ABSTRACT: Triaxial tests are commonly used in soil mechanics to determine the shear strength of soils. In standard tests, either the development of volumetric strain is restricted (undrained), or the development of pore water pressure is inhibited (drained). In this work, a new approach to triaxial testing is proposed that couples the evolution of pore water pressure with the development of volumetric strain. The resulting unconventional strain and stress path is referred as a partially drained path. The experiments can be interpreted as true partially drained since time dependence due to pore water flow does not occur. This new approach offers a third possibility for conducting triaxial tests as element tests, besides fully drained or undrained tests. A series of monotonic tests were conducted on Karlsruhe fine sand. The obtained unconventional strain paths were simulated using Neohypoplasticity, a novel constitutive model for sand. The simulation results were evaluated concerning the experimental data. A good agreement between the experimental results and numerical calculations can be shown.

RÉSUMÉ: Les essais triaxiaux sont couramment utilisés en mécanique des sols pour déterminer la résistance au cisaillement des sols. Dans les essais standard, soit le développement de la déformation volumétrique est restreint (non drainé), soit le développement de la pression de l'eau interstitielle est inhibé (drainé). Ce travail propose une nouvelle approche des essais triaxiaux qui associe l'évolution de la pression de l'eau interstitielle au développement de la déformation volumétrique. La trajectoire de déformation et de contrainte non conventionnelle qui en résulte est appelée trajectoire partiellement drainée. Les expériences peuvent être interprétées comme de véritables essais partiellement drainés puisque la dépendance temporelle due à l'écoulement de l'eau interstitielle ne se produit pas. Cette nouvelle approche offre une troisième possibilité de réaliser des essais triaxiaux en tant qu'essais d'éléments, en plus des essais entièrement drainés ou non drainés. Une série d'essais monotones a été réalisée sur du sable fin de Karlsruhe. Les trajectoires de déformation non conventionnelles obtenues ont été simulées à l'aide de la Neohypoplasticity, un nouveau modèle constitutif pour le sable. Les résultats de la simulation ont été évalués par rapport aux données expérimentales. Une bonne concordance entre les résultats expérimentaux et les calculs numériques peut être démontrée.

Keywords: Partial drainage; triaxial; experiments; Neohypoplasticity.

1 MOTIVATION

In the realm of classical triaxial experiments performed mostly on fully saturated soils, a popular distinction emerges between two testing paradigms: (1) drained and (2) undrained conditions. In drained testing, the primary objective is to have a constant pore fluid pressure and to measure the volumetric deformations, while undrained testing seeks to have a constant volume of the sample. Due to some insufficiencies, it is important to note that undrained tests should not be considered isochoric because of membrane penetration and the compressibility of the substance consisting of grains, water, and gas (Niemunis and Knittel, 2020). Nevertheless, the in situ conditions in saturated soils often pose a challenge, where both pore water pressure changes and volumetric deformations occur simultaneously.

This phenomenon is commonly known as partially drained conditions, and frequently arises in geotechnics such as the foundation of offshore piles or structures in saturated soils.

This paper presents a novel experimental approach that couples the volumetric strain rate and pore water pressure rate within a specimen during a globally undrained triaxial test. This coupling is achieved by using the compressibility of a precisely defined gas bubble enclosed within the experimental setup. In such an experiment, strains, pore water pressure, and stresses within the specimen can be considered as uniform fields. Methods presented in the literature for

partially drained tests typically manipulate drainage resistance (Suzuki et al., 2020, Umehara et al., 1985) and are therefore not time-independent. In contrast, the presented novel approach can be assumed as a triaxial element test (Zürn et al., 2023). Consequently, this approach allows for unconventional stress and strain paths that bridge the gap between well-established drained and undrained conditions.

In this paper, the novel approach is introduced. Experimental data were obtained from a series of 8 monotonic triaxial tests. The novel constitutive model of Neohypoplasticity was used to recalculate the experimental results.

2 EXPERIMENTAL METHOD

To achieve the partial drainage conditions, a modification of a common triaxial set-up is sufficient. The experimental setup is shown in Figure 1. An enclosed gas bubble with adjustable initial volume $V_{a,0}$ and gas bubble pressure $p_{a,0}$ is connected to the pore water of the sample via the burette and drainage system.

A change in the sample volume ΔV leads to an outflow or inflow of water from the sample and a change of V_a. According to the law of Boyle-Mariotte $p_a \cdot V_a = \text{const.}$, such a change of V_a leads to a change of p_a. With the known initial variables $p_{a,0}$ and $V_{a,0}$ and the measurement of p_a using the pore pressure transducer, the actual gas bubble volume V_a can be calculated. Assuming that the change in volume of the sample is equal to the change in gas bubble volume $\Delta V \approx \Delta V_a$, we can calculate the volumetric deformation of the sample ε_{vol}.

3 EXPERIMENTAL RESULTS AND BACK-CALCULATION

3.1 Experiments

A series of monotonic tests was carried out with Karlsruhe fine sand (KFS), a uniformly graded fine sand. The grading curve and characteristic values of KFS can be found in the literature (Wichtmann , 2016). The tests which were conducted are given in Table 1. All medium-dense tests were prepared by moist tamping, the dense tests were prepared by air pluviation. For comparison, two additional tests (TMU6 and TMD23) from the literature were used (Wichtmann and Triantafyllidis, 2016).

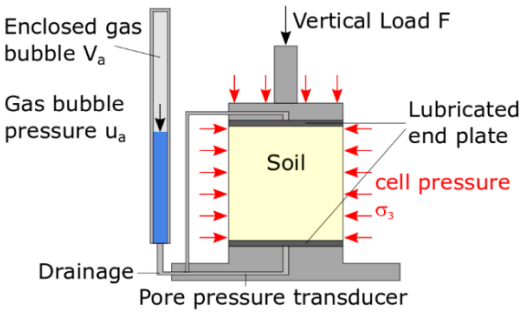

Figure 1. Experimental setup for the testing of partially drained conditions.

First, Figure 2 shows the evolution of the bulk moduli in the experiments calculated using

$$K_m = \dot{p}_f / \dot{\varepsilon}_{vol} \quad (1)$$

whereby, the pore fluid pressure p_f and the volumetric strain ε_{vol} are measured directly. First of all, it should be mentioned that the initial values of K_m can be reproduced well. However, the bulk modulus changes significantly during the test.

The well-known initial contractancy of the sample leads to a compression of the gas bubble. The bubble becomes smaller and stiffer, which increases the bulk modulus. In a subsequent dilatancy, the gas bubble becomes larger and softer, resulting in a decreased bulk modulus. The observed differences in the maximum strains are the result of test termination due to large stresses.

The stress path in the p - q diagram and the strain path in the ε_1 - ε_{vol} diagram are shown together with the corresponding simulations in Figure 3-6. It can be seen that all the test results are between the limits of the drained and undrained test and both volumetric deformations and pore water pressure changes occur simultaneously.

As the size of the gas bubble increases, the behavior of the tests changes from more undrained to drained conditions.

Table 1. Overview of the experiments on KFS.

Test	e_0 [-]	I_{D0} [-]	p_0 [kPa]	Gas bubble size
V1	0.896	0.42	200	large
V2	0.910	0.38	200	medium
V3	0.901	0.39	200	small
V4	0.698	0.95	200	large
V5	0.702	0.93	200	medium
V6	0.694	0.96	200	small
U1	0.901	0.41	200	zero (undrained)
D1	0.898	0.41	200	infinite (drained)
TMU6	0.728	0.87	200	zero (undrained)
TMD23	0.706	0.92	200	infinite (drained)

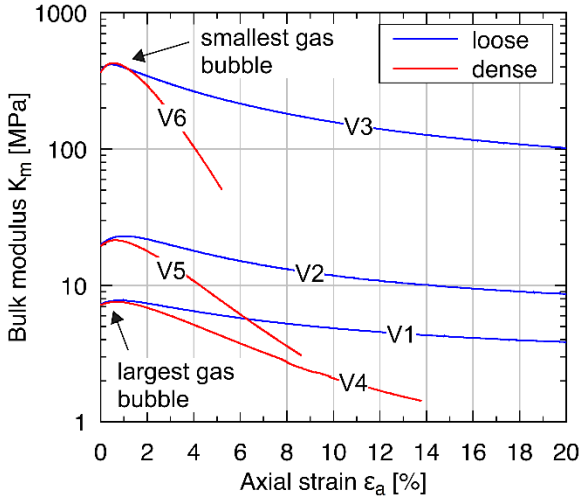

Figure 2. Evolution of the bulk modulus K_m for the different tests.

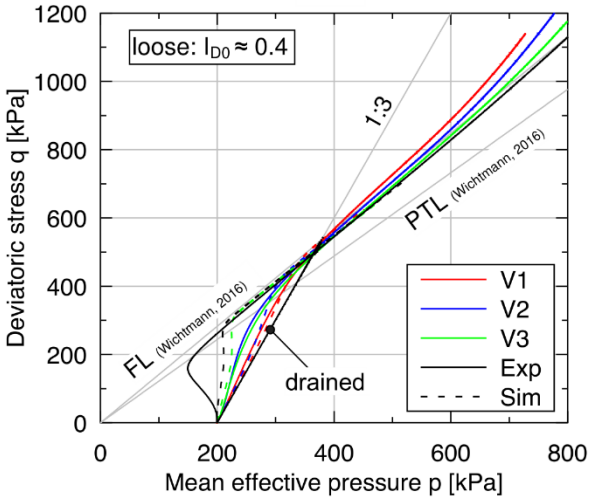

Figure 3. Stress paths for triaxial tests under different drainage conditions of loose KFS: experiments (solid lines) versus simulations with NHP (dashed lines).

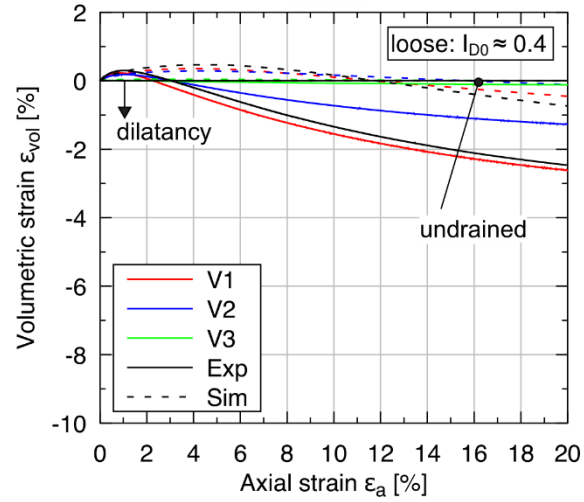

Figure 4. Strain paths for triaxial tests under different drainage conditions of loose KFS: experiments (solid lines) versus simulations with NHP (dashed lines).

The volumetric deformations increase, while the change in pore water pressure decreases. The tests can therefore be considered as partially drained.

The low initial contractancy of the medium-dense samples compared to the dense ones is due to the different preparation methods of the tests, as shown in the literature for KFS (Wichtmann, 2016).

3.2 Simulations using Neohypoplasticity

The Neohypoplasticity (NHP), which is a novel hypoplastic constitutive model for sand was used to recalculate the experimental results for partially drained conditions. For the main rate equation applies

$$\mathring{\boldsymbol{\sigma}} = k\,\overline{\mathrm{E}}\colon(\dot{\boldsymbol{\varepsilon}} - \boldsymbol{m}Y \parallel \dot{\boldsymbol{\varepsilon}} \parallel - \omega \boldsymbol{m}^z\langle -\boldsymbol{z}\colon\dot{\boldsymbol{\varepsilon}}\rangle - \boldsymbol{m}^d Y_d \parallel \dot{\boldsymbol{\varepsilon}} \parallel) \qquad (2)$$

were $\mathring{\boldsymbol{\sigma}}$ is the objective Jaumann-Zerema stress rate and $\dot{\boldsymbol{\varepsilon}}$ is the strain rate. More details about NHP can be found in the literature (Mugele et al. 2023).

In NHP, the mechanical behavior of non-cohesive soil is described using four state variables: (1) stress $\boldsymbol{\sigma}$, (2) void ratio e, (3) structure variable $\boldsymbol{z}$ and (4) last strain reversal $\boldsymbol{h}^r$. However, for the presented simulations the structure variable is initialized in such a way that their influence on the mechanical response vanishes. The small strain stiffness (increase due to $\boldsymbol{h}^r$) at the beginning of the monotonic deformation is fully considered. The constitutive parameters for KFS were taken from the literature (Mugele et al., 2023) and the test results presented in this work were not considered in the parameter calibration.

The element test simulations were conducted using the program code IncrementalDriver. A challenge for the recalculation of the partially drained tests of the experimental method presented is the bulk moduli, which varies significantly over the test (Figure 2). This corresponds to a non-linear restriction between the effective stress rates and the strain rates.

However, using the incremental driver, only linear restrictions between stress and strain rates can be specified. For simplicity, we have chosen the bulk modulus as a constant. The used value of K_m was calculated as the average value over the total strain of the test. For example, a value of $K_m = 4.99$ MPa was obtained for test V1. A

restriction between the effective stress and strain rates can be calculated. This restriction depends on the chosen bulk modulus and is therefore different for the different tests.

The comparison of the simulations with the experiments indicates that the soil behavior can be qualitatively reproduced with the coarse estimation of the bulk modulus.

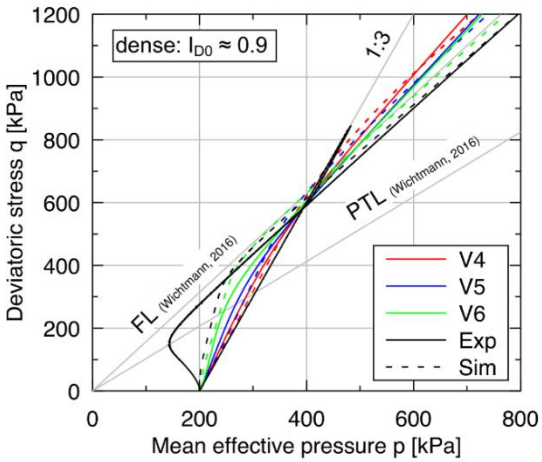

Figure 5. Stress paths for triaxial tests under different drainage conditions on dense KFS: experiments (solid lines) versus simulations with NHP (dashed lines).

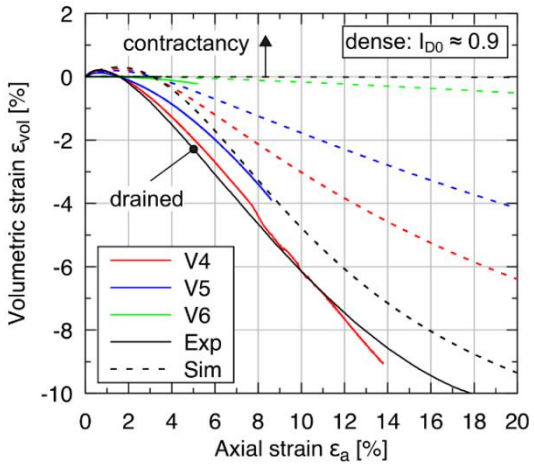

Figure 6. Strain paths for triaxial tests under different drainage conditions on dense KFS: experiments (solid lines) versus simulations with NHP (dashed lines).

The more drained the test is, i.e. the larger the gas bubble and the smaller the bulk modulus, the smaller the deviations of the stress path in the p - q diagram from the 1:3 line (corresponds to the drained test). Simultaneously, these tests and the simulations showed a larger volumetric deformation.

The opposite can be observed for a smaller gas bubble that results in a larger bulk modulus. Smaller volumetric deformations occur but deviations from the 1:3 line become larger.

4 CONCLUSION

The present study presents a method for conducting triaxial tests under partially drained conditions. It was found that:

- The experimental method presented was verified using a series of monotonic tests.
- Partially drained experimental element tests result in stress and strain paths lying between the two well-known extreme cases of undrained and drained tests.
- Simulations of the unconventional test results demonstrate that Neohypoplasticity can qualitatively reproduce the results.
- The quantitative discrepancies between the simulations and the experimental results could probably be improved by considering the nonlinear bulk modulus more accurately, calibrating the parameters, and initializing the structure variable.

Creep of organic soils due to small load increments

Fluage des sols organiques dû à de faibles augmentations de charge

ABSTRACT: Organic soils are susceptible to creep. When predicting settlement of organic deposits due to small load increments, the initial conditions, particularly the initial strain rate should be assessed carefully. Recent developments in predicting creep behaviour of clays are tested in an ongoing study on organic soil behaviour. A series of incremental loading tests on peat and organic clay shows that a framework of undisturbed isotachs cannot be used to predict strain rates in over-consolidated conditions. This complicates the applicability of conventional incremental loading test results for assessing field conditions. Additionally, the tests show the relevance of a large strain approach when dealing with soft organic soils.

RÉSUMÉ: Les sols organiques sont susceptibles de fluer. Lors de la prévision du tassement des dépôts organiques dû à de faibles incréments de charge, les conditions initiales, en particulier la vitesse de déformation initiale, doivent être évaluées avec soin. Les développements récents dans la prévision du comportement au fluage des argiles sont testés dans une étude en cours sur le comportement des sols organiques. Une série d'essais de chargement incrémentiel sur tourbe et argile organique montre qu'un cadre d'isotaches non perturbés ne peut pas être utilisé pour prédire les taux de déformation dans des conditions sur-consolidées. Cela complique l'applicabilité des résultats des tests de chargement incrémentiels conventionnels pour évaluer les conditions sur le terrain. De plus, les tests montrent la pertinence d'une approche à grandes déformations lorsqu'il s'agit de sols organiques mous.

Keywords: Settlement; creep; organic soils.

1 INTRODUCTION

Organic soils are known for their tendency to creep. Yet, most 1D creep theories are typically derived for clays. This paper discusses some results of a study that examines the applicability of the 1D creep theories for organic soils.

This study focusses on small load increments. These are increments for which the soil stress remains below the yield stress. For predicting creep due to small load increments, the initial conditions, such as strain rate prior to loading, play an important role.

2 TESTED MATERIAL

Two material types are selected for testing: peat sampled at Zegveld and an organic clay sampled near Bleskensgraaf, The Netherlands. Table 1 and Table 2 present the characteristics of the tested materials.

The material was sampled by the DLDS sampler. This sampler takes block samples, 400 mm in diameter and 500 mm in height. Details of the sampler are given by Zwanenburg (2017).

Table 1. Characteristics of the tested peat samples.

sample	Depth [m]	W [%]	γ [kN/m^3]
25	-3.90	673	9.41
26	-3.90	675	9.34
42	-7.48	830	9.13
55	-3.13	578	9.80
65	-7.71	843	9.60
67	-3.42	420	9.40
97	-3.42	585	9.58
99	-3.31	656	9.02
9	-2.93	587	9.57

Table 2. Characteristics of the tested organic clay samples.

sample	Depth [m]	W [%]	γ [kN/m^3]
1	-3.04	62	15.2
2	-3.04	118	13.0

The volumetric weights indicate that the samples might be unsaturated, which is explained by the presence of gas in the peat deposits. As indicated by Persekian (2011), the gas content might run up to 30%. The organic content of the tested peat samples is in the order of 79%.

The organic clay samples show natural heterogeneity, as shown by the water content, W and

volume weight, γ. The organic content of the clay is in the order of 3.6% for test 1 and 6.5% for test 2.

3 THEORY

This study follows the isotach frame as discussed by Leroueil (2006), Yin & Graham (1989), Den Haan (1992, 1999), Den Haan & Edil (1994), Leroueil et al. (1985).

The 1D creep compression and creep rate follows from:

$$\varepsilon_c = C_\alpha \log\left(\frac{\tau}{\tau_0}\right), \dot{\varepsilon}_c = \frac{C_\alpha}{2.3\tau} \quad (1)$$

in which, ε_c represents linear strain due to creep, $\dot{\varepsilon}_c$ creep strain rate, C_α creep parameter, τ intrinsic time and τ_0 reference intrinsic time, τ_0 = 1 day. With intrinsic time, τ as the time scale for soil deformation related to the isotach field, Den Haan (1992, 1999).

The relation between changes in intrinsic time and load steps follows from:

$$\tau_i = \tau_{i-1}\left(\frac{\sigma'_{i-1}}{\sigma'_i}\right)^{\frac{CR-RR}{C_\alpha}} \quad (2)$$

in which τ_i and τ_{i-1} represent the different intrinsic time values in the different load steps, σ'_i, σ'_{i-1} the effective stresses during these steps, CR the compression ratio and RR the recompression ratio.

For specific stress conditions, the intrinsic time can be found by Equation (2). When referring to the 1-day compression line, τ_{i-1} = 1 day, σ'_{i-1} is the yield stress, σ'_{vy} and OCR = over-consolidation ratio, Equation (2) turns into:

$$\tau = OCR^{\frac{CR-RR}{C_\alpha}} \quad (3)$$

Recent developments (Yuan & Whittle, 2018) allow for a constant or non-constant spacing between the isotachs by introducing a parameter β. For $\beta = C_\alpha/(CR\text{-}RR)$, the Yuan & Whittle model aligns with Eq. (2). Smaller values for β mimic the conditions of reducing distance between the isotachs. The Yuan & Whittle model also introduces an activation of creep on changes in loading.

Vergote (2020) describes non-linear isotachs caused by structural changes due to unloading. Disturbed isotachs will lead to larger strain rates on unloading compared to the undisturbed isotachs.

4 TEST SET UP

In total 9 incremental loading tests, IL, have been conducted on peat and 2 IL tests on the organic clay. The applied loading scheme is given in Figure 1. Additional testing, including constant rate of strain, CRS testing is still ongoing.

The tests use a WILLE oedometer test set-up. A 1 kN load cell provides the load measurement. An LVDT is placed directly on the top cap to measure vertical displacements. The initial sample height, h_0, was 20 mm for the peat samples and 30 mm for the organic clay samples.

To validate Equations (1) and (2), the tests include multiple loading and unloading steps. The duration of the different load steps is 24 hours except for the steps 2 and 10 which were extended to 168 hours (1 week). This loading scheme allows to determine the relevant parameters from the conventional 24 h loading steps to examine the creep strain and strain rate for the 168-hours steps. In this way parameters are derived and applied in the analysis of the same test, eliminating the possible effect of heterogeneity between the samples. For the organic clay tests only 24 hours load steps were applied. After the unloading step, multiple loading steps with reducing OCR have been applied. This allows for examining the influence of OCR on the calculated and observed strain rates.

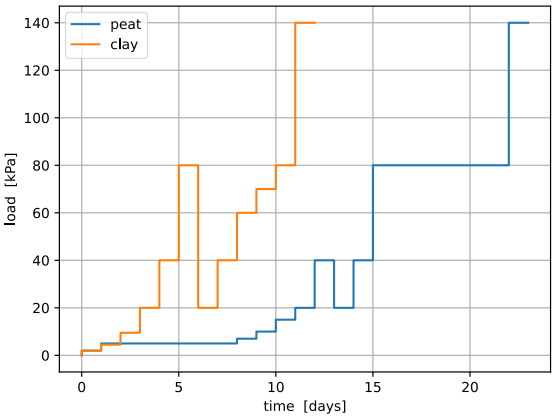

Figure 1. Applied loading schemes.

5 RESULTS TESTED PEAT SAMPLES

Figure 2 shows some results for test 25, which are considered typical for the tests on peat.

Table 3 shows that the ratio (CR-RR)/C_α ranges from 8.3 to 19.7 for the tested peat and 11 to 23 for the tested organic clay, see Table 5. Consequently, the relation between load increments and intrinsic time increments is highly non-linear and small deviations in for example OCR in Eq. (3) has a strong influence on the calculated intrinsic time.

The 1-day compression line, Figure 2a, starts to bend at $\varepsilon_a > 0.4$. This is explained by the finite layer thickness and can be addressed by using a large strain approach (Den Haan, 1999). The strain rate in step 2, with a vertical load of 5 kPa and representing OC conditions is clearly lower than found in step 10, with a vertical load of 80 kPa, representing NC conditions.

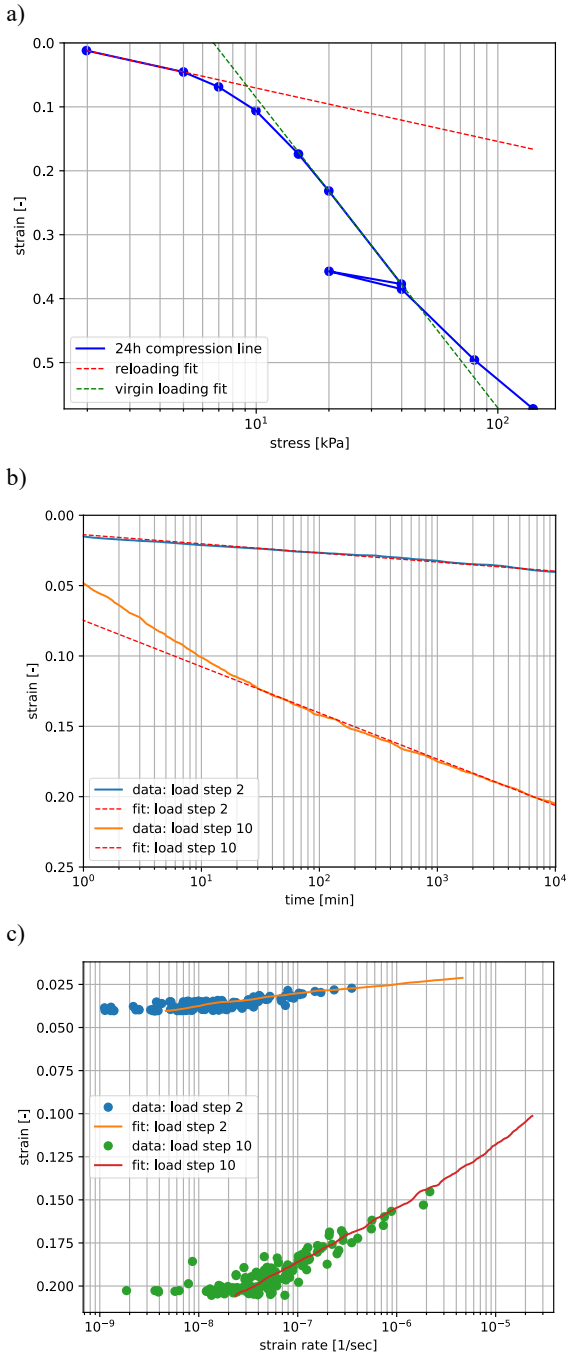

Figure 2. Results of test 25, a) 24h compression curve, b) time – strain development for load steps 2 and 10, c) strain rate – strain development for load steps 2 and 10.

Table 3. Comparison between calculated and measured creep strain rate at the end of step 2, OCR_2 = OCR in step 2, $C_{\alpha,10} = C_\alpha$ derived from step 10.

nr	(CR-RR) /C_α	$C_{\alpha,10}$	OCR_2	$\dot{\varepsilon}_{cal}\times10^{-9}$ [1/s]*	$\dot{\varepsilon}_m\times10^{-9}$ [1/s]
25	12.7	0.0329	1.8	0.073	4.6
26	13.4	0.0315	2.1	0.0084	3.2
42	15.9	0.0303	2.7	0.00003	2.1
55	19.7	0.0309	3.1	4.0×10^{-8}	1.0
65	10.7	0.0344	2.3	0.03	4.6
67	8.8	0.0374	2.2	0.21	8.8
97	8.7	0.0372	2.2	0.2	7.4
99	8.3	0.0429	1.8	1.5	13
9	11.2	0.0391	2.5	0.0074	3.2

**Calculated using Equation (1).*

Table 3 summarizes the results. The creep parameter is evaluated from step 10, $C_{\alpha,10}$, by curve fitting, as indicated by the red dotted line in Figure 2b. The curve fitting yields $\mu_{C\alpha} = 0.035$ with coefficient of variation, COV = 0.12. The OCR in step 2 fluctuates around 2.3.

Figure 2a shows the curve fitting of the compression line providing the RR and CR values, which are combined with $C_{\alpha,10}$ to obtain (CR-RR) /C_α values as presented by Table 3.

The last column in Table 3 presents the measured creep strain rates found at the end of loading phase 2. The obtained values are in the order of 10^{-9} to 10^{-8} 1/s. Using Eq. (1), the strain rates are assessed for the same test phase. The calculated values, column 5 of Table 3, show a large variety and clearly underpredict the measured values. Small changes in (CR-RR)/C_α cannot explain the differences.

Using $\dot{\varepsilon}_m$, Eq. (1) and (3) yield an effective OCR, OCR_{eff}, which corresponds to the observed strain rates. Table 4 compares OCR_{eff} and OCR. On average, OCR_{eff} is 62% of OCR.

Table 4. Comparison of OCR_{eff} and applied OCR

nr	OCR_{eff}	OCR_2	OCR_{eff}/OCR_2
25	1.33	1.8	0.74
26	1.34	2.1	0.64
42	1.31	2.7	0.48
55	1.29	3.1	0.42
65	1.40	2.3	0.61
67	1.42	2.2	0.64
97	1.45	2.2	0.66
99	1.40	1.8	0.78
9	1.44	2.5	0.58

It should be noted that for normally consolidated conditions, step 10, the calculated and measured strain rates are in good agreement. This is visualised by test 25. For $C_\alpha = 0.0329$, see Table 3, and $\tau = 10^4$ min (6×10^5 sec), Eq. (1) gives $\dot{\varepsilon}_{cal} = 2.4\times10^{-8}$1/s, which

corresponds nicely to the measured creep strain rate at the end of loading stage 10 in Figure 2c.

6 RESULTS ORGANIC CLAY

Figure 3 shows the compression curve as a function of void ratio for the two oedometer tests on organic clay. Table 6 shows a good agreement between the measured and calculated strain rates for normally consolidated conditions. For over-consolidated conditions, however, the measured strain rate decreases mildly whereas the calculated strain rate is orders in magnitude smaller. It should be noted that when including a reducing C_α, the calculated strain rates would reduce even stronger for increasing OCR.

Table 5. re-compression ratio, RR, compression ratio, CR, creep parameter C_α and yield stress σ'_{vy} for oedometer test 1 and 2.

Test	RR	CR	C_α	$(CR-RR)/C_\alpha$	σ'_{vy} [kPa]

7 CONCLUSIONS

The tests on peat and organic clay show the same tendency. Calculated creep strain rates for normally consolidated conditions correspond to the measured creep strain rates. For over-consolidated conditions, however, calculations following Den Haan (1992, 1999) underpredict the creep strain rates. The difference between the measured and calculated creep strain rates increases for increasing OCR.

A reducing C_α with OCR does not improve the calculations. Instead, disturbed isotachs (Vergote 2020), might provide a framework within which an explanation for this behaviour could be found. This will be part of a follow-up study.

The tests on organic clay show that the difference between the measured and predicted strain rate is found for both, the initial re-loading steps below the natural yield stress as well as for the re-loading steps in the second part of the test. In the field, initial strain rates are induced typically by long term creep or aging and unloading might not be relevant field conditions. This difference in stress conditions between field and incremental loading tests results in a difficulty for the assessment of the initial creep strain rate in the field.

The last loading steps, in the tests on peat, show an increase in stiffness, which is explained by the finite layer thickness. This shows the relevance for a large strain approach when dealing with organic soils.

Discharge flow rate under sheet piles, a prediction model

Débit de décharge sous palplanches, un modèle de prédiction

ABSTRACT: The discharge flow rate beneath water-retaining structures is an important parameter in designing water retaining structures. This paper presents a framework to model and predict discharge flow rate using an evolutionary-based technique. The proposed method is data-driven and searches mathematical structures to representing a complicated system. A comprehensive data set including around a thousand data lines is used to create and test the prediction model. Data divided into training and testing data sets (testing data set not introduced to the model in the training stage) using special statistical approach to ensure relevance, validity and compatibility of the training and testing data sets. The main advantage of the proposed models is to provides an optimum explicit structure for the model directly from the data unlike black box models and the capability of the model is tested by introducing an unseen data set to ensure the model is capable of generalisation. Results revealed the high accuracy of the developed model in predicting flow rates both for seen and unseen data cases. A parametric study on the presented models confirmed consistency of the parameter relationships with the database and expected behaviour of the system based on traditional empirical methods.

RÉSUMÉ: Le débit de rejet sous les ouvrages de rétention d'eau est un paramètre important dans la conception des ouvrages de rétention d'eau. Cet article présente un cadre pour modéliser et prédire le débit de rejet à l'aide d'une technique basée sur l'évolution. La méthode proposée est basée sur les données et recherche des structures mathématiques pour représenter un système complexe. Un ensemble de données complet comprenant environ un millier de lignes de données est utilisé pour créer et tester le modèle de prédiction. Données divisées en ensembles de données de formation et de test (ensemble de données de test non introduits dans le modèle lors de la phase de formation) en utilisant une approche statistique spéciale pour garantir la pertinence, la validité et la compatibilité des ensembles de données de formation et de test. Le principal avantage des modèles proposés est de fournir une structure explicite optimale pour le modèle directement à partir des données, contrairement aux modèles de boîte noire, et la capacité du modèle est testée en introduisant un ensemble de données invisible pour garantir que le modèle est capable de généralisation. Les résultats ont révélé la grande précision du modèle développé dans la prévision des débits pour les cas de données visibles et invisibles. Une étude paramétrique sur les modèles présentés a confirmé la cohérence des relations entre les paramètres avec la base de données et le comportement attendu du système sur la base des méthodes empiriques traditionnelles.

Keywords: Sheet piles; seepage; flow rate; evolutionary computing.

1 INTRODUCTION

One of the most important interests of geotechnical researchers is to look into the safety of structures like dams that are used to retain water bodies. The rate at which the water outflows from the body of such structures is the core of this research attention, because it could potentially be a starting point for any failure due to seepage-related issues which could be catastrophic i.e. the piping phenomenon to name an example. The amount of water seeping out and the rate at which the discharge happens therefore is the main focus point for design safety of these. Large exit quantity of water from the structure on the downstream side can be dangerous as it could threaten stability of the structure as a whole due to increases possibility of piping phenomenon. Therefore, mechanisms must be in place to ensure the exit quantity of water is kept under watch and indeed limited to ensure structural safety and stability. The high values of the discharge flow rate can endanger the water retaining structure stability. One of the very commonly used tools to contribute to this aim is sheet pile. Sheet piles can in fact be considered an effective shield and are used to

cut the discharge rate and volume of water passing through the porous medium (geotechnical materials) under the water retaining structure. There is a mathematical constitutive differential equation that governs the seepage flow rate and various methods have been used to solve the equation (Zhang et al. 2017).

While analytical methods offer much more desirable exact solutions to the problems, they cannot be used in analysing large scale problems due to calculations getting too complicated. Numerical approaches however offer approximate but with high enough accuracy levels solutions to complicated large scale problems. Numerical methods can hit problems numerically when singularity occurs (i.e. sharp shaped corners etc.) in discretisation process which makes solving the problem numerically further problematic (Lei et al., 2020).

Scaled Boundary Finite Element Method (SBFEM) introduced by Song and Wolf (1997) aimed at removing some limitations with existing finite element based numerical techniques and been used so far by many researchers (Johari and Heydari, 2018). As per any other method SBFEM has a downside too and it is the fact that each calculation of discharge flow must be analysed by an expert. Data mining and machine learing approches have been used by researchers therefore to overcome this issue as the analysis could be done by models that learn from data eliminating the lenghty manual case-by-case analysis (Yalchin et al 2019).

In this research an evolutionary data mining -based method called Evolutionary Polynomial Regression (EPR) is implemented to learn the behavioural pattern and make predictions for the rates of discharge flow that happens through (passing under) sheet piles. The database used to train and develop the model was built of one thousand lines that were created synthetically using SBFEM.

2 EVOLUTIONARY POLYNOMIAL REGRESSION

To be able to learn and make predictions of the behaviour of the system being modelled, EPR uses data and in the data it looks to find trends and relations presents them in the form of a set of explicit polynomial expression which is accessible by the user and could be judged for suitability considering the known effect of any parameter used as input and how it is expected to affect the output. Therefore, if a model deemed not representative then the user could pick another more suitable one. The maximum number of terms in the mathematical expression can be adjuted to avoid over complexity or under-representavieness of the models by the user to strike the right balance. This is the very important advantage of EPR compared to blackbox systems like ANN.

$$y = \sum_{j=1}^{n} F(X, f(X), a_j) + a_0 \tag{1}$$

Where **y** = outputs (vector)**;** $\mathbf{a_j}$ = parameters of the model; **F** = EPR-developed function; **X** = inputs (variable); **f** = user-defined fuction; **n** = terms number (how many) in polynomial that user wants to see as the maximum. The general functional structure is constructed from elementary functions by EPR using a Genetic Algorithm (GA) strategy.

EPR is very interactive in communicating with the users as the output is an explicit expression mathematical terms relating the variables to the output; therefore, use has full access to the model and is able to check that the contribution by various inputs are in line with the understanding of the phenomena by the engineers (Ahangar Asr et al., 2023).

3 PREPARING DATA

A thousand line of data used to train the EPR model in this work. These data lines were developed using an SBFEM model (figure 1) and many possible scenarios were considered to ensure that the data set contains almost all aspect of the behaviours of water passing through these water retaining structures (Ahangar Asr et al., 2023).

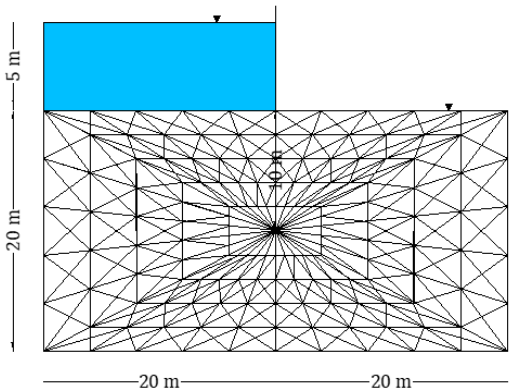

Figure 1. SBFEM model.

4 MODEL DEVELOPMENT

The source of data containing the thousand data line were divided into two subsets. The larger data set containing about eighty percent of data was the used to develop the model by training EPR and the

remaining was not introduced to EPR at all therefore suitable to test the outcome models. This approach is very robust as it not only tests the capability of the model in making accurate predictions but also because the test data are not seen by EPR when the model was being developed, the testing process also shows the generalisation capabilities of the developed model to the cases that are not experienced by EPR when training. This does not mean that the model extrapolates. The data was statistically analysed to ensure an even distribution is made and the training and testing sets are close statistically to avoid extrapolation (Ahangar Asr et al., 2023). Table 1 shows the input parameters and training and testing subsets of data used to develop and verify the model are presented in figures 2 and 3.

Table 1. Input parameters.

Parameters	**Range**
Input parameters	
Sheet pile's height (D)	0.25-10 m
Upstream water level (H)	1-5 m
Anisotropy ratio of deposit materials (K)	0.2-1
Output parameter	
Normalized flow rate Q_{Nor}	1.42×10^{-6} – 8.54×10^{-5}

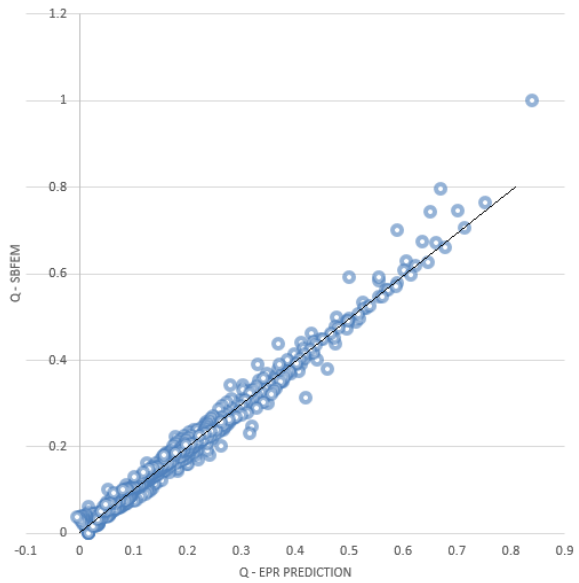

Figure 2. Training data against predictions.

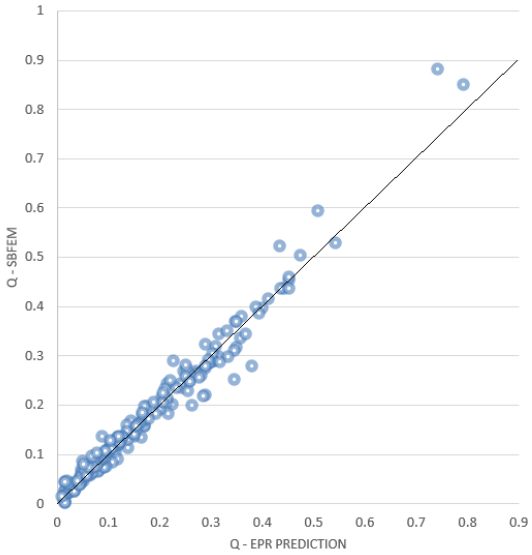

Figure 3. Test data against predictions.

The parameter defined as coefficient of determination or COD (Eqn. 2) was used by EPR to judge the accuracy levels of the models developed:

$$\mathbf{COD} = 1 - \frac{\sum_{N}(\mathbf{Y}_a - \mathbf{Y}_p)^2}{\sum_{N}\left(\mathbf{Y}_a - \frac{1}{N}\sum_{N}\mathbf{Y}_a\right)^2} \qquad (2)$$

Where $\mathbf{Y}_a$ = value of the output (actual); $\mathbf{Y}_p$ = value of the output (EPR prediction); N = count of the data point used to calculate the coefficient of determination (COD) value.

Coefficient of determination values calculated for training data was 98.11%. This showed exceptional capability of the EPR model to learn from the data patterns presented and make predictions for the data which was used to train the model. The coefficient of determination calculated for the testing data which has not been previously introduced to EPR in training stage was 97.24%. This clearly shows that not only the suggested evolutionary polynomial regression technique was able to, to a very high degree of accuracy, capture the seepage phenomena behaviour under the sheet piles, but also can very rigorously generalise the predictions to cases that were not previously familiar to (not seen by EPR). EPR learns form data no matter where it comes from. Actual data from field measurements and synthetic data could therefore be used in one set. Synthetic data could be the main data source or could be simply used to fill any gaps in data where no measured data is available.

5 UNDERSTANDING THE EFFECTS OF CONTRIBUTING PARAMETERS

To understand whether the developed model is a true representation of any contributing parameter effect on the phenomenon, meaning that changes in every individual parameter or any combination of them - where applicable - are having the effect on the model output that is also expected in the real world, an analysis on the parameters is conducted. All parameters were allocated with their average values in the range used apart from the parameter effect of its change on the model was being scrutinised. The change in the model output values then was recorded as the parameter in question varied from its minimum to maximum values. The effects on the predictions of the EPR model was then shown in the form of a series of graphs, each produced for an input parameter. Figure 4 shows an example analysis outcome of this type. It can be seen for instance that the model shows that as the cut off wall length increases (generally meaning that the wall penetrates deeper in the soil), the flow rate drops. Which is consistent with the behaviour expected from the interaction between a cut of wall and the seepage phenomenon.

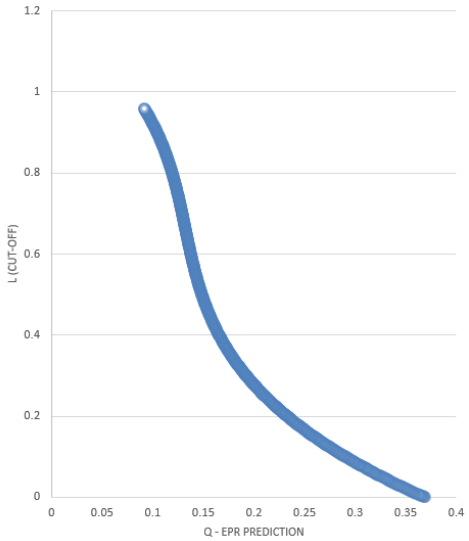

Figure 4. EPR prediction variations as the cut-off wall length changes.

6 DISCUSSION AND CONCLUSIONS

A model was produced by an artificial intelligence-based machine learning technique to simulate and represent the seepage flow rate under sheet piles. The data was divided into training and testing subsets. Relevant pre-analysis was conducted on the data to ensure that the two subsets were statistically consistent. Testing data ensured not to be shown to the EPR during the training stage and once the models developed, they then used to measure the generalizations (but not extrapolation) capabilities of the developed models. Effect of individual contributing parameters on the developed model predictions was assessed. It was shown that the proposed method developed a model that could predict discharge flow rate under sheet piles to a very high accuracy level. This was particularly important because the model could make predictions for the cases where the data were not seen by EPR during the model development processes, to a similar level of accuracy. It can be concluded that the model has successfully captured and learned the underlying relations between the contributing input parameters and was able to replicate their true (expected) effects on the model outcome. An advantage of the proposed modelling data is that as new and more comprehensive data becomes available, the EPR could be retained, and the model amended to ensure more realistic and up to date predictions are made in light of the new data becoming available.

