 kN – the load mobilised in Stage 11, as pile settlements reached 10% of the helix diameter (36 mm).

The test stages deemed stable were then treated using the load extrapolation to ∞-displacement, described above. The result of this assesment is shown in Figure 4(a) which illusrates how it is only the last

few stages where the effect is significant and how the resulting collapse load can be affected. Figure 4(b) shows the resulting hyperbolic interploation through the treated load-displacement data, along with the failure loads, R_{∞} = 177 kN and $R_{80\%}$ = 162 kN. In this example, the difference with respect to the ultimate resistance quoted by Zhang (1999) is less than 5% but with this revision, it is clear that the result is based on stable data.

Figure 5 further illustrates the impact of this reappraisal by comparing the revised results of three tests: *A1 C Long* has already been presented, *A2 C Short* is the same as A1 but with a shorter embedment of 3.1 m, and *A3 C Long* has only two helices with a spacing of 3 helix diameters but is otherwise the same as A1. In all cases, someof the later load stages did not trend to a stable displacement-time response and the revised load-displacement curves led to a reduction in the inferred ultimate resistance, of up to 15% in the case of A2.

4 FINAL COMMENTS

The purpose of the work presented was to a) develop a sense of the quality and robustness of the field test data relating to HSP that had been published previously and b) reform the data base on the basis of tests that can be demonstrated to be well-controlled and then presented in a uniformized manner to aid further interpretation. This evaluation has also informed the testing specification that will be employed for field testing undertaken as part of the project HELIPORT.

Given the cost of undertaking field load tests on piles (generally), it is imperative that good control of the process is maintained to ensure the data produced are of the best quality and the investment is not wasted. Clear load control (ICE, 2007) and creep (ASTM, 2020) criteria should be specified and checked, and loading stages should be of sufficient length to ensure that it can be verified reliably that the pile settlement will stabilise – from this assessment the load should be held 30 minutes and/or until the creep condition (e.g. 0.1 mm/20 min.) is met.

ACKNOWLEDGEMENTS

The work presented was financed by the Fundação para a Ciência e a Tecnologia (FCT), Portugal, via the project HELIPORT doi. 10.54499/2022.08947.PTDC and UIDB/04625/2020. The authors would like to express their gratitude to the funding institution. Thanks also to Prof. Chalaturnyk of the University of Alberta for providing the original data files of Zhang (1999).

APPENDIX 1.

Derivation of Brinch-Hansen 80% failure criteria parameters from hyperbolic function:

$$R_{80\%} = \frac{s_{80\%}}{m.s_{80\%}+c} \qquad [1.1]$$

$$0.8R_{80\%} = \frac{0.25s_{80\%}}{m.0.25s_{80\%}+c} \qquad [1.2]$$

Solving simultaneously,

$$\frac{\cancel{s_{80\%}}}{ms_{80\%}+c} = 1{,}25\left[\frac{0.25\cancel{s_{80\%}}}{m0.25s_{80\%}+c}\right]$$

$$0.25ms_{80\%} + c = 1.25(0.25)m.s_{80\%} + c$$

$$\big(1 - 1.25(0.25)\big)c = (1.25(0.25) - 0.25)ms_{80\%}$$

$$\Rightarrow s_{80\%} = {}^{11c}/_{m} \qquad [1.3]$$

Substituting into [1.1],

$$R_{80\%} = \frac{{}^{11c}/_{m}}{m.\left({}^{11c}/_{m}\right)+c}$$

$$\Rightarrow R_{80\%} = {}^{11}/_{12m} \qquad [1.4]$$

Modelling the interaction of an underground structure with the soil in a megalopolis

Modélisation de l'interaction d'une structure souterraine avec le sol dans une mégapole

I. Boyko, V. Nosenko*, O. Lytvyn
Kyiv national university construction and architecture, Kyiv, Ukraine
v.s.nosenko@gmail.com

ABSTRACT: The paper presents an assessment of the interaction of the elements of the "soil-tunnel" system under conditions of changes in the stiffness of the structure when soil parameters change. The study was carried out using numerical modelling and field tests with cyclic loads typical for such structures. In megacities, large-diameter underground tunnels are being constructed; they are several kilometres long and pass-through soils with different properties. An example of such a facility is the construction of a 3.6 m diameter tunnel in Kyiv with a length of about 10 km. Its depth varies from 5 to 90 m. In some parts of the tunnel, due to long-standing erosion processes, the semi-hard clay surrounding the tunnel is replaced by much weaker flowable sandy loam, so there is a need to strengthen the weak foundation. To evaluate the effectiveness of different options for strengthening the foundation, field tests were carried out by injecting polymer mortars into the soil in different volumes and over different areas, followed by cyclic load tests. During the test of the weak base in its natural state, vertical displacements of 3.7 cm were recorded. These displacements are 2 times higher than in semi-hard clay. The volume of mortar used for the reinforced foundation was justified so that the displacements did not exceed the permissible operational requirements. Subsequently, numerical modelling of the interaction of natural and reinforced foundations with an underground structure at different stages of its life cycle was carried out in a physically nonlinear formulation.

RÉSUMÉ: L'article présente une évaluation de l'interaction des éléments du système "environnement du sol-tunnel" dans des conditions de changement de la rigidité de la structure lorsque les paramètres du sol changent. L'étude a été réalisée à l'aide d'une modélisation numérique et d'essais sur le terrain avec des charges cycliques typiques pour de telles structures. Dans les mégapoles, des tunnels souterrains de grand diamètre sont construits; ils mesurent plusieurs kilomètres de long et traversent des sols aux propriétés différentes. Un exemple de ce type d'installation est la construction d'un tunnel de 3,6 m de diamètre à Kiev, d'une longueur d'environ 10 km. Dans certaines parties du tunnel, en raison de processus d'érosion de longue date, l'argile semi-dure entourant le tunnel est remplacée par un limon sableux fluide beaucoup plus faible, d'où la nécessité de renforcer les fondations fragiles. Pour évaluer l'efficacité des différentes options de renforcement de la fondation, des essais sur le terrain ont été réalisés en injectant des mortiers polymères dans le sol en différents volumes et sur différentes zones, suivis d'essais de charge cyclique. Lors de l'essai de la base faible dans son état naturel, des déplacements verticaux de 3,7 cm ont été enregistrés. Ces déplacements sont 2 fois plus élevés que dans l'argile semi-dure. Le volume de mortier utilisé pour la fondation renforcée a été justifié de manière à ce que les déplacements ne dépassent pas les exigences opérationnelles admissibles. Par la suite, la modélisation numérique de l'interaction des fondations naturelles et renforcées avec une structure souterraine à différents stades de son cycle de vie a été réalisée dans une formulation physiquement non linéaire.

Keywords: Underground structure; numerical modelling.

1 INTRODUCTION

Modern cities face many complex geotechnical challenges. It is necessary to solve the issues of deep pits, design and construction of foundations of high-rise buildings under loads of various types in different geological conditions, taking account the presence of existing buildings when laying underground structures, and much more. The problem of insufficient territory in large cities is solved by using underground space (Broere, 2016). The work of many geotechnics shows the level of complexity and relevance of issues related to the use of underground space for the construction of buried engineering structures, such as subway tunnels in the historic environment (Burghignoli et al. 2013). The peculiarities of designing and experimental research of tunnel-type structures are devoted to the works of many scientists (Mair, 2008). The downside of human activity in cities is the pollution of the territory and the

need to solve geo-environmental problems associated with the transport of household waste. For this purpose, large-diameter collectors are constructed, which are tunnels designed to transport household wastewater to the place of its treatment. These tunnels are several kilometers long and run through soils with different properties. The design and construction of such structures requires an integrated approach, including: initial analysis of the topographic and geological situation, surveys along the route of the structure, specification of soil parameters depending on the calculation methods used to assess the interaction between the soil environment and the structure, selection of construction technology, assessment of changes in soil parameters on the stress-strain state of the tunnel structures, improvement of soil properties in certain sections of the tunnel.

2 INTERACTION OF AN UNDERGROUND STRUCTURE WITH THE SOIL

The main purpose of this paper is to evaluate the interaction of the elements of the "soil environment-tunnel" system under conditions of changes in structural stiffness and soil parameters. The research was carried out both by means of numerical modelling and by conducting field tests of the tunnel elements with cyclic loads.

2.1 Tunnel construction

An example of such a complex geotechnical facility is the construction of a tunnel for a new main city sewer in Kyiv, which is about 10 km long. Its depth varies from 5 m to almost 90 m. The tunnel consists of an outer lining of 8 precast concrete segments forming a circle and an inner lining of reinforced concrete cylindrical fragments with a protective polymer coating inside. The tunnel for installing the collector was constructed using a 3,600 mm diameter tunnel boring machine with sectional installation of the outer segments to the ground and their wedging, after which the secondary lining was installed in the inner space of the primary lining, and the space between them was injected with cement mortar. In certain sections of the tunnel, temporary soil freezing, temporary water lowering and protective screens made of walls in the ground were used to protect it from the effects of active groundwater movement. At the stage of operation, the tunnel is a cylindrical structure with an internal diameter of 2760 mm. During operation, the internal walls of the tunnel structure are subjected to cyclic loading due to daily changes in its operation mode. The minimum pressure at the bottom of the collector is 10 kPa, and the maximum pressure is up to 30 kPa. The outer casing of the collector is under ground pressure, which varies depending on the depth of the deposit from 90 kPa to 450 kPa.

2.2 Geological conditions

For the vast majority of the tunnel's length, the geotechnical profile around the tunnel is represented by semi-hard, sometimes stiff, marl clay, which has the following physical and mechanical properties: density $\rho \approx 1.9$ t/m^3, cohesion c=70...95 kPa, friction angle $\varphi \approx 12°$, and modulus of deformation E≈35 MPa. This soil has low permeability properties, which provides additional protection for the tunnel. However, in some sections of the tunnel route, due to long-standing erosion and siltation processes, there is no clay, and the environment around the tunnel is represented by weak plastic sandy loam and flowable sandy loam. The main physical and mechanical properties of these sandy loams are: density $\rho \approx 1.8$ t/m^3, cohesion c≈10 kPa, friction angle $\varphi \approx 18°$ and modulus of deformation E≈6 MPa. These characteristics were further verified by testing the weak soil with a pressiometer.

2.3 Changes in soil properties

In order to avoid uneven deformations of more than 10 mm per 1 m of the buried structure length in areas with a sharp change in geological structure, it was proposed to strengthen weak sandy loam soils by injecting solutions into the soil. The following were considered as possible alternatives for injection: silicate, cement and cement-polymer mortars of different water-cement ratios (time to reach design strength is more than 1 day) and, as an alternative, rapidly hardening two-component polymer mortars (time to reach design strength is 15-20 minutes).

Analysing the possible technologies for strengthening the soil base, we can note the advantages and disadvantages of each. Cementation is a technology that can be used for most soils, but the disadvantage is that it takes several days to gain strength and has an average cost among other technologies. Silicification is used for hard sands and sandy loams, but is ineffective for water-saturated soils, which in this case are the main ones on the site of the buried structure. Silicification has the lowest cost per 1 m^3 of treated base compared to other technologies. When using polymer mixtures, the advantage is that in order to strengthen the soil base under existing buried structures, it is necessary to make technological holes for injectors of the smallest size (20 mm in diameter), while for other technologies the holes have a diameter of 50 mm. Another advantage of polymeric solutions is their fast curing

(up to 30 minutes) and, as a result, the ability to ensure a fast pace of work. The disadvantage is the highest cost among other technologies. Based on the technical and economic comparisons and taking into account the factor of rapid gain of the required strength and formation of bonds with the surrounding soil, injections using a two-component polymer solution were chosen as the main option. An important aspect of the injection technology is the possible heterogeneity of the artificially fixed soil mass and, as a result, the need to select injection modes to obtain the required deformation parameters of the fixed mass. To select the injection modes and predict the deformations of the consolidated soil base, a series of field studies of the technology with different injection modes and subsequent testing of the base by loading the tunnel segments were carried out at the experimental sites in real soil conditions.

2.4 Full-scale testing of tunnel segments

By applying a series of gradually increasing loads to the tunnel fragments placed in the soil, a series of field tests of the soil base in its natural state were carried out and vertical displacements were recorded, which in the range of operating pressures ranged from 16 mm to 37 mm for weak sandy loam soils, respectively (Figure 1). These displacements are significantly higher than those recorded for the areas where the subsoil was made up of semi-hard clays. After that, a series of experimental injections of polymeric mortar into weak sandy loam soils was performed to select the mode of supply and volume of such mortar so that the reinforced base had deformation characteristics close to semi-hard clay. For the reinforced base, vertical deformations ranging from 8 mm to 21 mm were obtained after the initial loading. This is 2 times less than for the unfixed base, but more than for the neighbouring areas with semi-hard clays. The reinforced base was reloaded, which corresponds to the operating mode of the reservoir with cyclic loads. After reloading, the deformations ranged from 5 mm to 11 mm. Such deformation values ensure compliance with the requirements for the allowable difference in deformation for neighbouring parts of the collector located in different soil conditions.

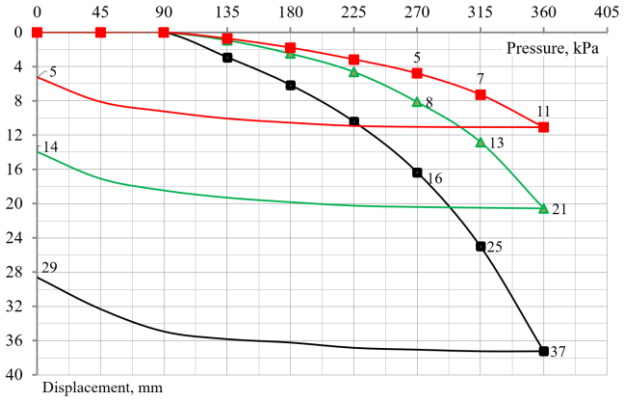

Figure 1. Dependence of displacements of the experimental tunnel section on the pressure on it at different properties of the base soil.

2.5 Numerical modelling of tunnel-soil interaction

To evaluate the effectiveness of various reinforcement options, numerical simulations of the stress-strain state of the soil medium-tunnel system at different stages of its life cycle were performed in a physically nonlinear formulation.

The soil model used in the numerical simulation allows to take into account changes in the deformation parameters of soils depending on the level of applied stresses and to describe the deformation processes of dispersed soils under complex loading/unloading trajectories.

To obtain correct results of numerical simulation, it is necessary to identify the model parameters in advance on the basis of laboratory soil tests or previously conducted field experiments.

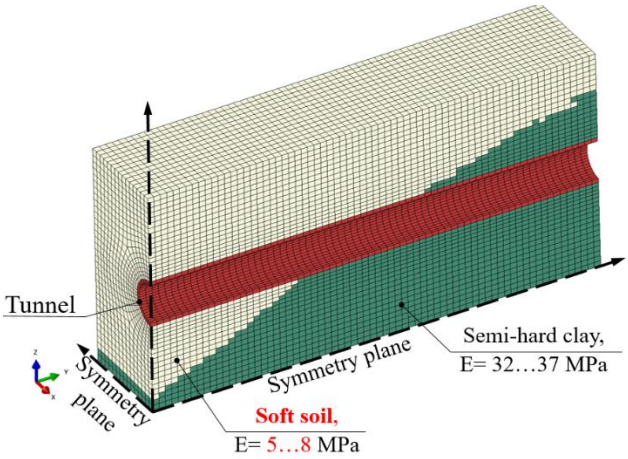

Figure 2. Finite element model of the "soil environment - tunnel" system.

.

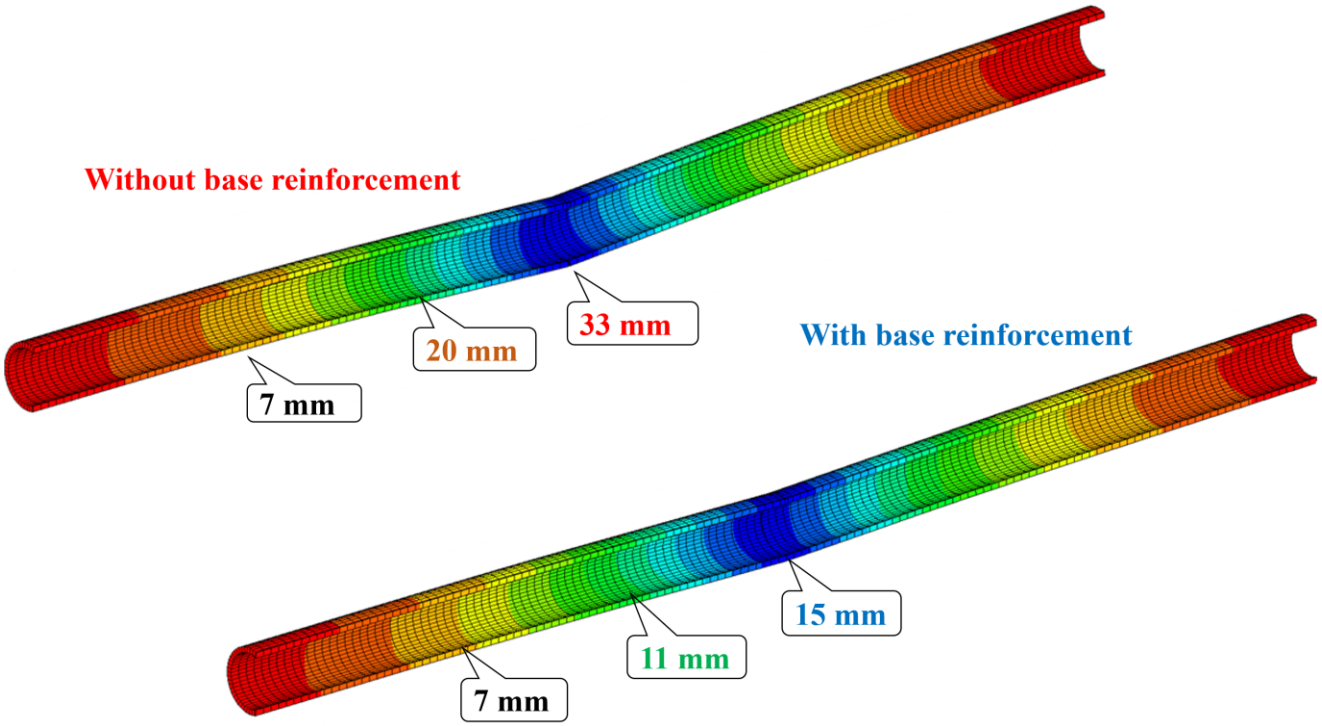

Figure 3. Comparison of displacements of the tunnel section obtained by numerical simulation for the variant without and with strengthening of the weak soil base.

According to the numerical modelling data, at the maximum pressure from the tunnel structures to the base during the operation of the reinforced base, the displacement reached to 13 mm, and the data of measurements of the structure displacement in the field experiment at the same pressure showed 11 mm.

The discrepancy between the numerical modelling and field experiments was up to 25% in the direction of overestimation of deformations in the modelling.

Three-dimensional numerical modelling of the tunnel-soil interaction in the transition zone from semi-hard clay to weak soils for two scenarios: the first, when the tunnel base was natural, and the second, with reinforced injection, showed a possible maximum difference in their displacements of 33 mm and 15 mm, respectively. Numerical modelling of the entire tunnel section in the zone of weak soils allowed us to select the effective number of weak base strengthening zones and the volume of polymeric mortar to strengthen and stabilize the weak soil and ensure safe operation of the tunnel.

3 CONCLUSIONS

The experimental results showed a decrease in the deformation of the fixed base under cyclic loads by up to 2 times compared to the unfastened base. On the basis of test injections with different volume of polymer mixture is established that in these soil conditions, the deformation of the fixed base depends on the injection mode and its volume.

A set of measures, including full-scale field tests and numerical modelling of the interaction between the foundation and the underground structure with the identification of foundation parameters, allowed us to substantiate an effective technology for strengthening a weak soil foundation and now we have experience of its safe operation. In the future, it is planned to extend this approach to the design of underground structures for sheltering people and energy facilities in Ukraine.

ABSTRACT: The article discuss data processing and development of predictive ground model on the basis of data from extensive engineering geological survey. Basic model inputs are spatial coordinates (X, Y, elevation). Ground model with assigned soil groups, deformation properties and ground water level is created with input of spatial coordinates. Basic statistical and machine learning algorithms (regression, classification, clustering) were used in Python script to develop predictive ground model. Predictions are compared with the ground model developed by engineering geologist. ground model was used to calculate the settlement of the embankment subgrade in the highway route D1 for international and domestic transport.

RÉSUMÉ: L'article traite du traitement des données et du développement d'un modèle prédictif du sol sur la base de données provenant d'une étude géologique approfondie. Les entrées de base du modèle sont les coordonnées spatiales (X, Y, élévation). Le modèle de sol avec les groupes de sols assignés, les propriétés de déformation et le niveau de la nappe phréatique est créé à partir des coordonnées spatiales. Des algorithmes statistiques de base et d'apprentissage automatique (régression, classification, regroupement) ont été utilisés dans un script Python pour développer un modèle de sol prédictif. Les prédictions sont comparées au modèle de sol développé par l'ingénieur géologue. Les résultats montrent une grande précision de prédiction avec une erreur acceptable, mais avec une plus grande efficacité si l'apprentissage automatique est utilisé. Les profils géologiques d'ingénierie obtenus ont été utilisés pour calculer le tassement de la plate-forme de remblai sur le tracé de l'autoroute.

Keywords: Ground model; data processing; settlement; machine learning.

1 INTRODUCTION

Application of machine learning algorithms is on the rise in geotechnical engineering. This is due to the huge amount of data produced (laboratory measurements, geological survey, in-situ testing etc.) and due to empirical nature of the profession. Machine learning was used to predict small strain shear modulus (Cruz, Santos, & Cruz, 2013), predict slope movements (Yang, Yin, & Liu, 2019) and liquefaction potential (Goh & Goh, 2007), (Samui & Sitharam, 2011). Additionally, there are articles that discuss the classification of subsoil or the mapping of some geological features (Šapina, 2016), (Zhou & Wu, 1994), (Tsiaousi, Travasarou, Drosos, Ugalde, & Chacko, 2018). The development of ground models through machine learning is somewhat comparable with geostatistical algorithms such as Kriging (Cressie, 1990).

In this study, machine learning is utilized to develop ground model for calculating settlement in a large infrastructural project (highway of length 15 km). The automatically generated ground model for settlement analysis must include deformation properties (oedometric modulus E_{oed}) of various soil groups. Oedometric moduli were assigned to different soil groups based on soil type and its physical state (consistency or density). Settlement calculations were

automatically performed in 111 ground profiles obtained solely by inputting spatial coordinates X, Y, Z.

2 METHODOLOGY

A dedicated application was developed to process and analyse the available data and create an engineering geological model with the settlement calculation. This application incorporates a suite of interconnected machine learning and neural network algorithms.

2.1 Material

Engineering geological data from bore logs are crucial for learning phase of model development. Following data were used for analysis:

- Text documentation of realized and archive boreholes
- Spatial coordinates of boreholes (*X, Y*) and their elevation *Z* (m a.s.l.)
- Ground water level
- Atterberg limits, grain size distribution curves, oedometric moduli

Visual Basic for Applications was used to extract:

- Borehole name
- Soil class USCS (American Society for Testing and Materials, 2017)
- Depth boundaries of single layer
- Soil consistency (set as lower consistency) → description (keyword) "soft to stiff " or "stiff to soft" → resultant consistency soft with symbol T
- Soil was set to organic (symbol O) in case of organic matter (keywords: detrit, rotten wood, wood, plants)
- Homogenized soil group f [CH-CV-CE, MH-MV-ME, CE, ML-MI], fs [CS, MS, SC, SM], fg [CG, MG, GC, GM], g [GF, GP, GW], s [SF, SP, SW], r [soft rocks], OR, Y
- origin/genesis of soil: quaternary sediment D (deluvial), F (fluvial) and Neogene sediments N (Figure 1)
- spatial coordinates of borehole X, Y, Z
- ground water level

A total of 444 boreholes were processed with 3558 soil layers. Laboratory tests, Atterberg limits (liquid and plasticity limit), percentage of fines, and grain size distribution curves were used to develop quasi homogenous soil groups. In total, 1071 samples were processed, with 109 oedometric moduli.

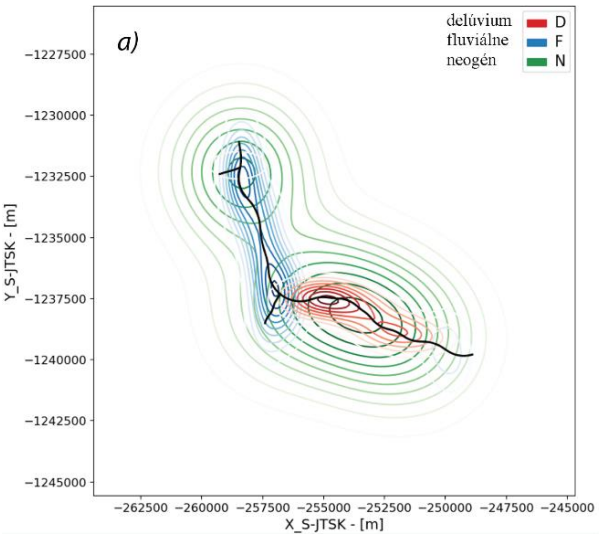

Figure 1. Distribution of soils in the highway route D1.

2.2 Methods of machine learning

Methods of supervised learning and unsupervised learning were employed to predict ground model including ground water level. The K-means clustering (KMC) algorithm was utilized to identify critical quasi-homogeneous sections along the highway route. The algorithm's inputs consist of the spatial coordinates of terrain surface & elevation and oedometric modulus. An elbow diagram was used to determine the optimal number of clusters, which was found to be 9 in this study.

The accuracy of the model is calculated as follows:

$$ACCURACY=TP/(TP+FP) \quad (1)$$

where *TP* is number of correctly assigned data points, *FP* is number of misclassified points.

2.3 Prediction of ground water level

Ground water level was predicted by deep feed forward artificial neural network (ANN). Algorithm inputs are spatial coordinates of terrain surface & elevation. For training, 75% of the total 405 groundwater level data points were used, while 25% were used for model validation.

2.4 Prediction of soil genesis

The Random Forest (RF) algorithm was trained for the classification task. Inputs for classification included the elevation, and the depth of the center of the homogeneous layer from the surface, in addition to spatial coordinates. Each borehole was subdivided into elements with thickness of 0.1 m (oversampling). The model consists of 10 decision trees, with equal weights for single classes and entropy as the optimization criterion. The number of data points for each genesis

are shown in Table 1. Overall, 65% of the data were used for learning, and 35% for testing. The accuracy of the model (Table 1) shown very good prediction of soil genesis.

Table 1. Number of inputs for model with soil genesis.

Soil genesis	km 0.0-6.0	Accuracy of model (%)
F - fluvial	8700	98.92
N-neogene	3860	96.29
D-deluvium	590	97.61
Overall	*13 150*	*98.09*

A different procedure was utilized to predict soil consistency. The Support Vector Machine (SVM) algorithm with bootstrap aggregation and One vs. One classification strategy was employed. Input parameters consisted of the same parameters as in previous models, supplemented by inputs for genesis and soil consistency. Furthermore, no subdivision was applied to soil layers (no oversampling of elements with thickness of 0.1 m). A regularization parameter C=50, with equal weights for classes, and 200 sub-models were used

Oedometric modulus and unit weights were assigned to soils based on their consistency, soil group, genesis, and highway part A – F.

3 RESULTS

3.1 Identification of homogenous units on highway route and prediction of groundwater level

The highway route, with 9 classes identified by K-means clustering (KMC) and resultant 6 quasi homogenous parts are depicted in Figure 2. These six quasi-homogeneous parts, labeled A – F, were identified across two sections of the highway route. The first part, A – C, predominantly consists of fluvial sediments, while the second part, D – F, is mostly characterized by deluvial sediments.

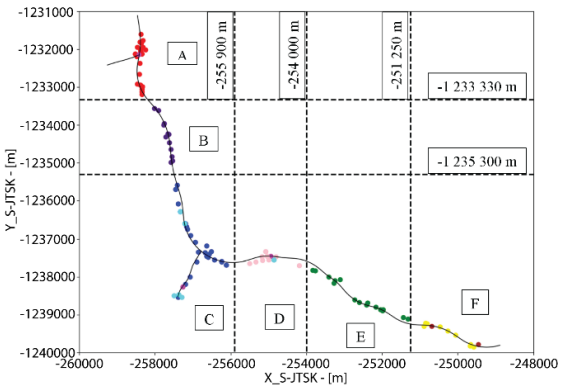

Figure 2. Result of KMC clustering algorithm.

Only results from part one are presented in this paper.

The maximum error between predicted and measured water level is 7.24 m, with an average error of 1.99 m.

3.2 Comparison of ground models of homogenous units on highway route

Differences in depths of observed parameters between machine created ground models (ML) and ground models developed by engineering geologist (EG) are shown in Figure 3. Differences were found in determining the depth of the surface cover (f/fs), thickness of gravelly (gZ, gK) sediments, depositional depth of the Neogene sediments (N), and groundwater level (HPV). The depth difference in estimating soil layers or groundwater levels is generally up to 2.0 meters. The largest error, 3.5 m can be found in the estimation of Neogene depth in profile km 13.550. The errors in profile km 8.475 are interesting due to the fact that no learning points were provided in this section (there are only cuts in this part and no embankments, thus no need for settlement calculation). The model was not trained within a radius of 1.0 km from this point; however, the error is only slightly above 2.0 meters. The ground models are developed for settlement analysis, thus, the comparison of settlement in chosen profiles is of interest.

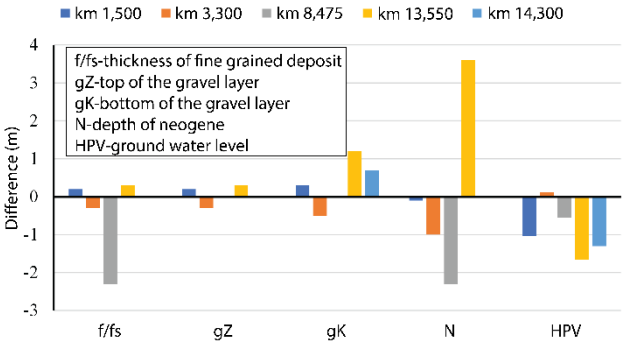

Figure 3. Comparison of profiles created by ML algorithm and human made (EG).

3.3 Comparison of measured and predicted settlements

Calculated settlements for ground models developed by machine and by hand are summarized in Table 2. A difference of up to 10% is considered very good and appears promising for the analysis. The comparison of predicted and measured settlements (by horizontal inclinometers) is presented in Table 2 and Figure 4. The maximum difference is slightly above 20%. It must be noted that such difference could be caused not only by the misprediction of ground model but also by the use of a simple analytical calculation model for

ground settlement analysis. Finally, a difference of 20% is considered acceptable, particularly if the model is intended for preliminary quantitative analysis.

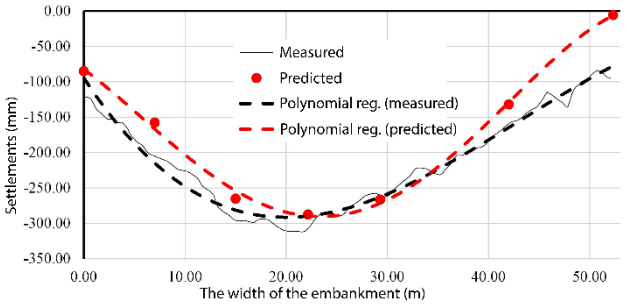

Figure 4. Comparison of calculated and measured settlements, HINK-17, km 6.416.

Bigger differences are only observed at the endpoints, where the measurements are affected by the design of the end of the guide casing embedded and the works in its vicinity.

Table 2. Comparison of calculated settlements for ground models developed by machine (ML) with Horizontal Inclinometer Measurements (HINK).

	HINK	**ML**
Section	Settlements (mm)	
km 1.500	106.14	126.72
km 2.081	123.44	113.20
km 6.416	292.64	287.48
km 6.653	270.96	257.58

4 CONCLUSIONS

This paper was focused on a real case of application of artificial intelligence in construction practice.

To determine ground settlement, it was necessary to create a spatial engineering geological ground model of the motorway section D1 Budimír-Bidovce, which included information about groundwater, soil horizons, and their geotechnical characteristics.

The presented predictive model can deliver robust and fast ground model development used for quantitative analysis of soil conditions at given site. The effectiveness of used approach was demonstrated on example of settlement analysis. Calculation of 111 settlement profiles takes only tens of minutes. The increase in robustness of the presented approach is enhanced by combining it with Building Information Modeling (BIM) and Geographic Information System (GIS) tools.

Automatic parameter calibration of advanced constitutive soil models and application to a boundary value problem

Calibration automatique des paramètres des modèles constitutifs avancés du sol et application à un problème de valeur limite

ABSTRACT: Simulating the nonlinear and anelastic behaviour of soils under monotonic and cyclic loading requires advanced constitutive models. Determining the parameters of these models is often time-consuming and requires a high level of expertise. Automatic calibration can help to simplify and speed up the calibration process and increase the accessibility of advanced soil models to less experienced users. In this paper, the automatic parameter calibration of the parameters for monotonic and cyclic loading is presented for Hypoplasticity with Intergranular Strain and SANISAND. The calibration is performed based on the results of drained and undrained monotonic triaxial tests, oedometric compression tests and undrained cyclic triaxial tests on sand. A thorough comparison of simulations with a manual calibration and the experimental data is presented. Hints on the transfer to a boundary value problem and on the robustness of the automatically calibrated parameters are given. It is shown that the automatic parameter calibration improves the accuracy of the constitutive model predictions.

RÉSUMÉ: La simulation du comportement non linéaire et anélastique des sols soumis à des charges monotones et cycliques nécessite des modèles constitutifs avancés. La détermination des paramètres de ces modèles prend souvent beaucoup de temps et nécessite un haut niveau d'expertise. L'étalonnage automatique peut contribuer à simplifier et à accélérer le processus d'étalonnage et à rendre les modèles de sol avancés plus accessibles aux utilisateurs moins expérimentés. Dans cet article, la calibration automatique des paramètres pour les charges monotones et cycliques est présentée pour Hypoplasticity with Intergranular Strain et SANISAND. L'étalonnage est effectué sur la base des résultats d'essais triaxiaux monotones drainés et non drainés, d'essais de compression oedométrique et d'essais triaxiaux cycliques non drainés sur le sable. Une comparaison approfondie des simulations avec une calibration manuelle et les données expérimentales est présentée. Des indications sur le transfert à un problème de valeur limite et sur la robustesse des paramètres calibrés automatiquement sont données. Il est démontré que le calibrage automatique des paramètres améliore la précision des prédictions du modèle constitutif.

Keywords: Constitutive model; automatic parameter calibration; monotonic and cyclic triaxial tests; heuristic optimization algorithms.

1 INTRODUCTION

Calibrating the parameters of soil constitutive models manually remains a complex and time-intensive task which requires a deep understanding of the model's features. Frequently, the model's parameters cannot be determined based on specific experiments or empirical relations. Instead, iterative adjustment of the parameters by back-calculating results from laboratory tests is often required. Throughout this process, the parameters undergo continuous refinement until a satisfactory agreement between the simulation and experimental data is reached. Thereby, the effort typically concentrates on refining one parameter, keeping the others fixed. Existing calibration software such as Ex-Calibre (Kadlíček et al., 2018) or GA-cal (Mendez et al., 2021) is limited to monotonic loading. The Automatic Calibration Tool numgeo-ACT was developed to simplify and speed up the calibration process for monotonic (Machaček et al., 2022) and cyclic loading (Brosz et al. 2023, Machaček and Staubach, 2023). In this work, the performance of numgeo-ACT is demonstrated by the calibration of a hypoplastic model (von Wolffersdorff, 1996) with Intergranular Strain extension (IGS) (Niemunis and Herle, 1997) and SANISAND-04 (Dafalias and Manzari, 2004). The results of the automatic parameter calibration are compared to the results of a manual

calibration (Wichtmann et al., 2019). The paper is structured as follows. Section 2 explains the automatic calibration software numgeo-ACT. Section 3 presents the setup used for the automatic parameter calibration while the results of the automatic parameter calibration and the comparison with a manual calibration are given in Section 4. Some hints on the transfer to a boundary value problem and on the robustness of the automatically calibrated parameters are given in Section 5.

2 NUMGEO-ACT

Numgeo-ACT[1] (Machaček et al., 2022) offers the possibility to automatically calibrate a large number of advanced constitutive soil models by using the freely accessible FE software numgeo (www.numgeo.de, Machaček and Staubach, 2021). The basis for the automatic calibration is a database containing all tests for the material to be calibrated (e.g. oedometric compression tests, monotonic/cyclic drained/undrained triaxial tests or simple shear tests). At the beginning of the calibration process, single element test simulations (1 finite element with one integration point) of all experiments stored in the database are performed with numgeo using an estimated set of parameters. The results of the simulations are then analysed and compared with the results of the experiments. A Fréchet distance measure (Eiter and Mannila, 1994) is used to calculate the discrepancy between simulation and experiment. To ensure that all variables have the same influence on the optimisation process, a comparison is made in scaled stress and strain planes according to the procedure documented in Machaček et al. (2022).

3 EXAMPLE CALIBRATION FOR KARLSRUHE FINE SAND

The experimental basis for the automatic parameter calibration (AC) is the database of Karlsruhe fine sand by Wichtmann and Triantafyllidis (2016a and 2016b). The parameters of the hypoplastic model $h_s, n, \alpha, \beta, e_{i0}, e_{c0}$ and e_{d0} and the parameters of the Intergranular Strain m_T, m_R, R, β_R and χ were calibrated simultaneously based on two oedometric compression tests, five drained and three undrained monotonic triaxial tests as well as six undrained cyclic triaxial tests. The critical friction angle was set to $\varphi_c = 33.1°$ according to Wichtmann et al. (2019) and was kept fixed during the optimisation process. For SANISAND-04, the parameters of the critical state λ, ξ, e_0, M_e und M_c were set according to Wichtmann et al. (2019) and a variation during the optimization of ± 5 % (Parameter λ, ξ and e_0) and ± 3 % (Parameter M_e and M_c) in relation to the initial value was allowed. The other parameters $G_0, m, h_0, \nu, n_b, n_d, A_0, c_h, z_{max}$ and c_z were optimized within the limits given in Table 2. Due to the limitations of the SANISAND-04 model in capturing the elasto-plastic response under constant-η loading (Taiebat and Dafalias, 2007), the oedometric compression tests were not included in the calibration. The results of the automatic parameter calibration are compared to a manual calibration with excellent simulation results (MC) presented by Wichtmann et al. (2019) on the same sand. It is worth mentioning that the experimental tests used in the MC differ slightly from the experimental tests used in the AC. In this work, the same numerical platform and implementation was used for AC and the back-calculations with the MC.

4 RESULTS & COMPARISON WITH MANUAL CALIBRATION

4.1 Hypoplasticity with IGS extension

The parameters calibrated by AC are presented in Table 1 together with the corresponding upper and lower parameter bounds for the hypoplastic model with IGS extension. A comparison of the results of the AC (red curves) with the results of the MC (blue curves) is given for the monotonic tests in Figure 1 and for the undrained cyclic triaxial tests in Figure 2. The initial stiffness and the deviatoric peak stresses of the drained monotonic triaxial tests are captured well by the AC and the MC, while the predictions of both approaches for the dilatancy behaviour deviate partly from the experimental results (Figure 1, upper row). The predictions of the undrained monotonic triaxial tests and the oedometric compression tests are in good agreement with the experimental data (Figure 1, lower row).

The comparison of the AC with the MC is given for the undrained cyclic triaxial tests in Figure 2 for the $p - q$ plane (p: mean effective stress, q: deviatoric stress). Again, AC and MC lead to very similar results.

Compared to the experiments, both approaches predict a too contractive behaviour during the first cycle, while all further cycles agree better with the experiments. The predictions of both approaches do not reach zero mean effective stress, instead the simulations end up in a lens-shape behaviour (a known shortcoming of the hypoplastic model with IGS). The

[1] https://github.com/j-machacek/ numgeo-ACT

prediction of the decrease of mean effective stress simulated with the parameters of the AC lead to a better agreement with the experimental results of the tests no. 1 and 5 reaching smaller mean effective stress for the same number of loading cycles (Figure 2). This shows that numgeo-ACT is able to find parameters which predict the cyclic loading slightly better than the MC. Given the models capabilities, both approaches predict the experimental data sufficiently well under monotonic and cyclic loading.

Table 1. Results of the automatic parameter calibration (AC), best fit parameters for the hypoplastic model with IGS extension with corresponding bounds.

Parameter	best fit value	Lower bound	Upper bound
φ_c / rad	0.578	-	-
h_s / GPa	17.5	0.001	45
n / -	0.21	0.1	0.5
e_{d0} / -	0.615	0.609	0.745
e_{c0} / -	1.091	1.049	1.166
e_{i0} / e_{c0} / -	1.11	1.05	1.30
α / -	0.17	0	0.5
β / -	2.91	0.1	6
m_T / -	1.1	1.1	10
m_R / -	5.7	2	10
R / -	2.47E-04	1.0E-04	2.5E-04
β_R / -	0.30	0.05	1.4
χ / -	0.86	0.4	7

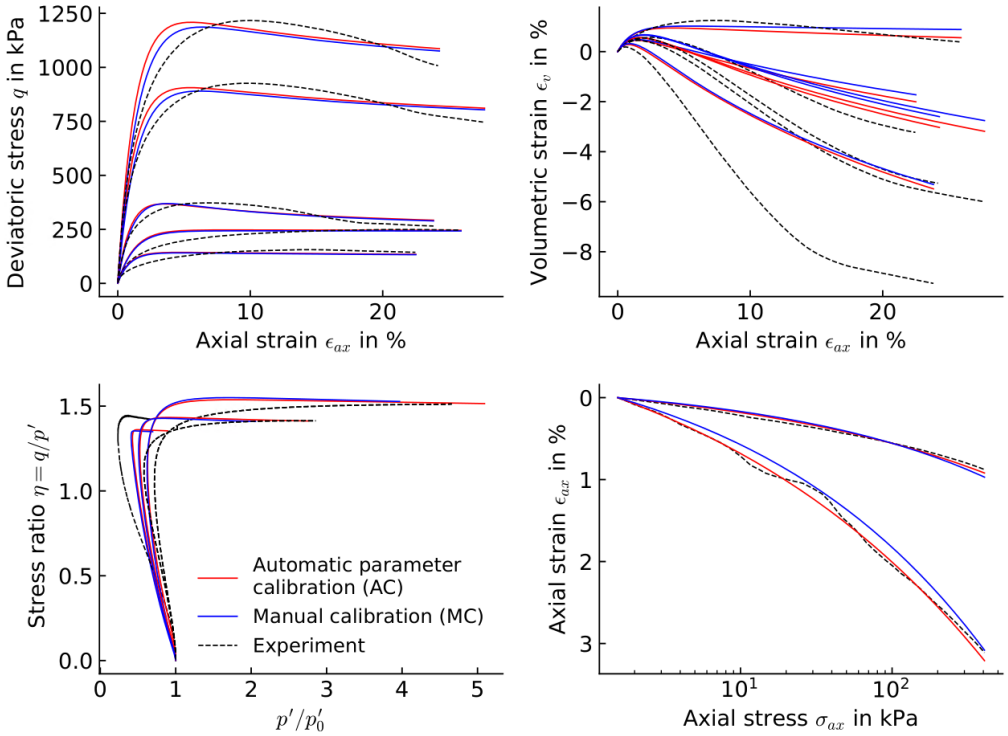

Figure 1. Comparison of the results of the automatic parameter calibration (AC, red curves) with the results of the manual calibration (MC, blue curves) for Hypoplasticity with IGS for drained monotonic triaxial tests (upper row), undrained monotonic triaxial tests (lower row, left) and oedometric compression tests (lower row, right).

4.2 SANISAND-04

The parameters for the SANISAND-04 model obtained by AC are presented in Table 2 together with the corresponding upper and lower parameter bounds. A comparison between the AC and the MC is presented for the monotonic tests in Figure 3 and for the cyclic tests by means of the excess pore water pressure in Figure 4.

As noticed for the hypoplastic model with IGS extension (Section 4.1), the predictions with AC are in very good agreement with the MC for SANISAND-04 for monotonic loading (Figure 3). Comparing the results of the cyclic tests, it is evident that the predictions of the AC for the trend of pore water pressure are in better agreement with the experiments than those of the MC.

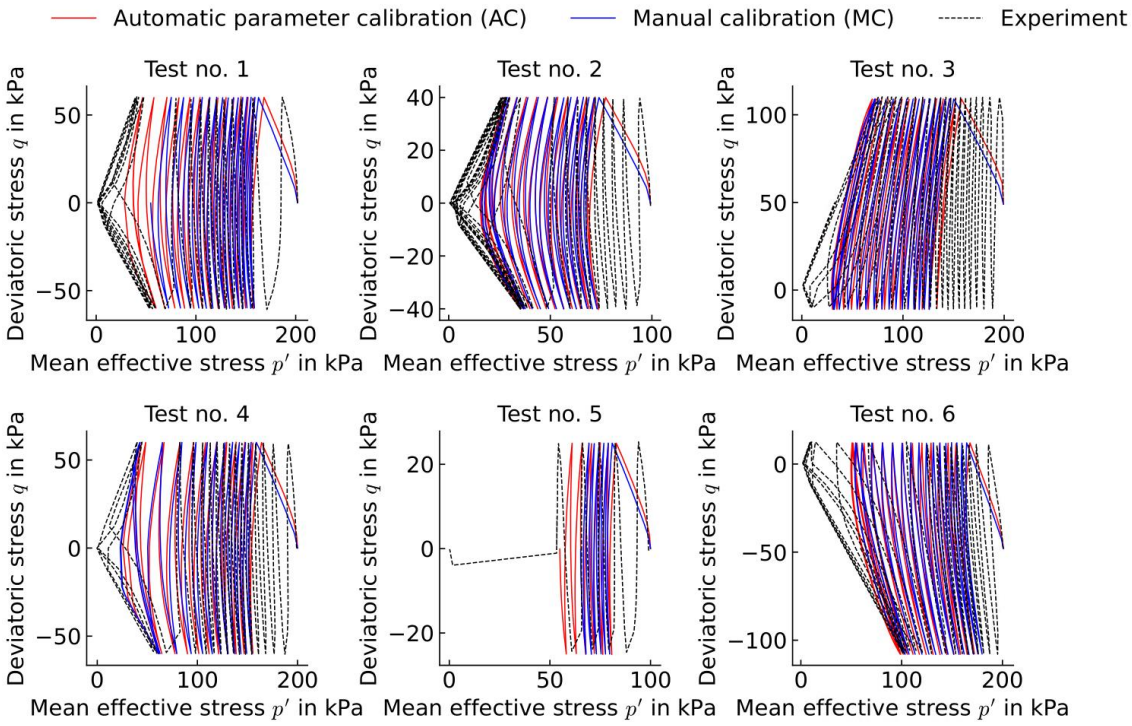

Figure 2. Comparison of the results of the automatic parameter calibration (AC, red curves) with the results of the manual calibration (MC, blue curves) for Hypoplasticity with IGS for undrained cyclic triaxial tests.

The MC predicts a too rapid increase of the porewater pressure compared to the experiments. Both approaches AC and MC reach zero effective stress in five out of 6 experiments.

5 ROBUSTNESS

The reproductability of the automatic parameter calibration was shown by Machaček et al. (2022). The robustness of automatically calibrated parameters in the application is shown using a boundary value problem of an earthquake-prone embankment which is based on centrifuge tests with Nevada sand by Muraleetharan et al. (2004). For the automatic parameter calibration of Nevada sand, four drained monotonic triaxial tests with constant mean effective stress, four undrained monotonic triaxial tests, two isotropic compression tests and two undrained cyclic triaxial tests were considered. For the SANISAND-04 model, the results are provided in Machaček and Staubach (2023).

6 SUMMARY AND CONCLUSION

The automatic parameter calibration software numgeo-ACT was developed to calibrate advanced constitutive soil models for monotonic and cyclic loading. Its performance was demonstrated by the parameter calibration for a hypoplastic model with Intergranular Strain and for SANISAND-04. The parameters for monotonic and cyclic loading were calibrated simultaneously based on two oedometric compression tests, five drained monotonic triaxial tests, three undrained monotonic triaxial tests and six undrained cyclic triaxial tests on soil samples of Karlsruhe fine sand.

Table 2. Results of the automatic parameter calibration (AC), best fit parameters for SANISAND-04 with corresponding bounds.

Para-meter	Best fit value	Lower bound	Upper bound
G_0 / kPa	66.1	50	200
υ / -	0.03	0.001	0.1
M_c / -	1.34	1.295	1.375
M_e / -	0.93	0.896	0.952
λ_c / -	0.121	0.116	0.128
e_0 / -	1.100	1.048	1.158
ξ / -	0.204	0.195	0.215
m / -	0.026	0.005	0.05
h_0 / -	16.9	1	20
c_h / -	0.73	0.3	1.1
n_b / -	1.1	0.6	2.5
A_0 / -	1.05	0.2	1.4
n_d / -	2.26	0.5	4
z_{max} / -	12.5	1	60
c_z / -	315	50	10000

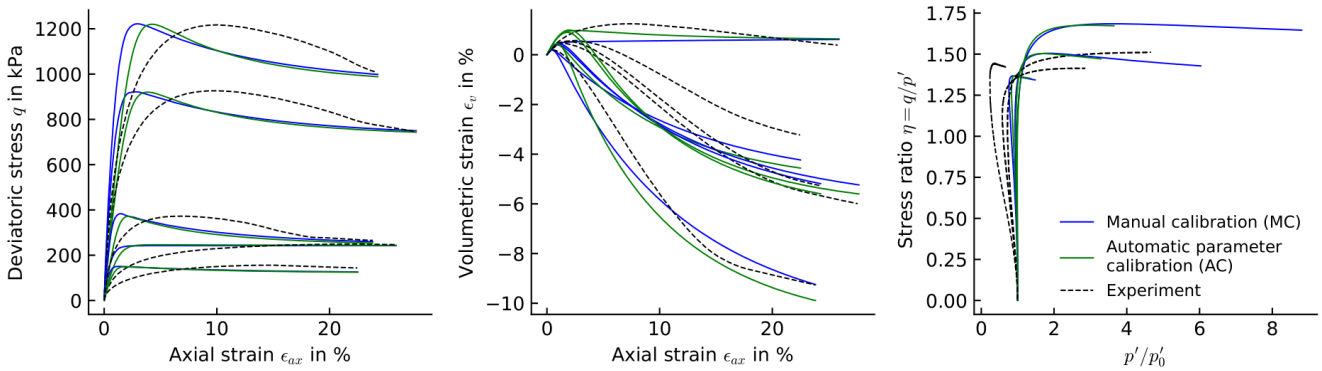

Figure 3. Comparison of the results of the automatic parameter calibration (AC, green curves) with the results of the manual calibration (MC, blue curves) for SANISAND-04 for drained monotonic triaxial tests (left and centre) and undrained monotonic triaxial tests (right).

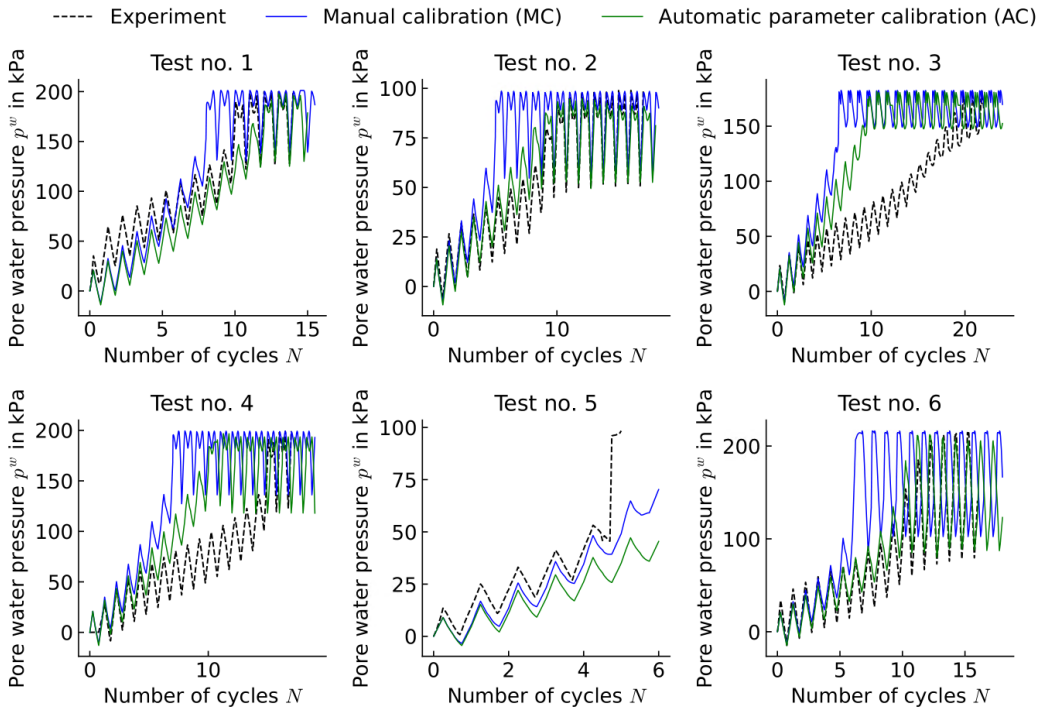

Figure 4. Comparison of the results of the automatic parameter calibration (AC, green curves) with the results of the manual calibration (MC, blue curves) for SANISAND-04 for undrained cyclic triaxial tests.

The results of the automatic parameter calibration were then compared to the results of a manual calibration from Wichtmann et al. Both approaches lead to very similar results and fit the experimental data of the monotonic and cyclic tests quite well. The automatically calibrated parameters give slightly better predictions of the pore water pressure build-up of the undrained cyclic triaxial tests. numgeo-ACT has proven to be an efficient and reliable tool to derive parameter sets for advanced constitutive soil models and allows for an optimised simulation of soil behaviour under monotonic and cyclic loading (Machaček et al., 2022, 2023 and Brosz et al., 2023).

ABSTRACT: Soil chemical stabilization with cement is a common technique to enhance the engineering and mechanical properties of in situ soils according to stress rates imposed by civil engineering projects. Usually, moderate quantities of cement are used, around 5 to 10% of the dry material. However, cement manufacturing is one of the biggest sources of greenhouse gas emissions, specifically carbon dioxide. For this reason, reducing cement content by a few percent in geotechnical structures built with cement stabilized soils (CSS) has a high environmental interest, particularly in view of the involved volumes of material. This work aims to contribute to a better understanding of the mechanical characteristics of stabilized soils with low cement contents. First, the mechanical behavior of a soil treated with 3% cement was studied for several curing times. Next, measured fracture parameters were correlated. Finally, these measurements were used to characterize the Mohr-Coulomb (MC) failure criterion. Results showed a high correlation between compressive and MC parameters. An alternative method for estimating MC parameters for CSS based on tensile and compressive properties was successfully checked. The proposed approach can be used to determine design parameters for geotechnical structures.

RÉSUMÉ: Dans les projets de Génie Civil, le traitement des sols au ciment est une technique courante pour améliorer les propriétés techniques et mécaniques des sols en place. En général, les quantités de ciment utilisé sont modérées, de l'ordre de 5 et 10 % du matériau sec. Toutefois, la fabrication du ciment est l'une des sources d'émission les plus importantes de gaz à effet de serre et en particulier de dioxyde de carbone. C'est pourquoi, réduire de quelques pourcent la teneur de ciment dans les structures géotechniques réalisées avec des sols traités présente un intérêt environnemental certain, notamment en raison des volumes de matériau impliqué. Ce travail vise à contribuer à une meilleure compréhension des caractéristiques mécaniques des sols faiblement traités. Pour commencer, le comportement mécanique d'un sol traité avec 3% de ciment a été étudié pour plusieurs temps de cure. Ensuite, les liens entre les différents paramètres de rupture mesurés ont été établis par corrélation. Enfin, ces mesures ont permis de caractériser le critère de rupture de Mohr-Coulomb. Les résultats ont montré une forte corrélation entre les paramètres de compression et les paramètres de MC. Une méthode alternative d'estimation des paramètres MC pour le CSS basée sur les propriétés de traction et de compression a été vérifiée avec succès. L'approche proposée peut être mise en œuvre pour obtenir les paramètres de dimensionnement des structures géotechniques.

Keywords: Cement-stabilized soils; earthworks, correlation analysis, Mohr-Coulomb.

1 INTRODUCTION

Cement stabilization of soils is a common technique to enhance the engineering and mechanical properties of in situ soils according to stress rates imposed by civil engineering projects (Correia et al., 2019; Preteseille & Lenoir, 2016). Use of cement-stabilized soils (CSS) cover a wide range of civil engineering applications such as embankments, foundations, slope protection, pavements and rail construction (Consoli et al., 2007; Diambra et al., 2018).

CSS constitute an intermediate class of geomaterials whose mechanical behavior is at the boundary between soil and rock mechanics (Lenoir et al., 2021; Schnaid et al., 2001). Compressive and tensile strength are widely employed as indicators of stabilization. Whereas compressive strength is linked to granular packing and bonding compounds, tensile strength is more related to the amount of cementitious compounds (Consoli et al., 2001). However, these characteristics represent a defined state of stresses and don't necessarily match with the service state of stresses of structures.

It is generally accepted that the failure mode of CSS can be represented with the Mohr-Coulomb (MC) criterion (Schnaid et al., 2001). Use of compressive and tensile properties to determine MC parameters for design purposes is related in literature (Lenoir et al.,

2021; Piratheepan et al., 2012; Sivakugan et al., 2014). Using direct and indirect measurements, the present work investigates the shear strength of a low-cement treated clayey soil.

2 MATERIALS AND METHODS

2.1 Materials

2.1.1 Soil

Studied material (A) was collected from the covering soil of an aggregate quarry at Soignies, Belgium (50° 34' 25.759'' N, 4° 2' 16.476'' E). The grain size curve is shown in Figure 1.

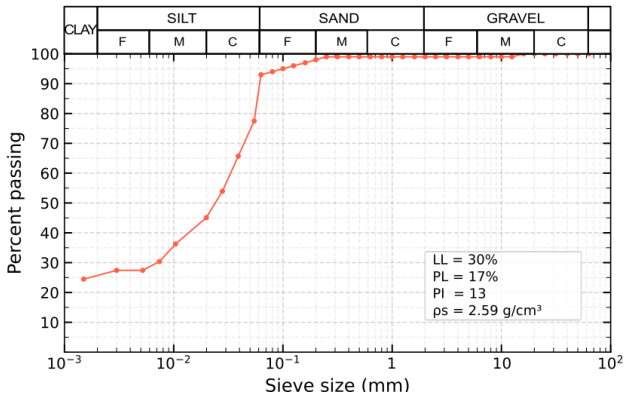

Figure 1. Particle-size distribution. F: fine, M: medium, C: coarse. PL: plastic limit, LL: liquid limit, PI: plastic index and ρ_s specific mass.

The soil is classified as A-6 (11), CL and A2 following the AASHTO (M 145-91), USCS (ASTM D2487-17) and GTR (NF P11-300) classification systems. The clay activity (A) is low A = PI/clay content = 0.29, which suggest a not significant swelling potential. Natural moisture content is below the PI (liquidity index < 0).

2.1.2 Soil treatment

Soil was treated with 3% of Portland-limestone cement (weight of dry material) CEM II/A-LL 42.5 R (NF EN 197-1). Main constituents of the binder are clinker (80-94%) and limestone (6-20%). The Optimum Moisture Content (OMC) and Maximum Dry Density (MDD) were determined following the standard Proctor compaction tests (NF P94-093): OMC = 15.5%, MDD = 1.79 g/cm^3. Reference values for sample preparation are 96% of MDD at OMC.

Samples were tested after several curing times (CT): 7, 28, 90, 180 and 360 days. For curing, samples were stored in a room with temperature controlled at 20 °C in plastic bags to keep constant moisture content.

2.2 Experiments

Experimental program is summarized in Table 1. For Unconfined Compression Strength test (UCS), Direct Tensile Strength test (DTS) and Indirect Tensile Strength test (ITS), tests are carried out on a Zwick/Roell Z150 press. Crosshead speed was 0.1 mm/min for UCS and DTS and 0.3 mm/min for ITS.

2.2.1 UCS

Tests followed the standard EN 13286-41:2021. Principle of testing is presented in Figure 2 (a). The maximum load registered, corresponding to the failure load, is equal to the UCS. Due to it is a compressive load, its value is positive.

2.2.2 DTS

Tests followed the standard EN 13286-40. As vertical load is a traction load, its value is negative (Figure 2 (b)). Minimal value corresponds to the DTS.

2.2.3 ITS

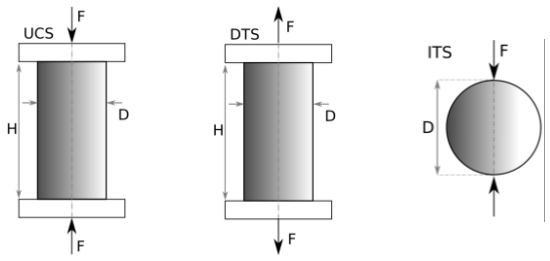
Tests followed the standard NF EN 13286-42. Principle of test is displayed in Figure 2 (c). Analytical solution of stresses at the center of the specimen during ITS test is used to construct the stress tensor (Piratheepan et al., 2012; Preteseille et al., 2014; Thompson, 1966).

2.2.4 Direct Shear test (DS)

Tests were carried out in a machine Sheartest VJT following the standard NF EN ISO 17892-10. Shear rate was 0.12 mm/min. The contact area used to calculate the normal (σ) and shear stress (τ) is corrected following the procedure proposed by (Skuodis & Tamošiūnas, 2014). Levels of normal stress varied between 2 and 250 kPa.

Table 1. Experimental program.

Test	Standard	D (mm)	H (mm)	CT (days)	Number of Samples	Number of Samples, total
UCS	EN 13286-41:2021	100	200		3	15
DTS	NF EN 13286-40	100	200	7, 28, 90,	3	15
ITS	NF EN 13286-42	100	100	180, 360	4	19
DS	NF EN ISO 17892-10	60	35		15	75



(a) (b) (c)

Figure 2. Characteristics of mechanical tests employed: (a) UCS, (b) DTS, (c) ITS.

3 RESULTS AND DISCUSSION

For UCS, DTS and ITS, mean values and standard deviation (SD) are presented in

Table 3. For DS, conventional linear regressions parameters c (cohesion) and φ (friction angle) corresponding to the MC criteria are presented for each CT with the coefficient of determination, R^2. R^2 is higher than 0.93 for 3 out of 5 CT studied, which suggest the suitability of this model to represent the failure characteristics of the studied material.

Linear regressions are used to represent UCS, DTS, ITS and cohesion as a function of CT (Xuan et al., 2012) following the eq. (1). Results, shown in

Table 3, reveal a good agreement between traction gain and CT. For UCS and c, unexpectedly, a poor correlation with CT is identified, with higher values for CT = 90 days. For φ, regressions also revealed a poor correlation (R^2=0.15).

$$y = a\,log_{10}(CT) + b \qquad (1)$$

Table 2. Regression models for experimental results.