Contract for the stabilization of the north cliff in Azenhas do Mar

Travaux de stabilisation de la falaise nord d'Azenhas do Mar

S. Almeida*, M. Pereira
Mota-Engil Engenharia S.A, Portugal

**sergioa@mota-engil.pt*

ABSTRACT: The Mota-Engil Engenharia S.A. Special Foundations Department executed the stabilization contract of the North Cliff of Azenhas do Mar located in Sintra for the Portuguese Environment Agency (APA). The intervened area extended along the northern Cliff section under the urban core of Azenhas do Mar with about 125 m of development and a maximum height of 45 m. This project was developed with two key objectives. The first was the need to seek to preserve the core of traditional housing that were built on top of the Cliff, considered of great patrimonial interest; the second with the requirement to increase the level of security of the area overlooking the restaurant and the ocean pool, built at the base of the Cliff whose attendance increases significantly during the Summer. The great exposure of this Cliff, either to the direct action of sea wave, or to atmospheric phenomena, more specifically to the formation of fog and fog with some persistence, contributes to a process of continuous erosion that was causing its progressive retreat, thus endangering the stability of buildings and other structures that are built at their top, especially those that are closer to the edge.It is intended to address in the first place the challenge of accessing the work area since it was delimited to the west by the sea and east by the buildings of Azenhas do Mar housing core. At the same time will also be addressed the means involved in the execution of work, deforestation, reperfilation of the Cliff, nailing, sprayed concrete and recovery and execution of new walls of mortar stone, procedures adopted, as well as the complexity related to the execution of works of this nature in a protected and national interest landscape.

RÉSUMÉ: Le Département des Fondations Spéciales de Mota-Engil a exécuté les travaux de stabilisation de la falaise nord d'Azenhas do Mar, située dans la municipalité de Sintra, pour le compte de l'Agence portugaise de l'environnement (*Agência Portuguesa do Ambiente - APA*). La zone d'intervention s'étend le long du tronçon de la falaise nord, en contrebas du centre urbain d'Azenhas do Mar, qui s'étend sur près de 125 mètres pour une hauteur maximale de 45 mètres. Ce projet a été développé avec deux objectifs fondamentaux en tête: Le premier concernait la nécessité de préserver le cœur de la ville construite au sommet de la falaise, considérée comme présentant un grand intérêt patrimonial, le second était lié au besoin d'augmenter le niveau de sécurité dans la zone surplombant le restaurant et la piscine océanique, construits au pied de la falaise, dont l'occupation augmente considérablement pendant la saison balnéaire. La grande exposition de cette falaise, tant à l'action directe des vagues qu'aux phénomènes atmosphériques, plus précisément à la formation de brumes et de brouillards qui persistent dans la région, contribuent à un processus continu d'érosion qui a conduit à son recul progressif, mettant ainsi en péril la stabilité des bâtiments et autres structures qui sont construits sur son sommet, en particulier ceux qui sont les plus proches de son bord. L'objectif est de répondre dans un premier temps à la problématique d'accès à la zone de travaux telle qu'elle était délimitée à l'Ouest par la mer et à l'Est par les bâtiments de cette zone résidentielle. En parallèle, les moyens mis en œuvre pour réaliser les travaux de déboisement, de reprofilage de la falaise, de clouage, de béton projeté, de récupération et de construction de nouveaux murs en pierre avec application de mortier, les procédures adoptées, la phase de construction et la complexité liée à la réalisation de travaux de cette nature dans une zone de paysage protégé et d'intérêt national élevé seront également abordés.

Keywords: Cliff; stabilization; erosion.

1 INTRODUCTION

In 2014, the Portuguese Environment Agency (*Agência Portuguesa do Ambiente - APA*) has promoted a competition for the development of a project covering: The stabilization of the northern cliff section under the urban area of Azenhas do Mar, near Sintra (Portugal), with about 125 m in length and a maximum height of 50 m, as we can see on figure 1. The rehabilitation of the ocean pool and surrounding areas, located at the base of that cliff.

Figure 1. Before the intervention.

This project was developed with two key objectives: The first was the need to preserve the core of traditional housing built on top of the Cliff, considered of great heritage interest.

The second should meet the requirement to increase the level of security of the area overlooking the restaurant and the ocean pool, built at the base of the Cliff, whose attendance increases significantly during the Summer.

The great exposure of this cliff, either to the direct action of sea waves or to atmospheric phenomena, more specifically to the formation of haze and fog with some persistence in the area, contributes to a process of continuous erosion causing its progressive retreat, thus endangering the stability of buildings and other structures built on top of it, especially those closer to the edge.

This situation of imminent danger was evidenced by the fact that a large part of the walls delimiting the properties at the top of the cliff were over areas that were already cantilevered, sometimes by two or more meters. To deal with this situation, it was necessary to intervene along a large part of the height of the cliff, in order to stabilize it. Regarding the restaurant and pool area, the existing stone cladding built in the 1950s and 1960s had to be rehabilitated to protect the cliff surface from erosion.

Some more specific work was carried out in some areas that were not yet covered and whose evolution has contributed to an increase in the risk of material falling from the cliff.

On figure 2 we can see the cliff after the intervention.

Figure 2. After the intervention.

2 CONSTRUCTION STAGES

One of APA's requirements was that, on the one hand, the project should contribute to attenuating erosion processes and consequently to minimizing the geomorphological evolution of the cliff surface and, on the other hand, that it should have as little impact on the landscape as possible, so as not to deprive the site of its characteristics, given that it is considered to be of high landscape interest. To this end, all the concrete solutions that were planned in the area visible from both the pool and the cliff on the south side of the river were clad in stone, so that they would have similar visual characteristics to the cladding already in place in the area overlooking the ocean pool.

Another requirement from the Portuguese Environment Agency (APA) was to start working on this project outside the bathing season so as to lessen the impact on the many bathers that often attend the beach of Azenhas do Mar. Prior to the actual work of stabilizing the cliff, Mota-Engil, together with the client APA, held several meetings to reach an agreement with some landowners so that they would provide access to their land to enable the work to be carried out, in particular through the possibility of setting up two tower cranes to access the work fronts.

It would not have been possible to carry out such work without the cooperation of the owners, as we would not have had the access to carry it out. One of the owners, Mr. Theber, made the entrance to his property available in order to provide the main access for equipment and materials and, consequently, for the assembly of the first tower crane with a 30-metre reach. Another owner, Sandra Ramos, provided access to her condominium terrace to allow a second tower crane with a reach of 64m to be erected, located in the center of the project, with capacity to reach the entire radius of the project (125m long).

Due to the need to carry out a large part of the work using a basket suspended on the tower crane, all

activities were conditioned by weather conditions, especially the wind speed, which is often high in the fall and spring in that part of the country.

For safety reasons, a system was implemented on the tower cranes that allowed us to check the wind speed. One of the major constraints of this project, in addition to what has already been said, was the fact that the number of workers was limited to the basket capacity (2 to 3 people), which largely affected the performance of these tasks.

After consignment on May 20, 2019, and following approval from the DPSS, we began the contract activities in accordance with the approved work plan: setting up the construction site, providing access to the work front, signs, fencing, demolition of two existing ruined buildings, laying foundations for the implementation of tower cranes. The project was drawn up by Mota-Engil's project team. These foundations were made using 22m long TM-80 ø139.7mm micropiles, 10 units for each foundation rock mass.

The equipment used was a Klem 803 extendable tower and the drilling method was rotopercussion.

2.1 Tower cranes assembly

Assembly was carried out using an auto car crane, duly dimensioned and stabilized on the work platform for the assembly of crane No. 2. Subsequently, crane No.1 was assembled with support of crane no. 2. Two safety cameras were installed on each of the cranes, so that crane operators had a field of vision in perfect safety conditions.

The equipment was rented from Ibergru. Once assembly was complete, the company EQS was asked to certify the set: crane, basket and drilling equipment.

A redundant system was manufactured and applied to both cranes.

2.2 Clearing of vegetation and all loose material Sanitation and partial demolition of blocks and partial reprofiling of cantilevered rock layers

Figure 3 shows one moment of the cleaning process.

Figure 3. Clearing and cleaning using ropes.

As it was not possible to carry out the dismantling through the use of explosives, other methods had to be used. One of the techniques used was the application of expansive cement.

The designated supplier was Geotek, which was supplying the material and was also available to monitor the work.

2.3 Shotcrete and systematic soil nailing

In order to protect and reinforce the entire upper area of the cliff, from the top to around +30.00 m above sea level, due to the need to prevent decompression of the area underlying the existing buildings, a systematic cladding was carried out using shotcrete with a minimum thickness of 0.10 m, combined with nailing with A500 NR ø32 mm steel rods, quincunx-patterned in a 2.0Vx2.0H mesh, 12.0 m to 10.0 m long.

Nailing was carried out at an inclination of 15º to the horizontal, in holes measuring 4" (approximately 101 mm) in diameter and sealed with cement grout. All soil nailing metal elements were hot-dip galvanized. The shotcrete used was c40/50 with metal fibers.

The areas where treatment was not planned were properly protected with a geotextile blanket. In figure 4 we can see the drilling and nailing process.

Figure 4. Drilling – Nailing.

2.4 Mortared stone cladding and recovery of the existing stone

In order to allow for a new work front, a properly dimensioned scaffolding was erected, thus allowing the existing stone to be recovered in that specific area, as we see on figure 5.

Catari was the supplier appointed to assemble the scaffolding. Scaffolding dimensions: 20 m long x 25 m high, the shoring was done to the slab of the existing restaurant building.

Figure 5. Recovery of the existing stone.

It was decided on site and recorded in a memo that the view from the viewpoint would determine which area would be covered in mortared stone. Thus, in the northernmost area with no view from the viewpoint, the final cladding would be with pigmented shotcrete and no mortared stone. In order to make it as homogeneous as possible, it was decided on site that pigmented concrete would be sprayed over the entire targeted area of the cliff before the stone was laid. This work allowed the areas where it was not possible to apply the mortared stone to be as homogeneous as possible. In our opinion, this measure added value to the aesthetics of the project. The work on the cliff crest was largely carried out using lifelines and ropes.

All the material to be used in the stone cladding was collected from the base of the cliff.

This material was treated and transported by buckets and placed in the baskets for application. One of the important works to stabilize the cliff was the retreat of the houses' walls. A glass railing was applied to the top of the wall, a solution chosen by the owner, and the existing ditch along the south façade of the "Cabana Mar" house was improved along the cliff. In some specific areas, caves/cavities in the cliff were also filled with cyclopean concrete.

After the work was completed, it was necessary to ensure the renaturation of the occupied areas, namely the construction site and the area in front of the site, where tower crane no. 2 was erected. The project was drawn up by Vibeiras and approved by the Institute for the Conservation of Nature and Forests (ICNF). Vibeiras, a company belonging to the Mota-Engil group, drew up the project and carried out the work.

2.5 Quality plan

Figure 6 shows the nailing test. The following tests were carried out prior to the work, in order to check and control the materials used on site: Preliminary tests on shotcrete designed with fibers (compression / bending and energy absorption); Compressive strength test on the cement grout used to seal nailing; Preliminary test on nailing Execution of three molds to choose the final coating and its grain size, as well as the tone and spacing of the joints between the limestone; Fiber-reinforced cement and setting accelerator; Compression test; Bending test; Punching-bending test (energy absorption); Compression test: The compressive strength of fiber-reinforced shotcrete was determined by a simple cylinder compression test.

The concrete was poured into a projection box with dimensions of 60x60[cm] at the base, 80x80[cm] at the top and 20 cm high, and 6 cylindrical test specimens with a diameter of 6 cm and a height of 12 cm (ground) were removed. The compression tests were carried out every 50m3. Bending test: The bending test carried out by recording the Load-Deformation curve allows the behavior of fiber-reinforced shotcrete to be assessed. Concrete is shot on a panel that would allow 3 beams of 50(L)x12.5(W)x7.5(H)[cm] to be taken from it. Punching-bending test: The punching-bending test carried out on a shotcrete slab, recording the Load-Deformation curve, makes it possible to appreciate the multidirectional action of the fiber network. In these tests, the energy absorption is measured in a test on a 60x60x10 cm slab, supported on all 4 edges, leaving a free span of 50 cm.

The load is applied to the center of the slab with a contact surface of 10 cm x 10 cm (EFNARC). In the diagram, by recording the load and the deformation in the center of the slab, the energy absorbed up to a deformation of 25 mm at 28 days is then calculated. This energy will be 700 J as a minimum.

Nailing Control Tests: Compression/viscosity and decantation testing: The compressive strength of the cement grout was determined by a simple compression test on a cylinder. The cylindrical specimens were identified, 3 specimens at 3 days. 3 at 7 days and 3 at 28 days, requiring at least the following compressive strengths: During the course of the work, three control tests made per type of geological formation. The control tests were carried out up to a force at least equal to 1.1 TL, where TL is the service tensile strength (defined by the designer).

The tests were carried out at the same speed and with the same force and displacement readings as the previous tests.

The test was carried out by applying loading and unloading cycles, with a successive increase in the test load in each cycle, up to a given maximum cycle load value. The maximum load proposed in this case was 0.80 fy, steel yield load = 442kN and 80% fy = 354kN. The load is then increased smoothly up to the maximum value of the cycle or test or until failure by pull-out occurs, Rt. The maximum number of load increments should be sufficient to define the shape of the load-displacement curve and should not normally exceed 20% of the maximum.After applying each load increment, the load is kept constant until the nailing displacement stabilizes, that is, the displacement measured between two consecutive readings (s1 - s2) must be less than 0.5 mm with readings taken at times: T= 0 min, 1 min, 2 min, 5 min, 10 min, 15 min, 20 min. Once the maximum load of the Rt or Pp cycle has been reached and the necessary waiting time has elapsed, the test nailing must be unloaded to the reference load P0 and the residual displacement shall be recorded. Additional load cycles can be carried out if necessary.

Bearing in mind the landscape and heritage value of the northern cliff of Azenhas do Mar, it was necessary to assess the characteristics of the final coating. To this end, three experimental panels were carried out to choose the final finish of the mortared stone cladding.

Study proposals were presented to define the thickness of the joints between stones, the color of the mortar, the type and color of the stone, the regularity of the face, among other characteristics. The study proposals for defining the thickness of the joints between stones, the color of the mortar, the type and color of the stone, the regularity of the face, among other characteristics, were submitted for approval by the land management bodies with jurisdiction over the site, namely the Portuguese Environment Agency (APA), Sintra Municipal Council (CMS) and the Institute for Nature Conservation and Forests (ICNF).

Figure 6. Nailing test.

3 RELEVANT QUANTITIES

- Systematic nailing with 10 and 12 meters - 3300m
- Nailing where required with 4.6 and 8 meters 909.40m
- Geodrains ø50mm - 132.00m
- Shallow drains - 220 units
- Shotcrete C-30/37 with metallic fibers - 654m3
- Fracture sealing - 42.83m3
- Clearing - 870m2
- Sanitation - 780m2
- Reprofiling - 372.50 m3
- Recovery of the existing stone - 380 m2
- Mortared stone cladding - 1889 m

4 FINAL CONSIDERATIONS

As a final note, we'd like to highlight that the European Commission (EC) selected the Azenhas project as an excellent example of a climate change adaptation project.

The inauguration of the project was attended by Mr. Eng. Matos Fernandes, Minister of the Environment, and his delegation. We would like to thank the entire Mota-Engil technical team, project manager Eng. Sérgio Almeida, technical director Dr. Miguel Pereira, safety technician Mr. Carlos Lalim, foreman Mr. Fernando Mesquita and his work team, who showed total dedication to the work in question, the Inspection team, Afaplan employees, Mr. Paulo Rangel, Eng. Igor Mateus, the owner of APA, in the person of Dr.

Catarina Patriarca, also Dr. Cátia Valente and the architect Paulo Figueiredo, for their total and constant availability. In figure 7 we can see the final work at the moment of the inauguration of the contract in the presence of the minister for the Enviromment, Mr. Matos Fernandes.

Figure 7. Inauguration of the contract in the presence of the Minister for the Environment, Mr. Matos Fernandes.

Overcoming geotechnical challenges to maximise re-use of an existing brownfield site for use as a rail test track

Surmonter les défis géotechniques pour optimiser la réutilisation d'un ancien site industriel comme voie d'essai ferroviaire

P. Anning*, J.K. Thillainadarajah, A. Kushwaha
AtkinsRéalis, London, UK

**peter.anning@atkinsrealis.com*

ABSTRACT: The Global Centre for Rail Excellence (GCRE) is a purpose-built rail facility for train testing and rail industry research. The project will comprise a looped track supported on significant cuttings and embankments. The project will be constructed on a site containing backfilled opencasts (pits) from previous coal mining, with the remaining site consisting of spoil tips, forestry and undisturbed common land. The site has a varied topography with the level difference of around 125m below the highest and lowest point. Various geotechnical challenges were encountered during the design development. With an aim to become UK's first net zero railway, the earthworks design aspired to utilise all site won material - mainly opencast mining waste / backfill. This material would not typically conform with the fill classes of the National Highways Specification for Highway works (SHW 2017). Trial embankments were constructed to test the suitability of site-won materials and compaction required to achieve specified stiffness at rail formation level. Prediction of settlement of the earthworks within the footprint of the historical open cast back fill is a major challenge. Historical underground mine workings are present beneath the site, shallow mine entries and workings are within influencing distance of the scheme. Remediation design has been undertaken to reduce the instability risk to the scheme utilising a risk based approach in partnership with the client.

RÉSUMÉ: Le Centre Global d'Excellence Ferroviaire (GCRE) est une installation spécialement conçue pour des essais de véhicules et la recherche dans l'industrie ferroviaire. Le projet comprendra une piste en boucle nécessitant des terrassements importants. Le projet sera construit sur un site contenant d'anciennes mines de charbon à ciel ouvert remblayées, des terrils, des forêts et de terres communales non développées. Le topographie du site est variable avec un dénivelé maximal d'environ 125 m.Divers défis géotechniques ont été rencontrés au cours de l'étude de conception. Avec pour objectif d'en faire le premier chemin de fer à zéro émission nette du Royaume-Uni, la conception des travaux de terrassement visait à utiliser tous les matériaux issus du site, principalement les anciens remblais. Cependant, ce matériau n'est généralement pas conforme aux classes de remblai définies dans les codes pour les Travaux Autoroutiers des Autoroutes Nationales (National Highways SHW 2017). Des remblais d'essai ont donc été construits pour vérifier la compatibilité des matériaux revalorisés avec le compactage requis pour une rigidité adéquate de la nouvelle plateforme. L'estimation des tassements des zones remblayées est un défi majeur, car des mines abandonnées sont présentes dans l'emprise du site, avec des structures d'accès peu profondes et des réseaux de mines présentes à proximité du site. Pour réduire le risque d'instabilité, la conception de cette réutilisation adaptative a utilisé une approche de gestion des risques en partenariat avec le maître d'ouvrage.

Keywords: Geohazards; risk; sustainability; instability; settlement.

1 INTRODUCTION

The Global Centre for Rail Excellence will form a purpose built site for train testing and rail industry research for the UK and European markets. An electrified high speed loop, approximately 7km in length to test trains at speeds up to 177km/h is proposed, the scheme will also include a platform test environment, rolling stock storage and maintenance facilities, operations and control offices, staff accommodation and a connection to the rail network via the Swansea to Onllwyn branch line (Figure 1). Once completed, this will be the world's first integrated testing facility for rail infrastructure and rolling stock.

The site covers 440ha in an area and is located at the head of the Dulais and Swansea valleys on the former Nant Helen opencast coal site and Onllwyn washery in Neath Port Talbot/Powys, Wales, UK. Planning permission for the scheme was granted in

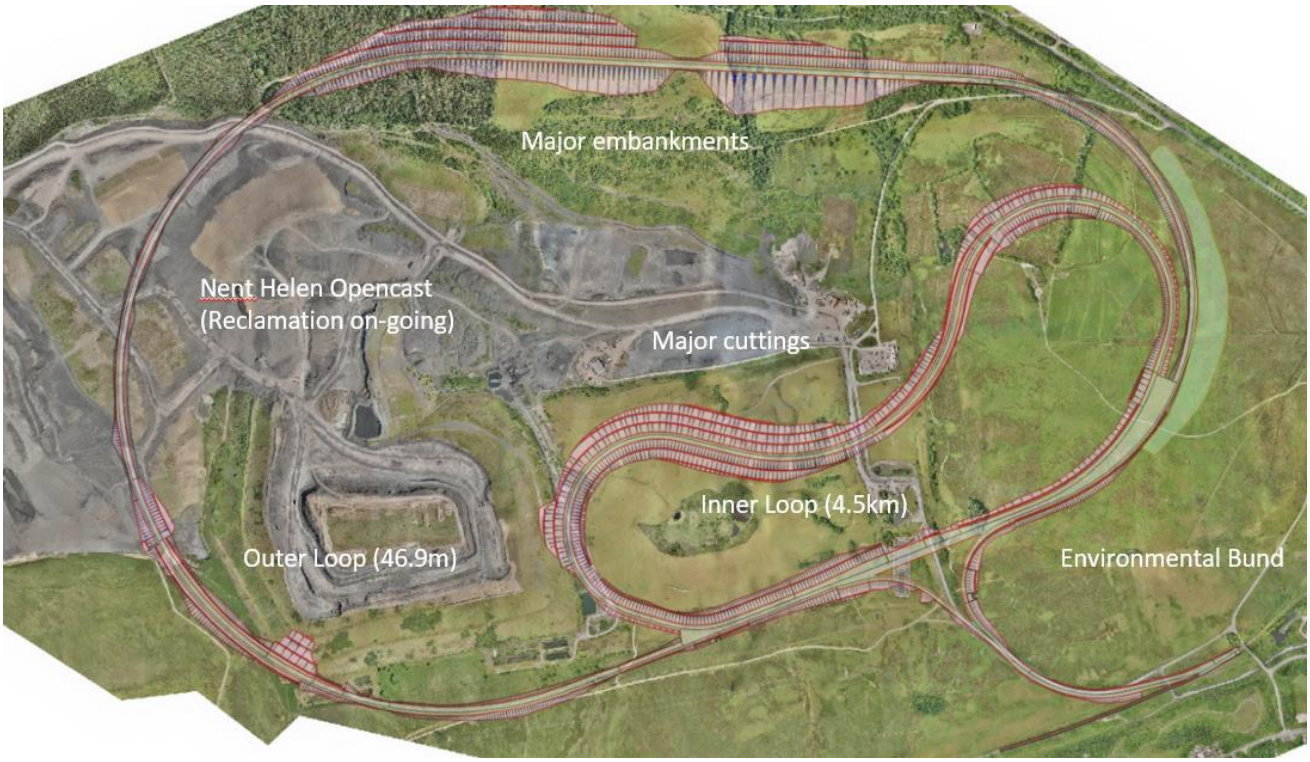

Figure 1. Earthworks layout in March 2023, the earthworks design is subject to change as the project progresses.

summer 2021. In June 2022 the contract for the detailed design and construction of the scheme's significant earthworks was awarded to Hirwaun-based Walters Group, with AtkinsRéalis as its design partner.

The contract covers approximately 3.5Mm3 of earthworks. The AtkinsRéalis scope also includes design of temporary and permanent drainage for the construction stage, landscape design and providing environmental services to support discharging planning conditions.

The design and construction schedule is currently undergoing optioneering with the earthwork layout and alignment subject to change however the challenges and geohazards discussed in this paper are relevant for all layouts.

2 GROUND CONDITIONS

Ground conditions at the site are dominated by the recent history of extensive opencast mining for coal. The depth of opencast workings varied from 40m to 150m, the opencasts have been subsequently backfilled with overburden and other waste material (Figure 2). Large tips of mining waste are also present above the original ground surface.

Outside the footprint of the opencast workings and tips, mining waste / Made Ground of variable thickness is present across the site at surface. Natural deposits of glacial till and peat are occasionally present in some, less disturbed parts of the site overlying weathered South Wales Coal Measures (SWCM) which become less weathered with depth.

Figure 2. Opencast mining backfill material.

3 GEOTECHNICAL DESIGN CHALLENGES

Historical open cast mining activities and the resulting variable ground conditions are the source of the main geotechnical challenges at the GCRE project. The thickness and extent of opencast backfill / tipped waste / Made Ground varies significantly across the site, superficial Glacial Till deposits are also present or absent variably across the site. The SWCM bedrock was encountered at variable depth, typically shallowly.

The variability in ground conditions is most pronounced at the transition between backfilled opencast workings and the wider site area where great thicknesses of opencast backfill gives way to shallower horizons of Made Ground and superficial deposits. The rate and amount of settlement varies such that differential settlement is a significant issue.

To better understand the variability in ground stiffness and susceptibility to settlement, the whole site was modelled in Leapfrog using data from current and historic boreholes combined with mine restoration plans. This information was used to identify locations of transition where ground stiffness was expected to change dramatically, and a remedial transition zone design was prepared.

One of the key goals of the GCRE project was to reduce the need to import fill and maximise the use of site won material (backfill / mining waste) which is mainly constituted of processed SWCM and does not conform to the fill classes of the Standards for Highways, Specification for Highway Works (2017). Although this could be achieved by processing through crushers and screen, it would significantly add to the cost and programme and increase the carbon footprint of the project.

As the material is significantly over size, the proportion of material of less than 37.5mm is likely to be less than 25% from particle size distribution. The determination of optimum moisture content and maximum dry density, therefore, becomes unrepresentative of the placed material as a whole. It was proposed that the quality of the earthworks construction is controlled by the use of plate load testing, where an acceptable subgrade stiffness isderived from the Ev2 load cycle. The Ev2 is the formation static modulus measured in accordance with Network Rail Standard NR/L2/TRK/4239 (Network Rail, 2020) and German Standard DIN 18134 (Normenausschuss Bausen, 2012). This method of quality control is commonly used on earthworks in France. It has also been used to evaluate compaction trials on High Speed 2 projects.

As part of detailed design, trial embankments were constructed on site to evaluate the performance of backfill / mining waste under compaction and understand the resultant stiffness. Four trial embankments ranging from 1m to 4m in height, and with different compaction layer thicknesses of 0.5m, 1.0m and 2.0m, were constructed and tested. Based on the assessment of the results, it was concluded that 1m thickness for fill layers would provide a balanced approach between earthworks stiffness/required compaction efforts and speed of construction to meet the programme.

Another key geotechnical challenge was creep settlement. The opencasts have historically been backfilled by tipping mining waste in an uncontrolled manner without systematic compaction, as a result the backfill material is experiencing continuous creep settlement. An ongoing surface monitoring regime suggests that the current rate of settlement is varying from 10mm to about 90mm per year, depending on depth of opencast mine fill and the associated backfill dates.

The predictions of the magnitude of creep settlement have been undertaken in accordance with the Building Research Establishment publication "Building on fill: geotechnical aspects" (Watts & Charles, 2015). An interpretation and extrapolation of the monitoring data from surface arrays installed at each opencast site, as well as historical satellite monitoring InSAR (Interferometric synthetic aperture radar) information, have been used to validate the creep settlement predictions, see Figure 3.

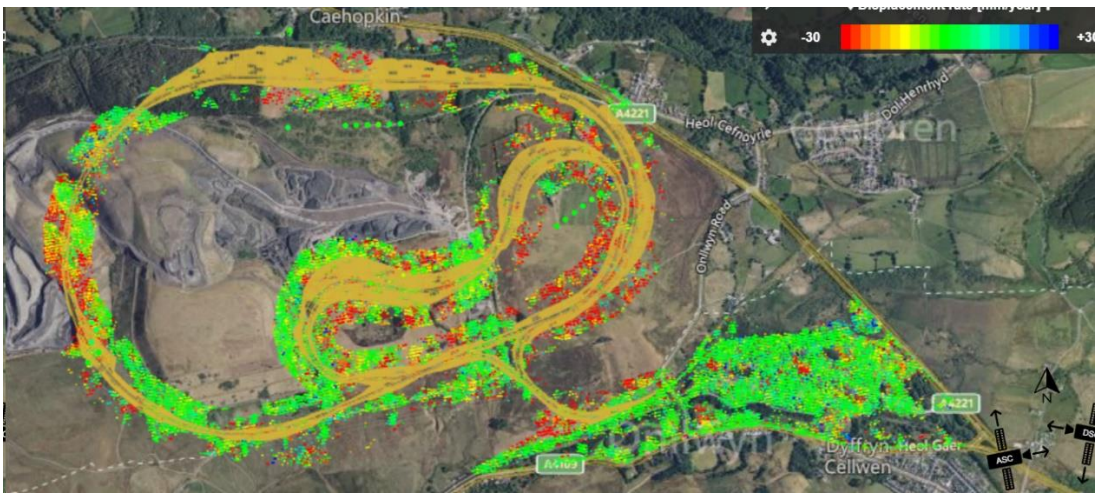

Figure 3. Extract from InSAR for GCRE.

The ongoing ground movement across the site is likely to result in settlements exceeding the widely accepted industry tolerances. GCRE aims to adopt an innovative approach to risk management and will

continuously monitor, inspect, survey and tamp tracks to ensure compliance. A possible redesign of the vertical alignment has been accepted as a likely mitigation measure in operation to accommodate excessive earthworks settlements.

4 UNDERGROUND MINING CHALLENGES

As well as open cast mining, the site has a long history of underground coal working. A desk based review was undertaken following the principles of the CIRIA Abandoned Mine Workings Manual C758D (Parry and Chiverrell, 2019) including, but not limited to, review of Coal Authority reports, mine abandonment plans, client records and ground investigation data.

The assessment concluded that underground workings and mine entries are very likely present across the site. Workings pose a risk to the proposed scheme given the shallow depth and lateral extent, and considering the mining method likely to have been employed which is liable to leave mining voids. The potential for collapse and void migration to surface from workings was identified particularly in the south and east (Figure 3). Untreated mine entries also posing a collapse risk are present at discrete locations across the site.

A risk-based remediation strategy was developed including phased ground investigation works, targeting the high-risk mining areas and sensitive operational locations. “Drill and grout” and “excavate and replace” treatment methods are proposed for shallow workings with additional capping and grouting of mine entries.

The remediation strategy was developed with the client, partners and stakeholders to reduce the mining risk to the scheme and enabling construction, as well as being economical, sustainable and able to meet programme and operational requirements.

5 CONCLUSION

Earthworks design has had to overcome a number of challenges in order to redevelop an existing brownfield site with a long history of opencast coal mining. The key geotechnical challenges are differential settlement, creep settlement and potential for site won material not conforming to standards.

Mine working and entry remediation design has been undertaken to protect the proposed earthworks, this has been done collaboratively with the client adopting a risk based approach to ensure an economic approach and programme needs are met.

The design work undertaken will allow the GCRE project to ‘reuse’ a landscape already significantly impacted by industrial activity and make use of the waste products of this industry.

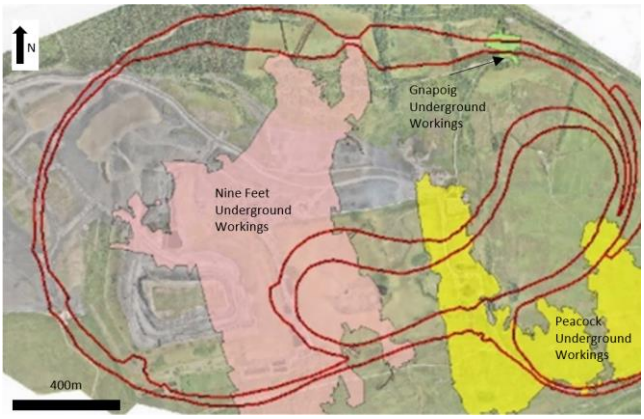

Figure 4. Shallow underground workings in three seams were assessed to be shallow enough to pose an instability risk to the project.

ABSTRACT: The upper part of Luanda is mainly made up of red sands, known locally as "muceque" soil. Luanda's red sands have collapsible characteristics and a metastable structure, prone to erosion phenomena that have caused much damage to the foundations of buildings, roads, airfields, and agricultural areas, with significant socio-economic consequences for the population. Despite the danger posed by the erosion of these soils, few studies on soil erosion by water have been conducted locally to date. To contribute towards filling this gap, this paper aims to review the literature on water erosion processes in these soils, highlighting the controversies in the literature regarding the designations and sequences of the forms of soil erosion that generally predominate. It stresses the need for a more significant effort to standardise criteria for classifying forms of soil erosion despite the complexity of the problem under study. Although the local bibliography is scarce, this work could be valuable in encouraging further research since erosion processes have created many problems in these soils.

RÉSUMÉ: La partie supérieure de Luanda est principalement constituée de sables rouges, connus localement sous le nom de "muceque". Les sables rouges de Luanda présentent des caractéristiques d'effondrement et une structure métastable, propices aux phénomènes d'érosion qui ont causé de nombreux dommages aux fondations des bâtiments, des routes, des aérodromes et des zones agricoles, avec des conséquences socio-économiques importantes pour la population. Malgré le danger que représente l'érosion de ces sols, peu d'études sur l'érosion des sols par l'eau ont été menées localement à ce jour. Pour contribuer à combler cette lacune, cet article vise à passer en revue la littérature sur les processus d'érosion hydrique dans ces sols, en soulignant les controverses dans la littérature concernant les désignations et les séquences des formes d'érosion du sol qui prédominent généralement. Il souligne la nécessité d'un effort plus important pour standardiser les critères de classification des formes d'érosion des sols malgré la complexité du problème étudié. Bien que la bibliographie locale soit peu abondante, ce travail pourrait être utile pour encourager des recherches plus approfondies car les processus d'érosion ont créé de nombreux problèmes dans ces sols.

Keywords: Red sands; rill; gully; ravine erosion; barroca.

1 INTRODUCTION

The occurrence of erosion phenomena on Luanda's "muceque" soils or red sands for several decades is a serious problem that needs urgent solutions (Nascimento, 1952). The red sands of Luanda are soils with collapsible characteristics and a metastable structure, prone to the appearance of erosion processes that have caused much damage to the foundations of buildings, roads, airfields, and agricultural areas, with significant socio-economic consequences for the population (Ferreira & Silva, 1957). There are various definitions of soil erosion in the literature. El-Swaify et al. (1982), for example, defined erosion as the "wearing away of the soil surface by erosive agents such as running water and wind", while Foth (1990) and Goudie (2004) defined erosion as "a three-stage process: detachment followed by transport and deposition", considering a third stage, called deposition, which occurs when there is no longer enough energy to transport the particles.

On the other hand, Nascimento (1952), Morgan (2005) and Lal (2006) define soil erosion as a two-stage process consisting of the detachment of particles

from the soil mass and their transportation by erosive agents, such as running water and wind, to another location.

The first research on soil erosion in Luanda documented in the literature dates back to 1949 when the Overseas Urbanization Office invited Portugal's National Civil Engineering Laboratory (LNEC) to carry out a "Study of the Regularization and Protection of Luanda's Gullies (Barrocas)" (Nascimento, 1952). At the time, the problem that most concerned the engineers was the appearance of gullies in lateritic sands, which were highly erodible compared to clay soils (Nascimento, 1952).

Lateritic sands are another name for Luanda's red sands or "muceque" soils, which are collapsible, metastable, and highly erodible. Despite the danger posed by their erosion, few studies on soil erosion by water have been conducted locally.

To contribute towards filling this gap, this paper aims to review the literature on water erosion processes in these soils, highlighting the controversies in the literature regarding the designations and sequences of the forms of soil erosion by water that generally predominate. It stresses the need for a more significant effort to standardise criteria for classifying forms of soil erosion despite the complexity of the problem under study.

2 LITERATURE REVIEW

2.1 Red sands of Luanda, Angola

In Angola, the first research work on collapsible soils documented in the literature dates back to the 1950s, when engineers from the Engineering Laboratory of the Directorate of Public Works and Transport Services of Angola encountered problems of cracking and settlement in buildings, road pavements, and the Luanda aerodrome, which were founded on this soil (Ferreira & Silva, 1957).

The upper part of Luanda consists mainly of red sands, locally known as "muceque" soil (Silva, 1965). The main geological and geotechnical characteristics of the red sands of Luanda were studied by Silva (1970), Silva and Teixeira (1973) and are summarised below. The geological formations of the Luanda region are divided into two groups, corresponding to the Quaternary and Tertiary periods, respectively. The Quaternary consists of islands, beaches and alluvial fans; coastal cordons; Cazenga Formation and Muceque or Quelo Formation, while the Tertiary consists of the Luanda Formation, Cacuaco Formation and Quifangondo Formation. The red sands belong to the Muceque or Quelo Formation (Pleistocene) and constitute most of the foundation soil on the "plateau" of Luanda, and its layer has thicknesses ranging from a few centimetres to 17 metres in the foral area and can reach 50 metres (Nascimento, 1952; Silva & Teixeira, 1973).

The granulometric distribution of the red sands / "muceque" soil is composed of sand particles (≥ 75%), silt particles (1% - 5%) and clay particles (8% - 20%). While the sand and silt particles have a similar mineralogical composition, based on quartz and feldspar, the clay fraction consists of kaolinite, illite and iron oxides (geotite and hematite) (Silva, 1970; Silva & Teixeira, 1973).

From a geotechnical point of view, the red sand or "muceque" soil has been classified, according to the Unified Soil Classification System, as sandy-clay soil (SC), sandy-silt soil (SM) or a combination of both sandy-clay-silt soil (SC-SM) (Silva & Teixeira, 1973). The collapsible behaviour of Luanda red sands was demonstrated by Novais-Ferreira and Silva (1961) using plate load tests and pile tests, while Silva (1970) demonstrated the collapsibility of this soil by performing oedometer tests. The results of these tests show that, with low moisture content, the soil can withstand high loads (up to 800 kPa) with little settlement. However, as soon as it becomes saturated, even with small loads, it settles drastically due to the failure of the bonds between the particles.

2.2 Red sands erodibility

The Erodibility is defined as the soil's resistance to detachment by splashing during precipitation, surface runoff or both (Renard et al., 1997; Morgan, 2005; Bastos, 2004). The erodibility of a given soil is closely related to its properties, for example, granulometric distribution, permeability, organic matter content and structure (Zhang et al., 2004; Morgan, 2005).

Bastos (2004) mentions that since the 1960s, studies on soil erodibility have been carried out by the National Civil Engineering Laboratory (LNEC) in Portugal and the Engineering Laboratory of Angola (LEA) to obtain erodibility criteria for tropical soils involved mainly in road cuts. The author cited Meireles (1967), who studied the soils of Angola, classifying them as *strongly*, *moderately* and *weakly erodible* according to criteria based on granulometry and plasticity. For the author, strongly erodible soils have low plasticity, represented by a liquidity limit (wl) < 21% and a plasticity index (PI) < 8%.

As for particle size, a criterion was established based on the percentage passing the #200 sieve: % passing #200 ≤ 20% - *strongly erodible soils*; 20% < % passing #200 < 40% - *moderately erodible soils*; % passing #200 ≥ 40% - *weakly erodible soils*.

Bastos (2004) analysed the geomechanical properties of unsaturated soils in relation to erodibility. The author found that the collapse coefficient was not related to erodibility (K). Nevertheless, it was assumed that the disintegration of the soil in water is related to the collapse and erosion phenomena; the differences in the efforts involved explain the results.

2.3 Forms of soil erosion by water

The primary forms of soil erosion are mentioned in the early days of the study of erosion in 1939 when Bennet (1939) considered that the way water flows over the surface of the soil essentially takes three forms (see Figure 1): sheet/interrill erosion, rill erosion, and gully erosion (Bennet, 1939; Hurni, 1975; El-Swaify et al., 1982; Brady, 1984; Goudie, 2004; FAO, 2019).

In the literature, the forms of soil erosion by water are identified by groups related to their origin; the most important are listed below: Rainfall causes *splash erosion*; Surface runoff causes *sheet/interrill*, *rills*, *gullies* and *ravines erosion*; and Subsurface runoff which gives rise to *pipe/tunnel erosion* (Adhikary, 2020) (see Table 1). Below, we analyse the various forms of soil erosion by water resulting from Precipitation, Surface runoff, and Subsurface runoff.

2.3.1 Splash erosion

Splash erosion is the process of removing particles from the soil mass due to the impact of raindrops (Telkar et al., 2015). As a result, aggregates can be broken and soil particles thrown several centimetres away (Brady, 1984; Morgan, 2005). El-Swaify et al. (1982) cited Ellison (1947), stating that raindrops initiate the erosion process.

2.3.2 Sheet erosion or interrill erosion

Sheet erosion is caused by the action of raindrops (splashing) and the transport of detached soil particles by flowing water in a thin sheet of surface runoff that contributes to the removal of a relatively uniform thickness of soil (Brady, 1984; Lal, 2006; Goudie, 2004; Telkar et al., 2015; Balasubramanian, 2017; Saroha & Ambedkar, 2017; FAO, 2019; Adnan et al., 2021).

2.3.3 Rill erosion

Rill erosion is a form of linear soil erosion with depths (H) < 0.5 m that creates small, shallow incisions/channels resulting from the concentration of water flow in depressions, tillage marks or previously eroded grooves on the soil surface (Gobin et al., 1999; Goudie, 2004; FAO, 2019). Soil detachment in rills is largely because of flow shear stress forces acting on the wetted perimeter of the rill channel (Flanagan, 2006).

2.3.4 Gully erosion

Gully erosion is an obvious and prominent form of linear soil erosion consisting of deeper incisions with depths (H) ranging from $0.5 \leq H \leq 5$ m that usually result in open and unstable channels, as well as a long evolution that can be characterised by several stages of development (Gobin et al., 1999; Dagar, 2018).

The "barranco" - a term used in Portugal - is the form of soil erosion that assumes other designation terms worldwide. For example, in English, it is called "gully erosion", which is known as "ravine" in France, "cárcava" in Spain, "lavaka" in Madagascar, "wadi" in Arabic, "donga" in South Africa, "barranco" in Argentina, while in Brazil it is known as "voçoroca/boçoroca" (Castillo & Gómez, 2016) and "barroca" in Angola (Nascimento, 1952; Bastos, 2004).

2.3.5 Ravine erosion

According to Dagar (2018), the advanced stage of gully erosion is the formation of ravines, which is considered the extreme and most dangerous form of soil erosion with depths (H) > 5 m (Gobin et al., 1999; Dagar, 2018).

2.3.6 Tunnel / pipe erosion

Tunnel erosion (piping erosion) is a specific form of underground erosion. It occurs mainly on soils characterised by specific properties (e.g. loess soils). Subsurface water flows can be concentrated in natural drains, which, like the surface, depending on their speed, tend to remove particles from the soil mass and transport them elsewhere (Valentin & Rajot, 2018).

Due to the widening and deepening of these piping or tunnels as erosion continues and the consequent weakening of the ceiling, the stability of the overlying layers is impaired, resulting in gully erosion (after the collapse of the ceiling) (El-Swaify et al., 1982; Goudie, 2004; Valentin et al., 2005).

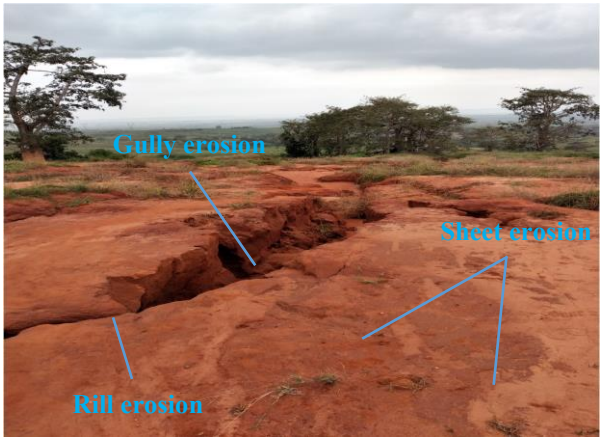

Figure 1. Examples of forms of soil erosion by water on a slope, Zango 5 – Luanda, Angola.

3 RESULT AND DISCUSSION

Based on consultation of the specialised literature, it was possible to compile Table 1, in which the stages of soil erosion were organised into three groups: 1. Precipitation (stage 1); 2. Surface runoff (stage 2, stage 3, stage 4, stage 5); and 3. Subsurface runoff (single stage).

The major controversies in the literature on soil erosion by water lie in the naming and sequencing of the forms of soil erosion, from the boundaries between interrill and rill to the confusion between the concepts of rill and gully as well as gully and ravine (Goudie, 2004). The discussion follows to understand better.

Table 1 shows that most of the discrepancies lie in soil erosion resulting from surface runoff, since precipitation and subsurface runoff both have a single, well-known erosion stage/form. Therefore, Hurni (1975), El-Swaify et al. (1982), Brady (1984), Foth (1990), Goudie (2004), Morgan (2005), Flanagan (2006), Valentin & Rajot (2018) and FAO (2019) considered three stages of erosion with the same designations and the following sequence: sheet, rill and gully, with gully being the advanced stage of surface erosion. On the other hand, Zachar (1982) considered four stages with two similar names but different meanings and sequences: sheet, gully, multi-form erosion, and rock erosion. In this case, sheet erosion includes splash and the related sheet erosion mentioned above, while gully corresponds to rill erosion.

The third group of researchers also consider four stages with different name meanings and the following sequence: sheet, rill, ravine, and gully (Guerra, 1997; Bastos, 2004; Vieira et al., 2019). Here, unlike the first group, these scholars consider interrill, rill, and ravine as the first three stages of surface erosion. The same authors consider the gully as the fourth and most advanced stage of surface erosion.

In addition, Gobin et al. (1999), Telkar et al. (2015), Saroha & Ambedkar (2017), Dagar (2018), and Bhat et al. (2019) also considered four stages of erosion with similar names but different sequences: sheet, rill, gully, and ravine being ravine the most advanced stage of surface erosion.

The last group of researchers also considers four stages with the same names and sequence as the previous first three stages, but the last name differs. They are in the following sequence: sheet, rill, gully, and stream bank erosion (Balasubramanian, 2017; Adhikary, 2020; Adnan et al., 2021). Here, unlike the previous group, these scholars consider stream bank erosion the fourth and most advanced stage of surface erosion.

The latter two groups of researchers consider ravine erosion and stream bank erosion to be their fourth stages, respectively. This is also contradictory because, according to Valentin & Rajot (2018), stream bank erosion is one form of soil mass movement.

With regard to the boundaries between interrill and rill, Goudie (2004) considers that the boundaries between them in hillside areas are often ill-defined and constantly changing. Regarding the difference between rill and gully, Goudie (2004) defines rill as incisions in the topsoil (A horizon), while gully are incisions in the subsoil (B or C horizons).

Other authors have established the difference between rill erosion and gully erosion as a function of depth (H) or size (depth (H) and drainage area (Ad)): Gobin et al. (1999) considered rill when $H < 0.5$ m, while Castillo and Gomez (2016) when depths (H) < 0.30 m. The Gully erosion has the following definitions: Gobin et al. (1999) when depth (H) ranges from $0.5 \leq H \leq 5$ m, while Castillo and Gomez (2016) when depths (H) > 0.30 m.

The difference between a gully and a ravine can be established by depth (H) or size. For this case, the information on gully erosion is described below to be compared with following paragraph about ravine.

Dagar (2018), citing Frevert et al. (1955), classified gully erosion based on their size into small gullies ($H < 1$ m and $Ad < 2$ ha), medium gullies ($1 \leq H \leq 5$ m and $2 \leq Ad \leq 20$ ha) and large gullies ($H > 5$ m and $Ad > 20$ ha).

On the other hand, Dagar (2018) citing Tejwani et al. (1975) mentions that in India ravines are classified based on Bed width (L), Depth (H) and Side slope (D) into Small ravine: L >18 m; H < 3 m; D (%) - variable; Medium ravine: L >18 m; H = 3-9 m; D (%) = 8-15 (uniform); Narrow ravine: L = variable; H > 9 m; D (%) - vertical (mostly steep).

Table 1. Summary of the forms of erosion proposed by some authors (Zachar, 1982; Valentin & Rajot, 2018; Adhikary, 2020).

	Designation of Forms / Stages of Soil Erosion by water					
	Rainfall	**Surface runoff**				**Subsurface runoff**
		no channel	channel			
Autores	stage 1	stage 2	stage 3**	stage 4**	stage 5	single-stage
Hurni (1975); El-Swaify et al. (1982); Brady (1984); Foth (1990); Goudie (2004); Morgan (2005); Flanagan (2006); Valentin & Rajot (2018); FAO (2019)	splash erosion	sheet / interrill	rill	gully	-	piping erosion
Zachar (1982)	sheet erosion		gully erosion	multi-form erosion	rock erosion	tunnel erosion
Guerra (1997); Bastos (2004); Vieira (2019)	-	sheet / interrill	rill	ravine	gully	piping erosion
Gobin et al. (1999); Telkar et al. (2015); Saroha & Ambedkar (2017); Dagar (2018); (Bhat et al., 2019)	splash erosion	sheet / interrill	rill	gully	ravine	-
Balasubramanian (2017); Adhikary (2020); Adnan et al (2021)	splash erosion	sheet / interrill	rill	gully	stream bank	pipe erosion

**These two forms of soil erosion (rill and gully) can result from subsurface erosion after the collapse of the pipe's erosion cover (Valentin et al., 2005).

While, Gobin et al. (1999) defined ravine erosion when the depth (H) > 5 m.

4 CONCLUSIONS

The review confirms that the soil analysed is very prone to erosion phenomena, as previous studies have shown. It also confirms the controversies in the literature regarding the designations and sequences of soil erosion forms.

There are cases of similar terms having different meanings and different sequences (for example, a ravine in the fourth and a ravine in the fifth stage). With regard to the depths of the forms, we found different values for the same erosion form. All this makes it difficult to understand the subject and communicate with people working in the sector, so we suggest a more significant effort is needed to standardise the criteria for classifying soil erosion forms.

Reliability analysis of a Po River embankment affected by underseepage

Analyse de fiabilité d'une digue du Fleuve Pô affectée par sous-infiltration

ABSTRACT: Backward erosion piping (BEP) is an internal erosion process that may develop as a consequence of seepage processes through the aquifers underneath river embankment structures. This phenomenon can be identified in the field by observing the formation of sand boils on the ground surface at or near the embankment toe. Along the Po River, more than 130 sections are affected by periodical sand boils, especially located in its middle-lower stretch. The paper presents the results of reliability analyses referred to BEP phenomena in a riverbank section located in Mazzorno Sinistro, in the province of Rovigo (Italy), whose stability has been threatened by periodical reactivations of this phenomenon. Fragility curves, describing the probability of BEP initiation with hydrometric level, are elaborated based on a two-dimensional model of the groundwater flow through the river section and on the application of the First-Order-Second-Moment (FOSM) method, assuming the main parameters as probabilistic variables. The soil profile and the probability distribution of the geotechnical parameters were obtained from the interpretation of several recent in situ and laboratory tests. Model results are compared to those obtained by applying the USACE theory and to the evidence of past reactivations.

RÉSUMÉ: Les canalisations d'érosion vers l'arrière (BEP) sont un processus d'érosion interne qui peut se développer à la suite de processus d'infiltration dans les aquifères situés sous les structures de digues fluviales. Ce phénomène peut être identifié sur le terrain en observant la formation de bouillons de sable à la surface du sol près du pied de la digue. Le long du Pô, plus de 130 sections sont affectées par des ébullitions de sable périodiques, en particulier dans sa partie moyenne-inférieure. L'article présente les résultats d'analyses de fiabilité relatives au phénomène BEP dans une section riveraine située à Mazzorno Sinistro, dans la province de Rovigo (Italie), dont la stabilité a été menacée par les réactivations périodiques de ce phénomène. Les courbes de fragilité, décrivant la probabilité d'initiation du BEP avec le niveau hydrométrique, sont elaborées sur la base d'un modèle bidimensionnel de l'écoulement des eaux souterraines à travers la section de la rivière et de la méthode du premier ordre-second-moment (FOSM), en supposant les principaux paramètres comme variables probabilistes. Le profil du sol et la distribution de probabilité des paramètres géotechniques ont été obtenus à partir de l'interprétation de plusieurs récentes essais in situ et en laboratoire. Les résultats du modèle sont comparés à ceux obtenus en appliquant la théorie bien connue de l'USACE et aux preuves de réactivations passées.

Keywords: Backward erosion piping; river embankment; fragility curve; USACE method; probabilistic analysis.

1 INTRODUCTION

Backward erosion piping (BEP) is an internal erosion process that excavates pipes in sandy foundations beneath river embankments, typically during high-water events. Its initiation and progression require a peculiar soil stratigraphy: a sandy foundation (aquifer), in hydraulic communication with the river, confined above by a fine-grained layer (blanket), characterized by a lower hydraulic load. The differential water head between the blanket and the aquifer can result in the concentration of hydraulic gradients in pre-existing holes or local discontinuities in the top layer, where flow velocities and gradients may become higher enough to drag sand particles to the surface forming sand volcanoes around the exit hole (sand boils). The ongoing process produces a progression upstream of erosion channels that weaken the foundation, potentially leading to embankment failure or breach, particularly during prolonged high-water periods or repeated reactivations. The Po River (Italy) counts more than one hundred sand boils of remarkable size (Gottardi et al., 2015). This generates the need to develop reliable strategies to quantify the potential risks for these critical structures connected to BEP. The analyses presented in this paper have been developed on a Po River embankment section located in Mazzorno Sinistro (RO), affected by three historic sand boils (Bertolini, 2024). The current study focuses on the most active one, located landside, within a ditch (Figure 1).

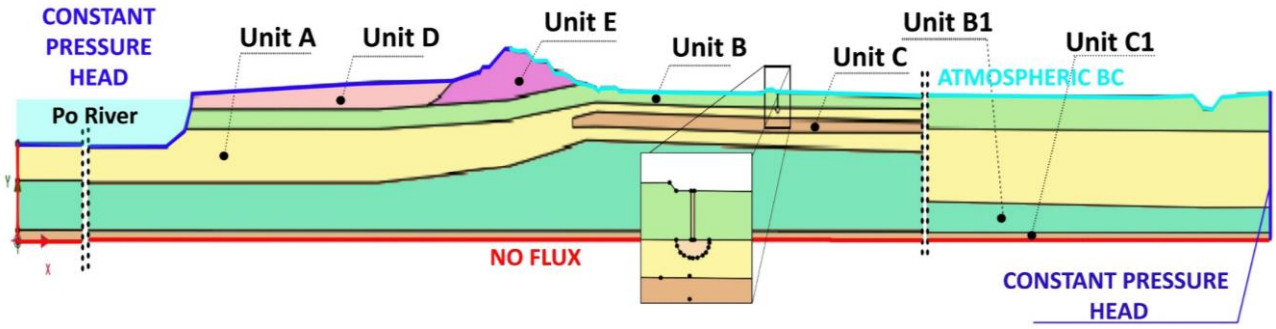

Figure 2. Soil stratigraphy of the investigated river section as adopted in the numerical modelling. The vertical dimension is magnified by double to ease its reading.

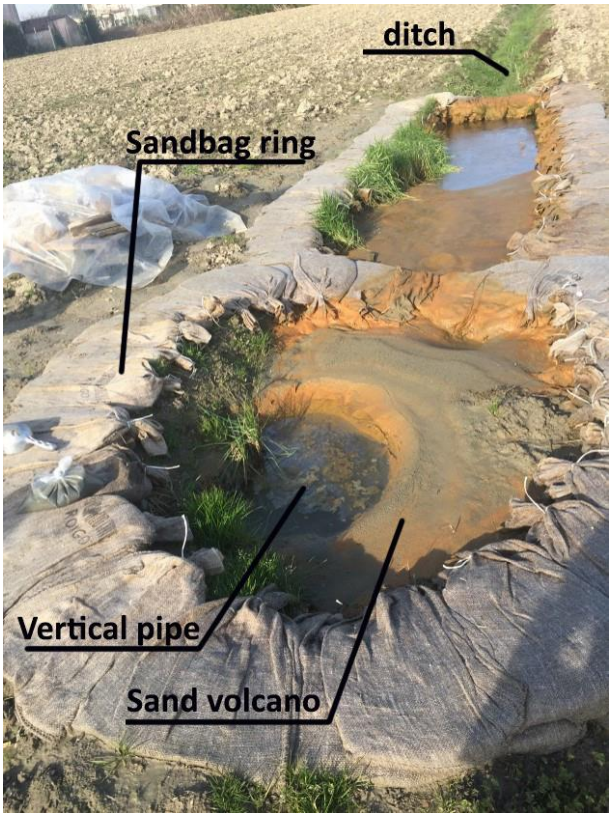

Figure 1. Photo of the sand boil reactivated in Mazzorno Sinistro in November 2019. The sandbag ring was positioned as an emergency measure to stop the progression of the erosion.

Fragility curves were calculated to assess the likelihood of BEP initiation, considering the probability distribution of the hydraulic soil properties obtained by laboratory and in-situ tests and multiple possible exit-hole configurations, and correlating it with river water levels. This involved employing two different strategies: the numerical results of a 2D finite element model simulating seepage beneath the river embankment and the analytical results obtained by applying the well-established Blanket Theory (USACE, 2000). The results of both strategies have been elaborated using a probabilistic approach, applying the First-Order-Second-Moment (FOSM) method (USACE, 1999).

2 THE 2D NUMERICAL MODEL

A 2D finite element (FE) model has been developed to simulate the saturated groundwater flow beneath the examined embankment section. Its primary objective was to compute the distribution of pore water pressure in proximity and within the exit hole of the historic sand boil, correlating it with incremental variations in river water head (H). The soil stratigraphy adopted in the model was deduced from in situ tests while the external profile of the section is from a topographic survey (Figure 2). The soil units involved in the process are the aquifer (unit A) and the overlying blanket (unit B). A peculiarity of the investigated site is the presence of an interbedded cohesive layer (named unit C) within unit A, which greatly reduces the thickness of the filtration section (from 9.4m to 6.9m) around the exit hole. The spatial domain, 36m x 1556m (length x height), has been discretized in 22524 triangular elements and 183541 nodes, with an average element size of 1.9m, refined up to 2cm in the proximity of the sand boil pipe and of the model boundaries subjected to imposed pressure heads.

The boundary conditions (BC) applied to the model are summarized in Figure 2. A no-flux boundary is applied to the base of the model since located within a low permeable clayey layer (Unit C1) not affected by the BEP phenomenon. The left-side of the model corresponding to the centerline of the river, for symmetry reason is associated to a no flux condition. On the berm and the riverside slope, it is imposed a Dirichelet condition in the form of a series of constant prescribed pressure heads simulating hydrometric levels of the river. In particular, the hydraulic loads are imposed to this boundary in 15 steady-state increments. To compare the 2D model's results with USACE ones, the loads have been referred to the landward phreatic level. Thus, hydraulic loads (H) equal to 0m and 8.85m correspond to the level of the phreatic water table and the crest, respectively. The landward water table in proximity of the sand boil is located ~0.65m below ground level, as revealed by the installed piezometric monitoring system. The

boundary conditions applied to the right side of the model are meant to reflect the groundwater condition of far-field which have been set as a series of constant hydraulic heads according to field monitoring data provided by a piezometer installed in unit A, 1123m distance from the embankment toe, landside. Atmospheric boundary conditions are applied to the outer slope and the landside field.

The described 2D numerical model has been adopted to generate fragility curves. Six random variables have been adopted to this scope: the permeability coefficients of units A, B and C (k_A, k_B, k_C), the diameter of the vertical exit hole (d_{exit}), the diameter of the hemisphere located at the base of the pipe and simulating the soil volume eroded by previous reactivations (d_{sphere}) and the permeability coefficient of both the exit hole and of the hemisphere (k_{exit}). Table 1 reports the mean value and the standard deviation of these random variables. CPT tests have been used to estimate the distribution of the hydraulic conductivities, which turned out to be well interpolated by a Gaussian distribution. A previous calibration of the 2D model over past sand boil reactivations suggested an optimal configuration of the existing exit pipe with a permeability coefficient equal to double the one of Unit A (k_A), then it varies in the range [k_A; 3 x k_A]. The average diameter of the exit hole is assumed equal to 0.2m, in accordance with field evidences (Marchi et al., 2021; Garcia Martinez et al., 2020a; 2020b) observed in another river embankment section located along the Po River (Bertolini et al., 2022a; 2022b). A value of 0.1m is assumed as the diameter of first activation and thus as lower boundary for the variation range of this random variable. As a result, the gaussian variation interval explored in the probability analysis results within the limits: average value +/- the standard deviation, that is [0.1;0.3]. Since the hemisphere is a stratagem of modelling whose geometry is not directly measurable but function of the erosive process occurred in the past reactivations, a diameter range of attempt between 0m and 4m has been adopted. The assessment of reactivation of the sand boil was carried out by comparing the critical hydraulic gradient of Terzaghi's (1960) formulation (i_{crit} ~0.969) with the average gradient within the vertical pipe, deduced from the numerical model. In particular, the average hydraulic gradient (i_{avg}) is estimated as the ratio between the pressure head loss between the top and bottom of the pipe and the length of the pipe itself (~2.68m in the selected location) while the critical hydraulic gradient of reactivation (~0.969) is defined as the gradient causing sand particles flotation within the open vertical pipe which occurs when the drag forces on the particles equal their submerged weight. A critical hydraulic gradient of first activation (~0.87) required to cause heaving of the landside top stratum prior to the piping have been also adopted.

A series of 13 simulations were conducted, which have been used to generate the fragility curves shown in Figure 3.

Table 1. Mean values of input parameters for the 2D numerical model of piping reactivation. In square brackets the SD.

Probabilistic variables	
Mean values [SD]	
k_A=3.19E-05 m/s [3.66E-07]	d_{pipe}=0.2m[0.1]
k_B=4.69E-09 m/s [3.21E-09]	d_{sphere}=2m [2]
k_C=7.86E-10 m/s [8.11E-10]	
k_{exit}=6.38E-05 m/s [3.19E-05]	

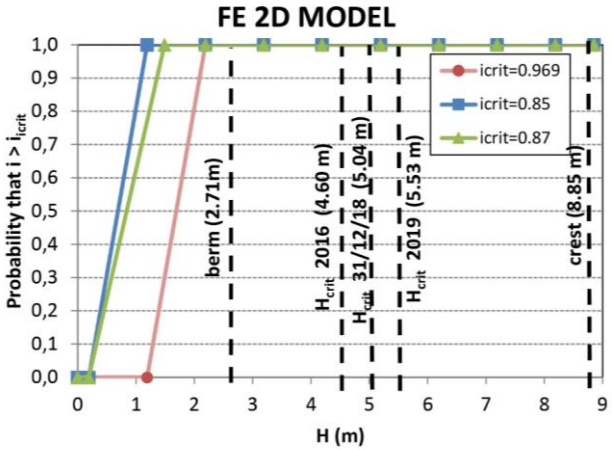

Figure 3. Cumulative probability of BEP initiation elaborated adopting the FE 2D numerical model.

A probability of 1 (i.e., certain BEP occurrence) is registered for hydraulic loads greater than 2m. It is also interesting to notice that an increase of 1m (from ~1m to ~2m) in the hydraulic load turns a likelihood of occurrence from 0 to 100%. The most significant random variables (for H=8.85m) are the permeability of the exit pipe (~55%) and the pipe diameter (~42%), while the remaining have low or null significance. In 2018, a reactivation of the sand boil was registered for a minimum hydraulic load of 5.04m. Another two reactivations of the same sand boil occurred a few years earlier, but the exact day of the BEP trigger and the (minimum) critical operating hydraulic load at the time are unknown. The peaks of these high-water events, under which surely the sand boil was active, were registered for hydraulic loads equal to 4.60m and 5.53m in the 2016 and 2019 events, respectively. The cumulative probability curve of BEP initiation forecasts correctly the three past activations but overestimates the minimum critical hydraulic load

being equal to H=2.5m the flood peak registered in May 2023 (25/5/23) which did not induce sand boil reactivation.

3 THE USACE APPROACH

The Blanket Theory was introduced within the technical manual USACE (1956) and is also described in the 2000 edition (USACE, 2000). The solution for semi-pervious top stratum of uniform thickness that extends infinitely landward of the levee, sketched in Figure 4 (case 7a of the methodology), was adopted for this study.

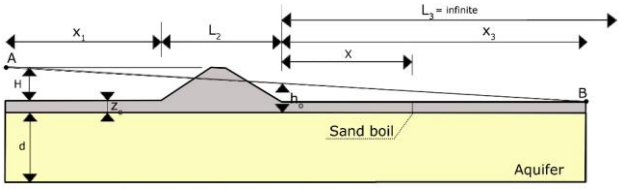

Figure 4. Scheme 7a of a section affected by BEP phenomenon characterized by a semi-pervious top stratum of uniform thickness riverside and landside (modified from USACE, 2000).

Table 2. Mean values of input parameters for the probabilistic safety assessment of the investigated section using USACE approach. In square brackets the standard deviation.

USACE APPROACH	
Deterministic variables	**Probabilistic variables**
x_1= 131.8 m	d= 6.13 m [2.47]
L_2= 66.4 m	z_b= 2.68 m [0.06]
L_3= infinite	k_A/k_B = 6818 [78]
x= 96.2 m	

The safety factor against (first) boiling or heaving computed according to the USACE approach is defined as the ratio of the exit gradient (i_{exit}) at the sand boil location to the critical gradient (i_{crit}). The exit gradient is a function of several variables, including the thickness of the aquifer and the blanket ("d" and "z_b," respectively), the ratio of permeability between the aquifer and the top stratum (k_A/k_C), the embankment base length (L_2), and the residual water pressure head at the embankment toe (h_o). Table 2 reports the "exact" values of the deterministic variables and the probabilistic distributions (in terms of mean value and standard deviation) of the stochastic variables assumed for the analysis. Among the latter, the thickness ranges of variation for the aquifer (d) and the blanket (z_b) have been retrieved from CPT test data. In particular, the range of variation of "d" is obtained from the interpretation of all the CPT tests performed in the section, while z_b from a selected number of tests performed in proximity of the sand boil, in order to be more representative of the blanket condition at the outflow point. Moreover, the depth of the ditch (~0.45m) in which the sand boil occurred has been subtracted from the estimated z_b value, to have an exit hole configuration more representative of site conditions and similar to the one adopted in the 2D FE model. Starting from the presumed expected values and standard deviation of the random variables, the moments of the performance functions were derived using Taylor's series method (specifically, the first-order second-moment - FOSM). The obtained fragility curves are presented in Figure 5.

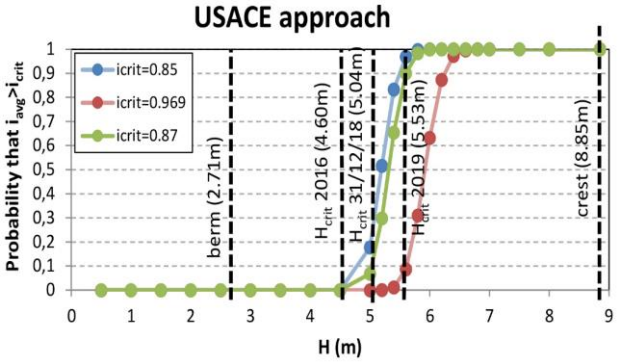

Figure 5. Cumulative probability of BEP initiation as deduced from the Blanket Theory.

The cumulative probability of BEP initiation remains null up to hydraulic loads of 4.5m and 5.5m, obtained for critical hydraulic gradients of 0.85/0.87 and 0.969, respectively. What emerges clearly is that for critical (first activation) gradients of 0.85 and 0.87, two of the three reactivations (i.e., 2016 and 2018) are not caught properly by the USACE approach, which underestimates the minimum critical hydraulic load causing sand boil activation. Similarly, the adoption of a critical (reactivation) gradient of 0.969 does not correctly predict all the three reactivations. Regarding this last observation, note that the analytical equations at the base of the Blanket Theory to estimate the seepage flow and the substratum pressure underneath the section are relative to an embankment configuration prior the possible formation of a landside open exit being these analyses usually performed in a design phase. It is also relevant to observe that the USACE solution is particularly sensitive to the thickness of the aquifer and of the blanket, with percentage of total variance equal to ~76% and ~24%, respectively (for H=8.85m).

4 CONCLUSIONS

The study describes the results of an analytical approach (Blanket Theory) and of a numerical FE

analysis, which can be adopted to predict the probability of BEP initiation in a river embankment along the Po River, prone to periodic sand boil reactivations during high-water events.

The soil profile, as well as the physical, mechanical and hydraulic properties of the site, have been deduced from field investigations and laboratory tests. The outcomes of the two different strategies were represented as fragility curves, denoting the probability of BEP initiation with increasing hydraulic loads. Results have been discussed considering observed reactivation in several real high-water events. The Blanket Theory tends to underestimate the probability of BEP reactivation. On the contrary, the FE analysis slightly overestimates the observed behaviour. Although these analyses are not directly comparable to each other, their application to this well-documented section suggests that the FE model can produce better results. In the near future, possible new reactivations should provide additional piezometric data that would enable the improvement of the calibration of FEM parameters.

Concept for sustainable lab and in-situ research on earthquake induced geohazards

Concept de recherche durable en laboratoire et in situ sur les géorisques induits par les tremblements de terre

ABSTRACT: Geohazards related to earthquakes, such as amplification effects, liquefaction, soil-structure interaction etc. are complex phenomena which need to be investigated with diverse set of approaches, both experimental and in-situ. In this paper two state of the art facilities for earthquake geotechnical research are presented, established in the Laboratory for soil dynamics and foundation engineering in IZIIS, Skopje, Macedonia. At first, in laboratory conditions, experimental setup consisted of original laminar container and detailed soil material characterization – Skopje sand is presented along with obtained results from series of element and shaking table tests. Second, an in situ geotechnical laboratory was established in urban part of Ohrid, N. Macedonia at the site of a nine-story building with two accelerometers installed on the building, 4 instruments installed at the foundation level as well as one surface and three downhole accelerometers 125 meters down the bedrock. With recent activities, real time recording, and health monitoring processes are enabled at the location. The large set of in-situ investigation, characterization of the geotechnical profile and enabled real–time earthquake recordings are valid data for detailed studies of amplification of site effects, liquefaction and SSI at the site. In the paper overall comments on obtained results from both facilities is obtained, with aspects for future application, correlation, and obstacles. Both resources, experimental and in-situ represent a well-proven example of a facility for continuous and sustainable research in earthquake geotechnical engineering.

RÉSUMÉ: Les géorisques liés aux tremblements de terre, tels que les effets d'amplification, la liquéfaction, l'interaction sol-structure, etc. sont des phénomènes complexes qui doivent être étudiés à l'aide de diverses approches, à la fois expérimentales et in situ. Dans cet article, deux installations de pointe pour la recherche géotechnique sismique sont présentées, établies dans le Laboratoire de dynamique des sols et d'ingénierie des fondations à IZIIS, Skopje, Macédoine. Au début, dans des conditions de laboratoire, le dispositif expérimental consistait en un conteneur laminaire d'origine et une caractérisation détaillée des matériaux du sol – le sable de Skopje est présenté ainsi que les résultats obtenus à partir d'une série de tests d'éléments et de tables vibrantes. Deuxièmement, un laboratoire géotechnique in situ a été créé dans la partie urbaine d'Ohrid, en Macédoine du Nord, sur le site d'un bâtiment de neuf étages avec deux accéléromètres installés sur le bâtiment, 4 instruments installés au niveau des fondations ainsi qu'un en surface et trois en fond de trou. Accéléromètres à 125 mètres sous le substrat rocheux. Avec les activités récentes, les processus d'enregistrement en temps réel et de surveillance de la santé sont activés sur place. Le vaste ensemble d'investigations in situ, de caractérisation du profil géotechnique et d'enregistrements sismiques en temps réel permis sont des données valables pour des études détaillées de l'amplification des effets de site, de la liquéfaction et des SSI sur le site. Dans le document, des commentaires globaux sur les résultats obtenus dans les deux installations sont obtenus, avec des aspects d'application future, de corrélation et d'obstacles. Les deux ressources, expérimentales et in situ, représentent un exemple éprouvé d'installation de recherche continue et durable en ingénierie géotechnique sismique.

Keywords: Skopje sand, laminar container, in-situ lab, geotechnical monitoring.

1 INTRODUCTION

Earthquakes, a significant natural hazard, affects built and human environment in seismic-prone regions globally, leading to social and economic losses. Recent notable earthquakes worldwide, including the most recent series in Turkey in 2023, highlight that geotechnical hazards play a substantial role in causing damages and economic losses. Instances of geohazards have been documented after earthquakes in Southern Europe, such as the 1979 event in Montenegro, the Emilia earthquake sequence in Italy in 2012, the Kraljevo earthquake in Serbia in 2013, the Durres

earthquake in Albania and the most recent Petrinje Earthquake in Croatia in 2020.

2 SUSTAINABLE LAB RESEARCH

2.1 Justification

While there were no well documented cases of liquefaction during the 1963 Skopje earthquake with a magnitude of 6.1, significant structural damage was attributed to pronounced site amplification effects in the Vardar valley.

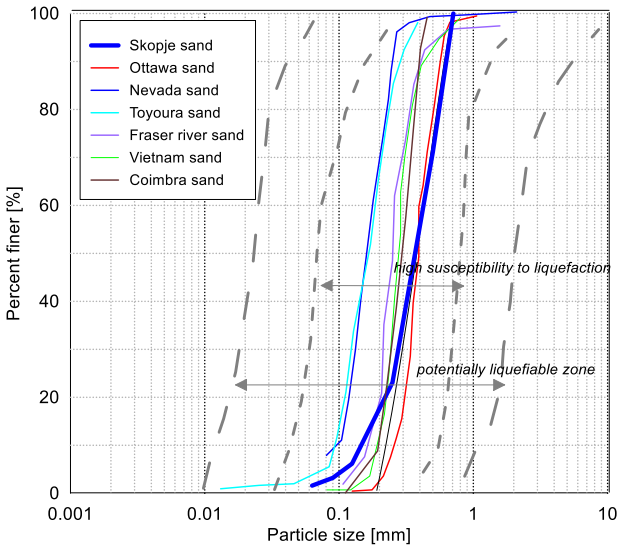

Figure 1. Grain size distribution compared with other sands from the literature (Bojadjieva et al., 2015).

Given the absence of seismic geotechnical codes in the region at that time, the lack of a seismic monitoring network, and limited knowledge about the city's geotechnical properties, there is assumption that liquefaction might have occurred but went undocumented and unassessed due to the overwhelming structural damage and other post-earthquake disaster management activities. Recent incidents in the Balkan region have underscored the importance of re-evaluating and enhancing understanding of soil behavior under cyclic loading.

To address these requirements, comprehensive experimental investigation to examine the monotonic and cyclic behavior of Skopje sand, has been proposed starting from 2013 and still ongoing.

2.2 Material

The material used for sustainable research in the lab, denoted as Skopje Sand, is chosen for testing not only based on the assumption that it is likely associated with liquefaction and significant deformations during earthquakes but is also justified by its potential for sustained, long-term use in experimental laboratory research. This continuous usage maintains consistent characteristics and facilitates ongoing improvements in results (Bojadjieva et al., 2022).

The grain size distribution curve of the sand (ISO/TS 17892-4:2004) is depicted in Figure 1, alongside other standard sands used in literature for investigating liquefaction phenomena. It is evident that the Skopje sand aligns well with the boundaries specified by Terzaghi (1996) for sands highly susceptible to liquefaction. Detailed analysis indicates that the sand is predominantly composed of silica oxides, allowing it to be classified as a siliceous sand material or soil class SP based on the USCS soil classification.

2.3 Research objectives – current states

Table 1 summarizes the so far performed research on the testing material. Figure 2 represents typical cyclic test for D_r = 55%, CSR = 0.20.

Table 1. Comprehensive research program -Skopje sand

Type of study	Topic	Reference
Simple shear tests	Cyclic behaviour	Bojadjieva (2015)
Triaxial tests	Monotonic, cyclic behaviour	Bojadjieva et al. (2015)
Shaking table tests	Cyclic behaviour, Liquefaction	Bojadjieva et al. (2022)
Simple shear tests	Liquefaction	Kitanovski (2018)
Triaxial tests	Monotonic, cyclic with fly ash	Angelova (2023)
Comparison triaxial vs simple shear tests	Liquefaction	Bojadjieva et al, (2019)
Numerical simulation	Monotonic, cyclic with hypoplastic model	Bojadjieva et al., (2020)

The produced experimental data provide researchers and practicing engineers a baseline data set for validation of numerical simulations (such as previous study in Edip et al., 2018), focused on liquefaction phenomena as well as future-induced settlement of buildings and evaluation of effective mitigation strategies. Figure 2 presents selected results from cyclic test on Skopje sand Dr = 55%, CSR = 0.20. Skopje sand is representative for the alluvial deposits around the Vardar River and the performed investigations can be a good basis for further definition and raising awareness about the liquefaction hazard in N. Macedonia.

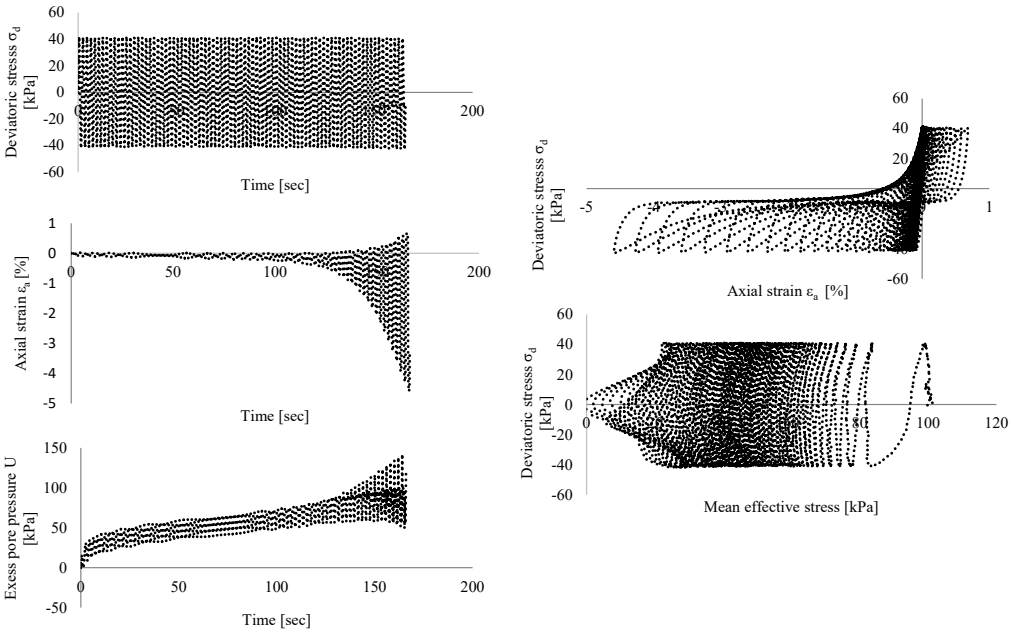

Figure 2. Results from cyclic test on Skopje sand for D_r = 55%, CSR = 0.20.

3 SUSTAINABLE IN-SITU RESEARCH

3.1 Ohrid 3d seismic network-Location Tower

Typically, monitoring is limited to either structures or testing sites, resulting in partial instrumentation either on the structures or in the soil.

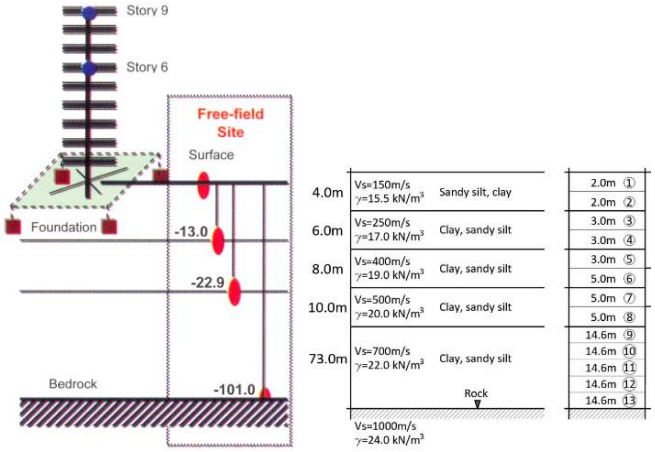

Figure 3. Instruments setup and soil model at the Location Tower.

The extent of damage to buildings, structures, and lifelines from earthquakes depends on the nature of the seismic energy and the characteristics of the soil and structures. To investigate the effects of local site conditions on strong ground motions and dynamic response of structural systems, a three-dimensional seismic network was established in the Ohrid Lake, N. Macedonia basin in the 1980s with support from the United States Geological Survey (USGS),(Petrovski et al., 1995). This array included three free field locations in the urban area of Ohrid, each with one surface and three downhole instruments, as well as a nine-story building site with instruments installed on the building and at the foundation level, and an outcropping rock site with one instrument. Since 2021, extensive efforts have been made to re-establish the network and provide continuous, real-time monitoring of the Location Tower (Bojadjieva et al., 2023), shown in Figure 3. Figure 4 represents recorded acceleration at bedrock and surface from the M. 4.8 earthquake - Kastoria, Greece, 24 km southeast of Korce, Albania, on 12 May 12:31 am (GMT +3).

Following the re-establishment, comprehensive research activities were conducted at the Location Tower, including geotechnical and geophysical in situ investigations using direct and indirect methods, direct simple shear and triaxial tests on soil specimens from various depths, and ambient vibration measurements of the structure.

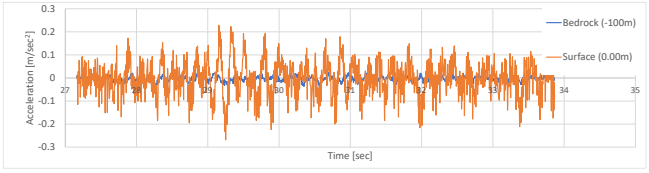

Figure 4. Recorded acceleration at bedrock (-101m and surface 0.0m).

The resulting dataset was used to achieve multiple research objectives, such as site response analysis, estimation of the small strain dynamic shear modulus G_{max} through comparison of different approaches, and analysis of soil-structure interaction validation with

records from the Location Tower, Figure 5. The Location is characterized with significant site effects as noted in Bojadjieva, 2019.

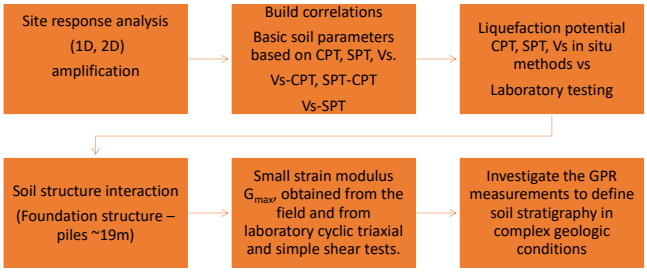

Figure 5. Concept of learning objectives at the in-situ laboratory.

4 FUTURE APPLICATIONS & CHALLENGES

The study on Skopje sand serves as a well-established source of laboratory-available sand, supporting ongoing research in earthquake geotechnical engineering. The achieved study reviewed in this paper is going towards significant contribution to the global database on the behavior of soil materials under cyclic conditions.

On othe other hand the Ohrid 3d seismic network, and particularly the Location Tower, with its unique instrumentation data, is important in-situ facility by providing high-quality earthquake records for both soil and structures in the urban area of the Balkan region. The revitalization of the network provides an opportunity to study the real-time interaction effects of earthquakes on structures and soil, thereby creating a solid foundation for enhancing earthquake resilience. Both presented concepts are sustainable and are expected to help towards reducing risk from earthquake induced geo-hazards.

Seabed and sub-seabed boulders as an engineering hazard in the marine environment; a risk mitigation strategy for subsea cables

Les risques techniques liés aux blocs rocheux de surface et enfouis dans l'environnement marin; une stratégie d'atténuation des risques pour les câbles sous-marins

L.J. Burley, E. Tataki, H.M. Taylor*, V. Terente, N. Dyer
Cathie, Newcastle upon Tyne, UK

**Helen.Taylor@cathiegroup.com*

ABSTRACT: Every subsea cable development presents a unique set of conditions and constraints. The exact approach to seabed and sub-seabed boulder mitigation work is defined not only by the nature of the environment, but also the options open to the developer in terms of financial budgets and available construction timescales. Boulders represent a significant geohazard for trenching and installation operations of subsea cables. This paper proposes a comprehensive risk mitigation strategy for seabed and sub-seabed boulders in the marine environment. Once the magnitude of boulder risk is known through appropriate surveys and risk assessments, the following steps can be considered: avoidance, removal, reduction and/or relocation or remediation of residual risks. Working through these steps ensures a suitable mitigation strategy is followed, reducing the risk through adequate design, installation and remediation planning.

RÉSUMÉ: Chaque projet en mer présente un ensemble unique de conditions et de contraintes. L'approche exacte du travail d'atténuation des risques liés aux blocs rocheux pour tout type de développement est définie non seulement par la nature de l'environnement, mais aussi par les options ouvertes au développeur en termes de budgets financiers et de délais disponibles pour achever les travaux d'ingénierie. Les blocs rocheux présents sur le fond marin et enfouis représentent un risque géologique important pour les opérations de creusement de tranchées en mer et d'installation de câbles sous-marins. Cet article propose une stratégie globale d'atténuation des risques liés aux blocs rocheux de surface et souterrains dans l'environnement marin. Une fois l'ampleur de ces risques connue, grâce à des études et des évaluations appropriées, les options suivantes peuvent être envisagées: éviter, enlever, réduire et/ou déplacer ou remédier aux risques résiduels. Ces étapes permettent de définir une stratégie d'atténuation appropriée, grâce à une conception adéquate, au choix de l'installation adaptée et à la planification de la solution de mitigation.

Keywords: Boulder mitigation; mitigation strategy; surface boulders; sub-seabed boulders; subsea cables.

1 INTRODUCTION

Seabed and sub-seabed boulders pose a significant geohazard to a wide range of offshore wind activities, including trenching and installation of export and inter-array cables. In the marine environment, boulders are often found in areas previously influenced by glaciation, such as the North Sea, Baltic Sea, and East Coast of USA etc. The sediment formations containing boulders are often related to glacial features, such as moraines and outwash plains (Johnson et al., 1993). Glacial soils may consist of a mixture of sediments with a variety of degrees of sorting, including boulders (Clarke, 2018). These boulders can vary in shape and size, can be found at and/or below the seabed and can be isolated or in high density clusters (known as boulder fields). As per ISO 14688-1 (2017), boulders are defined as soil particles with diameter >0.20 m. However, for the purpose of this paper, and as it will be discussed in subsequent sections, mainly boulders with diameter >0.30 m are considered a risk to cable installation operations.

Where boulders are present, and as with any other hazard, the first step is identification and quantification of the risk across the site (Wetton et al., 2024). This information, together with knowledge on proposed operations and equipment limitations, will determine the impact, relative to size and density of boulders, and whether any mitigation is required.

If mitigation is required, measures such as, avoidance, removal/ relocation of boulders, reduction of the risk or/and remediation should be considered (Figure 1). Unanticipated requirements in overcoming boulder constraints may result in significant additional costs to developers and contractors, should the risk of boulders and a sufficient mitigation strategy not be identified from the early stages of the development.

The size and number of boulders, as well as whether they have been identified as isolated or in clusters, can significantly influence the methods used for mitigating the risk. Recommended best practises for subsea cables, such as the (DNV GL, 2021), highlight boulders as a geohazard that can affect cable routing, installation and protection, recommending the performance of boulder clearance campaigns, however, without presenting a recommended methodology to plan for remediation.

In this paper, the above-mentioned steps will be elaborated outlining a methodology for mitigating the risk of boulders to subsea cables.

It should be noted that a similar mitigation strategy can be suitable for boulder risk to offshore structure foundations, however this paper focuses only on subsea cables.

Figure 1. Boulder mitigation strategy.

2 MITIGATION STRATEGY

The selection of a suitable boulder mitigation strategy is governed by several factors which could include: boulder quantity, distribution, project location, commercial factors, project schedules, etc. Figure 1 outlines a proposed strategy method. Each step will be described in more detail in the subsequent sections.

2.1 Identify and quantify

The first step in the proposed mitigation strategy is to identify and quantify the boulders across the area of interest. This is achieved by planning a survey strategy ensuring the most suitable data is acquired by specifying appropriate survey techniques and correct resolutions (Carbon Trust, 2020). To ensure a suitable survey is being performed, the timing needs to be carefully considered. Prior to a survey, a cable corridor needs to have been defined with indicative cable burial and boulder clearance tools already in consideration (Wetton et al., 2024).

Once the data has been acquired, boulders are quantified by undertaking a 'boulder picking' exercise, an interpretive exercise where boulders are identified, located, and the dimensions measured to produce a boulder listing. This interpretive exercise should be tailored to a specific mitigation strategy it is targeting. For cable routing, a more efficient approach for quantifying the number of boulders, at an early stage, could be to focus on the areas posing the highest risk, e.g., large boulders >1.5 m and boulder fields. By only focusing on quantifying the critical areas, the picking exercise is less time demanding, and data could be available at an earlier stage without compromising understanding. At a later stage, data can be reinterpreted to a stricter specification, within a smaller study corridor once the preferred installation tool is selected. This approach could potentially save time and resource during the interpretation phase. As a development progresses the survey corridor may decrease from ~150 m to <20 m, rendering detailed interpretation outside of the reduced corridor obsolete.

Once the boulder listing is available, this can be used to estimate the likelihood of boulder encounter and impact of encountering areas with different boulder density (high to low), for each section of the proposed cable route.

2.2 Avoid

As with any hazard assessment, avoidance should be the first mitigation option, which in the case of subsea cables, is undertaken, where feasible, through route engineering (Figure 2). Route engineering is a process of designing the shortest and most practical cable route possible, whilst avoiding known physical risks. An outline of considerations is highlighted in (DNV GL, 2021).

Each identified risk is evaluated and assigned a design constraint. Constraints may be seen as "hard", must be avoided or as "soft", avoid if practical, as shown in Table 1.