Test	a	b	R^2
UCS (MPa)	0.338	1.281	0.403
DTS (MPa)	0.077	0.053	0.840
ITS (MPa)	0.063	0.074	0.842
c (MPa)	0.050	0.238	0.473

A comprehensive correlation between studied parameters was done (Figure 3). Results agree with the linear correlation between $Log_{10}CT$ and the tensile strength enhancement (Table 2).

DTS and ITS are highly correlated ($R_{DTS\text{-}ITS}$ = 1.00). The ratio DTS/ITS is 1.04±0.09. For practical purposes this ratio is assumed as 0.8 (SETRA & LCPC, 2000). A moderate correlation is also identified between UCS and MC parameters ($R_{UCS\text{-}c}$ = 0.73 and $R_{UCS\text{-}\phi}$ = 0.66). Correlation between the tensile strength (either DTS or ITS) and the MC parameters are moderated, with higher coefficients for cohesion ($R_{DTS\text{-}c}$ = 0.39, $R_{ITS\text{-}c}$ = 0.43).

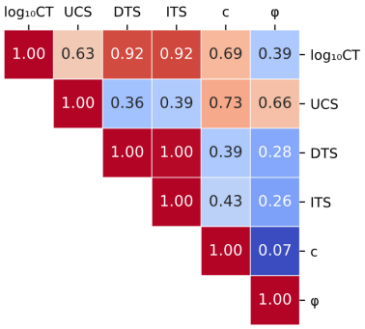


Figure 3. Correlation matrix of the dataset

Mean results after 7 days of cure are displayed in a $\{\sigma - \tau\}$ space in Figure 4. Here, principal stresses in the failure, i.e., the couple (σ_3, σ_1), are used to represent Mohr semi-circles for UCS $(0, UCS)$, DTS $(DTS, 0)$ and ITS $(ITS, -3ITS)$ (Jaeger et al., 2007). Direct shear results are depicted as both the couple (σ, τ) of individual tests (scatterplot) and the MC envelope (linear regression).

Results suggests a link between MC envelope and UCS and ITS values for a given CT as reported in the literature (Piratheepan et al., 2012). This approach states that the envelope of Mohr-Coulomb's failure corresponds to the tangent to the ITS and UCS semi-circles. Mathematically, it relies on either UCS or ITS, and the ratio $\xi = ITS/UCS$. This ratio varies within quite a narrow range 0.10 ± 0.02.

In Table 4, this approach is applied to the experimental dataset for a given CT and compared to the measured values from DS test. Results are in good agreement. When comparing the ratio between estimated and measured values, it varies between 0.84 and 1.22 with a mean of 1.07 for c and between 0.77 and 1.40 with a mean of 1.03 for φ.

It is interesting to remark that φ_ξ is close to a constant value (49.4±5.5°), which suggest that CT doesn't have effect on friction angle.

Table 3. Experimental results. Max and min values in bold

CT (days)	UCS (MPa)		DTS (MPa)		ITS (MPa)		DS		
	Mean	SD	Mean	SD	Mean	SD	c (MPa)	φ (°)	R^2
7	**1.53**	0.05	**0.13**	0.02	**0.14**	0.02	**0.24**	50.2	0.942
28	1.65	0.15	0.15	0.01	0.15	0.01	0.35	**36.3**	0.568
90	**2.41**	0.01	0.18	0.03	0.18	0.01	**0.37**	55.9	0.933
180	1.77	0.11	**0.26**	0.07	**0.23**	0.01	0.33	41.7	0.485
360	2.11	0.02	0.25	0.04	0.22	0.03	0.34	**62.0**	0.936

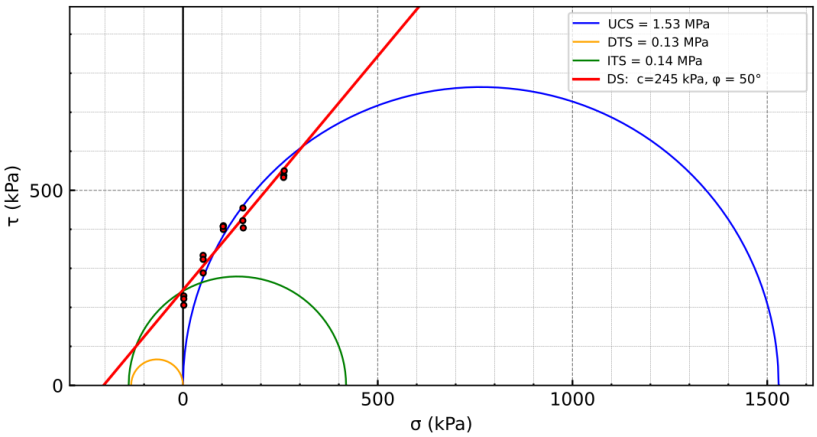

Figure 4. Mean results after 7 days of cure. UCS (blue), DTS (orange), ITS (green) and Direct shear (red).

Table 4. Measured (c, φ) and estimated (c_ξ, φ_ξ) MC param.

CT (days)	ξ	Estimated		$\frac{c_\xi}{c}$	$\frac{\varphi_\xi}{\varphi}$
		c_ξ kPa)	φ_ξ (°)		
7	0.09	271.0	51.0	1.11	1.02
28	0.09	293.4	50.9	0.84	1.40
90	0.07	368.8	56.0	0.99	1.00
180	0.13	402.9	41.0	1.22	0.98
360	0.10	405.0	48.0	1.18	0.77

4 CONCLUSIONS

This work shows that tensile properties are linearly correlated with curing time. Moreover, DTS≈ITS and DTS exhibit higher SD. The ITS/UCS ratio is 0.10.

For a given curing time, a good relationship is identified between UCS and MC parameters. The alternative method for estimating MC parameters for CSS based on ITS and UCS is successfully checked. Friction angle seems to be independent from CT.

ACKNOWLEDGEMENTS

The authors would like to thank the Gustave Eiffel University, Materials and Infrastructures Department (MAST) for the technical support and laboratory facilities to carry out this research.

ABSTRACT: This paper advocates for climate-responsive optimization in civil engineering, leveraging the NSGA-II algorithm. Conducting an in-depth study on a dike structure, the integration of pymoo with Plaxis 2023.2 via Python emerges as a potent decision support tool. Employing a plane strain approach with 15-noded triangular elements, the numerical model undergoes SRFEA for stability assessment. Three objectives, material demand (f1), LC2 exploitation (f2), and LC3 exploitation (f3), are systematically minimized by NSGA-II. Results, depicted in a Pareto surface, spotlight a wider spread for material demand, emphasizing its variability. Findings underscore the pivotal role of multi-objective algorithms in guiding sustainable civil engineering decisions amid climate change challenges.

RÉSUMÉ: Cet article plaide en faveur de l'optimisation adaptative au climat dans le génie civil, en exploitant l'algorithme NSGA-II. En menant une étude approfondie sur une structure de digue, l'intégration de pymoo avec Plaxis 2023.2 via Python émerge comme un puissant outil de soutien à la décision. En utilisant une approche de contrainte simple avec des éléments triangulaires à 15 nœuds, le modèle numérique fait l'objet d'une analyse de stabilité par SRFEA. Trois objectifs, la demande de matériaux (f1), l'exploitation LC2 (f2) et l'exploitation LC3 (f3), sont systématiquement minimisés par NSGA-II. Les résultats, représentés dans une surface de Pareto, mettent en lumière une plus grande variabilité de la demande de matériaux. Les conclusions soulignent le rôle central des algorithmes multi-objectifs dans la conduite de décisions durables en génie civil face aux défis du changement climatique.

Keywords: SRFEA; Multi-objective evolutionary algorithm; NSGA-II; decision support tool; dikes.

1 INTRODUCTION

The impact of climate change is compelling the civil engineering sector to prioritize the optimization of constructed structures. Geotechnical engineering frequently encounters the challenge of designing structures that must satisfy diverse objectives. The decision-making process regarding which solution to adopt for the final design is often intricate and far from straightforward.

This study is dedicated to present the advantages of employing a multi-objective evolutionary algorithm, NSGA-II, for the purpose of identifying trade-offs among various objectives. To achieve this, an extensive investigation of a dike structure has been undertaken in this paper, with the aim of discovering the most optimal solutions for three distinct objective functions.

2 GENERAL INFORMATION

2.1 Decision-making support tool

The following study presents implementation of a decision-making support tool, which enables users to make more reasonable and more optimal decisions considering their geotechnical problem. The presented routine incorporates multi-objective optimization framework *pymoo* (Blank and Deb, 2020) and integrates it via Python programming language (Van Rossum and Drake, 2009) with FEM-software Plaxis 2023.2 (Plaxis, 2023).

This paper implements the multi-objective Nondominated Sorting Genetic Algorithm (NSGA-II) from Deb et al. (2002), which offers an elitist-preserving approach. The NSGA-II combines a random parent population with its offspring in order to find a set of trade-offs which are represented by a Pereto-front, or a Pareto-surface, if there are more than two objectives defined. The algorithm has been succefully applied for solving multi-objective

geotechnical problems, e.g. Cerek and Grabe (2023), Cerek et al. (2023) and Das et al. (2016).

The self-programmed Python code triggers the FEM-simulations which deliver searched results. The outcomes are then evaluated by NSGA-II algorithm and the process repeats itself until predefined termination criteria are met. More to selection process of optimal solutions and set up of the algorithm can be found in Cerek and Grabe (2023) and Cerek et al. (2023). Once a set of trade-offs are found, the algorithm stops and a pareto-surface is displayed, where a user may find the problem's optimal solutions for defined objectives. Based on that, a fully aware decision might be made taken all important objectives into account.

Table 1. Soil parameters applied in FEM-model.

	Unit	Clay 1	Clay 2	Sand 1	Sand 2
γ_{unsat} (unsaturated unit weight)	(kN/m³)	16.0	15.0	18.0	19.0
γ_{sat} (saturated unit weight)	(kN/m³)	16.0	15.0	20.0	21.0
E' (Young´s modulus)	(MN/m²)	2.5	2.0	20.0	40.0
ν' (Poisson's ratio)	(-)	0.3	0.3	0.2	0.2
c' (effective cohesion)	(kN/m²)	10.0	10.0	0.1	0.1
s_u (undrained shear strength)	(kN/m²)	25.0	20.0	-	-
φ'* (effective friction angle)	(°)	17.5	17.5	30.0	35.0
ψ' (dilatancy angle)	(°)	0.0	0.0	5.0	5.0
$k_{x/y}$ (horizontal/vertical permeability)	(m/s)	$1.0E^{-9}$	$1.0E^{-10}$	$1.0E^{-4}$	$1.0E^{-4}$

* For undrained conditions, effective friction angle $\varphi' = 0.0°$

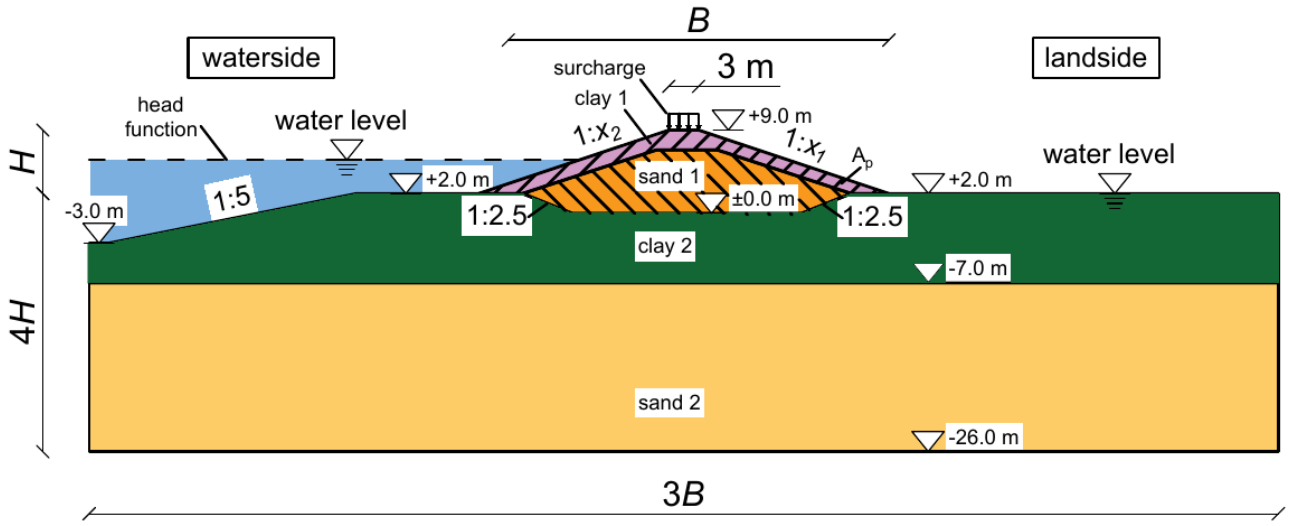

Figure 1. Model geometry.

2.2 Strength reduction finite element analysis (SRFEA)

In this research, all numerical simulations were performed using the commercial displacement-based finite element software Plaxis 2023.1 (Plaxis, 2023). The SRFEA was employed, which provides a Factor of Safety (*FoS*). The soil strength parameters were reduced until structural collapse was observed. Equation 1 outlines the formulation of *FoS*, with c', φ', and s_u representing the effective cohesion, effective friction angle, and undrained shear strength, respectively. The safety factors were not incorporated in our simulations, and all values represent characteristic data. Additionally, it's worth noting that, in the case of undrained shear strength, we solely applied a straightforward reduction of s_u.

$$FoS = \frac{\tan \varphi'}{\tan \varphi'_{mob}} = \frac{c'}{c'_{mob}} = \frac{s_u}{s_{u,mob}} \qquad (1)$$

3 NUMERICS

3.1 Numerical model

The finite element model employs a plane strain approach, employing 15-noded triangular elements. To ensure a dependable Factor of Safety (FoS), we meticulously refined the mesh by opting for a relative element size of 0.015. The total count of finite elements fluctuates based on individual model setups. In the interest of computational efficiency, we employed a coarser mesh for the lower soil layer without compromising model accuracy. Conversely, the mesh along the dike crest underwent refinement to accommodate the application of a line load.

In the scope of this study, we adopted a Mohr-Coulomb failure criterion. The model encompassed four distinct soil layers. It should be pointed out that fine-grained soil layers are modelled for undrained conditions, since quick loading rate is occuring within the simulation. The soil properties, as detailed in Table 1, and the model geometry, including the soil layers, are visually represented in Figure 1.

3.2 Model geometry

The selection of dimensions for the numerical model was guided by the recommendations provided by Mestat et al. (2004). These recommendations are based on correlations between the height of the dike H and the overall model depth, as well as between the width of the dike B and the total model width. The geometric configuration of the system is further characterized by two parametric variables, denoted as x_1 and x_2, which represent the horizontal components of the slope.

3.3 Calculation phases and loads

The model comprises four consecutive calculation phases. The initial phase, referred to as LC0, utilizes gravity loading to establish initial stresses. Subsequently, a plastic Nil-step phase (LC1) is executed, followed by a fully coupled flow-deformation analysis phase (LC2). In LC2, a head function is applied to the water level on the waterside of the dike. In the subsequent plastic calculation phase (LC3), a uniformly distributed surcharge load of 10.0 kN/m² is applied to the dike crest. Both LC2 and LC3 are followed by a safety analysis that incorporates SRFEA, as described in Section 2.2 of this paper.

Throughout all phases, the water level on the landside remains constant. In contrast, on the opposite side, it is initially set at +2.0 m. During the transient calculation phase, the water level progressively rises in a linear fashion up to +5.0 m. The critical load cases are indicated in Figure 1.

4 OPTIMIZATION PROBLEM

4.1 Problem definition

4.1.1 Variables

The geometry of the numerical model is parametrised by the horizontal components of the slope, as mentioned in Section 3.2. The lower boundaries x_l and upper boundaries x_u are given by Equations 2-3. The rounding of variables during the optimization process was set to two decimal places.

$$x_l = \{1.5; 1.5\} = \{x_{1,min}; x_{2,min}\} \quad (2)$$

$$x_u = \{4.5; 4.5\} = \{x_{1,max}; x_{2,max}\} \quad (3)$$

4.1.2 Objectives

This study delves into the intricacies of an optimization problem characterized by three semi-independent objectives, each represented by specific objective functions: f_1, f_2, and f_3 as detailed in Equations 4-6. Over successive algorithm generations, all objective functions are systematically minimized. Function f_1 pertains to the material demand A_p that is expresses by cross-sectional area. Both functions f_2 and f_3 are formulated as reciprocals of their respective FoS obtained from calculation phase LC2 or LC3.

$$f_1 = A_p \quad (4)$$

$$f_2 = \frac{1}{FoS_{LC2}} \quad (5)$$

$$f_3 = \frac{1}{FoS_{LC3}} \quad (6)$$

Consequently, optimization is performed for both horizontal components of the slope on the landside and waterside. This optimization is carried out with regard to minimizing material demand and ensuring a satisfactory factor of safety, both during the coupled flow-deformation analysis phase (LC2) and the plastic calculation phase (LC3).

5 STUDIES

This paper focuses on the multi-objective optimization of a dike structure using the NSGA-II algorithm. The algorithm, with an initial population of 100, was employed for this purpose. The termination criterion for design space tolerance was set to two decimal places, checked every second iteration to ensure a diverse range of outcomes.

Figure 2 depicts the results obtained from the optimization process. It is evident that the spread of solutions for the objective f_1 (material demand) is notably wider compared to f_2 and f_3. The Pareto surface

aids the decision-making process for the final design by offering an overview of possibilities.

The variables resulting from the optimization process are illustrated in Figure 3. It can be concluded that, for the selected objectives corresponding to defined load cases, a design with a steeper slope on the waterside is preferable, as the spread of solutions for this side is smaller. Conversely, results for the landside slope vary between the lower and upper boundaries.

Table 2 provides exemplary results for variables and objectives resulting from the optimization process (Sol1, Sol2), as well as for a traditional design (Sol3). It is crucial to emphasize that the difference in material demand between the presented solutions Sol1 and Sol2 is nearly 90%. This implies that choosing a design with a smoother landside slope would lead to a substantial increase in costs, CO2 footprint, and construction time. It should also be mentioned that the traditional design Sol3 would collapse under the applied surcharge load in LC3, even though it has flatter slopes and requires about 85% more material than Sol1.

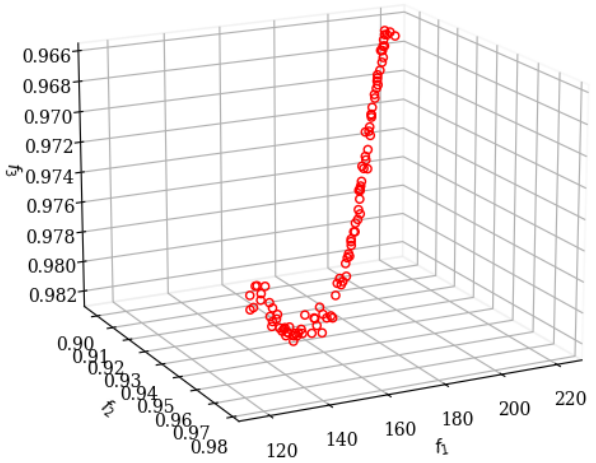

Figure 2. Pareto surface illustrating the optimization of three-objectives problem: f_1 – material demand; f_2 – exploitation for LC2; f_3 – exploitation for LC3.

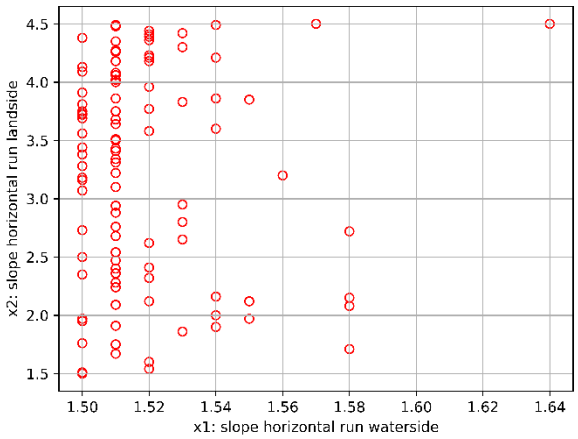

Figure 3. Results illustrating the optimization process variables x_1 and x_2 (horizontal components of the slope).

Table 2. Exemplary results of optimization process

	x_1	x_2	f_1	f_2	f_3
Sol1	1.50	1.51	117.65	0.98	0.98
Sol2	1.64	4.50	221.47	0.90	0.97
Sol3	3.00	3.00	216.60	0.95	>1.00

6 CONCLUSIONS

The study presented in this paper demonstrates that the application of multi-objective algorithms in the design process enhances problem understanding and provides a diverse set of solutions, which can be evaluated based on predefined objectives. The proposed routine, incorporating Finite Element Method (FEM) simulation and optimization techniques, has proven to be a valuable decision support tool in the design process, especially when dealing with numerous objectives that are challenging for classical human evaluation.

The adoption of this approach empowers engineers to make informed decisions, contributing to the creation of more sustainable structures. Consequently, it aids in the reduction and deceleration of climate changes caused by the civil engineering industry.

Performance-based interaction domains for pile groups

Domaines d'interaction basés sur les performances pour les groupes de pieux

R. Cesaro*, R. Di Laora, C. Iodice, A. Mandolini

Department of Engineering, Università della Campania "Luigi Vanvitelli", Aversa, Italy

**raffaele.cesaro@unicampania.it*

ABSTRACT: In many engineering problems the design of piles is ruled by a threshold acceptable value of absolute and differential settlements as well as rotations under working loads. To verify that settlements and rotations of a piled foundation, under some combined axial load-moment action, do not exceed acceptable values, the construction of 'performance-based' interaction domain would be a useful design tool. To this end, the response of pile groups subjected to combined actions including vertical load, Q, and moment components along x and y axes, M_x and M_y, is first investigated by means of a simple ad-hoc numerical code, fixing the settlement and/or rotation to a given threshold value. Closed-form expressions for the performance-based interaction domains in the Q-M_x-M_y space are then obtained by matching the numerical results. Due to the limited number of parameters involved, which are already required in routine design, the proposed domains can be easily employed for the design of pile groups.

RÉSUMÉ: Dans de nombreux problèmes d'ingénierie, la conception des pieux est déterminée par une valeur seuil acceptable des tassements absolus et différentiels, ainsi que des rotations sous des charges de travail. Pour vérifier que les tassements et les rotations d'une fondation sur pieux, soumise à une action combinée de charge axiale et de moment, ne dépassent pas les valeurs acceptables, la construction d'un domaine d'interaction "basé sur la performance" serait un outil de conception utile. À cette fin, la réponse de groupes de pieux soumis à des actions combinées, comprenant une charge verticale, Q, et des composantes de moment le long des axes x et y, M_x et M_y, est d'abord étudiée au moyen d'un code numérique simple ad hoc, en fixant le tassement ou la rotation à une valeur seuil donnée. Des expressions analytiques pour les domaines d'interaction basés sur la performance dans l'espace Q-M_x-M_y sont ensuite obtenues en mettant en correspondance les résultats numériques. En raison du nombre limité de paramètres impliqués, qui sont déjà nécessaires dans la conception courante, les domaines proposés peuvent être facilement utilisés dans la conception courante de groupes de pieux.

Keywords: Pile groups; eccentric loading; performance-based design; analytical solution.

1 INTRODUCTION

Piled foundations are designed to ensure an adequate safety margin against failure (Ultimate Limit State, ULS) and a satisfactory behaviour in terms of settlements and rotations under working loads (Serviceability Limit State, SLS). However, in many engineering problems the design is ruled by SLS checks, i.e., by some threshold values of settlements and/or rotation which must not be exceeded. The example of a wind turbine is paradigmatic in this sense, given that the foundation is generally designed not to exceed a rotation of 0.5° to guarantee that it is tolerated by the structure without loss of serviceability during the entire lifespan. In light of the above, employing interaction domains fixing acceptable values of settlements and/or rotations would facilitate the assessment of SLS requirements. While expressions for failure envelopes of pile groups under combined loads have been proposed by recent works (Di Laora et al., 2019 and 2022; Iovino et al., 2021; Sakellariadis and Anastasopoulos 2022; Cesaro et al., 2024), there are still no solutions available for performance-based interaction diagrams. To fill this lack, a simple numerical approach is first proposed to investigate the response of pile groups subjected to a vertical load, Q, and to an external moment vector inclined by the angle α_M with respect to the y axis (with M_x and M_y moment components along x and y axes, Figure 1), fixing settlements or rotations to a given value. Using the results obtained with the code as benchmarks, closed-form solutions for performance-based interaction diagrams are thereby provided which allow to assess all the combinations of loads leading to a specific value of displacement of the pile group. Note that the horizontal load component has been disregarded; this simplification is consistent with the design of tall structures (such as wind turbines or bridge piers) since, from an engineering viewpoint, in this case the horizontal load is usually negligible

compared to the vertical eccentric component. The proposed simple formulae are found to be in remarkable agreement with the more rigorous solution, and therefore represent a useful practical tool for the design of pile groups.

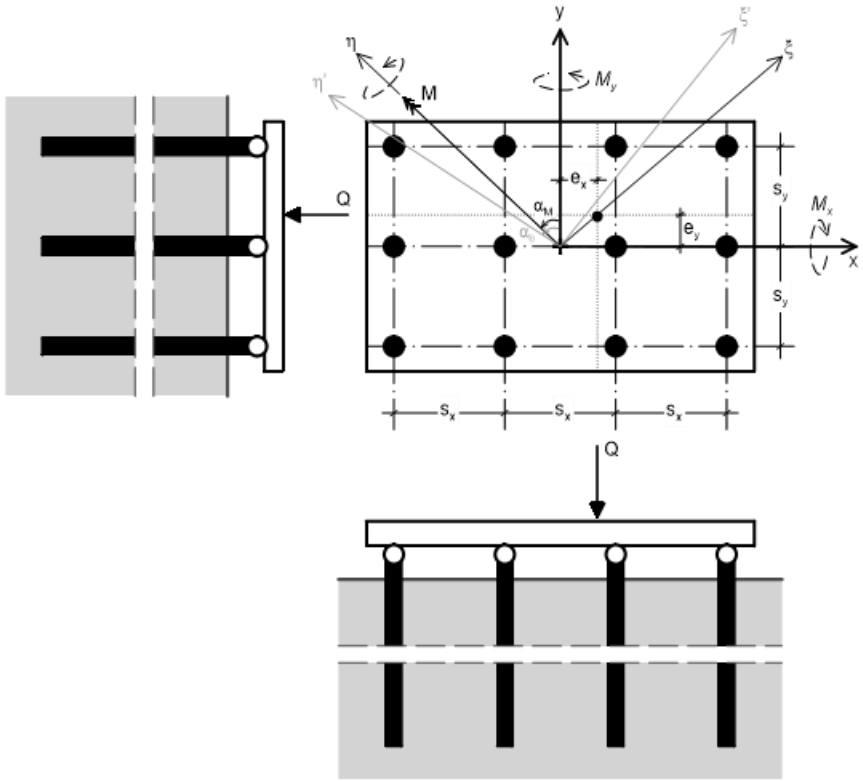

Figure 1. Pile group subjected to a vertical eccentric load (e_x and e_y, s_x and s_y are the eccentricities and the pile spacings along x and y axes, respectively).

2 NUMERICAL CODE

The numerical procedure to compute pile group settlement and rotation under an arbitrary load path and hence obtain the performance-based interaction diagrams, is detailed in the ensuing.

The following simplified assumptions have been made (Mandolini and Viggiani, 1997):

(a) Piles are modelled as uniaxial elements, characterized by a failure load in compression (N_u) and in uplift ($-S_u$), and by an elastic stiffness (k_s). The single pile load-settlement curve is described employing a hyperbolic relationship as suggested by Chin (1972) and the non-linearity is simulated using a stepwise linear incremental procedure;

(b) Piles heads are connected through a rigid free-standing cap having infinite strength;

(c) To account for pile group effects, interaction factors are used superimposing the effect of any pair of piles in the group (Poulos, 1968; Randolph and Wroth, 1979). Pile-to-pile interaction affects only the elastic component of the pile settlement because the non-linearity is essentially concentrated at the pile-soil interface (Randolph, 1994; Kanellopoulos and Gazetas, 2020).

As concerns the elastic axial stiffness, the adoption of a unique value for both compression and uplift is acceptable from an engineering standpoint since in many applications the base contribution is a small percentage of the total stiffness (Randolph and Wroth, 1978) and can thus be neglected. It should be pointed out that the numerical procedure can be employed by adopting a different load-settlement law to reproduce the load-settlement response of the single pile; likewise, the interaction coefficients can be evaluated by using one of the expressions and/or approaches available in literature. In this work the interaction coefficients, α_{ij}, are calculated using the approximated expression proposed by Randolph and Wroth (1979):

$$\alpha_{ij} = \frac{\ln(r_m/s_{ij})}{\ln(r_m/r)} \quad (1)$$

where s_{ij} is the distance between the piles i and j, r is the radius of pile j and r_m is the "magic radius", i.e., the distance at which the deformative field associated to

pile j displacement, and measured from its axis, is assumed to be negligible:

$$r_m = \left\{0.25 + [2.5\rho(1-\nu_s) - 0.25]\frac{G_L}{G_b}\right\} L \quad (2)$$

In the above equation L is the pile length; G_L and G_b are the soil shear moduli at the depth L and underneath pile base, respectively; ν_s is the Poisson's coefficient of the soil; ρ is a parameter depending on the soil homogeneity (equal to 1 for a homogeneous medium and to 0.5 for a "Gibson-type" soil), defined as $G_{L/2}/G_L$, where $G_{L/2}$ is the soil shear modulus at the depth $L/2$. As shown by Mylonakis and Gazetas (1998), for a floating pile the magic radius can be estimated as:

$$r_m \approx \chi_1\chi_2 L(1-\nu_s)\text{u} \quad (3)$$

where $\chi_1\chi_2$ is equal to 2.5 for an homogeneous halfsapce and 1 for a Gibson soil on rigid bedrock at depth 2.5L.

The elastic settlement, w_i, of a pile in the group of n piles, is given by:

$$w_i = \sum_{j=1}^{n} \frac{1}{k_{sj}} P_j \alpha_{ij} \quad (4)$$

Note that, the hypothesis (a) and (c) assure that the interaction factors do not vary with the load level. To account for pile non-linear behaviour under its own load, assuming Chin's hyperbole as the load-settlement curve for the single pile, the tangent compliance to be employed in the stepwise linear incremental procedure is given by:

$$\frac{dw_i}{dP_i} = \frac{1}{k_{si}\left(1-\frac{P_i}{P_{iU}}\right)^2} \quad (5)$$

where P_i and P_{iU} are respectively the load acting on pile i and its axial capacity in compression (N_u) or in uplift ($-S_u$) depending on the sign of P_i. This means that for $i=j$ the right-hand side of eq. (4) must be multiplied by the following factor:

$$\alpha_\psi = \frac{1}{\left(1-\frac{P_i}{P_{iU}}\right)^2} \quad (6)$$

For any (Q, M) pair applied to the pile group, the distribution of the axial loads at the head of each pile as well as the displacement components of the rigid raft must satisfy the following compatibility and equilibrium equations:

$$w_i = w_0 + \theta_x y_i + \theta_y x_i \quad (7a)$$

$$\sum_{i=1}^{n} P_i = Q \quad (7b)$$

$$\sum_{i=1}^{n} P_i x_i = M_y \quad (7c)$$

$$\sum_{i=1}^{n} P_i y_i = M_x \quad (7d)$$

where w_0 is the settlement of the cap evaluated at the origin of the reference system, θ_x and θ_y, are the rotations of the cap about x and y axis, respectively. Note that Equation (7a) must be written for each of the n piles.

The construction of the performance-based interaction domains corresponding to fixed values of the vertical settlement is shown in Figure 2 for a 3×4 pile group. With reference to loading paths in which a vertical eccentric load increases at constant eccentricity, M/sQ, with α_M = 0, the points of the domain are obtained by deriving Q (and, consequently, M) corresponding to a given w/d (e.g., 2, 5, 10%) in the load-settlement curves (Figure 2a) calculated by the above-described numerical procedure. From Figure 2b it is possible to notice that the perfomance-based domains are superimposed to the theoretical failure surface (Di Laora et al., 2019; Cesaro et al., 2024) until the selected w/d is reached (i.e., $w/d \leq 2\%$ if the performance diagram is calculated for w/d = 2%). It follows that these domains contract only on the side of positive Q, that is in the same direction of the considered w/d.

Likewise, it is possible to derive the domains limiting the rotation, θ, to a given value. The procedure can be applied by simultaneously setting θ and w/d (Figure 5). It should be observed that, contrary to the case of fixing w/d, choosing θ as performance parameter corresponds to a symmetric contraction of the domain along the M axis - a consequence of adopting the same curve for both positive and negative values of the rotation.

3 SIMPLIFIED FORMULATION

To provide an easy-to-use tool to estimate the performance-based interaction domains, simplified formulae are proposed.

If the performance parameter is the vertical displacement, the interaction domain can be approximated with the following expression:

$$\sqrt{\left(\frac{M_x}{M_{xu}}\right)^2 + \left(\frac{M_y}{M_{yu}}\right)^2} = \frac{4[\lambda_w Q(Q_c+Q_t) - Q^2 - \lambda_w^2 Q_c Q_t]}{\lambda_w^2 (Q_c - Q_t)^2} \quad (8)$$

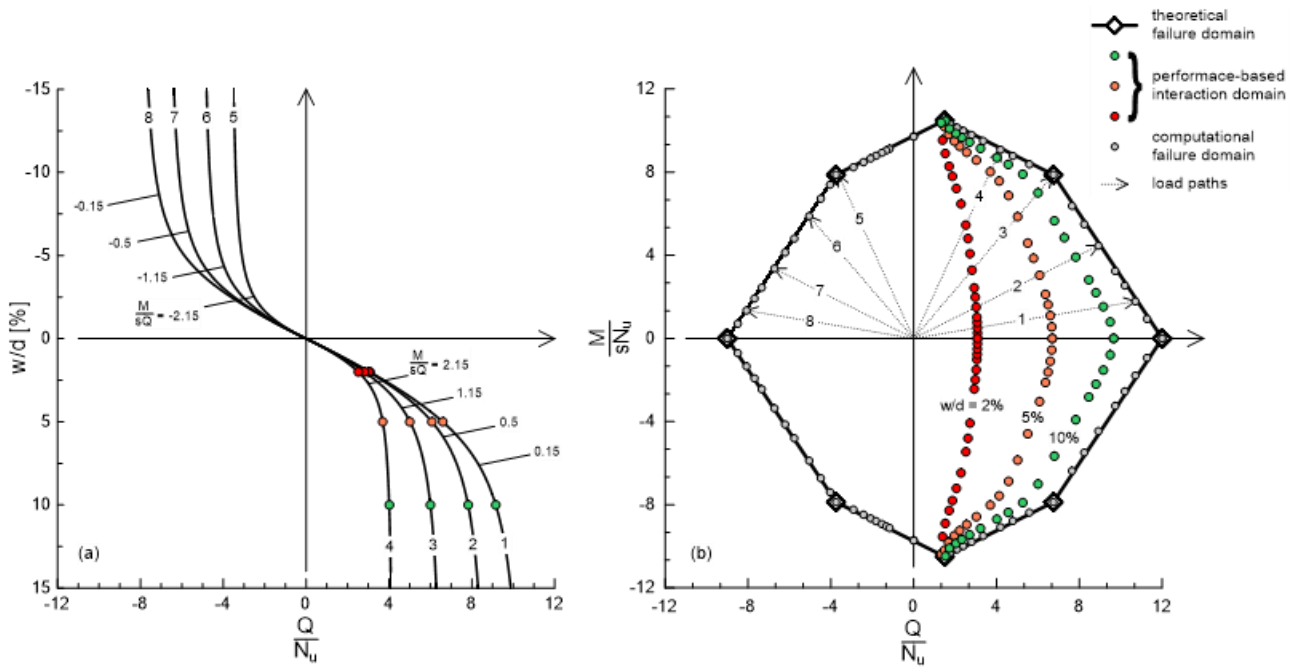

Figure 2. Load-settlement curves for a 3×4 pile group with applied vertical eccentric loads (Su/Nu = 3/4, s/d = 3, r_m/d=40, $k_s d/Nu$=80, α_M = 0, where d is the pile diameter) (a) and dimensionless interaction domains in the Q-M plane (b).

where Q_c and Q_t are the axial capacities of the group in compression and in uplift, M_{xu} and M_{yu} are the maximum ultimate moment capacities of the group around x and y axes and λ_w is the ratio between the vertical load corresponding to the fixed value of the vertical displacement and Q_c (or Q_t). M_{xu} and M_{yu} can be calculated from the failure domain, and for a value of α_M not corresponding to a vertex of the domain, a linear interpolation between two consecutive vertexes of the M_x-M_y failure locus is needed (Cesaro et al. 2024). The group vertical settlement taking into account the pile-to-pile interaction and the non-linearity of the single pile behaviour can be estimated as:

$$w = \frac{\lambda_w Q_u}{n k_s}\left[R_s + \frac{1}{(1-\lambda_w)} - 1\right] \qquad (9)$$

where R_s is the amplification factor for group settlement:

$$R_s = \sum_{i=1}^{n}\sum_{j=1}^{n}\alpha_{ij}/n \qquad (10)$$

Thus λ_w may be easily calculated as:

$$\lambda_w = \frac{1+\frac{K_v w}{Q_u} - \sqrt{1+\frac{K_v w}{Q_u}\left(\frac{4}{R_s}+\frac{K_v w}{Q_u}-2\right)}}{2\left(1-\frac{1}{R_s}\right)} \qquad (11)$$

where K_v (= nk_s/R_s) is the elastic vertical stiffness of the group. Taking r_m = $2L(1\text{-}\nu_s)$ and ν_s = 0.3, it is possible to investigate the influence of the pile slenderness ratio L/d and normalized pile spacing s/d, on the parameter R_S (Figure 3). It follows that R_S can be estimated as:

$$\frac{R_S}{n} = 0.9exp\left(-0.5\sqrt{\frac{ns}{L}}\right) \qquad (12)$$

where $R_G = R_S/n$ is the group reduction factor.

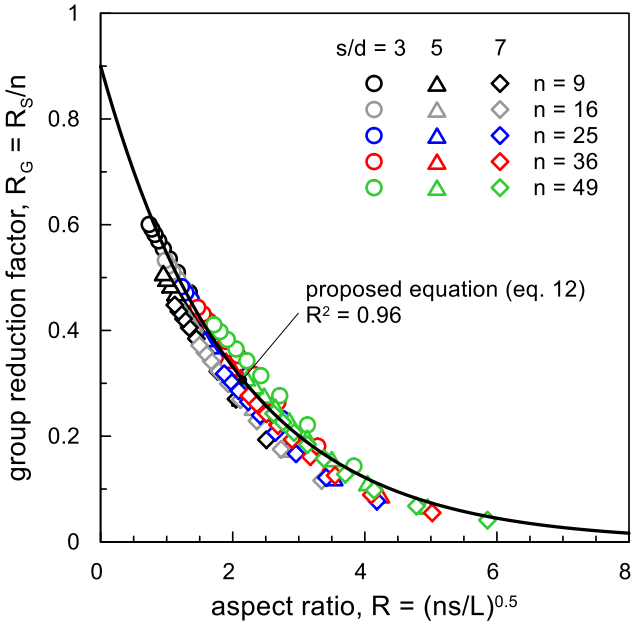

Figure 3. Group reduction factors.

Note that, Equations 9 and 12 allow to simply derive the pile group load-settlement curve under vertical centered load.

On the other hand, if the maximum cap rotation is the chosen performance parameter, the interaction domain can be estimated with the following expression:

$$\sqrt{\left(\frac{M_x}{\lambda_{\theta x} M_{xu}}\right)^2 + \left(\frac{M_y}{\lambda_{\theta y} M_{yu}}\right)^2} = \frac{4[\lambda_\theta^{0.5} Q(Q_c+Q_t) - Q^2 - \lambda_\theta Q_c Q_t]}{\lambda_\theta (Q_c - Q_t)^2} \quad (13)$$

where λ_θ is the ratio between the resultant moment corresponding to the fixed value of the rotation and M_u.

The cap rotation, taking into account the pile-to-pile interaction and the non-linearity of the single pile behaviour, can be estimated as:

$$\theta = \frac{\lambda_\theta M_u}{K_\theta (1-\lambda_\theta)} \quad (14)$$

then λ_θ is given by:

$$\lambda_\theta = \frac{\theta K_\theta}{M_u + \theta K_\theta} \quad (15)$$

where K_θ is the elastic rotational stiffness of the group, depending on the axis orientation about which the group capacity assessment is required (Figure 1):

$$K_\theta = \frac{n}{\sum_{i=1}^{n} \frac{\sum_{j=1}^{n} \xi_j' \alpha_{ij}}{\xi_i' k_s \sum_{z=1}^{n} \xi_z'^2}} \quad (16)$$

in which

$$\xi_i' = x_i \cos(\alpha_\theta) - y_i sin(\alpha_\theta) \quad (17)$$

It should be pointed out that for a given resultant moment acting on pile group around a generic axis η, the maximum cap rotation could occurs about a different axis η', i.e., $\alpha_M \neq \alpha_\theta$ (Figure 1). However, it can be observed that for a square group of identical piles the difference between α_M and α_θ is always negligible from an engineering viewpoint, thus the evaluation of the group capacity can be carried out in the same direction as the resultant moment vector.

As in the previous case, it is possible to define the group rotational stiffness as the ratio between the elastic rotational stiffness of the group in absence of interaction ($k_s \Sigma \xi_i'^2$) and the group rotational amplification factor $R_{S\theta}$, that can be estimate through the following expression (Figure 4):

$$R_{S\theta} = 0.4\left[n^{-1.45}\left(\frac{L}{s}\right)^{0.4}\right]^{-0.45} \quad (18)$$

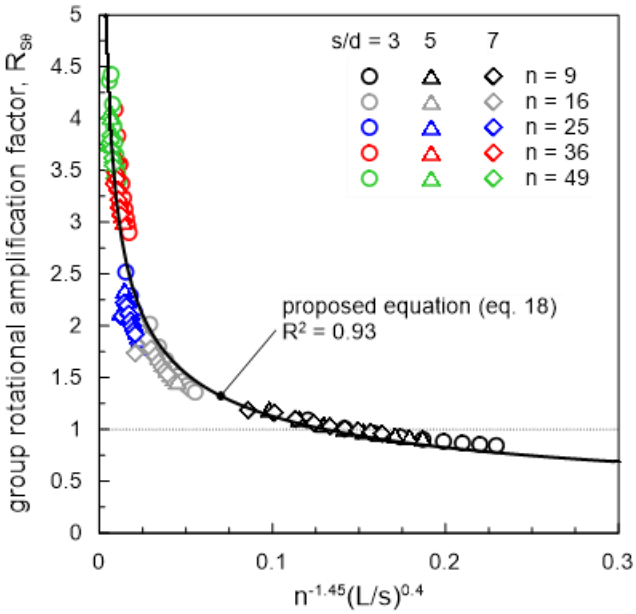

Figure 4. Group rotational amplification factor.

The domain derived by fixing both the performance parameters can be easily computed intersecting Equations (8) and (13) obtaining a very satisfactory match with the numerical results (Figure 5).

4 CONCLUSIONS

A simple numerical code to derive performance-based interaction domains is proposed based on the procedure presented in an early work by Mandolini and Viggiani (1997). This involved the selection of the load-settlement curve for the single pile and the possibility to account for the pile-to-pile interaction which is considered to affect only the elastic component of the single pile settlement. After calculating the load-displacement curves for different loading paths involving vertical eccentric loads applied to the pile group, the construction of the performance-based interaction domains is carried out by fixing settlement and/or rotation to a threshold value and deriving the corresponding load from the above curves. Simple formulae to employ in routine design are also provided taking into account the non-linear behaviour of the single pile and the pile-to-pile interaction. The results obtained employing the proposed formulae match very satisfactorily those derived with the numerical procedure. It is worth of note that the procedures and formulations presented have general validity since the results are depending on the input data. The proposed domains are straightforward design tool enabling to simultaneously

carry out SLS checks for all load combinations necessitating only the capacity and stiffness of the single pile as ingredients, thus avoiding complex finite element modelling of the whole foundation.

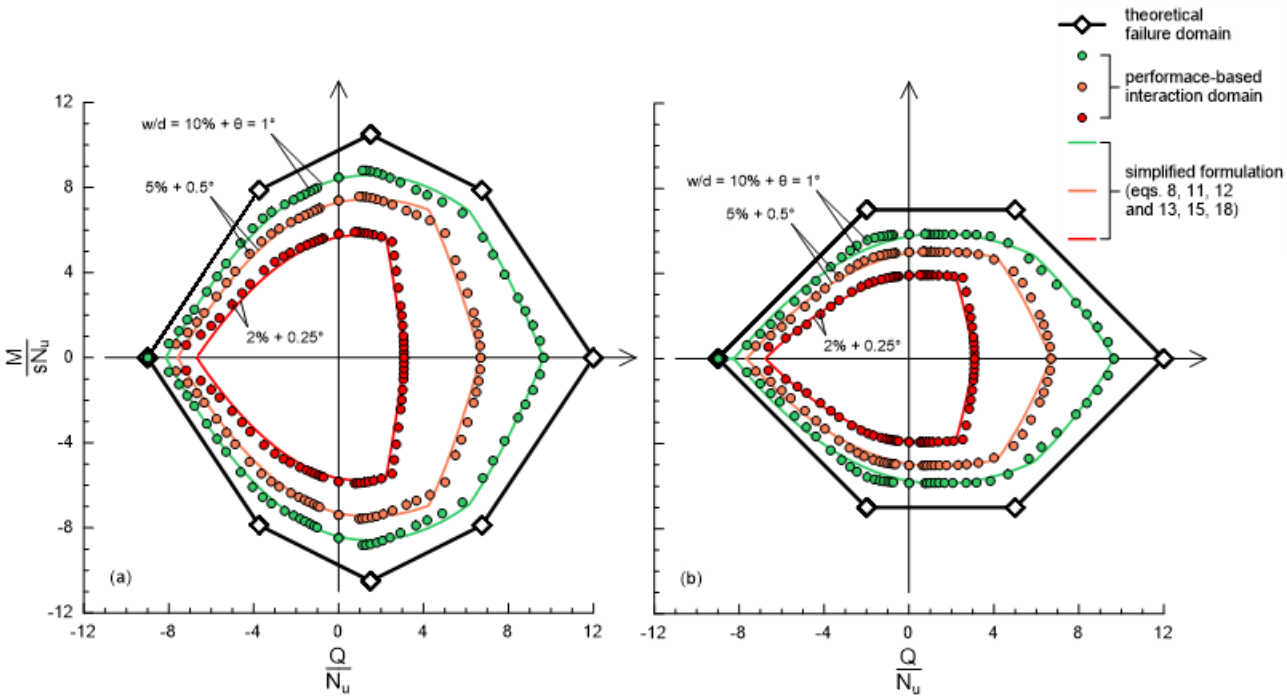

Figure 5. Dimensionless interaction domains in the Q-M plane for a 3×4 piles group (Su/Nu = 3/4, s/d = 3, r_m/d=40, k_sd/Nu=80): α_M = 0° (a); α_M = 90° (b).

Rheological study of soil-cement-GGBFS mixture

Etude rhéologique du mélange sol-ciment-GGBFS

S. Choudhary, P.K. Meena, A. Kumawat, L. Borana*
Indian Institute of Technology Indore, India

**lalitborana@iiti.ac.in*

ABSTRACT: The rheological parameters of the soils and soil-cement mixtures, such as storage modulus, loss modulus, viscosity, flow points, shear stress, yield stress, and many more, are being studied to examine and understand the response of the soil microstructure subjected to external stress. In this study, a stress-controlled rotational rheometer is used on several test specimens of clay soil mixed with Ordinary Portland Cement (OPC) and Ground Granulated Blast Furnace Slag (GGBFS). The soil specimens underwent shear deformations at the rate of 0.01% to 100% using a 50 mm diameter measuring shaft at various time intervals during the Amplitude Sweep Test (AST). AST was performed to investigate the viscoelastic properties of the soil paste having OPC (15% by weight of dry soil) and different proportions of GGBFS (0%, 20%, 30%, and 40% by dry weight of OPC). The obtained test results showed that, when the strain rate was low, storage modulus (G') exceeded loss modulus (G") for all the samples (15%C-0%G, 15%C-20%G, 15%C-30%G, 15%C-40%G). Notably, the sample with 20% GGBFS replacement (15%C-20%G) exhibited the highest G' value among all compositions, which indicates that the 20% GGBFS replacement sample deforms and returns to its original state more quickly than the other samples.

RÉSUMÉ: Les paramètres rhéologiques des sols et des mélanges sol-ciment tels que le module de stockage, le module de perte, la viscosité, les points d'écoulement, la contrainte de cisaillement, la limite d'élasticité et bien d'autres sont étudiés pour examiner et comprendre la réponse de la microstructure du sol soumise à des contraintes externes. Dans cette étude, un rhéomètre rotatif à contrainte contrôlée est utilisé sur plusieurs éprouvettes de sol argileux mélangées à du ciment Portland ordinaire (OPC) et à du laitier de haut fourneau granulé broyé (GGBFS). Les échantillons de sol ont subi des déformations par cisaillement à un taux de 0,01% à 100% à l'aide d'un arbre de mesure de 50 mm de diamètre à différents intervalles de temps au cours du test de balayage d'amplitude (AST). L'AST a été réalisée pour étudier les propriétés viscoélastiques de la pâte de sol contenant de l'OPC (15% en poids de sol sec) et différentes proportions de GGBFS (0%, 20%, 30% et 40% en poids sec d'OPC). Les résultats des tests obtenus ont montré que, lorsque la vitesse de déformation était faible, le module de conservation (G') dépassait le module de perte (G") pour tous les échantillons (15%C-0%G, 15%C-20%G, 15%C-30%G, 15%C-40%G). Notamment, l'échantillon avec 20% de remplacement de GGBFS (15% C-20% G) présentait la valeur G' la plus élevée parmi toutes les compositions, ce qui indique que l'échantillon de remplacement de 20% de GGBFS se déforme et revient à son état d'origine plus rapidement que les autres échantillons.

1 INTRODUCTION

At present, the extensive production of industrial wastes such as fly ash, ground granulated blast furnace slag (GGBFS), silica fumes, and more presents a major global concern due to its significant environmental, social, and economic implications. As industries continue to expand and manufacturing processes intensify, the need to dispose of the generated wastes also intensifies significantly (Buddhdev and Timani, 2021). Ground Granulated Blast Furnace Slag (GGBFS) is one of such industrial by-products of steel industries that are produced in millions of tonnes globally, including India. GGBFS is a well-known Supplementary Cementitious Material (SCM) that possesses pozzolanic and latent hydraulic properties, and it is used to partially replace Ordinary Portland Cement (OPC) to a certain extent depending on applicability. Over the past few decades, OPC has been widely employed in the stabilization of soft clay soils. The soil-cement mixtures, comprising soil, cement, and water, exhibit qualities like better strength gain, reduced permeability, compressibility, improved durability, etc., that make them suitable for a variety of applications, ranging from road construction to foundation stabilization (Choudhary et al., 2023). However, the use of OPC raises notable environmental concerns due to the carbon dioxide (CO_2) emissions generated in its manufacturing process. OPC is directly accountable for approximately 5% of artificial CO_2 emissions, with 1 tonne of cement production yielding 800 kg of CO_2 (Damtoft et al., 2008; Gartner,

2004). In recent years, researchers and engineers have explored the incorporation of SCMs like ground granulated blast furnace slag (GGBFS) to enhance the performance of soil-cement blends further. GGBFS undergoes a strong reaction with calcium hydroxide, a by-product of cement hydration, resulting in the production of additional cementitious compounds like calcium silicate hydrate (CSH) and calcium aluminate hydrate (CAH) (Yi et al., 2015).

In the current scenario, most of the SCMs have been under-utilized except for Fly Ash (FA). FA has been widely employed to enhance the mechanical properties of fine-grained soils, such as maximum dry density, swelling, optimum moisture content, consistency limits (Barman and Dash, 2022), shear strength, compressibility (Singh et al., 2021a, 2021b) and many more. However, there is very limited information available in the research studies regarding the utilization of GGBFS in geotechnical engineering. D.D. Higgins et al. (1998) studied the possible utilization of GGBFS to improve the strength of lime-stabilised clay soils. The authors conducted experimental tests on different lime/slag ratios on two different clay soils, Kaolinite and Kimmeridge Clay. From this study, it was found that with an increase in the curing period, the strength of the clay-lime-GGBFS mixture also increased significantly for both the above-mentioned soils. It was also found that GGBFS alone has no effect on the strength enhancement of the soils and it requires an activator like lime, cement, etc. to provide significant strength. Yi et al. (2015) used Carbide-slag (CS) activated GGBFS for the stabilization of soft clay soils. The investigation focused on exploring the strength gained behaviour of soft clay soils when added with CS-GGBFS at varying proportions by performing a series of UCS tests. The results revealed that maximum unconfined compressive strength gain was observed for an optimum CS content of 4-6% in the soil-CS-GGBFS mixture. The UCS values were almost twice for CS-GGBFS stabilized soft soils in comparison to cement-treated soft soils.

Some researchers have conducted comprehensive investigations, including rheological evaluations, to investigate as well as understand the possible advantages and limitations related to the usage of GGBFS in soil-cement mixtures. Rheology, the study of the flow and deformation of materials, provides insights into the material's behaviour under external stress conditions. Amplitude sweep test (AST) in rheology is often employed to investigate the viscoelastic properties of materials, including soil-cement mix. AST involves applying oscillatory shear stress or strain to a material and observing its response over a range of amplitudes while maintaining a constant frequency. By varying the level of oscillatory amplitudes, the material's viscoelastic properties can be assessed by measuring its storage modulus, loss modulus, and yield stress as a function of the applied stress. The storage modulus (G') reflects the material's elastic or 'solid-like' behavior, while the loss modulus (G") represents its viscous or 'liquid-like' behavior. Yield stress, on the other hand, marks the transition from a solid-like to a fluid-like state, crucial for understanding flow initiation under stress. A few researchers used rheology to investigate different characteristics of virgin clay soils and clay combined with various additives. Celik and Akcuru (2020) investigated the use of Bottom Ash (BA) as a mineral component in permeation grouts made of cement. This study tested 28 various mix proportions with six different BA contents and four different water contents using a number of analytical and experimental procedures. According to the findings, there was no noticeable change in yield stress values for any water-to-binder (w/b) ratio when BA was substituted. The substitution of BA had some minor effects on yield stress; nonetheless, for all combinations, there was a noticeable downward trend in yield stress values as the w/b ratio increased. Wang et al. (2021) examined how temperature and hydration time affect the rheological characteristics of Ordinary Portland Cement (OPC) slurries, particularly emphasizing the simulation of high-temperature conditions in a laboratory setting. Portland cement PO42.5 samples with water-to-cement ratios (W/Cs) spanning from 0.5 to 2.0 were prepared for the rotational viscometer. The research also explored the rheological models and the laws governing the observed changes in rheological parameters for cement slurries exhibiting different degrees of hydration across varying temperatures ranging from 30°C to 80°C. Newton, Bingham, and power law models were applied to fit the rheological test data, and a mathematical analytical expression was introduced for the fitted curve. It is worth noting that GGBFS can augment the engineering properties of clay soil when used as a partial replacement for OPC in soil-cement mixtures. However, there is limited information available regarding the rheology of GGBFS-mixed soil-cement combinations.

In this study, rheological parameters like viscosity, yield stress, and flow behaviour index are investigated to understand the rheological characteristics of GGBFS-mixed soil-cement mixtures. Rheology is conducted at different time intervals with various GGBFS proportions as replacements for OPC.

2 MATERIALS AND METHODOLOGY

2.1 Materials

Clay soil used in this study was collected from a test site in IIT Indore, Madhya Pradesh, India. OPC and GGBFS were obtained through collaboration with industrial partners. Figure 1 illustrates the particle size distribution (PSD) curve of the soil. In accordance with the Unified Soil Classification System (USCS), adopted from ASTM D-2487-98, the soil is categorized as highly compressible clayey soil. The index properties of the clay soil are listed in Table 1.

Table 1. Index properties of clay soil.

Property	Value
Natural water content (%)	14.50
Optimum moisture content (%)	28.5
Liquid limit (%)	79.20
Plastic limit (%)	35.62
Specific gravity	2.70
Shrinkage limit (%)	11.35
Maximum dry unit weight (kN/m^3)	1.44
USCS soil classification	CH

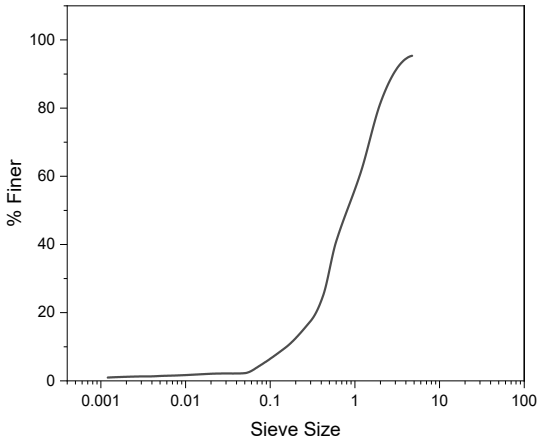

Figure 1. Particle size distribution (PSD) curve of clay soil.

For preparing the test samples, fine clay soil (passing through 600 microns) was mixed with 15% OPC (by dry weight of soil), and three different percentages of 20%, 30%, and 40% of GGBFS were used to replace OPC in the same soil-cement mixture. The soil-OPC-GGBFS mixture was thoroughly mixed for 15 minutes using a mechanical mixer. To maintain consistency and provide sufficient hydration opportunities, the water was added as 1.5 times the liquid limit of clay soil (Choudhary et al., 2023). After the mixing, the slurry sample prepared was kept for 60 minutes in a bowl to provide appropriate time for the hydration process (Buddhdev and Timani, 2021). The bowl was covered with a moisture-retaining film for this entire time to prevent any moisture loss. The different proportions of clay soil, OPC, and GGBFS taken for the testing sample preparation are shown in Table 2.

Table 2. Different proportions of the mix used for this experimental study.

Soil (g)	OPC (By weight of soil) (%)	GGBFS Replacement (By weight of OPC) (%)	Final amount (Soil+ OPC+ GGBFS) (g)
300	15%	0%	300+45
		20%	300+36+9
		30%	300+31.5+13.5
		40%	300+27+18

2.2 Testing procedure

The Amplitude Sweep Test (AST) was performed to study the response of the soil-OPC and soil-OPC-GGBFS mixture under the application of external stresses. To ascertain the rheological characteristics of the sample, Anton Paar-Modular Compact Rheometer (MCR) 102 with a 50mm diameter parallel plate measuring shaft is employed. Table 3 illustrates the configurational setup for AST with controlled shear deformation (CSD) referred from previous studies (Khaidapova et al., 2018).

Table 3. Configuration setup of conducted Amplitude Sweep Test (AST).

Parameters	Corresponding values
Plate distance	D= 2mm
Shear deformation	γ= 0.01% to 100%
Number of Measuring points	25 points
Angular frequency	0.5 Hz ($\omega = \pi$ s-1)
Duration of experiments	15 min

A small quantity of 15-20 grams of the prepared sample is carefully placed on the rheometer's fixed measuring plate. A normal force of FN = 12N was applied during the test to maintain an undisturbed quasi-elastic soil structure after lowering the top measuring plate up to the required measuring gap of 2 mm. For the given soil-OPC-GGBFS mixture, the test samples underwent six tests performed at 20-minute intervals, starting from 60 minutes post mixing process, to observe the variations of different

rheological properties like G', G" with respect to shear strain.

3 RESULTS AND DISCUSSION

3.1 G'/G" vs. shear strain

The amplitude sweep test demonstrates the relationship between various rheological properties, including the loss modulus (G"), storage modulus (G'), flow point, and yield point, as shown in Figure 2. It exhibits three distinct phases. Phase 1: In this phase, both the loss modulus (G") and storage modulus (G') are parallel, indicating the elastic behavior of the sample. This means that the material primarily stores and releases energy when subjected to deformation, and it quickly returns to its original shape once the deformation is removed. Phase 2: The point where G' and G" become equal signifies the transition from elastic to Newtonian behavior of the sample. Phase 3: The final phase indicates that the bonding between sample particles is breaking down, and the viscous characteristics start to dominate. In this phase, G" (loss modulus) has a higher value than G' (storage modulus). It represents the material's tendency to flow and deform readily, with less ability to return to its original shape after deformation.

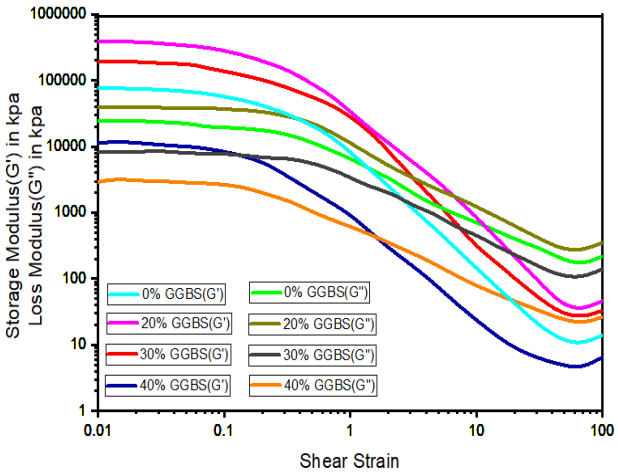

Figure 2. Amplitude sweep test data for clay soil with 15% OPC and 0%, 20%, 30%, and 40% GGBFS replacement.

As shown in Figure 2, the major focus of AST was to examine the viscoelastic behaviour of samples with 15% OPC sample with different percentages of GGBFS replacement (0%, 20%, 30%, 40%). From the results, it can be observed that when the shear strain was low, G' exceeded G" for all the samples (15C, 15%C-20%G, 15%C-30%G, and 15%C-40%G). Notably, the sample with 20% GGBFS replacement (15%C-20%G) exhibited the highest G' value among all compositions. This indicates that the 20% GGBFS replacement sample primarily stores and releases energy when subjected to deformation and returns to its original shape more quickly than the other samples. As the applied shear strain increased, G" surpassed G', and the samples began to exhibit fluid-like behavior. The point at which this transition from elastic to viscous behavior occurs, represented by the intersection of G" and G', is indicated as the flow point. In Figure 2, the order in which the flow point was reached for the compositions is as follows: 15%C < 15%C-40%G < 15%C-30%G < 15%C-20%G. It implies that the sample with 20% GGBFS replacement has the least tendency to behave like a fluid compared to the other samples, as it reached the flow point later.

3.2 Flow points

Figure 3 illustrates the relationship between flow point values with respect to varying GGBFS replacement in soil when mixed with OPC. Li et al. (2018) presented a distinct relationship between the packing density and the rheological properties. It states that, as the packing density decreases leads to the requirement of higher water content and lower workability. The angular particles in the GGBFS form a framework in the packing system and reduce the packing density of the soil sample. From Figure 3, it is evident that when 20% of GGBFS is used to replace OPC in the mixture, the material becomes fluid enough to flow (the flow point tends to increase). However, further increment in the GGBFS content increases the viscosity and reduces the flow point of the composite mixture.