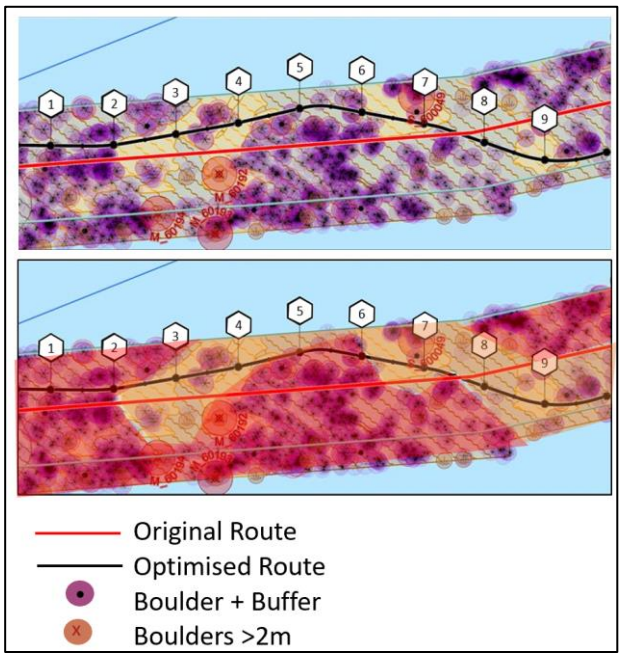

Figure 2. Route engineering example.

Table 1. Boulders as cable route constraints.

Individual Boulders Size (m)	Boulder Fields Density	Constraint Level	
< 0.5	Low		Low
0.5 - 1.5	Medium	Soft Constraint	Medium
1.5 - 2	High		Severe
> 2	-	Hard Constraint	

In most cases, it is impractical to avoid every boulder, especially where there is the presence of boulder fields, hence why boulder fields are not a hard constraint in Table 1. Together with boulders, there are other constraints to consider, which may take precedence over boulders, such as unexploded ordnance (UXO) and cable installation limitations (e.g. maximum bend radius and turning radius of tool). The aim of route engineering is to identify the most favourable route by avoiding any hard constraints and as many soft constraints as possible. Where soft constraints are intersected, the shortest route through, should be selected. Alongside reducing the risk of surface boulders, route engineering may assist with the mitigation of sub-seabed boulders. Where areas of concentrated sub-seabed boulders have been identified route engineering can also work to avoid these.

In practice, it is often the case, possibly due to limitations in identifying sub-seabed boulders, that only surface boulder information is available for a project. Actions can be taken, such as avoiding formations known to contain boulders, which can be identified through developing a geological Ground Model early in the project. Predicting or avoiding sub-seabed boulders may not always be possible and thus the risk remains as a residual risk within a project.

2.3 Remove/Relocate

Following route engineering and especially if there were areas of boulders where avoidance was not possible, a boulder clearance campaign may be required. Clearance campaigns mainly target surface boulders with mitigation methods including Boulder Grab (BG) and Clearance Plough (CP). For sub-seabed boulders, clearance is generally more challenging with tools such as pre-lay/pipeline ploughs existing in the industry. The following sections summarise some of the possible clearance methodologies.

2.3.1 Boulder Grab (BG)

BGs are used to remove and relocate boulders along a cable installation corridor. They resemble a mechanical claw and are typically fitted with thrusters, ultra-short baseline (USBL) and video feed to aid positioning over the boulder. The boulder is captured within the claws and relocated, to a pre-agreed location, off the main installation corridor.

BGs are suitable for areas with lower density of boulders or individual boulders rather than large boulders fields, due to time taken for vessel positioning and the operations undertaken to remove and relocate the boulder. Typically, the maximum boulder size a generic BG can relocate ranges from ~2 to 3 m. This will significantly depend on the percentage of the boulder that is buried, as a suction force can be created, increasing the working loads for the equipment.

Minimum survey requirements for this operation would include exact location and dimension of the boulder to be removed. An understanding of shallow geology of the soil matrix and boulder rock type would be beneficial.

Typical time duration for the relocation of one boulder, using this method, is 30-60 mins, depending on the relocation area and other seabed constraints. Note this does not include transiting times between individual boulders.

2.3.2 Clearance Plough (CP)

For sites with higher densities of boulders, a CP may be more suitable. CPs are towed along the seabed pushing/relocating surface, or near surface, boulders to either side, leaving a 'cleared' corridor of ~15 m width with a maximum penetration into the seabed of ~0.2 m (depending on soil type). CPs are generally limited to boulders up to ~1.5 – 2.0 m in size and therefore if larger boulders are present at the site, this method

would have to be used in conjunction with another, such as route engineering or a BG.

Minimum survey requirements for this operation would include location, including dimensions, of larger boulders (>1.5 m), location of boulder fields with density, high resolution bathymetric data and shallow geology information.

The operation speed of these ploughs is typically between 150-500 m/hr depending on the geotechnical conditions of the seabed and the density of boulders.

For boulder clearance within a Lease Area (i.e., for the inter-array cables), scheduling of the operations at the right development phase for the project should be considered. Preferably, seabed clearance operations should be carried out prior to installation. Should this operation be undertaken after the wind turbines generators (WTG) foundations have been installed, the vessel (and CP) would have to veer off a significant distance to avoid the structure and areas of seabed may be left uncleared which could later impact burial operations along the inter-array cable or require an alternative mitigation method.

2.3.3 Pre-Lay Plough (PLP)

PLP is a combined clearance and trenching plough, where the plough's share creates the "Y-shape" trench, with the mouldboards pushing the spoil away. PLPs are generally able to create a trench up to ~1.8 m deep, in a single pass. In certain conditions, the trenching capability may allow for mitigation of sub-seabed boulders, depending on the size and depth of the boulder. Advanced PLP systems also have the capabilities to include integrated backfill operations.

Similarly to the CP, the PLP requires the identification of boulders greater then ~1.5 – 2 m in diameter, as these will likely require a different mitigation measure. The scheduling should be considered, operations to be undertaken prior to construction of WTGs, as per the CP.

Similar survey requirements to the CP are required for a PLP, with the addition of more detailed understanding of the shallow geology to predict tow forces and speed. Available information on sub-surface boulders, i.e. density and expected dimensions, are also useful.

PLPs require much higher tow forces than CPs, especially in sandy soils, with some of the larger ploughs requiring up to 300 tonnes of towing force. This results in the need for more specialised vessels with higher bollard pull or the addition of tug vessels. These larger ploughs may also require an "A Frame" launch and recovery system with sufficient deck space for the large plough.

Due to the specialised nature of this tool, there is limited availability on the market and can often be in high demand, emphasising the need for early planning.

2.3.4 Summary of removal methodologies

When selecting the most suitable solution for boulder removal, boulder density and location of the boulders should be considered, and it is likely to significantly influence the decision. Figure 3 shows a schematic of how the number of boulders affects the clearance operations duration for a BG (green line) and CP (red line). As can be seen with ploughing, dependent on density, operation speed is relatively consistent. Although, there will likely be some variation depending on soil type. Whereas with the BG, clearance would be more effective in low density areas. Operation time would also be heavily dependent on the spacing of the boulders.

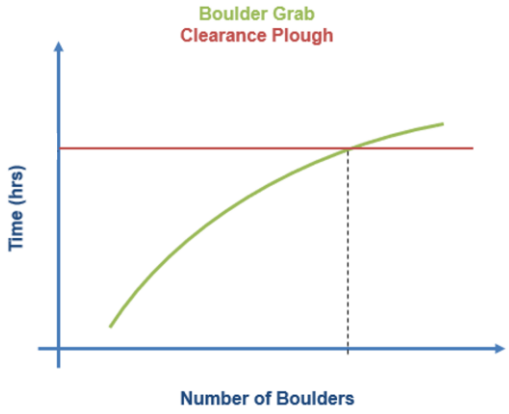

Figure 3. Effect of number of boulders to clearance operation timescales.

A brief suitability assessment for each of the methodologies is shown in Table 2. The table uses a traffic light ranking system for general suitability based on some of the main consideration factors; where green is high, orange is medium and red highlights low suitability for each solution. As can be seen, not one methodology is suitable for all factors. The final mitigation plan will likely include a combination of methodologies with the cable route zoned in accordance with the most suitable tool.

Table 2. Boulder clearance tools suitability assessment.

Consideration Factors	BG	CP	PLP
Time			
Cost			
Availability			
Sub-seabed boulder – clearance			
Efficiency – Higher density			
Efficiency – Lower Density			

2.4 Reduce

Detailed data on sub-seabed boulders are not always available. Consequently, even with the above mitigation measures of avoid and remove, the risk of sub-seabed boulders generally remains. The presence of sub-seabed boulders can result in reduced/no burial of a cable with contractors generally insisting on a *'Reasonable Endeavours'* clause within their contract.

Where sub-seabed boulders are expected, in order to reduce the risk, the selected cable installation tool should be considered based on the ground conditions and identified trenching risks (DNV GL, 2021). Some installation tools can be fitted with a structure, similar to a small scale 'clearance plough', to protect the installation tool from boulders.

Most installation contractors will highlight all boulders >0.3 m as potential risk to cable installation for all tools. However, some cable installation tools may be more suitable than others, e.g., a cable plough would likely be able to withstand larger boulders compared to other trenching tools. Table 3 below summarises the advantages and disadvantages, with regards to boulders, of the three most commonly used installation tools.

2.5 Remediate

Following the above mitigation steps, the risk to boulders should be considerably reduced. However, if boulders still pose a risk to a site and cannot be further mitigated against, additional costs should be factored into a project to allow for external protection for the cables if required. Areas with significant number of unmitigated boulders could lead to shallow/no burial of the cable leaving it exposed to external hazards such as fishing, shipping and on-bottom stability. Some remedial measures for protecting exposed/reduced burial areas of cable are listed below.

Rock fill protection: a rock berm could be specifically designed with sufficient height to cover and protect the cable. Rock berms are installed using specific vessels fitted with a fall pipe, used to place the rocks on the seabed over a cable.

Rock Bags: bags are placed on top of a cable to create a layer of protection. The bags are made from a durable material, often high strength geotextile or heavy-duty mesh, and filled with rocks of a specific size and weight to make them suitable to the local environment.

Concrete Mattressing: concrete or steel mats are placed over an exposed cable. The mats are generally made of heavy-duty panels that are interconnected to form a solid layer over a cable. These panels are designed to withstand the weight of the seabed and any external forces that may be encountered.

Cable Protection Systems (CPS): such as tubular protective sleeves that can be fitted around a cable to provide additional protection/armouring. These sleeves can be made from various materials, can be either flexible or rigid and are normally fitted during cable lay operations. Tubular sleeves are more susceptible to external hazards, such as anchoring, and are often used in combination with mattresses or rock placement.

Table 3. Advantages and disadvantages of commonly used trenching tools, with regards to boulders.

Tool	Advantages	Disadvantages
Jet Trencher	Fitted with retractable swords which can lift and/or widen the separation distance during trenching, potentially allowing for the swords to bypass any encountered boulders. Potential for remedial passes, should burial not be achieved on the first pass.	Contractors generally state that boulders >0.3 m will potentially impact burial. However high densities of boulders of smaller dimensions would also be problematic. Dependent on Contractor. If larger boulders are encountered, the jet swords could be damaged and a reduction in depth of lowering is observed.
Mechanical Trencher	Trencher may be able to manoeuvre boulders, depending on the soil type/matrix and size of the cutting chain. Should a boulder be encountered the mechanical cutting boom can be retracted, continuing burial albeit at a reduced burial depth.	Contractors generally state that boulders >0.3 m will potentially impact burial. However high densities of boulders of smaller dimensions would also be problematic. Dependent on Contractor. Boulders may generally lead to reduced lowering. Encountering boulders may result in cutting chain wear and cause damage to the cutting chain picks. If an area cannot be trenched due to significant density of boulders, the trencher would have to unload cable, recover and reposition, resulting in exposed cable and increased duration in operations.
Cable Plough	Cable ploughs generally have the capability to push the boulders to one side out of the cable lay path, depending on size and position.	Ploughs are generally not suitable for inter-array cables, as the vessel is forced to veer off on approach to WTG, leaving a section of un-buried/surface laid cable. Large boulders can misalign ploughs/plough ride out.

3 EXAMPLE THEORETICAL STUDY

When choosing the most appropriate mitigation method, it is likely that a combination of all of the above steps will be required in order to sufficiently mitigate the risk. The following describes a potential theoretical mitigation strategy following a survey, designed to identify the required range of boulders within a corridor wide enough to have a high likelihood of successful cable route engineering.

An export cable is to be installed through an area with identified (Identify - Step 1) surface and sub-seabed boulders, using the example from Figure 2. The original route is shown as a red line. Route engineering (Avoid - Step 2), has been carried out by avoiding any hard constraints (large boulders >~2 m) and choosing the shortest path through boulder fields, where possible. The optimised route is shown as black line Figure 4.

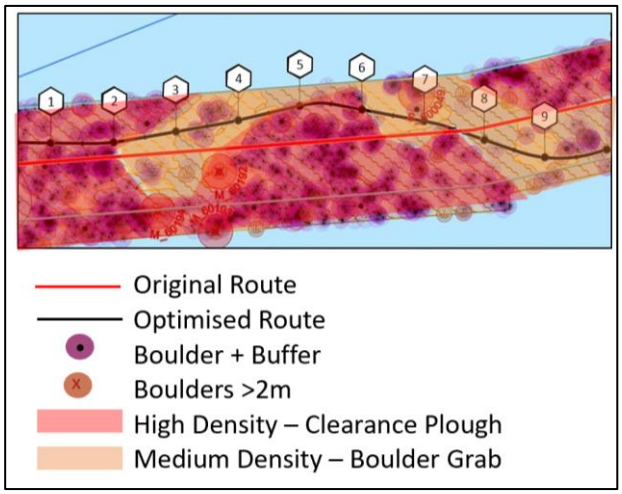

Figure 4. Example strategy.

Once the most optimum route is designed, and if boulders still pose a risk to the cable, removal/ clearance should be considered (Relocate - Step 3). As seen in Figure 4, a BG might be more suitable for the medium dense areas (e.g., between KP6 and KP8), whereas a CP would be more suited in denser areas (e.g., between KP1 and KP2). However, this will depend on distance between areas. In practice, a CP might be used for the full extent.

For Step 4 and 5 (Reduce and Remediate), the most suitable installation tool should be selected taking into consideration the ground conditions along the route, including any areas of boulders that could not be avoided or cleared by the above steps. For these 'un-cleared' areas, an allowance for remedial protection such as rock placement should be considered.

4 CONCLUSIONS

Whilst it is not always possible to remove the risk boulders pose to submarine cables entirely, the positive implications of investing project time and costs early on by following a mitigation strategy has proven to reduce unforeseen additional time and costs later on in a project.

Ensuring the most suitable detection method is chosen at the identification stage, as part of a survey campaign, is critical in detecting and measuring the presence of boulders. As part of the proposed Boulder Mitigation Strategy, the dimensions and distribution of boulders along a cable route is also key for selecting the most appropriate boulder clearance tool(s), if required. Poor selection of clearance tools can lead to downtime for several reasons i.e., tool damage etc.

If boulders remain a risk to the site and cannot be mitigated against employing the suggested strategy, it is important additional costs and time are factored into a project to accommodate the continually monitored risk of an unknown but expected boulder encounter.

ABSTRACT: Landslips continue to impart significant safety risk, disruption, and financial impact in the Southern Region of Network Rail (NR). Between 2019 and 2022 there were over 50 landslips (earthwork failures) per annum, causing between 7 and 9 line closures a year. The impact also has a significant financial burden, with annual repair and delay costs increasing by over £120m. An improvement / game changer was required to reverse the trend. The scope of the project was to consider a more radical identification and assessment methodology beyond the earthwork examination approach currently being undertaken.

RÉSUMÉ: Les glissements de terrain continuent d'entraîner des risques importants pour la sécurité, des perturbations et un impact financier dans la région sud de Network Rail (NR). Entre 2019 et 2022, il y a eu plus de 50 glissements de terrain (défaillances de terrassements) par an, provoquant entre 7 et 9 fermetures de lignes par an. L'impact a également un fardeau financier important, avec des coûts annuels du au réparations et au retards augmentant de plus de 120 millions de livres sterling. Une amélioration / un changement de jeu était nécessaire pour inverser la tendance. L'objectif du projet était d'envisager une méthodologie d'identification et d'évaluation plus radicale au-delà de l'approche d'examen du terrassement actuellement en cours.

Keywords: Earthwork; railway; landslip; hazard.

1 CONTEXT

Earthworks failures (landslips) continue to impart significant safety risk, disruption and financial impact in the Southern Region of the UK rail network, managed by Network Rail (NR). In the last 3 years there have been almost 50 earthwork failures per annum, causing between 7 and 9 line closures each year. Peaks in 2018/19 (69), 2019/20 (104) and 2020/21 (58) have pushed resources, budgets, and staff to breaking point.

This impact also has a significant financial burden, with individual failures costing on average c£3.5m (repair), c£1m (delay) and pushed annual repair costs to increase by over £100m. An improvement was required to undertake larger scale proactive remedial works in areas at risk of failure, rather than reactive works post-failure development. To achieve this requires a new way of thinking, to understand failure locations and triggers, and the development of optimal management strategies.

2 PROJECT

The THUMPER project commenced in October 2021. The initial focus was a detailed review of the Tonbridge to Hastings (TTH) railway line to better determine sections that at a higher risk of future failure. The line was selected as historically there have been a greater number of earthworks failures along its length than anywhere else in the Southern Region; in the last 20 years there have been 437 recorded failures in the Southern Region, 57 were located on the TTH line which equates to 13% of earthwork failures, 6 times the average number of failures for Southern Region. The present inspection driven intervention works are not preventing continuing earthwork failure

on the line. Currently there is a repetitive cycle of small reactive (often emergency) remedial fixes taking place on the TTH line, with works often being undertaken adjacent to or within the same earthwork length as previous failures. To better predict where earthwork failures are most likely in the future, a better understanding of the failure mechanisms and past earthwork performance on the line was required.

2.1 Basis of research

The research undertaken for the THUMPER project focussed on the natural geohazards, historical construction practices, subsequent earthwork performance and key trends relating to earthwork failures along the TTH line. All available geotechnical data has also been utilised to derive site specific geotechnical parameters and automated slope stability analysis unedertaken to support earthwork failure risk designation.

The initial consideration is the age of the assets present; the youngest earthwork on the TTH line is now 171 years old. These earthworks were constructed around 75 years prior to the conception of modern geotechnical design and were constructed to the basic empirical methods of the day, resulting in earthwork slopes that are over-steep by modern standards. Even if the earthworks had been constructed to modern standards, they are now over 50 years older than would be the standard 'design life' of such structures under Eurocode.

Given the age of earthworks on the line, general deterioration of the slope will have occurred by now and thus, if particular areas of the line are experiencing repeated failures, then other localised ground model changes in these locations must be driving the higher frequency of failures. However, the hisotric failure data available is very limited and the initial task was therefore to increase the amount of historic data through desk based geomoprhological mapping. The data was used to identify patterns within the past failures to determine conditions resulting in higher frequency of failures, consequently posing greatest risk of future failure. However, causality of the failures is ultimately more important and further detailed work will be required to take the findings of this work further.

2.2 Site setting

The TTH line is 32 miles 59 chains in length (approx. 52.7km) and is located in the south-east of England, running between the towns of Tonbridge in Kent and Hastings on the East Sussex coast. The railway crosses the central area of the Weald (an eroded anticline) along a generally northwest to southeast alignment and geology along the line is formed of alternating outcrops of the Tunbridge Wells Sand Formation, Wadhurst Clay Formation and Ashdown Formation which are heavily faulted (Gallois, 1965). The terrain is comprised of successive steep valleys and ridge lines reflective of the alternating ground conditions with numerous spring lines.

Figure 1. Location Plan.

3 FINDINGS

3.1 Construction History

The TTH line was built between 1844 and 1852, making earthworks on the route between and 171 and 179 years old. The relative age of the line in comparison with the rest of the UK network is highlighted on Figure 2.

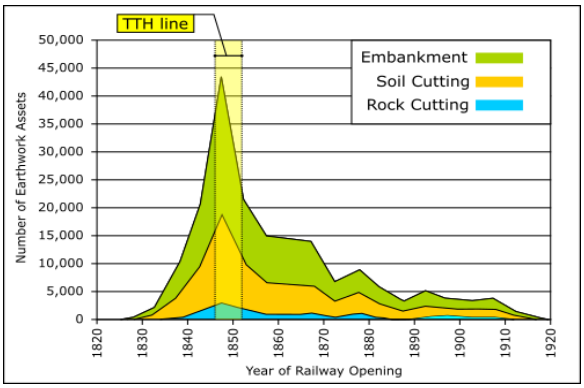

Figure 2. UK earthwork assets by date with the Tonbridge to Hastings Line highlighted (derived from Cobb, 2015).

Construction methods comprised large teams of manual labourers undertaking excavations using pick and shovel and utilising horse drawn wagons to end tip fill to form adjacent embankments, without any sorting or compaction (Skempton, 1996). Deliberate cost cutting by the contractors is documented on the TTH line tunnels and it was important to determine if any similar practices were employed on earthwork

construction that may have resulted in the particularly high number of failures on the TTH. It was thought likely that if present this would take the form of finished earthworks being steeper than than proposed, or omission of planned drainage. Both of these would result in huge reductions in volume of cut and fill over each construction section.

The available historical data indicated that the earthworks on the line were proposed at a gradient of 1V:1.5H (33°), although local variations where rock outcrops are present would be anticipated. The LiDAR data suggests that both cutting and embankment slopes along the line are typically at a slightly steeper angle of 34° to 36°.

No construction period drainage plans have been found; the earliest available data of any detail is from the British Railways drainage plans produced in the 1950s / 60s. Generally, the drainage along the route is less extensive than commonly seen on other lines of similar age. Furthermore, the drainage was found to vary considerably depending on area, with little or no drainage being provided in the northernmost section versus relatively comprehensive drainage in the lower section.

Although earthworks appear to have been finished to slightly steeper angles than proposed, no obvious trend was identified attributing a greater density of failures to a particular construction section. Some sections of the line did show a greater concentration of failures, however the rapidly changing geological conditions make it difficult to attribute poor earthwork performance to one factor. Given the distribution of failures along the line, it is believed that the key issues are primarily as a result of the geological conditions rather than faulty construction.

3.2 Earthwork & failure mapping

The 2020 NR LiDAR-derived bare-earth digital elevation models (DEMs) have been used to locate and map whole earthworks, earthwork failures and past remedial works along the line. A geodatabase was established to record key data for each failure including ground model, adjacent slope aspect, drainage, slope angle and other attributes to characterise each earthwork and failure.

Whole earthwork extents were mapped using the LiDAR data so that attributes and ground models could be assigned holistically, rather than continuing to look at the line in terms of the 5 chain asset lengths, as this artificially divides up the earthworks. This allowed the earthworks to be split up into sections reflecting the ground conditions and geomorphological features. In total 126 embankments, 147 cuttings were mapped along the TTH line.

A total of 458 individual failure locations have been identified based on the historical data, CIV185 data, and geomorphological mapping, comprising 176 within embankments and 282 within cuttings. Out of the 273 whole earthworks, 144 (53%) have failures mapped within their extent. The use of high-quality LiDAR data has resulted in the identification of 441 previously un-recorded earthwork failures or past remedial works. This has been of primary importance to both improve the overall failure data for the route, allowing greater analysis of failure trends, and to improve the accuracy of the spatial extent and attributes which are thought to act as precursors for failure.

3.3 Geographical & geological failure trends

Failure on the Up and Down sides of the line were found to be fairly evenly distributed, with no obvious trend suggesting that one side of the line was more susceptible to failure. Cutting failures were found to be more common (76% of total) where the adjacent land slopes towards the earthwork. This appears to indicate that failures within cuttings are more likely where these conditions prevail, although it is probable that the local dip of strata is a more important factor than aspect of the adjacent land in most locations, particularly cut slopes in the Wadhurst Clay Formation.

Cutting failures are more frequent within sections of the route with a composite slope where a geological boundary is present. At these locations spring lines are common and it is known that a large number of the cuttings on the line have notable seepage points within them. The presence of spring lines in cutting slopes is a key driving factor to future failure as evidenced by the highest risk cuttings being present where composite slopes are present.

Embankment failures appeared to show no obvious trend with regard to adjacent land aspect, but unsurprisingly were found to be most common in areas where the embankment was underlain (or likely to be underlain) by superficial deposits (46%) or where directly underlain by the cohesive Wadhurst Clay Formation (35%). It is important to note that due to the construction methodology employed on early railways, topsoil was not generally removed prior to the end tipping of unsorted fill, resulting in a relict low strength layer beneath the fill. This led to singificant settlement issues after tipping resulting in many large scale failures during or shortly after construction, as well as a legacy of instability issues.

3.4 Failure type and triggers

Historic earthwork failure data is limited, with nothing available outside of newspaper snippets prior to 1950;

good records of failures are available from 2000 onwards. Data on failure mechanism and triggering factors are only available for later failures recorded within NR's CIV185 failure database and selected historic failure records from the archives. Associated trends and are limited as a result.

Between 1950 (earliest available recorded failure data) and 2000 most recorded earthwork failures or remedial works are within embankments. Post 2000 most recorded failures are located within cuttings and are linked to heavy rainfall events and saturated ground conditions. There is an apparent trend of general increase in the reporting of cutting failures in recent years, although earlier failure datasets are potentially skewed due to the lack of reporting of small failures not affecting the track and more recent records by planned remedial work on embankments.

Cutting failures typically comprise relatively small scale shallow translational or rotational failures that occur repeatedly within the same whole earthwork, spreading laterally along the slope or re-occurring close to a previous failure / repair. In comparison, embankment failures are generally larger scale and many of them are thought to have occurred relatively soon after construction. As a result, cuttings are considered on a whole to pose the greatest risk of future ongoing failure, particularly considering that the youngest slopes on the line are now over 170 years old.

4 CONCLUSIONS

The TTH line review has allowed a greater understanding of the earthwork performance on the line as well as providing a historical baseline from which to judge this performance. It has allowed NR to identify a total 17 embankment and 47 cutting sites that are considered to be at risk of first-time failure or continuation of existing failures that were not previously considered a high priority based on earthwork exams alone. This has been based on the historical performance of the earthworks, as well as the specific geology and geometry of those assets.

This would not have been possible utilising inspection data; one of the key issues with using inspection data to identify areas of earthwork risk is that an earthwork close to its critical state may show no visible signs of movement, yet fail in the next few days. Furthermore, many of the initial indicators may be hidden by vegetation, infrastructure etc. or occur in a timescale that is less than the return frequency of inspections. Therefore, basing works off condition ratings is unlikely to fix the highest risk areas or prevent a continuation of the current issues on the TTH and elsewhere on the UK rail network.

The work on the TTH line has been wholly desk-based utilising existing available data. Whilst further work is required to refine the areas at risk, it has proved the value of undertaking such a review across a relatively wide area. Further targeted investigation into each of the sites will allow further refinement of the high priority sites and where applicable design appropriate poactive remedial works to improve the earthwork condition and reduce the likelihood of failure. This approach is far more sustainable than undertaking heavy engineering of failed sections and can often utilise lighter touch engineering such as targeted slope strengthening and drainage. Whilst undertaking large scale preventative works will be costly to implement, the longer-term savings vs emergency remedial works, delay compensation and safety of the operational railway in a location of known earthwork instability would be considerable and will work towards providing a more resilient network for the next 100 years.

ABSTRACT: As the population in cities all over the world is increasing, the effects of climatic action on the resilience of communities is becoming more and more important. Cities situated in deltas are also under strong urbanization demands and these demands have to be met with due consideration of the challenges presented by climate change, land subsidence and sea-level rise. Within this context, the local geological conditions in the Netherlands present a particularly pressing challenge where water pressure under a clay cover may increase. The static equilibrium of the cover layer might be adversely affected, and uplift failure can be imminent. A recent research program into this failure path has been initiated. Besides the field tests and advanced numerical modelling approaches, the research program also made use of centrifuge tests to quantify the extent of uplift, cracking, and deformation phenomena. This contribution intends to exhibit the aspects of the centrifuge tests conducted as part of this study. The experimental setup design and design considerations will be explained as well as the instrumentation methodology and the reasoning behind the instrumentation choices. This contribution aims to improve the stability assessment of dikes under uplift conditions.

RÉSUMÉ: À mesure que la population des villes du monde entier augmente, les effets de l'action climatique sur la résilience des communautés deviennent de plus en plus importants. Les villes situées dans les deltas sont également soumises à de fortes demandes d'urbanisation et ces demandes doivent être satisfaites en tenant dûment compte des défis présentés par le changement climatique, l'affaissement des terres et l'élévation du niveau de la mer. Dans ce contexte, les conditions géologiques locales aux Pays-Bas présentent un défi particulièrement pressant, car la pression de l'eau sous une couverture argileuse peut augmenter. L'équilibre statique de la couche de couverture pourrait être affecté négativement et une rupture par soulèvement pourrait être imminente. Un programme de recherche récent sur cette voie d'échec a été lancé. Outre les essais sur le terrain et les approches avancées de modélisation numérique, le programme de recherche a également eu recours à des essais par centrifugation pour quantifier l'ampleur des phénomènes de soulèvement, de fissuration et de déformation. Cette contribution vise à exposer les aspects des essais de centrifugation menés dans le cadre de cette étude. La conception de l'installation expérimentale et les considérations de conception seront expliquées ainsi que la méthodologie d'instrumentation et le raisonnement derrière les choix d'instrumentation. Cette contribution vise à améliorer l'évaluation de la stabilité des digues en conditions de soulèvement.

Keywords: Dike stability, macro-stability, uplift failure, flood defences, centrifuge testing.

1 INTRODUCTION

In densely populated Dutch delta regions, an unfavorable geological condition is encountered where a thin clay cover is found over permeable layers. While this stratification does not pose significant challenges for most engineering applications, it creates a unique set of issues for dike engineering purposes. The problem is accentuated by large riverbeds and increasing severity and frequency of weather and precipitation extremes. The Dutch dike engineering approach focuses on macro-stability calculations, considering a scenario where the dike stability is lost due to buckling or uplifting of the clay cover. This concern arises when the water pressure within the sand beneath the top layer increases due to rising external water levels. When the water pressure matches the

weight of the top layer, it begins to rise or "float". Subsequently, under the influence of horizontal compressive forces, the top layer may experience deformation, potentially leading to buckling or bursting – this is a geometrically non-linear 'second-order' effect –. The expected formation of bending cracks, along with the resulting reduction in the bending capacity, can exacerbate the risk.

To address the risk of bursting, the current assessment and design approach involves a simple rule: for top layers with a thickness of 4 meters or less, no shear strength is assigned when the safety factor is 1 or lower. This particular rule is based on expert judgement without extensive support from calculations, experiments, or empirical data. However, it is widely believed that this approach errs on the side of caution and tends to lead to designs that are overly conservative. The above-mentioned risk is especially pressing in the Eastern part of the Netherlands, where the Holocene top layer is commonly situated on top of a relatively rigid and permeable Pleistocene sand layer. It is plausible that high-water levels in adjacent rivers and estuaries may generate locally high pore pressures directly under or beside a dike. Consequently, the effective normal stresses at the layer interface decrease, eventually to zero, giving rise to uplift and sliding failures (Van et al., 2005). A pictorial description of the problem is illustrated in Figure 1.

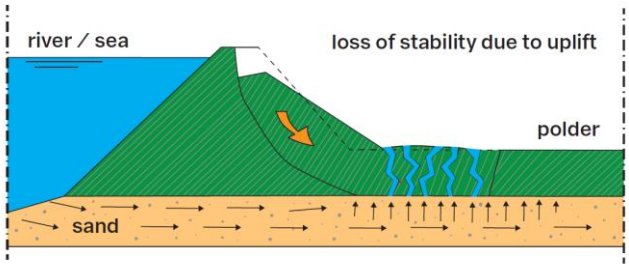

Figure 1. A sketch of buckling or uplifting mechanims over a dike clay cover.

In order to study the dike deformation mechanisms, a series of centrifuge experiments are carried out at the 5 m radius Deltares Geo-Centrifuge. The goal of the experimental program is to better understand the mechanisms that affect the behaviour of the dike and cover layer under extreme water levels. The forthcoming proceeding paper will introduce the experimental methodology and early findings of the experimental program by elaborating on an exemplar test carried out at the Deltares Geo-Centrifuge. It should be noted that centrifuge testing is part of the activities carried out under an overarching project, for a broader description, interested readers are referred to Zwanenburg et al. (2024). This project combines physical and numerical models as well as field experiments.

2 MATERIALS AND EXPERIMENTAL SETUP

Figure 2 illustrates a sketch of the experimental setup together with the soil layers, instrumentation details, and the model-scale dimensions.

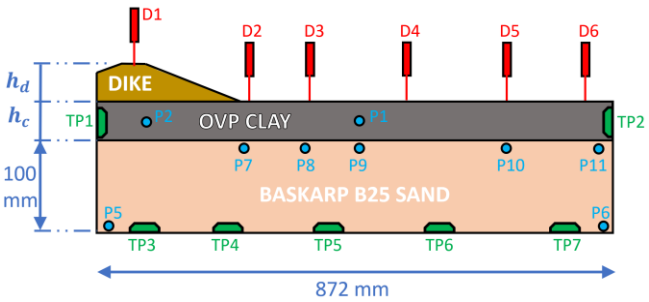

Figure 2. A sketch of the experimental setup.

2.1 Materials

The geo-materials used in the centrifuge model included Baskarp B15 and B25 sands and Oostvaardersplassen (OVP) clay. The model construction commenced with the addition of a precalculated amount of Baskarp B25 in the strongbox to serve as a permeable layer which underlies the cover layer (OVP Clay). The sand is placed by wet pluviation and tamping, achieving a relative density of 90%. Once the placement of the basal sand layer was finalized, remoulded OVP clay slurry was placed on top of the sand, being consolidated with an overburden pressure of 20 kPa within the strongbox and forming the cover layer. Please note that block samples consolidated to 40 kPa were also used in the wider experimental program. Upon completion of consolidation, the sand dike consisted of Baskarp B15 sand, constructed above the cover layer. Further details on the engineering properties of the OVP clay and Baskarp sands can be found in Fern et al. (2017) and Rosenbrand et al. (2022), respectively.

2.2 Experimental Setup

The models are prepared in a strongbox which can withstand the centrifugal accelerations and with a transparent window allowing in-flight image capture for digital image analysis. The width and length of the strongbox is 200 and 872 mm, respectively. The depth of the strongbox is 450 mm. The base plate of the strongbox is instrumented with total pressure sensors, abbreviated as ‘TP’ in Figure 2. Similarly, additional total pressure sensors are affixed to the side walls, capturing the lateral pressure changes in the cover

layer. An array of eleven pore water pressure sensors is distributed over the model, abbreviated as P in Figure 2. Notably, P5 and P6 indicate the pressure head of the influent and effluent flow. P7 to P11 measure the porewater pressure at the sand-clay interface. Finally, P1 and P2 give important insight into the pore water pressure within the OVP clay cover layer. Surface vertical deformations are monitored by six hard sensor points instrumented with DCDTs. These sensors are essentially similar to Linear Variable Differential Transformers (LVDT), but they do not incorporate any spring-loaded system, preventing jamming under the action of a centrifugal acceleration field. Beyond the conventional instrumentation, the deformations are monitored with a camera system, enabling post-testing digital image correlation analyses. Due to the large aspect ratio of the transparent window, a total of two cameras are used for monitoring the entirety of the model. A photograph of the intact dike is shown in Figure 3.

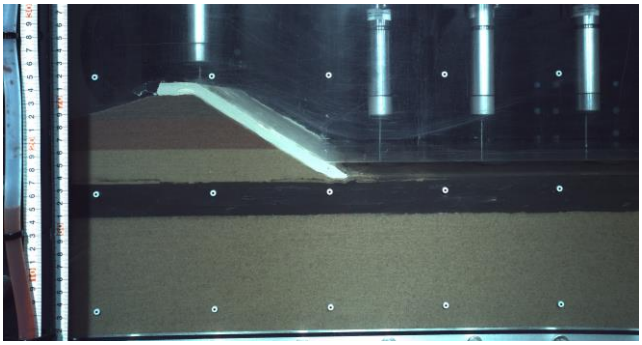

Figure 3. A photograph of the dike before failure occurs (note that a thin layer of Vingerling K147 clay (white) is used as an armor layer to retain water within the dike body).

3 EXPERIMENTAL METHOD

One of the primary objectives of the tests are to see if increments of hydraulic pressure on the riverside would cause uplift failure on the landside. With this in mind, during the centrifuge flight, the experimental assembly allows for adjustment of the hydraulic head on the river side while keeping the landside head constant. The influent flow is supplied from the left-hand-side, see Figure 2, using a series of diffusers. Water is allowed to leave the permeable sand from the right-hand side of the assembly.

The centrifugal acceleration regime applied to the model is illustrated in Figure 4. The hydraulic loading regime necessary to induce uplift is estimated on equivalent finite element calculations, assuming a stress field equivalent to an effective centrifugal acceleration of 80g. The hydraulic loading regime is illustrated in Figure 5, where the difference in influent (P5) and effluent (P6) pressure heads can be seen.

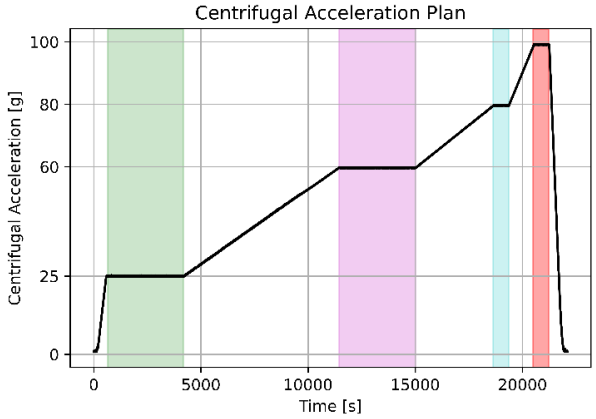

Figure 4. Centrifugal acceleration during the experiment.

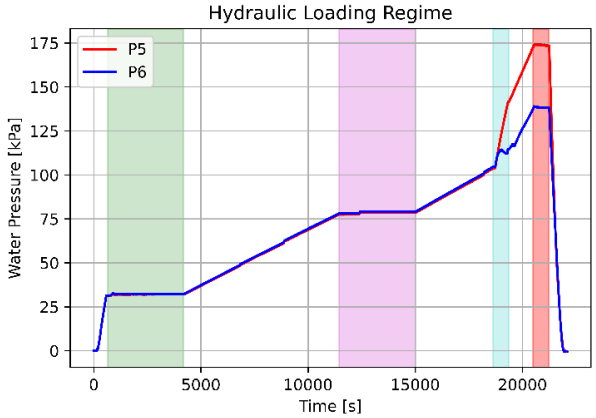

Figure 5. Hydraulic loading regime during the test.

As a result of increasing the hydraulic head difference across the model, uplift of the cover layer is triggered. Vertical displacements measured by the DCDTs are illustrated in Figure 6 (notice that the background coloring in the graph coincides with different phases of the experiment as illustrated in Figure 4 and Figure 5). A photograph capturing the moment of uplift is also shown in Figure 7.

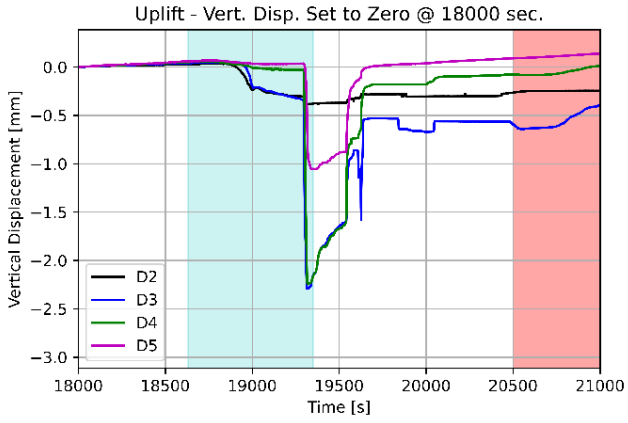

Figure 6. Vertical displacements measured by the DCDTs at the initiation of uplift.

Figure 7. Uplift and separation of the cover layer.

Figure 8 illustrates the overall deformation observed at the end of the test where multiple failure planes within the dike body are visible which also bring about settlements (reduced free-board). In addition to the dike body failure, the cover layer exhibits severe cracks, most notably at the toe. The cracks extend diagonally, and its slope is steeper than that of the dike slope. Multiple wells have also formed as a result of the increased hydraulic heads which reduce the integrity of the cover layer.

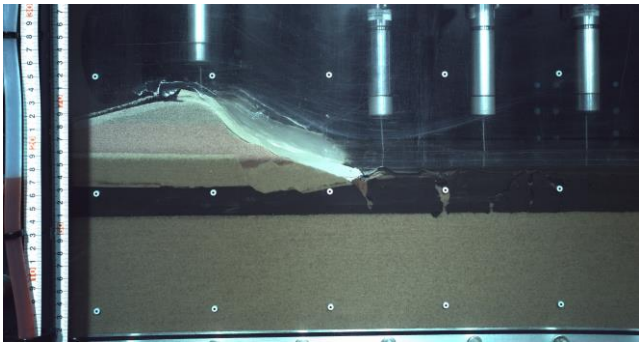

Figure 8. Overall deformation pattern of the model.

4 OBSERVATIONS AND CONCLUSIONS

This proceeding paper aimed at demonstrating the general aspects of the centrifuge scope undertaken at Deltares Geo-Centrifuge. Main observations and conclusions from the testing program can be summarized with the following items:

- Although the presently described test only constitutes a singular test within the experimental program, uplift of the cover layer was observed in all tests.
- Uplift phenomena occurs when the limit equilibrium state is satisfied, i.e., the ratio of the vertical pressure exerted by the cover layer is equal to the water pressure below the cover layer, or when $\sigma_v / \sigma_w = 1$.
- The cover layer cracks due to uplift. This crack is seen as a diagonal crack occurring at the toe of the dike, see Figure 7 (to the right of the first white dot in the figure).
- Uplift at a centrifugal acceleration of 80 g causes the cover layer to rise approximately 2.5 mm, see D4 measurements in Figure 6. There have been observations of much severe uplift deformations within the experimental program.
- When g-level increases the vertical displacement of the cover layer reduces. It should be noted that the cover layer remains in an uplifted condition and the ratio σ_v / σ_w remains unaltered when increasing the g-level. The exact cause of this is still under investigation.
- Figure 7 shows that in the uplifted zone the hydraulic head in the sand layer is maximised by the weight of the cover layer. A further increase in hydraulic head at the left boundary will further increase the head at the uplifted zone.
- Failure was found by a combination of a steep sliding plane at the active side that connects the opening at the cover layer with the sand layer.
- In the test series, no passive failure plane is visible, instead the cover layer seems to be horizontally compressed in combination with a further increase in curvature of the uplifted zone. The later could mean that the lateral stiffness of the cover layer might play a role in the observed deformation patterns.

ABSTRACT: Typhoon activities lead to numerous rainfall-induced erosions, debris flows, and landslides. Monitoring and analysing potential natural disasters are needed worldwide. Thermal imagers are characterized by noncontact and long-distance detection capabilities, rendering them suitable for landslide monitoring. The purpose of the study was to monitor the unstable slope in a mudstone area by analyzing surface infrared temperature changes. A landslide case in a mudstone area in southern Taiwan was monitored for this pilot study. Thermographs obtained by a handheld thermal imager from various times were analyzed for monitoring the surface temperature changes on slope faces. In addition, an unmanned aerial system (UAS) mounted thermal imager was used to capture digital orthophoto thermal images for setting up a three-dimensional monitoring net. Infrared temperature changes per unit time served as monitoring variables and were compared with isotherms for detecting infrared temperature changes. These images indicated that wet soil had higher water content and exhibited a lower surficial infrared temperature change. A thermal imager can reveal changes in surface radiation temperatures and can be used for monitoring landslide-induced surface temperature changes. Accordingly, the use of thermal imagers for potential unstable slope monitoring may be optional.

RÉSUMÉ: Les activités des typhons entraînent de nombreuses érosions, coulées de débris et glissements de terrain induits par les précipitations. La surveillance et l'analyse des catastrophes naturelles potentielles sont nécessaires dans le monde entier. Les imageurs thermiques se caractérisent par des capacités de détection sans contact et à longue distance, ce qui les rend adaptés à la surveillance des glissements de terrain. Le but de l'étude était de surveiller la pente instable dans une zone de mudstone en analysant les changements de température infrarouge en surface. Un cas de glissement de terrain dans une zone de mudstone du sud de Taiwan a été surveillé pour cette étude pilote. Des thermographes obtenus par une caméra thermique portative à différents moments ont été analysés pour surveiller les changements de température de surface sur les faces des pentes. En outre, un imageur thermique monté sur un système aérien sans pilote (UAS) a été utilisé pour capturer des images thermiques orthophoto numériques afin de mettre en place un réseau de surveillance tridimensionnel. Les changements de température infrarouge par unité de temps ont servi de variables de surveillance et ont été comparés aux isothermes pour détecter les changements de température infrarouge. Ces images ont indiqué que le sol humide avait une teneur en eau plus élevée et présentait un changement de température infrarouge superficiel plus faible. Une caméra thermique peut révéler les changements dans les températures de rayonnement de surface et peut être utilisée pour surveiller les changements de température de surface induits par les glissements de terrain. Par conséquent, l'utilisation de caméras thermiques pour la surveillance des pentes potentiellement instables peut être facultative.