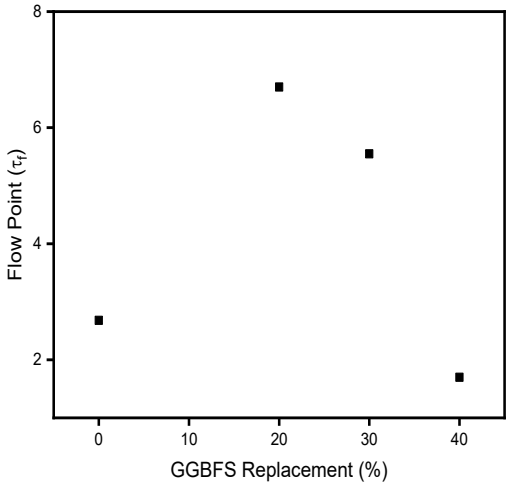

Figure 3. Variation of flow point with the addition of OPC with different GGBFS replacement ratios.

4 CONCLUSIONS

This study investigates the influence of various GGBFS ratios on the rheological parameters of clay soil blended with OPC. A set of experimental tests conducted through the Amplitude Sweep Test explores the deformation behavior. The conclusions drawn from the experimental findings are as follows:

i. It has been observed that adding GGBFS with OPC has a considerable impact on the stiffness, structural stability, and shear behaviour of re-constituted soil because the reaction happening between OPC and GGBFS makes very good bonding with soil particles.
ii. The increase in GGBFS replacement raises the flow point, loss modulus, and storage modulus, which indicates that the soil stability and strength have increased due to good soil particle interlocking.
iii. With an increase in GGBFS content, the viscosity of the Soil-OPC-GGBFS mixture also increases, which increases the flow point values. This increased viscosity has the consequence of decreasing the mixture's inclination to flow and disperse.

It is to be noted that the current study mainly focussed on the deformation behaviour of the soil-OPC-GGBFS mixture for a certain proportion. However, there are many aspects of this study, such as dynamic mechanical analysis, time-dependent deformation behaviour, optimization of GGBFS content at different moisture content, in-depth microstructural analyses, and long-term durability of GGBFS-blended soil-cement mixtures under diverse environmental conditions to better understand the impact of GGBFS on the soil-cement mixtures.

Influence of volumetric boundary conditions on the water-retention behaviour of reconstituted and intact clay shales

Influence des conditions limites volumétriques sur le comportement de rétention d'eau des schistes argileux reconstitués et intacts

ABSTRACT: Tunnelling in swellable soils is a challenging procedure with high risk of damage into the tunnel structure. To minimize the risk of damage to the tunnel support, a rigid or ductile principle of tunnel structure design are often applied to hinder or tolerate deformation in the ground upon swelling, respectively. Considering the coupled interactions between tunnel structure and the swelling rock, prediction of hydration process in swelling clay shales requires investigation of the water retention behaviour of shale under different tunnelling relevant boundary conditions. In this study, the main focus lies on the volumetric boundary conditions. For this purpose, the soil-water retention curves (SWCCs) of both intact and reconstituted Opalinus clay shale (OPA) were determined experimentally. This was carried out for each of the two materials under constant volume conditions in microcells, representing stiff tunnel lining, as well as without volumetric constraints, representing unsupported tunnels, where the intermediate states (deformation tolerant tunnel linings) can be fairly defined through interpolated. In contrast to bentonite that exhibits a noticeable influence of the volumetric boundary conditions, experiments on Opalinus indicated a rather smaller or eventually no influence in case of intact and reconstituted OPA, respectively. This phenomenon is believed to be attributed to mineralogy and fabric of samples.

RÉSUMÉ: Le creusement de tunnels dans des sols gonflants est une procédure difficile qui présente un risque élevé d'endommagement de la structure du tunnel. Pour minimiser le risque d'endommagement du support du tunnel, un principe rigide ou ductile de conception de la structure du tunnel est souvent appliqué pour entraver ou tolérer la déformation du sol en cas de gonflement, respectivement. Compte tenu des interactions couplées entre la structure du tunnel et la roche gonflante, la prédiction du processus d'hydratation dans les schistes argileux gonflants nécessite l'étude du comportement de rétention d'eau du schiste dans différentes conditions limites pertinentes pour le tunnel. Dans cette étude, l'accent est mis sur les conditions limites volumétriques. À cette fin, les courbes de rétention d'eau dans le sol (SWCC) des schistes argileux d'Opalinus (OPA) intacts et reconstitués ont été déterminées expérimentalement. Cette opération a été réalisée pour chacun des deux matériaux dans des conditions de volume constant dans des microcellules, représentant un revêtement de tunnel rigide, ainsi que sans contraintes volumétriques, représentant des tunnels non soutenus, où les états intermédiaires (revêtements de tunnel tolérants à la déformation) peuvent être assez bien définis par interpolation. Contrairement à la bentonite qui présente une influence notable des conditions limites volumétriques, les expériences sur l'Opalinus ont indiqué une influence plutôt faible, voire nulle, dans le cas de l'OPA intacte et de l'OPA reconstituée, respectivement. Ce phénomène serait attribué à la minéralogie et à la composition des échantillons.

Keywords: Swelling shale; soil-water retention behaviour; volumetric constraints.

1 INTRODUCTION

Underground construction in shales is of special interest not only because shales are considered as host rock for nuclear waste repository, but also several passageways as well as utility tunnels have been excavated in swellable clay shales. To assess the swelling evolution in shales, it is essential to properly evaluate the mechanical as well as hydraulic behaviours such as soil-water retention characteristics of the shale. However, the literature shows that the mechanical boundaries can dramatically impact the hydraulic behaviour as of Bentonite is a specific type of smectic clay. To address this phenomenon for tunnelling application, the new Belchen highway tunnel (Ziegler et al., 2022a) was chosen as the case study and the influence of tunneling-relevant boundary conditions on the SWCC of Opalinus clay shale which was the host rock in this project, was studied.

2 MATERIAL AND METHODS

This section gives a brief overview of the material studied, the sample preparation and the methods used to determine the water retention behaviour.

2.1 Material tested

Opalinus Clay (OPA) is a marine clay shale that was formed during the Jurassic period. The material consists of various types of facies, which are determined by the quantity of quartz, carbonates, and clay minerals. The studied OPA originates from the construction site of the new Belchen highway tunnel in the Jura Mountains in Northern Switzerland, which connects Basel and Lucern. Mineralogical studies revealed a composition that closely resembled the shaly facies of OPA at Mont Terri Underground Research Laboratory (Ziegler et al., 2022b).

The material was tested as intact rock, as well as in a reconstituted state as compacted powder. For the intact samples, the drilling cores were carved to a diameter of 3 cm on the lathe and then cut to a height of 8 mm using a diamond band saw. For the reconstituted samples, intact material was first ground to less than 0.25 mm grain size and then compacted to a dry density of 2.0 g/cm³.

2.2 Soil-water characteristic curve

In this study, a total of four soil-water characteristic curves (SWCCs) for intact OPA and compacted OPA powder (each 2 samples) at an initial dry density ρ_d of 2.0 g/cm^3 were determined. In each case, one sample was used for SWCC at constant volume and one for free swelling conditions. Starting point for determined SWCCs were the preserved in-situ water content and suction of the intact OPA, and the hygroscopic water content of OPA powder and its resulting suction after compaction. From this state, the samples were both saturated and dried. These two states were selected as initial states as they are relevant most of geotechnical applications. The in-situ water content and the corresponding suction of the intact material form the initial state for the practical background of this study, i.e. swelling during mechanised tunnelling. The hygroscopic water content and the corresponding suction in the compacted state of the OPA powder are in turn the starting point for all experimental hydro-mechanical tests in the main project. Initial conditions are summarized in Table 1. Two values are given for intact OPA, as the initial states differ slightly for the two different volumetric boundary conditions. To ensure constant volume conditions, samples were installed in microcells as proposed by Seiphoori et al. (2014).

Since the vapor equilibrium technique (Delage et al. (1998), VET) is appropriate to use in combination with microcells, this experimental method was used in this study to determine SWCCs. By doing so, the suction range between 3 and 350 MPa was covered.

Samples for constant volume conditions were prepared according to Section 2.2. For free swelling conditions, compacts of powder or shards of intact OPA were directly stored in small plastic containers in desiccators. These desiccators contain oversaturated salt solutions in order to expose the samples to a defined suction. Nevertheless, the final suction of the samples was measured with a chilled mirror hygrometer (CMH). The void ratio needed to determine the degree of saturation (S_r) for the free swelling SWCC was determined via immersion weighing in paraffin oil (Christ et al., 2022). Experimental data was fitted with the van Genuchten equation (van Genuchten (1980), Equation 1):

$$\theta = \theta_r + \frac{\theta_s - \theta_r}{[1+(\alpha\psi)^n]^m} \quad (1)$$

where Θ is the volumetric water content, Θ_r the residual volumetric water content, Θ_s the saturated volumetric water content, m, n, α are soil/fitting parameters and ψ the total suction.

The air-entry value (AEV) was determined according to the commonly used graphical construction method (Pasha et al., 2016), where the AEV is defined as the intersection of the tangent through the inflection point of the SWCC and the horizontal line of S_r=1. Here, this exact value was explicitly calculated corresponding to Soltani et al. (2021) via the first and second derivatives.

Table 1. Initial parameters of intact and reconstituted samples.

		Intact	Reconstituted
ψ_{init}	[MPa]	60-65	68
S_r	[%]	63-67	18

Another method to obtain information about the water retention behaviour of a soil is to derive it from the pore size distribution using MIP. The method associates the mercury intrusion with the drying path of a SWCC by considering the mercury intrusion at a given pressure p to be the same as the air intrusion at a matric suction ψ_m (Ferrari and Romero, 2019).

3 RESULTS AND DISCUSSION

Soil water characteristic curves (SWCCs) of compacted OPA powder and intact OPA for free swelling and volume constant conditions are shown in

Figures 1 and 2, respectively. Fitting curves were obtained by the least square method using the van Genuchten equation (Eq. 1), leaving out residual and saturated volumetric water contents or rather degrees of saturation. Fitting parameters are summarised in Table 2. It should be noted that these are not classic SWCCs, where a material is installed as a slurry and then dried (initial drying), rehydrated (main wetting) and dried again (main drying). The focus of the SWCCs in this study is on the initial state, which results from the in-situ state (intact material) or the initial state of all experimental tests in this study (powder).

Table 2. Van Genuchten fitting parameters and AEV of determined SWCCs in this study.

		Reconstituted		**Intact**
		free	VC	combined
n	[-]	1.503	1.558	2.132
m	[-]	0.335	0.358	0.452
α	[1/MPa]	0.290	0.211	0.019
ψ_{AEV}	[MPa]	1.49	2.07	26.34

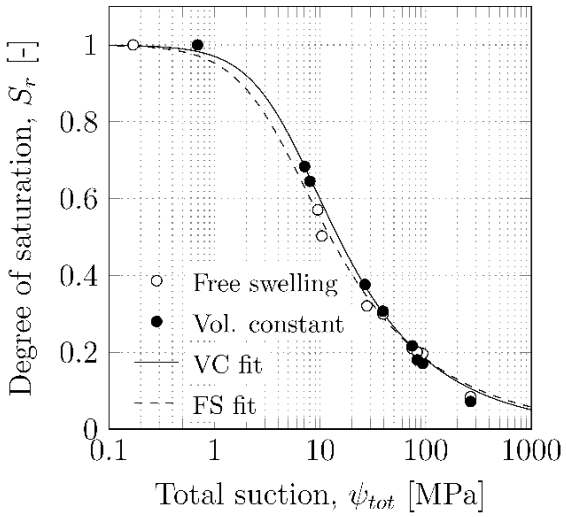

Figure 1. Soil-water characteristic curves of reconstituted OPA – experimental data and van Genuchten fit.

The derivation of the matric suction—saturation relationship should be limited to the low-suction range, in which capillarity dominates the water retention properties (Romero et al., 1999).

For OPA powder, the initial state corresponds to a suction of 68 MPa at a degree of saturation of 18%. A minor difference between volume constant and free swelling boundary conditions can be observed in the wetting branch. No difference can be seen in the drying branch, which is due to the fact that the applied volumetric boundary conditions are irrelevant for drying and the associated potential shrinkage of the sample. Microcells for the preservation of volume-constant boundary conditions were introduced in Seiphoori et al. (2014) as part of investigations into the water retention behaviour of compacted bentonite in the context of radioactive disposal.

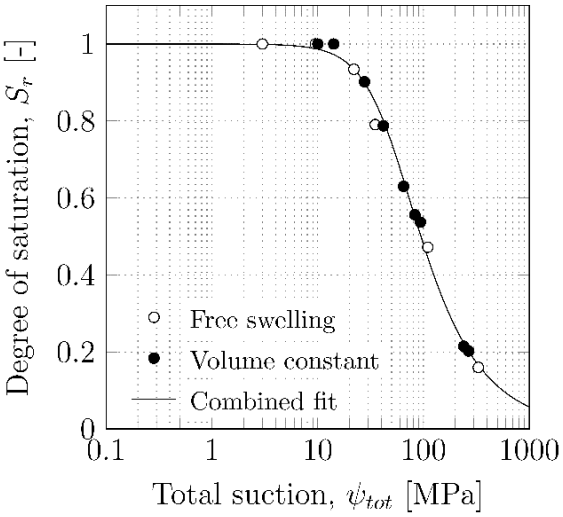

Figure 2. Soil-water characteristic curve of intact OPA – experimental data and van Genuchten fit.

In this study, a more evident influence of the volumetric boundary conditions on water absorption during hydration was observed. It was argued that further hydration is inhibited by the prevention of continued subdivision of the clay particles by the constant-volume boundary conditions, which in turn prevents further water absorption on and between the clay particles. In the present study, the SWCC of compacted OPA powder at constant volume boundary conditions shows a slightly higher degree of saturation at the same total suction than the SWCC without volumetric constraints. A look at the underlying data shows that this difference is due to the prevented expansion of the material. The water content is almost the same in both cases at the same total suction. With free swelling, however, the void ratio increases steadily as total suction decreases, whereas it remains the same for the constant-volume SWCC. The fact that the influences of the volumetric boundary conditions are not as pronounced in this case as in the study by Seiphoori et al. (2014) can be attributed to the mineralogy of the two materials analysed. While Seiphoori et al. (2014) investigated MX-80 bentonite, which has a smectite content of 85%, OPA consists of only 11-16% illite/smectite mixed layer minerals. Smectites are the clay minerals with the highest water absorption capacity. As a result, MX-80 has a significantly higher swelling capacity and therefore reacts more sensitive to restrictions in volumetric swelling. In view of the fact that the different volumetric boundary conditions for determining the SWCC were taken into account in order to consider the tunnelling relevant volumetric boundary conditions of

rigid lining, *no lining* and *deformation-tolerant lining*, it can be concluded that a combined SWCC is sufficiently accurate given the minor deviations observed.

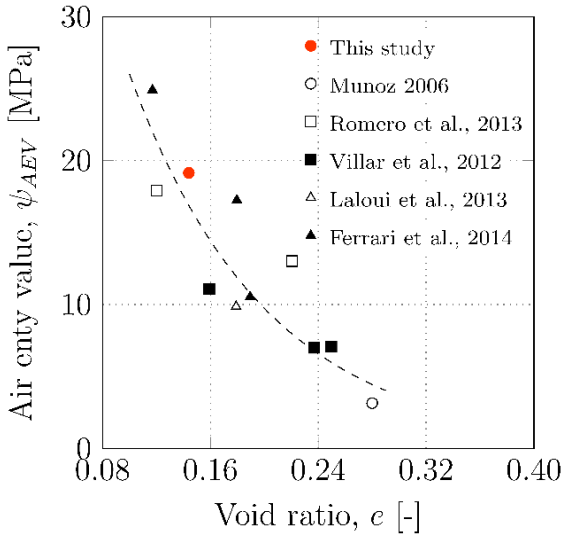

Figure 3. Air-entry value over void ratio from Ferrari et al. (2014) complemented with data from this study.

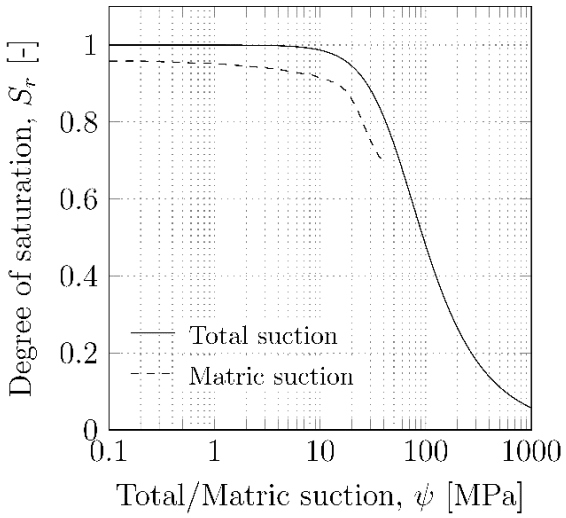

Figure 4. Separate consideration of matric and total suction in the context of the SWCC of intact OPA.

The initial state of intact OPA samples was at a total suction ψ_{tot} between 60 and 65 MPa and corresponding degrees of saturation between 63 and 67%. Experimental data of the SWCCs in Figure 2 show no difference for both volumetric boundary conditions considered. The points all appear to lie on the same scanning curve. Thus, no distinction was made in the fitting between the two different boundary conditions and all points were merged to derive a single combined parameter set. The fact that there is no recognisable difference between free and constant-volume swelling for the intact OPA in the SWCC can be attributed to a further point in addition to the influence of mineralogy already mentioned above. Diagenesis and the resulting structure play the decisive role here. As shown in Christ et al. (2023), the structure of the intact material acts as an additional attractive force and further reduces the swelling capacity. As OPA is ground, the swelling pressure and the water uptake capacity according to Enslin-Neff increase significantly. Both increase more with increasing grinding fineness. Due to the once again lower swelling capacity of the intact OPA compared to the OPA powder, the volumetric boundary conditions no longer play a significant role in the determination of the SWCC. An influence can no longer be identified from the data.

Air-entry values (AEVs) determined according to Equ. 1 are also summarised in Table 2. From a physical point of view, the AEVs are not actual air entry values, as they were determined using the wetting path and not the drying path. Nevertheless, they are considered here as characteristical values of a SWCC. It is noticeable that the AEV of the intact material is more than ten times the AEV of the powder. The magnitude of AEVs depend on different factors, like the density, grain size-distribution or aggregation (Nishimura et al., 2012), and thus factors that influence the size of the pore diameters. The smaller the pore diameter, the greater the suction required for air to penetrate into the pore space and thus to bring the sample into an unsaturated state. Due to the higher dry density of the intact material (ρ_d=2.3 g/cm³) compared to the compacted powder (ρ_d=2.0 g/cm³), the observed difference is plausible. This is also confirmed by the pore-size distribution of the two materials. The peak of the pores and thus the most common pore diameter is 300 nm for the powder, whereas it is only 10 nm for the intact OPA. Ferrari et al. (2014) summarised data from various studies on the water retention behaviour of intact OPA. The yielded exponential fit is plotted with available data from the literature in Figure 3. The AEV from this study shows very good agreement with the data and the corresponding exponential fit. Note: The value in Figure 3 from this study differs from the value in Table 2 because it is based on the definition of the AEV in Ferrari et al. (2014). There, the AEV is the suction that correlates to a degree of saturation of 95% in the SWCC. As mentioned before, the SWCC can also be derived from the MIP data. Thereby, pressure that must be applied to penetrate mercury into the pores of the sample is converted to a matric suction. Figure 4 shows both SWCCs for the intact material, the van Genuchten fit of the total suction and MIP data of the matric suction. The two curves fit together very well. The bend in the two courses runs almost parallel. Due to the upper limit of the MIP, the SWCC of the matric suction ends at approx. 40 MPa.

The difference between the two curves is due to the osmotic suction of the sample or rather the pore fluid. Ferrari et al. (2014) showed with a separate determination of the osmotic suction of OPA with the contact and non-contact filter paper method that this matches quantitatively well. In the current study, the proportion of osmotic suction decreases slightly as the degree of saturation increases, from 18.8 MPa at S_r=75% over 16.8 MPa at S_r=80% and 14.2 MPa at S_r =85% to 13.5 MPa at S_r =90%. This is attributable to the fact that the sample is saturated via the vapour phase, which lowers the ion concentration in the pore fluid and. thus the osmotic suction.

4 CONCLUSIONS

In this study, the soil water retention behaviour of intact and powder compacted Opalinus clay has been assessed in free and constrained volume conditions. The experimental results indicated no significant influence of volumetric boundary conditions on the SWCC of OPA. The air-entry value obtained form current experiments was found to be consistent with other measurements in the literature. Finally, the MIP-driven SWCC of the matric suction showed the same trend as the SWCC of total suction.

ABSTRACT: Prediction and control of ground-borne noise and vibrations are amongst the largest environmental challenges for railway exploitation in urban areas. Empirical methods based on attenuation curves, similar to those presented by the Federal Transit Administration (FTA) and the Federal Railroad Administration (FRA), could be extremely versatile for a first estimative of the vibration levels at the ground surface. Despite the value of the presented curves, these have a generalist character, not allowing to attend to the particular and specific scenarios. Furthermore, both railway technology and construction techniques adopted in other regions of the world are quite distinct from USA reality giving rise to poor predictions when applied in distinct contexts. In this way, advanced numerical modelling is a reliable alternative, allowing incorporation of the geological and geotechnical profile, type and geometric configuration of the railway track and railway vehicle specific to each case under study and, therefore, achieving a more elaborate level of detail in the analysis. On this work, a 2.5D FEM-PML (Finite Element Method – Perfectly Matched Layer) numerical approach is used to compute the ground surface vibration curves for different scenarios. From the results obtained, it is possible to state that, even being a conservative approach in some of the scenarios under consideration, the application of the empirical methodology proposed by FTA/FRA should be considered only as a first indicator, and it is recommended that more detailed analyses be performed in situations that require a higher control of the permitted vibration levels.

RÉSUMÉ: La prévision et le contrôle du bruit et des vibrations transmis au sol constituent l'un des plus grands défis environnementaux de l'exploitation ferroviaire en zone urbaine. Des méthodes empiriques basées sur des courbes d'atténuation, similaires à celles présentées par la *Federal Transit Administration* (FTA) et par la *Federal Railroad Administration* (FRA) pourraient être extrêmement polyvalentes pour une première estimation des niveaux de vibration à la surface du sol. Malgré la valeur des courbes présentées, celles-ci ont un caractère généraliste, ne permettant pas de s'intéresser à des scénarios particuliers et spécifiques. En outre, la technologie ferroviaire et les techniques de construction adoptées dans d'autres régions du monde sont assez différentes de la réalité américaine, ce qui donne lieu à prévisions inadéquates lorsqu'elles sont appliquées dans des contextes distincts. De cette manière, la modélisation numérique avancée constitue une alternative fiable, permettant d'incorporer le profil géologique et géotechnique, le type et la configuration géométrique de la voie ferrée et du véhicule ferroviaire spécifique à chaque cas étudié et, par conséquent, d'atteindre un niveau de détail plus élaboré dans l'analyse. Dans ce travail, une approche numérique 2,5D FEM-PML (*Finite Element Method – Perfectly Matched Layer*) est utilisée pour calculer les courbes d'atténuation des vibrations pour différents scénarios. À partir des résultats obtenus, il est possible d'affirmer que, même s'il s'agit d'une approche conservatrice dans certains des scénarios considérés, l'application de la méthodologie empirique proposée par FTA/FRA doit être considérée uniquement comme un premier indicateur, étant recommandé d'effectuer davantage analyses détaillées dans des situations qui nécessitent un contrôle plus élevé des niveaux de vibration autorisés.

Keywords: Railway traffic; vibrations; numerical modelling; attenuation curves.

1 INTRODUCTION

Based on experimental data, the Federal Transit Administration (FTA) and the Federal Railroad Administration (FRA) proposed a general vibration assessment method. The main principle of such methodology consists in the evaluation of vibration attenuation curves, defined through the maximum value of the running RMS (root-mean-square) of the vertical velocity as a function of the distance to the railway infrastructure, which are subsequently corrected to meet the presence of buildings and taking into account their specificity (Quagliata, 2018) (Hanson et al., 2012).

The ground surface vibration curves were derived from the statistical treatment of experimental results. The consideration of such curves to specific scenarios should be adapted employing adjustment factors, also of an empirical nature. These are given as single values to add to the base level preconized by the reference curves.

Despite the value of the presented curves, and as can be understood, the empirical curves reported have a generalist character, not allowing to attend to the particular and specific scenarios, as discussed in Sadeghi et al. (2019). In this way, advanced numerical modelling is a reliable alternative, allowing incorporate the geological and geotechnical profile, type and geometric configuration of the railway track and railway vehicle specific to each case under study and, therefore, achieving a more elaborate level of detail in the analysis.

2 NUMERICAL MODEL

Alternatively, to the solutions reported previously, ground surface vibration curves can be evaluated through advanced numerical modelling, being subsequently corrected to meet the dynamics of the existing buildings in the vicinity of the railway infrastructure. For this purpose, a validated numerical approach is used to model the train-track-(tunnel)-ground system (Lopes et al., 2016).

This approach corresponds to a sub-structured methodology, where the modelling domain is divided into a 'stationary' component, composed by the track-(tunnel)-ground system, and a 'moving' component (train), where a 2D vehicle model is adopted and only vertical excitation is considered. The interaction between both is established by coupling the vehicle contact points with the remaining system. The basic formulation of the interaction scheme is summarised in Figure 1.

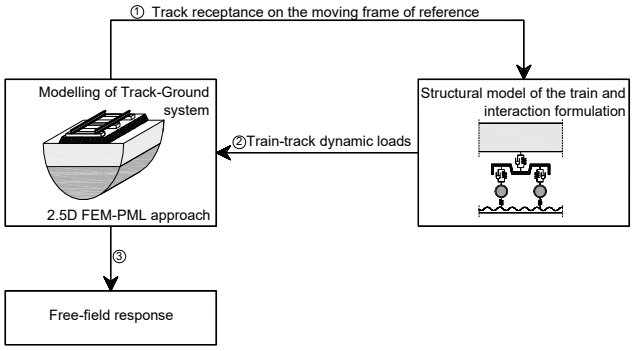

Figure 1. Representative scheme of the numerical modelling approach.

In terms of the track-(tunnel)-ground simulation, a 2.5D FEM-PML model is used. This formulation assumes a linear elastic behaviour of the different components and an infinite structure and invariable properties (geometrical and mechanical) in the direction of development of the track. Assuming these conditions, the three-dimensional solution of the problem is found through a 2.5D procedure based on the finite elements approach, where the analysis are carried out in the wavenumber/frequency domain. For its application, all the variables, i.e., loads (action) and displacements (response), are transformed to the wavenumber/frequency domain by means of a double Fourier transform, associated with the direction along the track and with time. Transformed quantities are functions of the Fourier images of x (longitudinal coordinate) and t (time), defined as wavenumber (k1) and frequency (ω). Moreover, a topic of particular relevance is the formulation of special procedures to treat the boundary effects inherent to the truncation of the domain associated with the finite element discretization. In order to avoid this spurious reflection of waves, a 2.5D PML approach is adopted. Full details about the mathematical formulation of the 2.5D FEM-PML model can be found in Lopes et al. (2014).

From this numerical approach, it is possible to compute vibration levels along the surface of the ground that are used to define the ground surface vibration curves.

3 PARAMETRIC STUDIES

3.1 General description

The numerical investigations in this study are based on the geometric and geomechanical properties illustrated in Figure 2. As can be seen, the scenario of analysis corresponds to a slab track in a tunnel.

To decrease computational effort, symmetry was used to reduce the modelling domain to half of its dimensions.

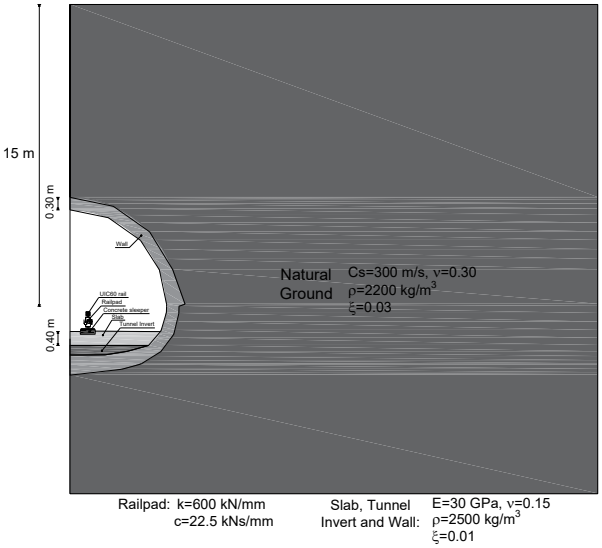

Figure 2. Geometry and properties of the track-tunnel-ground system.

Regarding rolling stock, the passage of the Alfa-Pendular vehicle is considered. The geometric properties and weight per axle can be found in dos Santos et al. (2016).

The train-track interaction is essential in problems involving the generation of vibrations. In the present work, the dynamic interaction mechanism is provided by the rail unevenness and the synthetic unevenness profile is generated according to the FRA proposal (Hanson et al., 2012).

The parametric studies consider two different train speeds (100 km/h and 200 km/h) and two different rail unevenness classes. At this respect, a distinction is made between the curves evaluated for a track in perfect conditions (Class 6 of the FRA classification) and a track in a not so good condition (according to Class 3 in the FRA classification).

3.2 Results and discussion

As initially stated, the numerical model 2.5D FEM-PML is applied for the prediction of vibration levels at the ground surface. In this way, Figure 3 presents the vertical vibration velocity for an observation point located at the ground surface, on the symmetry plane and considering the following variables: train speed equal to 200 km/h and maintenance Class 3. The ground surface vibration curves are defined through the maximum value of the running RMS (red line in Figure 3) of the vertical velocity as a function of the distance to the track.

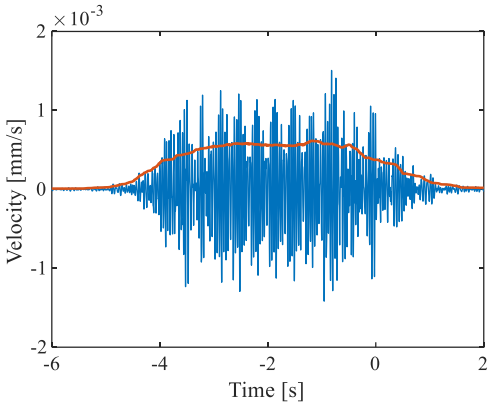

Figure 3. Vertical vibration velocity for an observation point located at the ground surface, on the symmetry plane.

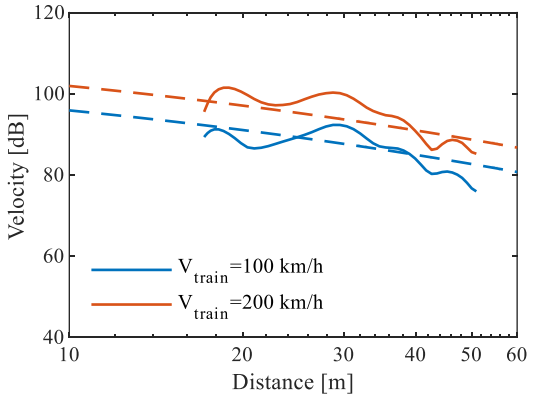
Figure 4 presents the comparison between the vibration attenuation curves evaluated through the numerical approach and the attenuation curves proposed by FTA for the different scenarios under analysis.

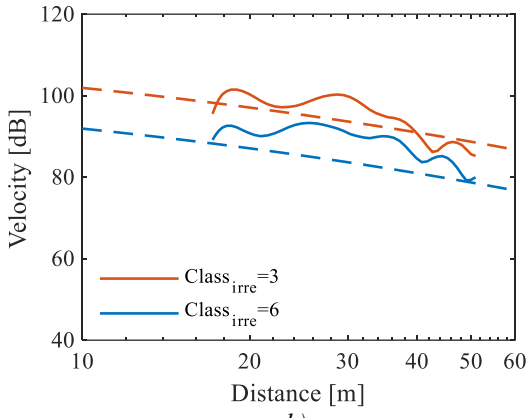
The FTA curves correspond to those defined for Rapid Transit and Light Rail Vehicles and it was assumed two adjustment factors: i) speed factor ($20\log(\text{speed}/\text{speed}_{ref})$, speed_{ref}=50 mph); ii) track quality factor (0 dB for Class 6; +10 dB for Class 3).

As can be seen from Figure 4, and as expected, the vibration levels increase with the train speed and the degradation of the track quality. These general trends are also verified from FTA proposal through the adjustment factors adopted.

A comparison between numerical and empirical results allows to identify, for the conditions admitted, maximum deviations around 8 dB, indicating a significant difference. For some cases, the FTA curves underestimate the vibrations levels.



a)



b)

Figure 4. Ground surface vibration curves (dB ref. 10^{-8} m/s): a) influence of the train speed; b) influence of the track condition (solid line – numerical result; dash line: FTA proposal).

4 CONCLUSIONS

Based on the results obtained from the parametric studies conducted, it can be concluded that the application of the empirical methodology proposed by FTA should be regarded as an initial indicator. It is advisable to perform more detailed analyses in situations that require stricter control of allowed vibration levels.

ABSTRACT: The prediction of local (i.e., site-specific) undrained shear strength from soil properties (e.g., water content, Plasticity index, Liquid Limit) is a cost-effective solution to preliminary assess the proper foundation type at a project site. Nevertheless, the local dataset is often incomplete and sparse to infer robust prediction of local strength parameters. To bypass such inconvenience, global or soil-type correlations might be employed to predict undrained shear strength from local soil properties measurements. However, by doing so two main drawbacks can arise: a great uncertainty is introduced for prediction of undrained shear strength due to the large number of soil types the global database is usually composed. Secondly, a problem of pertinence might arise when soil type-specific correlations are employed. In this study the local predictions of undrained shear strength are estimated integrating clustered global information through a Bayesian formulation, which allow to assess the problem of local dataset incompleteness. The methodology is shown by making use of an already compiled and published database.

RÉSUMÉ: La prédiction de la résistance au cisaillement non drainée locale (c'est-à-dire spécifique au site) à partir des propriétés du sol (par exemple, la teneur en eau, l'indice de plasticité, la limite de liquidité) est une solution rentable pour évaluer préliminairement le type de fondation approprié sur un site de projet. Néanmoins, l'ensemble de données locales est souvent incomplet et clairsemé pour déduire une prédiction robuste des paramètres de résistance locaux. Pour éviter de tels inconvénients, des corrélations globales ou par type de sol pourraient être utilisées pour prédire la résistance au cisaillement non drainé à partir de mesures locales des propriétés du sol. Cependant, ce faisant, deux inconvénients principaux peuvent survenir: premièrement, une grande incertitude est introduite pour la prévision de la résistance au cisaillement non drainé en raison du grand nombre de types de sols qui composent habituellement la base de données mondiale. Deuxièmement, un problème de pertinence pourrait surgir lorsque des corrélations spécifiques au type de sol sont utilisées. Dans cette étude, les prédictions locales de la résistance au cisaillement non drainé sont estimées en intégrant des informations globales groupées via une formulation bayésienne, ce qui permet d'évaluer le problème de l'incomplétude des ensembles de données locaux. La méthodologie est présentée en utilisant une base de données déjà compilée et publiée.

Keywords: Undrained shear strength; local dataset; global dataset; Bayesian; cluster-based.

1 INTRODUCTION

At a project site local (i.e., site-specific) geotechnical data are often incomplete and sparse. A typical scenario is the one where the amount of soil properties and Atterberg limits measurements exceed the number of undrained shear strength observations. It is then common practice to compute a weighted average of undrained shear strength measurements with direct and indirect estimates of it. However, the indirect estimates of undrained shear strength might carry large systematic uncertainties when global correlation are used (Collico and Arroyo, 2023; Ching and Phoon, 2019). On the other hand, when soil type-specific correlations are applied a problem of pertinence might arise. To assess such issues, Bayesian methodologies

have been proposed to assess and reduce systematic uncertainties by sequentially updating local information with global and regional measurements (Zhang et al., 2004; Wang and Cao, 2013; Wang et al. 2010). Despite being efficient, these approaches would require the complete set of independent variables to first construct and further validate correlations.

More recently Ching and Phoon (2019) and Wu et al. (2022) developed an efficient and elegant hybrid Bayesian methodology to assess uncertainty of local data and account for global geotechnical information. In this context, it might be pertinent to wonder whether global information or filtered ones according to some criterion should be considered for local undrained shear strength updating. This seems particularly relevant when incomplete and scarce information are available at the project site. A first approach would be to filter global information according to the same soil-types identified at the project site. Nevertheless, by filtering the database according to the same textural soil classification might not represent an optimal criterion. If a soil type classification problem based on some in-situ test is considered, it is thought that the geological textural classification might not be an exhaustive indicator of soil (Collico et al., 2023).

As alternative to filtering, unsupervised data-driven approaches, such as cluster-based solutions can be applied. In particular, cluster-based solution appropriately calibrated by engineers' interpretation and experience might provide an efficient way of data subdivision to allocate soil-similarity (Collico et al. 2024). Aware of that, in this study, the hybrid workflow proposed by Ching and Phoon (2019) is developed and extended to account for global cluster-based information and allocate data site similar for local undrained shear strength updating. The approach is demonstrated making use of already compiled and published databases such as CLAY/10/7490 (Ching et al., 2014) and S-CLAY/7/168 (D'Ignazio et al., 2016).

2 GLOBAL DATABASE DESCRIPTION

Let denoted as Y_g datapoints from global database here represenetd by four geotechnical parameters such as that: Y_g = [Y_{g1}=LL; Y_{g2}=PL; Y_{g3}=PI; Y_{g4}= w; Y_{g5}=Su/σ'_{v0}], with LL=liquid Limit, PL=Plastic Limit, PI=plasticity Index, w=water content and Su/σ'_{v0}=normalized undrained shear strength.

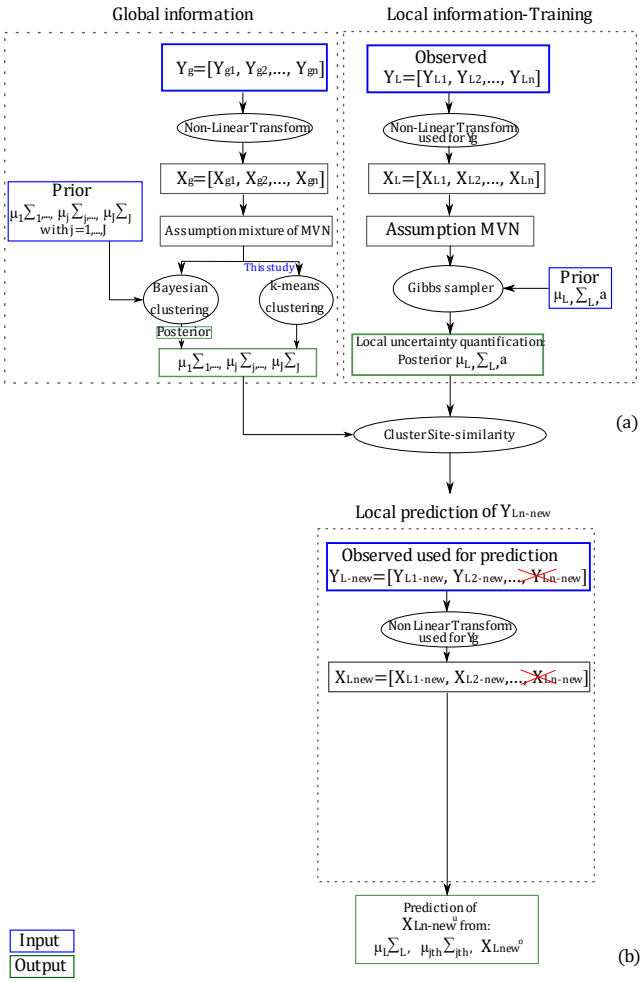

Figure 1. Workflow of methodology employed in this study.

2.1 Probabilistic model for Global information

The proposed method requires the definition of a global (i.e., no-local) multivariate Probability Density Function (PDF). Such no-local PDF is of mainly importance when scarce and incomplete X_L information is available at a project site.

To construct a valid multivariate normal distribution, the variables Y_g (non-normal distributed) (Figure 1) needs to be transformed into normally distributed ones X_g. This is accomplished through a non-linear transform (see Ching and Phoon, 2014). It is then assumed a linear dependence among X_g variables such that their probability density can be described by a $n-th$ dimensional Gaussian Mixture Model which reads:

$$f(X_g|\Theta) = \sum_{j=1}^{J} \pi_j f(X_g|\mu_j, \sum_j) \qquad (1)$$

with $f(X_g|\mu_j, \sum_j)$ denoting the j-th multivariate normal component (i.e., j-th cluster) with mean μ_j, covariance $\sum_j$ and weight π_j. J is the number of Gaussian mixture components and Θ vector containing

all Gaussian Mixture parameters (i.e., means, Covariances and weights). For J=1 eq. (1) recovers the definition of multivariate normal distribution. In this study the global datapoints are modelled by eq. (1) through the k-Means algorithm. Nevertheless, a Bayesian Mixture formulation could be also applied instead of eq. (1) allowing to infer prior knowledge about clusters depending on local dataset information.

2.2 Probabilistic model for Local dataset

Let consider the local dataset reported in Table 1 for a the Norwegian site of Drammen (D'Ignazio et al., 2016) as example. Table 1 represents an optimistic scenario at a project-site. A more realistic situation is the one where 60% of datapoints in Table 1 are missing. Let denote as X_{L^u} the missing entries and as X_{L^o} the observed datapoints of X_L. In such a case, great uncertainty would characterize local PDF parameters, making Bayesian inference necessary.

To construct a valid local PDF, the datapoints Y_L are transformed into X_L by considering the same non-linear transform coefficients employed for Y_g (Figure 1a). After transformation, the local datapoints X_L are assumed to be distributed according to a multivariate normal distribution as:

$$f(X_L|\mu_L, \sum_L) = mvn(X_L|\mu_L, \sum_L) \quad (2)$$

with $\mu_L, \sum_L$ mean and covariance matrix of local PDF.

2.3 Bayesian formulation for incomplete datasets

To assess the local data incompleteness the Bayesian formulation proposed by Ching and Phoon, (2019) is employed. We here recall only the main steps of the methodology.

As a first step, the prior knowledge of the unknown random variables has to be defined (Figure 1a). Therefore, the prior knowledge of μ_L, $\sum_L$ and hyperparameters a for $\sum_L$ parametrization, need to be elicited. Having denote as $f(\mu_L)$ and $f(\sum_L)$ the prior density distribution of μ_L and $\sum_L$, their conjugate form is assumed since enable exact sampling. The prior knowledge of μ_L is taken as a normal multivariate distribution, while $\sum_L$ is modelled as the inverse Wishart distribution such as:

$$f(\mu_L) = mvn\,(\mu_L|\mu_0, C_0) \quad (3)$$

$$f(\sum_L) = IW\,(\sum_L|\sum_0, v) \quad (4)$$

Table 1. Local observation for a Norway Site (Drammen).

The mean μ_0 is taken as zero mean vector of $nx1$ dimension, while the prior covariance matrix C_0 (nxn) is taken to be a diagonal matrix with very large diagonal elements (i.e., 104), such that $f(\mu_L)$ tend to be uninformative. Concerning $f(\sum_L)$ the inverse-Wishart distribution is assumed with scale matrix $\sum_0$ and degree of freedom $v = n + 1$. To make $f(\sum_L)$ noninformative a heirarchical form can be applied (Huang and Wand 2013; Ching and Phoon 2019):

$$f(\sum_L|a) = IW\,(\sum_L|\sum_0, v) \quad (5)$$

$$f(a_i) = IG(a_i|\alpha, \beta) \quad (6)$$

where $(a = [a_1, \ldots, a_n])$ are the random hyperparameters required for $\sum_L$ parametrization. The prior of each hyperparameters $f(a_i)$ is assumed an inverse gamma distribution with scale and shape parameters α, β. In this study α, β are taken as 0.5 and 10^{-4} respectively such that a non-informative linear dependence and variance is assumed (Wu et al., 2022).

2.4 Local posterior inference

The Posterior inference of the local unknown random variables (μ_L, $\sum_L, a$) is derived through the Gibbs sampler (GS) (Geman and Geman, 1984), which decompose the unknown random parameters into groups to randomly sample each group conditional on the remaining ones. This allows to sequentially draw T times the unknown random variables, to final generate (T-t_b) random samples of μ_L, $\sum_L$ and a, which are asymptotically distributed as the target posterior distribution. t_b is defined as burning period (i.e., the

number of generated samples to be discard for posterior inference). It worth noticing that, when missing information characterize the local dataset, by partitioning local mean and covariance matrix accordingly, the Bayesian formulation allow to draw T samples of missing datapoints X_{L^u} conditional to the observed X_{L^o} ones (see Ching and Phoon, 2019 and Wu et al., 2022).

2.5 Local prediction integrating cluster-based information

When the local training dataset is scarce and incomplete, the statistical uncertainty of local PDF parameters $(\mu_L, \sum_L, a, X_{L^u})$ can be significant, propagating into local soil parameters prediction, here denoted as X_{L-new}. In this case, it is reasonable to rely on global information, which are statistically more robust. Nevertheless, global databases might be composed of too different soil-types leading to a too generic prediction of local soil parameters. In this context, the clustering approach previously described in section 2.2 might come in help since enable to filter global information "similar" to the local site of interest. The data similarity between each t-th local samples, generated during the Gibbs sampler, and the j-th global cluster is quantified as follows:

$$p(\mu_{L,t}|\mu_{gj}, \sum_{gj}) = \frac{\pi_j f(\mu_{L,t}|\mu_{gj}, \sum_{gj})}{\sum_{j=1}^{J} \pi_j f(\mu_{L,t}|\mu_{gj}, \sum_{gj})} \quad (7)$$

with:

$$f(\mu_{L,t}|\mu_{gj}, \sum_{gj}) = \left|\sum_{gj}\right|^{-1/2} \cdot (2\pi)^{-n/2} \cdot \exp\left(\left[-0.5(\mu_L - \mu_{gj})^T \sum_{gj}^{-1} (\mu_L - \mu_{gj})\right]\right. \quad (8)$$

and π_j weigth of the j-th Gaussian mixture component.

Once site similarity of the t-th sample is assessed, prediction of X_{L-new} can be inferred according to the hybrid method proposed by Ching and Phoon (2019) as:

$$f(X_{L-new-t}|hb) = f\left(X_{L-new}|\mu_{gj}, \sum_{gj}\right) \cdot f(X_{L-new}|\mu_L, \sum_L) \quad (8a)$$

$$f(X_{L-new-t}|hb) = \sum_{t=tb+1}^{T} w_t \cdot f\left(X_{L-new-t}|\mu_{hb,t}, \sum_{hb,t}\right) \quad (8b)$$

with $\mu_{gj}, \sum_{gj}$, mean and covariance matrix of the most similar j-th global cluster, $\mu_{hb,t}, \sum_{hb,t}$ mean and covariance matrix of the hybrid multivariate distribution given by product of $f(X_{L-new}|\mu_{gj}, \sum_{gj})$ and $f(X_{L-new}|\mu_L, \sum_L)$ and w_t is the weight of each condition density distribution $f(X_{L-new-t}|hb)$.

3 CASE STUDY

To capture the benefit of cluster-based information on local prediction, the Norway site, Drammen (Table 1), extracted from D'Ignazio et al. (2016) is considered. The local dataset is subdivided into training (to derive posterior estimated of local PDF parameters) and testing. Four case scenarios are exploited:

- Only 40% of datapoints of Table 1 is considered available for training, while the remaining 60% is considered missing. We denote such scenario as Incomplete case;
- All the datapoints of Table 1 are considered for training. Such case is denotated as Complete scenario.
- For both Complete and Incomplete scenarios, global information employed in eq. (8) is subdivided in one (no-cluster scenario) and two clusters (cluster-based scenario) for a total of four different cases (i.e., Incomplete no-cluster, Incomplete cluster-based, Complete no-cluster, Complete cluster-based). It is worth noticing that for illustration purposed optimal data subdivision (criterion such as BIC) is not considered.

For local X_{L-new} prediction, we will assume that all information (LL, PL, PI, $w = Y_{L-new^o}$) will be available except for Su/σ'_{v0}, which is here taken as variable of interest to be predicted (i.e., $Su/\sigma'_{v0} = Y_{L-new^u}$).

4 RESULTS

As a first step both local and global datapoints are transformed from Y into X domain (Figure 2a and Figure 2b). As a second step global information are subdivided according to the number of clusters selected (i.e., one and two in this study). The k-means algorithm is used as illustrative example. Figure 2c reports the global database subdivision re-transformed in the original Y space when two clusters are selected.

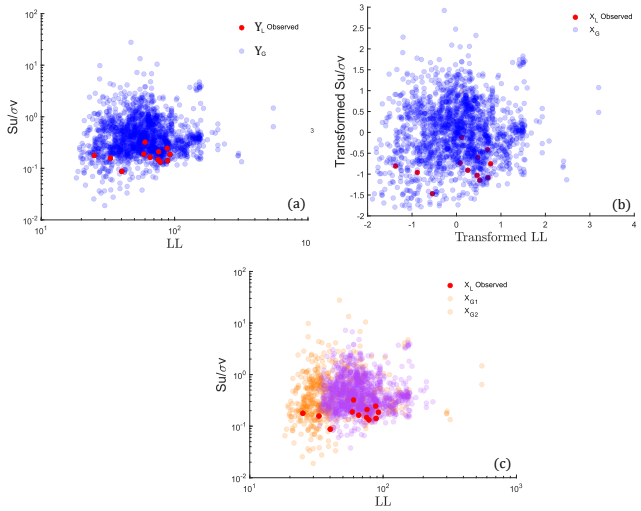

Figure 2. Global and local Normalised undrained shear strength and Liquid Limit datapoints: a) in the original Y space. b) in the X space. c) subdivided according to two clusters after k-NN algorithm.

As a third step the Gibbs sampler is run to compute posterior estimates of local PDF parameters (μ_L, $\sum_L$, a) and (μ_L, $\sum_L$, a, $X_L{}^u$) for the Complete and Incomplete case scenarios respectively. These posterior estimates are then employed to further generate X_{L-new} to be converted into the original Y space. It is worth noticing that at this stage no testing datapoints have been used. The generated samples X_{L-new} would then represent soil parameter prediction if no additional information at the site is acquired.

As an example, Figure 3 reports the generated (T-t_b) samples of local undrained shear strength and LL according to the four scenarios considered. It can be observed that by considering the Complete scenario, no major difference subsists between generated samples of no-cluster (Figure 3a) and cluster-based (Figure 3b) cases. This does not come as surprise since a not clean separation among clusters subsists. When 40% of datapoints are considered for training (Incomplete scenario), generated samples start to converge to global datapoints scatter independently whether one or two cluster are considered (Figure 3c, Figure 3d respectively).

When additional local information becomes available (i.e., testing datapoints), the local undrained shear strength $Y_{L-new}{}^u$ can then be predicted from the observed testing datapoints $Y_{L-new}{}^o$ and trained PDF parameters μ_L, $\sum_L$, a, for the four scenarios. It can be observed that when the training is performed using the complete local dataset a better prediction of undrained shear strength in terms of accuracy and precision is obtained.

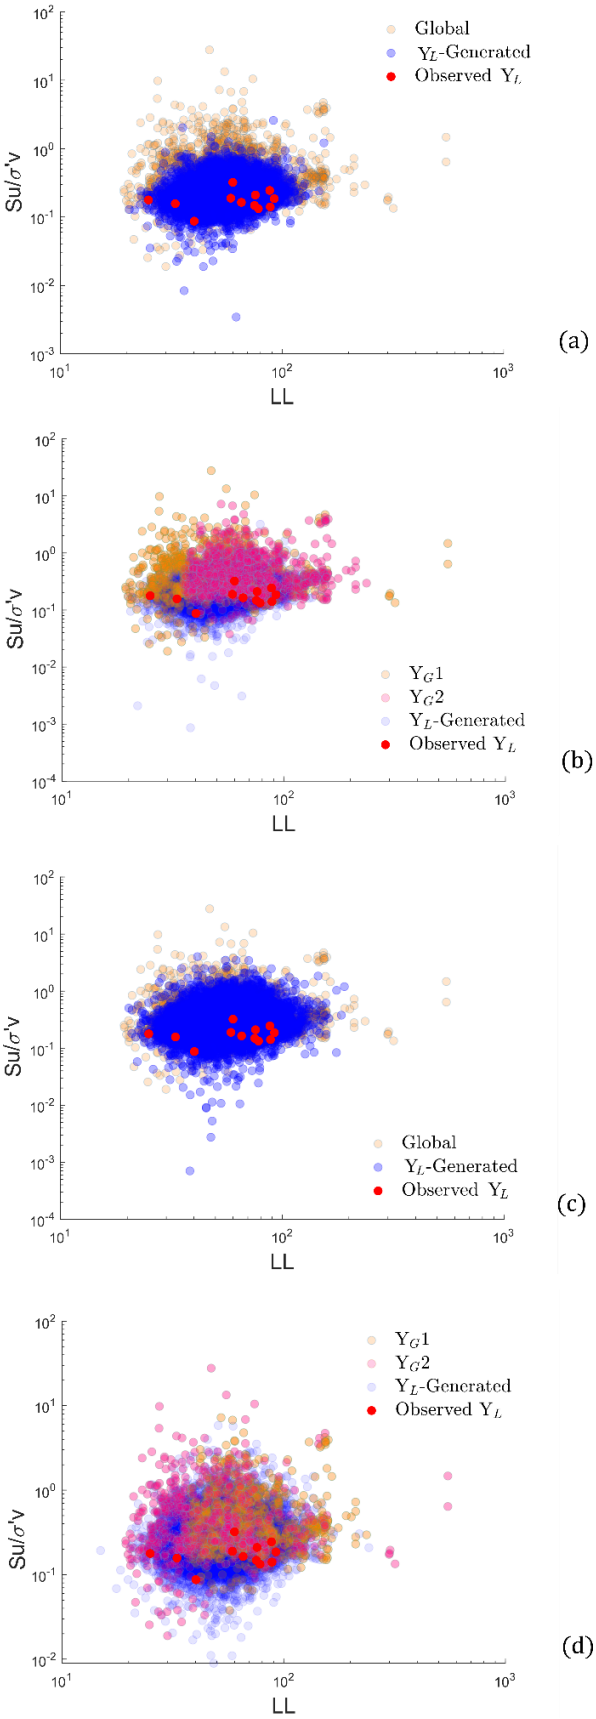

Figure 3. Generated $Y_{L\text{-}new}$ samples for: a) Complete no-cluster scenario. b) Complete cluster-based scenario. c) Incomplete no-cluster scenario. d) Incomplete cluster-based scanrio.

The accuracy seems to slightly increase for both Complete and Incomplete scenarios when clustering approach is employed. Nevertheless, such difference is negligible since the two clusters introduced according to the k-means approach are not characterized by major difference in terms of Pearson correlation and Covariance.

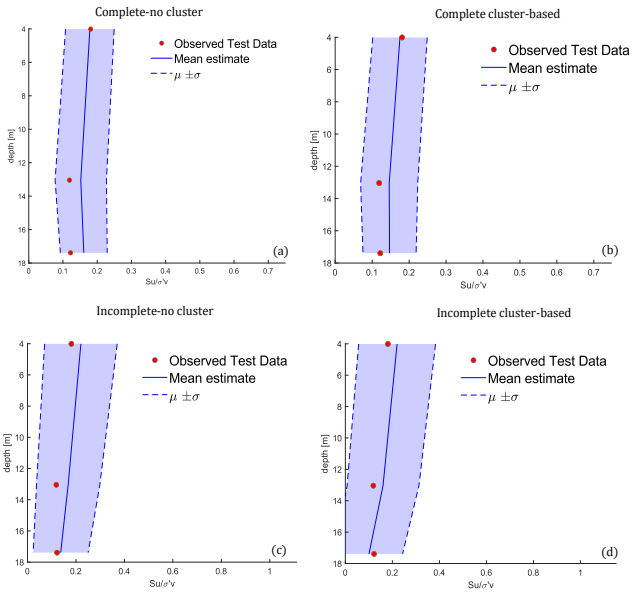

Figure 4. Predicted Su/σ'_{v0} for: a) Complete no-cluster scenario. b) Complete cluster-based scenario. c) Incomplete no-cluster scenario. d) Incomplete cluster-based scanrio.

5 CONCLUSIONS

This paper propose a Bayesian formulation (implementing and extending the formulation by Ching and Phoon (2019)) to integrate cluster-based global knowledge for local undrained shear strength prediction, and assess the challenge of local database incompletness. The work hihglight how cluster-based knowledge might slighlty increase accuracy of local undrained shear strength prediction. Neverthless, the work hihglights how cluster-based solution should be integrated with reason within the described Bayesian formulation. To do so, the approach proposed could provide more significance improvement to local undrained shear strength prediction when a Bayesian Mixture formulation is employed for global dataset manipulation. This would allow to account for more insightful information based on local dataset structure and enegineering experience.

ABSTRACT: Design of deep excavations involves the definition of the retaining walls and struts to support earth pressures. Despite the experience and the procedures available to estimate the forces acting on the struts, their prediction is still difficult and comparison between field measurements and numerical simulations suggest that there are many factors not taken into account in the routine calculations. This paper presents a software (DAARWIN) that can be used to manage field data and to perform backanalysis in an automatic manner to predict soil parameters. It is a cloud based platform combined with the Plaxis Finite Element code, that uses genetic algorithms to solve the backanalysis. This software has been applied to the identification of soil parameters and strut loads in a real case involving a deep excavation from Toulouse Metro in France.

RÉSUMÉ: La conception d'excavations profondes implique la définition des murs de soutènement et des entretoises pour supporter les pressions des terres. Malgré l'expérience et les procédures disponibles pour estimer les forces agissant sur les entretoises, leur prédiction reste difficile et la comparaison entre les mesures sur le terrain et les simulations numériques suggère que de nombreux facteurs ne sont pas pris en compte dans les calculs de routine. Cet article présente un logiciel (DAARWIN) qui peut être utilisé pour gérer les données de terrain et effectuer une rétro-analyse de manière automatique pour prédire les paramètres du sol. Il s'agit d'une plate-forme basée sur le cloud combinée au code Plaxis Finite Element, qui utilise des algorithmes génétiques pour résoudre la rétro-analyse. Ce logiciel a été appliqué à l'identification des paramètres du sol et des charges des entretoises dans un cas réel impliquant une excavation profonde du métro de Toulouse en France.

Keywords: Backanalysis; optimization; deep excavation; retaining walls; strut loads.

1 INTRODUCION

Deep excavations using diaphragm walls usually include the installation of struts to temporarily ensure their stability. Traditional and empirical procedures to design diaphragm walls are not accurate when estimating strut forces as they oversimplify the earth-pressure distribution. Moreover, even when a "beam-on-spring" approach is used for wall design (a popular procedure among practising engineers), the strut loads may be underpredicted , due to soil arching effects and stress redistribution (Karlsrud & Andresen, 2005). This is a classical soil-structure interaction problem in which both soil and concrete stiffness play a fundamental role. Despite the huge development of numerical codes for geotechnical design, the working load supported by the struts is difficult to predict and a conservative approach is usually proposed (Goh et al., 2017, Zhang et al., 2019). In fact, in reported cases where the loads in the struts were monitored, their values were not totally consistent with the calculated ones (Moormann, 2002; Finno et al., 2002; Houhou et al., 2019). Several factors have been described to explain the differences between measured and computed strut loads, as installation effects, stiffness of the wales, temperature changes and pre-stressing (Moorman, 2002). This is why the observational method has been a valuable methodology to control excavation works and therefore, monitoring has become an essential task. Within this context the interpretation of field instrumentation in actual excavations can be enhanced if a numerical geotechnical model is used.

In this regard, geotechnical backanalysis can be a powerful tool to compare field measurements with predictions of the model. Backanalysis in Geotechnics is useful to calibrate soil constitutive models from

laboratory tests, but also to identify soil properties from field measurements. Some of the Finite Element programmes for geotechnical design developed so far include a backanalysis feature (Levasseur et al., 2008; Hashash et al., 2010; de Santos, 2015). The software DAARWIN (SAALG, 2023), coupled with Plaxis, performs backanalysis in a systematic manner and is able to manage the information provided by an initial design and by field data.

This paper presents an application of DAARWIN to a well documented case study, the Saint-Agne Metro Station, located in Line B of the Toulouse Metro, France, (Houhou et al., 2019), and focusses on the estimation of the struts loads.

Based on the information from this project, a numerical model has been built using finite elements in Plaxis 2D and Plaxis 3D, subsequently the influence of the loads produced by the struts was analyzed. The backanalysis of the measurements obtained during the excavation process improved the characterization of the soil layers and was useful to analyze the loads of the struts.

2 BACKANALYSIS USING DAARWIN

Backanalysis is also referred as "inverse problem", that is, estimating the parameters of a soil constitutive model from field measurements. An "objective function" is defined, which depends on the differences between measurements obtained through instrumentation and values calculated through a conceptual model. The solution to the identification problem is obtained by searching for the minimum of the objective function, for which optimization algorithms are used (Levasseur et al., 2008; Hashash et al, 2010; de Santos, 2015).

Traditionally, the backanalysis methodology was carried out manually, however, numerical techniques allow to perform that task in an automatic manner. Thus, backanalysis can be used in a systematic way to continuously analyze field data from monitoring and to assess the validity of the assumptions made during the design stage (Ledesma and Romero, 1997). That fills the gap between models from the design phase and measurements during construction and helps in the interpretation of the field instrumentation, reducing uncertainty.

The software DAARWIN is in fact a cloud-based platform based on machine learning algorithms (genetic algorithms) that integrates the management of field data from monitoring with numerical analyses using Plaxis code, and is able to identify parameters of geotechnical constitutive models by comparing measurements with finite element calculations. All the analyses in DAARWIN are performed using a parallel high-performance cloud-computing architecture running 200 server instances per backanalysis. The software was developed by a start-up company from a University research work (SAALG, 2023). A complete description of the methodology can be found in de Santos (2015).

3 DESCRIPTION OF THE CASE STUDY

The Saint-Agne station is located on the new Line B of the Toulouse Metro, France. This station is a 55.2 m × 17.15 m rectangular deep excavation, described in detail in Vanoudheusden et al. (2005), Zghondi et al. (2009), and Houhou et al. (2019). The retaining structure consists of a diaphragm wall cast in situ with a thickness of 1.0 m and reaching a depth of 20.65 m. During excavation to a depth of 17.2 m, the retaining walls were supported at the top by partial slabs and diagonal beams and at depth by 2 or 3 levels of temporary steel struts. Figure 1 shows a typical section of the diaphragm wall.

The excavation area was monitored in two sections. Each section included an inclinometer on the diaphragm wall and 4 vibrating wire strain gauges installed at each strut level with an automatic data acquisition system. Maximum measured horizontal displacement was about 9.7 mm at inclinometer 1. Construction activities included staged lowering of the water table, excavation and shoring. In each stage, the water table was first lowered to 1m below the bottom of the next excavation stage, then the soil was removed and the props were installed 0.4–0.5 m above the bottom of the excavation. This procedure was carried out for each phase until reaching the end of the excavation.