1 INTRODUCTION

Taiwan has a monsoon climate. The west-south monsoon currently takes place in May to September affects the monsoon climate in Taiwan. Moreover, Taiwan is located in the path of typhoons in the Pacific Ocean area, which is prone to typhoons. High-intensity rainfall and prolonged high cumulative rainfall tend to initiate landslide and debris flow in Taiwan (Chen, 2016).

Mudrock is a class of fine-grained siliciclastic sedimentary rocks. Mudstone is a common type of mudrock in Taiwan. Mudstone strata are exposed in west-southern hillslopes along the south and east coasts of Taiwan. Mudstone is the most unstable type of sedimentary rock in the area and is prone to

weathering and water disintegration. Rainfall erosion of mudstone can be attributed to the formation of an erosion gully. The saline matter in mudstone is prone to dissolution by rainfall, which renders soil masses quite barren. Growth of plants is inhibited in such barren soil masses.

Mudstone has a complex structure and does not possess a bedding plane. The particle size of mudstone ranges between silt and clay, and its color varies from gray to black. Black mudstone consists of organic material. Mudstone is young in geologic age with poor cementation and is prone to disintegration because of softening by water. Mudstone is competent as stone under dry conditions but cracks easily on the surface under wet conditions. Cyclic dry and wet conditions cause surficial plate peeling in mudstone.

The evolution of a mudstone slope involves four stages (Lin, 1995): At the beginning, rainfall seeps into the surficial cracks of mudstone and then evaporates; finally, dry shrink occurs, and the base rock is separated. This separation enables further seepage of the rainfall into the cracks.

The separated mudrocks are eroded by rainfall, or they move down the slope due to gravity and continue to be deposited at the toe of the slope at a nearly 20° to 30° talus gradient. Rainfall continues to seep through the surficial cracks to deeper layers. Weathered slope surficial soil falls to the slope toe and retreats as the surficial layer of the mudstone collapses, thus engendering a repeated cycle.

The compression strength of the mudstone is 0.2–2.8 MPa (Lee et al., 1994). The average thickness of weathered surficial soil on the mudstone is from 2 to 10 m. In the bold area, the thickness of weathered surficial soil is less than 1 m, and the soil has low permeability to soluble salts, which reduces the survivability of plants and increases the ease of erosion (Wang, 1988). The index properties of the mudstone in southwestern Taiwan are outlined as follows: specific gravity, 2.67 to 2.77; water content, 1.73% to 17.91%; liquid limit, 24% to 42.2%; void ratio, 0.21 to 0.51; plastic limit, 7.4% to 25.4%; and plastic index, 10.5 to 18. The sand, clay, and silt particle contents are 2% to 23%, 16% to 42%, and 55% to 79 %, respectively; thus, the mudstone can be classified as CL-ML or CL (Chen, 2006).

In the mudstone area in the Kaohsiung City in southern Taiwan, various sunlight incident angles cause large infrared temperature changes in the east and west sides of the slopes (Figure 1). The maximum difference in temperature is 15–18 °C in winter and 2–5 °C in summer (Hsu et al., 2005).

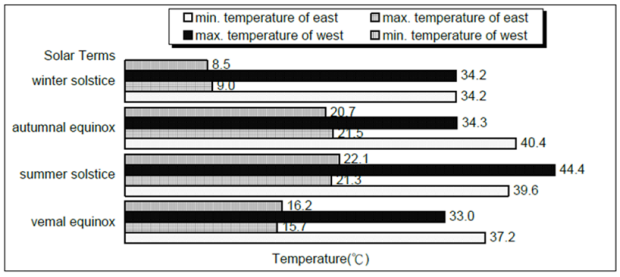

Figure 1. Infrared temperature changes at the east and west sides of the slopes (Hsu et al., 2005).

2 INFRARED TEMPERATURE CHANGES OF MUDROCK

A thermal imager is a noncontact, nondestructive, and rapid testing instrument for examining inner structural conditions through surficial infrared temperature. The imager's applications extend from military use to medicine, science, industry, agriculture, mining, and engineering.

The advantages of using a thermal imager for monitoring surficial infrared temperature changes of objects include remote monitoring, large-area monitoring, clear visibility, wide infrared temperature monitoring range, rapid response, and lightweight (Clark et al., 2003).

A previous study applied a thermal imager to monitor tension cracks on rock slopes (Baroň et al., 2014) and revealed that the thermal imager could provide information for rapidly evaluating the risk of rockfall and the distribution of tension cracks. In nondestructive inspections, a thermal imager has been used to inspect a shotcrete-protected slope (Wu et al., 2005; Chen and Jiang, 2018). The existence of caves behind the shotcrete surface results in higher infrared temperature changes than those observed under shotcrete surfaces without caves.

Applying thermal imagers for monitoring surficial infrared temperature changes necessitates environmental temperatures lower than the average temperature of rock surfaces, good visibility, low direct sun exposure, absence of heavy snow cover, and bare rock surfaces (Baroň et al., 2014).

The purpose of the study was to monitor the landslide in a mudstone area for testing the feasibility of thermal imagers for nondestructive inspections of surficial changes in a large area.

3 STUDY AREA AND METHOD

3.1 Study Area

The mudrock areas in the Kaohsiung City in southern Taiwan served as the study area. The annual rainfall in

the study area is up to 1800 mm, and the average temperature is between 23 and 25 °C. The area is bare with sparse vegetation.

A landslide disaster occurred in the study area at 11:00 on September 28, 2016 because of torrential rains engendered by Typhoon Megi. The landslide site was determined to be located at a latitude of 22°47'20.0"N and longitude of 120°22'45.7"E. The landslide buried one building and left three residents dead. The landslide area was measured to be 3000 m^2. A field investigation was conducted on October 6, 2016, a week after Typhoon Megi (Figure 2). The results of the field investigation revealed mudstone and sandstone with water-softened mud. Moreover, the results indicated high water content in the field mudstone and ground cracks. The landslide exhibited high soil mobility and mass movement and blocked the trail. The movement could have been induced by the softening of the mudstones because of the long-term high water content.

3.2 Geologic and Hydrologic Conditions

The landslide occurred at the Gutingkeng Formation between late Miocene and Pleistocene. The formation is a combination of gray mudstone and sandstone with interbedded limestone and exhibits a bare land after weathering.

The annual rainfall in the study area was 1747 mm in 2014, 1497 mm in 2015, and 3023 mm in 2016. The rainfall was 1255 mm on September, 2016 and up to 3023 mm in December, exceeding the average annual rainfall (i.e., 1800 mm) in the area. The landslide was induced by a cumulative rainfall of 482 mm engendered by Typhoon Megi on September 28, 2016; it occurred immediately after the rainfall (Figure 3). The area received 19 days of rainfall in September, which resulted in high water content and softened the mudstone.

Figure 2. The scar of the monitored landslide (October 6, 2016).

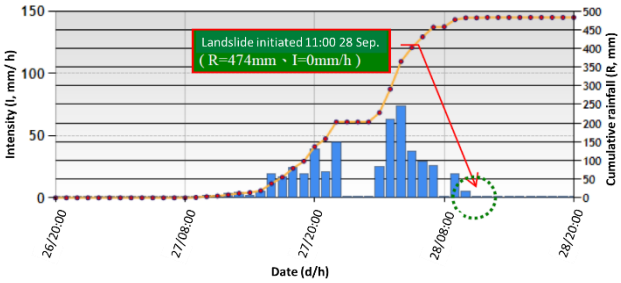

Figure 3. Rainfall time history at the nearest rain gauge station during Typhoon Megi (source NCDR, 2016).

3.3 Method

Two types of thermal imagers were used for monitoring the landslide area, namely a handheld infrared thermal imager (NEC G100D) and an unmanned aerial system (UAS). The handheld type was used for monitoring the facade of the landslide. The handheld imager has a sensitivity of 0.08 °C, image resolution of 200 megapixels, and focus length ranging from 10 cm to infinity. The UAS of the NEC F30W thermal imager is small in size and lightweight.

A post-processing package was used for thermal image analysis. The functions of the software include regional temperature distribution curves, infrared temperature profiles, isotherms, dynamic infrared temperature changes, and three-dimensional temperature change trends. Infrared temperature changes in multiple regions were analyzed to show the highest, average, and lowest temperatures in a regional area; the results were indicated on a thermal image (Figure 4).

This study monitored the landslide area to derive results that can be used for postdisaster prevention and mitigation. Changes in infrared temperature (△T) in a period (t) served as a monitoring index for the surficial temperature changes in the landslide area (Chen and Jiang, 2018). The landslide monitoring process in this study involved three stages. The first stage involved a preliminary field investigation and handheld thermal-imager-based monitoring at the landslide site for selecting the potential movement area for further monitoring. The second stage involved monitoring using the handheld thermal imager in the morning and afternoon. The third stage involved monitoring using the UAS thermal imager, and the derived results were compared with those obtained in the second stage.

4 RESULTS

4.1 Handheld Thermal Imager Monitoring

The landslide movement was monitored on March 24, 2017, using the handheld thermal imager.

Thermographs were divided into 36 grids (Figure 5) for the monitoring window from 09:00 to 13:30. The frequency of monitoring was 30 min. Figure 6 displays the thermographs obtained from the field investigation. The infrared temperature on the monitored slope increased from morning to noon. The main erosion gully as indicated in the middle of the thermograph, shows that the study area had a lower temperature than did other areas as well as the vegetation areas. The left side of the slope exhibiting a sandstone base and a small erosion gully had a lower temperature than did the right side of the slope exhibiting a mudstone area. The thermograph reveals different temperatures under different vegetation conditions and types of base materials.

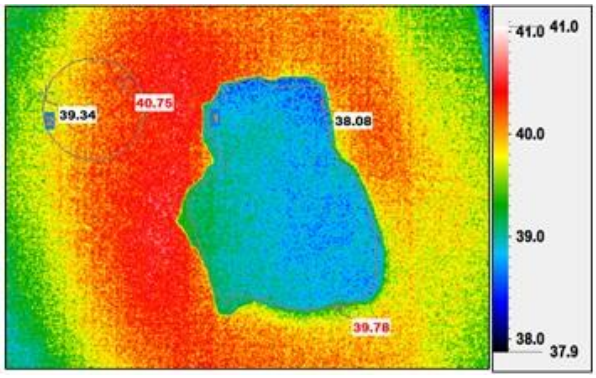

Figure 4. Example of multiregional thermal image analysis (temperature unit: degree).

The monitoring index △T/t can be calculated from the infrared temperature change △T for the current time minus the former time in the period t. The index changed as the environmental temperature increased. The index showed no obvious fluctuations between 09:57 and 10:24. The index exhibited high fluctuations in grids 7, 13, and 19, corresponding to the erosion gully on the left side of the monitored area, at 11:27. The main erosion gully in the middle of the area—represented by grids 11, 15, 21, and 28—revealed a high change in temperature at 11:58.

Figure 7 illustrates a histogram constructed for the changes in infrared temperature between 09:27 and 13:01, revealing that grids 7, 13, and 19 had the highest changes, followed by grids 14, 15, 20, and 21. The day of monitoring was sunny, and the sunshine streaked from the right to left of the imager in the afternoon. Shadow areas corresponding to grids 4, 5, 6, 10, 11, 12, 16, 17, 18, 22, 23, 24, 28, 29, and 30 demonstrated a low decrease in temperature. Grids 6, 12, 16, 17, 18, 20, 21, 22, and 23 exhibited a decrease in temperature engendered by the changes in solar orientation.

The erosion gully corresponding to grids 7, 13, and 19 showed a considerable change in ΔT/t. However, the main erosion gully of the landslide corresponding to grids 10, 16, and 22 was affected by the shadow and exhibited negligible changes. To identify potential high-change areas, an isothermal graph was overlapped with the visible image. The resultant image confirmed that the two gullies in the monitored landslide area had lower infrared temperature than did other naked areas (Figure 8).

Figure 5. Grid numbers for the monitoring of the landslide.

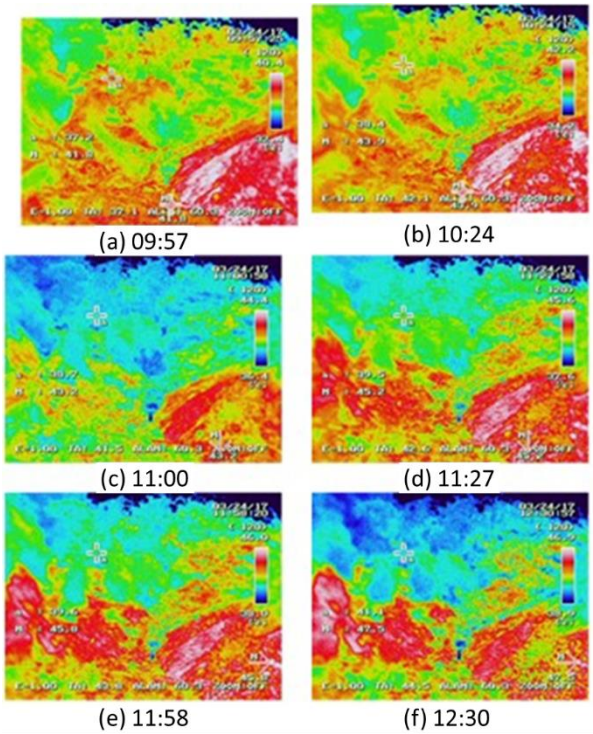

Figure 6. Thermographs of the monitored landslide (captured on March 24, 2017).

4.2 UAS Thermal Imager Monitoring

The thermal images obtained by the UAS thermal imager on April 28, 2017 were compared with those obtained by the handheld thermal imager. The UAS aerial thermograph revealed a lower temperature in the two erosion gullies and shadow areas than in other

areas (Figure 9). The highest temperature was 43.1 °C on the left side of the sandstone slope, and the lowest was 22.73 °C on the right side of the shadow gully. Compared with the thermograph obtained using the handheld thermal imager, the aerial thermograph obtained using the UAS thermal imager showed more considerable temperature changes in the gully areas. In terms of monitoring distance, the UAS thermal imager was closer to the landslide compared with the handheld thermal imager. However, the UAS image was limited because the imager was airborne for 15 min without finding a fixed position for monitoring.

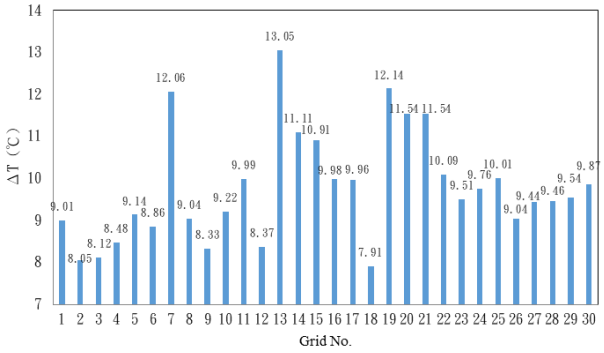

Figure 7. Statistics of the infrared temperature changes (⊿T) between 09:27 and 13:01 (recorded on March 24, 2017).

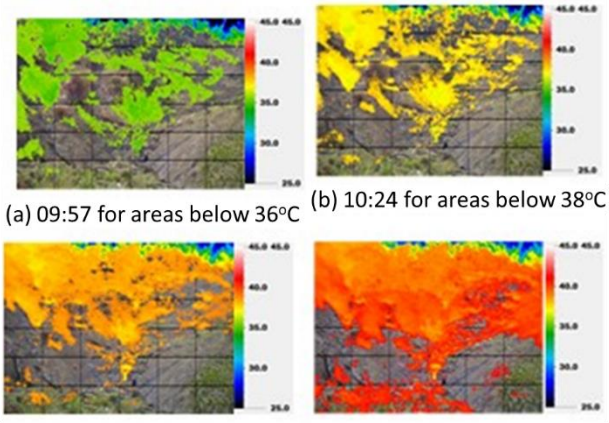

Figure 8. Handheld thermograph (captured on March 24, 2017).

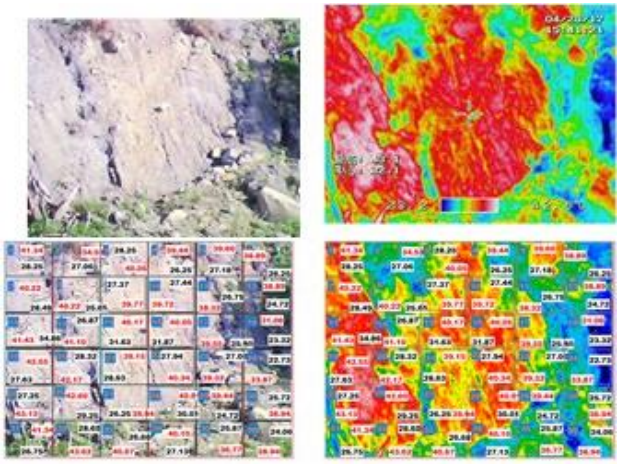

Figure 9. Aerial thermograph (captured by UAS thermal imager on April 28, 2017).

5 CONCLUSION

The study applied handheld and UAS thermal imagers for monitoring topography changes engendered by a landslide in a mudstone area. Field investigations showed that the landslide could be attributed to the torrential-rainfall-induced high water content in the mudstone and the surficial-rainfall-eroded gully. The derived thermal images demonstrated that the eroded gully exhibited a lower infrared temperature and was associated with higher temperature sensitivity when compared with the surrounding areas. Sandstone demonstrated a higher change in infrared temperature than did mudstone, in addition to being associated with higher temperature sensitivity. The erosion gully was associated with high sensitivity to infrared temperature changes and was affected by the shade. The infrared temperature image was overlapped with the visible image to find the high-water-content areas, bare land areas, and surficial cracks. Future research needs to prolong the monitoring period for better reflecting the changes in infrared temperature in slope areas.

Evaluating the interface shear strength of geocomposite drain and HDPE geomembrane layers in landfill cover systems

Évaluation de la résistance au cisaillement de l'interface entre le drain géocomposite et la géomembrane en PEHD dans les systèmes de clôture de décharge

F. Chihi*, G. Varga
Department of Engineering Geology and Geotechnics, Faculty of Civil Engineering, Budapest University of Technology and Economics. Budapest, Hungary

**chihi.feten@emk.bme.hu*

ABSTRACT: This study evaluates the shear strength of geosynthetic drain-HDPE geomembrane interfaces under dry and submerged conditions at normal stresses of 10, 20, and 30 kPa using a comprehensive large-scale direct shear testing program. Results revieled higher shear stress in dry conditions, with a significant reduction upon submersion due to water's lubricating effect. Despite a lower friction angle, the geocomposite drain maintains a consistent friction angle in residual shear strength tests, crucial for landfill cover stability. The geocomposite's lighter weight and reduced height are advantageous, potentially compensating for lower friction angles and contributing to slope stability. The outcomes of this study provide significant insights, which are essential in refining the engineering design of landfill cover systems incorporating geosynthetics. Further research is needed to fully understand the impact of the geocomposite physical properties on the overall slope stability.

RÉSUMÉ: Cette étude évalue la résistance au cisaillement des interfaces entre les drains géosynthétiques et les géomembranes HDPE sous conditions sèches et submergées à des contraintes normales de 10, 20 et 30 kPa, en utilisant un programme de tests de cisaillement direct à grande échelle. Les résultats révèlent un stress de cisaillement plus élevé en conditions sèches, avec une réduction significative lors de la submersion due à l'effet lubrifiant de l'eau. Malgré un angle de friction inférieur, le drain géosynthétique maintient un angle de friction constant dans les tests de résistance au cisaillement résiduel, crucial pour la stabilité des couvertures de décharge. Le poids plus léger et la hauteur réduite du géocomposite sont avantageux, compensant potentiellement les angles de friction inférieurs et contribuant à la stabilité des pentes. Les résultats de cette étude fournissent des aperçus significatifs, essentiels pour affiner la conception technique des systèmes de couverture de décharge incorporant des géosynthétiques. Des recherches supplémentaires sont nécessaires pour comprendre pleinement l'impact des propriétés physiques du géocomposite sur la stabilité globale des pentes.

1 INTRODUCTION

The efficacy and sustainability of landfill sites critically depend on the performance of their cover systems, which serve as hydraulic barriers. These cover systems are designed to prevent environmental contamination by inhibiting water ingress into waste material. The integrity of these hydraulic barriers is essential in ensuring the long-term stability and environmental safety of landfill sites. Therefore, the engineering and material composition of landfill cover systems are areas of ongoing research and development, seeking to enhance their performance and durability under various environmental conditions.

However, the operational success of these landfill cover systems is frequently compromised by structural failures, predominantly manifested as sliding and slope instability (Cortellazzo et al., 2022; Shi et al., 2020). Such failures are largely attributed to a confluence of factors including low shear strength parameters, the excessive weight of conventional soil cover systems including granular drainage layers, and steep slope angles inherent in landfill designs (Zornberg et al., 2011). These failures not only pose significant risks to the structural integrity of the landfill but also have far-reaching implications for environmental safety. The low shear strength at the interfaces of different layers within the cover system is a critical factor contributing to these failures. The heavy weight of granular drains exerts substantial

pressure on the underlying structures, intensifying the risk of sliding, particularly on steeper slopes. Addressing these challenges is essential for the development of more robust and reliable landfill cover systems.

In response to these challenges, geosynthetics have emerged as a viable alternative to traditional materials in landfill cover systems (Müller & Saathoff, 2015). The use of geosynthetic drains offers a promising solution to reduce the overall weight of the cover system and optimize its design. Geosynthetics, known for their durability and versatility, can effectively enhance the stability of landfill covers. However, despite these advantages, the potential for sliding failures remains a concern. The interface shear strength between the geosynthetic layers and adjacent materials, especially under various hydraulic conditions, is a critical aspect that necessitates thorough investigation (Kavazanjian Jr. et al., 2006; Touze-Foltz et al., 2021). This understanding is essential to leverage the benefits of geosynthetics fully while mitigating the risks associated with their integration into landfill cover systems.

Therefore, this paper aims to experimentally evaluate the interface shear strength between geosynthetic drain and HDPE geomembrane (GM) layers in landfill cover systems. By conducting a series of tests under different hydraulic conditions, the study seeks to quantify the shear strength at these critical interfaces. These findings are compared with existing literature on traditional granular drains, offering a comprehensive understanding of the performance of geosynthetics in comparison to conventional materials. This research attempts to provide valuable insights into optimizing landfill cover designs, enhancing their stability, and ensuring environmental safety, thereby contributing significantly to the field of landfill engineering.

2 MATERIAL AND METHOD

2.1 Geocomposite drain

The triple layered geocomposite drain (GTD) is characterized by a tripartite structure, each layer contributing distinct functional properties to the overall system.

The upper and lower layers of the geocomposite drain consists of a needle-punched geotextile made from polypropylene (PP). Thes layers serve primarily as a filter, preventing the ingress of fine particles into the drainage core while allowing water to pass through. The needle-punching technique enhances the mechanical interlocking of the fibres, thus imparting both strength and durability to the geotextile.

At the heart of the triple-layered system lies an internal drainage core, made from PP. The core is designed in a "V" shape, which optimizes the flow of water through the drainage system. This configuration facilitates efficient drainage while maintaining structural integrity under varying stresses (Figure 1).

Figure 1. Geocomposite drain used in the testing program.

The entire structure is sewn together, creating a cohesive and robust drainage system. The triple drain exhibits a thickness of 5 mm, characterised by an opening size of 90 nm. The permeability on a plain surface is 100 mm/s. It weights 520 g/m^2, which is considered very light compared to the conventional granular drains, hence it contributes to its stability. It boasts a tensile strength of 16 kN/m, indicative of its ability to withstand significant mechanical stress without compromising its structural integrity or performance.

2.2 HDPE

The HDPE GM employed in this research is characterized by a smooth surface texture. With a thickness of 2 mm, it strikes a balance between flexibility and robustness.

2.3 Testing program

For the direct shear tests, geocomposite drain samples and HDPE GM were cut into 200x200 mm. A rigid, flat wooden board served as the substrate for the geosynthetic samples during the tests. To ensure the integrity of the samples during testing, each geocomposite drain specimen was carefully glued to the board to prevent any folds, wrinkles, or unwanted movements that could influence the test results (Figure 2).

The direct shear tests were carried out using a 200x200 mm test area. Each test was conducted under three different normal stresses: 10 kPa, 20 kPa, and 30 kPa representative of the stress exerted by a 1.5 m

thick cover system (Othman, 2016). To ensure the consistency each test was replicated three times. The shear parameters were then determined based on the average of these three results. Following the ASTM D5321/D5321M – 14 Standard, a constant shearing speed of 0.3 mm/min was maintained throughout all tests. The shear displacement was set to 10% of the shearing area, aligning with the standard testing protocols for such materials.

The lower HDPE specimen was first placed in the lower container of the direct shear apparatus, followed by the upper geosynthetic layer, along with its superstratum. Special attention was paid to ensuring that only the specimens were in direct contact within the test area.

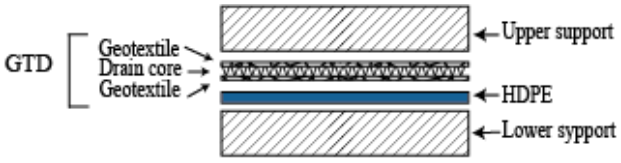

Figure 2. Test configuration.

To comprehensively evaluate the frictional characteristics under various service conditions, tests were performed under both dry and submerged scenarios. For the submerged tests, geosynthetic specimens were fully immersed in water before the beginning of the shearing process. This approach was integral in simulating the limit conditions that the HDPE-geocomposite drain interface might encounter in actual landfill cover systems.

3 RESULTS AND DISCUSSION

The direct shear tests conducted on the geosynthetic drain and HDPE geomembrane interfaces reveal their interaction under varying normal stresses and hydraulic conditions. The experimental outcomes, represented in Figure 3, demonstrate the shear stress response to shear displacement for both dry and submerged states at normal stresses of 10 kPa, 20 kPa, and 30 kPa.

The graphical representation outlines a clear escalation in shear stress levels corresponding to an increase in normal stress across both environmental conditions. This increment is consistent with the theoretical understanding that higher normal stresses engender an elevated frictional force at the interface.

The post-initial increments shear stress behaviour with respect to the shear displacement revealed a linear trend with no notable peak. Such steady-state friction behaviour is indicative of an absence of pronounced strain hardening or softening, which implies a stable interface shear strength within the displacement range and condition tested. The lack of peak shear stress values within the range of displacement tested suggests that the interface does not exhibit a failure indicating good interfacial compatibility and stability.

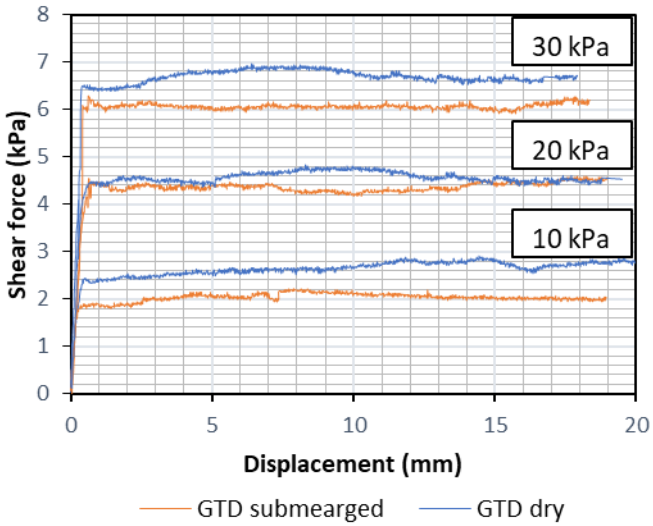

Figure 3. Shear stress and stress ratio vs. horizontal displacement of HDPE-GTD (average values).

The analysis of test results shows a clear difference in shear stress values between dry and wet conditions. When dry, the interface always showed higher levels of shear stress for all the different normal stresses compared to when it was wet. This phenomenon underlines the reduction in shear strength due to the lubricating effect of water at the interface. The reduction was reflected in the friction angle results (Table *1*) In the context of residual shear strength, both dry and submerged HDPE-GTD interfaces demonstrate a consistent friction angle, suggesting a stable residual strength. This is particularly significant for landfill cover system designs, where the post-peak strength is critical to long-term stability and safety.

The shear envelope representation of the test results presented in Figure 4, was compared to the trend line of smooth HDPE-coarse soil proposed by Dixon, et al. (2006). It shows that the shear strength obtained in the test is slightly lower.

Although the interface friction angle of the geocomposite drain-HDPE is lower than that of traditional granular soil drains, it is important to consider the overall stability factors in landfill cover system design. The geocomposite drain offers a considerable advantage due to its lighter weight and reduced height. These characteristics can significantly offset the lower interface friction angle by reducing the driving force on the slopes, thus enhancing stability.

Table 1. Geomembrane–Drain interface peak and residual shear strength parameters.

	Residual shear strength, τr	
Interface	Friction angle (°)	Friction angle (°)
HDPE-GTD (dry)	13.5	11
HDPE-GTD (submerged)	10	9.5

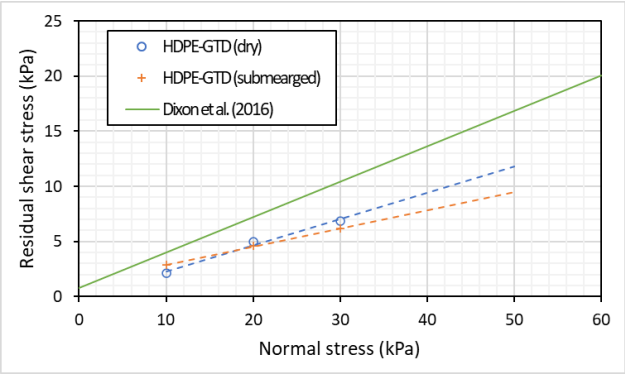

Figure 4. Residual strength envelopes (Dixon, et al. (2006)).

4 CONCLUSIONS

The direct shear tests on the geosynthetic drain-HDPE geomembrane interfaces have provided valuable insights into their interfacial behaviour under different conditions.

- The interface exhibits higher shear stress when dry compared to submerged, highlighting the reduction in shear strength due to the lubricating effect of water.
- Residual shear strength analysis reveals consistent friction angles for both dry and submerged conditions, important for the long-term stability of landfill covers.
- Although shear strength is slightly lower than that of traditional granular soil-HDPE interfaces, the geocomposite drain's lighter weight and reduced height enhance slope stability.

The characteristics of geocomposite drains effectively compensate for lower interface friction angles, advocating their use in landfill cover system design for balanced stability and safety. Future studies should investigate the drain's lighter weight and reduced height contributing to the overall slope stability of the cover system to further validate their suitability for landfill applications.

A simplified procedure for FE analysis of an earth dam under seismic loading

Une procédure simplifiée pour l'analyse EF d'un barrage en terre sous chargement sismique

A. Choudhury, P. Ghosh*, S.K. Mishra

**priyog@iitk.ac.in*

ABSTRACT: The behaviour of an earth dam under seismic conditions can be predicted by geotechnical engineers using a variety of numerical tools. This study performs the finite element (FE) analysis of an earth dam subjected to seismic ground motion. The choice of material constitutive model is critical in any numerical analysis as it should correctly simulate the soil behaviour under earthquake loadings. The current study proposes a simplified technique to avoid complicated user-defined material models. The shear modulus reduction of geomaterials under seismic loadings is introduced into the elastoplastic Mohr-Coulomb model available in the FE software ABAQUS using the user-defined field variable interface. By calibrating the damping of the model with the help of Rayleigh damping, the current numerical results are found to be in good agreement with those recorded using instruments and reported by other researchers using an advanced geotechnical engineering software. To reinforce the applicability of the proposed technique, the analysis is done with varying solver types and flow rules. Good and comparable results are obtained in all cases.

RÉSUMÉ: Le comportement d'un barrage en terre dans des conditions sismiques peut être prédit par les ingénieurs géotechniques à l'aide de divers outils numériques. Cette étude effectue l'analyse par éléments finis (EF) d'un barrage en terre soumis à un mouvement sismique du sol. Le choix du modèle constitutif du matériau est critique dans toute analyse numérique car il doit simuler correctement le comportement du sol sous les charges sismiques. La présente étude propose une technique simplifiée pour éviter les modèles de matériaux compliqués définis par l'utilisateur. La réduction du module de cisaillement des géomatériaux sous charges sismiques est introduite dans le modèle élastoplastique de Mohr-Coulomb disponible dans le logiciel FE ABAQUS à l'aide de l'interface de variables de champ définie par l'utilisateur. En calibrant l'amortissement du modèle à l'aide de l'amortissement de Rayleigh, les résultats numériques actuels s'avèrent être en bon accord avec ceux enregistrés à l'aide d'instruments et rapportés par d'autres chercheurs utilisant un logiciel d'ingénierie géotechnique avancé. Pour renforcer l'applicabilité de la technique proposée, l'analyse est effectuée avec différents types de solveurs et règles de flux. Des résultats bons et comparables sont obtenus dans tous les cas.

Keywords: Earth dam; finite element analysis; earthquake; seismic loading; ABAQUS.

1 INTRODUCTION

Earth dams are used worldwide to retain water or semi-fluid waste. The safety and stability assessment of such geotechnical structures under seismic loadings is an engrossing task. Several researchers (Prevost et al., 1985; Cascone and Rampello, 2003; Hwang et al., 2007; Rampello et al., 2009; Wu et al., 2021) used various numerical techniques to analyse the behaviour of earth dams under seismic conditions. The behaviour of earth dams was predicted using multiple techniques, including the finite element (FE) method, the finite difference method, and other numerical methods. Some of the researchers employed the equivalent linear technique to model geomaterials, while the hardening soil model (Schanz et al., 1999) or some other yielding constitutive model was utilised by others. The researchers conducted these numerical analyses using various commercially available software packages meant explicitly for geotechnical engineering applications. Sometimes, to study the behaviour of geotechnical structures in different physical settings, it becomes necessary to use some generalised multiphysics simulation tool. In that case, it is essential to implement soil models that can correctly simulate the behaviour of the soil under seismic conditions. Thus, coding complicated soil models as user-defined material models becomes necessary. To avoid this, the present study proposes a simplified procedure where, using the user-defined field variable interface of the FE software ABAQUS (Dassault Systèmes Simulia Corp., 2020), the shear modulus reduction of soil with respect to increasing

shear strain is introduced into the elastoplastic soil model following the Mohr-Coulomb failure criteria.

The proposed simplified procedure is used to analyse the behaviour of the Liyutan earth dam (situated in Taiwan) subjected to the Chi-Chi earthquake ground motion of 1999. Feng et al. (2010) investigated the response of this earth dam subjected to the same ground motion using the FLAC 6.0 code (Itasca, 2008). The results obtained using the proposed technique agree with the recorded values (by Central Water Resources Office, 1999) and those obtained by Feng et al. (2010).

2 MODEL DETAILS AND ANALYSIS METHODOLOGY

The simplified cross-section of the Liyutan dam employed by Feng et al. (2010) is used for the present analysis. The dam is divided into three sections – upstream shell (U/S), core and downstream shell (D/S), as shown in Figure 1. It is an earth dam with semi-permeable shells and an impervious core of clayey material. The FE mesh of the dam is also shown in Figure 1. The FE mesh contains 5523 four-noded plain strain elements (CPE4R). The size of the elements is chosen such that the length is less than one-tenth of the wavelength associated with the frequency of the input ground motion, which contains considerable energy (Kuhlemeyer and Lysmer, 1973).

The analysis consists of two broad steps – first is the static step, where the initial static state of the dam is established, and the second is the dynamic step (either explicit or implicit), which involves the time history analysis. The earthquake time histories in both horizontal and vertical directions are applied at the base of the dam, and the results are obtained in terms of the permanent horizontal and vertical displacement at the crest, mid-height of upstream (U/S) face and downstream (D/S) face. The accelerations at the crest are also noted. Similar to the research by Feng et al. (2010), the dynamic analysis is uncoupled; that is, the effect of transient seepage and excess pore water pressures is not considered. Feng et al. (2010) conducted a steady-state seepage analysis (with a 60 m water level) to get the initial stress state and then used that stress state to set the initial small strain shear modulus of the geomaterials. However, in the present analysis, the initial shear modulus is assumed to be constant and independent of the effective mean stress. Additionally, as the types of elements are different, ABAQUS by default does not let the seepage phase come before the dynamic step. Hence, the steady state seepage step is avoided in the current analysis, and the static stresses are directly established. Although user-defined elements can solve this problem, they are not considered to avoid complications.

The properties of the geomaterials that form the earth dam and the proposed simplified procedure are detailed in the subsequent sections.

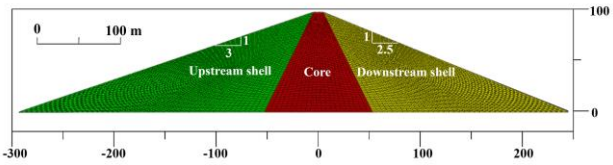

Figure 1. Simplified cross-section and FE mesh for the numerical analysis of the dam.

2.1 Material properties

The elastic and shear strength parameters of the three components of the earth dam are given in Table 1. The maximum shear modulus, i.e., the small strain shear modulus, is represented as G_{max}. The shear modulus (G) reduction curves of the geomaterials are shown in Figure 2.

The dam is modelled using the elastoplastic Mohr-Coulomb model. Initially, a non-associated flow rule (where the dilation angle is zero) is used. Results are later obtained using the associated flow rule and contrasted with the preliminary results. In this case, the dilation angle equals the friction angle of the soil. The shear modulus reduction of the soil is implemented in this model by the simplified procedure outlined in section 2.2. Rayleigh damping given by equation (1) is used to impose damping in the system:

$$[C] = \alpha[M] + \beta[K] \quad (1)$$

where $[C]$, $[M]$, and $[K]$ are the damping, mass and stiffness matrices, respectively. The terms α and β are the mass and stiffness proportional damping coefficients, respectively, which can be expressed as

$$\alpha = \xi \cdot \omega_i \quad (2)$$

$$\beta = \xi \cdot (\omega_i)^{-1} \quad (3)$$

where ξ is the damping ratio, and ω_i is the angular frequency. Typically, ω_i can be equal to the frequency that is in the middle of the dominant frequencies of the input wave (Itasca, 2008); alternatively, it can be equal to the fundamental frequency of the structure as that is the major mode of vibration (Idriss et al., 1973). In the present analysis, these two methods of calculating the damping coefficients are employed and the results are compared. Hereafter, the first method is referred to as R1, and the second as R2. The analysis is performed at three different values of damping ratio (ξ) – 5%, 10%,

and 15%, and the optimum value is found, which gives results close to the recorded (by Central Water Resources Office, 1999) and previously calculated values (by Feng et al., 2010).

The fundamental period of the dam is calculated using the default Lancozs solver in ABAQUS and is found to be 0.62 s.

Table 1. Elastic and shear strength properties of geomaterials (from Hnang, 1996 and Central Water Resources Office, 1995).

Zone	Density (t/m^3)	Shear modulus (G_{max}) (Pa)	Poisson's ratio (ν)	Cohesion c' (kPa)	Friction angle (ϕ) (°)
Upstream shell	2.18	5.0×10^8	0.34	94	41
Core	2.08	3.5×10^8	0.45	34	27
Downstream shell	2.18	6.0×10^8	0.3	82	35

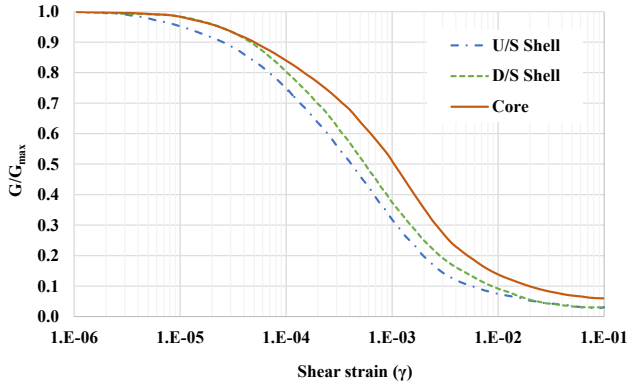

Figure 2. Shear modulus reduction curves of geomaterials (from Central Water Resources Office, 1995).

2.2 The simplified procedure

When the soil is subjected to a cyclic load, it loses its strength gradually. This reduction is represented as the shear modulus reduction curve, where the shear modulus reduces with increased shear strain. Parallel to this, due to the stress reversals and reduction in shear modulus, the damping of the soil increases as the shear strain increases. Using the user-defined field variable interface of the ABAQUS software the reduction in shear modulus with an increase in shear strain is implemented with the help of a simple algorithm, as shown in Figure 3.

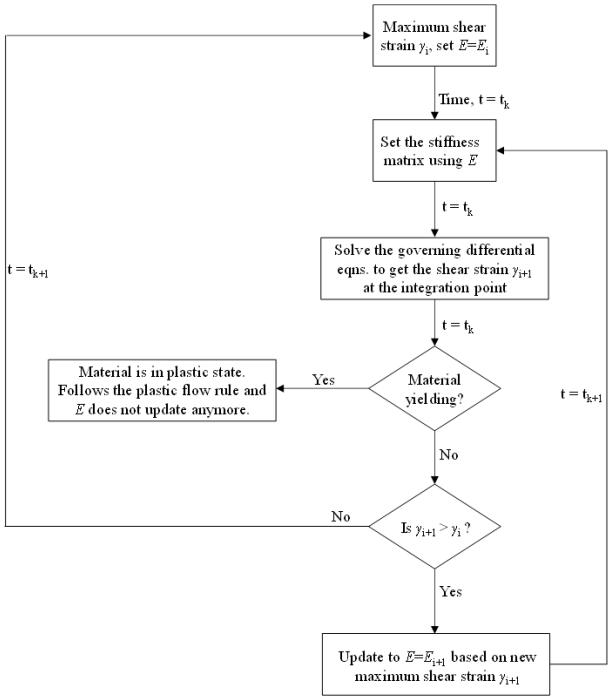

Figure 3. Flow chart for the algorithm used to implement the proposed simplified approach.

The soil is considered homogenous and isotropic; hence, the shear modulus (G) and elastic modulus (E) can be related by the following equation:

$$E = 2G(1 + \nu) \qquad (4)$$

where ν is the Poisson's ratio. Using Figure 2 and equation (4), the calculated elastic modulus (E) is assigned a field variable equal to shear strain in the ABAQUS material manager. The elastic modulus is updated at each integration point based on the maximum value of shear strain (i.e., the field variable) up to that time instant. The current new maximum shear strain is saved using the solution-dependent state variable. Feng et al. (2010) used the equivalent linear sigmoidal model with the Mohr-Coulomb failure model (Itasca, 2008), where the modulus reduction turns off when the material has plastic flow. Similarly, in this simplified approach, the elastic modulus stops reducing as soon as the material yields and enters a plastic flow state.

The proposed technique cannot reflect the hysteretic damping of the soil. Hence, considerably higher damping is enforced with the help of Rayleigh damping to substitute this in an average sense. Thus, this method ultimately gives an outcome that averages the effect of stress reversals and the number of cycles by giving weightage to the maximum strain generated from the peak seismic load during the time history.

2.3 Input ground motions

The horizontal and vertical ground motions recorded at the recording station at the base of the dam during the Chi-Chi earthquake of 1999 are used as input ground motions. These ground motions are shown in Figure 4 and Figure 5. The peak accelerations of horizontal and vertical ground motions are 0.149g and 0.108g, respectively. The horizontal ground motion has the following dominant frequencies – 0.244 Hz, 0.69 Hz, and 0.87 Hz, whereas the vertical ground motion has a dominant frequency of 0.255 Hz (Feng et al., 2010). The acceleration time histories are 45 s long, but the analysis is carried out for 60 s so that the transient response of the earth dam gets sufficiently attenuated.

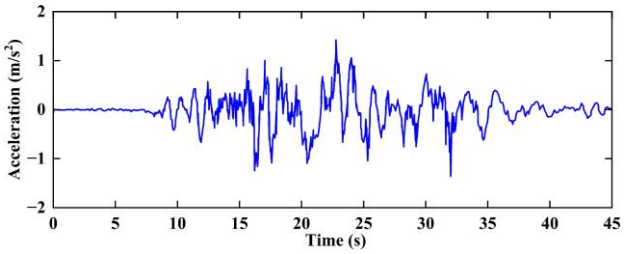

Figure 4. Horizontal acceleration recorded at the base of the Liyutan dam after the Chi-Chi earthquake of 1999 (from Feng et al.,2010).

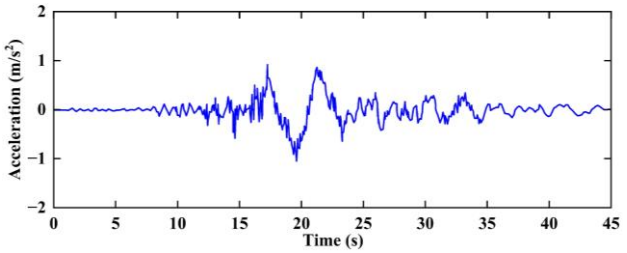

Figure 5. Vertical acceleration recorded at the base of the Liyutan dam after the Chi-Chi earthquake of 1999 (from Feng et al.,2010).

3 RESULTS

Four different time history analyses are carried out using ABAQUS varying the solver type – explicit (E) or implicit (I), method of selection of Rayleigh damping parameters – R1 or R2, and the flow rule – non-associated (N) or associated (A). These four analyses are named as – ER1N, ER2N, IR2N and ER2A, respectively.