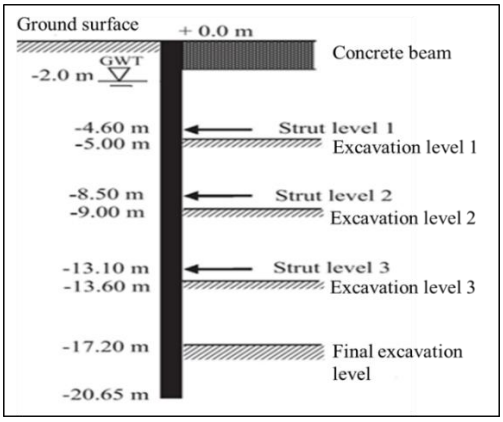

Figure 1. Typical wall cross-section (modified from Hohou, 2019).

The soil profile with the main geotechnical parameters initially provided is shown in Table 1,

adapted from Houhou et al. (2019), where a 3D simulation using code FLAC and the elastic-Mohr Coulomb model was presented. Here, code Plaxis 2D and 3D was used, with the Hardening Soil model with small strains as constitutive law, and an automatic backanalysis was carried out to better match the field instrumentation.

4 BACKANALYSES PERFORMED

A sensitivity analysis was carried out first, in order to detect the parameters that have more influence on the variables measured. This is a standard first step in DAARWIN (Cordoni, 2023). Once the parameters controlling the problem were detected, it was possible to define the conditions for the backanalysis (parameters to identify and range of the values in the search space). This is the case presented in this paper.

The most significant layers, in terms of influence on the measured displacements were identified as layers 4, 7, 8 and 9 (see Table 1), and the main parameters to identify were E_{50}, E_{ur} for those layers. To simplify the analyses, the following relations were adopted: $E_{oed}=E_{50}$ and $G_o=2.6\ E_{50}$. The rest of the parameters were fixed and based on the information provided (Table 1). Note that in excavation problems, the unloading-reloading modulus, E_{ur}, plays an important role when predicting displacements. The values identified in the backanalysis were, for the sandy clays (layer 4), E_{50}=50 MPa, E_{ur}=200 MPa; for the fine to medium sands (layer 7), E_{50}=60 MPa, E_{ur}=220 MPa; for the sandy clays (layer 8), E_{50}=210 MPa, E_{ur}= 540 MPa; and for the clays (layer 9), E_{50}=270 MPa, E_{ur}=1010 MPa. These values obtained are consistent with the geological and geotechnical information available. In particular the high modulus of the lower clays corresponds to the type of material involved (a molasse). Figure 2 shows the comparison between the measured horizontal displacements and the computed ones using those parameters.

5 STRUT LOADS

The loads of the struts were obtained from the numerical analyses. In the papers describing the case, an efficiency factor of 0.5 was defined to account for the difference between the theoretical load obtained in the calculations and the measured value (Houhou et al., 2019). That is, the measured load was half of the theoretical load computed from the shortening of the struts obtained considering the horizontal displacement in the inclinometers at the level of the strut. This is in fact a reduction of the theoretical strut stiffness by a factor of 2, which may be due to the stiffness of the connection between the struts and the wall.

When using the backanalysis procedure, the strut loads were more consistent with the measured values and an efficiency coefficient was not required. However, it was noticed that wall dis-placements are not very sensitive to the strut stiffness beyond a minimum value. In fact, multiplying or dividing the current strut stiffness by a factor of 3 had little influence on wall displacements. That explains the difficulty in determining numerically the force at the struts. Figure 3 shows the measured and computed strut loads. Note that differences can be as high as 1000 kN, which points out the difficulty in matching strut loads.

6 CONCLUSIONS

The paper presents an application of the software DAARWIN to a real case involving a strutted deep excavation. That software is able to manage field data and to perform backanalyses in an automatic manner, which can be very useful in geotechnical design and construction and particularly when combined with the observational method.

Table 1. Main initial parameters of the soil layers: natural specific weight, permeability, earth pressure coefficient, Poisson's ratio, cohesion, friction angle, dilatancy angle, Young modulus (after Houhou et al., 2019).

Layer	Depth(m)	γ(kN/m^3)	K(m/s)	K_o	ν	c'(kPa)	φ'(°)	ψ(°)	E(MPa)
1. Fill	0-1.2	20	$6\cdot10^{-4}$	0.5	0.3	0	25	0	66-78
2. Clays	1.2-2.8	22	$1\cdot10^{-9}$	1.6	0.3	80	33	0	78-94
3. Clay sands	2.8-5.2	21	$1\cdot10^{-7}$	1.6	0.3	52	37	3	94-117
4. Sandy clays	5.2-7.6	22	$5\cdot10^{-8}$	1.6	0.3	84	32	0	117-141
5. Fine to medium sands	7.6-8.6	21	$1\cdot10^{-6}$	1.6	0.3	0	36	5	141-151
6. Sandy clays	8.6-10.2	22	$5\cdot10^{-8}$	1.6	0.3	84	32	0	151-167
7. Fine to medium sands	10.2-12.7	21	$1\cdot10^{-6}$	1.6	0.3	0	36	5	167-191
8. Sandy clays	12.7-21	22	$5\cdot10^{-8}$	1.6	0.3	84	32	0	191-274
9. Clays	>21	22	$1\cdot10^{-9}$	1.6	0.3	80	33	0	274-360

Regarding wall displacements, they are well reproduced using backanalyzed parameters, however, measured strut loads are still difficult to simulate, because they are less sensitive to global wall displacements.

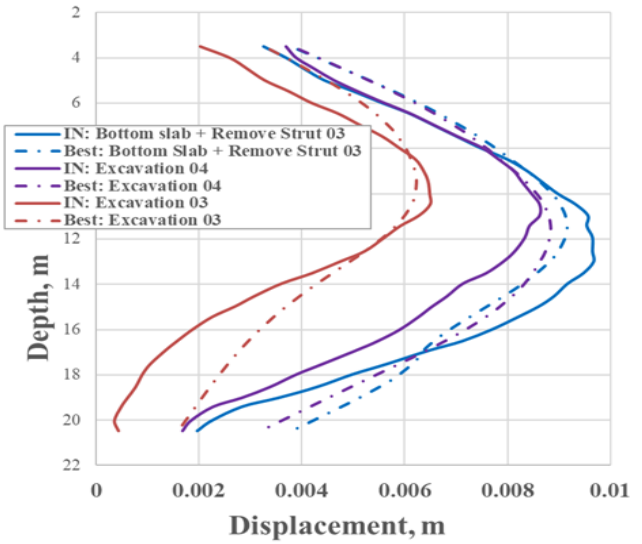

Figure 2. Measured and computed wall displacements.

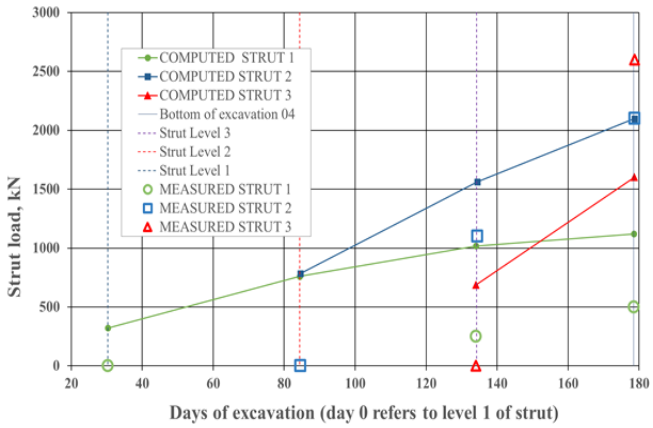

Figure 3. Measured and computed strut loads.

ABSTRACT: Dynamic probing tests, namely in the case of the super-heavy version, are commonly used in geotechnical investigations, particularly in heterogeneous soils, stiff soils, compacted to very compacted soils and in decomposed rock. The more usual approaches to obtain the subsequent geotechnical parameters consists in transforming the N_{20} DPSH results in equivalent N_{SPT} and use the correlations established with this latter. However, the usual correlations used in our days are based in the concept of corrected SPT values, namely N_{60} and $(N_1)_{60}$, which creates an important limitation to its use in DPSH results. A research work consisting in pairs of SPT and DPSH tests executed side by side with the same equipment (hammer, anvil, rods, etc.), both instrumented with energy measurements obtained from the SPT Analyzer (PDI), was performed in the Institute Polytechnic of Guarda (IPG, Portugal) experimental site. The obtained results revealed differences between the Energy Transfer Ratios (ETR) of DPSH and SPT tests, which seems to be related with the different penetration devices (SPT sampler and DPSH cone). Departing from that it was possible to compare both the test results (N_{SPT} and N_{20}) and the respective corrected values, N_{60} or $(N_1)_{60}$. Presentation and discussion of results will be presented in the paper herein.

RÉSUMÉ: Les essais de sondage dynamique, notamment dans le cas de la version super-lourd, sont couramment utilisés dans les investigations géotechniques, notamment dans les sols hétérogènes, les sols raides, les sols compactés à très compactés et dans les roches décomposées. Les approches les plus usuelles pour obtenir les paramètres géotechniques ultérieurs consistent à transformer les résultats N_{20} DPSH en équivalent N_{SPT} et à utiliser les corrélations établies avec ce dernier. Cependant, les corrélations habituelles utilisées de nos jours reposent sur le concept de valeurs SPT corrigées, à savoir N_{60} et $(N_1)_{60}$, ce qui crée une limitation importante à son utilisation dans les résultats DPSH. Un travail de recherche consistant en des paires d'essais SPT et DPSH exécutés côte à côte avec le même équipement (mouton, enclume, tiges, etc.), tous deux instrumentés avec des mesures d'énergie obtenues à partir de l'analyseur SPT (PDI), a été réalisé dans le laboratoire expérimental site de le Institut Polytechnique de Guarda (IPG, Portugal). Les résultats obtenus ont révélé des différences entre les taux de transfert d'énergie (ETR) des tests DPSH et SPT, qui semblent être liées aux différents dispositifs de pénétration (échantillonneur SPT et cône DPSH). À partir de là, il a été possible de comparer à la fois les résultats des tests (N_{SPT} et N_{20}) et les valeurs corrigées respectives, N_{60} ou $(N_1)_{60}$. La présentation et la discussion des résultats seront présentées dans le document ci-dessous.

Keywords: SPT; DPSH; penetration resistance; energy transfer ratios; energy efficiency.

1 INTRODUCTION

Dynamic penetration tests are widely used in the geotechnical characterization of soil massifs, especially in heterogeneous, stiff/dense/compacted soils and decomposed rock, where static penetration is seriously limited. Among these, the Standard Penetration Test (SPT) is undoubtedly the more popular and common in-situ geotechnical test used worldwide, which gives it an important advantage for a successful applicability in a wide range of geo-materials. On the other hand, dynamic probing tests

have the great advantage of characterizing soil profiles continuously, especially in terms of strength (ISSMFE-TC16, 1989). Within this group of tests, Dynamic Probing Super-Heavy test (DPSH) is very similar to SPT in what concerns the mode of penetration and potential energy, thus very easy to be compared with, giving access to the available SPT correlations.

Both SPT and DPSH tests consist in the blow count needed for the penetration of a standard element by means of an impact produced by a hammer falling from a certain height. The hammer and falling weight are similar in these two tests, thus generating the same potential energy, while the main difference is related with the equipment that firstly penetrates the soil, namely a SPT 45 cm normalized sampler and a DPSH cone with diameter similar to the SPT sampler. Furthermore, SPT tests are performed inside a borehole previously drilled until the depth of each test (typically performed every 1.0-1.5 m), while DPSH is penetrated directly from the surface without need of a borehole, thus generating continuous profiles. The results of both tests correspond to the number of blows to penetrate a length of 30 cm (N_{SPT}) and 20 cm (N_{20}), respectively representing SPT and DPSH tests.

Given the similarity between both tests, it is of great practical interest to obtain DPSH normalized parameters identical to the SPT, opening an access to the most updated SPT correlations.

The International Geotechnical Society (ISSMFE, 1989) has established a reference value of 60% of the theoretical free fall of 474 J, E_{60}, for comparisons among tests performed by different equipment. The corresponding N value is designated as N_{60} and can be obtained from Eq. 1 as:

$$N_{60} = N \frac{E}{E_{60}} \quad (1)$$

where N corresponds to the energy E, which has to be known. The energy is to be obtained below the driving head (ISSMFE, 1989).

The more recent procedures and available correlations from SPT results, require the SPT normalized parameters, N_{60} and $(N_1)_{60}$ (Robertson et al., 1983, Seed et al., 1985, Skempton, 1986), represented by the Eq. 1 to Eq. 4. Thus, DPSH results should be represented by similar parameters. In the following sections an experimental frame performed in the Institute Polytechnic of Guarda (IPG), Portugal, experimental site under this subject is presented and discussed. The N_{60} and $(N_1)_{60}$ parameters are defined by the following equations:

$$N_{60} = C_E * C_R * C_B * C_S * N_{SPT} \quad (2)$$

$$C_E = \frac{ER_r}{60} \quad (3)$$

$$ER_r = \left(\frac{E_R}{E_P}\right) * 100 \quad (4)$$

$$(N_1)_{60} = C_N * N_{60} \quad (5)$$

where C_E represents the correction factor related with the energy transmitted to the rods, C_R and C_B the corrections related with the length of the rods and the diameter of the borehole, C_S the correction factor related with the liner, C_N the correction factor related with the overburden stress in granular soils, ER_r the energy ratio transferred to the rods, E_R the energy effectively transferred to the rods and E_P the potential energy of the hammer falling from a specific height.

More detailed information on the SPT normalized parameters can be easily found in the referenced bibliography.

2 EXPERIMENTAL WORK

The experimental frame related with this work was performed in the IPG experimental site, which has been used in the several studies related with in-situ tests in residual soils. The local geology corresponds to the residual soils, which are the result of the chemical weathering of Guarda granitic formation where the experimental site is located. Detailed information can be found in several available publications (e.g. Ávila Martins et al., 1963; Rodrigues, 2003; Cruz, 2010).

The experimental frame consisted in the execution of pairs of DPSH/SPT tests performed side by side, following the procedures recommended in Eurocode 7-Geotechnical design, part 3. A PDI SPT Analyzer equipment (1999) was used to measure the energy delivered to the rods of each DPSH and SPT blow and both tests were performed with the same equipment characterized by a 63.5 kgf hammer falling from 0.75 m height, which correspond to 476.3 J. The same rods were used in the execution of both tests, bore holes were performed without introducing casing and liners were not used in the SPT sampler. The blow frequency was the same in both tests (23 to 25 blows per minute). For comparing purposes, the number of blows considered in each test were taken at similar depths and the DPSH number of blows (N_{20}) was transformed (N_{30}), multiplying the earlier by 1.5, in order to have comparable lengths of determination.

After the execution of tests, the obtained field results were object of statistical treatment to analyse the energy efficiency and then globally compared in what concerns to the energy efficiency, field results at

the same depth ranges and normalized parameters. The normalized SPT parameters followed the current procedures (expressed by eq. 1 to 3), while for DPSH similar correction factors were applied except for the borehole diameter correction, which was discarded since the test is not executed inside a borehole.

The granitic residual massif under study consistently reveals an increase of the penetration resistance with depth, which is well represented both by SPT and DPSH tests, although with different evolution rates (Figure 1).

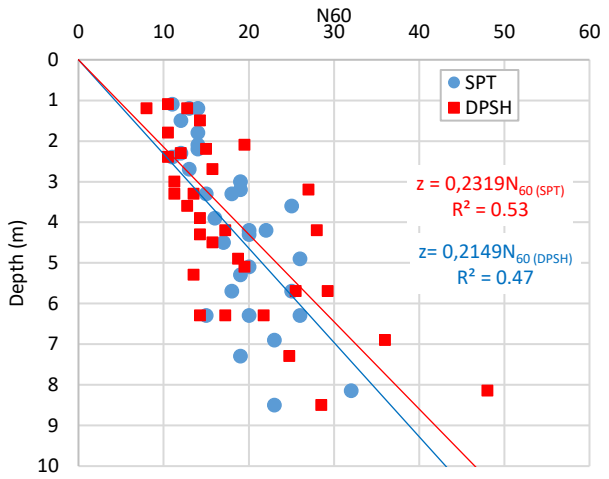

Figure 1. Evolution of penetration resistance with depth in the SPT and DPSH tests.

Compairing directly the global results of N_{20} with N_{SPT}, obtained at equivalent depths, it becomes obvious the (expected) lower blowcount of N_{20} (Figure 2), which is naturally justified by the different lenghts of penetration.

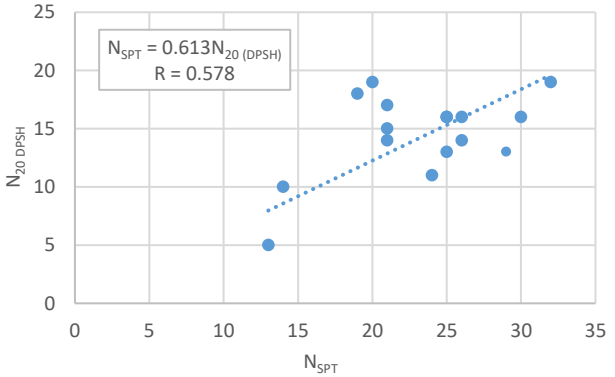

Figure 2. Relation between the penetration resistance N_{SPT} and N_{20}.

On the other hand, the experimental transmitted energy (ETR) results measured by the SPT Analyzer reveal that the delivered energy is not the same in each test (Figure 3), which can only be adressed to the different tip equipments (SPT sampler and DPSH cone) since all the other equipments are the same. In fact, the superficial contact area of the DPSH conic tip with the ground is constant the whole test (155.0 cm^2), while the area of SPT sampler varies according to a penetration length of 15 to 45 cm with internal and external contact with the ground (405.3 cm^2 a 1215.8 cm^2). The normalization of ETR by the N_{30} and N_{SPT} values seem to produce a more robust correlation between both tests (Figure 4).

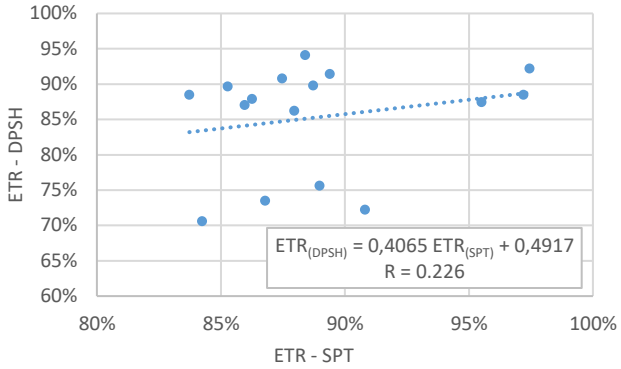

Figure 3. Relation between transmitted energy (ETR) in SPT and DPSH tests.

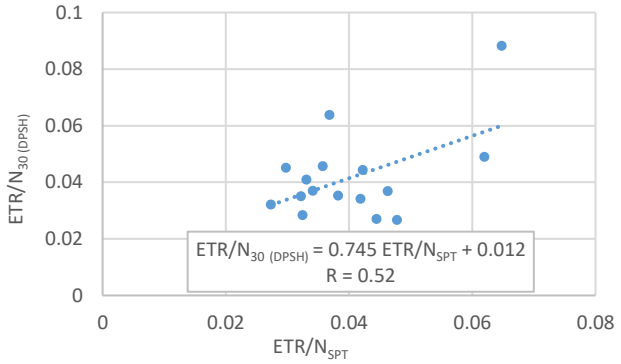

Figure 4. Relation between the ETR/N_{SPT} of SPT and ETR/N_{30} of DPSH tests.

The different obtained delivered energies seem to be related with the differences of contact areas, suggesting that higher contact generate a more efficient form to transfer to the soil the available energy generated by each blow. Figure 5 represents the mean ETRs obtained in the first, second and third 15 cm penetration phases of SPT tests and seems to corroborate the previous explanation, since the contact area of the SPT sampler with the soil is increasing with penetration.

As consequence, the comparison of normalized parameters instead of the simple blowcounts of each test is much more reliable, which is clearly proved by the diagram of Figure 6. Being so, if all the correction factors are applied, the normalized parameters obtained by both tests are equivalent, thus the available modes of correlation for SPT tests can be equally applied to DPSH tests. In the case of DPSH the C_B

factor (related with the diameter of borehole) should be considered equal to 1, while the remaining are applied as in the case of the SPT test.

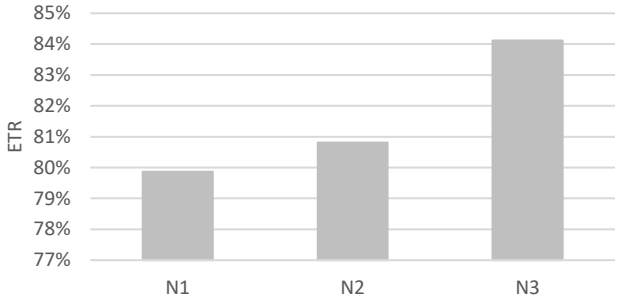

Figure 5. Evolution of ETR in the SPT tests.

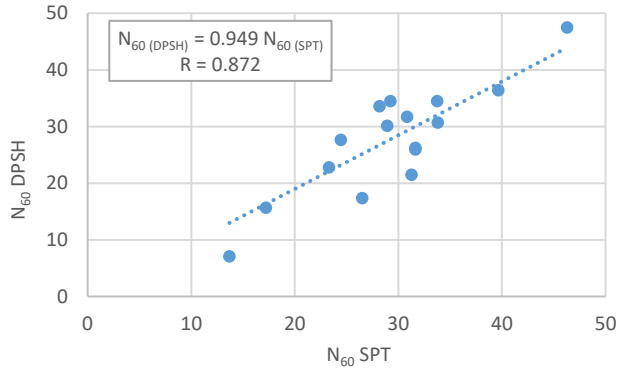

Figure 6. Relation between the N_{60} of SPT and $(N_{30})_{60}$ of DPSH tests.

3 CONCLUSIONS

The experimental frame presented herein clearly revealed that the energy efficiency is higher in the case of the SPT test than in the case of DPSH, which seems to be related with the higher contact area of the SPT sampler with the soil compared with the DPSH cone-soil contact. The higher the contact area the higher the energy efficiency. The comparison between normalized blow counts showed that the ratio between test results is basically equivalent. As consequence of the present findings, if the field work is performed with hammers of known (measured, calibrated) energy efficiencies (as it should) it is possible to obtain DPSH normalized parameters (considering C_B =1) that can be used in the current correlations settled for SPT tests. Naturally, this is a limited experience within certains strength and depth ranges, as well as in very specific geologic environment, and so the study should be enlarged to other geo-materials with other strengths and different test depths to validate this conclusions. For the time being, local calibration with 1 or 2 pairs of SPT-DPSH tests will allow to evaluate the sustainability of the findings presented herein.

ABSTRACT: This investigation explores the influence of physical properties on capillarity and uniaxial compressive strength from 56 specimens of basalts from Madeira Island, Portugal. Three well differentiated basalt types belonging to the Upper (massive and vesicular basalt) and the Middle (altered massive basalt) Volcanics Complexes were studied. Water absorption coefficient by capillarity and uniaxial compressive strength were assessed as a function of real and apparent densities, total and open porosities, water absorption at atmospheric pressure and unit weight applying simple and multiple linear regressions to obtain reliable prediction models. Water absorption coefficient by capillarity equations show high correlation coefficients ($R > 0.98$). The proposed best equation is expressed as a function of water absorption at atmospheric pressure and apparent density. Meanwhile, the best fit for uniaxial compressive strength, given by apparent density, open porosity, and unit weight has a moderate correlation. While apparent density has a predominant statistical weight in the prediction of uniaxial compressive strength, open porosity has a minor contribution. Unsupervised clustering processes using principal component analysis identifies three well differentiated groups whose inner cohesion is intimately related to open porosity (very low to high porosity), pore size and type (fine intercrystalline and large vesicular pore type, respectively) and the natural weathering degree of basalts. Some results obtained in this research could be used as indicator parameters in geotechnical classifications to assist with fast decisions when using basalts as building materials or as a foundation in civil engineering construction.

RÉSUMÉ: Cette étude explore l'influence des propriétés physiques sur la capillarité et la résistance à la compression uniaxiale de 56 éprouvettes de basaltes de l'île de Madère. Trois faciès bien différenciés appartenant au Complexes Volcaniques Supérieur et Moyen ont été étudiés. Le coefficient d'absorption d'eau par capillarité et la résistance en compression uniaxiale ont été comparés et liés aux masses volumiques réelles et apparentes, aux porosités totales et ouvertes, à l'absorption d'eau à la pression atmosphérique et au poids unitaire en appliquant une analyse statistique avancée. Le coefficient d'absorption d'eau par capillarité obtenu par des modèles de régression linéaire simple et multiple montrent des coefficients de corrélation élevés ($R > 0,98$; respectivement). La meilleure équation proposée est exprimée en fonction de la masse volumique apparente et de la porosité ouverte. Le meilleur ajustement pour la résistance à la compression uniaxiale, donné par la masse volumique apparente et la porosité ouverte, présente une corrélation modérée, où la masse volumique apparente avait un poids statistique prédominant dans la prédiction de cette variable, avec une contribution mineure de la porosité ouverte. L'analyse non supervisée de groupes identifie trois groupes bien différenciés dont la cohésion interne est intimement liée à la porosité ouverte à la taille, au type de pores et au degré d'altération naturelle des basaltes. Certains résultats obtenus pourraient être utilisés comme paramètres indicateurs dans les classifications géotechniques pour permettre une prise de décision rapide dans l'utilisation des basaltes comme matériaux de construction ou comme fondations pour les constructions de génie civil.

Keywords: Volcanic rocks; multivariate analysis; spontaneous imbibition; petrophysical properties; building rock.

1 INTRODUCTION

Research on the physico-mechanical properties of basalts is currently booming due to their potential use as reservoirs for hydrogen (Yaseri et al., 2023) and CO_2 (Iglauer and Al-Yaseri, 2021) storage in the accelerating race to find solutions for energy transition and climate change mitigation.

In Madeira Island, basalt studies are more focused on its use as a foundation material in civil engineering works, on its performance in slope stability for risk assessment, and on its use as an ornamental and building stone, both in new construction and in the conservation and restoration of the regional architectural heritage (Sempere-Valverde et al., 2023, Alves et al., 2019, Maia and Aslani, 2016, Lourenço et al., 2010). While physical (e.g. density, porosity, etc.) and mechanical (e.g. uniaxial compressive strength, elastic modulus, indirect tensile strength, point load index, etc.) properties of basalts are widely assessed worldwide (Pereira et al., 2021, and references therein), research on water transport mechanisms remains scarce.

Basalts used as building stones and with a pore size distribution ranging from 0.1 μm to 10 μm (within the medium range of capillary active pore size) are found to be more prone to deterioration due to the physico-chemical processes induced by both water sorption and solutes' transport (Çelik and Kaçmaz, 2016). Moreover, basalts exhibit variations in their resistance due to material weathering, as showed by numerical evaluations on slope stability (Silva et al., 2023). Both erosion processes and changes in the hydraulic conditions of basaltic grounds due to water level variations are suggested as causes of such deterioration. From our own field experiences, we recognise that episodic slope collapses are either caused by torrential rains or stagnant water. In the latter, fluid movements are induced first by permeability and then by capillarity. Thus, the existence of a parameter that relates fluid transport integrated with other geoengineering properties is of foremost importance to better develop prevention plans and minimise geological hazards.

To address this problem, water transport in volcanic rocks has started to be considered in an internal database that has been developed by Laboratório Regional de Engenharia Civil (LREC) since 2012 (Vieira de Sousa et al., 2012) and is currently expanding to cover more territory of Madeira Island and incorporate parameters of critical importance in predicting both hydric and mechanical properties. In fact, capillarity and permeability have proved to be indicators of susceptibility to deterioration and possible collapse of volcanic rocks (Cueto et al., 2018, Perneta and Vieira de Sousa, 2023).

Therefore, the main objective of the present study is to determine the influence of physical properties on capillarity and uniaxial compressive strength. For this purpose, the results will be analysed by applying multivariate statistics and empirical equations will be provided to estimate these parameters. Final considerations will be addressed in the context of the application of these parameters as accurate indicators within geoengineering properties.

2 MATERIALS AND SAMPLING

2.1 Geographical and geological setting

The Madeira Island is the largest and most populated of the homologous Archipelago and is located in the eastern sector of the North Atlantic ocean, between latitudes 32º 38' N and 32º 52' N. It corresponds to a volcanic edifice (1861 m above sea level) that has been originated by a hot spot. Madeira Island comprises three main volcanostratigraphic terms: (a) Lower Volcanic Complex (CVI. > 5.57 My); (b) Middle Volcanic Complex (CVM. 5.57 - 1.8 My); and (c) Upper Volcanic Complex (CVS. 1.8 - 0.007 My) (Ramalho et al., 2015, Brum da Silveira et al., 2010), with alkali olivine basalts being an important rock material in this island (Hughes and Brown,1972).

2.2 Basalts

Three massive, one vesicular and one altered massive basalt samples were selected to carry out this study, from which 56 specimens in total were extracted. Massive basalts were quarried in São Vicente (Bc-SV) and São Martinho, Funchal (Bc-SA, Bc-SB), and the vesicular basalt sample (Bv-SV) was cored in São Vicente. Both belong to the Funchal Unit, CVS. The altered massive basalt (Bca-E) was obtained in Encumeada, Ribeira Brava, in the geological context of CVM, Penha d'Águia Unit.

At mesoscale, massive basalts are dark grey in colour and show almost no signs of weathering. In the Bc-SV sample, a very isolated vesicular porosity type can be seen (2.62 ± 1.80 mm). The Bc-SA and Bc-SB samples show a vesicular porosity type smaller than those observed in Bc-SV (0.88 ± 0.36 mm, 0.79 ± 0.24; respectively), but also isolated, and widely dispersed throughout the samples. In both samples, discontinuity surfaces are observed with increasing depth. These are fissures and, less frequently, stylotites-like discontinuities, with a very fine aperture (~1 mm), open or partially cemented by a whitish mineral. In sample Bc-SA the fissure density increases significantly compared to sample Bc-SB.

In vesicular basalts, macroporosity extends over 30-40% of the sample, has no preferential organisation and has a size variation in the range of 1.5 mm to 6 mm.

The altered compact basalt sample, Bca-E, is generally grey in colour, with some brownish areas. It has about 10% vesicular porosity and, in some specimens, this macroporosity is partially cemented by a whitish mineral. Isolated and narrow-opening fissures are present. The matrix of Bca-E is more porous than the rest of the studied basalts, probably and partly due to the natural weathering of the rock mass (W_2 in accordance with ISRM (1981)).

Bc-SV, Bv-SV and Bca-E samples were collected from outcrops, meanwhile Bc-SB and Bc-SA samples were obtained from a borehole drilled at depths of ~20 m to 35 m.

3 METHODS

The cylindrical specimens were cut according to the specifications of each test standard, i.e. h/d=1 (~70 mm). The number of specimens tested in each experiment, as well as the porous facies classification based on Anon. (1979), are stated in Table 1.

Petrophysical properties, namely real, ρ_r, and apparent, ρ_b, densities and total, p, and open, p_o, porosities were determined following the NP EN 1936 (2008) standard. Water absorption at atmospheric pressure, A_b, and water absorption coefficient by capillarity, C, were respectively carried out in accordance with NP EN 13755 (2008) and NP EN 1925 (2000) standards. The studies of spontaneous imbibition of water were completed with the analysis of capillary curves based on the SF model of Hall and Hoff (2021). To obtain the mechanical properties, tests have only been carried out to determine the uniaxial compressive strength, σ_c, according to NP EN 1926 (2008). The unit weight, γ_d, was obtained through the relation of total weight of oven-dried specimen and total volume of the specimen.

The descriptive and multivariate statistical analyses of the results were carried out using IBM SPSS Statistics 25.0.0 as in Cueto (2020), namely scatter diagram analysis, multiple linear regressions (LR), principal component analysis (PCA), and hierarchical cluster analysis (CA). Unsupervised cluster analysis using simplified PCA variables was performed employing the K-Nearest Neighbours algorithm from the scikit-learn Python 3 library (Jupyter Notebook 6.5.2).

4 RESULTS AND DISCUSSION

Table 1 shows the physical and mechanical properties results of the studied basalts, classified accordingly to Anon. (1979) as (i) very low - low porous, (ii) medium porous, and (iii) medium - high porous type. This grouping is exactly coincident with the massive, vesicular, and altered massive facies, respectively.

All multivariate analyses, whether dependent (LR) or interdependent (PCA and CA), prove that p_o is one of the main controlling factors in both hydric and mechanical properties. The higher the p_o, the higher the C and A_b, and the lower the σ_c. Empirical equations presented in Table 2 reveal that C can be predicted with high precision from Eq. 1. LR identified the variables A_b ($\beta = 0.999$) and ρ_b ($\beta = 0.019$) as significant predictors of C. This model is highly significant ($p < 0.001$; $R = 0.98$), however, among equations 1 to 4, Eq. 2 and Eq. 4 are the most efficient ones, because only one parameter is needed to estimate C and the models remain highly significant. This finding is reasonable since A_b and p_o are related through the saturation coefficient (Benavente, 2002). Equations 5 to 7 for estimating σ_c found, on the other hand, have moderate correlation coefficients (Table 2). The simplest (Eq. 7) predicts σ_c from ρ_b and maintains almost the same p (< 0.001) and R (~0.81) values.

The capillarity analysis shows two pore families controlling the water movement in Bv-SV. Large vesicular pores are well interconnected through the fine intercrystalline matrix porosity, extending and enhancing capillary suction. Despite this, the C results are lower than expected. This could be because the macropores size distribution is skewed towards values greater than 1.5 mm, which is the smallest size measured in this sample. Additionally, vesicles were detected overlapping each other, leading to an increase in the size of the macropores in their confluence zone. It has been verified experimentally that the mass of the water column is conditioned by the maximum pore size for capillary mobility. Jurin's Law for a wetting liquid supports this, as the capillary height for a pore radius of 1 mm is 1.5 mm. This suggests that gravity forces would be the primary mechanism in this situation and that fluid movement by capillarity would be insignificant (Hall and Hoff, 2021, Benavente, 2002).

Figure 1 displays the outcomes derived from unsupervised cluster analysis simplifying the PCA variables to assess the data quality from the categorization of rock facies. This process discriminated the three well-differentiated studied petrological varieties.

Table 1. Physico-mechanical properties of the studied basalts. Massive facies dominate the leftmost part in Figure 1, whereas vesicular facies is concentrated in the upper-right area. In the lower-right corner are grouped altered massive basalts.

Certain specimens of this last facies, however, are more related to massive facies due to their prominent physical properties as ρ_r and ρ_b. As a result, they are assigned to a zone closer to the massive facies group.

Nonetheless, the classification does not fall much short because it places these specimens outside of the massive facies' high point concentration and, in some cases, relatively near to the altered massive facies. Consequently, the specimens labelled in Figure 1 might be considered transitional since they fall between two facies.

These findings suggest that the inner cohesion of basalts facies is intimately related to open porosity (very low to high porosity), pore size and type (fine intercrystalline and large vesicular pore type, respectively), and the natural weathering degree of basalts (Table 1).

CA, performed with the shortest distance method (nearest neighbour) using the Euclidean distance as a measure of dissimilarity between specimens, aids unsupervised cluster analysis by identifying the three clearly distinguished facies.

These results underline the fact that if an unsupervised classification algorithm can perform a classification process with an extremely high level of accuracy, how much more could a supervised classification algorithm do with a large number of specimens? It may not only be able to categorise, but it may also be able to detect samples or specimens that lie between two facies and create additional sorts of inputs depending on the training data if properly labelled. This would shorten the time and cost of laboratory work, accelerate the generation of results, and help in making informed decisions.

Table 2. Logarithmic expressions of capillary absorption coefficient, C ((g/m^2)/s$^{0.5}$), and uniaxial compressive strength, σ_c (MPa), as a function of physical properties: water absorption at atmospheric pressure, A_b (%), apparent density, ρ_b (kg/m^3), open porosity, p_o (%), unit weight, γ_d (kN/m^3). R, multiple correlation coefficient.

Eq.	Logarithmic expressions	R
1	$LogC = -2.781 + 0.990 \cdot LogA_b + 0.867 \cdot Log\rho_b$	0.9828
2	$LogC = 0.213 + 0.974 \cdot LogA_b$	0.9827
3	$LogC = -2.179 + 0.611 \cdot Log\rho_b + 0.658 \cdot Logp_o$	0.9668
4	$LogC = -0.086 + 0.629 \cdot Logp_o$	0.9665
5	$Log\sigma_C = -27.767 + 12.240 \cdot Log\rho_b - 0.042 \cdot Logp_o - 8.510 \cdot \gamma_d$	0.8214
6	$Log\sigma_C = -12.736 + 4.333 \cdot Log\gamma_d - 0.026 \cdot Logp_o$	0.8147
7	$Log\sigma_C = -14.330 + 4.795 \cdot Log\rho_b$	0.8107

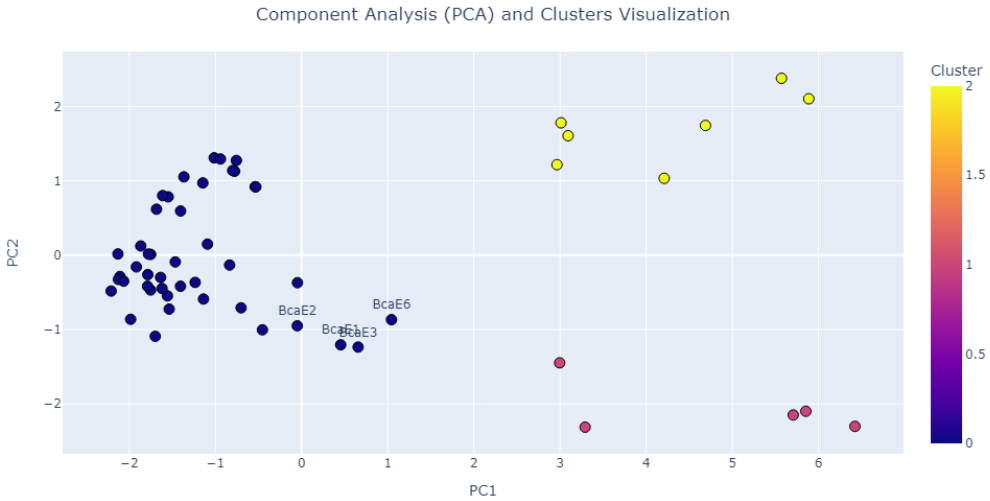

Figure 1. PCA and clusters visualization obtained from unsupervised cluster analysis. Massive (blue), vesicular (yellow) and altered massive (pink) basalt specimens. The labelled specimens belong to the altered massive facies, yet they exhibit prominent physical properties (i.e. ρ_r, ρ_b) similar to massive facies.

5 CONCLUSIONS

This investigation contributes to a better understanding of the physical properties influence on hydric and mechanical properties of basalts from Madeira Island, applying multivariate statistical analyses, and provides valuable insights for their application in geoengineering projects.

The equations developed in this study for water absorption coefficient by capillarity and uniaxial compressive strength can be used as reliable prediction models and can assist in assessing their suitability as construction and building materials, and for improving known classifications in civil engineering projects.

Unsupervised clustering processes using principal component analysis classified the basalts into three well-differentiated groups based on open porosity, pore size and type, and the natural weathering degree of basalts. This finding suggests that this approach can be used to guide the selection of specific types of basalts for different applications, considering their intrinsic controlling factors. In addition, this process can be further enhanced with the use of supervised classification algorithms for categorising samples accurately and identifying transitional specimens between facies into larger petrophysical databases, leading to more efficient and cost-effective laboratory work, faster generation of results, and better-informed decision-making.

Future works for gaining deeper understanding of water movement in vesicular basalts will be conducted, expanding the number of samples to be tested and conducting further microscopic analysis or employing advanced imaging techniques to identify and quantify the actual pore structure. This will provide a more comprehensive interpretation of the pore size distribution and its impact on sorption mechanisms.

ACKNOWLEDGEMENTS

The authors are grateful for the financial support provided by the European Union - Next Generation EU, by the Spanish Ministry of Universities, the University of Alicante (project reference: MARSALAS22-09), and the fellowship from “la Caixa” Foundation (ID 100010434) with the code LCF/BQ/DR22/11950029. Analysis of the feasibility of applying reinforcement for laying direct foundations

Analyse de la faisabilité de l'application de renforcements pour la pose de fondations directes

M.C.C.S. da Silva*, P.C. de A. Maia
Universidade Estadual do Norte Fluminense Darcy Ribeiro, Campos dos Goytacazes, Brasil

ABSTRACT: With urban expansion, the need to build in massifs with low support capacity and high deformability is increasingly common. A solution to this geotechnical problem is soil manipulation to improve its performance. In this sense, geosynthetics have been playing a prominent role in replacing conventional reinforcement solutions. The bibliography shows that the use of these materials, particularly in the case of shallow foundations, increases the load capacity and decreases the magnitude of settlements. The present study aims to analyze the technical feasibility of applying reinforcement for laying shallow foundations, with emphasis on the use of geosynthetics, as well as the parameters with the greatest influence on increasing the load capacity and reducing the magnitude of the settlement of the soil- reinforcement. The main parameters studied include: the characteristics of the foundation mass and the reinforcement, the geometry of the foundation and the nature of the loading. From an analytical model, variations of these parameters were simulated, within an acceptable range, seeking to estimate the load capacity based on Terzaghi's theory. In addition, a sensitivity analysis was carried out using the First-Order Second-Moment. The results make possible to determine under what conditions of stiffness of the foundation and reinforcement the execution of the technique is safely efficient. According to the analysis of the data in reduced models, it can be stated that the reinforcement ensured greater stability, enabling the construction in soils of low resistance.

RÉSUMÉ: Avec l'expansion urbaine, la nécessité de construire dans des massifs à faible capacité de support et à forte déformabilité est de plus en plus courante. Une solution à ce problème géotechnique est la manipulation du sol pour améliorer ses performances. En ce sens, les géosynthétiques jouent un rôle de premier plan en remplacement des solutions de renforcement conventionnelles. La bibliographie montre que l'utilisation de ces matériaux, notamment dans le cas de fondations peu profondes, augmente la capacité de charge et diminue l'ampleur des tassements. La présente étude vise à analyser la faisabilité technique de l'application de renforcements pour la pose de fondations superficielles, en mettant l'accent sur l'utilisation de géosynthétiques, ainsi que les paramètres ayant la plus grande influence sur l'augmentation de la capacité de charge et la réduction de l'ampleur du tassement du sol. renforcement. Les principaux paramètres étudiés comprennent : les caractéristiques du massif de la fondation et du ferraillage, la géométrie de la fondation et la nature du chargement. A partir d'un modèle analytique, les variations de ces paramètres ont été simulées, dans une plage acceptable, en cherchant à estimer la capacité de charge selon la théorie de Terzaghi. De plus, une analyse de sensibilité a été réalisée en utilisant le Second-Moment du Premier Ordre. Les résultats permettent de déterminer dans quelles conditions de rigidité de la fondation et du renforcement l'exécution de la technique est efficace en toute sécurité. Selon l'analyse des données en modèles réduits, on peut affirmer que le renforcement a assuré une plus grande stabilité, permettant la construction dans des sols de faible résistance.

Keywords: Reinforcement; shallow foundation; geosynthetic.

1 INTRODUCTION

Currently, with urban expansion, it is very common to build in masses that have low support capacity and high deformability. The solution to this geotechnical problem is the use of techniques to improve the performance of the mass.

Conventional treatment methods range from replacing part of the weak soil with a suitably thick layer of stronger granular fill, increasing the size of the foundation base, or a combination of the two methods, for example. However, a more economical alternative is the use of geosynthetics to reinforce the soil.

In the soil-structure-geosynthetic interaction mechanism, the synthetic material, which deforms according to the structure's request, adds a portion of tensile strength to the soil due to the friction developed. Particularly, in the case of shallow foundations laid on masses with low load capacity and high compressibility, the introduction of geosynthetics

provides an increase in support capacity and a significant reduction in settlements.

2 OBJECTIVES

The main objective of the article is to define the stiffness conditions of the mass and reinforcement in which the application of the technique, in the case of direct foundations, is efficient with safety and economy.

3 METHODOLOGY

The concept of soil reinforcement was initially published by Vidal (1969) and was consolidated in the pioneering work of Binquet and Lee (1975a, 1975b) with an evaluation of the behavior of sand mass reinforced with metal strips. Over time, with new requirements and technologies in relation to material, shapes and sizes, metallic strips were replaced by geosynthetics.

The Figure 1 below shows the configuration and parameters of a foundation reinforced with geosynthetic. The main parameters studied include depth of the first reinforcement layer (u), geosynthetic width (b), number of reinforcements (N), spacing between layers (h) and total reinforcement thickness (d).

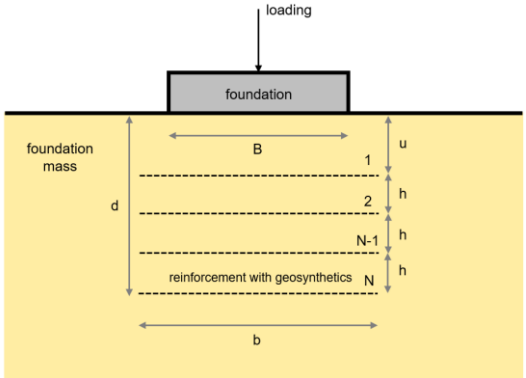

Figure 1. Configuration and parameters of a foundation reinforced with geosynthetic.Source: Adapted from Corrêa, 2021.

The performance of the reinforcement element, in this case, the geosynthetic element, is related to its sizing and the specification of the values of its relevant properties. In the case of reinforcing a shallow foundation, the following properties are worth highlighting: the tensile strength, the deformation at failure, the tensile stiffness modulus and creep behavior, as well as the adhesion and the friction angle of the soil-soil interface. geosynthetic.

The methodology for calculating the load capacity was defined based on the bibliography, considering the models proposed by Sharma et al. (2009). Initially, it was considered that the reinforced mass behaves similarly to a foundation on a mass with two types of soil.

Figure 2 presents the schematic section of a shallow foundation placed on soil.

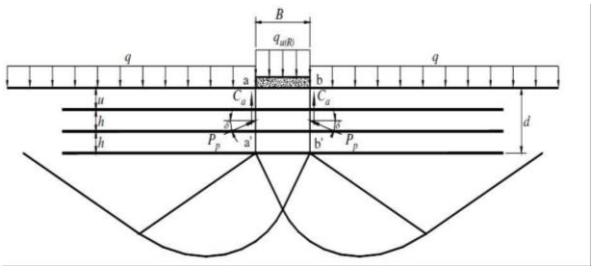

Figure 2. Similar failure in foundations laid on solid ground with two types of soil. Source: Sharma et al., 2009.

The failure mechanism is characterized by punching in the reinforcement layer followed by general shear failure in the unreinforced mass.

$$q_r = q_0 + \frac{2(C_a + P_p sen\delta_p)}{B} - \gamma_t d + \Delta q_t \quad (1)$$

where, q_r is the load capacity of the reinforced soil, q_0 is the load capacity of the unreinforced soil, C_a is the adhesion force, P_p is the force resulting from the passive thrust of the soil, δ_p is the angle of the passive force with the horizontal, which can be adopted as $0{,}5\varphi_r$, where φ_r is the angle of friction of the soil used as reinforcement, B is the width of the foundation, , γ_t is the specific weight of the layer of reinforced soil, d is the thickness of the layer reinforced and Δq_t is the increase in load due to the tension in the reinforcement.

The load capacity of a shallow square foundation on reinforced soil is then determined by the equation:

$$q_r = q_0 + \frac{4c_a d}{B} + 2\gamma_t d^2\left(1 + {}^{2D}/_{d}\right)\frac{K_s tan\varphi_r}{B} + \frac{4\sum_{i=1}^{N} T_i tan\delta_p}{B} - \gamma_t d \quad (2)$$

where, K_s is the punching thrust coefficient, T_i is the tensile force in the synthetic material and N is the number of reinforcement layers.

It is worth mentioning that, for this estimate, the traction of a geogrid of the Fortrac model, from Huesker, was considered, which has a traction resistance of up to 2500kN/m.

The punching thrust coefficient was obtained using the abacus proposed by Chen (2007), which relates K_s as a function of the friction angle.

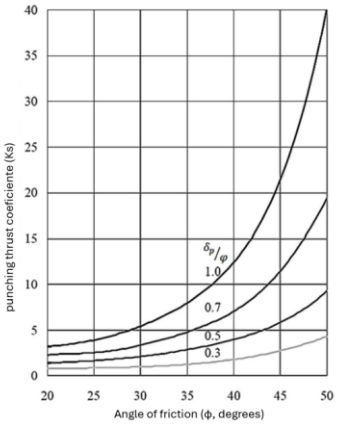

Figure 3. Punching thrust coefficient as a function of friction angle. Source: Adapted from Chen, 2007.

For the acceptability criterion of probabilistic analysis, the Brazilian standard does not specify numerically. The bibliography shows model evaluation criteria regarding the reliability index and probability of rupture. The tables below show the relationships found.

4 RESULTS AND DISCUSSION

In this sense, the first considering a medium-sized building, with an allowable load capacity $qadm = 200kPa$ and a 1 meter square footing and the other considering a large building, with a permissible load capacity $qadm = 500kPa$ and a 3 meter square footing.

It is worth mentioning that, for both cases, a rigid, square foundation was considered, based on a sand mass, reinforced with a geogrid. In the applied method, the input data are the average values and variances of the soil parameters, the geometric characteristics of the foundation, and the estimated values of the other soil parameters necessary for the deterministic analysis.

Therefore, the thickness of the minimum reinforcement layer was 0.5m and the maximum was 3m, varying from 0.5m to 0.5m. In addition, the base width (B) and specific weight (γ) were also considered.

From this, the First Order Second Moment method is applied, verifying the effect of varying the number of layers (N) and the thickness of the reinforced layer (d) on the probability of rupture and the reliability index.

The analysis considers that the foundation mass can be sand that is not very compact and moderately compact.

Some considerations are made in the literature about the massive configuration for this case. It was observed that the load capacity of the soil suffers an insignificant increase for conditions with more than six layers of reinforcement, a result confirmed by Das (1989) and Omar et al. (1993), which was also observed in this work.

Considering a soft mass, for the situation in question, the best reinforcement contribution occurs when the number of layers is equal to 2. From the graph below, it is also possible to see that the increase in the number of layers after this number, has not a significant effect.

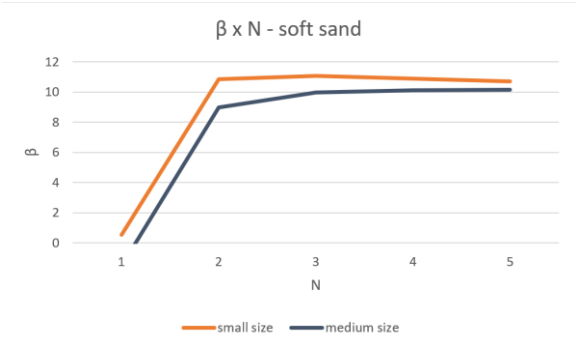

Figure 4. Behavior of the foundation mass vs. reliability index considering a soft mass in a small building and medium-sized building.

There is a consensus in the literature that the reinforcement length should be around 5B and the ideal number of layers is normally limited to up to 5. For higher numbers of layers, it has been demonstrated in the literature that there is no significant gain in capacity of the soil, only generating an increase in costs for the enterprise.

For the mass and reinforcement configurations considered in this analysis, it was possible to notice that, for all types of soil considered, and for the two loading conditions, when the number of layers is above

3, no significant increases in the index were generated. of reliability.

The graphs below show the behavior of the number of reinforcements for a less compact massif, a significant increase in the reliability index can be seen when including reinforcement (with just one layer).

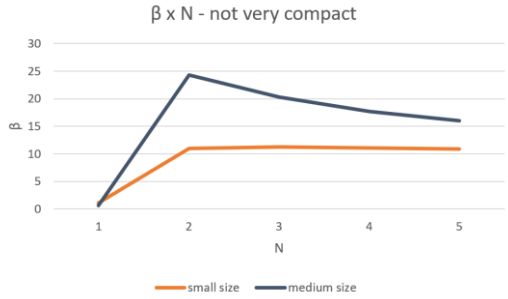

Figure 5. Behavior of the foundation mass vs. reliability index considering a less compact mass in a small building and a medium-sized building.

Furthermore, tests also demonstrated that for reinforcement to be efficient, the last layer must never be located at a depth greater than 2B. In this analysis, the depth of the reinforcement layer thickness reached 3 meters in both cases. Thus, it is possible to see graphically that, when a small building is considered, and therefore, the foundation is 1 meter wide, when the reinforcement exceeds 2 meters in thickness, there is no major influence on the reliability index.

The graphs below show the relationship between the reliability index and depth for the types of soil considered.

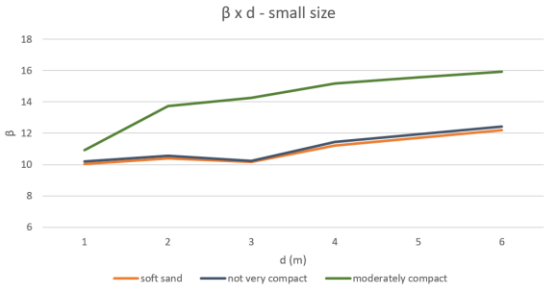

Figure 6. Behavior of the foundation mass vs. reliability index for a small building of a soft sand, not very compact and moderately compact.

The literature also shows that for direct foundations based on clay soils, Shin et al. (1993) and Omar et al. (1993) concluded that a good depth for the first layer of reinforcement is 0.4B, regardless of the anchorage length. The ideal length for anchoring was defined within the range of 4.5B to 5B. According to the authors, to influence the improvement of load capacity, the number of layers of reinforcement must be limited to 5, in addition the first layer of reinforcement must not be located at depths greater than 1.8B.

5 CONCLUSIONS

According to the analysis carried out, it is possible to state that the reinforcement substantially increases the load capacity and reduces the magnitude of settlements, allowing better behavior of the foundation from the point of view of resistance and deformability. The results suggest that the effectiveness of reinforcement is greater in masses with low support capacity.

However, increasing the number of reinforcement layers and the thickness of that layer beyond a specific number, 3 layers and 2.5m, does not produce a significant increase in load capacity.

Rate-dependent confined crushing in granular media

Écrasement confiné dépendant du taux dans les milieux granulaires

S.K. Das*
NIT Rourkela, Rourkela, Odisha, India
**dassoukat@nitrkl.ac.in*

ABSTRACT: Does granular material show strain rate-dependent response, especially with quasi-static loading conditions? The answer is both yes and no since it depends on various factors like particle shape, size and crushability. Such time-dependent behaviour in granular materials is extremely important in various industries where both particle crushing and loading rates are combined. The focus of the research has been to numerically exploit the strain rate effects at the grain scale level and link it with macroscopic response while simultaneously taking into account the evolution of particle size distribution during the fragmentation process. The numerical simulation of one-dimensional (1D) compression shows quasi-static loading, which presumably produces a rate-independent response, and can demonstrate significant rate-dependent features during particle crushing. The variation in the contact force distribution within the granular assembly at different loading rates, dictates the stress response and the crushing events. Relatively low strain rate compression favours homogeneous crushing involving a large number of particles that consequently reduces the strength via fragment rearrangement. Conversely, a high strain rate promotes localized crushing within fewer particles, and thus strain hardening is observed.

RÉSUMÉ: Les matériaux granulaires montrent-ils une réponse dépendante du taux de déformation, en particulier dans des conditions de chargement quasi-statiques ? La réponse est à la fois oui et non, car cela dépend de divers facteurs tels que la forme, la taille et la broyabilité des particules. Ce comportement dépendant du temps dans les matériaux granulaires est extrêmement important dans diverses industries où la fragmentation des particules et les taux de chargement sont combinés. L'objectif de la recherche a été d'exploiter numériquement les effets du taux de déformation au niveau de la granulométrie et de les relier à la réponse macroscopique tout en tenant compte simultanément de l'évolution de la distribution de taille des particules pendant le processus de fragmentation. La simulation numérique de la compression unidimensionnelle (1D) montre un chargement quasi-statique, qui produit vraisemblablement une réponse indépendante du taux, et peut présenter des caractéristiques significatives dépendantes du taux pendant le broyage des particules. La variation de la distribution des forces de contact au sein de l'assemblage granulaire à différentes vitesses de chargement dicte la réponse au stress et les événements de broyage. Une compression à faible taux de déformation favorise un broyage homogène impliquant un grand nombre de particules, ce qui réduit par conséquent la résistance via le réarrangement des fragments. En revanche, un taux de déformation élevé favorise un broyage localisé dans moins de particules, et donc un durcissement par déformation est observé.

Keywords: Crushable; granular; rate-dependent; DEM; quasi-static.

1 INTRODUCTION

Strain rate plays a major role in determining the time-dependent responses (creep, stress relaxation, delayed plasticity, etc.) of geomaterials (Karimpour and Lade, 2013; Lade and Karimpour, 2010). Contrary to the popular belief that time dependency is prevalent among the cohesive geomaterials (clay, rock and concrete) only, a list of laboratory experiments has confirmed that significant time effects are observed in granular soils as well (Augustesen et al., 2004; Kongkitkul et al., 2008).

The importance of rate-dependent behaviour in granular materials has been recognized since the mid of the 20th century. Initially, the primary focus was limited to the overall macroscopic strength-stiffness gain with increasing strain rate (Casagrande and Shannon, 1948; Lee et al., 1969). However, researchers have recently paid greater attention towards understanding the micromechanical attributes behind the macroscopic rate dependency of granular materials.

Crushability is considered to be the primary grain-scale parameter that controls the rate-dependent response in granular materials (Augustesen et al., 2004). Researchers surmise that during rate-dependent loading, stress waves traverse through the grain contacts leading to individual grain reorienting itself to accomplish a new equilibrium position. The time difference between such processes (wave propagation

and post-crushing rearrangement) leads to rate-dependent material response (di Prisco and Imposimato, 1996).

In order to explore the causes of crushing and to track the mechanism inside the sample during rate-dependent breakage, advanced experimental procedures such as X-rays, CT scans, etc. are being used nowadays (Andò et al., 2013; Mahbub and Haque, 2016; Parab et al., 2014). However, some crucial micromechanical parameters that control the variables influencing the breakage of particles and the inherent time dependency are still hard to achieve. The essence of the present work revolves around the micromechanical understanding of the interaction between time dependency and particle breakage. Various micro-micro-scale parameters such as stress-strain profile, contact force distribution, spatial contact force and particle size distribution are analyzed in order to explain the time-dependent behaviour of the crushable granular materials.

2 MODELLING SCHEME

In a crushable granular assembly, the micromechanical processes associated with strain rate-dependent fragmentation cannot be assessed through conventional geotechnical experiments. In addition, it is hard to distinguish the effects of post-fragmented particles on the rate-dependent response during progressive loading. To cope up with such experimental limitations, strain rate-dependent loading and grain crushing are simulated numerically using discrete element modelling (DEM). Besides studying the micro-processes, DEM simulation also helps to overcome the limitation of laboratory experiments by mimicking test conditions where grain breakage is restrained.

2.1 Model geometry and applied strain rate

In the present study, one-dimensional (1D) compression (oedometric compression) (Figure 1a) on a granular assembly consisting of particles with a diameter ranging between 1 mm to 3 mm, is simulated using 2D DEM using Particle flow code (PFC-5, Itasca) (Itasca, 2015). At the first stage of modelling, the program generates a square box filled with 1932 disc-shaped circular particles (Figure 1a). The initial width of the box is 0.15 m, and the height is 0.15 m. The particles are generated randomly without allowing any overlap with a near-uniform grain size distribution (*gsd*) having d_{50} of 2 mm and initial porosity of 20%. Uniform *gsd* is chosen because it is well known that such an assembly is prone to crushing as compared to an assembly with a wide range of particles due to a reduced cushioning effect (Ben-Nun et al., 2010; Karimpour and Lade, 2010).

Two different monotonic strain rates (0.2/s and 20/s) corresponding to a high and a low strain rate are adopted. The strain rates are chosen such that during the analyses the samples remain in the quasistatic regime which is checked by measuring the inertial number at different strain levels (Figure 1b). The lateral movement of the horizontal walls is restricted to ensure 1D compression. To eliminate any boundary effect-induced stress anisotropy, the specimen dimensions and the size of the particles are chosen such that the scale ratio, which is the ratio of the side of the specimen to the mean particle diameter d_{50} comes out as $\geq$ 25 for all the analyses (Cheng et al., 2017).

2.2 Material parameter and breakage model

The selected material parameters, listed in Table 1, are chosen such that the macroscopic and microscopic responses of the granular assembly resemble the experimentally observed behaviour of coarse sand.

Table 1. DEM model input parameters.

Parameter	Value
The density of the	2650
Particle diameter (d) (m)	0.001 - 0.003
Initial porosity (n_0)	0.2
The initial number of	1932
Normal and shear stiffness	1×10^9
Inter-particle friction	0.6
Largest grain diameter	0.003
Weibull modulus (m)	4.0
Material tensile stress	14.5

The present study has followed the updated replacement method described by Ben-Nun and Einav (Ben-Nun and Einav, 2008). Here, a critical force is calculated based on the assigned Brazilian breakage criterion and compared against the acting normal forces at any instant of time. Once the average contact normal force on a grain exceeds the threshold breakage force, the particle is deleted and replaced by a set of smaller particles (Figure 1c). The fragmented particle volume (area in case of 2D) is increased quickly to regain the original volume of the mother particle to ensure the conservation of mass (Figure 1d).

3 RESULTS AND DISCUSSIONS

3.1 Stress-strain response

Axial stress-strain responses under one-dimensional compression at strain rates $\dot{\varepsilon}_a$=0.2/s & 20/s are depicted in Figure 2 for both non-crushable and crushable granular groupings. Simulations proceeded until around 5% strain due to increasing computational demands at higher strain levels due to excessive crushing. Typically, axial stress rises with strain in granular samples during confined 1D compression without a clear differentiation between elastic and plastic changes. Crushable granular materials largely reflect this but with sporadic fluctuations because of pronounced crushing incidents. For non-crushable granules (Figure 2a), stress ascends more swiftly during high strain rate compression.

At lower rates ($\dot{\varepsilon}_a$=0.2/s), compression occurs with minimal strength gain until 1.5% axial strain. However, by 4%-5% axial strain, both strain rate responses align in stress magnitude. Stresses in crushable samples deviate consistently throughout (Figure 2b). The high strain rate response in crushable specimens follows the non-crushable sample response until 3% axial strain, then strengthens. Conversely, the crushable specimen under a low strain rate softens post 3.5% axial strain compared to its non-crushable counterpart. A consolidated stress-strain outcome is shown in Figure 2c, highlighting these observations. The deviations between crushable and non-crushable responses stem from rate-dependent particle crushing.