The permanent horizontal (↔) and vertical (↕) displacements recorded by the Central Water Resources Office (1999) and those calculated by Feng et al. (2010) at the crest, mid-height (M/H) of upstream (U/S) face and downstream (D/S) face of the dam are given in Table 2. In comparison, the results obtained from the present analyses are tabulated in Table 3.

Table 2. Permanent horizontal and vertical displacements of the dam (in cm) from literature.

	Analysis type	
Location (direction)	**Recorded[a]**	**Calculated[b]**
U/S – M/H (↔)	-2.70 to -3.90	-2
U/S – M/H (↕)	-5.40 to -6.80	1.3
Crest (↔)	-0.70 to -4.30	-5.5
Crest (↕)	-5.00 to -7.90	-5.8
D/S – M/H (↔)	1.80 to 2.90	-0.4
D/S – M/H (↕)	-2.60 to -3.40	0.2

[a]Central Water Resources Office, 1999; [b]Feng et al., 2010

Note: Negative sign '-' means leftward horizontal (↔) or downward vertical (↕) displacement.

On comparing the results tabulated in Table 3 with those in Table 2, it can be seen that 10% Rayleigh damping gives permanent displacements that are a good fit with the recorded and calculated data in the literature. Method R2 gives mostly lower permanent displacements than R1 (except on the D/S side). Such observation agrees with the fact that the fundamental period of vibration of the dam is dominant during the vibration, and hence its damping affects the dynamic behaviour more. The implicit analysis gives results that are not much different from its explicit counterpart. But overall, it predicts slightly higher values. The associated flow rule predicts lower displacement in most of the cases. This is because the increase in dilation angle causes the yield acceleration to increase (Eskandarinejad and Shafiee, 2011; Sharifi et al., 2020).

The peak horizontal and vertical accelerations noted at the crest of the dam for 10% damping are close to the value obtained in the literature, which can be seen in Figure 6 and Figure 7. The comparison of horizontal and vertical acceleration time histories noted at the crest from the ER2N analysis for 10% Rayleigh damping with those from the literature are shown in Figure 8 and Figure 9, respectively. Time histories for the other three analyses are similar and not shown for brevity.

Table 3. Calculated permanent horizontal and vertical displacements (in cm) in the present study.

Location (direction)	Damping (%)	Analysis type ER1N	ER2N	IR2N	ER2A

All the displacement and acceleration values at the crest are obtained by averaging the output of all the nodes at that level.

4 CONCLUSION

The FE analysis of an earth dam subjected to the Chi-Chi earthquake ground motion of 1999 is performed in the present study using the commercially available software ABAQUS. A simplified procedure to implement the shear modulus reduction of the soil subjected to cyclic loading is proposed and employed. Four different analyses are carried out by varying the solver type, method of calculating the Rayleigh damping parameters and the flow rule of the soil model. For a damping ratio of 10% enforced using Rayleigh damping, the permanent displacements and peak accelerations are found to be within an acceptable range compared to the recorded and calculated results in the literature. The implicit solver gives marginally higher values than the explicit solver, whereas the

associated flow rule predicts lower displacements and peak accelerations. Rayleigh damping parameter calculated using the fundamental frequency of the dam dampens the overall response more. Overall, the permanent displacements and accelerations are well predicted in the present study, except for the permanent vertical displacement of the crest (where a higher value is obtained). It is also to be noted that the results obtained here are the most critical values this scheme can give. Hence, the proposed simplified procedure can be judiciously used for the dynamic analysis, provided it is properly calibrated (using data recorded from instrumentation or analysis using comprehensive soil models) to get the correct damping ratio.

Change of soil permeability during and after soil liquefaction

Changement de perméabilité du sol pendant et après la liquéfaction du sol

ABSTRACT: In addition to the direct casualties caused by earthquakes, soil liquefaction induced by earthquakes can also lead to subsequent damage. Therefore, it is necessary to have a better understanding of soil liquefaction. Although previous studies have reported an increase in soil permeability during soil liquefaction, the rates of increase suggested by different scholars vary. As a result, this study conducts a series of shaking table liquefaction tests on loose to medium sand to further investigate this issue. The porewater pressure and settlement history are monitored, and the permeability history before, during, and after liquefaction is back-calculated based on the consolidation theory. The results show that the permeability during and after liquefaction is approximately 1.2 and 0.9 times the original value, respectively.

RÉSUMÉ: Outre les victimes directes causées par les tremblements de terre, la liquéfaction des sols induite par les tremblements de terre peut également entraîner des dommages ultérieurs. Il est donc nécessaire de mieux comprendre la liquéfaction des sols. Bien que des études antérieures aient signalé une augmentation de la perméabilité du sol lors de la liquéfaction du sol, les taux d'augmentation suggérés par différents chercheurs varient. En conséquence, cette étude mène une série d'essais de liquéfaction sur table vibrante sur du sable meuble à moyen pour approfondir cette question. La pression interstitielle et l'historique de tassement sont surveillés, et l'historique de perméabilité avant, pendant et après la liquéfaction est rétrocalculé sur la base de la théorie de la consolidation. Les résultats montrent que la perméabilité pendant et après la liquéfaction est respectivement d'environ 1,2 et 0,9 fois la valeur d'origine.

Keywords: Permeability, liquefaction, 1-D consolidation, shaking table.

1 INTRODUCTION

Most researches on soil liquefaction focus on the damages during shakings. However, damages may happen after shakings. Ambraseys and Sarma (1969) found sand boils occur at nearly 20 minutes after the Niigata earthquake during the dissipation of excess pore water pressure (EPWP). The EPWP dissipation rate is considered to be crucial for sand boil formation (Housner, 1958; Seed, 1979). Haigh et al. (2012) proved that the permeability (k) of sands increase with the generation of EPWP by experiments (Ueng et al., 2017). Adamidis and Madabhushi (2016) conducted one-dimensional tests to explain one-dimensional stiffness (E_0) changes with effective stress, in which stiffness during post-liquefaction EPWP dissipation is not constant. Brennan and Madabhushi (2011) proposed an EPWP function of time that could be used in back-calculating coefficient of consolidation (C_v), and the found C_v is not constant during dissipation, which indicates the permeability also varies. Zeybek and Madabhushi (2023) successfully simulate the post-liquefaction EPWP dissipation observed in the centrifuge tests, and found E_0 is more dominant than k in the consolidation process after liquefaction. In this study, the variation in permeability will be assessed using the test results obtained from torsional shaking table experiments, employing 1-D consolidation theory.

2 MATERIALS AND TEST SETUP

This study adopted the torsional shaking table to conduct model tests for observing the change of permeability during and after shakings. The configurations of test are shown in Figure1 (a). Four pore pressure transducers, an accelerometer, and a displacement (settlement) transducer are installed. The detailed configuration can be referred to Tsai et al. (2022). Moreover, seepage test can be also performed using the designed tube.

The testing material is C306 sand, categorized as SP, and its basic properties is provided in table 1. Water pluviation method is adopted in this study, and the schematic diagram is provided in Figure1 (b). The relative densities of specimens were set 68% (void ratio= 0.69). After finishing depositing specimens, torsional shakings were applied with a frequency range of 10 Hz to 25 Hz for 20 seconds to induce

liquefaction. In addition to the shaking test, constant-head seepage tests were performed for the same specimen prior and after vibration to obtain the permeability prior and after liquefaction, respectively.

Table 1. Basic Properties of C306 sand.

Materials	C306 Sand
Specific gravity of solids	2.65
Median size D_{50}(mm)	0.193
Coefficient of uniformity C_u	1.36
Coefficient of curvature C_d	1.1
e_{max}	0.922
e_{min}	0.598

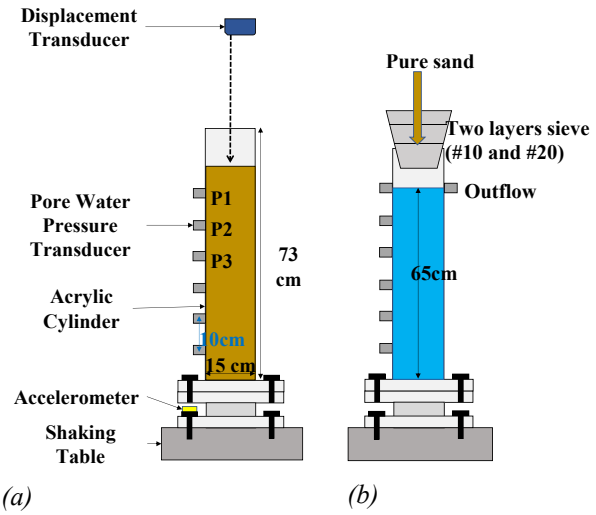

Figure 1. (a) Testing model (b) Specimen preparation method.

3 TEST RESULTS

Figure 2 shows the measured time history of PWP, settlement, and acceleration. Specimen liquefied within top 50-cm as indicated from the EPWP result (Figure 2(a)). The EPWP stayed at the high level (i.e. liquefaction condition) for a period of time (~ 20 sec) after shakings The high EPWP lasts differently at different elevations. Long durations were observed at the shallow depth, indicating the EPWP dissipates from the bottom to the top. On the other hand, it could be observed that settlement started right after shakings, and ended after fully dissipation of EPWP. The significant settlement rate was found during the shakings and the settlement continues after the shakings. These model tests with a relatively small size were conducted to observe the change of permeability during liquefaction under 1-g environment, and it may fail to offer an appropriate range in estimating the liquefaction permeability of soils in field due to the scale of tests.

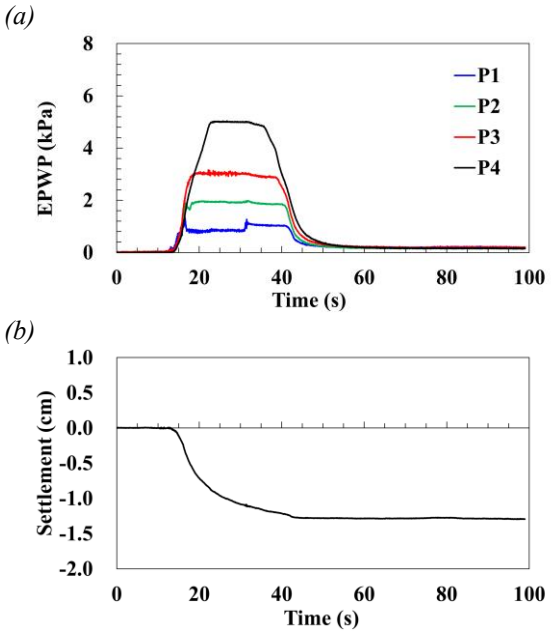

Figure 2. Test results (a) EPWP (b) settlement time history.

4 PERMEABILITY FROM 1-D CONSOLIDATION

From the additional 1-D consolidation tests of C306 sand, the relationships of E_0 and effective stress could be obtained, and could be explicated by the function (of effective stress) shown in Figure 3 with the suggestions from Zeybek and Madabhushi (2023). During the shaking table test, the effective stress in the specimen also varies due to EPWP. Hence, the changing r_u versus time (Figure 4) is considered in calculating changing E_0 due to varying effective stress. The consolidation degree (U) is estimated Equation (1) based on the measured settlement as shown in Figure 5.

$$U\ (\%) = \frac{S_n}{S_{final}} \tag{1}$$

where S_n is the settlement of each time step, and S_{final} is the final settlement of tests. Settlement initiates immediately after shakings and reaches its ultimate magnitude once the complete dissipation of EPWP has taken place. Hence, the settlement covers the time span from the initiation of shakings to the end of testing period. Afterward, C_v could be calculated during the test through Equation (2) to (4) as shown in Figure 6.

$$T_v = \frac{\pi}{4}\left(\frac{U}{100}\right)^2 \tag{2}$$

$$T_v = 1.781 - 0.933log(100 - U) \tag{3}$$

$$C_v = \frac{T_v H_{dr}^2}{t} \quad (4)$$

Where T_v Time factor calculated through Equation (2) or Equation (3) depending on U (60 or >60). After obtaining Tv, C_v (Figure 6) could be evaluated through Equation (4). H_{dr} is the longest drainage path for water in the specimen, and t is the consolidation time. Finally, k could be estimated from the obtained C_v and E0 (Haigh et al., 2012) per Equation (5).

$$k = \frac{C_v \gamma_f}{E_0} \quad (5)$$

As shown in Figure 7, k reach maximum of 0.035 cm/s during soil liquefaction and continue decreasing as the consolidation proceeds. According to the seepage test, k is 0.029 cm/s and 0.025 cm/s before and after liquefaction. The results indicate that liquefaction induces a higher permeability (about 15% higher) due to loosen contacts between particles. The loosen contacts make water flow through specimens more readily without bypassing grain contacts as explained by Ueng et al. (2017). However, after the liquefaction, k is lower caused by a denser condition due to consolidation. In Figure 7, k in the end of settlement is close to the value obtained from seepage test after liquefaction. Hence, k during the EPWP build-up process (beginning of settlement) lower than 0.029 that would be wrong was eliminated herein. This paper presented the view from 1-D consolidation to evaluate the changing permeability of sands during liquefaction, and it is worth noted that the evaluation of true E_0 of liquefied sands is critical.

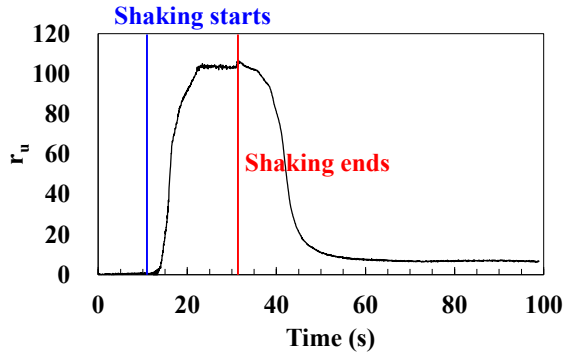

Figure 4. Measured ru time history.

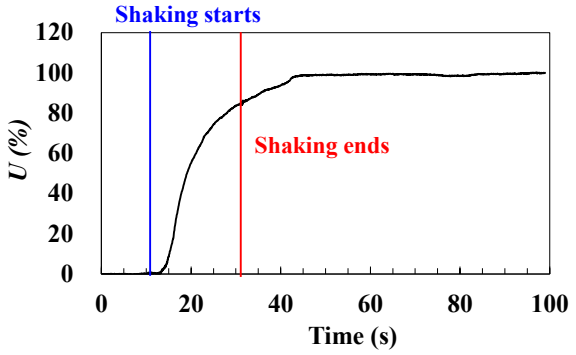

Figure 5. Consolidation degree (U) versus time.

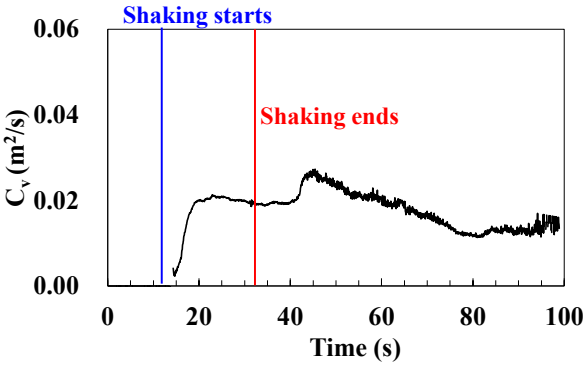

Figure 6. Derived Cv time history.

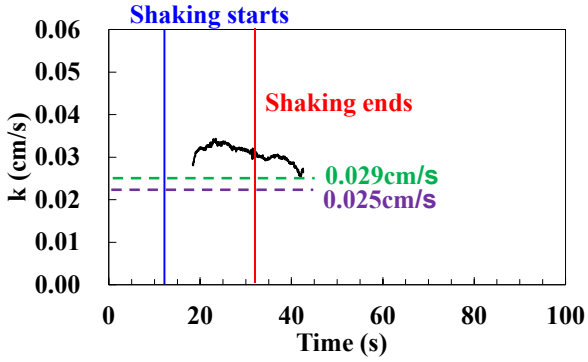

Figure 7. Derived k time history.

5 CONCLUSIONS

This study conducted torsional shaking table tests to evaluate permeability variations in liquefied soil. The settlement was measured, and in conjunction with 1-D consolidation theory, the permeability during soil liquefaction was calculated.

Notably, the onset of settlement was immediately observed following the shaking events. Furthermore, the test results demonstrated a notable increase in permeability (denoted as k) of up to 15% upon soil liquefaction. Interestingly, post-liquefaction, the permeability decreased due to a denser condition resulting from consolidation processes.

The current design practice did not consider the effect of changing permeability due to liquefaction. However, the changing permeability may be related to liquefaction settlement, which may influence the serviceability of structures with enough bearing capacity. These findings provide valuable insights into the dynamic behavior of liquefied soil, highlighting the temporal evolution of permeability and its correlation with settlement patterns.

ABSTRACT: Rainfall-induced soil erosion in hilly regions is considered a significant geohazard due to its potential to cause substantial damage to infrastructure and human settlement. Soil improvement through microbial-induced calcite precipitation (MICP) using native bacterial strain is a novel approach that can alleviate concerns regarding this issue. The current study presents the soil improvement potential of a native urease-producing bacterial strain isolated from the slope failure region of Uttarakhand, India. The strength improvement and erosion resistance of treated soil were investigated through unconfined compressive strength (UCS) and rainfall-induced erosion tests, respectively. Further, the durability of the treatment was confirmed through the wet-dry cycle of the treated soils. The test results exhibited an enhancement in soil strength due to the binding of soil grains with precipitated calcite crystals. The rainfall simulation test revealed a significant reduction in soil mass loss after the MICP treatment, which was confirmed through microscopic investigations. Interestingly, the treated soil samples showed negligible soil erosion even after subjecting the samples to seven wet-dry cycles.

RÉSUMÉ: L'érosion des sols induite par les précipitations dans les régions montagneuses est considérée comme un géorisque important en raison de son potentiel de causer des dommages importants aux infrastructures et aux établissements humains. L'amélioration des sols grâce à la précipitation de calcite induite par des microbes (MICP) à l'aide d'une souche bactérienne native est une nouvelle approche qui peut atténuer les inquiétudes concernant ce problème. La présente étude présente le potentiel d'amélioration des sols d'une souche bactérienne produisant de l'uréase native isolée de la région de rupture de pente de l'Uttarakhand, en Inde. L'amélioration de la résistance et la résistance à l'érosion du sol traité ont été étudiées respectivement par des tests de résistance à la compression non confinée (UCS) et d'érosion induite par les précipitations. De plus, la durabilité du traitement a été confirmée par le cycle sec-humide des sols traités. Les résultats des tests ont montré une amélioration de la résistance du sol en raison de la liaison des grains du sol avec des cristaux de calcite précipités. Le test de simulation de pluie a révélé une réduction significative de la perte de masse du sol après le traitement MICP, ce qui a été confirmé par des analyses microscopiques. Il est intéressant de noter que les échantillons de sol traités ont montré une érosion négligeable même après avoir soumis les échantillons à sept cycles humides-secs.

Keywords: Rainfall-induced soil erosion; urease-producing bacteria; MICP; unconfined compressive strength.

1 INTRODUCTION

The hilly regions are prone to geohazards such as soil erosion, landslides, and debris flow (Froude and Petley, 2018), significantly impacting socio-economic facilities. These events occur over weathered soil slopes that possess soil mass of low strength characteristics and are susceptible to loss of strength due to natural agents such as rainfall. Traditional chemical soil stabilization methods, such as cement (Daraei et al., 2018), have been used to provide interparticle bonding, improving the soil slope characteristics. However, using these methods brings environmental concerns such as carbon emissions, due to which researchers are exploring different environmentally friendly soil stabilization methods that can reduce the dependency on these chemical stabilizers. Microbial-induced calcite precipitation (MICP) is a bio-engineering technique that uses the metabolic activity of the urease-producing bacteria to catalyze the urea hydrolysis process in the presence of urea and calcium chloride (Dejong et al., 2010). The $CaCO_3$ crystals formed due to the process bind the soil particles together and enhance the soil properties. This technique has been explored for applications such as soil erosion mitigation (Devrani et al., 2021; Dubey et

al., 2021), slope stabilization (Gowthaman et al., 2022) etc. However, few studies have been carried out on its application for rainfall-induced soil erosion such as Xiao et al. (2022). The surfaces of soil slopes are in close proximity to the atmosphere and experience periodic Wet-Dry (W-D) cycles as a result of diurnal shifts in cloudy and sunny weather, as well as the accompanying rainfall-evapotranspiration process (Tang et al., 2016). These cycles act as a slope weathering agent and is a severe concern for geotechnical and geological engineers, that results in irreversible deformations in the geomaterials and deteriorates its strength properties to a significant extent. The deterioration in the mechanical characteristics of the calcarenite rocks due to the W-D process was confirmed by Ciantia et al. (2013). Since the MICP-treated soils are often compared with the carbonate sediments, they may likely undergo deterioration due to the prolonged W-D process. Research studies such as Gowthaman et al. (2022) have investigated the effect of W-D cycles on the strength of MICP-treated soil. However, the result of the W-D cycle on the erosion resistance of MICP-treated soil under direct rainfall impact has not been studied before. Thus, the resilience of the MICP-treated soils against this process must be investigated.

Therefore, the current study investigates the potential of the MICP technique through a native bacterium from the hilly region for soil strength improvement and resistance against rainfall-induced soil erosion. Further, the durability of the treated soil sample was investigated by subjecting the soil samples to seven W-D cycles.

2 MATERIALS AND METHODS

2.1 Soil properties

A soil mixture of silty sand (85 % sand +15 % silt) was prepared and used to study the soil improvement through MICP. Table 1. presents the values of different soil properties and the testing method adopted.

Table 1. Soil properties.

Soil properties	Values	Testing method
Specific gravity	2.7	ASTM D854
Min. dry unit weight, kN/m^3 (γ_{dmax})	13.3	ASTM D4253
Max. dry unit weight, kN/m^3 (γ_{dmin})	16.2	ASTM D4254
Coefficient of uniformity (C_u)	5.2	ASTM D6913
Coefficient of curvature (C_c)	1.8	ASTM D6913

2.2 Ureolytic bacterium and bacterial suspension

A urease-positive bacterial isolate R1_5 was used to trigger the bio-cementation process. The bacterium was cultivated in nutrient broth (NB) medium (13 g/l) in a shaking incubator at 200 rpm for 18-24 h at 30ºC. The bacterial suspension with OD_{600} = 0.8-1.0 was used for soil treatment.

2.3 Soil sample preparation

A split mold set of 0.038 m diameter and 0.076 m height with an open top and closed bottom was used to prepare soil columns for the strength test. A circular splash cup of 0.1 m diameter and 0.025 m height was used to prepare soil samples for rainfall-induced erosion testing. Both soil mould and splash cups have a small opening at the bottom to facilitate drainage. A piece of filter paper was placed at the bottom of the mould and cup to prevent the migration of particles. The soil samples in both tests were prepared at 30% relative density, representing the loose soil condition using the air pluviation method followed by the tamping technique.

2.4 MICP-treatment

The soil treatment was carried out in stages. At each stage, one pore volume of solution was added through surface percolation in a split set mould and splash cup. The most feasible MICP-treatment sequence from Devrani et al. (2023) was adopted for soil treatment. For treatment, the soil was initially flushed with water to remove air voids. Then, a pretreatment solution with $NaHCO_3$ and NH_4Cl was added to advance the formation of bicarbonate radicals and the rate of hydrolysis, respectively, and left undisturbed for 6 h. The bacterial suspension of OD_{600}= 0.8-1.0 was added to allow uniform attachment of bacteria. Later, cementation solution (CS), which consisted of Urea, $CaCl_2.2H_2O$, $NaHCO_3$, and NH_4Cl, was prepared and added. Then, autoclaved nutrient broth (NB) and CS were added consecutively for 14 days. After that, the soil samples were rinsed with water and then oven-dried and tested.

2.5 Unconfined compressive strength testing

The treated soil column samples were dried, and unconfined compressive strength testing was carried out as per IS:2720 (Part 10). 1991. The sample was tested at a strain rate of 1 mm/min. The load values and vertical displacement were continuously recorded, and the axial stress corresponding to sample failure was reported as the unconfined compressive strength

(UCS) of the sample. The testing was performed on triplicate samples, and the average values is reported.

2.6 Rainfall-induced erosion testing

The untreated and treated splash cups were dried, and their initial weights were measured. Then, splash cups were placed under a simulated rainfall of 120 mm/h at a slope angle of 30º in a rainfall erosion simulator for 1 h and then allowed for oven-drying for a minimum of 42 h at 70 ± 1ºC to remove the moisture following the method suggested by ASTM (2003) and Gowthaman et al. (2022) and then final weight was measured. The weight difference between the initial weight, i.e., before the test, and the final weight, i.e., oven-dried weight, was used to calculate the percentage soil mass loss due to rainfall. The soil samples were subjected to 7 wet-dry cycles to investigate the potential of MICP-treated soil and were compared with untreated soil samples. Triplicates were investigated for untreated and treated soil samples, and their average and standard deviation are reported. Later, the erosion resistance of soil due to bacteria-induced bio-cementation was confirmed through scanning electron microscopy (SEM).

3 RESULTS AND DISCUSSION

3.1 Unconfined compressive strength of MICP-treated soil

The untreated soil was cohesionless with no strength. However, a solidified soil column was obtained upon treatment, and unconfined compression testing was performed. The test results demonstrate an unconfined compressive strength of about 495 kPa upon soil treatment. A typical stress-strain behavior of the MICP-treated soil is shown in Figure 1. The strength improvement in the soil is attributed to the precipitation of calcite crystals and the binding of soil particles together. It was also established that soil strengthening is possible in the presence of silt content; however, the strength values are reduced compared to strength values in soil with low silt content, as observed by Karimian and Hassanlourad (2022).

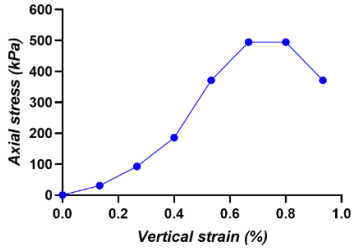

Figure 1. Typical stress-strain curve of MICP-treated soil.

3.2 Erosion of untreated and MICP-treated soil

The soil samples subjected to rainfall testing showcased soil loss in both untreated and treated samples. However, the soil loss rate in untreated samples was much higher and ranged from 22.11 % to 68.64 % after 1st and 7th wet-dry cycles, respectively. Whereas the soil samples upon MICP treatment reduced the soil loss to about 2.1 % after 1st cycle, which loss to only about 4.43 % after 7th cycle. Figure 2 represents the soil loss in untreated soil samples, ranging. However, the soil loss after MICP treatment was significantly lower. The reduction in soil loss values indicates improvement in shear strength characteristics of the soil due to the binding of soil particles together that does not allow the soil particles to disintegrate due to the impact of raindrops and runoff over the soil surface under high intense rainfall.

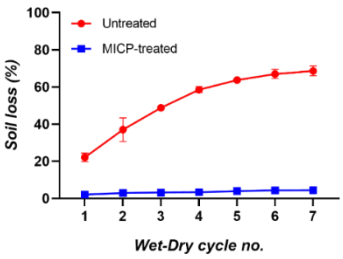

Figure 2. Soil loss in untreated and MICP-treated soil after different wet-dry cycles.

3.3 Scanning electron microscopy (SEM)

The soil specimens after the erosion testing were studied under scanning electron microscopy (SEM). Figure 3 and Figure 4 present the untreated and bio-cemented soil specimens after rainfall-induced erosion testing. The formation of calcite crystals due to bacteria-induced bio-cementation can be observed in Figure 4, and the resistance of the cemented soil particles against the rainfall can be speculated from the bound soil particles, which can be clearly visible even after being subjected to 7 wet and dry cycles, unlike untreated specimens in which only sub-angular shape soil grains with no binding can be observed. The strength improvement and erosion resistance of the bio-cemented soil particles is due to the calcite crystal formation that bonded the soil particles together.

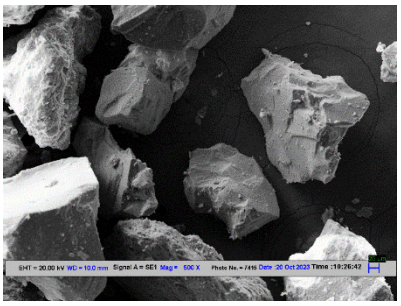

Figure 3. Untreated soil specimen after wet-dry cycle.

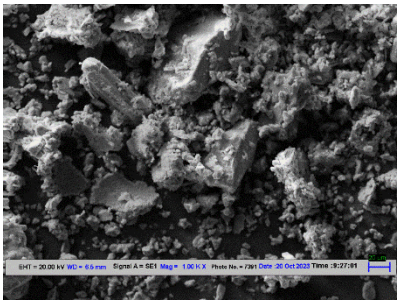

Figure 4. Bio-cemented soil specimen after wet-dry cycle.

4 CONCLUSIONS

The study investigates the potential of a ureolytic bacterial isolate for soil strength improvement and erosion resistance against rainfall-induced soil erosion. A solidified soil column with a UCS of 495 kPa was formed after MICP treatment with the bacterial isolate. The soil erosion test results revealed an 11-fold resistance of the treated samples against rainfall-induced erosion compared to untreated samples after 1st wet-dry cycle. Further, the erosion resistance in treated samples increased to 16-fold, when compared to untreated samples after 7 wet-dry cycles. The low values of soil loss in MICP-treated samples showcase the potential of the treated soil samples for resilience against a more significant number of wet-dry cycles, which can be investigated further.

ABSTRACT: Evaluating undrained shear strength in clayey soils, especially soft sensitive clays in Finland, is crucial for several geotechnical engineering applications. In-situ investigation methods, including field vane and piezocone testing, offer versatile methodologies to assess the soil parameters, overcoming issues related to undisturbed soil sampling. Challenges in using the field vane in soft sensitive clays are discussed, as well as the improvements offered by piezocone testing. However, evaluating cone factors to assess the undrained shear strength is not straightforward, owing to soil strength anisotropy and overconsolidation effects. The paper focuses on assessing the undrained and remoulded shear strength in Finnish soft sensitive clays based on an extensive experimental program conducted at four different test sites, comparing the results obtained from piezocone, field vane, and fall cone tests. Discrepancies among these methods are highlighted, as well as possible improvements in devices and test interpretation to assess the soil parameters correctly.

RÉSUMÉ: L'évaluation de la résistance au cisaillement non drainé dans les sols argileux, en particulier dans les argiles sensibles et molles de Finlande, revêt une importance cruciale pour plusieurs applications en génie géotechnique. Les méthodes d'investigation in situ, telles que le test de la gaine et le test de la piezocone, offrent des approches polyvalentes pour évaluer les paramètres du sol, surmontant ainsi les problèmes liés à l'échantillonnage non perturbé du sol. Les défis liés à l'utilisation du test de la gaine dans les argiles sensibles sont discutés, ainsi que les améliorations offertes par le test de la piezocone. Cependant, l'évaluation des facteurs de cône pour évaluer la résistance au cisaillement non drainé n'est pas aisée, en raison de l'anisotropie du sol et de la surconsolidation. L'article se concentre sur l'évaluation de la résistance au cisaillement non drainé et remaniée dans les argiles sensibles de Finlande, sur la base d'un vaste programme expérimental mené sur quatre sites d'essais différents, comparant les résultats obtenus à l'aide du piezocone, du test du scissomètre et du test du pénétromètre à cone tombant. Les divergences entre ces méthodes sont mises en évidence, de même que les améliorations possibles des dispositifs et de l'interprétation des essais pour évaluer correctement les paramètres du sol.

Keywords: Clays, cone penetration, fall cone, piezocone, sensitivity, shear strength, vane.

1 INTRODUCTION

The accurate determination of undrained shear strength (s_u) in clayey soils is a crucial aspect upon which critical decisions regarding foundation design, embankment stability, and overall geotechnical infrastructure depend. In the context of Finnish clays, undrained shear strength assessment has been a subject of particular interest, notably through the utilization of the Field Vane Shear Test (FVT) and the Cone Penetration Test with pore pressure measurements (CPTU) (Di Buò 2020; Selänpää 2021; Länsivaara et al. 2022). Furthermore, it is common practice to collect undisturbed samples for conducting the fall cone tests (FCT) to assess the intact and remoulded strength properties of soft sensitive clays in Finland.

FVT is established as a common practice for determining undrained shear strength. Recent research

studies conducted at Tampere University of Technology (Selänpää et al. 2017) have revealed the potential underestimation of undrained shear strength in soft sensitive clays when using FVT due in part to soil disturbance caused during predrilling and vane insertion, strain rate effects, non-uniform shear stress distribution around the vane, uncertainties in soil-rod friction evaluations, waiting time between vane insertion and rotation, apparatus maintenance, and calibration, as well as measurement system accuracy and errors.

Moving beyond the traditional FVT, the CPTU offers a rapid and continuous in-situ approach to evaluate s_u, providing readings of cone tip resistance (q_c), sleeve friction (f_s), and porewater pressure measured behind the shoulder (u_2) (Lunne et al. 1997).

Nevertheless, the cone factors N_{kt} and $N_{\Delta u}$ are needed to evaluate s_u from CPTU data based on the correlations $s_u=(q_t-\sigma_{v0})/N_{kt}$ and $s_u=(q_t-\sigma_{v0})/N_{\Delta u}$, where q_t is the corrected cone tip resistance for unequal end area effects (Jamiolkowski et al. 1985; Robertson and Campanella 1988; Lunne et al. 1997), σ_{v0} is the total vertical stress, and u_0 is the in-situ water pressure.

In overconsolidated clays, characterized by dilative stress-strain behaviour, the cone-bearing factor N_{kt} determination is rather challenging due to the strain level at which laboratory undrained strength is defined and the noted decrease of overconsolidation ratio (OCR) with depth (D'Ignazio & Lehtonen 2021).

Moreover, further challenges arise when taking into account the s_u anisotropy in clay in stability analysis, specifically active ($s_{u,A}$), passive ($s_{u,P}$), and direct simple shear ($s_{u,DSS}$) modes. These differences in undrained shear strength behavior occur due to the unique stress paths, direction of loading, and strain levels associated with each loading mode (Bjerrum 1973).

In this scenario, the CPTU data can be employed to assess the s_u in compression, whereas the FVT is more directly associated with determining simple shear, $s_{u,DSS}$. Consequently, making a direct comparison between these two tests may yield different results.

In the study of soft sensitive clays, a critical focus lies in assessing remoulded shear strength ($s_{u,rem}$) and soil sensitivity (S_t). These clays exhibit a relatively stiff response in their undisturbed state but transform into a viscous liquid upon remoulding, as initially noted by Rosenqvist (1953). The S_t is a parameter defined as the ratio of peak s_u to the corresponding $s_{u,rem}$ at the same water content (w). The term 'quick clay' characterizes highly sensitive clays with S_t values exceeding 50 and $s_{u,rem}$ values below 0.4 kPa (Rankka et al., 2004). However, establishing an unambiguous definition of quick clays remains challenging, as various classification systems have been put forth, including those by Rosenqvist (1953), Bjerrum (1954), Holtz et al. (2011), and Rankka et al. (2004).

Traditionally, $s_{u,rem}$ and S_t are determined through fall cone tests on soil samples. However, this method can be costly and time-consuming, especially when faced with the challenges of obtaining high-quality undisturbed samples (Ladd and DeGroot, 2003; Di Buò et al., 2019). Consequently, the prospect of assessing soil sensitivity through field testing becomes increasingly attractive.

CPTU provides a promising solution for estimating remoulded strength, utilizing f_s that reflects the frictional resistance encountered as the sleeve penetrates the soil. It is important to note that several authors have addressed concerns about the accuracy and resolution of sleeve friction measurements in soft, sensitive clays, where measured friction values can dip below 1 kPa (Lunne et al. 1997). These challenges can be mitigated by employing piezocones with higher resolution and precision (Di Buò et al., 2022).

Additionally, $s_{u,rem}$ can be measured using FVT. In this approach, the vane's rotational speed is increased to 6°/s, and measurements are taken after a 3600° vane rotation. Selänpää et al. (2017) discussed issues related to inaccuracies in remoulded strength evaluation based on FVT, which may stem from device-related factors, such as loose connections between the vane axle and the rotating system, vane tilt movements causing a 'wave' effect, and potential variations in pore pressure distribution around the remoulded area.

One aim of this paper is to exploit data obtained from an extensive experimental program conducted on Finnish soft sensitive clays (Di Buò 2020, Selänpää 2021, Länsivaara et al. 2022) and evaluate profiles of s_u from CPTU, FVT, and FCT test with particular emphasis on the values of the factors N_{kt} and $N_{\Delta u}$. Moreover, a comparative analysis is conducted among CPTU, FVT, and FCT methods to assess the remoulded shear strength, aiming to explore disparities arising from the diverse approaches.

In the following sections, the raw, direct measurements of FVT and FCT are utilized. They have not been empirically corrected based on plasticity.

2 EXPERIMENTAL DATA FROM SITES

The data included in this paper are a part of an extensive research project conducted by the Research Centre Terra at Tampere University in collaboration with the Finnish Transport Agency. The primary objective of this study was to establish robust correlations for estimating s_u and the preconsolidation stress (σ'_p) in Finnish soft clays. Furthermore, this research aimed to promote the utilization of CPTU as a solution to address challenges associated with the

traditional FVT method. For a more comprehensive understanding of this research and its findings, details are given by Di Buò (2020), Selänpää (2021), and Länsivaara et al. (2022).

The experimental program encompassed various test sites across Finland. However, the focus of this paper is on four specific sites within the country, namely Perniö, Masku, Paimio, and Sipoo. The main geotechnical properties of the investigated sites, including water content (w), plasticity index (PI), and soil sensitivity (S_t), are detailed in Table 1. The investigated clays are characterized by low OCR (1.2 – 1.50), high natural water content (40 – 120), and plasticity index, ranging between 20 and 70. The Masku and Sipoo clays are characterized by lower sensitivity compared to the Perniö and Paimio clays.

These sites have been investigated by using a low-capacity cone (7.5 MPa), which is suitable in sensitive clay deposits, and an innovative electric downhole FVT device equipped with a casing. Moreover, samples have been retrieved with a tube sampler to overcome the difficulties related to sample disturbance in soft sensitive clays. Details of the devices and testing procedure are discussed by Selänpää et al. (2017), Di Buò (2020), and Länsivaara et al. (2022).

Table 1. Geotechnical properties of the investigated clays.

Site	Depth	w (%)	PI (%)	S_t
Perniö	2.0 – 3.0	100 – 110	40	40 – 60
	3.0 – 4.0	70 – 100	30	50 – 70
	4.0 – 6.0	70 – 90	30	50 – 70
	6.0 – 8.0	90 – 110	40	70 – 90
Masku	3.0	80	40	20
	5.0	120	70	20
	7.0	60 – 80	50	20
Paimio	3.0 – 5.0	40 – 80	20	60 – 100
	6.0 – 7.0	90 – 110	40	80 – 90
	7.0 – 9.0	70 – 90	40	60 – 80
Sipoo	2.0 – 3.0	80 – 100	50	20 – 40
	5.0 – 7.0	90 – 110	60	20 – 30
	8.0 – 9.0	80 – 100	50	15

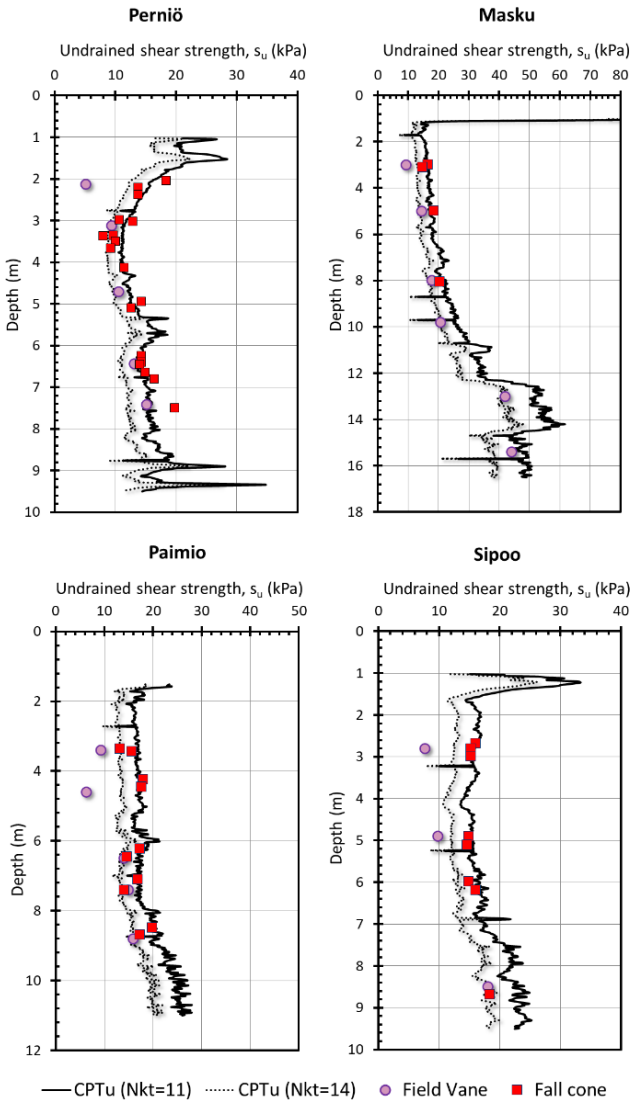

Figure 1. S_u profiles based on CPTU, FVT, and FCT with indications of the best-fit N_{kt} factor.

3 EXPERIMENTAL PROGRAM RESULTS

3.1 Undrained shear strength evaluation

The undrained shear strength profiles, derived from CPTU, and the intact strength determined using the FVT and FCT are illustrated in Figures 1 and 2 using q_{net} and Δu_2, respectively, for each of the 4 sites. Notably, a single representative CPTU profile was selected for each site, specifically those characterized by the highest data quality.

The N_{kt} and $N_{\Delta u}$ factors were assumed to optimize the fit of the FVT and FCT data. It is evident that, across all the sites examined, the s_u values determined by the FCT consistently exceed those obtained from the FVT. In some instances, such as Paimio and Sipoo, it is possible that the FVT data may have been affected by inaccuracies related to device or testing issues, resulting in unrealistically low s_u values.

The calculated N_{kt} values range from 11 to 14, while $N_{\Delta u}$ values range from 8 to 11, with the lower values providing a better fit to the FCT data. The variability in the evaluation of s_u results from many variables: soil heterogeneity, device precision and accuracy, interpretation methods, and operator skills, to name a few.

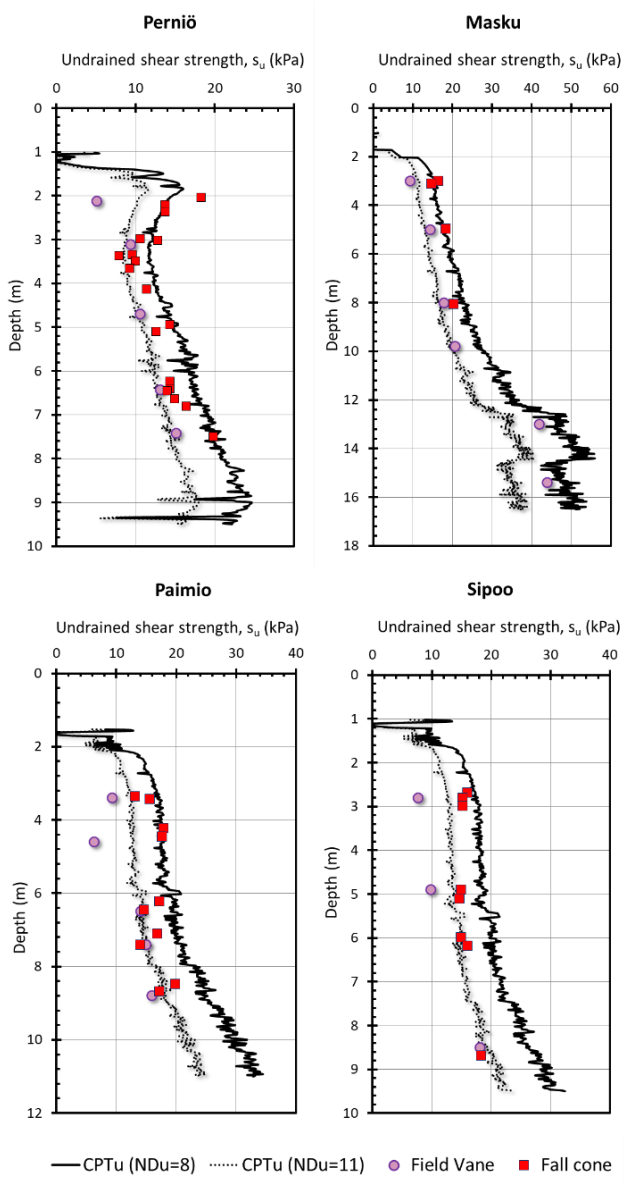

Figure 2. S_u profiles based on CPTU, FVT, and FCT with indications of the best-fit $N_{\Delta u}$ factor.