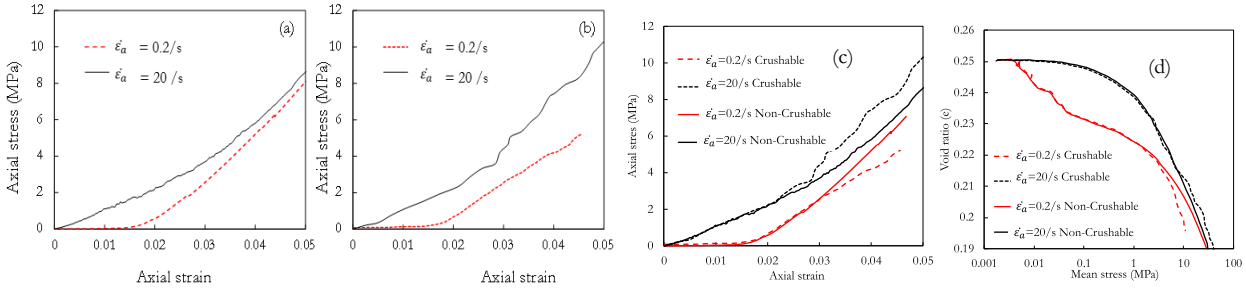

Figure 2. Axial stress vs. axial strain response for (a) non-crushable and (b) crushable granular materials; (c) combined axial stress-axial strain (d) combined void ratio-mean stress response for crushable and non-crushable granular material.

Thermodynamically, if fragmentation prevails, energy dispersed through compression decreases, leading to hardening (Wu et al., 2016). Yet, current simulations suggest strain rates can alter this behaviour by affecting the overall crushing in the sample. The sample can show hardening or softening in stress-strain behaviour (Figure 2c) and dilation or compression in volumetric behaviour (Figure 2d) due to the combined effect of rate and crushing.

3.2 Crushing response

To track the development of crushing influenced by different strain rates, gsds are plotted in Figure 3a, corresponding to different strain levels for two strain rate scenarios. Plotting gsds is a conventional way to quantify the amount of crushing in a sample before and after a compression test. The gsds at a low strain (2%) are almost mirror images of the initial gsd regardless of the strain rate settings because of the absence of any crushing. As loading progresses, higher crushing is observed under a slow strain rate i.e. $\dot{\varepsilon}_a$=0.2/s, whereas it remains visibly less for the high strain rate case. This

illustrates a pattern: a faster loading rate results in lesser crushing and vice versa.

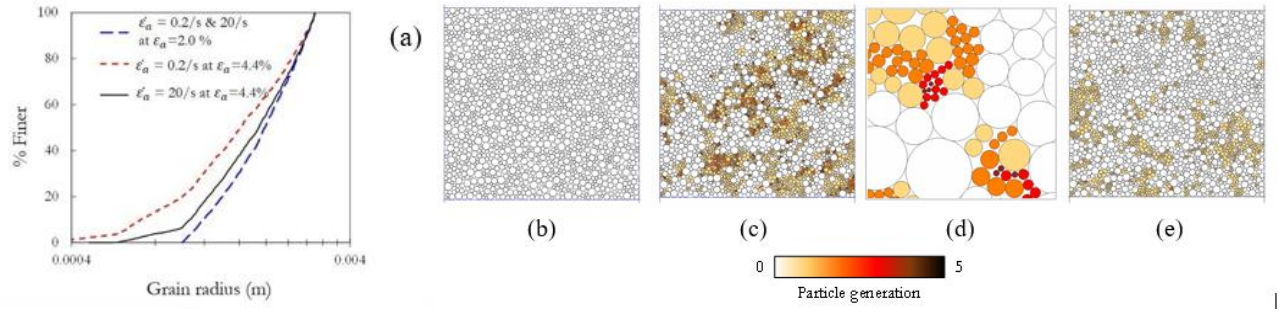

Figure 3. (a) Evolution of grain size distribution at two strain levels 0.02 and 0.044. Evolving crushing topology (b) initial state, at strain 2% for $(\dot{\varepsilon}_a = 0.2/s)$ *and* $(\dot{\varepsilon}_a = 20/s)$ *(c) advanced stage at strain 4.4% for* $(\dot{\varepsilon}_a = 0.2/s)$ *(d) Up to fourth generation of particles in the zoomed figure* $(\dot{\varepsilon}_a = 0.2/s)$ *(e) at strain 5.0% for* $(\dot{\varepsilon}_a = 20/s)$.

Images of the crushed DEM samples under both low and high strain rates are depicted in Figure 3(b-e). Notable variations in crushing progression between the two strain rate scenarios are evident as loading advances (4.4% strain). With faster loading, crushing has primarily yielded the initial particle generation (Figure 3e), while at a slower rate, crushing has progressed up to its fourth cycle (Figure 3c-d).

3.3 Contact force distribution

In order to explore the micromechanics behind such time-dependency along with crushing, contact force distribution is traced at different stages of loading (Figure 4). The non-crushable samples with different loading rates give a similar response when the loading reaches an advanced stage (strain 4.4%, Figure 4a) which indicates granular materials are less sensitive to time-dependent loading, especially at the quasi-static regime. Hence, the axial stress difference also reduces (Figure 2a). However, the responses are dissimilar in the case of the crushable granular samples (Figure 4b) since both the samples, have different rates of compression, and possess different numbers of particles due to crushing.

In the simulations, the prescribed breakage criterion is controlled by the average normal contact force on particles. Increased modal contact force density, as seen in Figure 4a, implies more uniform crushing in low strain rate samples, unlike the high rate sample where the wider contact force distribution suggests that less number of particles are carrying the majority of the load. Therefore, the overall force is distributed among a larger number of particles for low rate sample and hence a softening is observed in the macroscopic stress-strain profile.

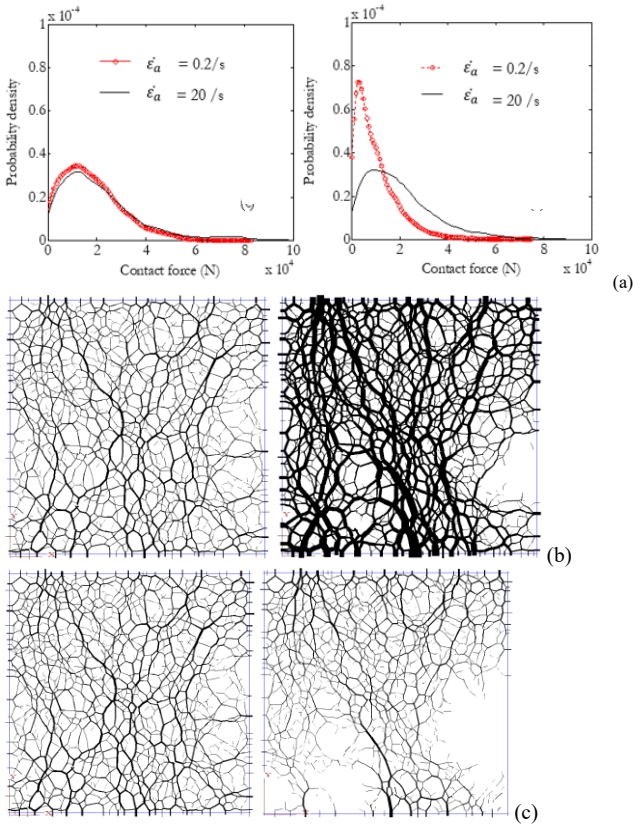

Figure 4. Contact force distribution at strain level 0.044 for non-crushable (left) and crushable sample (right) Force chain at 2% strain for (b) $(\dot{\varepsilon}_a = 0.2/s)$ *(c)*$(\dot{\varepsilon}_a = 20/s)$*; at stress level 581 kPa for (a)* $(\dot{\varepsilon}_a = 0.2/s)$ *(b)* $(\dot{\varepsilon}_a = 20/s)$.

Figure 4b-c reveals force chain distributions in granular assemblies at the same axial strains and stress levels respectively. At 2% axial strain, high strain rate samples exhibit thicker contact forces than their slower counterparts (Figure 4b). At a uniform 581 kPa stress, force chains are homogeneously distributed in low rate samples unlike the high rate sample where the same stress is heterogeneously distributed around the boundaries of the sample (Figure 4c). Slow strain rate samples allow more particle interactions, leading to homogeneous contact force distribution resulting in

extensive crushing, followed by strength reduction. In high-strain rate samples, localized crushing results in material densification and hardening.

4 CONCLUSIONS

The present study offers a vivid picture of the rate-dependent response of granular material using DEM. It shows the micromechanical insights of the crushable and non-crushable granular assemblies while subjected to strain rate-dependent loading. The following conclusions can be drawn from the present investigation.

For non-crushable granular materials, the strain rate sensitivity is pronounced in the low strain level, whereas, at the higher strain it attains the same stress irrespective of the rate of loading.

In the case of crushable granular materials subjected to slow strain rate compression, a large number of particles undergo crushing, since homogeneous contacts between the particles are established. Crushing increases the number of contacts which consequently reduces the mean contact force in the sample. Hence, the overall strength is reduced.

On the contrary, the high-rate sample gains strength because of localized crushing-induced material densification around the sample boundaries followed by sample hardening.

Slog: an open geotechnical software

Slog: un logiciel libre pour le calcul géotechnique

J. de Sauvage*
Université Gustave Eiffel, Bron, France
**jean.de-sauvage@univ-eiffel.fr*

ABSTRACT: In the era of complex numerical modelling, the geotechnical engineering practice always resort to simpler numerical tools, exhibiting the key phenomena. Such software is important for teaching since it allows to better understand the principles underlying the design of structures. They are also important for expertise or research on the one hand because they are easy to use and on the other hand because they establish a clear link between the assumptions made and the results. Most of this software is distributed under proprietary licenses, generating a "black box" effect and offering little flexibility to take a particular situation into consideration. From a teaching point of view, it is often useful to consider aberrant hypotheses in order to show their consequences. The Gustave Eiffel University is therefore developing geotechnical calculation software, entitled Slog. Open access and developed with Python, a widely used language, this software aims to federate a community of user-contributors, particularly among geotechnical teachers and students. In order to be able to easily compare different potential structures on the same site or, conversely, to be able to assess the relevance of a structure in different sites, the user is led to independently define the ground model and the anthropogenic actions. The intersection between both is carried out automatically, allowing the user to easily modify the properties of one or the other automatically. This flexible and scalable process is useful for teaching. The detailed example of the study of the stability of reinforced soils is presented here.

RÉSUMÉ: À l'ère de la modélisation numérique complexe, la pratique de l'ingénierie géotechnique recourt toujours à des outils numériques plus simples, mettant en évidence les phénomènes clés. De tels logiciels sont importants pour l'enseignement puisqu'ils permettent de mieux comprendre les principes sous-tendant le dimensionnement des ouvrages géotechniques. Ils sont également importants pour l'expertise ou la recherche d'une part parce qu'ils sont faciles à utiliser et d'autre part parce qu'ils établissent un lien clair entre les hypothèses formulées et les résultats. La plupart de ces logiciels sont distribués sous licences propriétaires, générant un effet de « boîte noire » et offrant peu de flexibilité pour prendre en compte une situation particulière. D'un point de vue pédagogique, il est souvent utile de considérer des hypothèses aberrantes afin d'en montrer les conséquences. L'Université Gustave Eiffel développe ainsi un logiciel de calcul géotechnique, intitulé Slog. En libre accès et développé avec Python, langage très utilisé, ce logiciel a pour vocation de fédérer une communauté d'utilisateurs-contributeurs, notamment parmi les enseignants et étudiants géotechniques. Afin de pouvoir comparer facilement différentes structures potentielles sur un même site ou, à l'inverse, pouvoir évaluer la pertinence d'un ouvrage dans différents sites, l'utilisateur est amené à définir indépendamment le modèle de sol et les actions anthropiques. L'intersection entre les deux s'effectue automatiquement, permettant à l'utilisateur de modifier facilement et automatiquement les propriétés de l'un ou de l'autre. Ce processus flexible et évolutif est utile pour l'enseignement. L'exemple détaillé de l'étude de la stabilité des sols renforcés est présenté ici.

Keywords: Geotechnical software; open access; teaching modelling.

1 INTRODUCTION

Complex numerical modeling, specifically by finite elements, is today widely developed in geotechnical engineering, integrating the most complex constitutive laws and, when used correctly, produce predictions in accordance with field observations (El Arja, 2020). However, in engineering practice, geotechnical calculation still uses simplified tools exhibiting the key phenomena. As an example, the c-phi reduction method makes it possible to determine the safety factor of a slope but, in practice, most studies are carried out using traditional tools considering a bundle of potential failure surfaces and evaluating, for each of them, the ratio between motor and resistant efforts (Pilot, 1966).

Such software is important for teaching since it allows a better understanding of the principles underlying the design of structures. With some commercial finite element software students can have the impression that "you just have to press a button". However, it would be simplistic to locate the sole interest of simplified digital tools there. They are also important for expertise or research on the one hand

because they are easy to use and on the other hand because they establish a clear link between the calculation hypotheses retained and the results produced. The goal here is not to condemn this or that calculation method but to emphasize the usefulness for the geotechnical engineer of having access to all the calculation hypotheses and being able to modify them as he wishes, avoiding the "black box" effect. Open software provides the flexibility to take into consideration a particular situation. From an educational point of view, it also makes it possible to integrate aberrant assumptions into the calculation in order to show their consequences. Open software dedicated to geotechnical engineering can be found but they are generally devoted to one specific application. One can think for example about geotecha (https://github.com/rtrwalker/geotecha) for the consolidation of soft soils or PyGeo (https://github.com/CalvinNeo/PyGeo) for the recognition of structural surfaces.

Université Gustave Eiffel is therefore developing geotechnical calculation software, entitled Slog, freely distributed through its GitHub platform (https://github.com/Ifsttar/Slog). Developed using Python, a widely used programming language, this software aims to bring together a large community of user-contributors, particularly among geotechnical teachers and students. Accessible to the greatest number of people through the use of Python, Slog aims to respond to the difficulties of geotechnical engineers by taking into account the specificities of this domain.

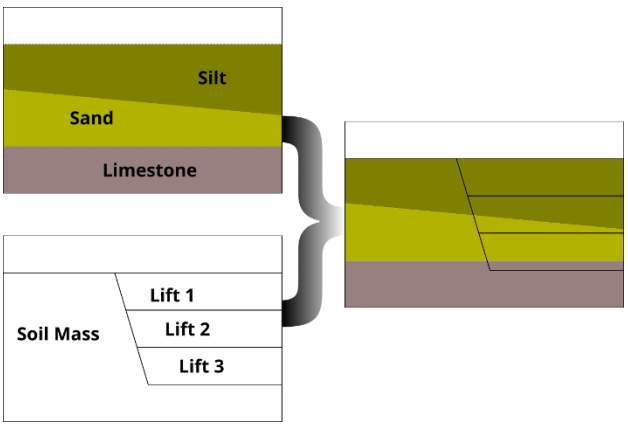

Figure 1. Domains considered for the study of a soil-nailed wall (top left: geology, bottom left: anthropogenic actions, right: intersection.

In order to be able to easily compare different potential geotechnical assets on the same site or, conversely, to be able to evaluate the relevance of an asset in different sites, the user is led to independently define a "geology" (partition of the space in blocks of soil) and an "asset" (set of anthropogenic actions). The intersection between "geology" and "asset" is made automatically, allowing the user to easily modify the properties of one or the other automatically. This flexible process proves useful on an educational level. A detailed example is presented here: the study of the stability of soil-nailed wall. This example is deliberately simplistic to make the screen output easier to read. In practice, a large number of slices must be considered and, depending on the method chosen (Fellenius, Bishop, perturbations, etc.) the geometry of the failure surface must be adapted.

2 DESCRIBING THE TERRAIN

One of the specificities of geotechnical engineering is to be placed in a merely known environment: the soil in place. This particularity leads to the definition of a terrain model, based on the study of geological maps, on the analysis of geotechnical surveys and laboratory tests as well as on extrapolations. During a project, the terrain model can therefore evolve according to new investigations and the revision of some assumptions. At the same time, the project itself may have to evolve between the different study phases. Where most software requires defining *ab initio* a domain divided into homogeneous zones, Slog suggests defining two distinct domains, one representing the terrain model (constituted of „Faciès" objects) and the other representing the anthropogenic actions, *i.e.* the building project. The software itself generates a unique domain for the study by realizing the intersection of the two domains thus defined by the user.

As an example, let us consider a soil-nailed wall excavation project in a layered soil (See Figure 1). The user first defines a Geology consisting of a layer of Silt above a layer of Sand, itself above a layer of Limestone. Secondly, the user defines the domains linked to anthropogenic action: a "Soil Mass" domain corresponding to the part of the soil that the project plans to leave in place and three domains "Lift1", "Lift2" and "Lift3 » corresponding to successive excavation lifts. The software then generates by automatic intersection the division of the space usable for the calculations. The automatic intersection algorithm is taken from (Foster et al., 2019).

If additional tests carried out during the design study indicate that the sand layer actually has a higher modulus than the initial estimate, the user can simply modify the Geology and the terrain model automatically inherits the new properties. In the same way, if during the project, it is decided to review the dip of the sand/silt interface, this can be done on the Geology and the calculation of the intersection with the Anthropic Action immediately gives a new terrain model for the calculation. Note that, when constructing

a Geology, Slog determines if all the facies constitute a partition of space, that is to say that they cover all the points of the calculation domain on the one hand and that they do not overlap each other. If this condition is not met, an error message is returned.

The Object Oriented programming implemented in Slog allows all the elements of a class to inherit the properties of this class (see Figure 2). In particular, the Geology facies like the anthropogenic geometry elements all inherit from the Polygon class. The latter are therefore the boundaries of the different geotechnical elements and the fact that they share properties facilitates the calculation of their intersection but above all allows them to be defined according to a similar procedure (list of vertices given in the trigonometric direction). This procedure facilitates interfacing between Slog and software such as GMSH (Geuzaine and Remacle, 2009), an open access mesher. Although the calculations carried out in Slog do not *a priori* require a mesh, the GMSH geometry module is very useful for generating geometries.

The Class Diagram presented in Figure 2 also allows to understand the overall structure of the terrain model. What has been presented so far actually constitutes a given configuration of the project. In particular, the division presented in Figure 1 assumes that 3 excavation lifts have been carried out but nothing prevents a subsequent configuration from including an additional lift or an embankment at the wall tip. A project is therefore a list of Configurations. Finally, for each Configuration, a set of structural elements (Geotextiles, nails, walls, etc.) are superimposed on the terrain which must also interface with the terrain model.

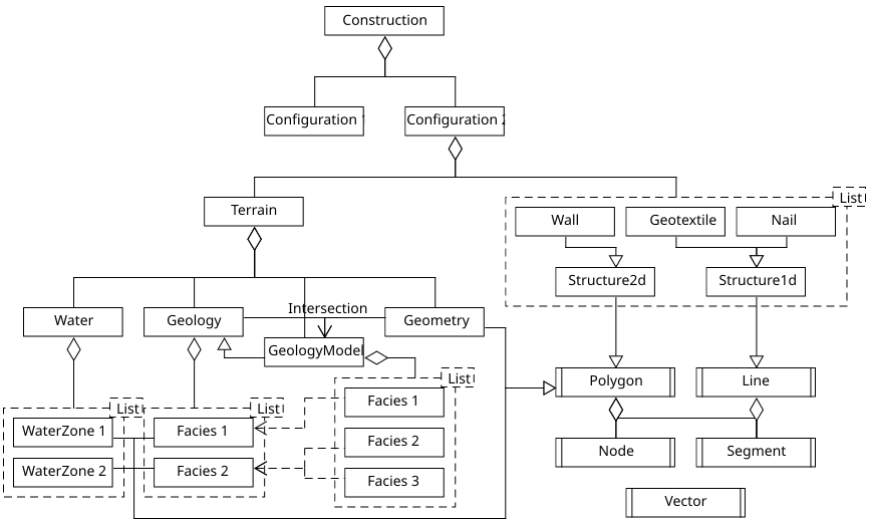

Figure 2. Slog structuring class diagram.

3 MANAGING STRUCTURAL ELEMENTS

Here we call structural elements the anthropogenic elements that can be taken into account in the calculation. We can thus think of nails, reinforcements or geotextiles in the case of reinforced soil support but more generally, these structural elements include diaphragm walls, sheet piles or even gravity walls. We could also think of injected soil elements but the strong proximity between "2d Structure" type objects and "Facies" type objects allows the user, depending on the needs of his calculation, to decide if he prefers represent jet grouting as a structural element or an element of Geology.

Note at this point that the current version of Slog is purely two-dimensional. A three-dimensional version is expected to be developed but has not yet been developed and, in engineering practice, many calculations are carried out in 2D. Thus, the truly linear elements (nails, anchors, etc.) and the surface elements (geotextiles, sheet piles, etc.) are both represented by linear elements. Unlike most geotechnical software, the structural elements being defined in parallel with the terrain model, they have no impact on the Geology and the Facies crossed remain continuous. In order to separate the upstream soil and the downstream soil of a sheet pile for example, it is necessary to translate this separation into "Anthropogenic actions". Through the intersection of Geology and Anthropogenic Actions, this discontinuity will then be apparent in the domain study. From an educational point of view, this choice makes it possible to impose on the user a reflection on the nature of the structural elements that he introduces.

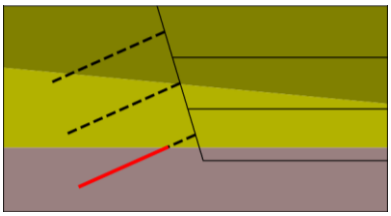

Figure 3. Addition of Nail objects and highlighting of intersection between the nails and the limestone (red).

In Figure 3 the example of the excavation presented above is completed by nails. The Polygon intersection function allows, in this case, to automatically determine the intersection between the nails and the Limestone layer. In practice, *nail3.intersect_polygon(limestone)* returns the list of intersections between nail 3 and the limestone layer. This list can contain several elements (if the limestone layer is concave) but it can also be empty (for example, if the nails were horizontal in our example). In any case, the following bit of code can be applied:

```
> for elem in clou3.intersect_polygon(limestone):
>     elem.ConstituveLaw = FZhao_limestone_grout
```

By having defined *FZhao_limestone_grout* as the law of Frank and Zhao (Frank and Zhao, 1982) with parameters corresponding to the interface between limestone and grout, these two lines of code make it possible to attribute the correct mechanical characteristics to this interface and without worrying about whether this interface actually exists. This robustness makes it possible to easily modify the geometry chosen for the project. Indeed, if we ultimately decide to consider horizontal nails, it is not necessary to redefine all of the interfaces.

4 CALCULATIONS METHOD

4.1 Choice of a failure surface and determination of safety factor

In order to determine the stability of the soil-nailed wall studied, we first choose a failure surface. On Figure 4, the example of logarithmic spirals is given but Slog includes also circles and slip lines. Currently, the definition of failure surfaces is not implemented in classes with dedicated methods and it only relies on functions defined in a separate modulus, called *slog_calculations.py*.

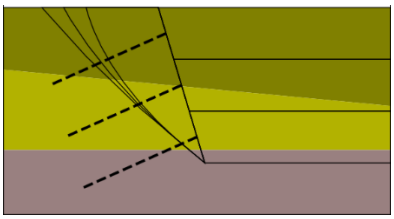

Figure 4. Computation of three logarithmic spiral failure surfaces.

In order to use the slice method, the failing block is subdivided into slices. This is enabled by the polygon intersection functions of Slog. Note that the slices thus created, inheriting from the Polygon class, are intrinsically equipped with the *self.area* method allowing the calculation of their surface and therefore their weight. On Figure 5, a slice intercepts different Facies and the calculation of its weight is easily done by subdividing it into the intersections with these different Facies.

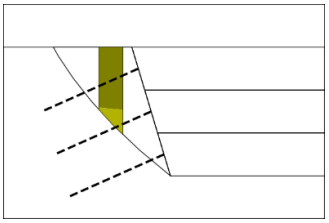

Figure 4. top left, choice of a rupture surface and slice zones; top right, automatic creation of the slices used for the stability calculation; bottom, intersection with nail.

In order to apply the slice method, it is essential to determine the resisting forces along the failure surface at the base of each slice. This requires the knowledge of the length of the slice basis as well as the maximal friction which can be mobilised on this basis. Here the basis is defined as the intersection between the failure line, the slice and the Facies *sand*. Therefore it inherits parameters from the Facies *sand* and, among them, the friction angle ϕ. This process is implemented in the function *sliceResistance* in the package *slog_calculations.slope_stability.*

In the case of nailing, specific stabilizing forces linked to the presence of nails must be added to the friction forces. To do this, it is necessary to determine the position of the intersection between the failure surface and the nails. This is, once again, done easily through the intersection method.

Once this point has been determined, the stabilizing force to be included in the slope stability calculation is computed using the intersection between the nail and the stable soil mass since the intersection inherits from its „parents“.

4.2 Modelling the nails

One way to determine these stabilizing forces is to integrate the equation of the beams along the nail taking into account the movement of the failing block and the friction at the interface between the nail and the different Facies it crosses (Delmas et al, 1986). To do this, it is necessary to implement a finite difference type calculation along this nail, which must therefore be discretized. The discretization of the nail is easily done using the linspace tool from the numpy library. As mentioned in section 3, Nail type objects have a method allowing them to define their interface with Facies. Each element of the discretized nail can therefore be assigned to a given interface and thus be provided with a friction model (e.g. Frank and Zhao law).

4.3 Encapsulation of calculation methods

Currently, the only calculation available in Slog is the slope stability (with or without nails) and it is not implemented in an Object Oriented way. Before including new calculations, the developers focus on the transition from functions packages to method libraries. However, the example of soil-nailed walls hereby presented aims at illustrating the powerfulness of the Object Oriented description of the Geology and the Geometry.

5 CONCLUSIONS

The Slog software, built in the form of a Python library offers a structure that is both robust and easy to use, allowing on the one hand the use of existing geometric libraries and on the other hand the creation of numerous calculation models. Development under a free license also allows the free use of the code by students, teachers and professionals alike, allowing everyone to have access to the entire calculation code and therefore to understand and question the assumptions underlying the results obtained. However, the „black box“ effect of geotechnical softwares can only be removed if the open source code is accompanied by a clear theroritical manuel. A significant effort has still to be carried out regarding this point.

Finally, open development should allow the creation of various modules but also the federation of a community of user-contributors around tools such as a forum. Apart from the educational interest of this software, Slog can then become a medium for disseminating research results. One of the main specificities of geotechnical calculation is based on the definition of the terrain model and close attention will be paid to this by developers.

ACKNOWLEDGEMENTS

The development of Slog was made possible by the work of Jad Sadek, as part of a mission from the Junior-Enterprise X-Projets. Through his availability, his alertness and his rigor, he made it possible to set the heart of the terrain model system.

ABSTRACT: The seminal work of Nogami & Novak in 1976 for the harmonic response of end-bearing piles in homogeneous soil strata, is extended in this study to generate a benchmark semi-analytical model for piles in vertically inhomogeneous soils. Following the classical dynamic model and previous work to treat soil inhomogeneity under static axial loads, the pile is modelled as a rod, and the soil as an approximate continuum of the Tajimi type. The approximation resides in reducing the number of the elastodynamic equations which govern the soil motion to one, which satisfies the equilibrium in the vertical direction, by eliminating certain stresses and displacements in the soil. This is based on the physically motivated assumption that the vertical normal and shear stresses in the soil are essentially controlled exclusively by the vertical component of the soil displacement, for the axisymmetric problem at hand. Soil inhomogeneity is introduced via a generalized power law variation of the soil shear modulus with depth. The proposed generalized formulation can treat any type of soil inhomogeneity by employing in the solution pertinent shape functions to capture the soil modes, which satisfy the boundary conditions of the pile-soil system. The solution is expressed in terms of series and includes: (i) displacements and stress fields in the soil and along the pile-soil interface; (ii) displacements and normal stresses along the pile length, and (iii) dynamic pile head stiffness and damping.

RÉSUMÉ: Le travail fondateur de Nogami et Novak en 1976 sur la réponse harmonique des pieux d'appui en sol homogène est étendu dans cette étude pour générer un modèle semi-analytique de référence pour les pieux dans les sols verticalement inhomogènes. En suivant le modèle dynamique classique et les travaux précédents sur le traitement de l'inhomogénéité du sol sous des charges axiales statiques, le pieu est modélisé comme une tige et le sol comme un continuum approximatif de type Tajimi. L'approximation réside dans la réduction du nombre d'équations élastodynamiques qui régissent le mouvement du sol à une seule, qui satisfait à l'équilibre dans la direction verticale, en éliminant certaines contraintes et déplacements dans le sol. Cela repose sur l'hypothèse physiquement motivée selon laquelle les contraintes normales et de cisaillement verticales dans le sol sont essentiellement contrôlées exclusivement par la composante verticale du déplacement du sol, pour le problème axisymétrique en question. L'inhomogénéité du sol est introduite par le biais d'une variation généralisée de la loi de puissance du module de cisaillement du sol avec la profondeur. La formulation généralisée proposée peut traiter tout type d'inhomogénéité du sol en utilisant, dans la solution, des fonctions de forme pertinentes pour capturer les modes du sol, qui satisfont aux conditions aux limites du système pieu-sol. La solution est exprimée en termes de séries et comprend: (i) les champs de déplacement et les champs de contrainte dans le sol et le long de l'interface pieu-sol; (ii) les déplacements et les contraintes normales le long de la longueur du pieu, et (iii) la rigidité et l'amortissement dynamiques de la tête de pieu.

Keywords: Complex dynamic pile stiffness; analytical model; generalized soil inhomogeneity; soil-pile interaction.

1 INTRODUCTION

The consideration of dynamic soil-structure interaction (SSI) is crucial to evaluate the seismic vulnerability of structures. It is well known that the assumption of a fixed-base condition at the foundation level causes an underestimation of the natural period of superstructures (Mylonakis and Gazetas, 2000). During the last decades, a variety of methods of various levels of accuracy and sophistication have been developed to take into account the effect of the foundation (e.g., Veletsos and Meek, 1974; Gazetas, 1984; Maravas et al., 2014; Anoyatis and Lemnitzer, 2017b; 2023; Cui et al., 2022). On one hand, powerful finite element commercial software can handle a variety of complex soil–pile configurations, such tools can be computationally expensive. On the other hand, analytical models provide a cost-effective alternative solution for soil–pile interaction analysis and allow engineers to test different design scenarios and optimize the pile and superstructure for given soil conditions. For dynamic analyses in particular, analytical models are further free of the selection of appropriate mesh size and absorbing boundaries (e.g. viscous boundaries, infinite elements, boundary elements) to control radiation conditions and avoid spurious reflections. The proposed solution models the pile as a rod, following the classical strength-of-materials solution, and assumes perfect bonding at the soil-pile interface. The soil is modelled as an approximate continuum of the 'Tajimi' type, applied by Novak and Nogami to piles in homogeneous soils under axial and lateral inertial loading (Nogami and Novak, 1976; Novak and Nogami, 1977). Such models reduce the number of dependent variables by eliminating certain stresses and displacements in governing elastodynamic equations.

Key to the Tajimi approach in axial mode is the physically motivated assumption that the vertical normal, σ_z, and vertical shear stresses, τ_{rz}, in the soil, are controlled solely by the vertical displacement u_z (Mylonakis, 2001; Anoyatis and Mylonakis, 2012; Anoyatis et al., 2013, 2019, 2023). The influence of radial displacement is neglected by Nogami and Novak, 1976 and is considered to be vanishingly small by Mylonakis, 2001. This reduces the two equations of classical axisymmetric elasticity to one. The solution derived in this work extends the study of Anoyatis et al., 2023 to treat any type of soil inhomogeneity, applying pertinent mathematical techniques.

The soil-pile system response is expressed in terms of a generalized Fourier series of eigenfunctions (soil modes) along the vertical coordinate. The soil modes are obtained by employing appropriate shape functions to tackle soil inhomogeneity. Apart from its intrinsic theoretical interest, the proposed model has distinct advantages over other simple analytical models, e.g., Winkler-type solutions, (Novak, 1974; Scott, 1981; Anoyatis and Lemnitzer, 2017a) and more advanced models (e.g., Anoyatis et al., 2019, 2023) as it tackles any type of soil inhomogeneity in the vertical direction, consider the continuity of the medium in the vertical direction, and is free of empirical constants. The predictive power of the model is verified against the recent work of Anoyatis et al., 2023 for given types of inhomogeneity.

2 SOIL-PILE SYSTEM

The problem investigated in this study is depicted in Figure 1: A single, solid vertical pile of length L and circular cross section of diameter d is embedded in an inhomogeneous soil layer that rests on a rigid rock. The pile is subjected to an axial harmonic force of amplitude P and cyclic frequency ω, that is $P\,e^{i\omega t}$.

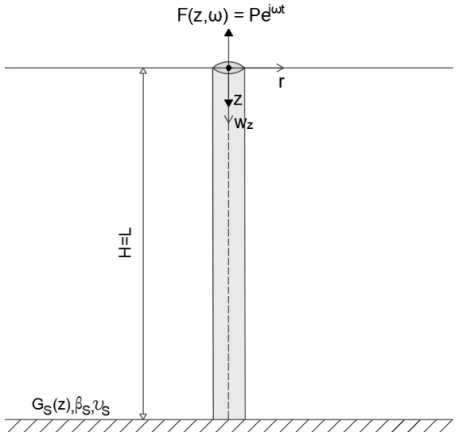

Figure 1. Problem under investigation.

The pile is modelled as an elastic rod of Young's Modulus E_p and mass density ρ_p. The soil layer is characterized by its soil mass density ρ_s, Poisson's ratio ν_s, and hysteretic material damping β_s. Soil inhomogeneity is considered through a depth-dependent complex-valued shear modulus $G_s^* = G_s(z)(1 + 2i\beta_s)$. The variation of soil shear modulus with depth is expressed by a power law function:

$$G_s^* = G_{sH}^* \left[b + (1-b)\left(\frac{z}{H}\right) \right]^n \qquad (1)$$

In Equation (1), z is the vertical coordinate, n and b are dimensionless inhomogeneity parameters. b links the stiffness at the surface of the layer G_{s0} to the stiffness at its base G_{sH}, that is, $b = (G_{s0}/G_{sH})^{1/n}$.

3 SOIL ANALYSIS

The equilibrium of vertical forces acting on a soil element in axisymmetric conditions in cylindrical coordinates yields the governing differential equation:

$$\frac{\partial(\tau\, r)}{\partial r} + r\,\frac{\partial \sigma}{\partial z} + r\,\rho_s\,\frac{\partial^2 u}{\partial t^2} = 0 \tag{2}$$

where $u = u_z(r,z,\omega)$ is the vertical displacement, $\tau = \tau_{rz}(r,z,t)$ and $\sigma = \sigma_z(r,z,t)$ are the vertical soil shear and normal stresses. The first and the second terms represent axisymmetric shearing and compression stresses, respectively, while the third term accounts for the development of inertial force due to vertical oscillations. The stress-displacement relations for axisymmetric deformations in a Tajimi - type continuum are written as in Nogami and Novak, 1976; Anoyatis et al., 2023:

$$\sigma \approx -\eta_s^2\, G_s^*\,\frac{\partial u}{\partial z} \tag{3a}$$

and

$$\tau \approx -G_s^*\,\frac{\partial u}{\partial r} \tag{3b}$$

where $\eta_s^2 = 2(1-\nu_s)/(1-2\nu_s)$ is a compressibility parameter related to the Tajimi approximation, as discussed in the earlier works of Mylonakis, 2001 and Anoyatis et al., 2019. Substituting Equations (3) into Equation (2), and considering harmonic displacement $u = u(r,z,\omega)e^{i\omega t}$ the equilibrium equation is rewritten in terms of soil displacements as:

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u}{\partial r}\right) + \eta_s^2\frac{\partial}{\partial z}\left[\frac{G_s^*(z)}{G_{sH}^*}\frac{\partial u}{\partial z}\right] + \left(\frac{\omega}{V_{sH}^*}\right)^2 u = 0 \tag{4}$$

where $V_{sH}^* = V_{sH}\sqrt{1+2i\beta_s}$ is the complex shear wave velocity in the soil at depth $z = H$.

The solution to Equation (4) can be expressed as the product of the solutions of the two ordinary differential equations that arise from the application of the method of separation of variables:

$$R'' + \frac{1}{r}R' - q^2 R = 0 \tag{5a}$$

and

$$(\bar{G}_s\Phi)' + \lambda\bar{G}_s\Phi + \left(\frac{\omega}{V_{pH}^*}\right)^2\Phi = 0 \tag{5b}$$

where $\bar{G}_s = G_s^*(z)/G_{sH}^*$ expresses in a dimensionless form the profile of soil stiffness and V_{pH}^* is the complex propagation velocity of P-waves in the soil medium at depth $z = H$. q and λ are variables that emerge from the application of the method of separation of variables, and they are linked through the compressibility coefficient as $q = \eta_s\sqrt{\lambda}$. The general solution to Equation (5a) has been obtained in the past work of (Mylonakis, 2001). Equation (5b) is a general Sturm-Liouville equation and $\Phi = \Phi(z,\omega)$ are the associated soil modes, the solution of which has been found in the recent work of (Anoyatis et al., 2023) for two patterns of soil inhomogeneity $n = 1$ (linear) and $n = 2$ (parabolic). The solution derived in this paper can treat any type of inhomogeneity. The technique used to find the soil modes will be shown in detail in Section 3.1.

Displacements and shear stresses in the soil are expressed in terms of generalized Fourier series as:

$$u = \sum_{m=1}^{\infty} B_m\, K_0(q_m r)\, \Phi_m \tag{6}$$

and

$$\tau = \sum_{m=1}^{\infty} G_s^*\, B_m\, q_m\, K_1(q_m r)\, \Phi_m \tag{7}$$

where B_m are Fourier coefficients, and K_0 and K_1 are the modified Bessel functions of the second kind, zero and first order, respectively.

3.1 Soil modes

Equation (5b) can be solved by expressing the soil modes $\Phi = \Phi(z,\omega)$ in terms of a Fourier series as:

$$\Phi_m(z,\omega) = \sum_{j=1}^{\infty} S_j(\omega)\,\Psi_j(z) \tag{8}$$

in which S_j are the Fourier coefficients to be determined, and $\Psi_j(z)$ is a shape function of the form $cos(\alpha_j z)$ in which $\alpha_j = (\pi/2H)(2j-1)$.

Fundamental to this analysis, is the orthogonality identity of the shape functions:

$$\int_0^H \Psi_j\,\Psi_k\,dz = 0,\ j \neq k \tag{9}$$

Substituting Equation (8) into Equation (5b), making use of Equation (9) and, using the concept of the weak formulation, yields the following equation:

$$\sum_{j=1}^{\infty} S_j^m \int_0^H \bar{G}_s\,\Psi_j'\,\Psi_k'\,dz - \sum_{j=1}^{\infty} S_j^m\,\lambda_m \int_0^H \bar{G}_s\,\Psi_j\,\Psi_k\,dz - \left(\frac{\omega}{V_{pH}^*}\right)^2 S_k^m \int_0^H \Psi_k^2\,dz = 0 \tag{10}$$

The eigenvalues, λ_m, and the corresponding eigenvectors, S_j^m, depend on the frequency and can be obtained by solving the system of equations which emerges from Equation (10), ω time. The real and the imaginary part of the first soil mode at $\omega = 0$, $\omega = 0.5\,\omega_1$, $\omega = \omega_1$ for a damped soil medium ($\beta_s = 0.05$), $b = 0.25$ and $n = 1$ are illustrated in Figure 2, using $N = 50$ modes. Each mode is normalised by its value at $z = 0$.

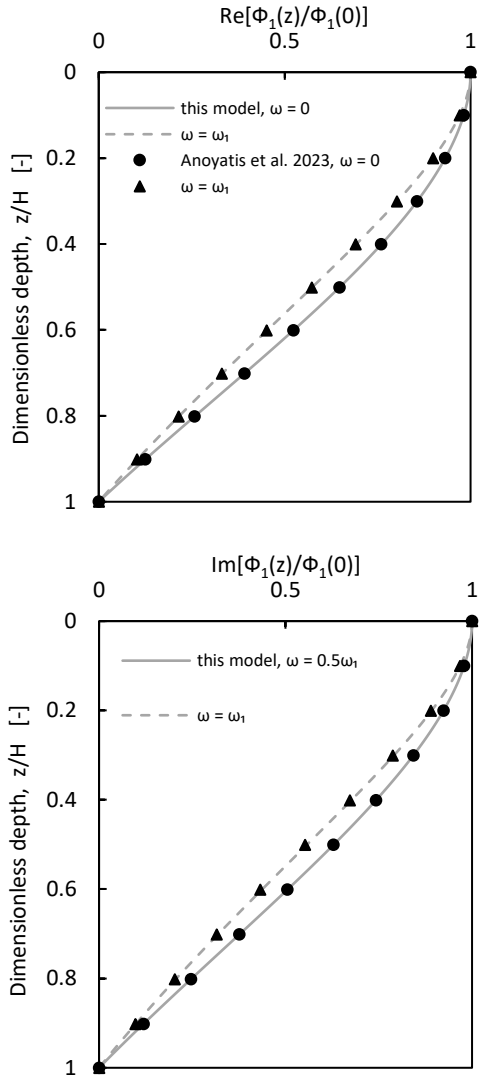

Figure 2. Real and imaginary parts of the first soil mode. Comparison with the closed form solution of Anoyatis et al., 2023.

Figure 3 shows the derivative of the first soil mode, $\Phi_1'(z,\omega)$, which has been normalised respect to its value at $z = H$. The dynamic effect on the soil mode can be clearly seen at the resonance frequency ($\omega = \omega_1$). Evidently, the results obtained by using the approximate proposed model with the semi closed-form solution developed by Anoyatis et al., (2023) are in excellent agreement.

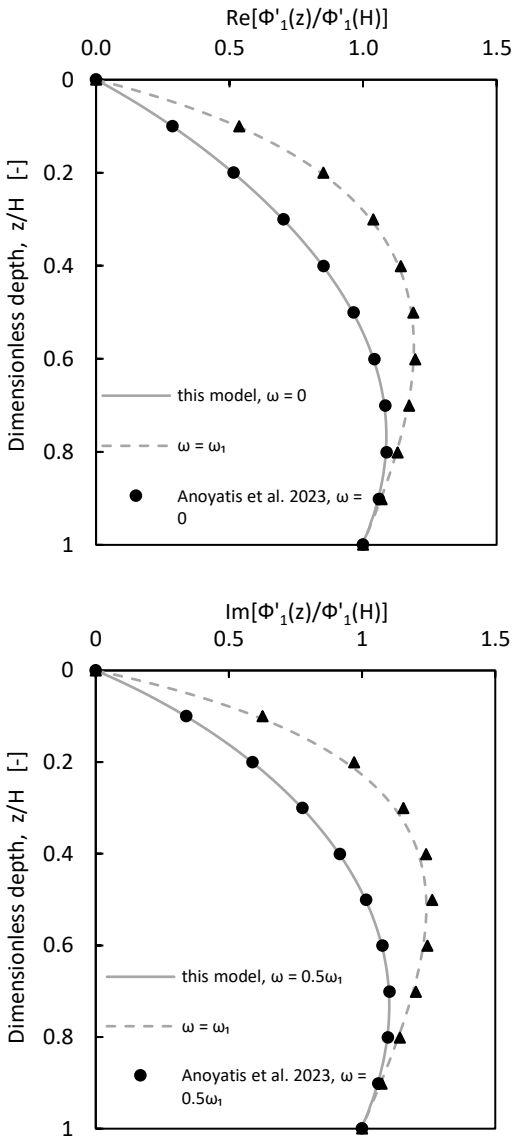

Figure 3. Real and imaginary parts of the derivative of the first soil mode. Comparison with the closed form solution of Anoyatis et al., 2023.

4 SOIL-PILE INTERACTION ANALYSIS

The equilibrium of vertical forces acting on a pile segment yields the equation of the pile motion.

$$-E_p A_p \frac{\partial^2 w}{\partial z^2} + \pi d \tau_0 - \omega^2 \tilde{m}_p w = F \qquad (11)$$

where A_p is the pile cross sectional area, $\tilde{m}_p = \rho_p\, A_p$ is the pile material density, and $\tau_0 = \tau(r = d/2, z, \omega)$ is the vertical shear stress at the soil-pile interface. $F = F(z,\omega)$ can be expanded in Fourier series as:

$$F(z,\omega) = \sum_{m=1}^{\infty} f_m\, G_s^*\, \Phi_m(z,\omega) \qquad (12)$$

where the coefficients f_m are obtained by applying the orthogonality of the soil modes:

$$f_m = \int_0^H F(z,\omega)\,\Phi_m\,dz \,/ \int_0^H G_s^*\Phi_m^2\,dz \quad (13)$$

Substituting Equations (6), (7) and (12) into Equation (11), considering perfect bonding at the soil-pile interface and utilizing the weak form, yields the following equation which allows the evaluations of the coupled B_m Fourier coefficients:

$$E_pA_p\sum_{m=1}^{\infty}B_m\,K_0(s_m)\int_0^H\Phi_m'\Phi_k'\,dz\;+ \\ 2\pi\,s_k\,B_k\,K_1(s_k)\int_0^H G_s^*\Phi_k^2\,dz\;- \\ \omega^2\,\tilde{m}_p\sum_{m=1}^{\infty}B_m\,K_0(s_m)\int_0^H\Phi_m\Phi_k\,dz \\ = P\,\Phi_k(0) \quad (14)$$

where $s_m = q_m d/2$ is a dimensionless parameter.

The pile response w is given by the following expression:

$$w(z,\omega) = \sum_{m=1}^{\infty}B_m\,K_0(s_m)\,\Phi_m(z,\omega) \quad (15)$$

5 PILE STIFFNESS AND DAMPING

The pile head stiffness is defined as the ratio of the force P acting on the pile head over the corresponding displacement:

$$K^* = P\Big/\sum_{m=1}^{N}B_m\,K_o(s_m)\,\Phi_m(z,\omega) \quad (16)$$

where $K^* = K^*(\omega)$ is a complex-valued stiffness. The real part represents the dynamic stiffness, and the ratio of the imaginary part over twice its real part, the damping ratio $\zeta(\omega) = Im[K^*(\omega)]/2Re[K^*(\omega)]$.

Results of the normalised dynamic pile head stiffness with normalised excitation frequency, for two values of E_p/E_{sH}, for a pile slenderness ratio $L/d = 25$, and for three types of inhomogeneity i.e., $n = 0.5$; $n = 1$, and $n = 2$ are shown in Figure 4. The soil has a stiffness ratio between the surface and the bottom $b = 0.25$ (Eq. (1)), damping ratio $\beta_s = 0.05$ and Poisson's ratio $\nu_s = 0.4$. The values for the pile-soil material density ratios are $\rho_p/\rho_s = 1.25$ for $E_p/E_{sH} = 100$ and $\rho_p/\rho_s = 1.5$ for $E_p/E_{sH} = 1000$. The number of modes used is 50.

The proposed predictions are compared against results from the work of Anoyatis et al., 2023. It is shown that the models are in perfect agreement. Some general trends are observed: for frequencies below the resonance, the dynamic stiffness decreases monotonically with frequency. Such attenuation is stronger for stiffer soils, i.e., $E_p/E_{sH} = 100$. At resonance, a drop in stiffness is observed. Beyond the resonance, the stiffness increases. For $n = 0.5$ the values of the dynamic pile stiffness are higher than the case of $n = 1$ and 2 since the corresponding soils are stiffer. As a consequence, the resonance is reached at higher values of excitation frequency.

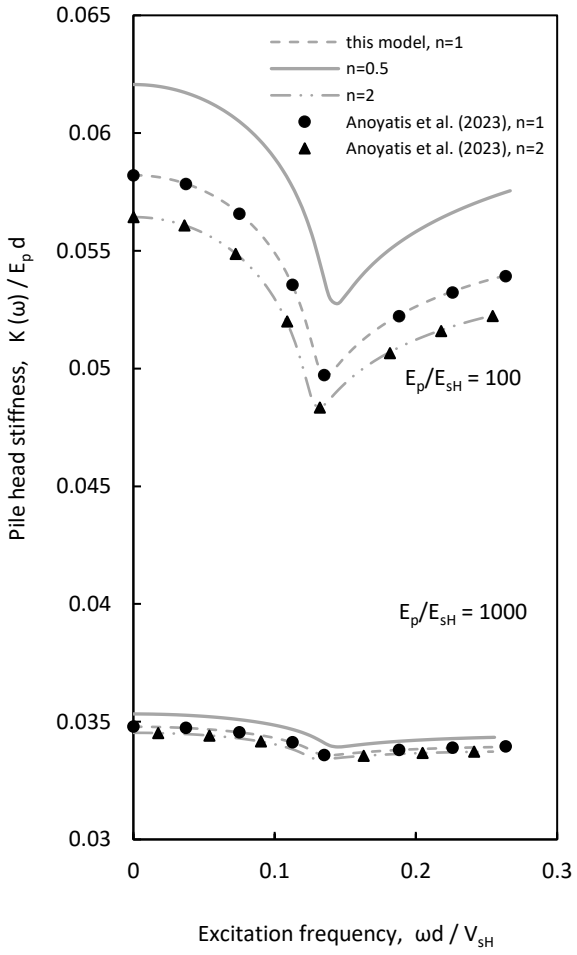

Figure 4. Variation of normalized dynamic pile head stiffness with normalized excitation frequency, for different types of soil inhomogeneity. Comparison with results from Anoyatis et al., 2023.

Figure 5 plots the variation of the pile head damping $\zeta(\omega)$ with the dimensionless frequency ω/ω_1 for $n = 0.5$ and for selected values of pile slenderness ratios. For all cases examined, the damping is practically unaffected by frequency in the low-frequency range. In the vicinity of the first resonance, it exhibits a jump, marking the emergence

of travelling waves in the medium, and thus radiation damping.

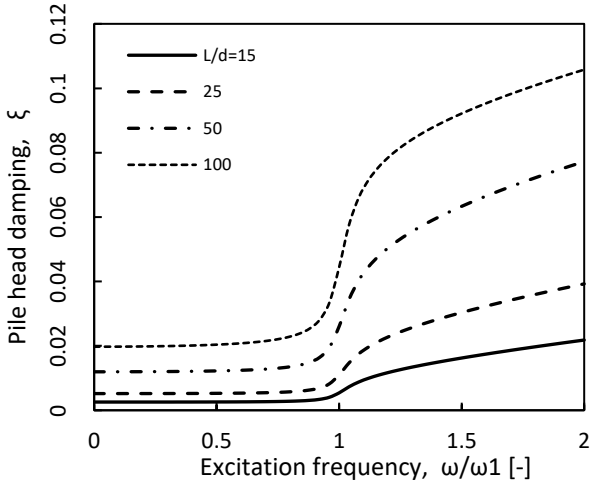

Figure 5. Variation of damping ξ with excitation frequency ω/ω_1. $n = 0.5, b = 0.25,\ \beta_s = 0.05,\ \nu_s = 0.4, E_p/E_{sH} = 1000,\ \rho_p/\rho_s = 1.5$.

6 CONCLUSIONS

A novel semi-analytical solution is derived for the analysis of end-bearing piles that are embedded in a generalized vertically inhomogeneous soil stratum over a rigid base that is subjected to an axial harmonic force. The proposed approximate-continuum solution uses pertinent trigonometric functions to approximate the actual shape functions. This approach is shown to generate results that are in perfect agreement with results obtained from the more rigorous model developed by Anoyatis et al, 2023, limited to specific types of soil inhomogeneity, linear and parabolic variation of the soil stiffness with the depth. The proposed model, with minor modifications, could further take into account transient loads and generate time histories of the pile response, displacement and stress fields.

The Python scripts and data of this study will be made openly available on the KU Leuven webpage titled 'Soil–Structure Interaction Toolkit', at the URL: https://bwk.kuleuven.be/projects/SSItk/, which aims to host scripts and data for a wide range of commonly met soil-pile interaction problems.

ABSTRACT: Multi Temporal Interferometric Synthetic Aperture Radar (MT-InSAR) is a remote sensing technique used for monitoring surface deformations with high precision and spatial resolution. This study aims to evaluate the effectiveness of this technique for tunnelling monitoring by complementing data gathered by conventional optical monitoring and comparing the resulting dataset with FE numerical analysis using Plaxis3D software. The comparison generally reveals good agreement, indicating the potential of MT-InSAR for monitoring tunnelling-induced displacements. The integration of MT-InSAR with conventional monitoring and numerical analysis can provide a comprehensive understanding of the behaviour of the ground during the excavation process, contributing to the development of efficient and safe tunnelling practices.

RÉSUMÉ: Le radar interférométrique à synthèse d'ouverture multitemporelle (MT-InSAR) est une technique de télédétection utilisée pour surveiller les déformations de surface avec une précision et une résolution spatiale élevées. Cette étude vise à évaluer l'efficacité de cette technique pour la surveillance du creusement des tunnels en complétant les données recueillies par le contrôle optique conventionnel et en comparant l'ensemble des données obtenues avec l'analyse numérique par éléments finis à l'aide du logiciel Plaxis3D. La comparaison révèle généralement une bonne concordance, ce qui indique le potentiel de la technique MT-InSAR pour la surveillance des déplacements induits par le creusement de tunnels. L'intégration de MT-InSAR à la surveillance conventionnelle et à l'analyse numérique peut fournir une compréhension complète du comportement du sol pendant le processus d'excavation, contribuant ainsi au développement de pratiques de creusement de tunnels efficaces et sûres.

Keywords: Tunnelling; MT-InSAR; finite element; displacements; monitoring.

1 INTRODUCTION

The excavation of large diameter tunnels in urban areas may represent a potential risk for existing buildings, particularly in complex geological conditions and in densely exploited underground space. Monitoring tunnelling induced displacement during construction is therefore required to ensure the structural health of the above buildings and nearby infrastructures and to guarantee their serviceability levels. Datasets gathered from monitoring can be used to validate the numerical analysis of complex soil-structure interactions during tunnelling, thus enabling a better support to corrective measures during construction.

Nowadays, in addition to conventional optical prisms and levelling devices, buildings' movements can be monitored by processing data from synthetic aperture radar (SAR) satellites. The ability of radar satellites to measure the field of displacements induced by tunnel excavations in urban areas has quickly improved in the last decade (Perissin et al., 2012; Barla et al. 2016; Milillo et al, 2018; Giardina et al., 2018). High-resolution SAR satellites, such as the COSMO-SkyMed (CSK) or TerraSAR-X constellations, have been launched and new and more advanced ones are going to be. At the same time, data processing techniques have been implemented in research and commercial platforms and the use of Multi-Temporal Interferometric Synthetic Aperture Radar (MT-InSAR) technique for structural health monitoring of buildings and infrastructures has emerged (Ferretti et al., 2011; Caprino et al., 2023).

In this paper, ground and buildings movements measured by MT- InSAR analyses of satellite images recorded during tunnel construction for a branch of metro Line 9 (now Line 10 south) in the city of

Barcelona (Spain) are used to complement data gathered by conventional optical monitoring and compared with the results of Finite Element analysis of the effects of tunnelling on a residential building in the area. This allows to discuss the potential and limitations of MT-InSAR to provide additional information for the verification and validation of numerical models in urban tunnel construction.

2 CASE STUDY

2.1 Ground conditions and works

The paper refers to the case study of a mechanised tunnel excavation in the city of Barcelona. The excavation, belonging to the Line 9 (L9) project, was executed with a 12.06 m diameter Earth Pressure Balance (EPB) Tunnel Boring machine (TBM) and was part of the L9 branch connecting Barcelona to its port logistics activities zone. Tunnelling, in this area, started from Foneria station and was headed towards Ildefons Cerdà station (from the left to the right in Figure 1), about 700 m apart from the first one. The tunnel alignment crosses a densely urbanised area with a cover to diameter ratio, C/D, in the range 2.5-3.0. The geological profile along the alignment (Figure 1) involved Quaternary soft alluvial and detrital deposits (QM, QS and QR), overlaying Miocene hard formations (M1U and M2L) consisting of siltstone and argillite. The water table is located in the alluvial deposits at a depth of about 8 m from the ground surface and at 22-28 m above the tunnel crown.

The first 100 m or so of the excavation were quite challenging due to the presence of mixed ground conditions at the tunnel face, including a thin layer of highly permeable gravels at the tunnel crown. This contingency caused loss of pressure in the EPB cutter head and, as a result, some overexcavation was experimented just before the boring machine approached a well monitored 10-storey residential framed building (Figure 1) having a 2-level underground parking garage. Below the building, tunnelling became even more difficult because the alignment curves (radius of curvature of 300 m) right where the building south façade is located (Figure 1). The challenging tunnelling conditions led to volume losses in the range 0.5-1.0% that gave rise to significant ground movements. As the EPB machine moved towards the north façade of the building (from Block B towards Block A in Figure 2b), the mixed ground conditions at the tunnel face gradually changed to approximately uniform conditions with the harder Miocene materials occupying nearly the whole excavation section. Also, the tunnel depth slowly increased contributing to lower observed volume losses.

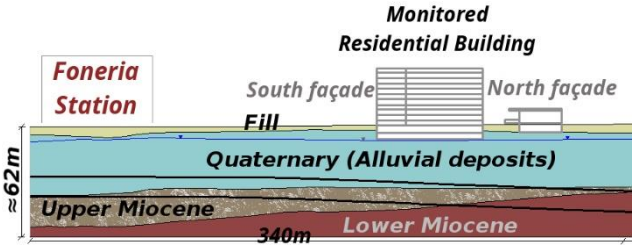

Figure 1. Geological profile in the area of study.

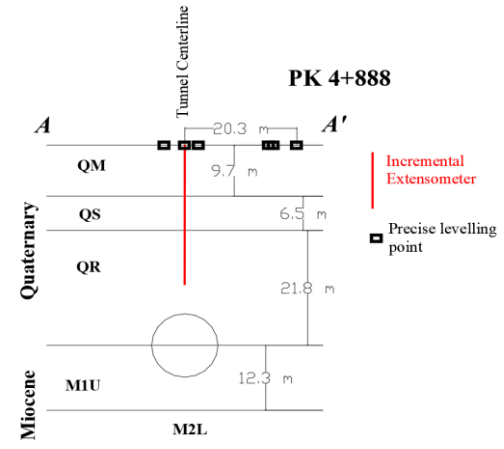
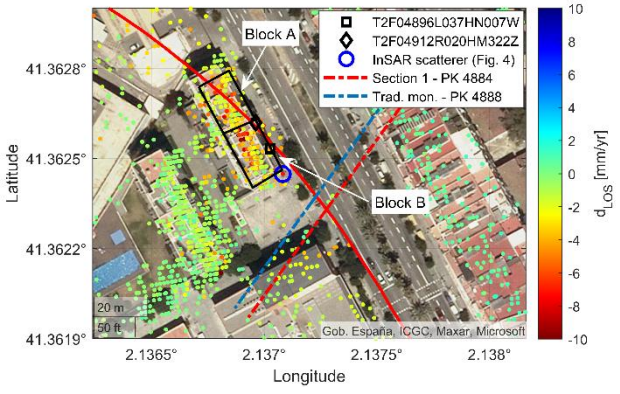
2.2 Monitoring

A comprehensive instrumentation system was set up to monitor tunnelling operations. Manual and automatic instruments were used to measure surface and subsurface ground movements (Figure 2a), as well as 3D movements of the framed building and its basement (Di Mariano et al., 2021).



(a)



(b)

Figure 2. (a) Conventional monitoring at PK4888; (b) InSAR scatterers, selected monitoring sections and LPs.

To complement the database of measurements taken with conventional monitoring, for the purpose of this work MT-InSAR data were also used (Figure 2b). 32 SAR images were acquired by the TerraSAR-X full archive in Stripmap mode in an ascending path

direction, from January 7th 2009 to October 2nd 2012, and processed by TRE-Altamira by SqueeSAR®, an advanced algorithm for surface displacement detection developed by Ferretti et al. (2011). Further details on the methodology can be found in Di Mariano et al. (2024).

3 NUMERICAL MODELLING

To study the complex Soil Structure Interaction (SSI) phenomenon produced by tunnelling below the monitored residential building, fully coupled 3D numerical analyses were carried out with the commercial Finite Element (FE) code PLAXIS 3D. For simplicity purposes, a geological profile with horizontal stratigraphic layers was considered (Figure 3). The numerical model reproduces the tunnel curved alignment, the operating parameters of the EPB boring machine and the installation of the lining. It also reproduces the conicity of the shield, the weight of the back-up trailer and the eccentric position of the lining with respect to the EPB shield. The model replicates the excavation process with a step-by-step procedure that allows to consider the segments width. Nevertheless, the segmentation of the lining in the tunnel transverse direction is not considered.

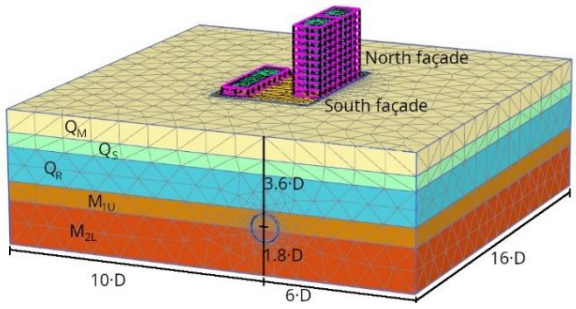


Figure 3. FE model (D = tunnel diameter).

A non-linear type of the hyperbolic constitutive model, formulated in the frame of friction hardening plasticity, was used to represent the behaviour of all ground materials. The model considers the nonlinear ground stiffness decay as shear strains increase. On the other hand, linear-elastic laws were assumed for all structural elements, which were far from failure conditions.

Table 1. Soil parameters.

	(kN/m³)	c' (kPa)	,	$E_{50,ref}$ (MPa)	$E_{ur,ref}$ (MPa)	$E_{oed,ref}$ (MPa)	m	K (m/s)
Q_M	17	0	29	16	48	12	0.9	5e-4
Q_S	19.6	0	34	11	33	10	0.65	4e-4
Q_R	21	1	30	15	46	10	0.6	1e-5
M_{1U}	21	1	36	46	180	25	0.8	2e-5
M_{2L}	22.5	10	33	278	833	100	0.9	1e-7

The main geomechanical parameters used in the analysis reported in this paper are shown in Table 1. They were inferred from both laboratory and in situ investigations. A few attempts have been made to adjust the initial estimate of soil stiffness parameters to adequately reproduce the ground movements observed along the line, also considering the effect of contingency ground treatments that were undertaken during the underpassing of the residential building in the model.

4 RESULTS

Figure 4 shows a comparison between the settlement time history evaluated by processing SAR images of the scatterer, circled in blue in Figure 2, and the corresponding settlement calculated by FEA. In the same figure the settlement profile of the close LP T2F4896L037HN007W has also been added for further comparison. Overall, the numerical results match well both InSAR and optical levelling data.

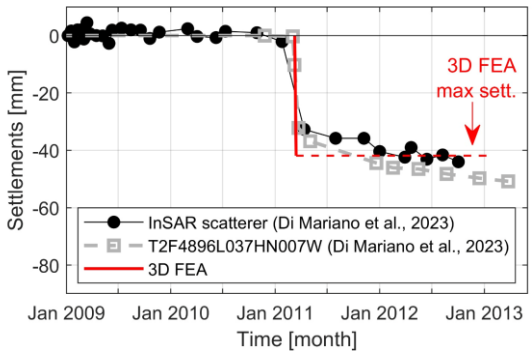

Figure 4. Time series comparison between InSAR scatterer, levelling point and corresponding FEA output.

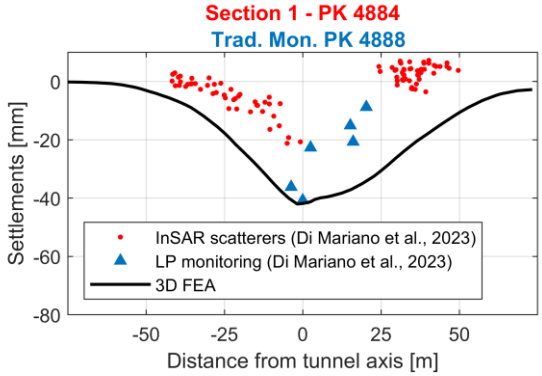

Figure 5. Settlement trough: satellite data (InSAR), conventional optical levelling (LP) and FEA results.

In Figure 5 the displacement of Permanent Scatterers and Levelling Points after the full passage of the TBM across the transverse section at PK4888 are compared with the computed settlement profile. The PS displacements along the satellite LoS, gathered

in a 10 m wide band across the section, were projected along the vertical direction, assuming that the ground displacements due to tunnelling were predominantly vertical. This assumption may lead to an acceptable error, lower than 5% on the maximum settlement (Della Ragione et al., 2023). The levelling points (same Figure 5) also confirm that such error is not large.

The FE calculated profile matches only two LP measurements, while it generally overestimates the overall settlement trough that, despite the scatter of the MT-InSAR data, emerges clearly from both sets of measurements. Further inspection is needed to understand such discrepancy and validate the model.

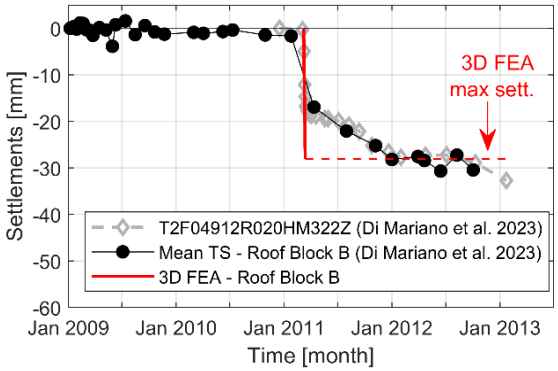

Figure 6. Block B roof displacement (InSAR, LP, FEA).

Finally, in Figure 6 the time histories of displacement of the PSs that belong to the roof of Block B is averaged and compared both with that of the prism T2F04912R020HM322Z, on the same building roof, and with the corresponding numerical calculation. A good matching can be appreciated in this case.

5 CONCLUSIONS

The paper compares the movement monitored by processing SAR images collected by the satellite TSX1 (TerraSAR-X) during the construction of Line 9 of Barcelona metro with the numerical results of the construction process obtained with the commercial code Plaxis3D. Data gathered during construction by conventional optical monitoring are also shown. The comparison indicates the potential of MT-InSAR to monitor the effects of tunnel excavation in urban areas. Even though MT-InSAR cannot substitute terrestrial measurements, since the latter provides a reliable benchmark for the former, it can indeed complement optical monitoring as a mean to verify and validate numerical modelling. This is possible due to the large amount of data than can be retrieved by processing images even long after the work completion.

ACKNOWLEDGEMENTS

SAR images were processed by TRE-Altamira as part of a research agreement with Barcelona TECH (UPC). The authors are grateful to the company and in particular to Dr Jordi Sanchez, Dr Beatriz Royo and Dr Stefano Cespa for their support. The optical survey data were kindly provided by Infraestructures de la Generalitat de Catalunya, S.A.U.

A t-z approach for the design of axially loaded piles in consolidating soil

Une approche t-z pour la conception de pieux chargés axialement dans un sol consolidant

A.E. Detlefsen, A. Franza*, K.K. Sørensen
Aarhus University, Aarhus, Denmark

*anfr@cae.au.dk

ABSTRACT: This paper presents a t-z model for the analysis of vertically loaded single piles in consolidating soil, using a beam on hyperbolic vertical springs whose tangent stiffness is a function of the normalised mobilised stress in the soil (affected by the consolidation-induced increase in effective stresses) and load history (accounting for loading, unloading and reversed loading). The validation is carried out with published experimental and analytical results. Next, a parametric study illustrates, for floating and end-bearing piles, the temporal evolution of settlement and neutral plane, considering with a simplified approach both displacements and non-displacement piles. Contrarily to end-bearing foundations, the neutral plane location of floating piles is sensitive to the temporal evolution of excess pore water pressure; thus, for the analysis of floating piles, t-z springs with a constitutive law dependent on effective stress should be adopted.

RÉSUMÉ: Cet article présente un modèle t-z pour l'analyse de pieux simples chargés verticalement dans un sol consolidant, utilisant une poutre sur des ressorts verticaux hyperboliques dont la raideur tangente est une fonction de la contrainte mobilisée normalisée dans le sol (affectée par l'augmentation induite par la consolidation des contraintes effectives) et de l'historique de charge (tenant compte des phases de chargement, de déchargement et de chargement inversé). La validation est réalisée avec des résultats expérimentaux et analytiques publiés. Une étude paramétrique illustre, pour les pieux flottants et les pieux en butée, l'évolution temporelle du tassement et du plan neutre, en considérant, avec une approche simplifiée, à la fois les pieux à déplacement et les pieux sans déplacement. Contrairement aux fondations en butée, la localisation du plan neutre des pieux flottants est sensible à l'évolution temporelle de la pression interstitielle excessive; ainsi, pour l'analyse des pieux flottants, des ressorts t-z avec une loi constitutive dépendant de la contrainte effective devraient être adoptés.

Keywords: Consolidation; pile; settlement; t-z curve; neutral axis.

1 INTRODUCTION

When piles are affected by a combination of external loads and consolidation processes, performance-based design requires the estimate of settlements. Despite numerical modelling capabilities (Russo et al., 2020; Liang et al., 2023), practitioners mostly rely on simplified load capacity assessments (e.g. Danish National Annex to Eurocode 7; EN 1997-1 DK NA:2007) or neutral plane-based approaches to assess the effects of consolidating soil (Fellenius, 2023). However, these simplified methods have limitations. This paper presents an analytical model for the soil-pile interaction suitable for serviceability assessments.

2 INTERACTION MODEL

The proposed soil-pile interaction model is a beam on nonlinear t-z springs whose behaviour is affected by the consolidation. Namely, this model is based on a two-stage analysis method (i.e. consolidation-induced greenfield settlements used as input for the interaction analysis), Terzaghi's 1D consolidation theory for non-uniform initial excess pore water pressure distributions (Lovisa et al., 2010), the Euler-Bernoulli beam theory for the pile, nonlinear t-z springs (distributed along the shaft and base of the pile) as a ground model.

For the t-z springs, the approach of Chen et al. (2009) is adopted. The initial stiffness K_0 is estimated according to Randolph & Wroth (1978), if not stated otherwise, with base $K_{0,b} = \frac{d_p E_{s,0}}{1-\nu_s^2}$ and shaft per running meter $K_{0,s} = \frac{\pi E_{s,0}}{(1+\nu_s)\ln(2\, r_m/d_p)}$, where $E_{s,0}$= initial Young's modulus, ν_s = soil Poisson's ratio, r_m = magic radius, d_p = pile diameter. According to the Duncan hyperbolic stiffness degradation, the tangent stiffness for further loading or reverse loading is $K_{tan} = (1 - F_m/F_u)^2 K_0$, where F_m is the mobilised force at the spring, F_u is the ultimate

spring force obtained by integrating the failure shaft friction τ_f or base pressure q_f, whereas $K_{tan} = K_0$ in the case of unloading (i.e. spring reaction F_m attains the largest, in magnitude, positive or negative force mobilised at the spring). If not stated otherwise, the beta-method model is used to estimate $\tau_f = \beta\sigma'_v$ and $q_f = N_q\sigma'_v$ from the vertical effective stress σ'_v, obtained from the consolidation analysis. The model neglects effective stress variation at the soil-pile interface induced by local soil shearing in the near-pile soil region; therefore, the interaction and consolidation analyses are uncoupled (Kim et al., 2011). The self-weight of the pile is disregarded in this paper, although it can be included. The solution is solved using the Finite Element Method in incremental steps. For further details refer to Detlefsen (2023).

3 RESULTS

3.1 Validation

The model predictions are compared, with analytical and centrifuge results of a pile in consolidating soil for the two scenarios illustrated in Figure 1.

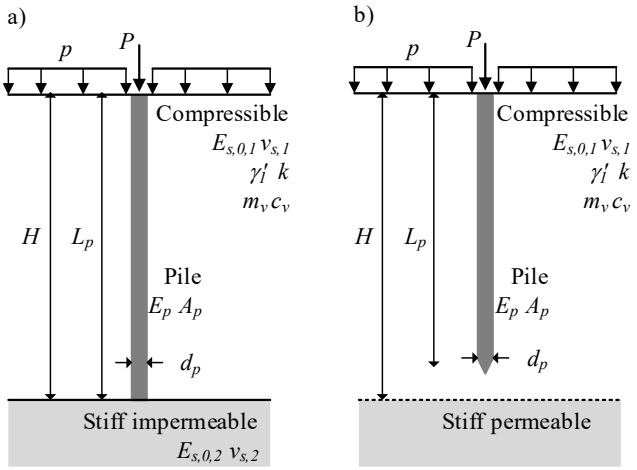

Figure 1. Modelled pile and ground conditions for a) end-bearing pile, and b) floating pile.

First, the model is validated against results obtained by Chen et al. (2009) using a similar analytical formulation for an end-bearing pile in consolidating soil and one-way drainage towards the surface (impermeable stiff bottom layer at the pile base). Figure 1a displays the problem geometry and parameters. The pile has length L_p = 10 m (equal to the consolidating layer thickness H), diameter d_p = 0.5 m, Young's modulus E_p = 20 GPa, and head load P. The compressible layer has γ' = 10 kN/m^3, $\beta = K\tan\phi'$ = 0.3. For the base layer, $E_{s,0,2}$ = 500 MPa, $\nu_{s,2}$ = 0.3, and ultimate base pressure q_f = 4.6 MPa. Surcharge pressure is set to p = 150 kPa. For direct comparison, along the shaft the initial tangent stiffness of the nonlinear springs $K_{0,s}$ is set to match the values adopted by Chen et al. (2009), associated with a displacement of 0.5 mm at $\tau_{f,0}$, which for r_m =17.5 m is associated with a gradient $E_{s,0,1}/z = 10.5$ MPa/m according to Randolph & Wroth's expression. Chen et al. (2009) adopted a 1D non-linear consolidation method, in which the coefficient of consolidation, c_v, and the coefficient of compressibility, m_v, are varying during consolidation. However, in this paper, Terzaghi's one-dimensional consolidation theory is adopted using m_v = 10^{-4} m^2/kN and c_v = 0.1644 m^2/day.

Figure 2 shows the response of the unloaded pile, in terms of mobilised shaft friction and axial force along the pile, for an average degree of consolidation $U_{v,avg}$ = 0.5 and 1. Also, Figure 2a reports ultimate shaft friction profiles τ_f during consolidation, as affected by excess pore water pressure dissipation and the impermeable bottom boundary. An excellent agreement with benchmark results is seen in Figure 2. Similarly, there is agreement with Chen et al. (2009) for the case of the loaded pile with P of 200 kN (Detlefsen 2023), which led to a downward shift in the neutral plane due to the external head load from a depth of 9 m to 8.5 m.

Second, the centrifuge test results from Lam et al. (2009) are simulated. As shown in Figure 1b, the experiment modelled a floating pile in consolidating clay under two-way drainage conditions (with the clay layer located between two coarse-grained layers); the base distance from the bottom coarse-grained layer is one diameter. The model pile was installed at 1 g; then, the model was spun up to 60 g for 16 hours, until an average degree of consolidation of 90% was reached. The tubular aluminium pile (E_p = 70 GPa, outer diameter d_p = 1.2 m, length L_p = 16.8 m) was embedded in fully saturated clay (height H = 18 m; pre-consolidation pressure of 80 kPa before centrifuge testing; effective unit weight γ' = 6.3 kN/m^3; water table at the clay surface) and having on both sides dense Leighton Buzzard 100/170 sand layers. The top sand layer had a unit weight γ_{dry} = 15 kN/m^3 and a thickness of 3 m, giving a surcharge load p = 45 kPa. In the analytical model, it is assumed for the clayed layer $E_{s,0,1}$ = 2.76 MPa, Poisson's ratio $\nu_{s,1}$ = 0.35, β = 0.3, N_q = 10.7, and r_m = 27.1 m. From back-analysis, using the method suggested by Lovisa et al. (2010), the coefficient of consolidation c_v = 0.0433 m^2/day and m_v = 3.64 10^{-4} m^2/kN were estimated from measured subsurface excess pore water pressures and greenfield surface settlements, respectively (Detlefsen, 2023).

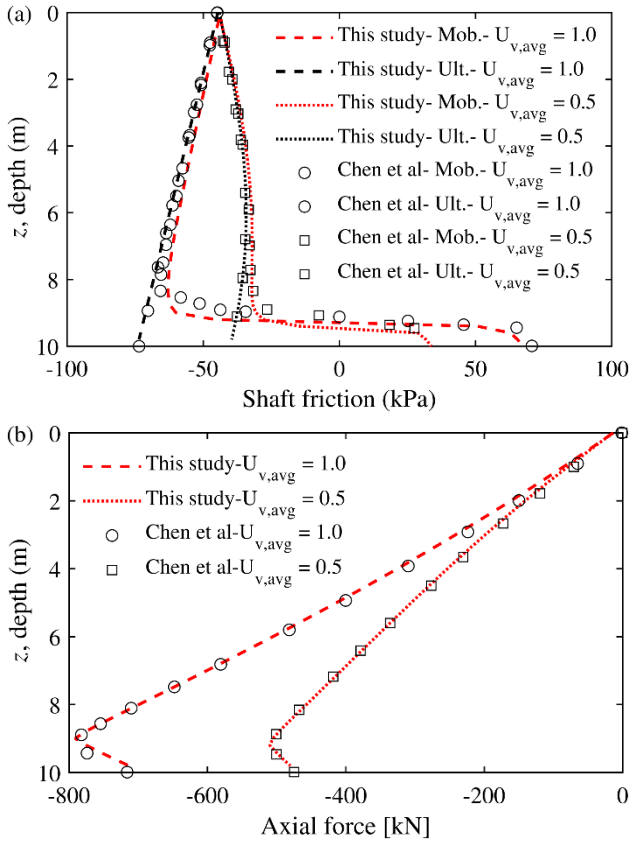

Figure 2. Comparison with analytical results for an unloaded pile: (a) shaft friction; (b) axial force.

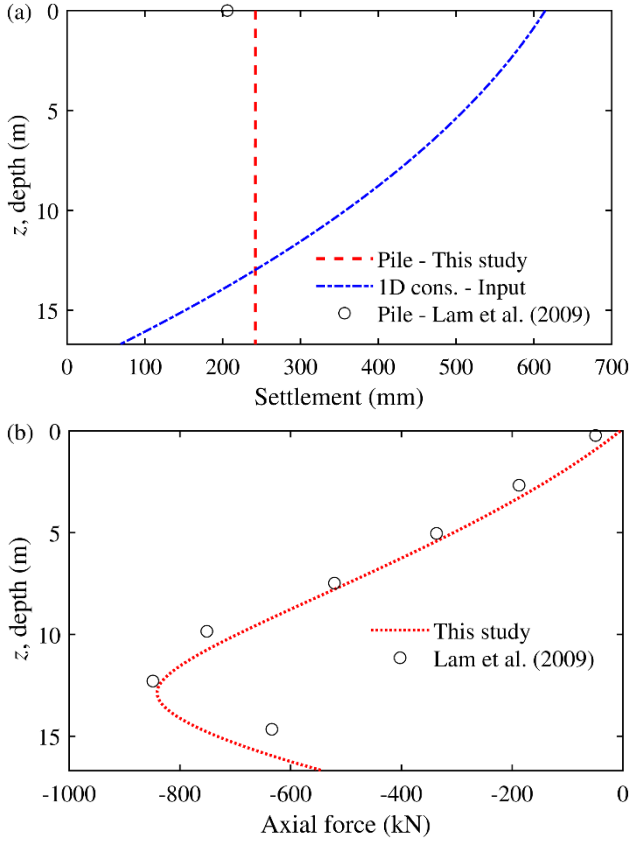

Figure 3. Comparison with centrifuge test results: (a) axial force; (b) greenfield and pile settlements.

Figure 3 compares prototype experimental and analytical results at 90% average degree of consolidation of. Despite a slight overestimation of the consolidation-induced settlement of the pile (predicted settlement of 242 mm instead of 206 mm, due to the stiffening effect of the base coarse-grained layer which was neglected), the predicted axial force profile is in satisfactory agreement with the experimental data. The axial force profiles show there is agreement between the experimental and analytical neutral planes, being at a depth of approximately 0.75 L_p.

3.2 Sensitivity study

A parametric study of the neutral plane depth and consolidation-induced settlements is carried out. The considered case study generalises the prototype experimental scenario in Figure 1b for head load P of 0 (for unloaded piles) or 1000 kN (for loaded piles).

Two different head load histories prior to consolidation and application of service loads are considered for displacement and non-displacement piles respectively. This is done to approximately take the effect of residual stresses and unloading stiffness along displacement piles into account, which will differ from ground stiffness and stress distributions of bored piles. Prior to the surcharge application p, (i) "non-displacement" piles have the head load P monotonically applied; (ii) "displacement piles" were subjected first to a head load of 99% the load capacity, then unloaded, and finally reloaded to the target P. During the consolidation, the head load P is kept constant. For both head loading and consolidation, the load transfer of the t-z springs is described by K_{tan}, as previously detailed. Results are normalised as for Kog (2016): the depth of the neutral plane is divided by the pile length giving $\psi = z_{np}/L_P$, while the normalised settlement of the pile head is $\Delta = \Delta_p E_p A_p/(p\, H^3)$.

Figure 4 displays the results for unloaded piles ($P = 0$) with a length $L_P = 0.4\, H$ to $1.4H$, where H is the thickness of the consolidating layer. The embedment L_P/H is found to impact the temporal evolution of the neutral plane depth ψ of floating piles ($L_P/H < 1.0$), whereas ψ is not affected by the time factor T_v for end-bearing piles ($L_P/H \geq 1.0$). This trend of ψ is also notable in Figure 5 which compares the neutral plane depth ψ of loaded piles when having an embedment for floating $L_P/H = 0.8$ and end-bearing $L_P/H = 1.2$. Thus, it is important to model the soil-pile interaction for floating piles in consolidating soil.

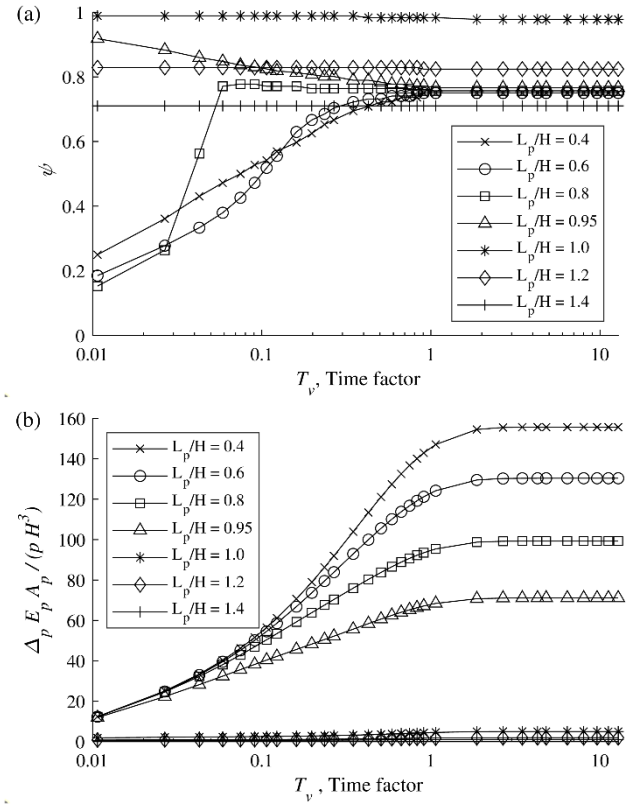

Figure 4. Settlement response of unloaded non-displacement piles against time factor with varying embedment depth: (a) neutral plane depth and (b) normalised settlements.

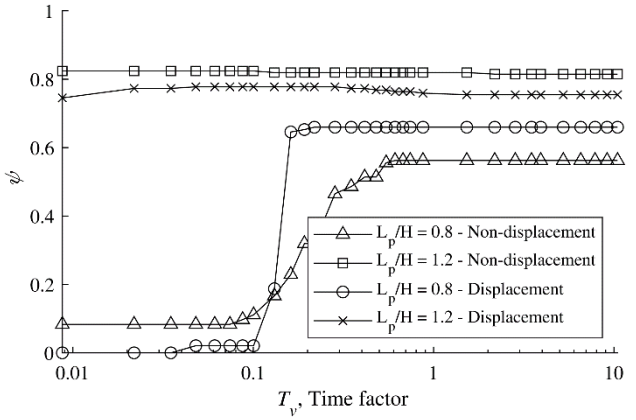

Figure 5. Normalised neutral plane depth of loaded (P = 1000 kN) displacement and non-displacement piles with varying embedment length.

4 CONCLUSIONS

This paper presents a beam on hyperbolic t-z springs model for the time-dependent stress analysis of unloaded and loaded piles in consolidating soil. A parametric study illustrated the importance of modelling the excess pore water pressure dissipation and installation in the case of floating piles.

Future work will address a consistent stiffness formation in terms of effective stresses.

Port silo foundations on piles under vertical cyclic stresses

Fondations de silos portuaires sur pieux soumis à des contraintes cycliques verticales

P. Dogaru
General Construct Grup Srl, Constanta, Romania

R. Ciortan*
Technical Sciences Academy of Romania, Bucharest, Romania

**ciortanromeo@yahoo.com*

ABSTRACT: A particular category of structures relating to port operations is represented by the metal silo buildings in which bulk goods, especially grain, are handled and stored. The proper foundation solution for silo bins in Constanta port (Romania) is based on concrete bored piles to undertake the high loads and transfer them to the soil. A particularity of the port infrastructure consists of weak soil layers regarding bearing capacity. This aspect, alongside the cyclical nature of the loading/unloading activity, leads to a different approach to determining the bearing capacity of a bored pile within the indirect foundation system of the steel silo bin. The highly demanding nature of the cyclic actions mentioned above (10-12 annual load-unload cycles), along with the over-unitary value of the ratio between the live and dead loads, promotes a complex approach regarding the bearing capacity of the piles. Moreover, the studies and calculations have indicated that the cumulative residual pile settlement (after in-situ analysis of several loading-unloading cycles) is a critical factor in considering the bearing capacity of the bored pile. Consequently, considering some technological constraints, the bearing capacity of a pile against vertical loads is approx. 20% lower for cyclic loads rather than static loads, which is essential when designing infrastructure solutions.

RÉSUMÉ: Une catégorie particulière de structures liées aux d'exploitation portuaires est représentée par les silos métalliques dans lesquels les marchandises en vrac, en particulier les céréales, sont manipulées et stockées. La solution de fondation appropriée pour les silos du port de Constanta (Roumanie) est basée sur des pieux forés en béton pour supporter les charges élevées et les transférer au sol. L'une des particularités de l'infrastructure portuaire réside dans la faiblesse des couches de sol en termes de capacité portante. Cet aspect, ainsi que la nature cyclique de l'activité de chargement/déchargement, conduit à une approche différente pour déterminer la capacité portante d'un pieu foré dans le système de fondation indirecte du silo en acier. La nature très exigeante des actions cycliques mentionnées ci-dessus (10-12 cycles annuels de chargement et de déchargement), ainsi que la valeur sur-unitaire du rapport entre les charges vives et les charges permanents, favorisent une approche complexe en ce qui concerne la capacité portante des pieux. En outre, les études et les calculs ont indiqué que le tassement résiduel cumulatif du pieu (après l'analyse in situ de plusieurs cycles de chargement et de déchargement) est un facteur critique dans l'examen de la capacité portante du pieu foré. Par conséquent, compte tenu de certaines contraintes technologiques, la capacité portante d'un pieu contre des charges verticales est inférieure d'environ 20 % pour des charges cycliques plutôt que statiques, ce qui est essentiel lors de la conception de solutions d'infrastructure.

1 INTRODUCTION

Silo bin storage foundations are usually based on piles because of the high loads to be transferred to the soil and the existence of weak layers on site in terms of bearing capacity (e.g., the nature of the fills used in the process of widening/forming harbour berths). Cyclic loading imposed by the silo functioning is probably the most complex mode of foundation soil loading, and modelling such loading requires analysis of both the soil-structure interaction and the cyclic loading-unloading behaviour of the soil.

Moreover, given the highly particular character of these bulk storage facilities (in this case study - grain) by using metal cells made of thin-walled sheets and profiles (working with active compression zones) in conjunction with a poorly load-bearing infrastructure, the identification of structural design solutions by considering the dynamic character of long-term operation becomes very complex and complicated.

2 CASE STUDY

The present study analyses the results of cyclic loading-unloading tests, through 8 cycles, on test bored piles realized on the site of berth 80 in the port of Constanta, during the development of a grain terminal with a capacity of approximately 198,900

tonnes was built (see Figure 1). The grain storage silo consists of:

- a group of 4 cells with a capacity of 10,000 tonnes;
- a group of 8 cells with a capacity of 10,000 tonnes;
- a group of 6 cells with a capacity of 10 900 tonnes;
- a group of 6 cells with a capacity of 2 250 tonnes;

Using the full-scale working model (test bored pile) results, a comparative analysis of the influence of cyclic loading in determining the final value of the ultimate vertical load-carrying capacity of a concrete bored friction pile at the studied site was performed.

Figure 1. Grain terminal at berth 80 - port of Constanta.

An essential condition for the safe operation of the grain terminal's service technology was the limitation of differential settlement between the structures supporting its specific equipment. In this respect, the differential settlement that may occur between the pile groups of the grain silo infrastructure and the metal towers supporting the cargo elevators was also considered.

The geotechnical investigation for the construction located behind the 80 berths, Port Constanta South, was done by drilling six geotechnical boreholes 42.00m deep. To complete the information on the last intercepted layer, three of the drilled holes were continued to a depth of 42.00 m.

To simplify the sequence of the intercepted strata, they have been grouped into three lithological complexes, resulting in the following synthetic lithological column of the site:

- C1 (at depths of 0.00 - 11.80 m). - the complex formed by anthropogenic fill (predominantly composed of cohesive strata): clay, dusty clay, sandy clay, clayey dust; weakly cohesive strata: clayey sand, dusty sand, clayey sandy dust and non-cohesive strata: fine sand - large, with small gravel. All this succession of strata contains boulders and limestone blocks. At the top of drill holes F1, F2, F3, and F6, iron ore deposits from the deposition of ore over time have been traced over a variable thickness of 0.10 to 0.80 m;
- C2 (at depths of 9.40 - 35.80 m). - The intermediate complex is composed of an alternation of cohesive strata (clay, greasy clay, dusty clay, sandy clay, clayey dust), weak cohesive strata (clayey sand, dusty sand, sandy clay dust) and non-cohesive strata (fine sand, fine - medium sand, coarse sand, granular-pebble gravel. All this sequence of strata contains concretions and limestone - boulder elements);
- C3 (at depths of 30.80 - 42.00 m). - lower complex, is composed of an alternation of chalky clay / chalky, whitish dusty clay with concretions and limestone boulders. Drilling was stopped in this complex without crossing it (at depths of 40.00 - 42.00 m).

To determine by testing the ultimate compressive load-bearing capacity of the test pile, three thresholds (values) of vertical load force, 7000 kN, 8500 kN and 10,000 kN, respectively, were considered for analysis. The aim was to identify the maximum compressive bearing capacity of the pile by referring to the value of the recorded and especially to the cumulative values of the residual settlements of the loading-unloading cycles considered. The pile cumulative settlement value during the cyclic test thus becomes the determining factor in the evaluation of the vertical bearing capacity, also taking into account that in the group behaviour of the piles, this value increases considerably and can lead to differential settlement of the grain cells's foundations in the studied site.

3 RESULTS

Considering the results of the cyclic compression tests carried out on the test piles, the following aspects were highlighted, as follows:

- For a loading force value of 7000 KN, the resulting value of the residual settlement after the eight load-unload cycles is about 2mm. After the first two load-unload cycles, the value of the residual settlement was stabilised below 1mm for each cycle, which leads to the hypothesis of an "elastic" response of the foundation soil.
- For a loading force value of 8500 KN, the resulting value of the residual settlement after the eight load-unload cycles is about 32mm. After the first five load-unload cycles, the value of the residual settlement was stabilised below

2mm for each cycle with a discharging character.

- For a loading force value of 10,000 KN, the resultant value of the residual settlement after the eight load-unload cycles is about 112mm.

After the first four load-unload cycles, the residual settlement had a constant character and a value of approx. 7 mm for each cycle.

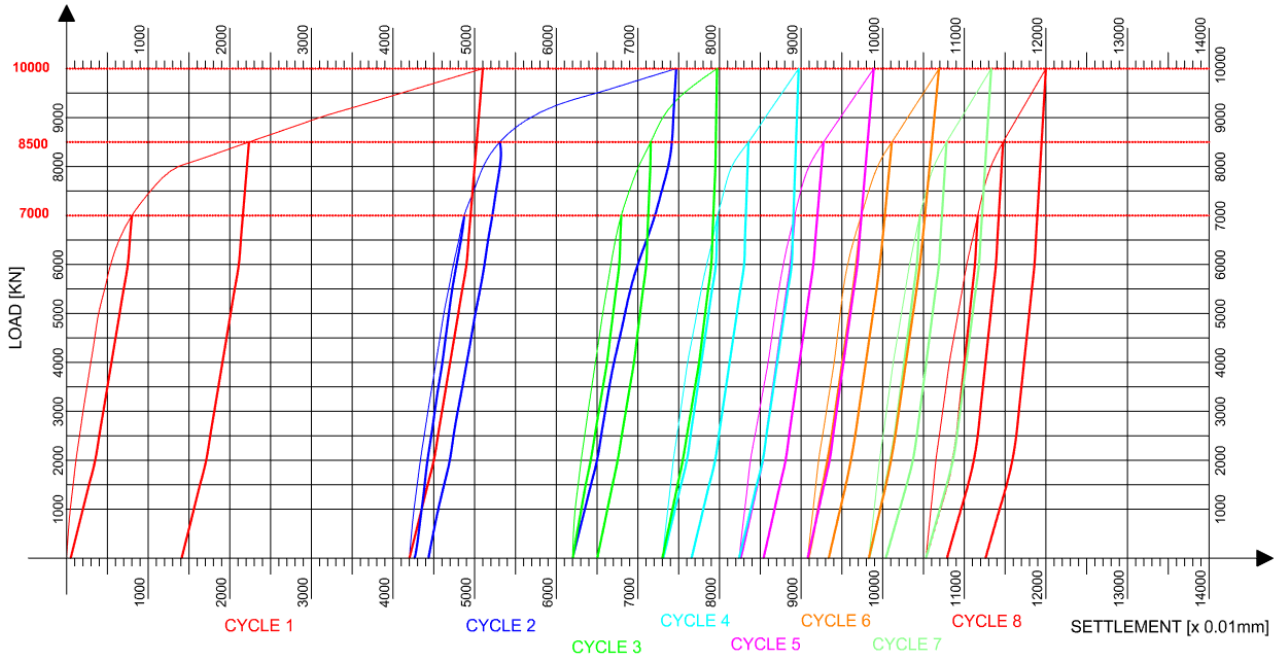

Figure 2. Load-settlement curves (8 cyclic compression tests of Pile P.I3) for the loads of: 7000kN;8500kN;10000kN.

Also, from the graphical analysis shown below in Figure 3÷5, it can be seen that if the loading load decreases to 7000 kN, the deformation is much smaller, having an almost linear character during the load-unload cycles.

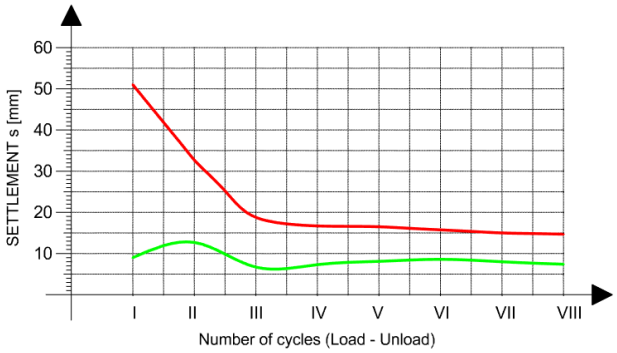

Figure 3. Load-settlement curves (8 cyclic compression tests of Pile P.I3) for the load of 10000kN.

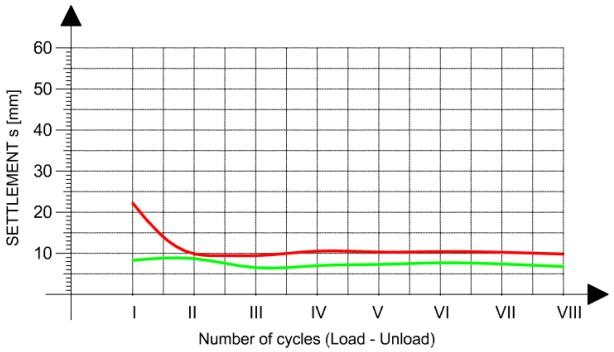

Figure 4. Load-settlement curves (8 cyclic compression tests of Pile P.I3) for the load of 8500kN.

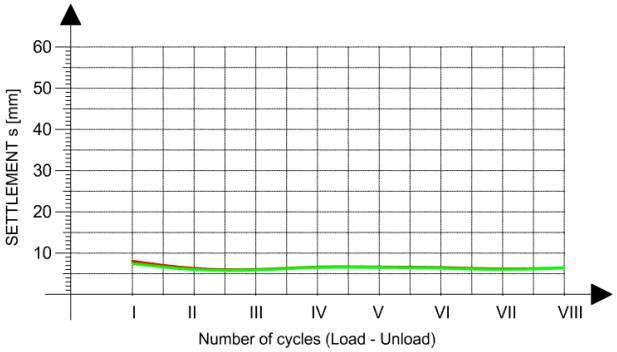

Figure 5. Load-settlement curves (8 cyclic compression tests of Pile P.I3) for the load of 7000kN.

The ratio between maximum settlement (load sequence) and its specific return (unload sequence) shows that it is higher at 10000 kN load, decreases at 8500 kN load and becomes unity at 7000 kN load (Figure 6).

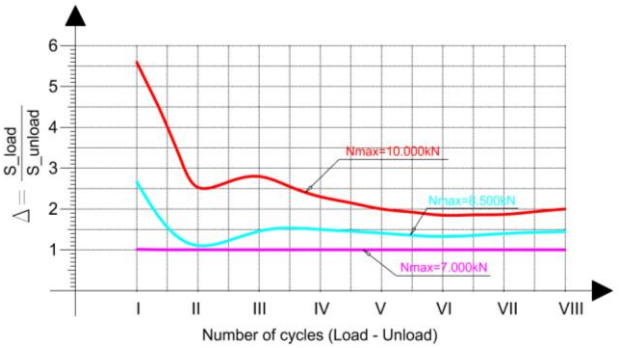

Figure 6. Ratio of maximum load-unload settlement registered values.

The cumulative size of the residual settlement increases with the number of loads, but it can be seen that this evolution is zero for the 7000 kN load (Figure 7).

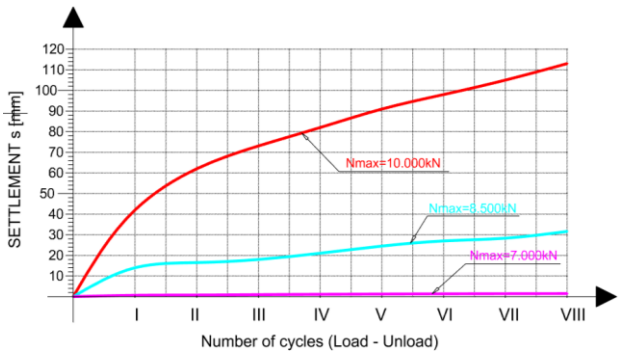

Figure 7. Cumulative residual settlement diagram for 8 load-unload cycles.

4 CONCLUSIONS

In the case of friction piles, the effect of cyclic loads must be considered as the cumulative residual settlement occurs, thus exceeding the permissible values and those required by the operation of technological equipment.

For the above, determining the bearing capacity of a friction pile should be conditional on the acceptable value of the resultant residual settlement (by summation) over the loading-unloading cycles considered in the test phase of the test piles. Thus, the cumulative residual pile settlement (after analysis of the loading-unloading cycles considered) should be considered as a determining factor that provides the bearing capacity of the pile.

Consequently, the specific nature of the foundation soil in port areas, which consists of fills, then sands and clay formations, and at-depth limestone in various states of degradation, requires that in the case of grain terminals, the foundation piles should be checked for cyclic actions given the variability of live load. The studies and calculations have shown that in the field conditions in the port of Constanta, considering some technological constraints, the design bearing capacity of piles at vertical loads is approx. 20% lower for cyclic loads than for static loads, which is essential to consider when designing infrastructure solutions.

Effect of strain-softening and strength anisotropy on the undrained resistance of deeply embedded pile/pipe section

Effets de l'adoucissement mécanique et de l'anisotropie sur la résistance non drainée des fondations profondes

Y.P. Dong*

ABSTRACT: The bearing capacity of soils is critical for the design and analysis of foundations. The classical solutions derived from methods of characteristics and bound theories are based on the rigid plasticity and associated flow rule, which may not be realistic for natural soils. The undrained shear strength of soft clays exhibits strain-softening and anisotropic behavior in the lab tests, which creates complexity to choose appropriate strength parameters in conventional design process. In addition, the stress-strain characters are non-associative and path dependent, which also affects the bearing capacity of soils. This paper investigates one classical stability problem (i.e. deeply-embedded pile/pipe section) using the finite element analysis and MIT-E3 soil model, and demonstrates the effects of strain-softening and strength anisotropy on the undrained resistance of soils. The computed results are compared with analytical solutions and finite element limit analysis. These findings have strong practical implications to predict the bearing capacity of foundations and interpret insitu tests.

RÉSUMÉ: La capacité portante des sols est essentielle pour la conception et l'analyse des fondations. Les solutions classiques, dérivées de la méthode des caractéristiques et des théorèmes de l'analyse limite, reposent sur la loi d'écoulement associée au comportement rigide-plastique, qui peut ne pas être réaliste pour les sols naturels. La résistance au cisaillement non drainée des argiles molles présente un adoucissement et un comportement anisotrope lors des essais effectués en laboratoire, rendant le choix de paramètres de résistance adaptés complexe au cours du processus de conception. De plus, les caractéristiques contraintes-déformations sont non-associatives et dépendent du chemin suivi, ce qui affecte également la capacité portante des sols. Cet article examine un problème classique de stabilité (c. -à-d. section de pieux/pieux tubulaires profondément encastrés) utilisant l'analyse par éléments finis et le modèle de sol MIT-E3, et démontrant les effets de l'adoucissement mécanique et de l'anisotropie sur la résistance non drainée des sols. Les résultats calculés sont comparés aux solutions analytiques et à l'analyse des limites par éléments finis. Ces découvertes ont d'importantes répercussions pratiques pour prédire la capacité portante des fondations et interpréter les tests in situ.

Keywords: Bearing capacity of soils; strain-softening; strength anisotropy.

1 INTRODUCTION

A class of solutions in soil mechanics are based on the rigid plasticity and associated flow rule, such as bearing capacity of rigid footings obtained from methods of characteristics and bound theorems (Terzaghi 1943), and lateral resistance of deep buried pile section (Randolph and Houlsby 1984). They have provided sound theoretical basis in many geotechnical problems such as design of foundations, and interpretation of strength parameters from insitu penetration tests. However, real soil behavior is not rigid plastic and associative as observed in the lab tests, and exhibits complex features including (i) anisotropic strain-stress-strength relation, (ii) non-associated flow rule, (iii) stress-induced dilations, (iv) strain hardening/softening, and (v) rate-dependency. This implies that the results and conclusions based on the classical plasticity theories may have limitations in practical applications.

For cohesive soils, the limiting capacity of foundations is normally derived based on the undrained assumption with isotropic strength properties such as Tresca or Von Mises criteria. However, natural clays generally exhibit strength anisotropy resulting from preferred direction in one-dimensional deposition (Ladd 1991; Whittle 1993). Figure 1(a) clearly demonstrates significant undrained shear strength anisotropy of K_0-normally consolidated soft clays from the results of standard laboratory triaxial compression (CK_0UC), extension (CK_0UE), and direct simple shear (CK_0DSS) tests. This indicates that soils at different region of the slope in Figure 1(b) may not reach failure states simultaneously, leading to

progressive failure mechanisms. Furthermore, the mobilized shear resistance in each mode of failure depends on the shear strain level in the soil.

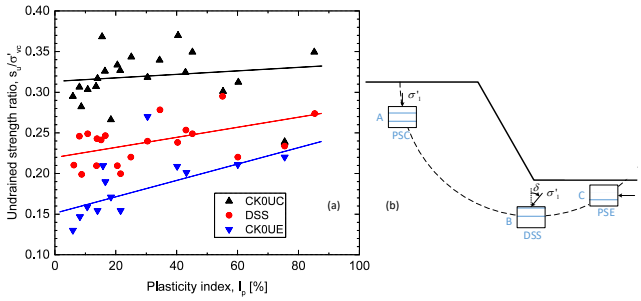

Figure 1. Undrained strength anisotropy (a) from CK0U and DSS tests on normally consolidated clays and silts, and (b) related shear modes on failure surface (Ladd 1991).

This paper investigates one classical undrained stability problems (i.e. deeply embedded pile/pipe section) using finite element analysis and the MIT-E3 model (Whittle and Kavvadas 1994), to highlight important effects of strain-softening and strength anisotropy on the undrained bearing capacity of non-associated clays. The computed results are compared with those from bound theories and finite element limit analysis.

2 DESCRIPTION OF THE MIT-E3 MODEL

The MIT-E3 model was developed to describe the rate-independent behavior of overconsolidated clays under cyclic loading, based on the observation of experimental data. The formulation of the MIT-E3 model was described in Whittle and Kavvadas (1994). In general, the model formulation comprises four components: (1) an elastoplastic model for normally consolidated clay including anisotropic and strain-softening behaviour; (2) nonlinear para-elastic equations to describe the small strain nonlinearity and hysteretic response in unloading and reloading; (3) bounding surface plasticity for irrecoverable, anisotropic and path dependent behaviour of overconsolidated clays, and (4) non-associated flow rules. Extensive comparisons with measured data from undrained shear tests performed in different modes (e.g. triaxial, plane strain, and simple shear) of shearing show that the model gives excellent predictions of conditions at maximum shear stress and describes accurately the nonlinear shear stress-strain behaviour (Whittle 1993; Whittle et al. 1994).

The model was implemented into Abaqus™ through a user-specified subroutine (UMAT) using an automatic explicit substepping algorithm with error controls, and details of the integration and verification were described in Dong (2023).

2.1 Plane strain tests

The soil behaviour in plane strain conditions are relevant to some typical geotechnical problems in practice, and are particularly focused in this paper. Figure 2 shows the computed effective stress paths and stress-strain response for the K_0- normally consolidated undrained plane strain compression (PSK_0UC) and extension (PSK_0UE) tests for Boston Blue Clay (BBC).

The normalized peak shear strength in compression mode, $s_{u,PSC}/\sigma'_{vp} = 0.344$, occurs at small strain level $\varepsilon_a = 0.2\%$, and the post-peak strain-softening effect is significant. While in the extension mode, a smaller shear strength $s_{u,PSE}/\sigma'_{vp} = 0.187$ is mobilized at larger strain level $\varepsilon_a > 3\%$, and no strain-softening effect is shown. These test results clearly demonstrate complex soil behavior that is strain-softening, anisotropic, and stress-path dependent.

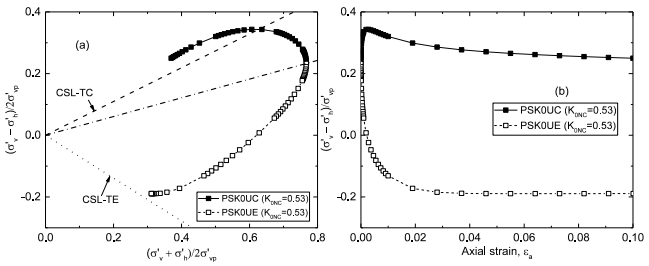

Figure 2. Simulated results of PSK0UC and PSK0UE tests of BBC from the MIT-E3 model.

2.2 Direct simple shear test

Figure 3 shows the computed effective stress paths and shear stress-strain behaviour of the K_0-normally consolidated undrained direct simple shear tests (CK_0DSS) for BBC with two different K_{0NC} values. The produced results are consistent with the previous plane strain compression/extension tests.

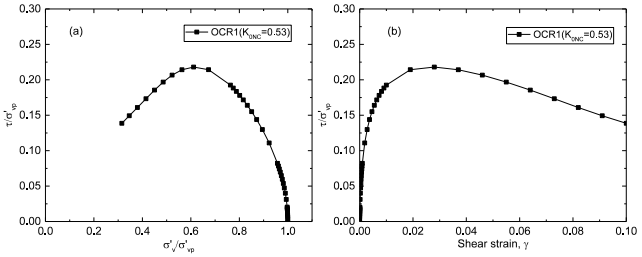

Figure 3. Simulated results of CK0DSS tests of BBC from the MIT-E3 model.

2.3 Directional shear cell test

The directional shear cell (DSC) was developed to investigate the soil behaviour under controlled rotation of principle stress directions (Arthur and Menzies

1972; Sture et al. 1987). Normal and shear stresses can be applied independently on four sides of the plane-strain device, thus achieving rotation of major principal stress direction in the plane of loading from plane-strain compression through maximum shear to extension. In the tests, soil specimens are sheared by imposing principal stress increments oriented at angle, δ, to the original direction of deposition. Figure 4 shows the computed stress paths from the DSC tests on the K_0 -normally consolidated BBC in the depositional plane, and clearly demonstrates that the undrained shear strength are affected by the loading directions and principle stress rotations. The undrained strength can be well represented by the elliptic envelope proposed by Davis and Christian (1971), which will be described in the next section. Figure 4 presents coresponding incremental shear stress-strain response in the depositional plane, and clearly demonstrates variation of mobilised shear strength with the strain under different loading directions.

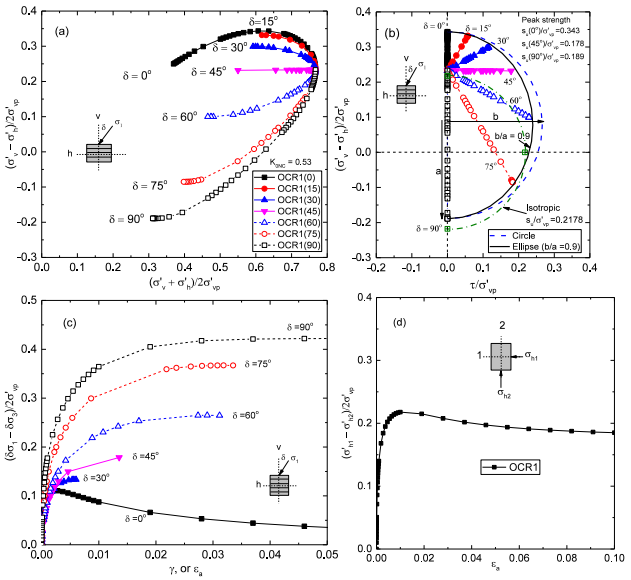

Figure 4. Simulated results of CK0DSC tests of BBC from the MIT-E3 model.

3 ANISOTROPIC STRENGTH ENVELOPE OF K0-CONSOLIDTED CLAY IN PLANE STRAIN CONDITIONS

The anisotropic strength function by Davis and Christian (1971) is well suited to the undrained strength envelope of K_0-consolidated soft clays, which can be expressed as an elliptical strength envelope in the deviatoric shear stress space $\left[\left(\sigma_x-\sigma_y\right)/2,\tau_{xy}\right]$, using eq. (1),

$$F=\left(\frac{q_{xy}-h}{a}\right)^2+\left(\frac{\tau_{xy}}{b}\right)^2-1=0$$
$$q_{xy}=\left(\sigma_y-\sigma_x\right)/2;h=\left(s_{u,0^\circ}-s_{u,90^\circ}\right)/2 \quad (1)$$
$$a=\left(s_{u,0^\circ}+s_{u,90^\circ}\right)/2;b=\frac{a\times s_{u,45^\circ}}{\sqrt{s_{u,0^\circ}\times s_{u,90^\circ}}}$$

where σ_x,σ_y and τ_{xy} are the normal and shear stresses in the x,y plane; q_{xy} is the average deviator normal stress, representing strength; h represents centre of the ellipse; $s_{u,0^\circ}$, $s_{u,45^\circ}$ and $s_{u,90^\circ}$ are the undrained shear strengths at $\delta=0^\circ,45^\circ$, and 90° for compression, respectively; and a,b are parameters to determine the size of the ellipse.

This anisotropic strength criterion can represent the undrained strength envelope of K_0 -normally consolidated BBC in the directional shear cell (DSC) tests, with parameters $b/a=0.9$. Figure 4 also includes the strength envelope and undrained shear stress-strain path in the horizontal bedding plane which is isotropic, with the undrained shear strength $s_{u,iso}/\sigma'_{vp}=0.2178$.

Ukritchon (1998) implemented this anisotropic strength criteria into the finite element limit analysis (Sloan 2013), and provided the upper and lower bound solutions for several plane-strain stability problems (e.g. strip footing, pile section, slope stability, and braced excavation). These solutions can be used to compare the results from finite element analyses using the MIT-E3 model.

4 RESISTANCE OF DEEPLY-EMBEDDED PILE/PIPE SECTION

4.1 Finite element model

The undrained resistance of deeply-embedded pile/pipe section in homogeneous clay (Randolph and Houlsby 1984), is conducted to investigate the effect of strain-softening and strength anisotropy. It also has practical significance to derive the limiting pressure on laterally loaded vertical piles and vertically loaded horizontal pipes embedded in deep cohesive soils, as well as interpretation of T-Bar penetration tests. The geometry and mesh of this analysis is shown in Figure 5, and plane strain condition is assumed considering that the pile/pipe is long. Quadratic elements (CPE6MPH: A 6-node modified quadratic plane strain triangle, pore pressure, hybrid, linear pressure, hourglass control) are used in the analysis for more accurate results in undrained condition. The ground is set as weightless in K_0 -normally consolidated state

(with the initial stress condition $\sigma'_{v0} = 100kPa, K_{0NC} = 0.53$, $OCR = 1$), and zero initial pore water pressure. However, the loading is applied in both isotropic bedding plane and anisotropic depositional plane.

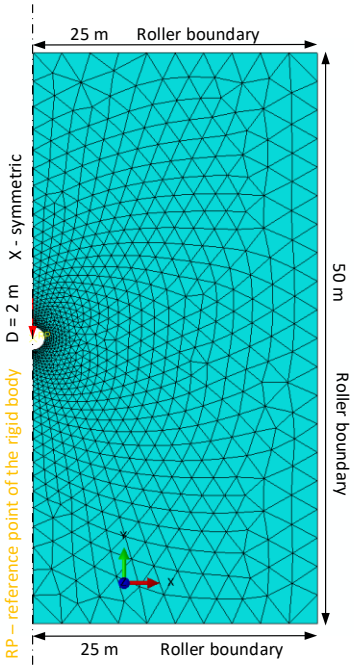

Figure 5. Finite element model.

4.2 Available solutions

Randolph and Houlsby (1984) derived analytical lower and upper bound solutions for the lateral resistance in isotropic soils by the method of characteristics. The limiting pressure factor N_p is reported in eq. (2),

$$N_p = \frac{P}{s_u D} = \pi + 2\Delta + \cos\left(\frac{\pi}{4} - \frac{\Delta}{4}\right)\left(\sqrt{2} + \sin\left(\frac{\pi}{4} - \frac{\Delta}{4}\right)\right) \quad (2)$$

where P is the applied lateral load, D is the diameter of the section, s_u is the undrained shear strength of the clay, $\sin\Delta = f_s / s_u$ is the interface roughness ratio (0 for perfectly smooth, 1 for perfectly rough), f_s is the limiting shear stress at the interface.

Ukritchon (1998) studied this problem in both isotropic and anisotropic soils using the finite element limit analysis and the anisotropic criterion by Davis and Christian (1971). The isotropic case is the same as the lateral loading of vertical pile section in Randolph and Houlsby (1984), whereas the anisotropic case is more related to the vertically loaded pipe section in deep soils and the T-bar penetration tests in geotechnical site investigation (Stewart and Randolph 1994). For anisotropic soils, the limiting pressure is defined in eq. (3) using the modified factor N'_p and the average strength $s_{u,avg}$,

$$\frac{P}{D} = N'_p s_{u,avg} = N'_p \frac{\left(s_{u,0^\circ} + s_{u,90^\circ}\right)}{2} \quad (3)$$

Randolph and Houlsby (1984) applied a uniform shear stress on the soil-pile interface to consider the friction on the pile, and the shear stress is equal to the undrained shear strength of the soil. However, this assumption may not be realistic in real situations where slippage and separation between the soil and pile can occur. To consider this effect, the interface is represented by contact pairs with Lagrangian algorithm, and the slip limit is specified by the peak undrained shear strength of the soil. For the analyses in the isotropic bedding plane, the slip limit is equal to the isotropic shear strength $s_{u,iso}$, whereas for the analyses in the anisotropic depositional plane, the slip limit is equal to the average strength $s_{u,avg}$. The obtained bearing capacity factor is smaller than the analytical solution from limit analysis.

4.3 Computed results

Figure 6 shows the normalised load-displacement response (in terms of $N_p \sim s/B$) from the MIT-E3 model in the isotropic bedding plane and anisotropic depositional plane. The peak bearing capacity factors in both cases fall below those from Davis and Christian (1971) and Ukritchon (1998), for both smooth and rough soil/pile interface. These results clearly demonstrate that the bearing capacity will be reduced on the clay with strain-softening behaviour, and the decrease is affected by the level of strain-softening.

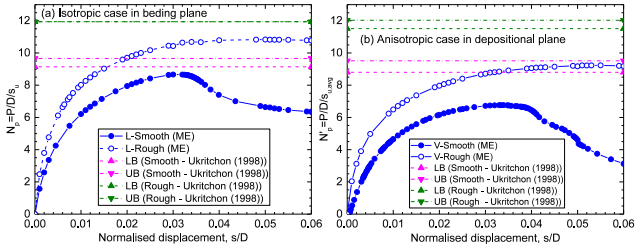

Figure 6. Normalised load-displacement response of deeply embedded rigid pile section in (a) the isotropic bedding plane, and (b) anisotropic depositional plane from the MIT-E3 model.

To diagnose the mechanism of strain-softening, Figure 7 shows the transformed horizontal shear stress (q_h / σ'_{vp}) and strain (ε_h) distribution in the soil around the pile at the peak resistance, for the smooth case. It can be seen that the shear stress in the elements with peak shear strain is below the peak shear strength of

the soil, indicating post-peak strain-softening. In contrast, the shear strain on the right side of the pile is so small that the peak shear strength of soils is not fully mobilised yet.

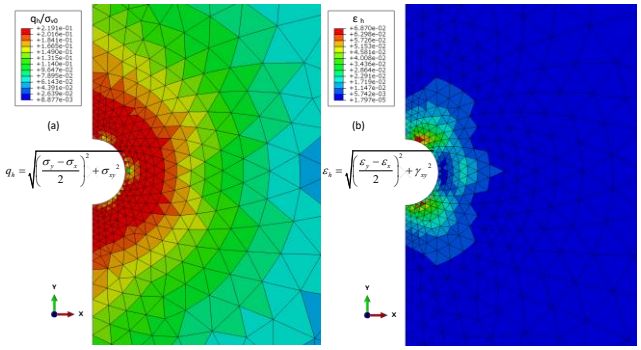

Figure 7. Distribution of transformed shear stress and strain in the soil around the rigid pile section with smooth interface in the isotropic bedding plane at the peak load from the MIT-E3 model.

For anisotropic soils, the computed resistance factor N'_p is much smaller than the analytical solution from Ukritchon (1998), based on the average peak strength ratio $s_{u,avg}/\sigma'_{vp} = 0.265$, and also smaller than the previous isotropic cases. This is mainly caused by the strain-softening and strength anisotropy of the soils, as discussed in the previous section. Figure 4 shows that the peak undrained strength is not mobilised at the same strain level for different shear directions, and the compressive strength starts to decrease at relatively small strain before other shear strength modes are reached. Figure 8(a) shows the normalised strength (f) distribution around the pipe at the peak resistance for the smooth case, and it can be seen that the soil strength is not fully mobilised in a large area around the pile. Figure 8(b) shows the direction of major principal stress (δ) indicating shearing modes of the soil, which can explain the complex effect of strength anisotropy at different shearing modes and strain level.

Similar effect of strength anisotropy was also reported in Randolph and Andersen (2006), where an anisotropic soil model was used in the finite element analysis. These results clearly imply that (i) the computed resistance will be over-estimated in natural soils with strain-softening behaviour using analytical solution from rigid plasticity, (ii) the interpreted soil strength from T-bar tests will be under-estimated in anisotropic soils with strain-softening behaviour, and (iii) it may be difficult to select appropriate average strength values in conventional stability analysis.

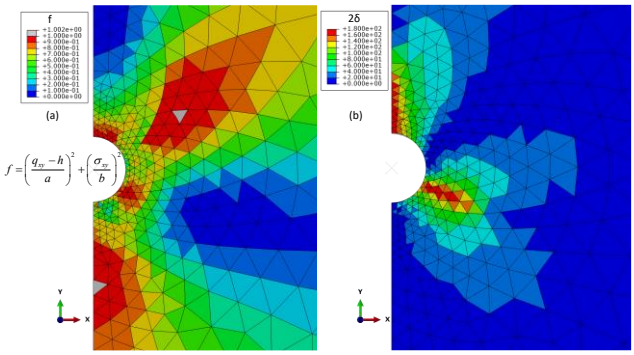

Figure 8. Distribution of normalised shear strength and principal stress direction in the soil around the rigid pipe section with smooth interface in the anisotropic depositional plane at the peak load from the MIT-E3 model.

5 CONCLUSIONS

The deeply-embeded pile/pipe section analysis has been investigated using finite element analyses and the MIT-E3 model, to demonstrate the effects of strain-softening and strength anisotropy on the undrained bearing capacity of non-associated clay. General conclusions are drawn for future applications:

- The undrained bearing capacity derived from the rigid plasticity and associated flow rule may have limitations in practical applications for natural soils with strain-softening and strength anisotropy behavior. Finite element analysis with realistic soil models can be useful to evaluate the bearing capacity of soils more accurately.
- The strain-softening behavior will reduce the undrained bearing capacity factor based on the peak strength, and the reduction depends on the degree of softening in the stress-strain path. This is because the peak strength is not mobilized simultaneously at all points in the soil due to the non-uniform strain distribution in the soil, and in some elements the peak strength is mobilized before the peak load is reached and the strength in those elements decreases while other elements are mobilizing the peak strength.
- The effect of strength anisotropy on the bearing capacity is more complex because the peak shear strength depends on different shearing modes and strain levels in the analysis. Selection of appropriate undrained strength parameters remains challenging in conventional stability analyses, and advanced finite element

analysis with anisotropic soil models can be a good option.

ACKNOWLEDGEMENTS

This research is an extension of previous collaborations with Prof. Andrew J. Whittle and late Prof. Scott W. Sloan. Prof Guy T. Houlsby is also acknowledged for discussion on bearing capacity problems.

Improvement of tubular piles by effective closure

Amélioration des pieux tubulaires par une fermeture efficace

M. Doubrovsky*, V. Dubravina
Odesa National Maritime University, Odesa, Ukraine
**m.doubrovsky@gmail.com*

ABSTRACT: Important problem of the piled structures design is ensuring of reasonable cost of piling. It can be provided by shortening either of piles length or the number of pipes in the pile foundation (keeping another pile's dimensions and material properties without changes). Both such approaches should provide a required bearing capacity of the pile foundation (axial compressing loads are considered). These results may be achieved if each short-cut pile is improved and bears the same loading as a pile of normal (initially designed) length or if each pile of normal length is improved and bears larger axial force in comparison with its initially designed capacity. The aim of the presented study was to clarify some possibilities to improve the pipe pile's bearing capacity using an internal rigid diaphragm (closure) placed inside the pile's shaft. It increases the bearing capacity of the tubular pile due to additional soil reaction inside the shaft (it was confirmed by known on-site measurements). Laboratory research aiming to study the mentioned effect was produced with the pipe pile's model pressed into sandy soil. These tests allowed us to clarify conditions of soil plagues formation at the pile's tip and under the diaphragm as well as their interaction. Also, some conclusions and recommendations were made clarifying the diaphragm's positive contribution to pile bearing capacity, the effect of the closure's location along the pipe shaft (distance from the tip), and the influence of the diaphragm's design (shape, etc.).

RÉSUMÉ: Le problème important de la conception des structures sur pieux est de garantir un coût de pieux raisonnable. Cela peut être obtenu en raccourcissant soit la longueur des pieux, soit le nombre de tuyaux dans la fondation sur pieux (en gardant les dimensions et les propriétés matérielles d'un autre pieu sans modifications). Ces deux approches doivent fournir une capacité portante requise de la fondation sur pieux (les charges de compression axiales sont prises en compte). Ces résultats peuvent être obtenus si chaque pieu raccourci est amélioré et supporte la même charge qu'un pieu de longueur normale (initialement conçue) ou si chaque pieu de longueur normale est amélioré et supporte une force axiale plus grande par rapport à sa capacité initialement conçue. Le but de l'étude présentée était de clarifier certaines possibilités pour améliorer la capacité portante du pieu tubulaire en utilisant un diaphragme rigide interne (fermeture) placé à l'intérieur du fût du pieu. Cela augmente la capacité portante du pieu tubulaire en raison d'une réaction supplémentaire du sol à l'intérieur du puits (cela a été confirmé par des mesures connues sur site). Des recherches en laboratoire visant à étudier l'effet mentionné ont été réalisées avec le modèle du pieu enfoncé dans un sol sableux. Ces essais ont permis de préciser les conditions de formation des invasions de sol en pointe de pieu et sous le diaphragme ainsi que leur interaction. En outre, certaines conclusions et recommandations ont été formulées clarifiant la contribution positive du diaphragme à la capacité portante du pieu, l'effet de l'emplacement de la fermeture le long du fût du tuyau (distance de la pointe) et l'influence de la conception du diaphragme (forme, etc.).

Keywords: Tubular pile; bearing capacity; internal diaphragm.

1 INTRODUCTION

Modern marine transportation and offshore structures such as deep-water port berths, oil and gas platforms, raid and offshore fixed single point moorings, submerged stores, and others often include steel tubular piles of essential length (80-100 m and more) as main bearing elements. Such tubular piles should provide high bearing capacity in case of external axial loads application (Doubrovsky et al., 2018, Tomlinson and Woodward, 2008, Randolph et al., 1991).