3.2 Evaluation of $s_{u,rem}$ and S_t

The assessment of $s_{u,rem}$, and S_t in soft sensitive clays presents notable challenges stemming from the inaccuracies associated with field test devices, including CPTU and FVT, as well as considerations related to sample quality and laboratory test procedures in the case of FCT. In the case of the FVT, the value of $s_{u,rem}$ is obtained from the residual torque reading after 10 full revolutions of the rotated vane. For the FCT, after a peak s_u is obtained, the sample is remoulded and tested again using a free-fall drop cone weight to obtain $s_{u,rem}$. For the CPTU, the normal assumption is that the remoulded strength is equal to the measured sleeve friction, i.e., $s_{u,rem} = f_s$ (e.g., Lunne et al. 1997). However, a recent database study (Mayne et al. 2023) has shown that while f_s provides a reasonable value of $s_{u,rem}$ in a variety of clays having low-medium sensitivity, in fact, f_s in highly-sensitive to quick clays overpredicts the $s_{u,rem}$ by a factor of 2 to 10.

Figure 3 presents a comparison of field data on 16 clays in terms of remoulded vane strength (s_{ur}) versus measures of sleeve friction (f_s). The database included 11 clays of low-medium sensitivity ($S_t < 15$) and 5 clays that are of high sensitivity ($S_t > 15$).

Notwithstanding these challenges, it is evident that FCT stands out as the most reliable method for evaluating $s_{u,rem}$, provided that the natural water content (w) is maintained. The data collected from the surveyed sites in Finland are presented in Figure 4, illustrating that CPTU is incapable of accurately directly estimating $s_{u,rem}$ due to limitations in sleeve sensor resolution. In contrast, FVT yields closer agreement with the values measured via FCT, although the results consistently exhibit higher values. These observations have been previously discussed by Selänpää et al. (2017) and Di Buò et al. (2022).

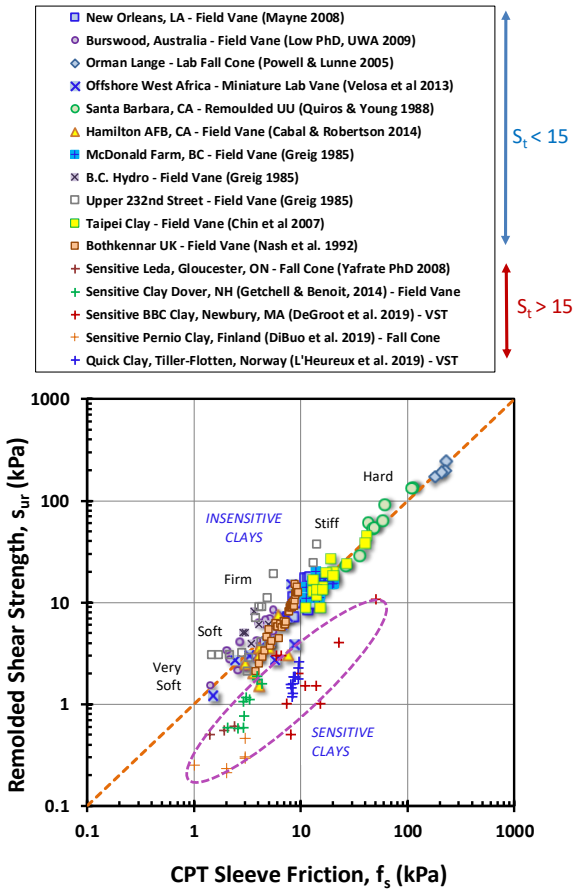

Figure 3. Measured values of remoulded undrained shear strength from FVT (s_{ur}) versus CPTU sleeve friction (f_s) for 16 clays (after Mayne et al. 2023).

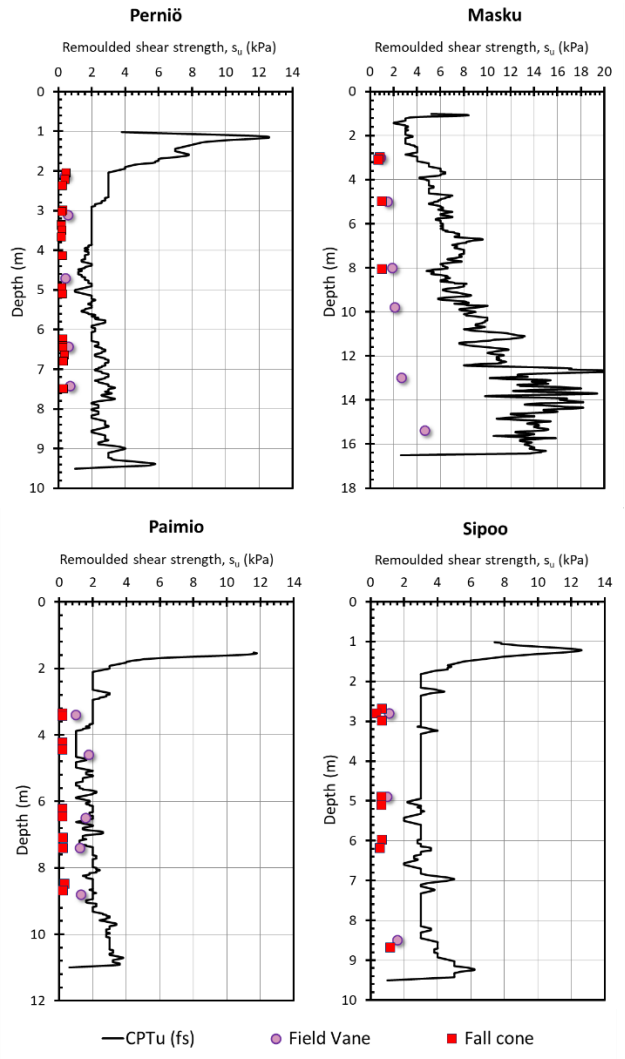

Figure 4. $S_{u,rem}$ profiles based on CPTU, FVT, and FCT.

4 CONCLUSIONS

Assessing the strength parameters s_u, $s_{u,rem}$, and S_t in soft sensitive clays is rather challenging, owing to several factors, including different devices, testing methodologies, interpretation methods, and soil properties variability. This paper reports findings obtained from 4 test sites located in soft sensitive clay deposits in Finland. The primary outcomes of this research study can be summarized as follows:

- The intact strength, as determined by the FCT, generally exceeds the s_u measured by the FVT.
- The best fit N_{kt} values fall within the range of 11 and 14, while $N_{\Delta u}$ values span from 8 to 11, with the lower value fits better the FCT data;
- The CPTU sleeve friction is not a suitable method to correctly estimate $s_{u,rem}$ due to the limited resolution of the load cell sensor, whereas the FVT provides comparable values to those measured through the FCT.

ABSTRACT: A slope adjacent to a northbound regional motorway, outside the city of Barcelona, has shown signs of instability, which have affected the functionality of the road. An extensive instrumentation system has allowed to observe the movement of the slope and locate the slip surface in various sections. The paper presents the study of the instability phenomenon and its origin by means of 2D numerical analyses. Monitoring data has been used to validate the numerical model and to reproduce the observed slope behaviour. In the present work, the features of the numerical study are described and the results are then compared with the in-situ observations.

RÉSUMÉ: Une pente adjacente à une autoroute régionale en direction nord, à l'extérieur de la ville de Barcelone, a montré des signes d'instabilité qui ont affecté la fonctionnalité de la route. Un vaste système d'instrumentation a permis d'observer le mouvement de la pente et de localiser la surface de glissement dans différentes sections. L'article présente l'étude du phénomène d'instabilité et de son origine au moyen d'analyses numériques 2D. Les données de surveillance ont été utilisées pour valider le modèle numérique et reproduire le comportement de pente observé. Dans le présent travail, les caractéristiques de l'étude numérique sont décrites et les résultats sont ensuite comparés aux observations in situ.

Keywords: Slope analysis; numerical modelling; monitoring; stabilizing measures.

1 INTRODUCTION

Instability phenomena on natural and cut slopes are, in general, highly complex phenomena that must be properly identified to select appropriate stabilising measures (Alonso, 2021, Argyroudis et al., 2019). An incorrect estimation of these phenomena can lead to the adoption of ineffective or even counterproductive solutions for their stabilisation (Corominas, 2006).

Road networks are often exposed to the instability phenomena of nearby slopes, with the consequent impact on their users, as well as on the same transport infrastructures. Identifying problematic areas and managing the associated risks represent a priority to guarantee both the functionality and safety of road networks (Mavrouli et al. 2019).

The present work summarises the results of a 2D numerical finite element (FE) analysis carried out to study the stability of a slope adjacent to a road north of the city of Barcelona. Slope monitoring has provided detailed information on the instability mechanism and the location of the slip surface. The numerical results are compared with in-situ observations.

2 DESCRIPTION OF THE CASE STUDY

The slope object of this study borders a motorway whose construction dates back to the late 1980's. On the upper part of the slope an old quarry is present, the exploitation of which lasted a little over 40 years, from around 1960 to 2004 (Fig. 1). The materials extracted from the quarry were dolomites and limestones used mostly in the construction industry.

To reduce the environmental impact of the quarry and prevent the degradation of the slope, restoration measures were implemented once the activity of the quarry ended. The open-pit mine was hence converted into a construction and demolition waste (CDW) disposal deposit. A few years after the slope restoration began, a number of anomalies and defects signs repeatedly appeared on the pavement of the motorway, at the toe of the slope (Di Mariano and Gens, 2023).

The first study to determine the origin of the pavement's faults was carried out in 2008 and some corrective measures were implemented along the toe of the slope. At that time, the road deficiencies were

attributed to the possible presence of expansive materials below the pavement of the road. The implemented corrective measures, which included the construction of a gabion wall (Fig. 1), were nevertheless inadequate to definitely recover the road safety and functionality. Later on, in 2017, when significant repair works were being executed, the Contractor was able to relate the road deformation signs exclusively to the movement of its adjacent slope. An extensive monitoring plan was hence deployed to keep track of the slope instability phenomenon and properly define its limits.

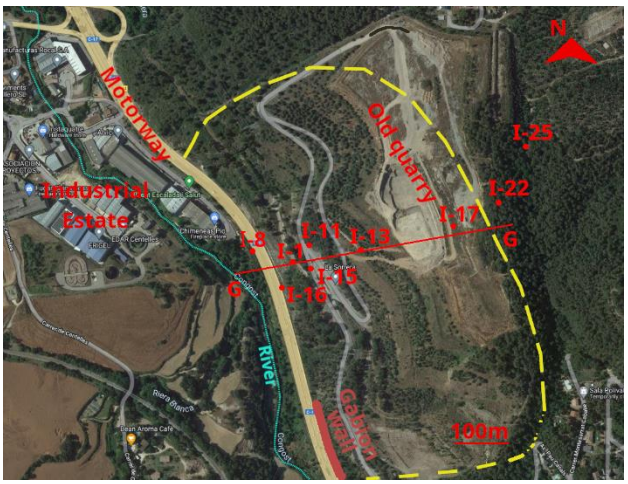

Figure 1. Layout of the motorway and the old quarry on the upper part of the slope (right-hand side). The picture also shows the industrial estate on the opposite side of the road with respect to the unstable slope (discontinuous line) and the location of Section G object of this study (Google maps image).

2.1 Geological Conditions

The lithological sequence of the slope in the area under study includes the materials listed in Table 1, from the most recent (RC) to the oldest (BC).

According to the latest available data, the failure surface of the slope is located at a depth of about 40 m, mainly placed within the shales layer (unit BC in Fig. 2), the upper part of which appears strongly weathered. During the exploitation of the old quarry, the excavation of the upper quaternary materials left the underlying shales layer exposed to atmospheric agents in many parts of the slope, probably favouring its weathering. When the restoration process began and the quarry was converted into a CDW disposal deposit, the hydraulic conditions of the slope changed mainly due to the fact that the base of the deposit was waterproofed.

The unstable slope directly affects the regional motorway, as well as nearly the entire old quarry location (Figs 1-2). It also indirectly affects the bed of a river located downhill from the motorway, an industrial estate located between the motorway and the river, as well as some telecommunications and electrical supply lines (Di Mariano et al., 2022).

Table 1. Lithological sequence of the slope under study.

Material	USCS	Description
RC	-	Construction waste materials
R	-	Anthropic fills
E	Not available	Eocene siltstones and sands
Q	GC	Sandy clays with gravel from the Quaternary Era
M*	CL	Alternation of dolomitic and calcareous rocks from the Middle Triassic
BC	SC, CL	Shale, claystone and sandstone deposits from the Lower Triassic

*(materials exploited in the old quarry)

2.2 Field Instrumentation

The motorway, its adjacent slope and the waste deposit, including their surroundings, are extensively instrumented. The monitoring system comprises topographic and geotechnical devices to control the evolution of both surface and subsurface ground movement, as well as to locate the slope slip surface (Figs 1-2 show all biaxial inclinometers, I, in section G). Topographic surveys include both geometric and GPS (Global Positioning System) levelling. Field monitoring also consists of open standpipes and vibrating wire piezometers (indicated as PZ in Fig. 2) to observe variations in the water table and pore water pressure evolution at the slip surface, respectively.

The main purpose of this extensive monitoring plan was to identify the origin of the slope instability. The observed movements indicated that the slope was indeed moving and that the depth of the slip surface was about 40 m (Fig. 2).

2.3 Origin of the instability and corrective measures

The removal of dolomitic and calcareous rocks from the head of the slope caused a gradual increase in the slope Safety Factor (SF), which decreased during the construction of the motorway, almost 30 years later, due to the cut made at the slope's toe. Later, when the old quarry was converted into a waste deposit, the head of the slope was loaded with time, producing a further and progressive decrease in its SF that eventually led to the instability of the slope when the restoration process was almost completed.

Once the origin of the problem in the motorway was identified, the Contractor performed some

numerical analyses to study the effect of possible corrective measures on the stabilisation of the slope. Different measures such as the construction of diaphragm walls as a reinforcement at the road level or the application of a ground load at the toe of the slope, with the consequent diversion of the river on the other side of the slope or the removal of the waste material at the head of the slope were considered. Among all of them, the latter was selected as the most appropriate in terms of environmental impact, flexibility, cost and time of execution. The unloading of the head of the slope began in 2018 and continued until February of 2022.

The slope movement rate varied over time with both the hydraulic conditions and the excavated volume of waste material. As soon as the unloading process started, the rate of the slope movement decreased, even though at the beginning it was yet quite sensitive to changes in pore water pressures. As the removal of waste material continuously reduced the driving forces on the slide, the movement became progressively slower. Currently, with the unloading process yet to be completed, the movement rate is approximately 0.3 mm/month.

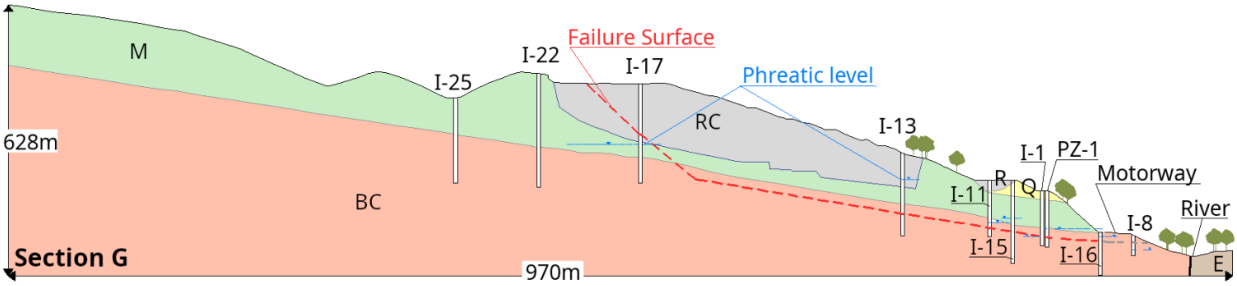

Figure 2. Geological profile along Section G of the slope. The failure surface observed through the inclinometer readings is indicated in red.

3 NUMERICAL MODEL

With all available data and information, the authors of the paper carried out new FE numerical analyses, with the commercial code PLAXIS 2D, to analyse the instability phenomenon in detail and reproduce the observed slope movement as well as the shape and dimensions of the observed slip surface.

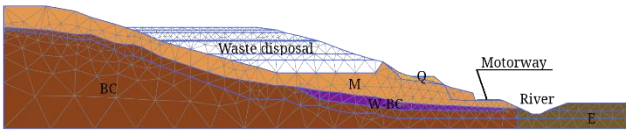

Figure 3. Detail of the FE mesh of the 2D numerical model.

Three different constitutive models were used to represent the ground materials behaviour, with the objective to analyse their influence on the movements distribution along the slope; the generalised Hoek-Brown criterion to account for the different weathering degrees of the rock masses (Hoek-Brown), a simple linear elastic perfectly plastic constitutive model (Mohr-Coulomb) and, finally, an advanced non-linear elastoplastic model with hardening plasticity (HS). The last two models are based on the Mohr-Coulomb failure criterion. In all numerical analyses, the hydraulic conditions approximately reproduce the evolution of the water table with time. Boundary conditions were standards, with a fixed lower boundary and the lateral ones allowing only vertical displacements. No restrictions were imposed on the top boundary.

At first, all numerical analyses were run with the numerical model shown in Figure 3, using the three previously mentioned constitutive models with equal, or equivalent, strength and stiffness parameters. The observed slope movement at inclinometer I-13 (Figs 1-2) and the numerical results associated to different constitutive laws are shown in Figure 4.

Table 2. Strength and stiffness parameters of the M, BC and W-BC deposits for the HS constitutive model.

Layer	c′ (kPa)	φ′ (°)	E_{50} (MPa)	E_{oed} (MPa)	E_{ur} (MPa)
M	20	30	1426	1069	2994
BC	33	38	8750	6560	18375
W-BC	0	18	10	7.5	21

The geomechanical parameters that characterize each ground layer were evaluated based on several laboratory and in situ tests. In Figure 3, the thin layer indicated with the symbol W-BC represents the upper weathered part of the BC deposit, identified from the boreholes, and along which part of the failure surface is located. This layer in the model is characterised by residual strength parameters and much lower stiffness values than those of the unweathered BC materials (Table 2). Such stiffness values were estimated from back-analysis. Table 2 contains the ground effective strength and stiffness parameters corresponding to the

HS constitutive model. As Figure 4 indicates, the HS model proved to be the one that best reproduces the slope horizontal movement with depth, confirming thus that it is indeed important to consider the strong non-linearity of ground materials. Also, in this case study, the unloading-reloading stiffness modulus (E_{UR}) plays a key role in characterising the ground behaviour; more relevant than the oedometric (E_{oed}) or secant modulus in drained triaxial tests (E_{50}).

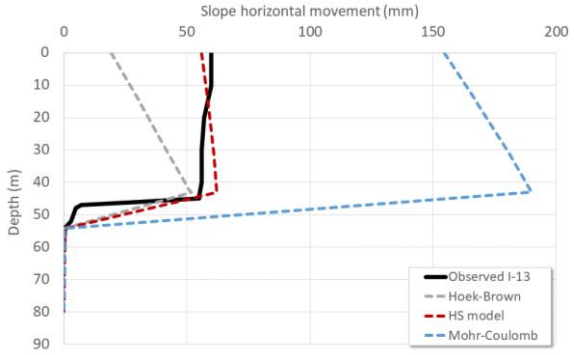

Figure 4. Observed horizontal movement with depth, at inclinometer I-13 and numerical results obtained with different constitutive models.

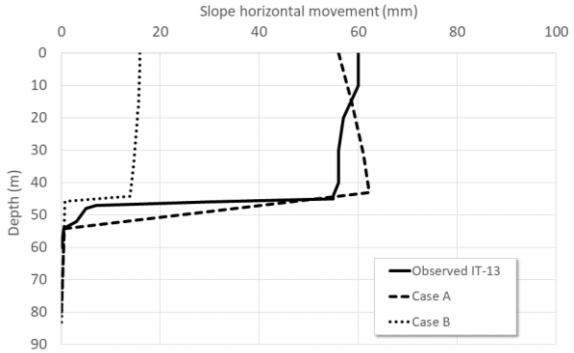

Figure 5. Observed horizontal movement, at inclinometer I-13 and numerical results, considering different slip surface thicknesses and the same HS constitutive model.

According to the different inclinometer readings, the thickness of the slip surface is not uniform throughout the slope, in general being thicker (up to about 10 m) further away from the motorway, as it is approximately represented by the varying thickness of the W-BC layer in Figure 3. In a second phase of this study, two different numerical models (both calculated with the HS model) were considered, each with a different thickness of the W-BC layer, in order to analyse how this feature affects the numerical results. Figure 5 shows the comparison between the observed slope horizontal movement, at inclinometer I-13, and the numerical results in two different scenarios: case (A), in which the thickness of the W-BC layer varies along the slope (Fig. 3) and case (B), in which the same layer has a uniform 2 m thickness. The results show that the thickness of this layer greatly affects the results and, in general, the movement of the slope.

4 SUMMARY AND CONCLUSIONS

The paper presents a case study about the instability phenomenon affecting a slope adjacent to a motorway connecting the city of Barcelona to the northern part of the Catalan region. To analyse the phenomenon and reproduce the slope movement as well as the observed failure surface, 2D finite element numerical analyses were carried out using different constitutive laws.

Considering the non-linearity of ground behaviour in elastoplastic models is crucial to reproduce the observed slope movement. The shape of the slip surface, as it is recorded by inclinometer readings, could only be adequately replicated considering the weathering of the shale deposits from the Lower Triassic. Ground movement distribution is strongly affected by the thickness of the failure surface.

ABSTRACT: Rainfall-induced shallow landslides are amongst the most common gravitational mass movements on slopes in steep terrain. The use of vegetation as a nature-based solution for shallow landslide risk reduction is receiving increased attention in the scientific community. Until now, no studies on the effects of vegetation on slope stability have been conducted for Nordic conditions. Additionally, direct comparison between the hydrological conditions in a forest and a neighbouring open field has never previously been carried out in this region. To contribute to filling this knowledge gap, a monitoring program is installed, and field investigations are conducted in a natural slope in the Flåm valley, located in western Norway. The case study site is situated on a slope partially used as hayfield, and partially covered by deciduous forest. Both the hayfield and the forest are assessed to compare the effects of the presence of vegetation on slope stability. Herein, preliminary results are presented. A detailed analysis of the monitored variables and the laboratory test results must be carried out before to conclude on the effectiveness of the existing forest as a shallow landslide mitigation measure at the case study site.

RÉSUMÉ: Les glissements de terrain peu profonds induits par les précipitations sont parmi les mouvements gravitationnels les plus courants sur les pentes en terrain escarpé. L'utilisation de la végétation comme solution fondée sur la nature pour la réduction du risque de glissements de terrain peu profonds suscite un intérêt croissant au sein de la communauté scientifique. Jusqu'à présent, aucune étude des effets de la végétation sur la stabilité des pentes n'a été menée dans des conditions nordiques. De plus, aucune comparaison directe entre les conditions hydrologiques dans une forêt et un champ ouvert voisin n'a jamais été réalisée dans ces conditions. Pour contribuer à combler cette lacune de connaissances, un programme de surveillance est mis en place et des investigations de terrain sont menées sur une pente naturelle dans la vallée de Flåm, située dans l'ouest de la Norvège. Le site d'étude est situé sur une pente partiellement utilisée comme champ de foin et partiellement recouverte par une forêt caduque. Le champ de foin et la forêt sont tous deux évalués pour comparer les effets de la présence de végétation sur la stabilité de la pente. Dans ce document, des résultats préliminaires sont présentés. Une analyse détaillée des variables surveillées et des résultats des tests en laboratoire doit être effectuée avant de conclure sur l'efficacité de la forêt existante en tant que mesure d'atténuation des glissements de terrain peu profonds sur le site d'étude de cas.

Keywords: Monitoring; nature-based solutions; hydromechanical root-reinforcement; shallow landslides.

1 INTRODUCTION

Rainfall-induced shallow landslides are amongst the most common gravitational mass movements on slopes in steep terrain (Masi et al., 2021). These types of landslides usually interest the uppermost layer of soil or weathered rock (Phillips et al., 2021), posing a serious threat to people, infrastructure as well as agroforestry production in mountain areas. Lately, the

use of vegetation as a Nature-based Solution (NbS) as a mitigation measure for shallow landslides is receiving increased attention in the scientific community (Capobianco et al., 2022). Vegetation can contribute to slope stability through both hydrological and mechanical processes. Plants can provide mechanical reinforcement through the tensile strength of the root network and the interaction between the roots and the soil and/or bedrock (Bischetti et al., 2005). The hydrological reinforcement effects of plants consist of reducing the amount of water in the soil, i.e., reducing the driving forces in the slope caused by pore water pressures. The water content is reduced through plants' ability to intercept water on their canopies and by root water uptake through transpiration (Chirico et al., 2013). Furthermore, vegetation can affect the stability of a slope by surcharge due to self-weight (Gray & Megahan, 1981) and by being subjected to wind (Kim et al., 2020). Soil permeability is also affected by the presence of roots in the vadose zone, resulting in a change in the infiltration and drainage capabilities of the slope (Vergani & Graf, 2016).

Site specificities, such as climate seasonality, environmental conditions and soil conditions can play a role in how vegetation affects the soil hydro-mechanical properties (Boldrin et al., 2021). Until now, no studies on the effects of vegetation on slope stability has been conducted for Nordic conditions. Additionally, direct comparison between the hydrological conditions in a forest and a neighbouring open field has never previously been carried out in this region. To contribute to filling this knowledge gap, a monitoring program is installed and field investigations are conducted in a natural slope in the Flåm valley, located in western Norway. The case study site is situated on a slope partially used as hayfield, and partially covered by deciduous forest. Both the hayfield and the forest site are assessed to compare the effects of the presence of vegetation on slope stability. This paper provides an overview of the case study site, a description of the monitoring program, field and laboratory campaign and some preliminary results. Finally, the plans for further data analysis and research are presented.

2 MATERIALS AND METHODS

2.1 Case study site

The case study site, the farm Ryo, is situated on the hillslopes of the Flåm valley in western Norway (Figure 1). The area is composed of fjords and mountains with small, populated areas concentrated in the lower river valleys. This unique setting is recognized by UNESCO as a world heritage site, and the cultural landscape is maintained by the local inhabitants through traditional farming methods. The mountainsides are steep causing frequent shallow landslides, rock falls and avalanches. Ryo is located about 600 m.a.s.l., and the land is partially used as hayfield, and partially covered by a naturally growing deciduous forest composed by alder (*Alnus incana*), birch (*Betula pubescens*), aspen (*Populus tremula*), and willow (*Salix caprea*) trees (Figure 2, Figure 3). The slope angle of the hillslope is approx. 30° around the farm. The soil in the area consists generally of landslide debris of phyllite rock, which over the years has decomposed into well-graded material.

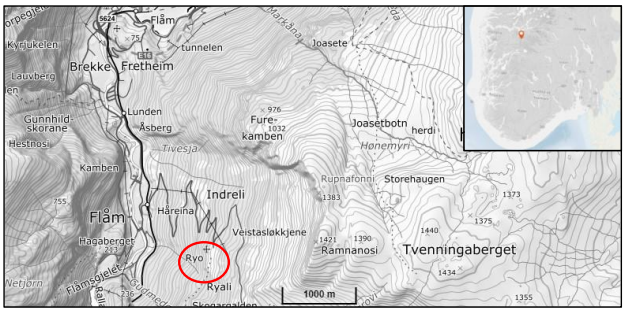

Figure 1. Location of the study site, Ryo. Source: www.norgeskart.no.

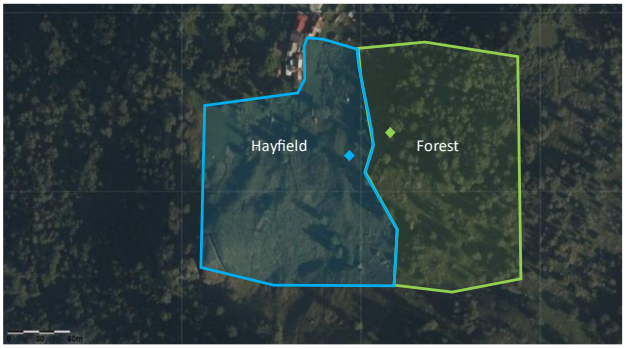

Figure 2. Satellite image of the case study site with approximate locations of the monitoring stations. Source: www.norgeibilder.no.

Figure 3. Photos from Ryo. Left: hayfield. Right: forested area before the growing season.

2.2 Monitoring setup

The locations of the two monitoring stations, one in the forest and one in the hayfield, are shown in Figure 2. In each location, a monitoring program was installed in May 2023, including two precision field tensiometers (Teros32), and four volumetric water content (VWC) sensors (Teros10, Teros 11) (Table 1). In addition to the measurement of VWC and soil suction, temperature is measured at all depths. The sensors are connected to data loggers, which log the measured variables every 15 minutes, and the data is wirelessly uploaded to the cloud through the cellular network. All the sensors and the data loggers were provided by the METER Company.

Table 1. Overview of monitoring equipment. T=Temp., c_ψ=matric potential and VWC=volumetric water content.

Depth [cm]	Variable	Sensor
10	VWC, T	Teros11
40	VWC, T, c_ψ	Teros10, Teros32
80	VWC, T, c_ψ	Teros10, Teros32
110	VWC, T	Teros11

In 2015, a weather station including, a Geonor T-200B series all weather precipitation gauge and a Lufft WS500 weather sensor measuring wind speed, direction, air temperature, relative humidity and air pressure, was installed at Ryo. Data from this weather station was intended to supplement the data collected by the monitoring equipment at the site. However, a site visit to the area showed that a component of the precipitation gauge had broken. Local, climatological data is therefore lacking from the start of our monitoring period (May 2023). To ensure a robust system for data collection of climate variables, a new weather station, of the model ATMOS 41W provided by the Meter Group, was installed in November 2023.

2.3 Field and laboratory investigations

Field investigations were conducted in September 2023. Soil profiles were excavated to a depth of approx. 60 cm respectively at 1.0 m and 2.5 m distance from the trunks of one young birch and one young alder, and at 1.0 m distance from an older birch in the forested area (Figure 4, left). The root distributions in the soil profiles were mapped in a grid of width 50 cm and depth 50 cm, with cell size of 10 cm x 10 cm (Figure 4, right). In each grid cell the root diameters were measured and the number of roots of different diameter classes (1-2 mm, 2-3 mm, …) was recorded. Roots with a diameter smaller than 1 mm were not counted.

Roots of different sizes were collected from each soil profile and brought to laboratory to test their tensional strength using a Quasar 250 Material Testing machine, developed by Galdabini SPA. To ensure proper preservation of the roots from collection to tensile testing, the roots were sprayed with a 20% alcohol solution and stored in the fridge before the tensile tests were performed (10 days from collection date). A total of 46 roots were tested. Thicker roots were debarked at their extremities and clamped directly, whilst the thinner roots were coiled around a rounded metal structure to distribute the stress and prevent breakage at the extremities. The results of the tensile tests have not yet been analysed and is therefore not presented herein.

Disturbed soil samples were collected from each sensor depth at the two monitoring locations (10, 40, 80 and 110 cm), and a total of eight undisturbed soil samples from depth 10-60 cm were collected from the soil profiles close to the three selected trees for soil characterisation in the laboratory. The undisturbed samples were collected using cylinders of Ø72 mm and length 20 cm.

The laboratory analysis of the collected soil samples is yet to be conducted. The laboratory campaign will include measurement of grain size distribution for all the samples, and soil density, organic content and field, residual, and saturated VWC for the undisturbed samples.

Figure 4. Left: Soil pits at dist. 1.0 and 2.5 m from a young birch. Right: Root distribution mapping grid. Cell size 10 x 10 cm.

3 PRELIMINARY RESULTS

3.1 Hydrological conditions

VWC and suction measured between May and October 2023 at 40 cm and 80 cm depth are presented in Figure 5. Air entry in the hayfield tensiometers around the beginning of June caused the sensors to malfunction until they were refilled the 12th of September. Suction data in this period are therefore not reliable. The forested area shows both higher suction and VWC values than measured for the hayfield. For both areas,

the deepest sensors shows both lower suction and VWC values than the shallowest sensors.

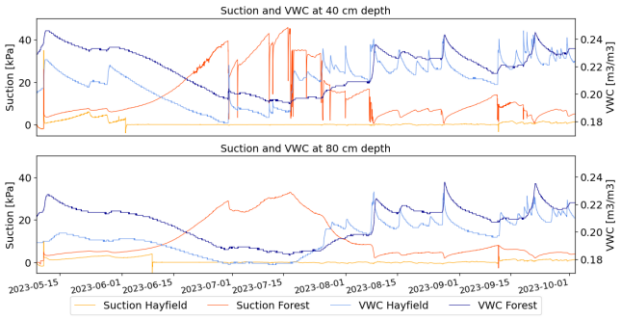

Figure 5. VWC and suction May-October 2023 at Ryo.

3.2 Root distribution

All trees have the highest number of roots in the smallest considered diameter class (1-2 mm). The younger trees do not have roots that are thicker than 15 mm, whilst it was recorded roots with diameters up to 27 mm for the older birch. The Root Area Ratio (RAR), i.e., the ratio between the rooted area and the total area of the soil profile, is calculated for each of the investigated trees (Figure 6). For the alnus, there is no clear difference in RAR from the soil profile at 1.0 m and 2.5 m distance from the stem. On the contrary, for the young birch, there seems to be a decrease in RAR with distance from the stem. The older birch has a peak in RAR at 20-30 cm depth, corresponding to the depth of its largest root (27 mm), whilst showing similar values as the younger trees otherwise. The obtained RAR values are of the same magnitude as found by Bischetti et al. (2005).

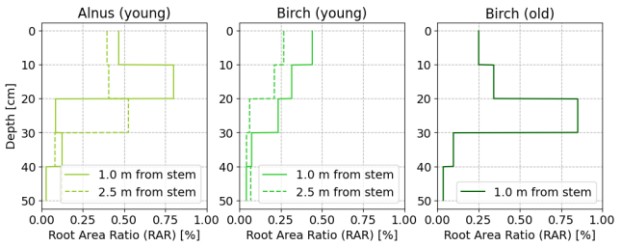

Figure 6. Root Area Ratio (RAR) with depth for the three investigated trees at Ryo.

4 FUTURE RESEARCH

The data gathered in this study will be analysed and used as input data for slope stability modelling, with the aim to assess the effectiveness of the existing forest at Ryo as a shallow landslide mitigation measure. Moreover, the effect of different forest management strategies for the area will be explored.

ACKNOWLEDGEMENTS

The authors would like to thank the Research Council of Norway for financial support, and the OsloMet Uni. for conducting the tensile tests on the roots.

Slope stabilization at Régua-Ferrão section of the Douro railway line

Stabilisation de talus sur le tronçon Régua-Ferrão de la ligne de chemin de fer du Douro

C.M. Dinis*, A.M. Pereira
Mota Engil Engenharia e Construção S.A., Lisbon, Portugal
**Carlos.Dinis@mota-engil.pt*

ABSTRACT: Mota-Engil Engenharia Deep Foundations Department has executed the slope stabilization works at the Régua - Ferrão section of the Douro railway line - Plot 3, for Infraestruturas de Portugal S.A. The works were consigned by 7th of January 2021, and completed by 10th of October 2022. The intervention area extended over 14 km on the right bank of the Douro River, divided by (10+1) slopes, between Peso da Régua and Ferrão railway stations at the district of Vila Real. The need for intervention on those slopes resulted from geological investigation, a survey of the slopes stability conditions, as well as of the slope areas with the greatest instability potential, combined with the risk factors identified, mainly the distance to the railway line and the boulders fall height, among others, resulted in an effective risk to people and goods including to railway line traffic. This contract covered the following tasks: nailing, nets, cable nets, slope crest drainage, railway line and slopes drainage, ballast guard walls and railway line ballast. Most of the intervened slopes did not have land access, so all the work had to be carried out using railway and river resources at night and under short railway line interdiction periods, resulting in very complex and demanding execution conditions.

RÉSUMÉ: Le Département des Fondations Spéciales de Mota-Engil Engenharia S.A. a exécuté les travaux de stabilisation des talus du tronçon Régua - Ferrão de la ligne du Douro - Plot 3, pour le compte de Infraestruturas de Portugal S.A. Les travaux ont démarré le 7 janvier 2021 et ont terminé le 10 octobre 2022. La zone d'intervention s'étend sur 14 kilomètres sur la rive droite du Douro, divisée par (10+1) talus, entre les gares ferroviaires de Peso da Régua et Ferrão, dans le district de Vila Real, au Portugal. La nécessité d'intervenir sur ces talus provient d'une reconnaissance géologique et d'une étude des conditions de stabilité du site, ainsi que des zones présentant le plus grand potentiel d'instabilité et de leurs modes de défaillance respectifs qui, combinés aux facteurs de risque identifiés, à savoir la distance par rapport à la voie ferrée et la chute de matériaux meubles ou instables en hauteur, entre autres, ont permis d'identifier un risque effectif pour les personnes et les marchandises et bien aussi pour le trafic ferroviaire. Des travaux de clouage, de pose de filets de guidage et de filets renforcés, de drainage des crêtes de talus, de drainage de la voie, de murs de protection du ballast et de ballastage de la voie ont été réalisés. La plupart des talus concernés n'ayant pas d'accès terrestre, tous les travaux ont dû être réalisés avec des moyens ferroviaires et fluviales, de nuit et sous accès fermé à la circulation, ce qui a ajouté des difficultés à la mise en œuvre déjà complexe des solutions de stabilisation.

Keywords: Slope stabilization; nails; reinforced concrete wall.

1 INTRODUCTION

The tender process launched by Infraestruturas Portugal began in May 2020, with an invitation letter to 13 Portuguese construction companies, of which only 3 responded to qualify. The most technically and economically advantageous proposal was presented by Mota Engil Eng. Construção SA, with the work being consigned in January 2021.

It is important to note that this project had initially been started by another contractor, in 2015, however, due to technical and economic difficulties on his part, he terminated the contract with the Construction Owner.

The project to stabilize the 10+1 slopes was carried out 90% under a nighttime railway ban, with the remaining 10% during daylight, with the respective railway safety measures.

During the almost 2 years of the project, there was a perfect harmonization of the project solutions and the construction conditions, which were always monitored by the inspection / Construction Owner, in the periodic fortnightly meetings, with the designer being involved in decisions whenever necessary. During the same period of work, the maximum labor load was around 30 workers, divided between 3 to 4 simultaneous work fronts.

During the same period of work, there was a need to apply or maintain speed restrictions on railway trains, for safety reasons, and some limitations were anticipated before the end of the project. Overall, the extremely difficult undertaking due to non-existent access and railway constraints was carried out regularly and in compliance with the partial deadlines that bound this contract.

2 CONSTRUCTION AND SLOPE STABILIZATION

The Douro railway line (Porto-Pocinho) from Km 103+900 to 117+930, intersects eleven unstable slopes between rail stations of Régua - Covelinhas and Ferrão (see Table 1). The work took place between the municipalities of Vila Real, Peso da Régua and Sabrosa.

The main players in this project were the following:

- Railway line owner: Infraestruturas de Portugal;
- Consultancy / designer: TPF;
- Contractor: consortium Mota Engil (MEEC) and Afavias;
- Supervision: consortium Gibb, Prospectiva and Quadrante.

2.1 Slope stabilization conceptual approach

Considering both the topographic, construction restraints and geological and geotechnical scenarios, the following main stabilization solutions were adopted at the eleven stabilized slopes (see Table 1):

- ϕ32mm steel nails combined with double torsion nets;
- ϕ32mm steel nails combined with double torsion steel nets and steel reinforcing cables;
- Underpinning with reinforced concrete walls lined by shale blocks;
- Cleaning, excavation, blocks removal, and slope reprofiling;
- Drainage systems improvement, mainly: deep drains, railway platform drains, slope crest and berms drains.

At the region where this section of the Douro railway line is located, between Peso da Régua and Ferrão, there are metamorphic formations of the Cambrian Schist-Grauvacic Complex. They are part of the Central Iberian Zone (ZCI) of the Hesperia Massif.

Table 1. Slopes identification and length.

Slope	Length	Note
Slope 1	200	Initial Contract
Slope 2	170	Initial Contract
Slope 3	180	Initial Contract
Slope 4	300	Initial Contract
Slope 5	350	Initial Contract
Slope 6	270	Initial Contract
Slope 7	200	Initial Contract
Slope 8	220	Initial Contract
Slope 9	250	Initial Contract
Slope 10	180	Initial Contract
Slope 11	50	New Contract

The structure of the rocky mass is dominated by the NW-SE orientation of the geological units and by the main fracture systems, with alignments between:

- NNE-SSW and ENE-WSW;
- NNW-SSE and NW-SE.

According to the Geological Chart of Portugal at scale of 1:50 000, Sheet 10-C of Peso da Régua and Sheet 10-D of Alijó, the metamorphic formations belong to the geological units of Allochthonous.

The geotechnical slope stabilization solutions were based on the studies carried out at the project first stage, supported by a parametric back-analysis.

Prior to all activities, land/rail access was created to the fronts of the slopes. To this end, MEEC transported the lighting towers to each specific location on the slopes, using a 2.4x18 (m) wagon; it prepared the temporary stockpiling areas for the materials; it made the necessary protections for the track and installed collective protections for these works and workers safety, lifeline systems for machines and climbing operators.

In this sense, as collective protection measures, steps were manually carved into the approximate contour of the slope to be intervened upon, to later allow the hammerers to enter for the construction of lifelines, topographical checks and markings, slope inspections and decision making/supervision of the work. The construction financial report is presented at the Table 2.

2.2 Slope stabilization solutions

The use of nailed nets was recommended in situations where the slope face was typically more decompressed, with small blocks (associated with fractures between F4-5 and F4-3), although the thickness of the decompression zone was expected to be relatively shallow (no more than 1m). The use of this system of nailed nets was also associated with slopes that typically showed inclinations of less than 3V:1H.

A system consisting of a triple-torsion hexagonal netting with an 8cm x 10cm mesh of Ø2.7mm wires galvanized in accordance with EN10264-2 was adopted. The net is associated with a 3m x 3m nailing mesh, measured on the slope face, and Ø12mm horizontal steel cables connected to the nailing heads.

The triple-torsion nets were hexagonal, with a mesh size of 8cm x 10cm, made of Ø2.7mm wires galvanized in accordance with NP EN 10244-2. The tensile strength of the Ø2.7 wire and the breaking load of the staples connecting the mesh panels was 1770 MPa. The system incorporated Ø8mm edge steel cables and exhibited a longitudinal tensile strength equal to or greater than 51kN/m, as well as a punching strength equal to or greater than 26kN.

The reinforcement cable panels consist of a mesh of Ø10mm steel cables, 40 x 40cm mesh, with double connections at the nodes. The cable netting panels are 6m high and 3m wide. The connections between adjacent panels were made with Ø12mm steel cables interwoven into the meshes.

The system was reinforced by a mesh of Ø16mm horizontal, vertical and perimeter steel cables. At the top of the panels (upper edges), a Ø20mm steel core cable was installed.

Figure 1. Multifunction drilling column under operation.

In the nailed net system (see Figure 1), nailing was made up of Ø32mm A500NRSD steel rods, sealed in Ø76 mm holes with cement grout, with lengths varying between 4.0 m, 6m and 8m. The nailing heads were made up of 200x200x10mm metal plates. Both the rod and all the metal elements of the nailing heads were galvanized to a thickness of 90 μm or more.

Figure 2. Multifunction drilling column MERLO 7028 with CPA 295 Montabert, working at railway line platform.

Several examples of the positioning and stabilization of drilling equipment (see Figure 2 and Figure 3), at height, on the railway platform, supported by a railway wagon, or suspended with drilling carts, connected to lifelines / suspension.

For the construction of the lifelines, we opted for standardized A500NRSD steel rods, Ø32mm, with a length of 2m and spaced 3m apart (double line).

The connection to the drilling equipment suspended/connected to the line was established using a mechanical TIRFOR, with a nominal load capacity of 16kN, properly connected with steel shackles of equal or greater load capacity.

For slope heights above 25m, it was decided to use suspended drilling carts, anchored to lifelines/built with nailed steel cables, as it was not possible to use conventional means of lifting the drilling columns (mobile crane or multifunction crane).

All the accessory and preparatory works related with the safety procedures and verification were set in accordance with Decree-Law 50/2005, which demands that the legal provisions defining that certifications of equipment anchored to lifelines / cart suspensions are currently necessary / required.

In most situations on the slopes of plot 3, with average heights of up to about 20m (see Figure 4), it was decided to use the lifting means, mobile crane or multifunction crane / equipped with a drilling column, stabilized at the track, at the railway platform level.

The set "mobile crane + wagon" was towed every night between Covelinhas Station, at PK 112+300, and the work site, varying between 113+400 and 117+940.

Figure 3. Multifunction drilling column working at the railway line platform.