Besides, piling works may provoke some environmental problems connected with the hammer's operation (noise, vibration, dynamic action, carbon footprint, etc.). One of the ways to reduce environmental hazards during pipe pile driving is decreasing piling work volume. It can be provided by shortening either of pile's length (i.e. depth of driving) or the number of pipes in the pile foundation (keeping another pile's dimensions and material properties without changes). Both such approaches should provide a required bearing capacity of the pile foundation despite the short-cut piles or fewer piles number (axial compressing loads are considered).

These results may be achieved if each short-cut pile is improved and bears the same loading as a pile of normal (initially designed) length or if each pile of normal length is improved and bears larger axial force in comparison with its initially designed capacity.

So, the study aimed to clarify some possibilities to improve the pipe pile's bearing capacity using an internal rigid diaphragm (closure) placed inside the pile's shaft. This innovation increases the bearing capacity of the tubular pile due to additional soil reaction inside the shaft as has been confirmed by known on-site measurements (Tomlinson and Woodward, 2008) and our previous physical modeling (Doubrovsky et al., 2022).

As in many cases, large diameter tubular piles of shelf structures are installed without plugging effect or with partial plugging (Randolph et al., 1991, White et al., 2010, Gudavalli et al. 2013, Lehane and Gavin, 2004), the approach based on the use of the closure of the pile's shaft looks rather attractive for deep water port, marine, and offshore engineering. So, it needs detailed consideration and study aiming to determine the method's peculiarity, an appropriate sphere of application, details of diaphragm design, and its proper location along the pile's shaft.

2 APPLICATION OF INTERNAL DIAPHRAGM IN STEEL TUBULAR PILES

Recommended technology to install the internal diaphragm was described (perhaps first) in Tomlinson and Woodward, 2008. A hole is necessary for the diaphragm to release water pressure in the soil plug and to allow the expulsion of silt. Stresses on the underside of the diaphragm are high during driving and radial stiffeners are needed.

According to Tomlinson and Woodward, 2008, the minimum depth above the pile toe for locating the diaphragm is the penetration below the sea bed required for fixity against lateral loading. There are formulas in some norms allowing the determination of the fixity's depth depending on soil properties and the pile's bending rigidity; roughly this depth may be determined in the interval of (5-7) d. However, further penetration is necessary to form the soil plug under the diaphragm by compacting the soil within the plug and developing the necessary base resistance. Thus, mentioned authors considered two locations for two soil plugs formation during the tubular pile driving: at the open end of the pile and under the internal diaphragm.

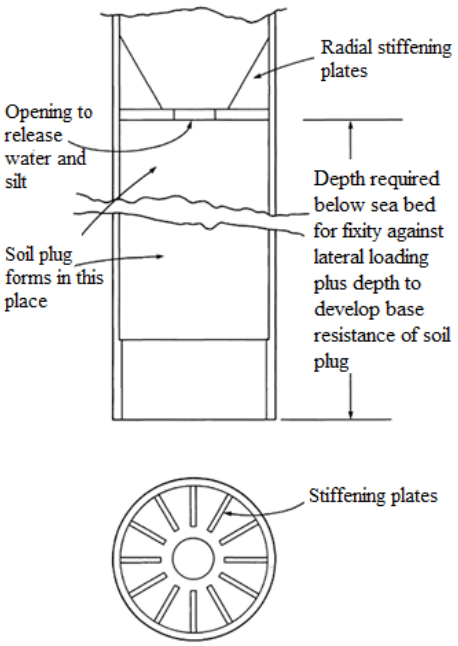

Figure 1. Steel tubular pile with the diaphragm.

As an example of the diaphragm's practical application, we may refer to the piling works at the Hadera coal unloading terminal near Haifa (Tomlinson and Woodward, 2008). Open-end piles 1424- and 1524-mm OD were proposed but initial trial driving showed that very deep penetrations, as much as 70m below sea bed in calcareous sands, would be needed to develop the required axial resistance. The blow count diagram showed quite low resistance at 36m below the sea bed. Trials were then made of the diaphragm method. A diaphragm with a 600 mm hole giving 83% closure of the cross-section was inserted 20m above the toe. This increased the driving resistance at 39m below the sea bed and another trial with a 300 mm hole (95% closure) gave a higher resistance at 37m. It was supposed that such improvement of piles bearing capacity was stipulated by soil plug formation below the mentioned diaphragms.

3 LABORATORY MODEL TESTING

Regarding that obvious effect (an increase of the pile's bearing capacity) has been achieved by the use of the rigid diaphragm, we intended to study the peculiarities of the considered approach by providing model static tests in laboratory conditions. We aimed to obtain parameters describing the considered pile driving process – both qualitative (related to the process in general) and quantitative (characteristic for the applied model pile-soil system) ones.

As to the method of pile installation, we suppose that traditional approaches (use of impact hammer or vibro hammer) are not reliable enough to provide safety of the rigid diaphragm fixed by welding inside

the pile's shaft and interacting with soil under the diaphragm. In order to avoid dynamic actions upon the diaphragm during pile penetration we prefer to consider a safer but more effective method of pressing load application (jacking) (White et al, 2010).

To clarify the above-mentioned items related to the tubular pile with an internal diaphragm, we fulfilled a series of experimental studies in the Geotechnical Laboratory of the Department "Sea, River Ports and Waterways" at Odessa National Maritime University (Odessa, Ukraine).

For pile testing, we used a soil box of dimensions: width of 600 mm, length of 750 mm, and depth of 1100 mm (Figure 2). For the model of the tubular open-end pile, we apply steel pipe d=50 mm external diameter, wall pipe thickness 1 mm, l=800 mm length. To drive the pipe into fine sand mechanical jack has been applied.

For experimental studies we used fine sand with the following characteristics: internal friction angle 33^0; density 14.5 kN/m^3; void ratio 0.71; moisture 0.07%; Young modulus 16 MPa, Poisson's ratio 0.3.

The first series of the experiment aimed to determine conditions of the soil plug formation at the tip of the open-end pile model. A detailed description of this study was presented in (Doubrovsky et al., 2022).

The second series of the experiment was devoted to clarification of the role and contribution of the internal diaphragm. For the model pile the diaphragm was produced as a circular steel plate (4 mm thickness), with its diameter corresponding to the inner diameter of the pile.

The internal diaphragm was fixed at several positions by changing the distance from the tip of the model pile: 0 (closed-end); 3d; 6d; 9d (total length of the pile was equal to 16d). As it is demonstrated by the diagrams presented in Figure 3, the application of the internal diaphragm provides increasing open-end pile bearing capacity. The degree of such an increase depends on the diaphragm location. For the considered options of the diaphragm fixing point, the minimum increment of the open-end pile bearing capacity relates to the 3d distance between the diaphragm and the pile tip, and the maximal increment is measured at the 9d distance.

Perhaps mentioned circumstances may be commented by the following way. The upper plug under the diaphragm may be formed if there is a proper base reaction developed inside the shaft. Such a situation may occur if the upper plug (being in the process of formation) meets the already-formed lower plug. The last transfers additional pressure to the soil under the toe and provokes an additional base reaction.

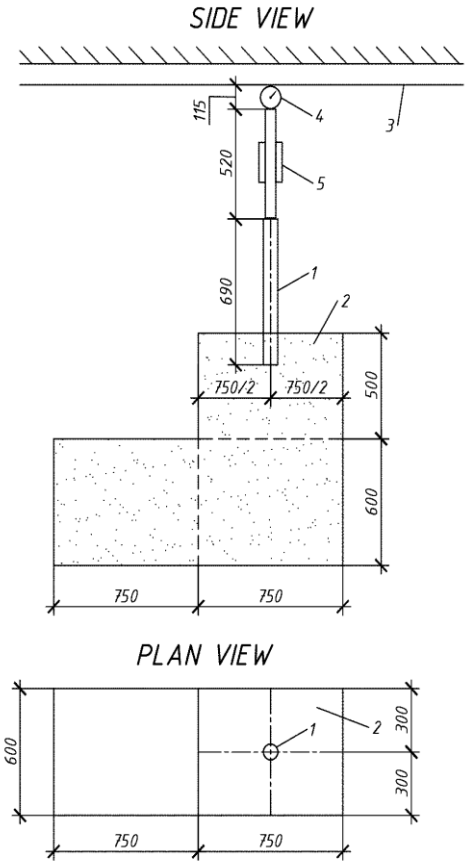

Figure 2. Scheme of the experiment: 1 – pile model; 2 – sandbox; 3 – bearing beam; 4 – force gauge (dynamometer); 5 – jack loading system (telescopic) (all sizes in millimeters).

Thus, the additional external force acts on the plug and increases soil density in it. In fact, after that stage, two plugs are combined and work as one large plug between the diaphragm and the pile's toe. The creation of the mentioned large plug and its effective contribution to the pile bearing capacity may be provided only in case of the "right" location of the diaphragm (not too low and not too high). For our model tests the maximal bearing capacity of the open-ended pile was measured in the case of the 9d distance of the diaphragm from the pile tip.

It may be explained, particularly, by the fact that for the considered test conditions, approximate driving depth t= (4-5)d at the initial stage of pile installation is needed to dense soil due to the development of the friction forces inside the pile's shaft and to form a lower soil plug at the pile tip. If then to apply similar consideration for the follow-on stage of the driving process – compaction of the soil under the diaphragm due to the similar friction forces, required penetration depth for this stage to form the upper plug may be of similar value (4-5) d.

So the total distance between the pile toe and the diaphragm may be considered as the sum of these two parts of the penetration depth, i.e., approx. (8-10) d. Such location of the diaphragm may be optimal to form two plugs consecutively and to combine them in one large plug.

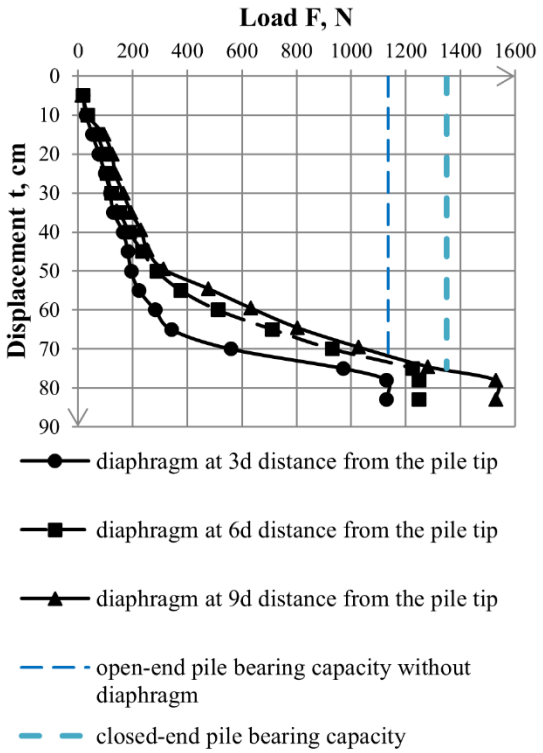

Figure 3. Dependencies between vertical axial load upon the model open-end pile and its displacements.

Regarding quantitative parameters of open-end pile bearing capacity (Figure 3), we would like to note that due to the diaphragm's contribution, pile bearing capacity may be increased (in our tests up to 15-20%). Another effect consists in the possibility to decrease pile driving depth (10-15%). Mentioned figures should be considered concerning possible experimental errors stipulated by differences in the reproducibility of the model ground preparation as well as measurement inaccuracy (about 10% in total).

For the conditions of our laboratory model testing (skipping the details of intermediate conversions and calculations), it was determined that the related prototype is a tubular pile of diameter 1.0 m driven up to 10 m into similar sandy soil. Its bearing capacity (sum of the toe and shaft bearing capacities) is 1723 kN. For comparison: the calculated value of the prototype bearing capacity according to the recommendation of the related Ukrainian code occurred to be 2020 kN (some 15% difference). Also, for plugging effect assessment we have to consider scale effects stipulated by the influence of internal pile diameter. This aspect is subject to a study for further investigations.

4 VARIATION OF INTERNAL DIAPHRAGM DESIGN

To assess the effectiveness of various forms of the pile's closure, we considered 3 types of diaphragm: flat, conical (in 3 variants, differing in the angle of the cone), and cylindrical (Figure 4, dimensions in mm).

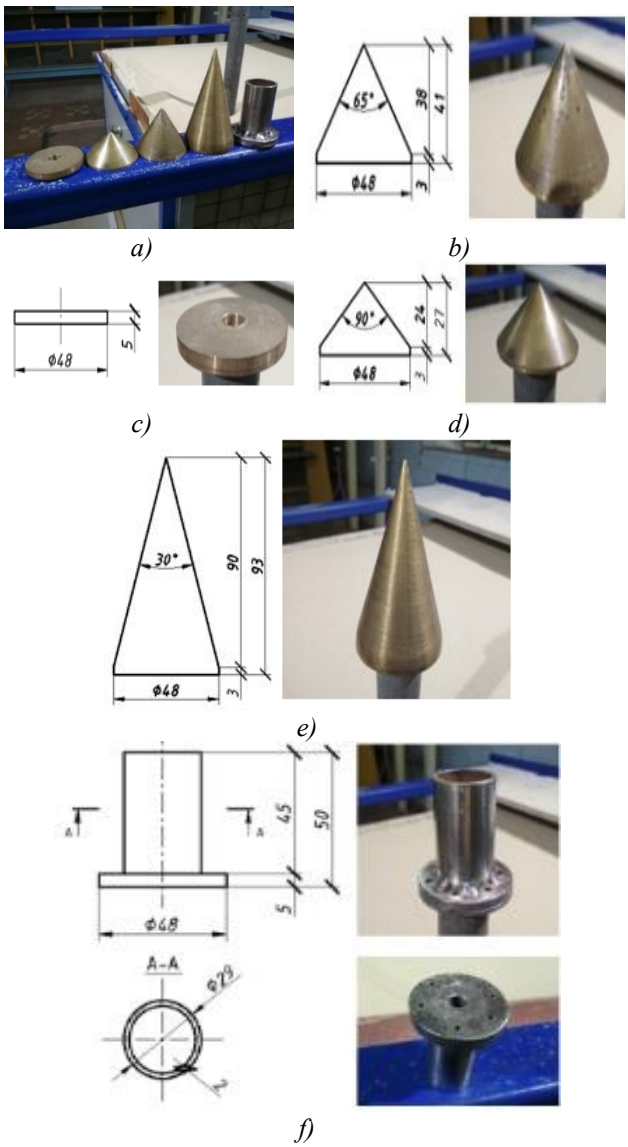

Figure 4. Details of the experimental pile (sizes in mm): a – closures of different shapes applied in the experiment; b – conic closure 65^0; c - flat closure; d – conic closure 90^0; e - conic closure 30^0; f - cylindric closure.

The driving of the model pile was carried out until the pile reached its bearing capacity, i.e. until the moment when the movements of the pile increased without an increase in the external load.

Of the three considered conical diaphragm options (with a cone angle of 30^0, 65^0, and 90^0), the best result was obtained for a pile's closure with an angle of 65^0.

A comparison of load-displacement dependencies for piles with different types of the diaphragm is shown in Figure 5. The last shows that the cylindrical diaphragm occurred to be the most effective and the flat closure was least effective.

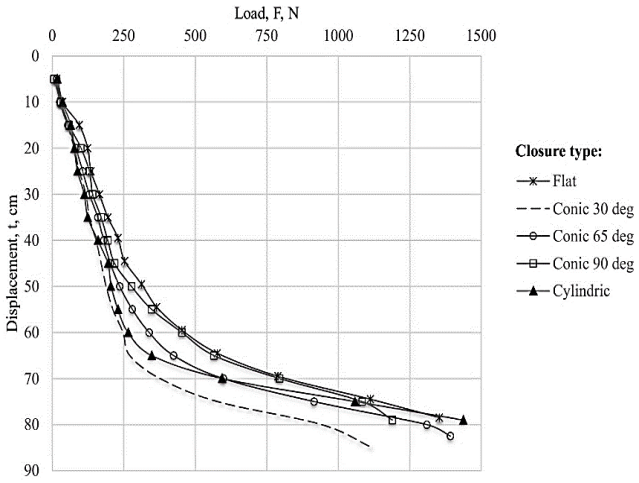

Figure 5. Dependencies between vertical axial load upon the model pile and its displacements for closure of different shapes located at 9d distance from the tip.

A comparison of the work of the model pipe pile in two extreme cases (with an open and closed-end) and in the cases of the diaphragm of effective shape (cylindrical and conical with a cone angle of 65^0) is presented in Figure 6.

To analyze the influence of the location of the closure on the bearing capacity of the pile, the experimental dependence of the resistance of the soil to pile driving N (equivalent to the vertical load on the pile) on the depth D of the cylinder diaphragm location is of interest. Figure 7 shows an example of such a relationship, summarizing the data we obtained in the experiments.

According to this diagram, by choosing in advance the location of the closure, it is possible at the initial stage to facilitate the pile driving compared to the pile with a closed-end, and at the final stage of pile installation, it is possible to approximate the value of the bearing capacity of the pile with closure to the parameters of the pile with a closed end. This ability to regulate the resistance to pile driving is important for the optimal and economical choice of technological equipment when installing the pile foundation of the structure.

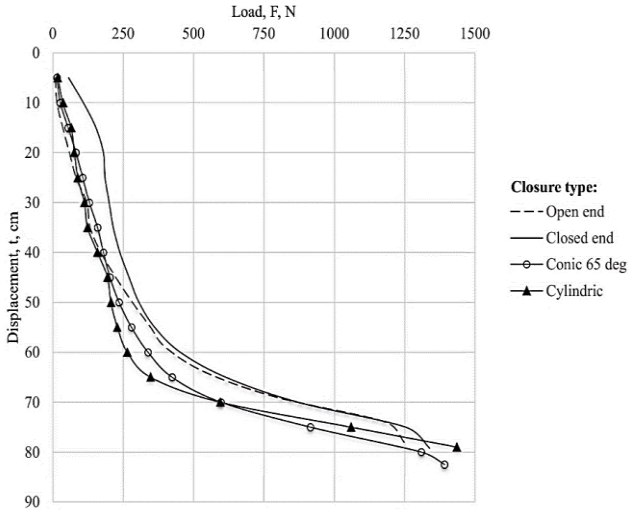

Figure 6. Dependencies between vertical axial load upon the model pile and its displacements for the absence of the closure (open and closed ends) and for the presence of the closure (conic and cylindric) located at 9d distance from the tip.

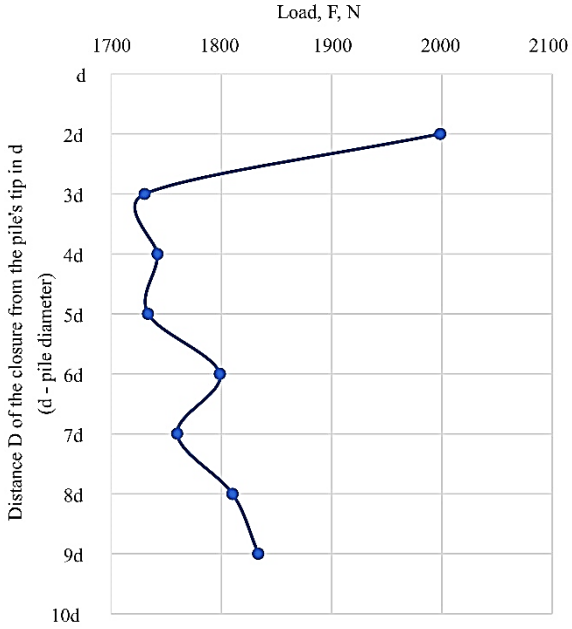

Figure 7. Dependencies between vertical axial load upon the model pile and cylindrical closure's location (distance from the tip D).

Obtained experimental dependencies (Figures 5 and 6) can be analytically described by approximating functions with good correlation indexes similarly to the method proposed earlier (Doubrovsky et al., 2022). For data interpreted in Figure 7 another approach should be worked out in the further numerical analysis.

5 CONCLUSIONS

As obtained from the presented initial series of our experimental studies, a rigid diaphragm inside the tubular open-end pile may be a useful element for increasing the pile's bearing capacity.

Consecutive formation of two soil plugs (the lower one formed just at the pile tip and then the upper one formed under the diaphragm) leading to their partial or full integration is most effective when the optimal location of the diaphragm inside the pile shaft is provided. From the point of view of pile bearing capacity under axial compressive load and for the considered experimental conditions, such proper distance between the pile tip and internal diaphragm occurred to be around 9d (d – pile diameter).

Improvement of the pile effectiveness determined by experimental modeling for the above-mentioned pile-soil conditions provides 15-20% increase of the bearing capacity or a 10-15% reduction of the driving depth.

An interesting possibility of regulating the value of the bearing capacity of the pile by changing the position of the diaphragm along the pile's shaft is brought out. Such an approach can be effective if the open-ended tubular pile does not provide the required bearing capacity of the pile, and the closed-end pile results in excessive bearing capacity or causes the use of too-powerful and expensive pile-driving equipment. The use of a pile with a closure leads to an intermediate option between piles with an open and closed-end, which allows for optimization of the design of the pile foundation of the structure and reduces the cost of piling work.

Another important effect of increasing the bearing capacity of a tubular pile through the use of an internal diaphragm is to reduce the volume of piling and accordingly to decrease noise, vibration, dynamic action, carbon footprint, etc., providing the improvement of the environmental situation at the construction site.

ACKNOWLEDGMENT

The authors would like to express gratitude to colleagues from the Geotechnical Laboratory of the Department "Sea, River Ports and Waterways" at Odessa National Maritime University for their valuable support and assistance in model test arrangement and fulfillment.

This study was supported at the Technion by a fellowship from the Lady Davis Foundation.

Mechanical characterization of a saturated marine clay for pavement design and performance

Caractérisation mécanique d'une argile marine saturée pour la conception et la performance des chaussées

ABSTRACT: The study investigates the resilient behaviour of a fully saturated marine clay, crucial for pavement design amidst concerns of rising groundwater levels affecting pavement structures. Traditional testing standards do not address saturated conditions, prompting a new approach. Undisturbed marine clay samples were collected in the Onsøy area, Norway and underwent Repeated Load Triaxial (RLT) tests to determine their resilient modulus (M_R). The study outlines sample preparation, consolidation and finally RLT test procedures. Results revealed low M_R values, indicating the soft nature of the Onsøy clay. Two distinct test procedures yielded contrasting stress dependency patterns, raising concerns regarding the accurate representation of the material's mechanical behaviour. Factors such as overburden stress, load repetition, pore water pressure and sample quality were explored. Sustained overburden stresses led to a stiffer response and higher sensitivity to shearing. Increased load repetitions stiffened the material further. Finally, an analysis of samples' disturbance was used to differentiate the two test procedures, showing that conducting RLT tests in a fully saturated sample without overburden stress produced poor-quality samples. The study's significance lies in characterizing a saturated material using non-standardized testing methods, offering insights into pavement design considerations.

RÉSUMÉ: L'étude se concentre sur le comportement résilient d'une argile marine entièrement saturée, qui est essentiel pour la conception des chaussées afin de faire face à l'augmentation du niveau des eaux souterraines. Les essais traditionnels ne prennent pas en compte les conditions de saturation, d'où la nécessité d'une nouvelle approche. Des échantillons d'argile marine ont été prélevés en Norvège et soumis à des essais triaxiaux à charge répétée (RLT) pour déterminer leur module de résilience (M_R). Les résultats ont révélé une faible résilience, indiquant la nature molle de l'argile. Deux procédures d'essai différentes ont donné des modèles de comportement mécanique contrastés, ce qui soulève des inquiétudes quant à leur représentation exacte. Les facteurs tels que la surcharge, la répétition de la charge et la qualité de l'échantillon ont été étudiés, montrant que des contraintes soutenues et des répétitions de charge plus élevées renforcent la rigidité du matériau. Une analyse de la perturbation des échantillons a été utilisée pour différencier les procédures d'essai, indiquant que la réalisation d'essais RLT dans un échantillon entièrement saturé sans contrainte de surcharge produit un échantillon de mauvaise qualité. Cette étude est importante pour mieux comprendre les considérations relatives à la conception des chaussées en caractérisant les matériaux saturés à l'aide de méthodes d'essai non normalisées.

Keywords: Subgrades; soft clay; resilient modulus; permanent deformation; repeated load triaxial test.

1 BACKGROUND

The stiffness of fine-grained subgrades is highly sensitive to the moisture content (Blackmore et al. 2020), hence impervious surfacing combined with proper drainage systems are important for the overall performance of a pavement structure (Charlier et al. 2009). For the same reason, the pavement's unbounded layers are in an unsaturated condition most of the time (Salour and Erlingsson 2013). However, depending on the terrain topography, parts of the pavement structure could be periodically exposed to the groundwater table (GWT), especially its subgrade, also known as the formation level.

Seasonal GWT variation is a common phenomenon, and some studies predict that sea level rise associated with more precipitation can cause a permanent increase in GWT, thus affecting the

formation layer in low-lying terrains (Chen and Wang 2023). Therefore, characterizing the resilient modulus (M_R) of subgrade materials in saturated conditions is important for pavement design and performance.

Existing M_R testing standards are not designed to evaluate saturated subgrades, thus a new test procedure was trialled for characterizing the M_R of a material on such condition. Undisturbed block samples of marine clay were collected in Norway and transported to Sweden where Repeated Load Triaxial (RLT) tests were conducted to characterize their M_R.

2 METHODOLOGY

2.1 Sampling

The material was sampled in the Onsøy area, located in southeastern Norway bordering the Oslo fjord. Undisturbed block samples were retrieved from 3 to 5 meters below ground level (bgl) using a Sherbrooke block sampler. The samples were about 25 cm high by 18 cm diameter, and after retrieval, they were involved in plastic foil and protected inside a 20 cm diameter plastic tube to minimize travel disturbances.

2.2 Material characteristics

The Onsøy substrata consists of a deposition area originating from rapid marine clay deposition from the last deglaciation phase followed by a gradual sedimentation process after the uplift of the region above sea level (Gundersen et al. 2019). The GWT is located at 1 m bgl and a medium to high plasticity dark grey silty clay is found between the dry crust (≤ 1 m bgl) and the bedrock (at 8 to 40 m bgl). Therefore, the block samples collected for this study are all in a saturated condition. Table 1 summarises the index properties of the material and Equations 1-2 are the best estimate for the effective, σ'_{v0}, and apparent preconsolidation, σ'_p, stresses as reported in Gundersen et al. (2019):

$$\sigma'_{v0} = 5.01 \cdot (z - 1) + 17.5, \quad 1 \leq z \leq 9 \qquad (1)$$

$$\sigma'_p = 6.9 \cdot (z + 4.54), \quad 3 \leq z \leq 20 \qquad (2)$$

where z is the depth in meters.

Table 1. Material index properties.

γ_s (kN/m^3)	a (kPa)	ϕ'_{cv} (°)	s_{uC} (kPa)	I_p (%)	w_s (%)
27.1	5	30	15.8	44	70

In Table 1, γ_s is the unit weight of solids, a is attraction, ϕ'_{cv} is the friction angle, s_{uC} is the undrained shear strength in triaxial compression, I_p is the plasticity index and w_s is the gravimetric moisture content.

2.3 Specimen preparation

The undisturbed block samples were trimmed down to 10 cm diameter and sliced down to 20 cm high. Following the trimming process, the sample was placed on a pedestal, where a flushed porous stone and water-soaked filter paper were resting.

Thereafter, water-soaked filter paper strips were placed around the sample, in a bid to accelerate the consolidation of the specimen, as the water flow would be both axial and radial in the sample. Subsequentially, a second water-soaked filter paper, a flushed porous stone and a top cap connected to the backpressure were placed above the sample, and a latex membrane was fitted around it with the aid of a membrane stretcher. Finally, a set of 3 LVDTs spaced at 120° were installed in the third mid-height of the sample to measure deformation during the RLT test. Figure 1 shows the aforementioned steps.

Figure 1. Specimen preparation steps.

The coefficient of earth pressure at rest k_0 of the material is 0.6 (Gundersen et al. 2019) and thus the horizontal in-situ stress is given by $\sigma_{3\text{-ref}} = k_0$ x σ'_{v0}. Table 2 summarises the effective in-situ stress as well as the initial void ratio e_0 before the consolidation.

Table 2. Reference stresses at retrieved depth and OCR.

Sample ID	Depth (m)	σ'_{v0} (kPa)	σ_{3-ref} (kPa)	Void ratio e_0 (-)
S1	4.85	36.8	22.1	1.87
S2	4.33	34.2	20.5	1.87
S3	3.83	31.7	19.0	1.87

2.4 Consolidation

Samples were flushed via the top cap, keeping the drainage valve open throughout. The flushing consisted of a saturation ramp where both backpressure u_{bkp} and cell pressure σ_3 were increased at the same rate, keeping a net confining pressure σ_{3net} = σ_3 - u_{bkp} of 10 kPa, until u_{bkp} reached 190 kPa.

The consolidation phase was initiated after a Skempton B-value higher than 0.95 was obtained. Thereafter, an anisotropic consolidation phase was started by simultaneously increasing σ_{3net} at 1.5 kPa/min and the deviatoric stress σ_d at 0.5 kPa/min to reestablish field stress levels. The consolidation was complete when the backvolume change flattened out, which took over 16 hours. A complete description of the method can be found in NGTS (2016).

2.5 Repeated load triaxial test

The testing procedures described in AASHTO T:307 (AASHTO 2003) and NCHRP 1-28A (NCHRP 2003) for characterising the resilient properties of subgrades are not designed for testing fully saturated samples or soft materials. For the latter, it was verified that the shear stresses proposed in those procedures would be higher than the shear strength of the clay used in this study, which would lead to premature failure during cyclic loading. Whereas, for the former, changing confining stresses rapidly in between stress paths, as in the NCHRP 1-28A procedure, does not accord with the consolidation stresses in a fully saturated and quite impermeable material such as clay, where such changes demand a lengthy stress equalization period.

Hence, two sets of stress paths were trialled instead. The first followed the same principle as in AASHTO T:307 (Table 3), consisting of three loading sequences going from a higher to a lower σ_3, containing five stress paths (100 cycles each) at increasing stress ratios while keeping a small static stress. It should be noted that the loading sequences started with the confining stress according to the one applied in the consolidation phase ($\sigma_{3\text{-ref}} = k_0 \times \sigma'_{v0}$), and that the static stress was only a fraction of the deviatoric stress imposed during the consolidation phase, as indeed is adopted in AASHTO T:307.

Table 3. M_R for sat. samples – test procedure 1 (S1 and S2).

Load. Seq.	Confining pressure (kPa)	Static stress (kPa)	Stress ratio (σ_1/σ_3) per stress path				
			1	2	3	4	5
1	σ_{3-ref}	10% $\cdot \sigma_{d-max}$	1.3	1.4	1.5	1.6	1.7
2	$0.75 \cdot \sigma_{3-ref}$		1.4	1.5	1.6	1.7	1.8
3	$0.5 \cdot \sigma_{3-ref}$		1.6	1.8	2.1	2.3	2.6

As the RLT test in test procedure 1 was conducted under stress relaxation, i.e. lower effective stress than the yielded at the consolidation phase, another testing procedure was developed, consisting of a RLT test conducted with the same overburden stress imposed in the k_0-consolidation. It included three loading sequences with σ'_v targeting 0.7, 1 and 1.3 times σ'_{v0}. Those figures would reflect the effect of constructing in cut, on-grade or in fill section. Each load sequence was divided into three stress paths (100 cycles each) whose vertical stresses reflect the typical stresses induced by traffic load on the top of the subgrade. Table 4 summarises the procedure and Figure 2 illustrates it.

Table 4. M_R for sat. samples – test procedure 2 (S3).

L. Seq	Confining pressure (kPa)	Static stress (kPa)	Stress ratio (σ_1/σ_3)		
			1	2	3
1	$0.7 \cdot \sigma_{3-ref}$	$0.7 \cdot (\sigma'_{v0} - \sigma_{3-ref})$	2.1	2.2	2.3

2.6 Response modelling

The test results were modelled using the Universal Model for M_R (Equation 3) (AASHTO 2008) to obtain material parameters that can be used to calculate the subgrade's M_R at different sets of stresses from the combination of overburden and traffic-induced stresses:

$$M_R = k_1 \cdot \left(\frac{\theta}{p_a}\right)^{k_2} \cdot \left(\frac{\tau_{oct}}{p_a} + 1\right)^{k_3} \quad (3)$$

where k_1, k_2 and k_3 are material parameters, θ is the bulk stress (kPa), τ_{oct} is the octahedral stress (kPa) and p_a is a reference pressure considered 100 kPa.

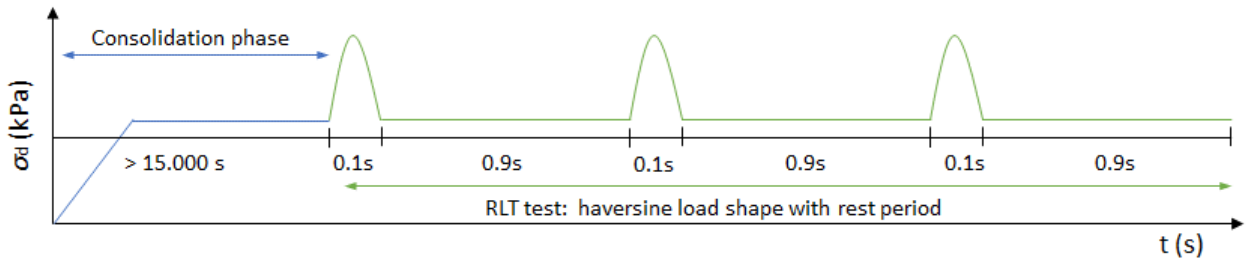

Figure 2. Schematic of RLT test on saturated S3.

3 RESULTS AND DISCUSSION

The best fit M_R prediction model was calculated and is presented in Table 5 along with the predicted M_R for stresses likely to be experienced on the top of the subgrade. Such stresses were calculated based on a typical road structure in Norway (Statens vegvesen 2013) of 1.5 m in thickness, given the adoption of a frost protection layer. Therefore, it resulted in θ = 44 kPa and τ_{oct} = 6.5 kPa, for a σ_3 = 10 kPa.

The $M_{R\text{-predicted}}$ for the Onsøy clay turned out to be in the low range, varying from 8 to 17 MPa, according to the different procedures employed for conducting the RLT test. These figures are in line with expected results for soft clays (Simonsen et al. 2002), however, the procedures yield quite different stress dependency patterns, which raises questions about which best represents the material's behaviour.

Table 5. Universal model best-fit parameters and stiffness.

Sample	k_1 (-)	k_2 (-)	k_3 (-)	R^2 (-)	$M_{R\text{-predicted}}$ (MPa)
S1	494	0.753	-13.532	.963	11.5
S2	232	0.442	-12.017	.930	7.7
S3	23 046	3.362	-34.316	.996	16.6

3.1 Effect of overburden stress

Samples 2 and 3 were subjected to a k_0-consolidation, but the cyclic loading phase differed as seen in Table 3 and Table 4, especially regarding the static stress or overburden. When the static stresses were sustained throughout the RLT test (S3), the material showed a stiffer response and a higher sensitivity to shearing, as can be seen in Figure 3.

3.2 Effect of load repetition

S3 was also subjected to a second RLT test where the same stress paths as in Table 4 were employed, however, 10 000 cyclic loads (N) per stress path were applied, instead of one hundred. Such test is usually performed to obtain the permanent deformation (PD) properties of the material; however, the focus was assessing the impact of load repetition on the M_R.

The average resilient strain from the last five cycles of each stress path was used for calculating the M_R in both tests whether N was 100 or 10 000. Figure 4 demonstrates the stiffening process that occurred when the sample was subjected to a higher number of load repetitions.

3.3 Effect of pore water pressure

The stress applied during consolidation targeted effective stresses by maintaining a constant backpressure, thus already subtracting pore water pressure (PwP). However, under cyclic loading, an excess PwP is generated. For the condition where the overburden was maintained throughout the cyclic phase, as in S3, the excess PwP was only about 2 kPa, in contrast to the condition where the overburden was removed, as in S1 and S2, where the excess PwP was about 4 kPa (Figure 5).

This is explained by the fact that in S1 and S2 a higher dynamic stress was imposed for a lower static stress, as can be inferred from Table 3, whereas in S3 a higher static and lower cyclic stress was imposed (Table 4), which is consistent with the estimates for the subgrade level.

Although the difference in excess PwP is minimal, the combination of higher excess PwP and higher cyclic stress results in more axial strain (Zhang et al. 2020), which may explain the lower stiffness observed for S1 and S2 compared to S3.

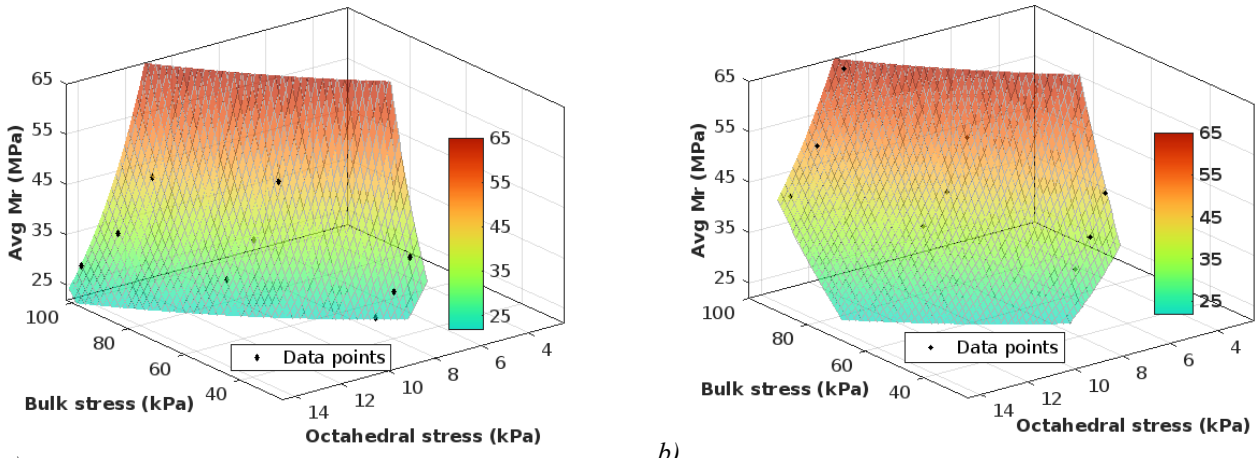

Figure 4. Predicted M_R a) S3 | N:100 b) S2 | N: 10 000.

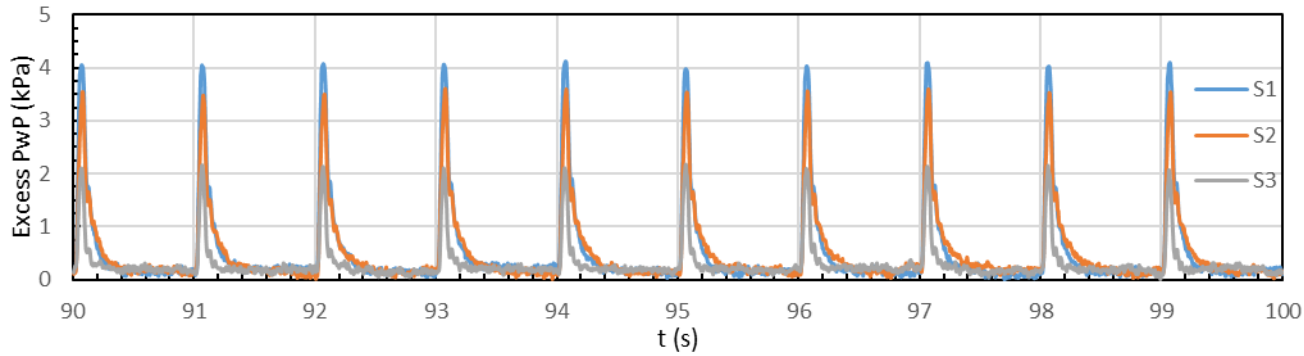

Figure 5. Excess PwP measured in the last stress path of the M_R test.

3.4 Effect of sample disturbance

The samples quality was assessed in terms of their normalized change in void ratio $\Delta e/e_i$ using the criteria for sample disturbance proposed by Lunne et al. (2006), where changes above 0.07 indicated poor to very poor sample quality. The $\Delta e/e_i$ for S1 and S2 was 0.117 and 0.137, respectively, whereas for S3 was 0.063. The hypothesis is that the stress relaxation observed in the test procedure 1 promoted such disturbance.

One of the effects of sample disturbance is the break of cementation bonds between particles that results in lower shear strength at small strains (<3-4%) (Lunne et al. 2006). As the traffic-induced stesses are rather low at the subrade depth (> 1.5m), they generate small strains and thus, the lower strenght caused by the sample disturance might explain the lower stiffness measured for S1 and S2 in comparison with S3.

4 CONCLUSIONS

Undisturbed samples of a marine clay were collected in the surrounding area of the Oslo fjord in Norway and had their resilient behaviour characterized in the laboratory via RLT tests, conducted on fully saturated samples. As this condition deviates from standard practice for characterizing the M_R, two procedures were trialled and evaluated in this study. Their differences concern the overburden stress and the confining stress path at subsequent load sequences.

Both procedures yielded low M_R values, confirming the soft behaviour of the Onsøy clay. Nevertheless, the test procedure 2 (with overburden) produced a stiffer response. The results were further discussed in terms of sample disturbance and the procedure 1 (without overburden) resulted in a poor-quality sample, which might explain the lower stiffness obtained when using such procedure. Furthermore, the material showed a stiffening behaviour as an effect of load repetition. The results are limited to one material in fully saturated conditions, but it can offer a better understanding of its behaviour for pavement design purposes. Future studies will concentrate on testing other soils as well as testing in unsaturated conditions.

ACKNOWLEDGEMENTS

This research is funded by the Swedish Transport Agency. The authors are grateful to the Norwegian

Public Roads Administration for providing the samples and discussing the testing method.

Integrating local data into geotechnical design through a predictive probabilistic approach

Comment une approche probabiliste permet d'intégrer les données locales dans la conception géotechnique

ABSTRACT: Site investigation and assessment of the soil and rock characteristics are essential parts of the geotechnical design process. These characteristics can be assessed from a variety of in situ tests. In France, the Ménard pressuremeter test is widely used. This in-situ testing method is used to determine the stress-strain relationship of the tested soil and to evaluate, among others, the Ménard limit pressure (p_{lM}) which is used to calculate the bearing capacity of a foundation. In this paper, we show how different predictive models can be used to infer a distribution, with depth, of the p_{lM} parameter for a new construction project, based on the historical data available in the vicinity. We then demonstrate how this information is used throughout the process of site investigations and geotechnical design. Before the site investigations, this approach allows for a preliminary overview of the mechanical characteristics of the soils, and for better targeted field investigations. This method is then used in the interpretative report, to ensure better reliability of the geotechnical design and construction recommendations.

RÉSUMÉ: Les reconnaissances géotechniques et les essais visant à caractériser les sols et les roches sont le fondement de toute conception géotechnique. Si cette caractérisation peut s'obtenir par une variété d'essais in situ, en France, on a largement recours au pressiomètre Ménard. Cette méthode d'essai permet de tracer une courbe contrainte-déformation du sol testé et d'en déduire, entre autres, la pression limite (p_{lM}) qui est utilisée pour la justification en portance des fondations. Dans cet article, nous montrons comment différents modèles prédictifs peuvent être utilisés pour établir la distribution, en fonction de la profondeur, de la pression limite p_{lM} au droit d'un projet de construction, à partir des données historiques disponibles à proximité. On montre ensuite comment cette information peut être exploitée dans la définition d'une campagne de reconnaissance et dans les études géotechniques. Avant toute reconnaissance, cette information donne une première image des caractéristiques mécaniques des sols, et permet d'établir un programme optimisé. Cette approche est ensuite exploitée lors de l'établissement du rapport d'étude et permet de fiabiliser la conception géotechnique et les préconisations relatives aux travaux.

Keywords: Probabilistic modelling; pressuremeter test; foundation design; indicator kriging.

1 INTRODUCTION

Building a ground model for geotechnical design starts by assessing available knowledge for the project site and its surroundings. Through site visit and desk study, a preliminary ground model can be established which forms the basis for planning field and laboratory tests.

Among the abundant data that is available to the geotechnical engineer, results from previous site investigation at the studied site or in the vicinity constitute a prime source of information. However, parsing through numerous site investigation reports is time consuming and building an unbiased and comprehensive synthesis is difficult. No one can check dozens of borehole logs and remember every bit of information.

We believed that a comprehensive synthesis of previous site investigations, in the form of a preliminary ground model, would help our engineers build optimised site investigation programs, targeted at verifying and updating the anticipated model.

It is with that goal in mind that Fondasol started a few years ago to work on two distinct projects: the first consisted in structuring the factual data from past site investigations, and second consisted in testing with our data scientists the various geostatistical algorithms available in the literature to build a predictive ground model from the structured data.

2 BUILDING A PRELIMINARY GROUND MODEL FROM HISTORICAL DATA

In France, the most common in-situ test is the Menard pressuremeter, which provides a stiffness modulus E_M used in settlements calculations and a measure of ground resistance through the limit pressure P_{IM} which can be used to estimate the bearing capacity of a foundation. As a prebored in-situ test, the geological nature of the soil is also provided on the borehole logs.

Being the most abundant test in our database, and the one that our engineers are the most familiar with, it is the one we decided to use to build the preliminary ground model. However, the methods exposed here could easily be applied to other in-situ tests where ground strength is measured at regular intervals with depth, such as SPT tests.

2.1 The first attempts

The first algorithms that we experimented with were aimed at predicting the most likely soil conditions at a given point in space. We naturally looked at kriging and its variants, but we faced multiple challenges mostly due to the nature of the data. We tried 2D kriging by layers of different thicknesses, 2D kriging of derived values (such as foundation depth for a given structure), 3D kriging, but results were not easy to read and the level of uncertainty of the results was even harder to display.

A deeper shortcoming of those classical geostatistical approaches stems for the fact that predicting the most likely outcome is of lesser importance than the distribution of likely values, much like when presenting the range of values obtained by in-situ tests in a given soil layer. A naïve way to do so is by representing a distribution of values equated to the mere histogram of empirical data in a given soil layer (example in Figure 1).

One limitation of such a simple sample by soil layer, is that the distribution will not display the natural tendency of soil characteristics improving with depth (at least for sedimentary soils), which will also tend to widen the distribution in case of thick layers.

Estimating the increment of soil characteristics with depth can easily be achieved with a simple linear regression and can then be supplemented by calculating a lower bound (or upper bound) line for a given risk, as suggested by Baguelin et al., 2000. Such representation is oriented towards determining characteristic values with depth but requires a strict classification of test results by homogenous layers beforehand, as well as assuming a linearly increasing characteristic, both of which can stand short of the empirical evidence.

To give a global overview of soil conditions on a site, in the form of a preliminary ground model eschewing the limitations of the aforementioned methods of kriging, sampling or linear regression, we have experimented more elaborate distributional models. They involve a mixture of non-parametric and parametric statistical models inferring how the distribution of the limit pressure evolves with depth.

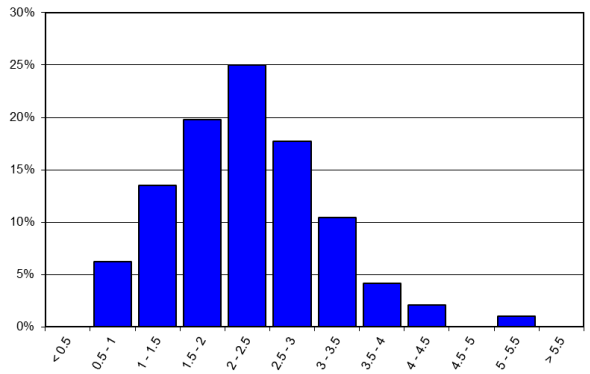

Figure 1. Histogram of the limit pressure (in MPa) in the Cretaceous White Chalk for a site west of Paris (Limay).

2.2 The current iteration

The models we are currently using infer 4 curves with depth corresponding to the following empirical quantiles: Q10, Q25, Q75 and Q90. These curves then determine 3 surfaces (as can be seen in figure 2):

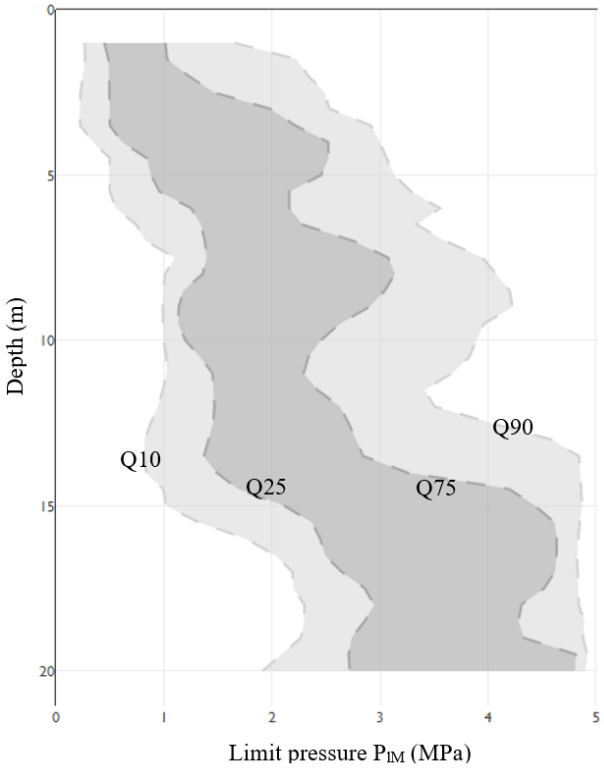

Figure 2. Example of the distributional model of the limit pressure with depth for a site north of Paris (Aubervilliers).

- A central zone corresponding to the two middle quartiles, where most likely values can be found (used for example when calculating the sleeve friction contribution to a pile's bearing capacity).
- A lower bound zone, between Q10 and Q25 where characteristic values are likely to be selected, say for shallow foundation design.
- An upper bound zone, between Q75 and Q90, for situations where higher values need to be considered, for example when assessing the drivability of a pile through a compact layer.

2.3 Constructing the distributional model

To help building the distributional model, the geotechnical engineer is presented with all the available boreholes from the database within a selected search radius. He must then exclude inappropriate boreholes based on geological and topographical criteria. As exposed in 2.4, this is very important to ensure a reliable distribution.

Typically, when studying a site in an alluvial plain, boreholes on the slopes rising towards the surrounding plateau have to be retreated even if they are fairly close to the site. This is, for example, shown in figure 3 where boreholes too close to the river or too high in altitude (to the north) are excluded.

Different distributions are then modelled at regular depth intervals from the selected boreholes including smoothing with depth as necessary and a weighing of distance.

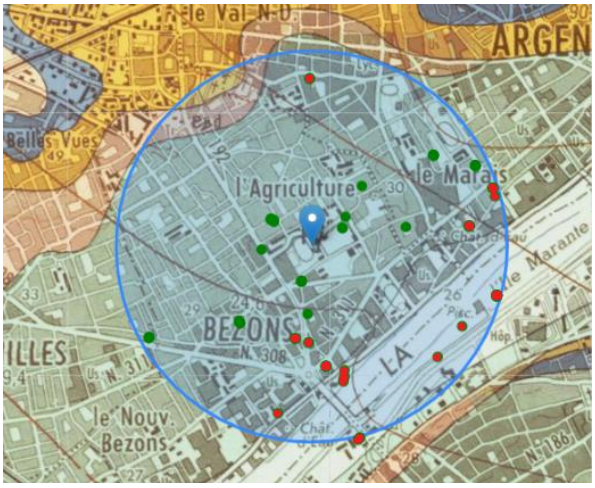

Figure 3. Example of borehole selection based on the geological and topographical context.

2.4 Adjusting the parameters

In order to measure the influence of the different parameters on the quality of the model, benchmarking was carried out through a leave one out process. The test samples consisted of groups of boreholes (corresponding typically to 1 or 2 site investigation reports) and the learning sample included all other boreholes in the vicinity.

Figure 4 shows an example of the fitting that was obtained for one of the test samples. This helped us adjust the model, with an essential part depending on a meaningful selection of the boreholes.

This is why we have kept the geotechnical engineer at the centre of the selection process, providing him with different visualisations of the geological data from boreholes to facilitate the selection and help identify outliers (for example due to improper positioning in the database). In the process of moderating boreholes, the engineer's judgement is very important to avoid excluding boreholes that could dutifully point out a geological anomaly.

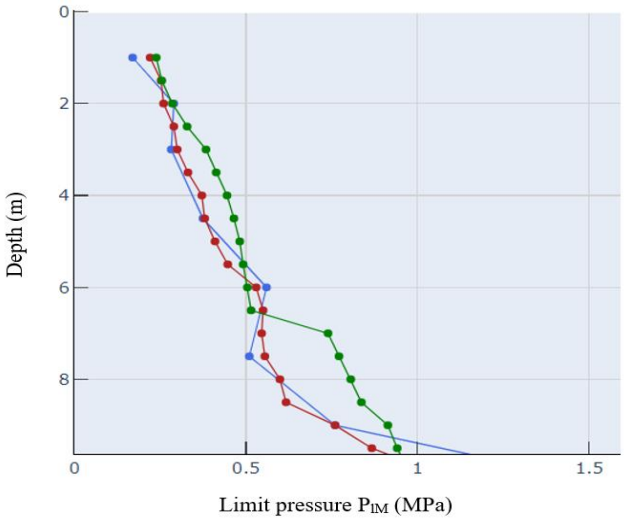

Figure 4. Test sample Q25 (blue) compared to the predicted Q25 based on surrounding boreholes (red = current algorithm, green = indicator kriging).

3 USING THE PREDICTED GROUND MODEL IN GEOTECHNICAL DESIGN

3.1 Preparing site investigations

The level of information provided by the preliminary ground model can be used by the geotechnical engineer to tailor an adapted site investigation program. We believe that the seasoned incorporation of surrounding data, instead of building a ground model exclusively from the ad hoc boreholes, is a crucial improvement in the realm of building risk mitigation.

This should also allow for more targetted investigations, and, depending on the uncertainties that need to be adressed, possibly modulating boreholes according to where it is most valuable to secure a reliable inital ground model.

3.2 Preliminary design

Our first example is a preliminary report for the reconstruction of a hotel in Nantes. Drilling even one borehole was extremely difficult due to the existing building occupying the whole lot and the density of underground pipes and cables in the adjacent streets.

It was decided to base the preliminary report solely on the predicted ground model and to postpone the site investigations to after the existing building was taken down. Figure 5 shows the predicted ground model constructed using the data from 11 boreholes and more than 200 pressuremeter tests.

Based on the predictive ground model, it was estimated that the new building would be supported by piled foundations, of approximately 13 to 15m in length and a preliminary estimate of their bearing capacity was provided. When the site investigations were carried out for the detailed design, this preliminary design proved to be conservative, with the bedrock encountered around a depth of 9.5m, allowing for slightly shorter piles.

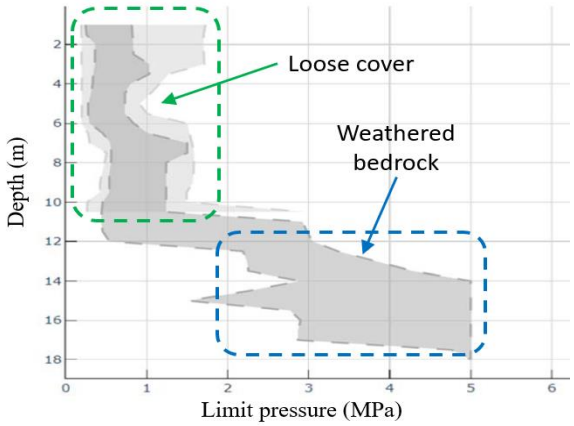

Figure 5. Distribution of P_{IM} with depth and its interpretation for the Nantes project.

3.3 Interpretative report

When comes the time to establish the final ground model for the geotechnical design, care should be taken to not give too much importance to the investigations carried out on the site and balance it with the data provided by the predictive model. With a limited number of boreholes, it is difficult to capture the variability of the soil conditions in full.

When the predictive model is based on abundant and reliable data, the point of the site investigation is to confirm or adjust the model. In this regard, the probable credibility of the site investigation results should be examined in reference to the predictive model.

Figure 6 shows the results of a single borehole conducted at a construction site in a sugar refinery north-east of Reims compared to the probabilistic P_{IM} distribution which was constructed using data from 35 boreholes in the immediate vicinity. We can see that the test results are totaly within the range of what was expected, and the design values have therefore been selected by the engineer based on the predictive model, roughly following the Q25 curve which seemed appropriate for piled foundations, and more reliable than using the test results of a single borehole.

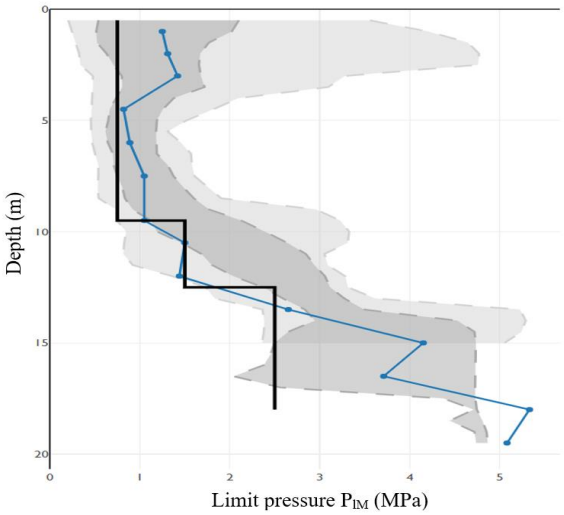

Figure 6. Predictive model from an interpretative report with field tests results in blue and design values in black.

4 FINAL WORDS

We believe that the use of historical data in geotechnical engineering supported by geostatistical algorithms will rapidly become the norm. It should, at first, allow for optimised site investigations with a reduced environmental footprint. But the final goal should be to optimise the construction itself, with a better estimate of the design's level of safety.

ABSTRACT: Geotechnical properties vary locally, and there are uncertainties in the parameter interpretation and in determining characteristic and representative values for geotechnical design. The impact of the testing methods on the intrinsic properties of high plastic clays is analysed in the paper. The laboratory tests for determining the liquid and plastic limits are by far the most widely used index tests and are often adopted to assess the mechanical behaviour of clay. The laboratory investigation results for determining liquid limits using the fall-cone method and method based on Casagrande-type devices were analysed. The density of the soil particles was determined by the pycnometer method by fluid displacement and the pycnometer method by gas displacement. Helium was used as the measurement gas. Test samples of fine-grained soils were taken on five bentonite deposits in the Western Carpathians, Slovakia. Chemical analyses confirmed geotechnical evaluations of fine-grained soil properties. Tests were performed on 15 samples of very high plastic and extremely high plastic clays. Significant differences were observed based on the laboratory method used.

RÉSUMÉ: Les propriétés géotechniques d'une formation varient localement et il existe des incertitudes dans l'interprétation des différents paramètres et dans la détermination des valeurs caractéristiques et représentatives nécessaires pour le dimensionnement géotechnique. L'impact des méthodes d'essai sur les propriétés intrinsèques des argiles à haute plasticité est analysé dans cet article. Les essais de laboratoire pour déterminer les limites de liquidité et de plasticité sont de loin les essais indicateurs les plus utilisés et sont souvent adoptés pour évaluer le comportement mécanique de l'argile. Les résultats des recherches en laboratoire pour déterminer les limites de liquidité en utilisant la méthode du pénétromètre a cône et la méthode basée sur les dispositifs de type Casagrande ont été analysés. La masse des grains a été déterminée par la méthode du pycnomètre par déplacement de fluide et la méthode du pycnomètre par déplacement de gaz. L'hélium a été utilisé comme gaz de mesure. En outre, des échantillons de sols fins ont été prélevés sur six gisements de bentonite dans les Carpates occidentales, en Slovaquie. Des tests ont été effectués sur 15 échantillons d'argile à plasticité très élevée et extrêmement élevée. Les évaluations des propriétés géotechniques des sols fins ont été confirmées par des analyses chimiques. Des différences significatives ont été observées en fonction de la méthode de laboratoire utilisée.

Keywords: Bentonite; particle density; gas pycnometer; fluid pycnometer; fall-cone method.

1 INTRODUCTION

Bentonite is a rock formed by the intense alteration of volcanic material. It consists mainly of clay minerals belonging to the smectite group, which are hydrated aluminium silicates containing Fe and Mg and Na or Ca. Bentonite has strong colloidal properties, and its volume increases severalfold in contact with water. The special properties of bentonite, such as high plasticity, swelling, water adsorption, viscosity and thixotropy, make it a valuable material for various uses and applications. Due to its viscosity and plasticity, bentonite is used in geotechnical engineering (e.g. diaphragm walls, grouting admixtures) and other areas of civil engineering, e.g. in Portland cement and mortars.

Bentonite is an important mineral raw material whose worldwide production is steadily increasing. The Slovak Republic is one of the major producers of bentonite in the world. Over the last 10-15 years, several bentonite deposits have been opened in Slovakia, most of which have yet to be explored and documented in detail. To better exploit bentonite from individual deposits in Slovakia, it is necessary to

determine the fundamental physical properties of bentonite and other material characteristics that predetermine its use in various sectors of the economy. In this study, we focused on testing the density of bentonite solid particles and plasticity by two different methods to determine an efficient method for its laboratory determination.

All tested samples were obtained from five significant deposits on the SW edge of the Kremnické vrchy Mts., Western Carpathians (Figure 1). The bentonite deposits are described by Gorniak et al., 2017; Baláž and Kúšik 2015, and the mineralogical and chemical characteristics of bentonites are discussed by Osacký et al. (2019).

2 METHODOLOGY

Two different methods were used to determine density (bulk density). Gay-Lussac pycnometer with water and a gas (helium) pycnometer (type ULTRAPYC 1200e, Quan-tachrome Instrument, method according to ASTM D6093-97:2011 and EN ISO 17892-3 were compared.

2.1 Material

For testing, bentonite samples (Table 1) were collected, and all were classified as clays with extremely high plasticity.

Table 1. Identification of bentonite samples for testing.

Locality (number of samples)	Specimen labelling
Lutila (4)	LUI-1, LUI-2, LUI-3, LUI-4
Kopernica (2)	KOP-2, KOP-3
Stará Kremnička (4)	STK-1, STK III-1, STK III-2, STK III-3
Jelšový Potok (3)	JP-1, JP-2, JP-3
Bartošova Lehôtka (2)	BL II-1, BL II-2

2.2 Testing methods for density determination

Laboratory testing of solids density was performed using the pycnometric liquid injection method and the gas injection method. All 50 ml liquid pycnometers (Gay Lussac shape) with a ground neck and a ground stopper with a longitudinal capillary orifice (m1) were calibrated at least three times prior to testing to ensure that the measured values of the pycnometer volume (V) did not differ by more than 0.010 cm^3.

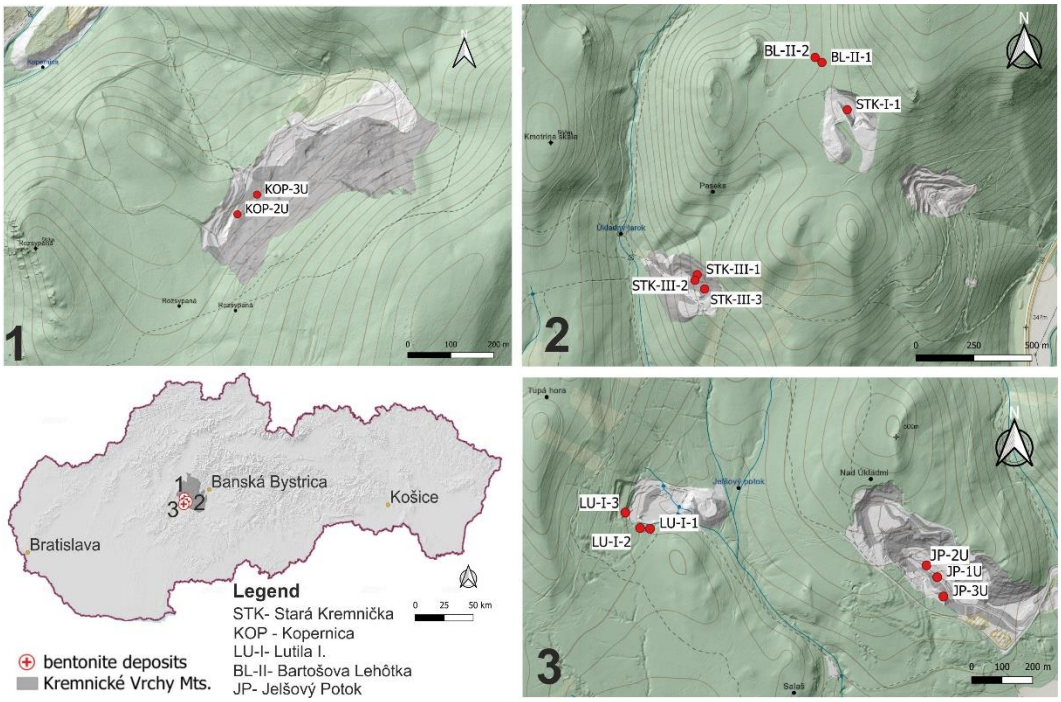

Figure 1. Deposits of bentonites in Kremnické vrchy Mts., Western Carpathians.

The test procedure consisted of several successive steps. The specific gravity (ρ_s) of the bentonite sample tested was calculated from the data obtained. Two identical samples were always tested in parallel.

The second method used (the gas injection method) is based on Archimedes' principle of fluid (gas) motion and the technique of gas expansion (Boyle's law). Gas can be considered an ideal displacement agent because it penetrates the smallest pores, thus ensuring maximum accuracy. For this study, helium was used.

A fully automatic Quantachrome Ultrapyc 1200e (accuracy < ±0.03%, measurement repeatability < ±0.015% was used as the measuring instrument.

2.3 Testing methods for plasticity determination

The basic test for the plasticity of clay characterisation is the liquid limit determination. Two laboratory methods for determining liquid limits were used: the fall-cone method and the method based on Casagrande-type devices according to EN ISO 17892-12.

3 RESULTS

Density values (ρ_s) of bentonite in the 2.46-2.73 g/cm^3 range were measured by the liquid injection method. From the graphical representation of the measured data (Figure 2), two groups with different densities can be distinguished. The more abundant cluster (about 75%) of the samples takes values in the range 2.61-2.73 g/cm^3. The second part of the samples (STK-1, STKIII-3, BLII-1, BLII-2) concentrates in the density range from 2.46 to 2.49 g/cm^3. Although not as pronounced, a similar pattern is evident in the data determined by the gas pycnometer method (Figure 3). Density values (ρ_t) were measured in the 2.36-2.53 g/cm^3 range. This is consistent with the montmorillonite content (Table 2). It ranges from 18.7% to 31% in the lower density samples. The montmorillonite content ranges from 64.5 to 76.6% in the higher density samples. For individual bentonite samples, the coefficient of variation ranged from 0.0037 to 0.0269%, and the standard deviation of volume ranged from 0.0027 to 0.02%. The determined volumes were in the range of values 2.1007 - 3.6997 cm^3. The weights of the specimens ranged from 5.0857 to 9.0561 g, corresponding to an optimally filled cuvette, i.e. 75% of its volume. The results from the measurements in the gas pycnometer show that the measured density values are consistently lower than those from the measurements in the liquid pycnometer. A statistical method comparison shows that they differ by 5-7% (Figure 2 and Figure 3).

Chemical analyses confirmed geotechnical evaluations of fine-grained soils properties. The montmorillonite content of the tested samples is presented in table 2. Bentonites could be divided into two groups: a small amount of montmorillonite (BL II 1, BL II 2, STK 1, STK III-3) and a high amount of montmorillonite (JP-1, JP-2, JP-3, KOP-2, KOP-3, LUI-1, LUI-4, LUI-3 KOP-3, LUI-1, LUI-4, LUI-3, LUI-2, STK III-1, STK III-2).

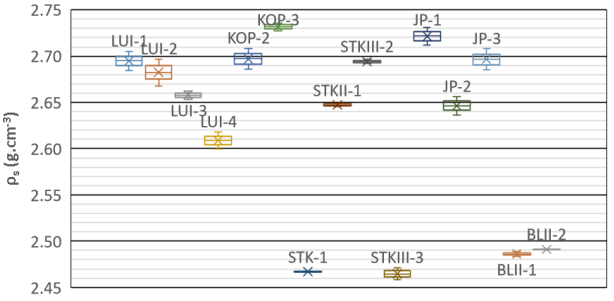

Figure 2. Density of solid particles by the liquid pycnometer method.

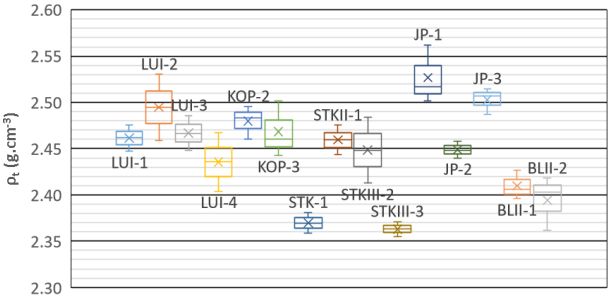

Figure 3. Density of solid particles by the gas pycnometer method.

Table 2. Montmorillonite content of the tested samples.

Sample	Montmorillonite (%)
STK 1, STK III-3	27,4 – 31,1
BL II 1, BL II 2	18,7 – 27,7
JP-1, JP-2, JP-3, KOP-2,	71,6 – 75,6
KOP-3, LUI-1, LUI-4, LUI-3,	74,0 – 76,6
LUI-2, STK III-1, STK III-2	64,5 – 68,4

The reliability or accuracy of density measurements using a pycnometer with a control fluid may be limited due to random or systematic errors. In particular, errors occurring during heating (boiling) of the pycnometer, when escaping air bubbles, may entrain soil particles, or in extreme cases, cause the soil to splash (overflow) through the neck of the pycnometer. Another possible error occurs when refilling the pycnometer with control fluid when the excess fluid should flow out through the capillary after the plug is inserted. A small air bubble may remain under the stopper or in the capillary, causing an underestimation of the measured density. Conversely, insufficient moisture removal from the pycnometer's surface will lead to an overestimation of the true density.

Density determination with a gas pycnometer allows high accuracy to be achieved because the measurement is fast and automatic. However, even with this method, some factors can negatively affect the test result. These include, in particular, uncontrolled variations in the temperature of the instrument during the measurement process,

contamination of the sample (e.g. by moisture), contamination of the cuvette or other parts of the pycnometer, and heating of the cuvette caused by prolonged use. Also, the petrophysical characteristics of the rock, in particular the structure of the rock pores (blind pores), may prevent the process of replacing the air with the gas (helium) used and thus overestimation of the sample volume and determination of a lower density (Viana et al., 2002). Considering the latter, the slight decrease in the measured density may be mainly due to the presence of air and moisture trapped in fine bentonite pores smaller than 100 ηm (Ondrášik & Kopecký, 2014).

The liquid limits of tested samples determined by the Casagrande method were 100% to 124%. The values of liquid limits determined by 80g/30° cone ranged from 90% to 114% (Figure 4).

These values confirmed the hypothesis that significant differences in the liquid limit values determined by the Casagrande apparatus and the fall cone for high plastic clays exist.

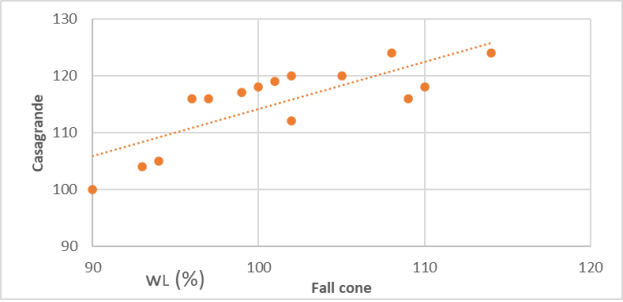

Figure 4. The liquid limits by the Casagrande and Fall cone method.

4 CONCLUSIONS

In this study, the results of the measurements of the density of solid particles according to EN ISO 17892-3 and the liquid limit according to EN ISO 17892-12 are presented. Fifteen bentonite samples were collected from mining deposits on the SW edge of the Kremnické vrchy Mts., Western Carpathians. The bentonite samples were tested by: the pycnometric liquid injection method (ρ_s) and the pycnometric gas injection method (ρ_t). The comparison between them showed a close 5-7% difference.

Determination of the density of solid particles with a gaseous pycnometer offers the advantages of a simple, fast, and, above all, fully automated instrument. Although experiments on bentonite samples have shown high accuracy, care must also be taken to investigate the influence of various service and material factors that may affect the density determination.

For high plastic clay specimens, significant differences in the liquid limit values determined by the Casagrande apparatus and the fall cone were determined.

Reinforced soil technique for temporary slope stabilisation in loose saturated ground

Technique de sol renforcé pour la stabilisation temporaire des pentes dans un sol meuble et saturé

G.R. French, S.D. Thomas*
OGI Groundwater Specialists Ltd, Durham, UK

**stephen.thomas@ogi.co.uk*

ABSTRACT: During 2020, a method to provide stability to an initially unstable soil excavation was required in loose saturated soil. The initial slope angle was up to 45° to the horizontal, with saturated ground causing local slip failures and running sand into the excavation. The excavation was surrounded by existing sensitive infrastructure, so it was not feasible to construct shallow excavation slopes, nor feasible to use techniques such as soil nails or anchors. It was neither feasible to use a steel sheet pile wall nor a secant pile wall. To provide soil reinforcement to enhance slope stability, a system was designed that incorporated the construction of a highly permeable angular drainage stone channel along the toe of slope, combined with aggregated cemented angular stone "wedges" compacted orthogonally to the toe of the slope. This combined drainage and reinforced soil system met the economic budget for the client. To comply with Eurocode 7 design standards, including using appropriate partial safety factors on the soil parameters, a PLAXIS 3D analysis was undertaken to demonstrate stability under drained conditions. This ground stabilisation was successful, with stability maintained for the required two years until the infrastructure was ultimately constructed and backfilled.

RÉSUMÉ: Au cours de l'année 2020, une méthode permettant d'assurer la stabilité d'une excavation de sol initialement instable a été nécessaire dans un sol meuble et saturé. L'angle de pente initial était de 45° par rapport à l'horizontale, le sol saturé provoquant des ruptures de glissement locales et du sable coulant dans l'excavation. L'excavation était entourée d'infrastructures fragiles existantes, de sorte qu'il n'était pas possible de construire des pentes d'excavation peu profondes, ni d'utiliser des techniques telles que des clous à terre ou des ancrages. Il n'était pas possible d'utiliser un mur de palplanches en acier ni un mur de pieux sécants. Afin de renforcer le sol afin d'améliorer la stabilité de la pente, un système a été conçu qui incorporait la construction d'un canal de drainage angulaire en pierre très perméable le long du pied de la pente, combiné à des « coins » angulaires en pierre cimentée agrégés compactés orthogonalement au pied de la pente. Ce système combiné de drainage et de sol renforcé a permis de respecter le budget économique du client. Pour se conformer aux normes de conception de l'Eurocode 7, y compris l'utilisation de facteurs de sécurité partiels appropriés sur les paramètres du sol, une analyse 3D PLAXIS a été entreprise pour démontrer la stabilité dans des conditions drainées. Cette stabilisation du sol a été couronnée de succès, la stabilité ayant été maintenue pendant les deux années requises, jusqu'à ce que l'infrastructure soit finalement construite et remblayée.

Keywords: Soil reinforcement; drainage system; stabilising slopes.

1 INTRODUCTION

The upgrade of an energy infrastructure of national significance took place in the United Kingdom in 2020. Part of this upgrade programme required the construction of a temporary battered excavation to install buried pipework infrastructure. The excavation level varied between 76.46 m STN10 and 76.66 m STN10, where STN10 was the site-specific datum. This resulted in an excavation depth of circa 3m to 3.5 m bgl.

One side of the excavation had exposed vertical piles, with pile caps constructed above. On three sides of the excavation, the slopes were battered at slope angles varying between 30°-45° (Figure 1) and displayed soil instability. During an initial site visit, water ingress was observed seeping through the sides of the excavation, together with progressive slope failure in the form of running sand (Figure 2).

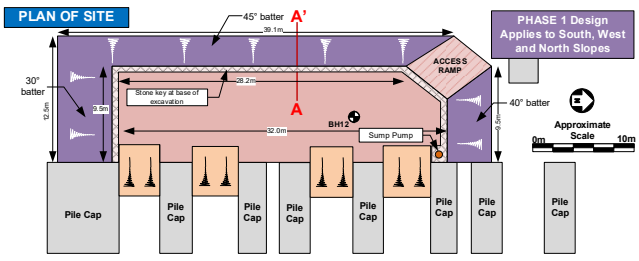

Figure 1. Site plan showing the layout of the excavation.

Figure 2. Excavation with unstable sloping sides.

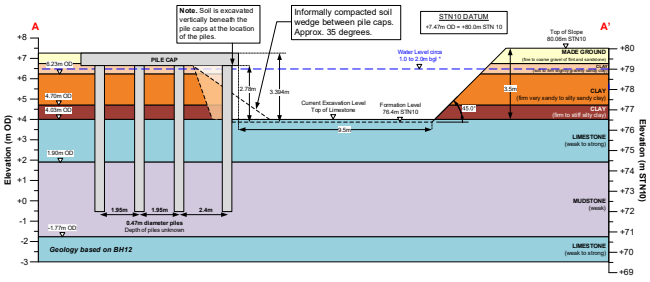

Figure 3. Conceptual model including the general excavation geometry.

As it was intended that infrastructure construction would only take 12 weeks during which undrained soil conditions were in place, the excavation had no slope reinforcement. However, due to a delay in construction programme, the excavation needed to remain open for up to two years longer than the anticipated 12 weeks, so resulting in drained (effective stress) conditions.

To provide stabilisation of the ground for a period of up to two years, the challenge to the civil engineers was to design a robust system to mitigate soil instability, including erosion protection. The constraints on any slope stabilisation were substantial, with traditional techniques such as sheet pile walls, king post walls, secant pile walls or soil anchors, excluded due to the potential impact on the surrounding sensitive infrastructure. This paper presents the design solution implemented by the civil engineers, together with the geotechnical modelling and analysis that was undertaken using PLAXIS 3D to support the design.

2 SITE CONDITIONS

The pipeline excavation had previously been constructed using battered slopes by a previous contractor. To the western, southern and northern sides of the excavation, there were slopes which were calculated to be in the range of 30° to 45°.

However, as a consequence of the high water-table, and steep slope angle, under drained soil conditions, the combination of the low drained shear strength and high groundwater seepage face resulted in local instability and running sand (Figure 2).

The geology on the site is characterised by predominantly superficial clay soils which overlay limestone and mudstone. The clay soils contain frequent lenses of sand and silt. The water level across the site is typically one metre below ground level. The geology with the construction detail overlaid is depicted in Figure 3. All elevations are presented relative to the site datum named STN10, where +7.47 m OD = 80.0 m STN10.

3 GEOTECHNICAL SOIL PARAMETERS

The geological sequence, as depicted in Figure 3, is summarised as follows:

Unit 0: MADE GROUND comprising gravel sized fragments of flint and sandstone.
Unit 1: Soft to firm slightly gravelly sandy CLAY.
Unit 2: Firm mottled very sandy to sandy silty CLAY.
Unit 3: Firm to Stiff dark grey silty CLAY.
Unit 4: Weak to strong dark grey LIMESTONE.
Unit 5: Extremely weak to weak thickly laminated grey MUDSTONE.

Derivation of geotechnical parameters for each unit are presented in the following sections. This derivation has required the incorporation of limited available site investigation, historical research, industry best practice, and authors' own judgement.

3.1 Unit 0: Made ground

Made Ground was described as fine to coarse gravel of flint and sandstone, from which it was considered appropriate to adopt drained parameters for this unit; with drained strength parameters presented in Table 1 used as inputs to the finite element analysis.

A conservative value of Young's Modulus has been selected (Table 1) based on a typical well-graded loose '*Sand/Gravel silty*' from Table 2 (Obrzud and Truty, 2010). Poisson's ratio was selected from a table of typical values for soils (Bowles, 1996).

Table 1. Geotechnical Characteristic Parameters – Unit 0 – Made Ground.

Parameter	Characteristic Value
Weight density, γ	17 kN/m^3
Angle of internal friction, φ	25.0°
Effective cohesion, c'	0.0 kPa
Young's Modulus, E'	7.0 MPa
Poisson's ratio, ν'	0.2

Table 2. Typical values of Young's Modulus for granular materials (MPa) (Obrzud and Truty, 2010).

USCS	Description	Loose	Medium	Dense
GW, SW	Gravels/Sand well-graded	30-80	80-160	160-320
GM, SM	Sand, uniform	10-30	30-50	50-80
GM, SM	Sand/Gravel silty	7-12	12-20	20-30

3.2 UNITS 1, 2 and 3 – Clay soils

The clay soils were broken down into three units based on the geological descriptions:

- UNIT 1: soft to firm dark brown slightly gravelly sandy Clay.
- UNIT 2: firm mottled orange and reddish brown very sandy to sandy silty Clay.
- UNIT 3: firm to stiff dark grey silty Clay

Weight density test data were not available for the natural clay soils, however a range between 17 kN/m^3 and 21 kN/m^3 was expected based on historical site investigation. Parameters in Table 2 have been selected based on this range and experience of working with similar soils.

Drained shear strength parameters for these units were selected on the basis that the excavation was expected to remain open for two further years. As shear strength data were not available to determine the drained strength parameters of the Clay, Plasticity Index (I_p) test data were used to determine undrained shear strength, together with equations outlined in British Standard: Code of Practice for Earth Retaining Systems (British Standard, 2015*,* Section 4.3.1.4).

Conservative values of Young's Modulus and Poisson's ratio were selected for each Clay unit using the typical values for soils (Bowles, 1996). Effective cohesion, *c'* is taken as 0.0 kPa as suggested in British Standard: Code of Practice for Earth Retaining Systems (British Standard, 2015)

A summary of the characteristic parameters used for each Clay unit for the slope stability analysis are presented within Table 3.

Table 3. Geotechnical Characteristic Parameters – Units 1, 2 and 3.

Parameter	Unit 1	Unit 2	Unit 3
Weight density, γ (kN/m³)	18	19	19
Angle of internal friction, φ'_{pk} (°)	21	21	21
Effective cohesion, c' (kPa)	0	0	0
Young's Modulus, E' (MPa)	2	5	7
Poisson's ratio, v'	0.2	0.2	0.2

3.3 Units 4 and 5 – Limestone and mudstone

Rock behaviour differs from soil as it is generally stiffer and stronger. A linear stress dependency, as obtained from the Mohr-Coulomb model is generally not sufficient. The Hoek-Brown failure criterion is a better non-linear approximation of the strength of rock, and accounts for several factors including strength, disturbance and weathered nature of the rock. Input parameters to PLAXIS 3D are as follows: Young's Modulus, E (kPa); Poisson's ratio, v (-); Uniaxial compressive strength (UCS) of intact rock, σ_{ci} (kPa); Intact rock parameter, m_i (-); Geological strength index, GSI (-) and Disturbance factor, D (-).

Borehole descriptions suggest the Limestone is medium strong and thinly to medium bedded. The Mudstone is described as extremely weak to weak and thickly laminated to medium bedded. The selection of Young's Modulus and Poisson's ratio (Table 4) is based on typical values of Young's Modulus available in the literature (Some Useful Numbers, 2016).

Table 4. Summary of Design Rock Parameters – Units 4, 5.

Parameters	Limestone Unit 4	Mudstone Unit 5
Young's modulus, E (kPa)	1.5 x 10^7	1.0 x 10^6
Poisson's ratio, v (-)	0.2	0.2
Uni-axial compressive strength of intact rock, σ_{ci} (kPa)	49,200	20,000
Intact rock parameter, m_i (-)	10	4
Geological strength index, GSI (-)	12	10
Disturbance factor, D (-)	0	0

4 GROUNDWATER

Groundwater was encountered in boreholes outside the excavation at levels of circa 1 m bgl, and observed seeping into the excavation up to circa 2 m above the toe of the slope. Approximately 30 m away from the excavation was an area of a previous excavation which had been backfilled with sand and gravel. This area became waterlogged due to the surrounding clayey soil having a much lower permeability, and acted as a hydraulic boundary which defined the position of the water table boundary condition at a distance of 30 m in the PLAXIS 3D finite element model (*PLAXIS 3D, 2019).*

5 DESIGN METHOD FOR SOIL STABILISATION USING SLOPE REINFORCEMENT

The excavation was surrounded by existing sensitive infrastructure, so it was not feasible to construct shallow excavation slopes, or feasible to use techniques such as soil nails or anchors. was neither feasible to use a steel sheet pile wall nor a secant pile wall. To provide soil reinforcement to enhance slope stability, a system was designed that incorporated the construction of a highly permeable angular drainage stone channel along the toe of slope, combined with

aggregated cemented angular stone "wedges" which are compacted orthogonally to the slope toe.
The construction sequence is as follows:

- Install a stabilising angular stone key at the toe of the slope (Figure 4) so groundwater can seep out of the batter without loss of soil fines.
- Sump pump residual water away from sump in the corner of the excavation.
- Install cemented aggregate wedges in the slope at spacings of 2.5 m. These wedges increase friction between the soil particles and prevent circular slip failure from occurring along the long west side of the excavation (Figures 4 and 5).
- Place angular stone onto the remaining exposed slope face, then push into the soil and compact with the bucket of the excavator. This will mitigate the surface erosion due to rainfall. Place the stone on exposed surfaces of the aggregate wedges to give a uniform appearance across the slope.
- Visually monitor the embankments during and after stabilisation works for any ground movement.
- Regularly refer to the Inspection, Testing and Monitoring (ITM) Plan, and to the staged sequence of installation.

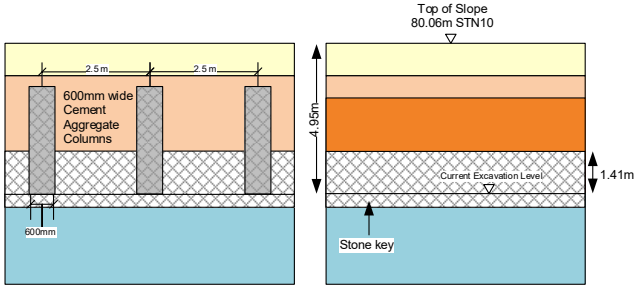

Figure 4. Inclined view of stone key aggregate wedges.

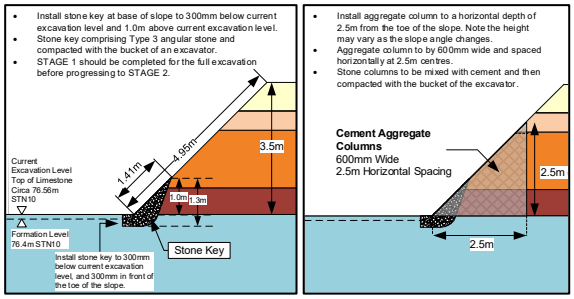

Figure 5. Sectional view of stone key aggregate wedges.

5.1 Unit 6: Compacted angular stone key used for drained reinforcement

The compacted angular stone key used MOT Type 3 (Figure 6) angular stone (SIMTEC Material Testing), with the weight density (Table 5), selected using a table of typical values (Some Useful Numbers, 2016).

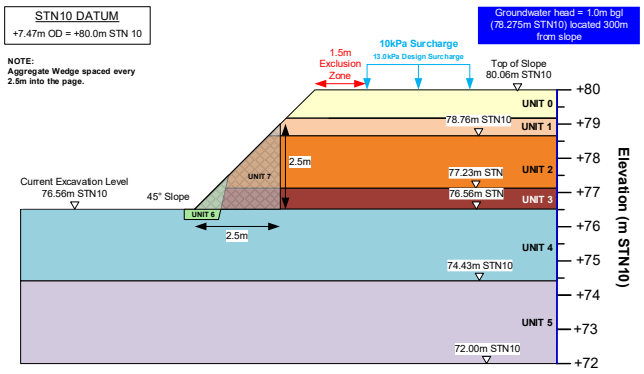

Figure 6. Conceptual model of the cemented angular stone soil reinforcement.

Table 5. Geotechnical Characteristic Parameters – Unit 6 Angular Stone Key.

Parameter	Unit 6
Weight density, γ (kN/m³)	19
Young's Modulus, E (MPa)	100
Contribution from particle angularity φ'_{ang} (°)	4
Contribution from the PSD, φ'_{PSD} (°)	4
Effective angle of shearing resistance, $\varphi'_{cv,k}$ (°)	38
Contribution from Dilatancy, φ'_{dil} (°)	6
Peak angle of internal friction, φ_{pk} (°)	44
Effective cohesion, c' (kPa)	0
Poisson's ratio, v'	0.2

Based on a gravel classification of 'GW - Medium Dense' Young's Modulus of compacted angular stone, was selected using values in Table 5. Shear strength was determined using the equations and tables presented in British Standard (British Standard, 2015) Section 4.3.1.3:

5.2 Unit 7 – Cemented aggregate wedge

Each aggregate wedge was constructed using angular stone mixed with cement. When cured, this resulted in a high strength similar to concrete.

Table 6 depicts the PLAXIS 3D Input parameters used based on typical properties of concrete available in the literature (Some Useful Numbers, 2016).

Table 6. Geotechnical Characteristic Parameters - Unit 7 Cemented Aggregate Wedge.

Parameter	Unit 7
Weight density, γ (kN/m³)	21.0
Young's Modulus, E (kPa)	1.0×10^6
Poisson's ratio, v'	0.2

Slope stability validation was conducted in accordance with Eurocode 7 (Eurocode, 2004 & 2009), utilising the 'Geotechnical Design by Calculation' method, undertaken using PLAXIS 3D Version 2019. PLAXIS 3D (*PLAXIS 3D,2019)* is a finite element software designed for three-dimensional analysis of deformation and stability in geotechnical engineering.

6 PLAXIS 3D SIMULATION OF DESIGN SOLUTION

PLAXIS 3D was used as the design tool to develop the proposed design solution. The software was used to check that the design provided sufficient ground resistance to prevent failure of the slopes under drained conditions. Partial factors of safety were utilised and the design adjusted (primarily the spacing of the cemented aggregate wedges) until the design complied with Eurocode requirements.

6.1 Partial factors of safety

The following partial factors of safety were selected in accordance with relevant design standards (British Standards, 2015).

- Partial factor, $\gamma_m = 1.25$ to reduce tan φ'_and c' for drained shear strength
- Partial factor, $\gamma_m = 1.40$ to reduce σ_{ci} for rock
- Load factor, $\gamma_L = 1.30$ to increase destabilizing actions of surcharge loading

As defined in Eurocode 7, non-factored parameters, are referred to as 'characteristic', with factored parameters used in calculations, referred to as 'design'.

6.2 Model geometry

The following geometry in Table 7 was adopted for input into the PLAXIS 3D Mathematical Model.

Table 7: Input Values to the Plaxis-3D model.

Input	Value
Existing excavation level	76.56m STN10
Top of existing batter	80.06m STN10
Slope angle	45°
Cemented aggregate wedge – width	0.6m
Cemented aggregate wedge – height	2.5m
Cemented aggregate wedge – horizontal length	2.5m
Model width (i.e. wedge horizontal spacing)	2.5m

6.3 Surcharge loading and exclusion zone

A characteristic surcharge of 10 kPa is applied to the top of the batter as required by Eurocode 7 (Eurocode, 2004). The surcharge load has been specified 1.5m from the crest of the batter, meaning that there must be a 1.5m exclusion zone to plant and machinery.

7 RESULTS OF SLOPE STABILITY FINITE ELEMENT ANALYSIS VALIDATION

Numerical modelling of the slope stabilisation using the cemented aggregate wedge approach was carried out using PLAXIS 3D, using input values of Table 7.

Due to the symmetry between each of the aggregate wedges, the domain of the PLAXIS model needed to be only 2.5 m wide. In the vertical dimension, the various geological units (Unit 0 to Unit 3) were input as horizontal layers. The slope angle was defined as 45°, with the 13 kPa design loading applied downwards outside the 1.5 m exclusion zone.

The compacted angular stone key (Unit 6) was simulated as an irregular shaped horizontal strip as outlined in Figure 4. The cemented aggregate stone wedge (Unit 7) was simulated as a 600mm wide triangular structure, 2.5 m deep in the centre of the model (Figure 4 and Figure 6).

Figure 7 and Figure 8 depict the contours of simulated soil displacement (i) based on the working design loads, and (ii) when loads increased until simulated failure is reached.

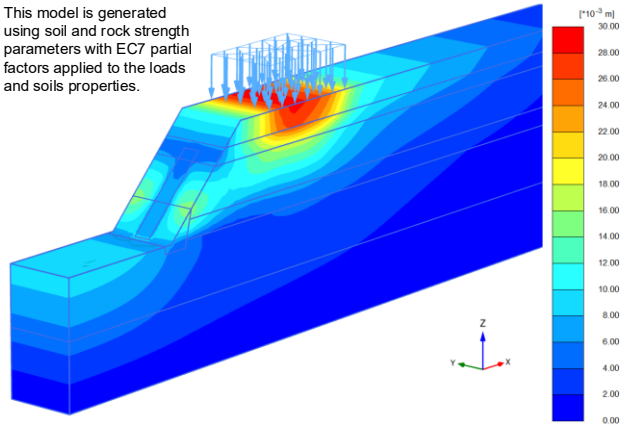

Figure 7. Displacement at working design load.

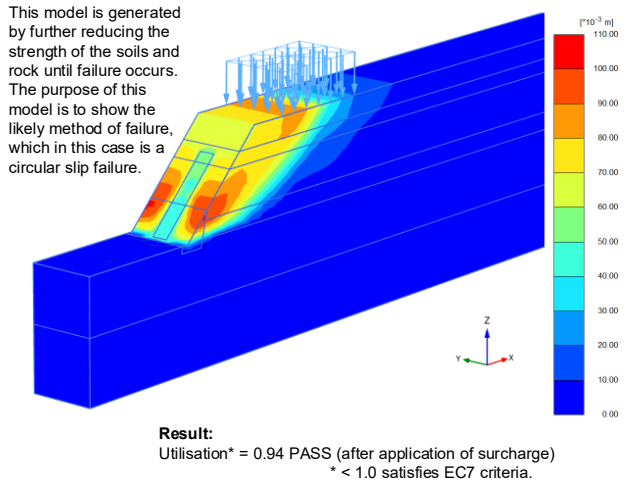

Figure 8. Displacement at model failure.

The PLAXIS 3D model evaluates the stabilizing design parameters required to produce sufficient forces to resist the destabilizing design actions just prior to model failure. The model then calculates the utilisation factor $\boldsymbol{U}$, from the equation $\boldsymbol{E_d / R_d}$ where:

$\boldsymbol{E_d}$ is the design value of the effect of destabilising actions, i.e. loads and stresses

$\boldsymbol{R_d}$ is the design value of the stabilising resistance to actions, i.e. the maximum load/stress that the structure can support before failure.

To demonstrate stability, Eurocode 7 requires the Utilisation, $\boldsymbol{U}$, to be less than 1.0. For the parameters and partial factors described in Table 7, PLAXIS calculates $\boldsymbol{U}$ **= 0.94**

8 CONSTRUCTION METHODOLOGY

The design process resulted in the completion of a series of critical documents required to ensure (i) the construction fulfils the design objectives to stabilise the excavation slopes for a period of at least two years, (ii) there is no collateral damage to surrounding infrastructure, and (iii) the construction is conducted to defined safety standards.

These critical documents included:

(a) Design Strategy document, including all relevant calculations
(b) Clear construction sequence drawings
(c) Design Risk Assessment (DRA)
(d) Inspection, Testing & Monitoring (ITM) Plan
(e) Signed design certificates
(f) Insurance certificates

All site personnel were required to be suitably trained, qualified and certificated to work on this sensitive site.

In summary, the construction proceeded safely with the excavation producing safe and stable exposed slopes for more than the two-year duration required.

9 CONCLUSIONS

An open cut temporary excavation was left open for longer than anticipated. This required the slopes to be stabilized due to the drained soils conditions that had developed, so causing the slopes to become unstable.

A unique slope stabilization solution was developed which comprised the installation of an angular stone key at the base of the slope (Figure 9), which helped to intercept groundwater and stabilize the top of the slope, together with cemented aggregate wedges installed within the slope to provide resistance to the overall soil mass (Figure 10).

The design solution was simulated in PLAXIS 3D with the utilization value, U, calculated as 0.94, demonstrating slope stability under Eurocode 7. Construction proceeded safely, with the excavation producing stable exposed slopes for longer than the two-year duration required.

Creative approaches for enhancing excavation shoring efficiency through diaphragm wall prestressing techniques

Approches créatives pour améliorer l'efficacité de l'étayage des fouilles grâce aux techniques de précontrainte des parois diaphragmatiques

M.C. Frydrych*
Warsaw University of Technology/Faculty of Civil Engineering, Warsaw, Poland
**mateusz.frydrych.dokt@pw.edu.pl*

ABSTRACT: Diaphragm walls are essential in geotechnical engineering for both retaining structures and deep foundations. However, modern projects encounter challenges in designing cross-sectional profiles precisely due to technical complexity. The growing demand for sustainable building materials further increases the difficulty of implementation. This paper proposes integrating prestressing technology to enhance diaphragm walls construction efficiency. Prestressed tendons are incorporated nonlinearly into the reinforcement structure, reducing bending moments, minimizing steel usage, and improving structural integrity. This unconventional concept, previously unexplored in scientific literature, represents a significant advancement. A dynamic numerical model is central to this research, enabling precise delineation of diaphragm wall cross-sections and meticulous analysis of displacements and forces under various scenarios. Advanced computational tools like the Sofistik application are utilized, with validation done using the Plaxis software. This unconventional approach has profound implications in geotechnical engineering, offering opportunities for optimization such as reduced material consumption, accelerated project completion, and cost savings. An exemplary application involves using diaphragm walls as cantilever structures spanning two underground floors, eliminating the need for additional support or ground anchorage. The presented approach can help the construction sector optimize costs while maintaining a sustainable approach.

RÉSUMÉ: L'utilisation généralisée des parois moulées en génie géotechnique présente des défis modernes en raison de spécifications complexes et de l'impératif de durabilité pour réduire les émissions de carbone. Une méthode novatrice est proposée ici pour optimiser la construction des murs de soutènement en utilisant la précontrainte. Cette approche intègre des tendons précontraints de manière non linéaire, réduisant les moments de flexion, minimisant l'usage de l'acier, réduisant les déplacements et améliorant l'intégrité structurelle. Cette méthodologie révolutionnaire, basée sur un modèle numérique dynamique précis, permet une analyse détaillée des déplacements et des forces transversales. La recherche, validée par des logiciels avancés comme Sofistik et Plaxis, offre des opportunités d'optimisation en réduisant la consommation de matériaux, en accélérant les projets et en économisant du temps et de l'argent. Une application remarquable est l'utilisation de murs diaphragmes en porte-à-faux pour couvrir deux étages souterrains, éliminant le besoin de supports supplémentaires. Cette approche novatrice améliore la faisabilité des projets pour les entrepreneurs et assure la prudence financière des investisseurs.

1 INTRODUCTION

Creative approaches to technology development have long been a focal point within both the scientific community and industry stakeholders interested in the subject. Notably, emerging optimal solutions increasingly prioritize ecological considerations and sustainable approaches within the construction sector. Is it feasible to introduce a new technology that aligns with contemporary expectations, while minimizing risks and enhancing cost efficiency? This article introduces the concept of prestressing the diaphragm wall used for excavation shoring, potentially obviating the need for one level of shoring strut or ground anchors. Furthermore, prestressing offers the potential to reduce the required amount of conventional reinforcement for the reinforced concrete section. The author emphasizes technological aspects such as project speed and the flexibility of action within the structure, ultimately optimizing both time and costs.

In many cases around the world, a conventional approach to constructing underground parts of buildings is being considered, usually using top&down or bottom-up methods. These methods require extra support like steel struts, strutted slabs, or ground anchors, leading to execution challenges such as slower excavation work with steel struts and the expense and feasibility issues with ground anchors.

In a typical approach beyond specific method to constructing underground parts of projects using diaphragm walls, the process generally involves the following phases:

- Constructing guide walls leading to the diaphragm walls.
- Excavating the trench in soil with bentonite slurry support.
- Placing a prefabricated reinforcement cage in the excavation filled with bentonite
- Pouring the diaphragm wall using the contractor method.
- After achieving adequate concrete strength, excavation of the pit can commence. Support is provided through steel struts or ground anchors, and these techniques can be combined based on stability needs and the number of underground levels.

2 INNOVATIVE PROPOSITION WITH EFFECTIVE RESULTS

This article presents an alternative approach to the implementation of underground parts of the investment, which may be attractive to the construction sector. This concept proposes placement prestressing system known in the bridge construction industry into the diaphragm wall, which, according to analyses, makes it possible to dispense with additional strutting, thus making it possible to build two underground storeys much faster and cheaper with the same level of safety. The use of prestressing in diaphragm walls reduces the use of steel and concrete and reduces the need for construction equipment due to the lack of the need to install steel struts or ground anchors. Thus, this type of approach can be environmentally friendly by reducing carbon footprint emissions, which is very important in today's approach to engineering (Pomponi and Stephan, 2021). Resigning from these elements may be invaluable from a logistic point of view, especially in densely built-up urban areas, where there are other buildings around the investment that cannot be disturbed by deep excavations (Łupieżowiec, 2021).

In the presented concept, optimization and an unconventional approach to constructing underground parts of projects involve incorporating a prestressing system with tendons within the reinforcement cage. These tendons, encased in plastic sheaths, are permanently attached to the cage and can be arranged linearly or nonlinearly as in bridge solutions, utilizing anchoring at the bottom of the reinforcement cage (Martí et al., 2013). The reinforcement cage with tendons can be placed in the excavation allowing them to be surrounded by concrete during pouring, effectively blocking tendon movement. This solution introduces a slight change to the technological process by placing modified reinforcement baskets in the bentonite:

- the prestressing cables are installed into the prepared reinforcement cage (which has been appropriately designed for the case of the pre-stressed diaphragm wall in question) in a dedicated system casing laid according to the detailed design, i.e., the geometry of the cables as well as the installation method and their length are designed according to the method proposed by the author.
- concreting then takes place as in the typical approach, with care being taken to ensure that the tremie pipes do not overwhelm the placed tendons.
- depending on the design assumptions, after the concrete obtains the required strength, the structure should be prestressed, after which further deepening of the excavation is possible.

Due to the possibility of non-linear arrangement of prestressing tendons, it is possible to obtain high efficiency of the prestressed cross-section. Concept of this method was presented in Figure 1.

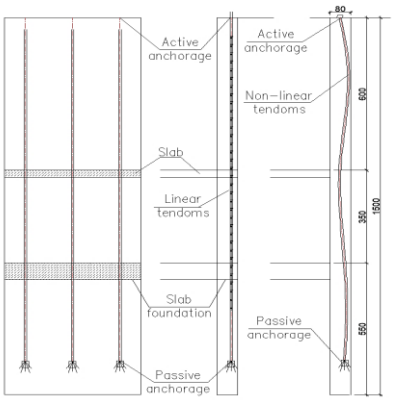

Figure 1. Cross sections of the method described for one section of the diaphragm wall with three prestressing tendons installed in linear proposition and non-liner proposition [own source].

3 NUMERICAL VALIDATION AND FEM RESULTS

To ensure the reasonableness of the obtained results in numerical analyses, it is necessary to pay attention to the quality of the input data (Michalak and Przybysz, 2021). In the case of structural prestressing, this is the value and impact of the prestressing force and the limits set by current design standards. Sofistik v2023 was chosen to analyse such an unconventional structural system using FEM, because this software

allows the analysis of prestressed structures loaded with soil pressure in one model, including the possibility of analysing multiple implementation phases, which is very beneficial in examining geotechnical issues. Thanks to the extensive reporting engine in the post-processor, it is possible to detect most numerical errors, which is extremely important in geotechnical issues, because the error in a given phase is transferred to the next ones and ultimately incorrect results are obtained. The idea of FEM operation is widely described in the literature and this article focuses on its application. In general computer calculations ultimately rely on these meticulous considerations (Kacprzyk and Rakowski, 2016): a) the idealization of the actual design, b) discretization of the issue, c) solution of optimal computer algorithms, d) verification and interpretation of results.

The obtained stresses from individual integrals of the stress field allow for the determination of internal forces and subsequent dimensioning. Due to the lack of dedicated software for this type of analysis, Sofistik was used - a comprehensive programming platform, which allowed the analysis of soil, reinforced concrete and prestressing issues in one model. The Sofistik model is run through a computational engine, and its outcomes are assessed using the WINGRAF module. In this module, it is possible to visualize the model geometry, given loads and results in the form of displacements and internal forces for individual phases, which is simplified in Figure 2.

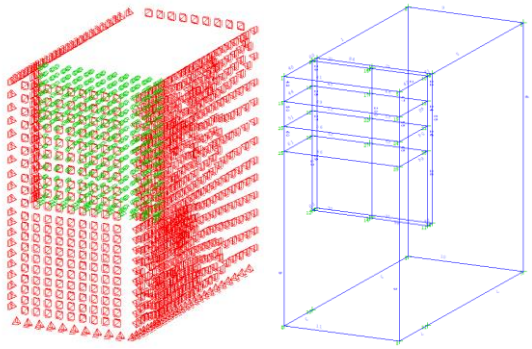

Figure 2. Geometry model result from Sofistik software with given boundary conditions in the form of an interface. This 3D model was created using solid elements [own source].

Before investigating the prestressed diaphragm wall method, the author created a diaphragm wall model for a simple cantilevered system using Sofistik and Plaxis software using Hardening Soil (Hs) model. Stress and displacement results from both programs were compared, revealing a convergence within 1.0 %. This agreement validated the accuracy of the diaphragm wall model in Sofistik without prestressing, confirming its suitability for analysing prestressed elements in the diaphragm wall (see Figure 3).

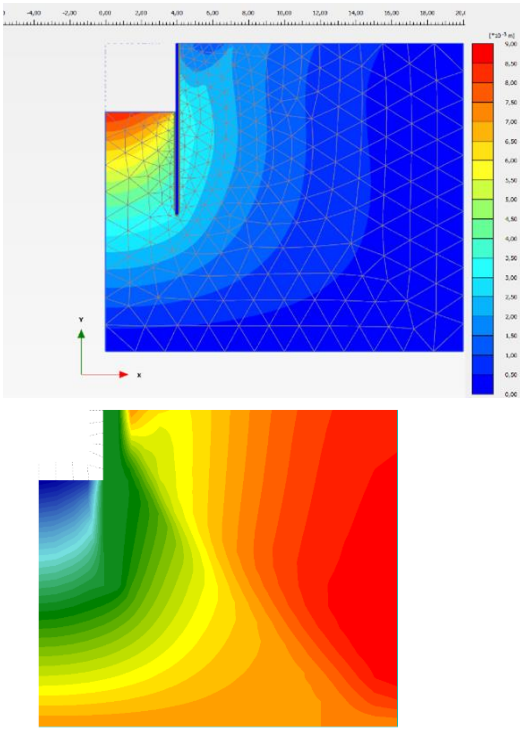

Figure 3. Presentation of validation results for vertical displacements in Plaxis and Sofistik software [own source].

After validating the numerical models in two software programs, the prestressing algorithm was developed for the diaphragm wall model. Aligning equations for reinforced concrete in soil with prestressing tendons posed a challenge, adapted to meet software and soil description Hs requirements. The algorithm enables input of prestressing force, tendon distribution, rheological coefficients, and tendon elongation study is presented in Figure 4. Results were visualized in Sofistik, allowing manual scaling for structural emphasis, useful for detecting irregularities in complex systems. This capability demonstrated the behaviour of the prestressed diaphragm wall in the soil body.

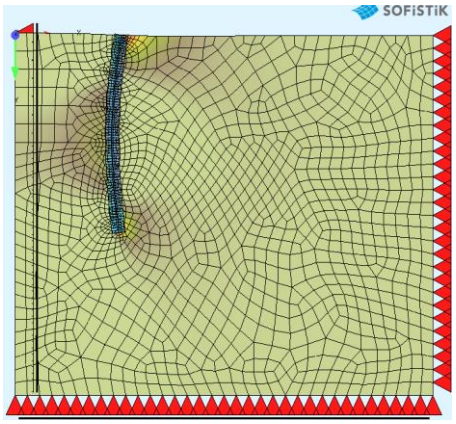

Figure 4. Operation of the prestressing algorithm with a linearly specified prestressing tendon located on the excavation side. Manually scale was used to present possibility of prestressing [own source].

Utilizing the provided model geometry and a developed prestressing algorithm, the author investigated the impact of incorporating prestressing tendons into the diaphragm wall cross-section. The goal was to confirm the viability of designing a diaphragm wall as an excavation enclosure reinforced with a prestressing system for two underground levels. The analysis demonstrated that prestressing significantly reduced horizontal displacements at the top for a 0.8 m thick wall exposed at 6.0 m. Without considering the prestressing system, constructing such a structure without additional reinforcement, like steel struts, would be unfeasible.

The final results for the final phase of the prestressed diaphragm wall based on optimized horizontal displacements and optimal, i.e. structure-safe, stresses are shown in Figure 5.

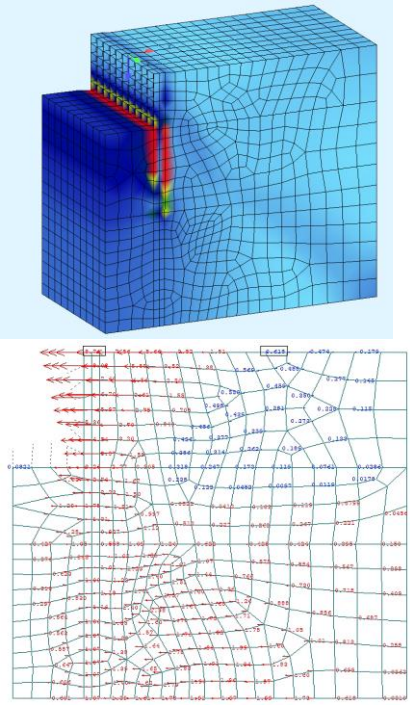

Figure 5. Presentation of the results of prestressing in a diaphragm wall as to stresses and horizontal displacements[own source].

The displacements of the cap of a diaphragm wall uncovered at 6.0 m with a thickness of 0.8 m are 16.2 mm without using additional expansion, which, given the assumed load of 5 kPa on the excavation surface, would make it impossible to design such a support. Uniform ground conditions were assumed in the form of sandy clay.

4 CONCLUSION

The article presents an unconventional approach to the design and implementation of diaphragm walls using prestressing. The open-source software Sofistik was used to develop this issue because there is no dedicated one. The model environment setting was checked with Plaxis. The results show many technological benefits such as:

- improved waterproofing of the enclosure, decreasing groundwater influx and enhancing watertightness.
- minimization or complete elimination of concrete tension, leading to reduced reinforcement in the concrete section.
- increased durability and reduced thickness of the excavation enclosure without compromising stiffness, allowing for more flexible building volume due to reduced enclosure thickness.
- decreased horizontal deformations of the excavation enclosure, ensuring safety for nearby structures.
- wider spacing between temporary excavation supports.

Future research will include detailed analyses considering various design situations using prestressing along with actual savings during construction. Eliminating one level steel struts or ground anchors is possible and can bring many benefits while maintaining the design assumptions.

Limit equilibrium solution for lateral pile capacity in cohesive soil

Solution d'équilibre limite pour la capacité latérale des pieux dans un sol cohésif

T. Gans-Or, S. Pinkert*
Ben-Gurion university of the Negev, Beer-Sheva, Israel
**pinkerts@bgu.ac.il*

ABSTRACT: This paper presents a limit equilibrium solution for the lateral pile capacity problem in cohesive soil. The solution is based on an implementation of the slice method, the mobilized strength concept, and optimization of slip surface geometries. This study shows an improvement in the inner slice forces inclination, which is inspired from previous upper-bound solution. The overall nature of the solution is of a lower-bound solution, as it satisfies full equilibrium and the concept of maximizing the applied load to failure. The obtained results show excellent agreement with the lower-bound solution for both cases of perfectly smooth and rough pile interfaces, and an overall good agreement to the entire range of soil-pile interface roughness. Based on this excellent agreement, further problems can be investigated using the developed limit equilibrium method.

RÉSUMÉ: Cet article présente une solution d'équilibre limite pour le problème de la capacité latérale des pieux dans un sol cohésif. La solution est basée sur la mise en œuvre de la méthode des tranches, le concept de force mobilisée et l'optimisation de la géométrie de la surface de glissement. Cette étude montre une amélioration de l'inclinaison des forces de la tranche intérieure, qui s'inspire des solutions précédentes de la limite supérieure. La nature globale de la solution est une solution de limite inférieure, car elle satisfait l'équilibre complet et le concept de maximisation de la charge appliquée jusqu'à la rupture. Les résultats obtenus montrent un excellent accord avec la solution de la limite inférieure pour les deux cas d'interfaces de pieux parfaitement lisses et rugueuses, et un bon accord général pour toute la gamme de rugosité de l'interface sol-pieu. Cet excellent accord peut servir de base à d'autres problèmes qui pourraient être étudiés à l'aide de la méthode d'équilibre limite développée.

Keywords: Lateral pile capacity; cohesive soils; mobilized strength; optimization; slice method.

1 INTRODUCTION

Lateral pile capacity is a key tool in geotechnical engineering, as piles are widely used to support moments and lateral forces. Lateral pile capacity estimation is traditionally expressed as a function of soil and pile properties multiplied by a resistance factor N (Broms, 1964). For cohesive soils, the lateral pile capacity, P_{ult}, is commonly described as:

$$P_{ult} = NS_uD \quad (1)$$

where S_u is the undrained shear strength and D is the pile diameter.

The lateral resistance factor of piles in cohesive soils has been evaluated by applying lower-bound (LB) and upper-bound (UB) plasticity theorems, which consider eligible stress fields and plastic work considerations, respectively (Yu, 2006). The exact solution for N is obtained when the LB and UB solutions converge. In these solutions, it has been shown that N is highly dependent on the soil-pile interface roughness, which can be described as αS_u where $0 \leq \alpha \leq 1$.

As of today, the exact solution for the resistance factor for the entire range of alpha is still inconclusive, except for a perfectly rough pile ($\alpha = 1$), where $N = 11.94$ was found to be the exact solution. In the case of a perfectly smooth pile ($\alpha = 0$) the highest LB solution is $N = 9.142$ (Randolph and Houlsby, 1984) and the lowest UB solution is $N = 9.2$ (Martin and Randolph, 2006). This paper presents the alternative of limit equilibrium (LE) solution for the lateral pile capacity problem.

2 IMPLEMENTING THE SLICE METHOD

Gans-Or and Pinkert (2023) suggested an alternative and novel approach for extracting the resistance factor,

using a modification of the slice method which is widely applied in slope stability calculations (for example: Fellenius 1936, Bishop 1955, Morgenstern and Price 1965, Spencer 1967). The slice method was chosen since it combines equilibrium principles and failure mechanisms. The soil shear strength is expressed using the mobilized strength, $S_{u,m} = S_u/Fs$, where $S_{u,m}$ is the mobilized undrained shear strength and Fs is a factor of safety. For any arbitrary potential failure slip surface, the pile capacity can be expressed as:

$$P_a = NS_{u,m}D \tag{2}$$

where P_a is the applied horizontal force per unit length. Unlike plasticity solutions that directly evaluate P_{ult}, the resistance factor N is calculated in terms of a general P_a and a Fs that is evaluated using a LE solution:

$$N = \frac{P_a Fs}{S_u D} \tag{3}$$

By minimizing the Fs, this work defines the resistance factor according to the maximal soil strength mobilization, which obtained along the most critical slip surface.

2.1 Numerical slice definition

For the LE solution, this work utilizes the slice method, in which the soil is subdivided into horizontal slices. To allow the investigation of numerous slip surfaces (as part of Fs minimization), the slices geometry is generalized in terms of numerical discretization, as described below.

Using polar coordinates, the area bounded by the slip surface is discretized into m slices, where each slice is tangentially incremented by $d\theta = \pi/m$. Figure 1 presents the general slice n, which is numerically described using (i, j, k) indices, where i is the slice radial index, j is the tangential index corresponding to i, and k is the tangential index corresponding to $i + 1$. A line stretching from (i, j) to $(i + 1, k)$ is located on the examined slip surface and is inclined in β_n. The arc extended from $(i, 1)$ to $(i + 1,1)$ is located on the soil-pile interface, and θ_i angle is at its middle.

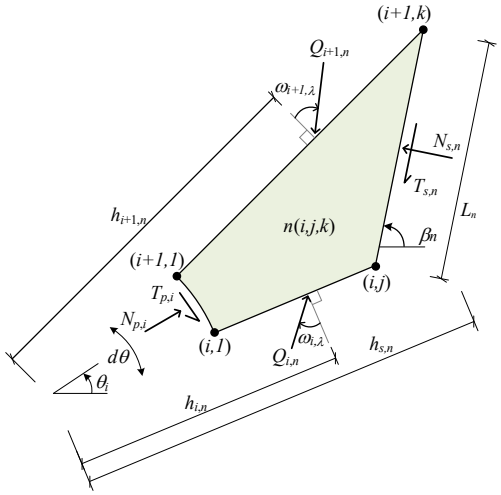

Figure 1. Horizontal Slice numerical definitions and applied forces.

2.2 External load discretization

The external load P_a is divided to each slice as the normal force $N_{p,i}$ and the mobilized shear (adhesion) force $T_{p,i}$ at the soil-pile interface. These forces satisfy equilibrium with P_a by:

$$\sum_{i=1}^{m} N_{p,i} \cos\theta_i + T_{p,i} \sin\theta_i = P_a \tag{4}$$

$$\sum_{i=1}^{m} N_{p,i} \sin\theta_i + T_{p,i} \cos\theta_i = 0 \tag{5}$$

Based on Gans-Or and Pinkert (2023), $T_{p,i}$ and $N_{p,i}$ are described as:

$$T_{p,i} = \alpha \frac{S_u}{Fs} R d\theta \tag{6}$$

$$N_{p,i} = \left(P - 2\alpha \frac{S_u}{Fs} R\right)\left(\frac{\pi}{4} - \frac{\theta_i}{2}\right) d\theta \tag{7}$$

2.3 Slice forces

There are several loads developed in response to external forces, as shown in Figure 1. $N_{s,n}$ represents the normal force and $T_{s,n}$ represents the mobilized shear force on the slice slip surface, given by:

$$T_{s,n} = \frac{S_u}{Fs} L_n \tag{8}$$

where L_n is the length of the slice slip surface. The interslice forces $Q_{i,n}$ and $Q_{i+1,n}$ which are located at distances $h_{i,n}$ and $h_{i+1,n}$ from the pile center, are inclined by ω_i and ω_{i+1}, respectively. Note that the interslice forces inclination ω is described by a general function, $f(\lambda, \theta_i)$, that will be described in Section 3.

2.4 Slice equilibrium

For any examined slip surface, all slices maintain both force and moment equilibriums. For forces equilibrium, the following regression rule was developed for each slice:

$$Q_{i+1,n} = Q_{i,n}\frac{sin(\beta_n-\theta_{r,i}+\omega_i)}{sin(\beta_n-\theta_{r,i+1}+\omega_i)} + \frac{N_{p,i}\,cos(\beta_n-\theta_i)-T_{s,n}-T_{p,i}\,sin(\beta_n-\theta_i)}{sin(\beta_n-\theta_{r,i+1}+\omega_i)} \quad (9)$$

For moments equilibrium, the following regression rule was developed for each slice:

$$Q_{i+1,n}h_{i+1,n} = Q_{i,n}h_{i,n}\frac{cos(\omega_i)}{cos(\omega_{i+1})} + \frac{N_{s,n}h_{s,n}\,cos(\beta_n-\theta_i)-T_{s,n}h_{s,n}\,sin(\beta_n-\theta_i)-T_{p,i}R}{cos(\omega_{i+1})} \quad (10)$$

where $h_{s,n}$ is the radial distance between the pile centre and the middle of L_n.

2.5 Factor of safety evaluation

Using these regression rules, two Fs values can be extracted for any slip surface; $F_{s,F}$ and $F_{s,M}$, representing Fs for global force equilibrium and moment equilibrium considerations, respectively:

$$F_{s,F} = S_u\frac{\sum_{i=1}^{m}\gamma_i\chi_i}{\sum_{i=1}^{m}\epsilon_i\chi_i-\eta(1+\zeta)} \quad (11)$$

$$F_{s,M} = S_u\frac{\sum_{i=1}^{m}\mu_i}{\sum_{i=1}^{m}\xi_i-2\eta H} \quad (12)$$

where η refers to the force and its location H at the extreme slices; $n(1,j,k)$ and $n(m,j,k)$. The other parameters in equations 12 and 13 are given by:

$$\chi_i = \frac{\prod_{z=i+1}^{m}sin(\beta_z-\theta_{r,z}+\omega_{z,\lambda})}{\prod_{z=i}^{m}sin(\beta_z-\theta_{r,z+1}+\omega_{z,\lambda})} \quad (13.1)$$

$$\zeta = \frac{\prod_{i=1}^{m}sin(\beta_i-\theta_{r,i}+\omega_{i,\lambda})}{\prod_{i=1}^{m}sin(\beta_i-\theta_{r,i+1}+\omega_{i,\lambda})} \quad (13.2)$$

$$\gamma_i = 2\alpha R d\theta\left[\begin{matrix}\left(\frac{\pi}{4}-\frac{\theta_i}{2}\right)cos(\beta_i-\theta_i)\\ +\frac{1}{2}sin(\beta_n-\theta_i)\end{matrix}\right] + L_i \quad (13.3)$$

$$\epsilon_i = P_a\left(\frac{\pi}{4}-\frac{\theta_i}{2}\right)d\theta\,cos(\beta_i-\theta_i) \quad (13.4)$$

$$\mu_i = \frac{L_i h_{s,i}\,sin(\beta_i-\theta_i)+\alpha R^2 d\theta}{cos(\omega_{m+1,\lambda})} \quad (13.5)$$

$$\xi_i = \frac{N_{s,i}h_{s,i}\,sin(\beta_i-\theta_i)}{cos(\omega_{m+1,\lambda})} \quad (13.6)$$

The Fs which satisfies all equilibrium requirements (both forces and moments) is achieved for a specific value of the constant λ that satisfies:

$$F_s = F_s(\lambda)|_{F_{s,F}(\lambda)=F_{s,M}(\lambda)} \quad (14)$$

2.6 Limit equilibrium solution

The LE solution presented in this work follows the nature of LB solution because:

1. Both LE and LB solutions satisfies full equilibrium, with a stress state that does not infer the (mobilized) failure criterion.
2. According to Eq. 3, Fs minimization correlates with P_a maximization, similarly to the efforts of LB solutions to maximize the P_{ult} value.

LE solution for the lateral pile resistance factor N yielded good agreement with traditional plasticity solution (Gans-Or and Pinkert, 2023). For the case of smooth soil-pile interface ($\alpha = 0$), the best LE solution was $N = 9.168$, which is margined by 0.3% to the best LB solution. For the case of rough soil-pile interface ($\alpha > 0$), an assumption for the boundary force η and its location H (Eq. 11 and 12) was made, and yet good agreements were found. Even though the LE solution corresponds to the LB nature, the geometry of the critical slip-surface (for each examined α) was found to be similar to UB solutions failure mechanisms.

Although the difference between LE solutions and LB solutions may seem negligible for practice use, it is of high academic interest to close this elusive gap. The process of improving the LE solution should focus on examining different inner slices forces inclinations functions (ω in Eq. 9 and 10), due to its high influence on N. Note that the motivation for improving these functions comes from the various existing slope stability slice methods which differ from each other by the inner slice's forces inclination assumptions (Duncan et al., 2014).

3 IMPROVEMENTS IN LATERAL PILE CAPACITY SOLUTION

The inclination function of ω was previously expressed in terms of a given linear shape function multiplied by a scalar (Gans-Or and Pinkert, 2023). In this work, a more adequate inner slice forces inclination function is suggested for improving the lateral pile capacity solution. The new function is inspired by previous UB failure mechanisms and the force distributions of Martin and Randolph (2006), by means of relating the ω distribution to a reference point located in a λR distance from the pile center

along the symmetricity axis. For example, Figure 2 shows a graphical implementation of the three cases of λ= 0.1, 0.5 and 0.9. For each λ value, a point in λR distance is set, from which a line (dashed) is stretched to the soil-pile interface, at a corresponding $\theta_{r,i} = \theta_i - d\theta/2$ angle. Then, the inner slice force inclination, ω_i, is perpendicular to this dashed line. Analytically, ω_i should satisfy:

$$\lambda = \frac{\sin \omega_i}{\cos(\omega_i - \theta_{r,i})} \quad (15)$$

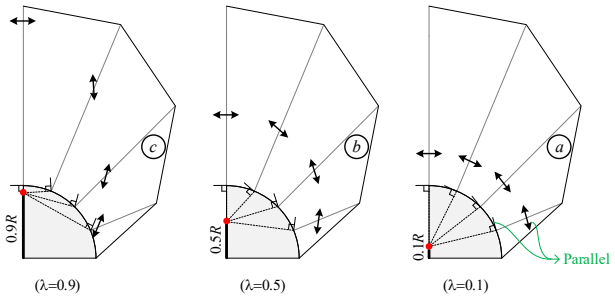

Figure 2. Graphical implementation of ω distribution according to a given λ.

As presented in equations 11 and 12, for each λ value any examined slip surface yields two independent safety factors: $F_{s,F}$ and $F_{s,M}$. Figure 3 presents a conceptual extraction of Fs that is based on Eq. 14. Then, by applying Eq. 3, the resistance factor of the soil can be extracted.

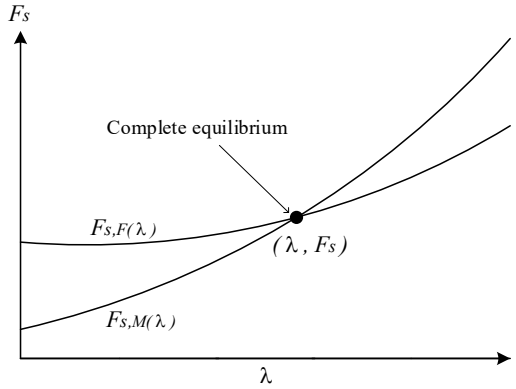

Figure 3. Conceptual extraction of Fs for any examined slip surface.