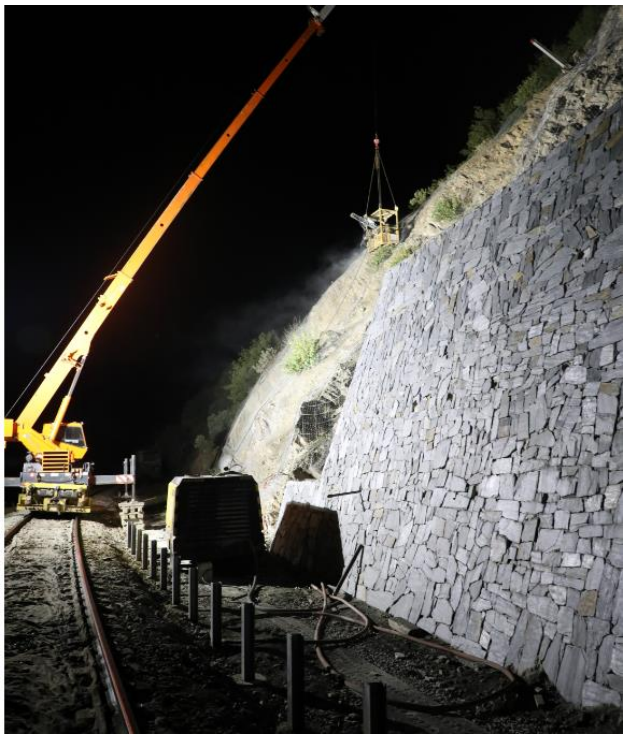

Figure 4. Crane position at railway line platform.

2.3 Underpinning reinforced concrete walls

For the underpinning reinforced concrete walls solutions, the concrete provided was part of resistance class C25/30, exposure class XC2(P), Dmax = 25 mm, chloride content equal to or less than 0.40 and slump class S3.

The concrete was stabilized and prepared for workability time of 3 hours, according to composition studies, since the shortest possible time between the end of manufacture and the start of unloading on site was around 2 to 2.5 hours.

The adoption of underpinning, rather than excavation work or stabilization with nets, was mainly associated with the existence of areas strongly conditioned by planar breakage and/or tilting phenomena involving large unstable volumes, in which, using excavation work, significant excavations would have to be carried out to properly stabilize the slope.

At those situations, nailed nets alone would not work as well as they could, especially for significant areas of cantilever or even with a negative slope inclination over the railway line.

There were two types of underpinning walls, with selection depending mainly on the slope geometry (height and inclination). For both types of underpinning walls, L-shaped nails were executed, and drains were installed, after the walls concreting, through Ø76mm holes. To facilitate drilling, it was recommended that empty holes should be placed at the walls before concrete pouring, using Ø90mm PVC pipes.

Still at the design stage, an attempt was made to avoid the use of reinforcement bars at the underpinning walls, as much as possible. There were many reasons for this, but the main advantage was that, by using simple concrete solutions, it was possible to define concretes with lower resistance and exposure classes, which was clearly suited to this type of work, since, due to access difficulties, the concrete was manufactured using rudimentary means, instead of concretes with the usual resistance classes chosen for regular reinforced structures.

The concreting activity was perfectly identified at the study and design stage. In order to better overcame the restraints, for the transport of ready-mixed concrete, two MEEC partner companies were involved:

- IED boats and river platforms;
- EDILAGES, which with one of its concrete mixer pump trucks, with a 28m boom, completed 90% of reinforced concrete underpinning walls.

Thus, using a river platform (SAPO) with a transport capacity of about 50ton, pulled by a tug (Pomba), some 800m^3 of concrete were transported between the banks of the Douro River, during approximately two months.

It should be pointed out some examples of complex works, as for instance: the positioning of scaffolding, the placement of formwork and the general civil works, alongside the railway line. Those works were carried out only with railway line traffic severe restrains or interdiction, as well as with constraints related to tight railway gauge in opposition to the geometry of the walls.

The construction works of the underpinning walls took place between March and July 2022, with concrete pouring works being done exclusively at night, with the support of railway and river resources that were adapted and provided specifically for this task (see Figure 5).

Figure 5. Railway loading gauge / scaffolding position close from railway line platform.

Concreting activities were always performed with the railway line closed between 9 p.m. and 6 a.m., where under optimal conditions 50m3 of concrete were transported and poured, in one night of work.

Coming from the Vila Real Hydraulic Plant, the ready-mixed concrete was transported to the left bank of the Douro River, where it was transferred to the concrete mixer on board at the Folgosa boat, provided by the IED company (Douro extractive industry). From there, it would continue for 10 to 25 minutes, depending on the distance from the slope (slope 10 to slope 6, respectively), where the river platform would be positioned, moored to the right bank. From this bank, it was then pumped up to the maximum height / elevation of the concrete underpinning wall (see Figure 6 and Figure 7).

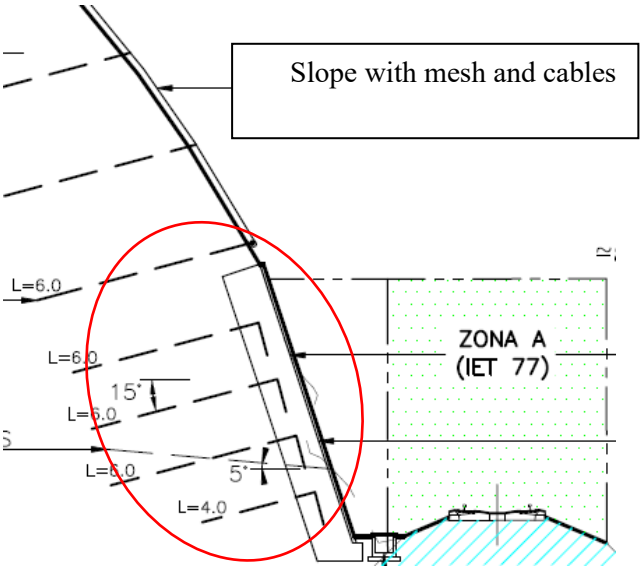

Figure 6. Underpinning wall with L shaped nails.

Figure 7. Underpinning wall concrete pouring operation.

Railway concrete transport equipment was also performed with the assistance of one concrete mixer wagon with a capacity of 6m^3 and a speeder for towing the set, which occasionally carried out transport between Ferrão Rail Station and Slopes 6 and 7 during the first phase of the works, while the river equipment was being prepared.

In the case of the concrete mixer wagon, transport times between the end of mixing and the start of pouring were still more than 2.5 hours, so it was quickly decided to use only the boat on-board mixer.

At Table 3 the main river/transport equipment's are presented.

3 FINAL REMARKS

The railway slope stabilization complex works had to be linked with all the demanding restraints, as for instance from the delay in the departure time of the railway trains to the simple coordination of the concrete pouring time. The simultaneous execution of 10+1 slopes, when the main site access was just the railway line under daily operation, required a very demanding logistics and site activities management.

Carrying out construction work and stabilizing slopes exclusively at night was also extremely demanding physically and psychologically for those directly involved in the construction. Habituation, routines, and complex works, some of them performed with suspended ropes, in a night environment with assistance of artificial light creates accelerated tiredness on employees, increasing the risk for construction site accidents, including material goods and physical damage.

ACKNOWLEDGEMENTS

The authors are grateful to Infraestruturas de Portugal, Douro railway line owner, for the permission to present this paper. The authors also emphasize the important role of the following main suppliers for the works success:

- Newinfra Unipessoal, Lda., sub-contractor for civil construction and drainage works;
- A. Bianchini, steel nets and cables supplier;
- I.E.D – Indústria Extrativa do Douro, sub-contractor for river transport and platforms;
- Betão Liz, concrete ready-mix and hydraulic mixtures supplier;
- Eurogalva, galvanizing and anti-corrosion protection systems supplier.

Resonant column round-robin testing

Essais de résonance en torsion: comparaisons inter et intra-laboratoires

ABSTRACT: Faced with seismic risk, to better understand and characterize the behaviour of soils, advanced geotechnical laboratory tests are necessary. These include, for example, torsional resonance tests. The American standard (ASTM D4015 – 15), which describes the process for carrying out these tests, points out the lack of interlaboratory tests to determine their accuracy. As part of the ASIRI+ project, a cross-test campaign was launched in France from the beginning of 2023 on two types of sandy materials (HN31 and a mixture of HN38, HN34, HN31, HN04). Three independent laboratories participated. The results of resonant column tests obtained are presented. The following evolutions are discussed: shear modulus vs distortion, damping vs distortion. Results are compared to empirical models.

RÉSUMÉ: Face au risque sismique, pour mieux comprendre et caractériser le comportement des sols, des essais géotechniques avancés en laboratoire sont nécessaires. Ceux-ci comprennent, par exemple, des essais de résonance en torsion. La norme américaine (ASTM D4015-15), décrivant le processus de réalisation de ces tests pointe le manque de tests interlaboratoires pour déterminer leur précision. Dans le cadre du projet ASIRI+, une campagne de tests croisés a été lancée en France à partir de début 2023 sur deux types de matériaux sableux (HN31 et un mélange de HN38, HN34, HN31, HN04). Trois laboratoires indépendants ont participé. Les résultats des essais de colonne résonante obtenus sont présentés. Les évolutions suivantes sont discutées : module de cisaillement vs distorsion, amortissement vs distorsion. Les résultats sont comparés à ceux issus de modèles empiriques.

Keywords: Resonant column apparatus; round-robin test; shear modulus; damping.

1 INTRODUCTION

Dynamic soil response is of considerable importance for loadings produced by earthquakes, machine foundations, wind, waves, and impacts. Two of the most important parameters in any dynamic analysis involving soils are the shear modulus and the damping ratio. Both the shear modulus, G, and damping, D, are dependent on the shear strain, γ. For earthquake problems, the variation of G and D with shear strain must be considered. In laboratory, the resonant column apparatus (RCA) constitutes a means of determining these parameters. Precision of these results depends of the nature of tested soils, specimen variation, operator or laboratory testing variation (ASTM, 2021).

In the 1970's, USA organized resonant column round robin testing program for determining the dynamic shear modulus and the damping ratio of Monterey sands (Chung, 1982). At the beginning of 2023, in France, three independent laboratories decided to organize intercomparison testing on sandy reconstituted specimens.

For this study, the methodology was quite free: reconstitution method, apparatus, drainage conditions, method of determining depreciation are chosen by each operator according to their constraints and practices.

2 MATERIALS AND METHODS

2.1 Materials

The material used in this research work were two sands:

- Hostun HN31 sand whose properties have been extensively studied by many research laboratories (Baudouin, 2010).
- A mixture of Hostun sands composed of 25% in dry weight of the fraction HN38 HN34 HN32

and HN 04 (fraction HN 04 cut at 0.63 mm).

Particle size distributions of each material is shown in Figure 1. Their physical characteristics are given in Table 1. Different properties are presented: the effective Grain Size D_{10}, the median Grain Size D_{50}, the coefficient of uniformity $C_u = D_{60}/D_{10}$, the coefficient of curvature $C_c = {D_{30}}^2/D_{10}D_{60}$.

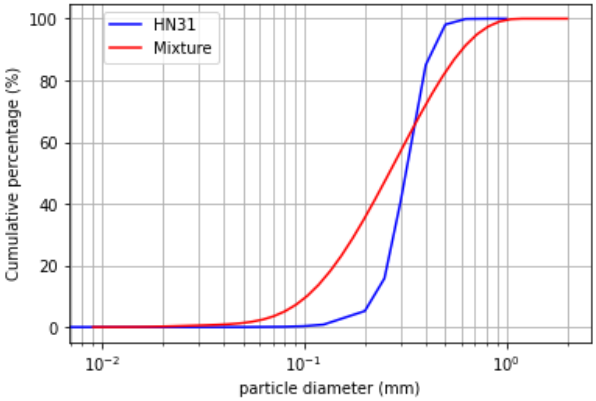

Figure 1. Particle-size size distribution (HN31 and mixture).

Table 1. Properties of HN31 and mixtures sands.

	HN31	**Mixture**
D_{10} (µm)	220	104
D_{50} (µm)	320	250
C_u	1.57	3.13
C_c	1.03	0.96

2.2 Specimen preparation

Three procedures of reconstitution of the samples were used: compaction, raining and compaction followed by freezing. Only the density was fixed. Grain bulk density was measured: 26.00 kN/m^3.

8 HN31 specimens and 7 mixture specimens were reconstitued in laboratories (with a density objective of respectively, 19.22 and 20.21 kN/m^3) . The height of the samples was about 100mm and the diameter about 50mm.

Void ratio of specimens before testing are presented in Figure 3 and Figure 4. HN31 and mixture specimens presented respectively density between 18.96 and 19.30, and between 19.63 and 20.11 kN/m^3).

2.3 Testing conditions

All specimens were saturated (Skempton coefficient 0,95<B<1,00). They were consolidated at an isotropic pressure σ'_0 = 100 kPa (HN31) or 300 kPa (Mixture). Some specimens were drained at their top and their base, others only at their base. Intermediate reconsolidation phases were carried out when the overpressures were too high (threshold determined by each laboratory).

2.4 Resonant column apparatus tests

The evolution of the shear modulus and the damping of a soil as a function of the distortion can be obtained by torsional tests on the RCA (Figure 2).

Figure 2. RCA in the Cerema laboratory.

The RCA is well suited for accurate measurements of soil stiffness and damping at low to medium shear strain amplitudes, typically between 0.0001% and 0.1% (ASTM, 2021). An axially and radially confined cylindrical sample is sheared by applying a sinusoidal torsional moment of predefined amplitude and increasing frequency to its top end, while the base end is fixed. Once the resonant frequency has been identified, it is used to calculate the soil shear modulus using a theoretical elastic model, which correspond to the applied shear strain amplitude. Two different approaches are generally applied to determine the damping rate using a RC test: steady-state and free vibration decay methods (Semblat et al., 2011). Both were used in this study.

The reduction in shear modulus and evolution of damping is obtained by repeating the test with increasing amplitudes.

The G modulus measured at the smallest amplitudes and distortions is called G_{max}.

3 RESULTS

3.1 Shear modulus as a function of distortion

Torsional RCA tests provide shear modulus decrease curves as a function of shear strain γ. The test results are presented for each type of specimens: HN31 (Figure 3) and mixture (Figure 4). Colors correspond to the initial void ratio of each specimen (from red to blue presented in the histogram).

Symbols correspond to different specimen preparation: ● is linked with compaction followed by freezing, + to raining and ★ to compaction.

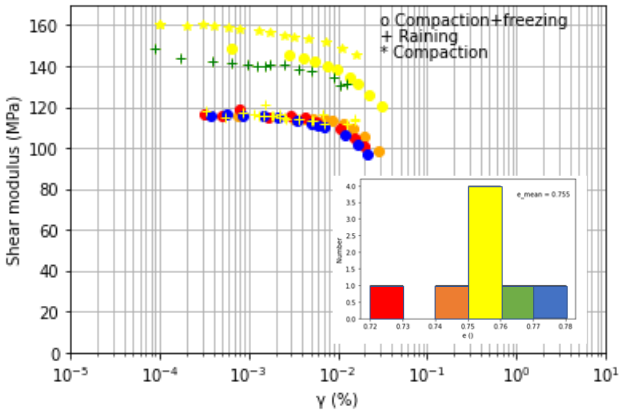

Figure 3. Shear modulus as function of distortion (HN31).

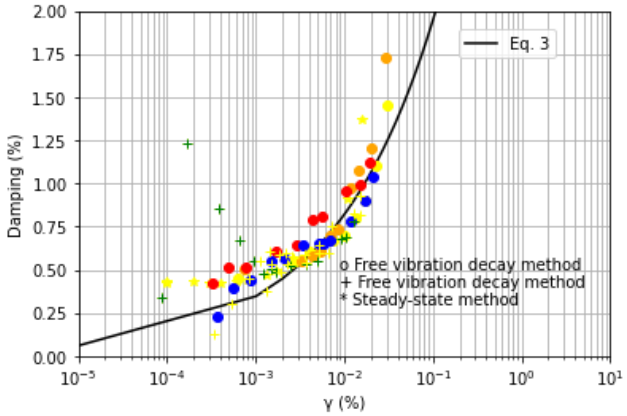

Figure 4. Soil damping as function of distortion (HN31).

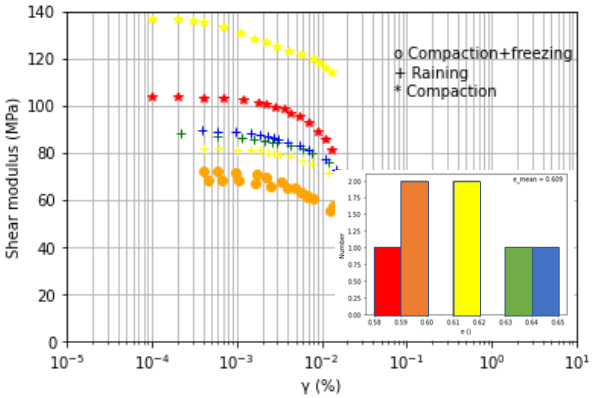

Figure 5. Shear modulus as function of distortion (Mixture).

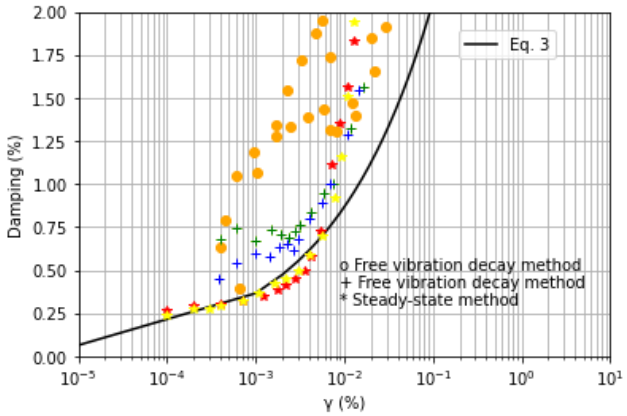

Figure 6. Soil damping as function of distortion (Mixture).

Two different apparatus were used (machine M1 ★ and machine M2 ● and +). Two different drainage conditions were used (drainage at the bottom of the specimen ★ and drainage at the top and the bottom of the specimen ● and +). The laboratories carried out several different tests on different specimens under the same drainage conditions and consolidation pressures.

The HN31 specimens present maximum shear modulus values varying between 120 and 160 MPa; those of the mixture, values between 65 and 140 MPa. The results of HN31 are less dispersed than those of the mixture. Results obtained with M1 (drainage only at the base of the specimen) are always higher than others. In Figure 3, yellow circle (●) and green plus (+) curves correspond to tests with technical problems (leak or inclination of the electro-magnets into the coils). Other curves are very closed but correspond to different initial void ratio. Void ratio after saturation and consolidation phases has to be considered, instead of initial one. In Figure 4, the yellow plus (+) curve corresponds to a laboratory test with a leak.

More generally, repeatability of tests for the same laboratory is observed.

3.2 Damping as a function of distortion

Torsional RCA tests also provide damping as a function of shear strain γ. The test results are presented for each type of specimens: HN31 (Figure 5) and mixture (Figure 6). Like for the previous figures, symbols are linked with specimen preparation and colors to the void ratio.

For both materials, the damping varies between 0 and 2%. The results of HN31 are less dispersed than those of the mixture. Steady-state and free vibration decay methods were used to determine the soil damping. The first one corresponds to ● and + symbols and the second one to ★ symbols. Figure 6 seems to show that steady-state method is more precise to determine the damping for very small distortions.

3.3 Discussion

Experimental results are compared to empirical relationships (solid and dotted black lines) that have been proposed in the literature for sandy soils in Figures 7, 8, 5 and 6. (Rollins et al., 2020) presented simplified equations for shear modulus degradation and damping of sandy soils in relation with confining

pressure and coefficient of uniformity (Equations. 1, 2 and 3):

$$\frac{G}{G_{max}} = \frac{1}{1+\left(\frac{\gamma}{0.0063{\sigma_0'}^{0.38}}\right)^{0.87}} \quad (1)$$

$$\frac{G}{G_{max}} = \frac{1}{1+\left(\frac{\gamma}{0.0046{C_u}^{-0.197}{\sigma_0'}^{0.52}}\right)^{0.84}} \quad (2)$$

$$D = 26{,}05\left(\frac{\gamma}{1+\gamma}\right)^{0.375} {C_u}^{0.08}{\sigma_0'}^{-0.07} \quad (3)$$

Normalized shear modulus is the current shear modulus G divided by G_{max}. In the Figure 7, measured values of G are above the empirical curves for HN31 specimens, whereas the empirical curves frame the measurements in the Figure 8 (mixture).

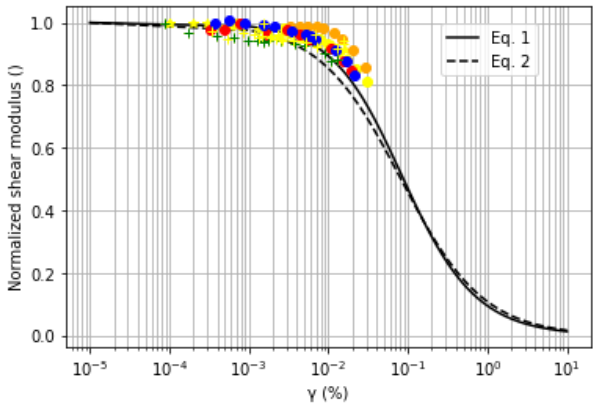

Figure 7. Normalized shear modulus as function of distortion (HN31).

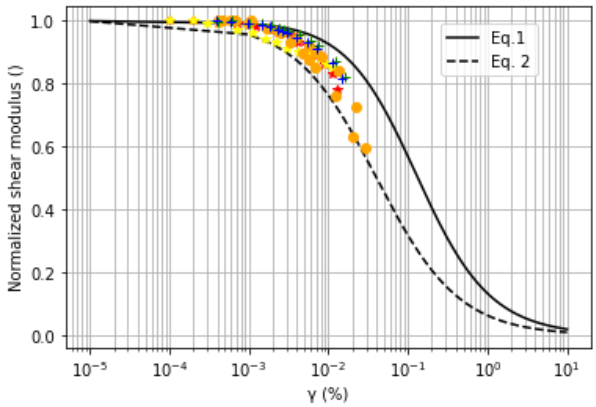

Figure 8. Normalized shear modulus as function of distortion (Mixture).

Regarding damping, the measured values coincide with the empirical curve proposed for the evolution of the damping of HN31 sand as a function of distortion (Figure 5). For the mixture, the empirical curve corresponds to the minimum of the measured values (Figure 6).

4 CONCLUSIONS

Finally, fifteen tests were carried out by three independent laboratories using a resonant column apparatus. Shear modulus and damping were determined on sandy specimens. In terms of shear modulus, the values are relatively dispersed explained by different sample preparation, different void ratio and hydromechanical problems during tests. However, the dimensionless modulus reduction curves are relatively close to each other and to the empirical curves in the literature. The HN31 sand damping values are also close to each other and are well reproduced by the empirical curves even though two different methods were used to determine them. An analysis of the test procedures and operating methods will be carried out to try to explain the dispersion of the curves. Other tests still need to be carried out.

Experimental investigation of influence of soil plasticity on compression characteristics and creep behaviour of clayey soils

Étude expérimentale de l'influence de la plasticité du sol sur les caractéristiques de compression et le comportement au fluage des sols argileux

M.N. Duy*, J. Jerman

ABSTRACT: Comprehending the creep mechanisms and determining the factors influencing compression and creep characteristics is indispensable for accurate long-term settlement predictions, a critical determinant of structural stability and safety of structures. Also, both natural and artificial slopes, as well as embankments, manifest varying rates of creep movements. Recent experimental investigations have highlighted the significant role played by the influence of soil composition, fabric structure, over-consolidation ratio (OCR), and plasticity in the time-dependent behaviour and compression characteristics of clays. However, a comprehensive description and correlation of these factors have yet to be proposed. To address this gap, an extensive experimental study was conducted under well-defined conditions. Reconstituted samples, including low-plasticity clay (kaolinite), high-plasticity clay (bentonite), and their mixtures, underwent standard and creep oedometric tests. We show that samples with lower plasticity exhibit reduced volume changes during compression and swelling and lower values of the creep coefficient (C_α). The stress dependency of C_α is more pronounced in mixtures containing bentonite compared to pure kaolinite. Also, strong OCR-dependency of C_α has been observed.

RÉSUMÉ: Comprendre les mécanismes de fluage et déterminer les facteurs influençant les caractéristiques de compression et de fluage est indispensable pour des prévisions précises de tassement à long terme, un déterminant essentiel de la stabilité structurelle et de la sécurité des structures. En outre, les pentes naturelles et artificielles, ainsi que les remblais, présentent des taux de fluage variables. Des recherches expérimentales récentes ont mis en évidence le rôle important joué par l'influence de la composition du sol, de la structure du tissu, du taux de surconsolidation (OCR) et de la plasticité dans le comportement dépendant du temps et les caractéristiques de compression des argiles. Cependant, une description complète et une corrélation de ces facteurs doivent encore être proposées. Pour combler cette lacune, une étude expérimentale approfondie a été menée dans des conditions bien définies. Les échantillons reconstitués, comprenant des argiles à faible plasticité (kaolinite), des argiles à haute plasticité (bentonite) et leurs mélanges, ont été soumis à des tests œdométriques standards et de fluage. Nous montrons que les échantillons ayant une plasticité plus faible présentent des changements de volume réduits lors de la compression et du gonflement et des valeurs plus faibles du coefficient de fluage (C_α). La dépendance du C_α à la contrainte est plus prononcée dans les mélanges contenant de la bentonite que dans la kaolinite pure. En outre, une forte dépendance de Cα à l'OCR a été observée.

Keywords: Soil plasticity; compression characteristics; creep behaviour; over-consolidation ratio; coefficient of secondary compression.

1 INTRODUCTION

Soil plasticity and composition have been shown to affect the mechanical response of clays, as has been presented by Olek (2022) in the context of creep behaviour. Soil creep characteristics are commonly described using a parameter known as the "coefficient of secondary compression - C_α" (Mesri, 1973). This parameter holds significance in engineering applications and constitutive modelling, particularly when estimating creep settlements. The time-dependent behaviour is traditionally characterised by linearly determining C_α through the relationship between the void ratio and the logarithmic function of time. Yin (1999) illustrated that the creep coefficient exhibits variation with the void ratio and the limitations associated with the logarithmic function used for linear performance. Nevertheless, for this paper, the linear formulation, as employed by Olek

(2022), is adopted to ascertain the parameter C_α. As for the stress dependency of C_α, there exist two conflicting perspectives. Barden and Laing (1969) assert that C_α is nearly independent of stress level, contrary to the findings of other researchers such as Lei et al. (2016).

Soil plasticity is the property governing deformation in soil without the occurrence of cracking or fracturing, making it a crucial aspect for analyzing long-term deformation, commonly known as creep deformation. The observed impact of clay plasticity on clay creep has been shown by Anagnostopoulos and Grammatikopoulos (2011), who conducted oedometer creep tests on thirteen types of natural clays in the broader Thessaloniki area, Greece. The findings suggest that the creep coefficient relies on both plasticity and water content. Additionally, Karstunnen and Yin (2010) established that the creep coefficient exhibits dependence on the process of destructuration specifically within intact natural clays. Despite these insights, there has been limited exploration into the influence of clay structure, including plasticity and its OCR on creep properties and soil responses, particularly when studying reconstituted samples of clays.

Varatharajan and Sivarajan (2011) observed that bentonite, a highly plastic clay, demonstrates more significant creep deformation compared to kaolin, a clay with lower plasticity. Nevertheless, the effect of long-term creep behaviour was not explored, leaving a gap in our understanding of this aspect. A comprehensive exploration of clay plasticity's influence on clay compression behaviour is lacking, highlighting a notable gap in our foundational understanding of time-dependent clay behaviour. To enhance our understanding of how soil plasticity influences the creep behaviour of clay soils, we have initiated a comprehensive experimental program involving the preparation of artificial mixtures of kaolin (K) and bentonite (B) and their mixtures.

2 METHODOLOGY AND MATERIAL

2.1 Methodology

The main goal of this contribution is to gather comprehensive experimental data on how plasticity influences compression (via standard oedometric tests) and creep behaviour (creep oedometric tests) of clays. Soil samples were prepared as mixtures with different proportion rates of kaolinite (K – low plasticity clay) and bentonite (B – high plasticity clay). Individual samples (further denoted as „mixtures“) are denoted such as 100K, 75K-25B, 50K-50B, 25K-75B, and 100B, showing the proportion of individual clays (such as 100K – 100% of kaolinite and 0% of bentonite clay). Plastic and liquid limits were determined for each mixture. Specifically, the plastic limit for each mixture was determined through interpolation using referenced values from (Sivapullaiah et al., 1985) and (Duque et al., 2022). For the determination of liquid limit (LL), the cone penetration method was employed. This method relies on the soil's shear strength, offering improved accuracy and preventing potential overestimation of the liquid limit, particularly in soils with LL exceeding 100% (e.g., bentonite) (Orhan et al., 2006).

Table 1 presents PL, LL, and plasticity index (PI) values. As anticipated, mixtures with a higher bentonite proportion demonstrate elevated PI values.

Table 1. PL, LL and PI of all mixtures.

Mixtures	PL(%)	LL(%)	PI
K	40	64.55	24.55
75K-25B	42.42	124.80	82.37
50K-50B	44.85	229.07	184.22
25K-75B	47.27	287.70	240.42
B	49.7	315.37	265.67

For oedometer tests, an analysis of soil compression, characterized by the critical state line slope (λ^*) in the e-ln(p) space, and swelling, represented by the unloading-reloading line slope (κ^*) in the same space, was performed. Parameters λ^* and κ^* are based on the definitions from the hypoplastic model for clays proposed by Masin (2005) and are equivalent to C_c and C_r. The creep oedometer tests undergo a minimum 7-day creep period after T_{eop}. This timeframe is deemed adequate, as indicated by prior research on reconstituted samples, where T_{eop} is typically achieved within 24 hours (Olek, 2022), (Lei et al., 2016). T_{eop} was determined for each creep stage by Casagrande‘s method (Taylor, 1948). The impact of soil plasticity on long-term settlement was explored by assessing the secondary compression coefficient (C_α):

$$C_\alpha = \frac{\Delta e}{\Delta \log t} \quad (1)$$

The current OCR was determined for every stress increment to address the influence of the OCR on determined soil characteristics. The OCR is defined as $\sigma'_p/\ \sigma'_z$, where σ'_p is the pre-consolidation stress and σ'_z is the applied experimental stress. In standard oedometer tests (refer to Table 2 for the applied stress levels), the kaolinite sample was subjected to a maximum of 1600 kPa, while the remaining samples were loaded to a maximum of 800 kPa due to the excessive deformation. In the case of creep oedometer

tests, bentonite is exposed to a maximum 200 kPa creep stage, while the other samples undergo a maximum of 400 kPa.

Table 2. Experimental plan, note the steps in brackets were performed only for mixtures and kaolinite.

Test	Creep Stress (kPa)/ Stress Increments (kPa)
Creep test	25-50-100-200(-400)
Standard oed. test	0-25-50-100-200-400-800(-1600-800)-400-200-100-50-25-0

2.2 Material

In preparing the investigated materials, specimens comprised dry kaolin and bentonite powder blended with distilled water. Prescribed guidelines dictate initial water content: W_i = 1.4-2.2LL for pure kaolinite tests, W_i = 1.2-1.6LL for pure bentonite tests, and equivalent water contents of 1.4-2.0LL for mixtures. Varied initial water content aims to assess its impact on compression characteristics and determine the content required for normal consolidation across diverse stress levels (e.g., 25, 50, 100 kPa), especially at low stresses. This procedure has been implemented to avoid comparing the mechanical behaviour of normally consolidated samples with over-consolidated ones.

3 RESULTS

3.1 Influence of initial water content on kaolinite compression characteristics

For kaolinite, we analysed compression curves and as expected, we found out that their shape is dependent on the initial water content, even after joining NCL as shown in Figure 1. The NCL is notably influenced by W_i, with a downward shift at lower W_i levels, converging after 200 kPa. This indicates over-consolidation at low stresses (~<200 kPa) for lower W_i. Utilizing the data, we establish a relationship between OCR and W_i, defining the highest NCL (W_i = 148.2%) as the benchmark for OCR = 1.0.

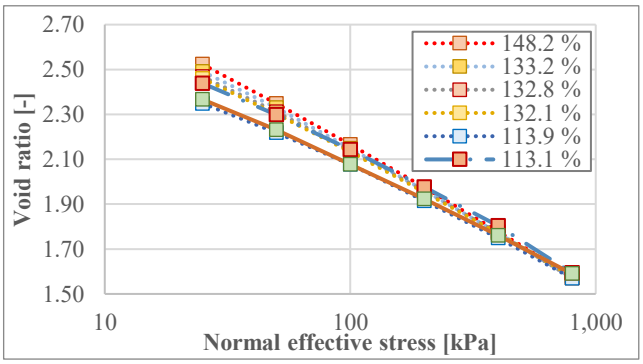

Figure 1. Influence of initial water content (W_i, in per cent) of reconstituted samples of kaolinite on NCL.

The OCR is referenced to the test with the highest initial water content, W_i = 148.2% (and thus the highest positioned NCL). Figure 2 depicts the relationship between OCR and W_i, revealing an inverse proportionality at low-stress levels. Around W_i = 130%, the OCR decreases to ~1.0 establishing this value as a limit. Beyond this limit, OCR remains stable. Thus, precise regulation of W_i is crucial to establishing an accurate NCL for the entire experimental scope. Figure 2 validates using W_i approximately twice the liquid limit for kaolinite, ensuring a normal consolidation state across all stress levels (25, 50, 100, 200, etc.)

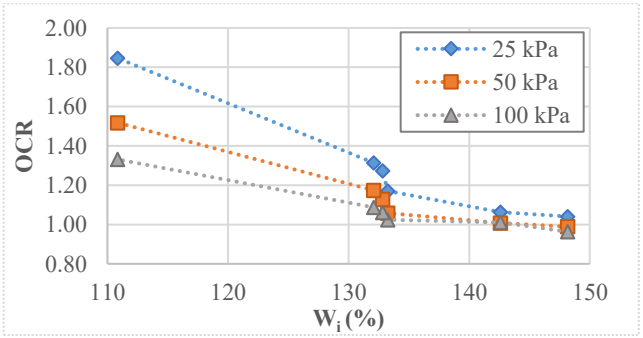

Figure 2. Correlation between initial water content and OCR of kaolinite at low-stress levels.

3.2 Influence of plasticity on soil compression characteristics

To examine the impact of plasticity on compression characteristics, Figure 3 illustrates the variation in λ^* and κ^* across all tested mixtures (represented by PI). The sample with lower plasticity (and lower proportion of bentonite) demonstrates reduced values of λ^* and κ^*, corresponding to lesser volume change during compression and swelling.

The primary consolidation duration (T_{eop}) is influenced by soil composition, as shown in Figure 4. Samples with higher bentonite percentages exhibit prolonged primary consolidation. Notably, for mixtures with bentonite (from 25K-75B to B), T_{eop}

reaches its maximum at 50 kPa, gradually decreasing until 200 kPa. In contrast, for kaolinite, T_{eop} is around 12 minutes at 25 kPa and remains relatively around 18 minutes during subsequent compression.

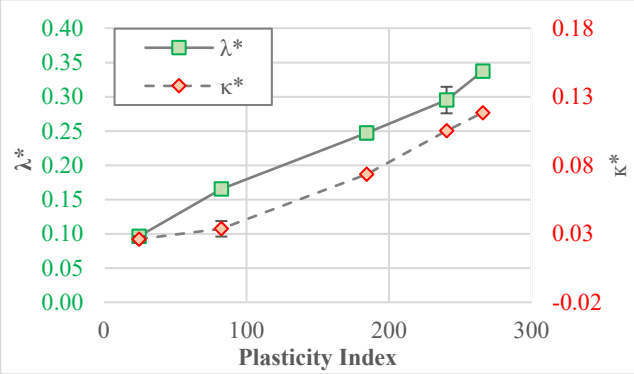

Figure 3. Evolution of compression indices (λ, κ*) with plasticity for different mixtures.*

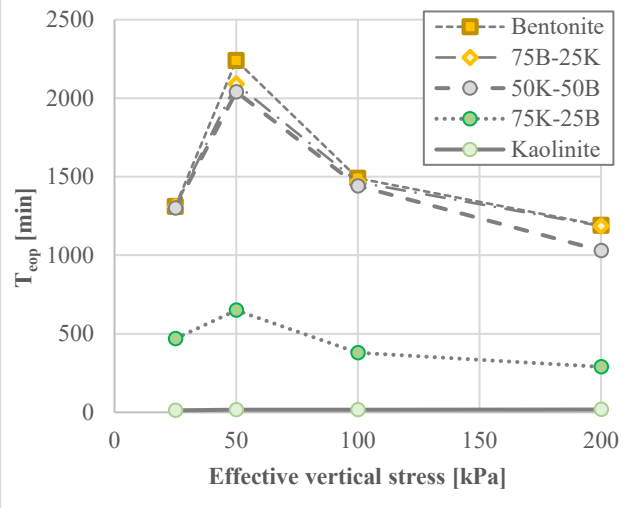

Figure 4. Influence of stress levels and soil plasticity on T_{eop}.

3.3 Influence of plasticity on creep behaviour

C_α is plotted against various soil compositions, represented by different Plasticity Index (PI) values at three stress levels (50, 100, 200 kPa), as depicted in Figure 5. Mixtures with higher plasticity manifest elevated C_α values, exhibiting significant changes among different stress levels. Conversely, the lower plasticity sample exhibits a contrasting trend; for instance, the C_α values for kaolinite remain nearly constant across all applied stress levels.

Figure 6 reveals another intriguing aspect: a trendline resembling the correlation between C_α and the stress level. Notably, the C_α values peak at 50 kPa across all mixtures containing bentonite. In the case of kaolinite, C_α for kaolinite shows only a statistically insignificant increase with applied stress across all applied stress levels. In the figures, we also present the values of OCR at all stress levels.

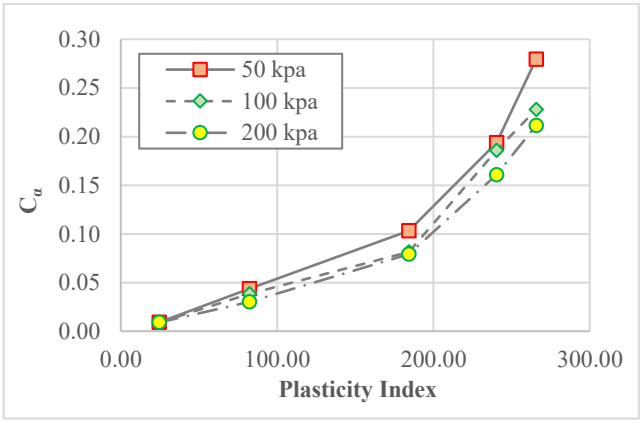

Figure 5. Correlation between C_α and soil plasticity.

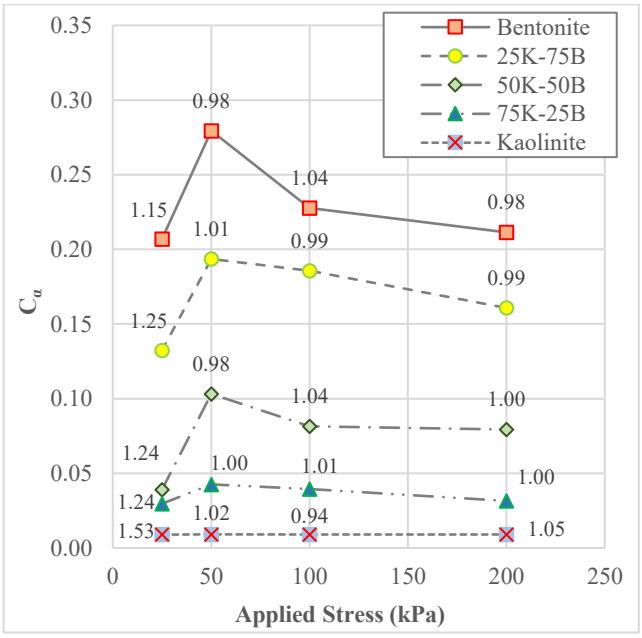

Figure 6. Influence of soil compositions on C_α at different stress levels. OCR at the current stress level is shown for all experiments.

All soil samples display over-consolidation in the 25 kPa stress range, with OCR values ranging from 1.1 to 1.53, and sample over-consolidation being the most likely factor in the low C_α at 25 kPa. Starting from 50 kPa, OCR values stabilize around 1. Capturing a definitive trend even for lower stresses requires additional experiments with high initial water content (W_i).

4 CONCLUSIONS

In this contribution, we presented an extensive experimental study consisting of 18 standard and 20 creep oedometric tests performed on low-plasticity clay (kaolinite), high-plasticity clay (bentonite), and their mixtures.

- Initial water content (W_i) plays a pivotal role in governing the OCR, especially at low stress

levels. Elevated W_i corresponds to a lower OCR value. Relatively low W_i (<130% for kaolinite) translates to samples being tested in overconsolidated state, which makes comparison of soil characteristics at low and high stresses impossible. It also induces a downward shift in the shape of NCL, evident at lower W_i levels and converging after reaching 200 kPa.

- Samples with lower plasticity exhibit reduced volume changes during compression and swelling, as evidenced by smaller values of λ* and κ*.
- Soils with higher plasticity display increased creep deformation, as indicated by higher values of the creep coefficient (C_α). The stress dependency of C_α is more pronounced in mixtures containing bentonite, as evidenced by a significant change in C_α, in contrast to the marginal change observed in kaolinite. Nevertheless, C_α attains its peak value at 50 kPa in all mixtures. A similar trend is also observed in T_{eop}. To accurately delineate the trend of C_α and T_{eop} with increasing stress levels, additional tests at higher W_i are essential. This precaution is necessary to prevent the manifestation of sample over-consolidation at 25 kPa, a probable cause for the lower C_α and T_{eop} at this stress level.
- Limitation of creep analysis arises from the limited amount of data, especially in case of bentonite and mixtures. That causes the shortcoming in investigating the influence of W_i on OCR at individual stress levels, correlation between OCR and C_α and statistical analysis of data.
- Primary objective is to correlate compression characteristics, creep coefficient, OCR, and soil plasticity. This requires thorough verification and determination of plasticity index values through an alternative experimental method for liquid limit, such as Cassagrande percussion cup method. Hence, more tests are essential to acquire a comprehensive dataset for subsequent statistical analysis.

Nonlinear finite element analyses of earthquake effects in slopes

Analyses non-linéaires par éléments finis des effets sismiques sur les pentes

A. Eikebrokk*, A.M. Kaynia
Norconsult, Sandvika, Norway

**anna.eikebrokk@norconsult.com*

ABSTRACT: Assessment of seismic slope stability traditionally rely on pseudo-static approaches whereby the seismic loads are simplified as static loads and applied to the model. These analyses tend to be conservative and may result in unnecessary and costly countermeasures. In many such cases, the slope will experience some permanent deformation, but it will not fail. Therefore, a more realistic approach is to assess the slope stability using finite element analyses and defining the seismic load in terms of acceleration time histories. The limit state is then defined by acceptable levels of displacements and strains, and satisfactory functionality of the construction possibly affected by the slope movement. In this study, the dynamics module of the finite element software *Plaxis 2D* has been utilized for the analyses. The conventional *Mohr-Coulomb model* is employed to characterize the soil's undrained behavior during the earthquake situation. This model is a linear elastic perfectly plastic material model in which the undrained shear strength is related to the soil's effective vertical stress. The cyclic shear strength in the model was determined through calculations and specialized cyclic laboratory tests conducted on soil samples from the site. The estimation of shear strength includes the effect of the static shear stress due to gravity, which was confirmed by the lab test results. Nonlinear finite element analyses using this approach have yielded promising results, suggesting that the approach is a more realistic method for assessing seismic slope stability.

RÉSUMÉ: Evaluation de la stabilité des pentes sismiques repose traditionnellement sur des approches pseudo-statiques où les charges sismiques sont simplifiées comme des charges statiques et appliquées au modèle. Ces analyses ont tendance à être conservatrices et peuvent entraîner des contre-mesures inutiles et coûteuses. Dans de nombreux cas, la pente subira une déformation permanente, mais elle ne faillira pas. Par conséquent, une approche plus réaliste consiste à évaluer la stabilité de la pente en utilisant des analyses par éléments finis et en définissant la charge sismique en termes d'historiques de temps d'accélération. L'état limite est alors défini par des niveaux acceptables de déplacements et de contraintes, et une fonctionnalité satisfaisante de la construction éventuellement affectée par le mouvement de la pente. Dans cette étude, le module de dynamique du logiciel d'éléments finis Plaxis 2D a été utilisé pour les analyses. Le modèle conventionnel de Mohr-Coulomb est employé pour caractériser le comportement non drainé du sol pendant la situation de séisme. Ce modèle est un modèle de matériau élastique parfaitement plastique linéaire dans lequel la résistance au cisaillement non drainé est liée à la contrainte verticale effective du sol. La résistance au cisaillement cyclique dans le modèle a été déterminée par des calculs et des tests de laboratoire cycliques spécialisés effectués sur des échantillons de sol du site. La résistance au cisaillement comprend l'effet de la contrainte de cisaillement statique due à la gravité, ce qui a été confirmé par les résultats des tests de laboratoire. Des analyses non linéaires par éléments finis utilisant cette approche ont donné des résultats prometteurs, suggérant que l'approche est une méthode plus réaliste pour évaluer la stabilité sismiques des pentes.

1 INTRODUCTION

Most seismic codes, including Eurocode 8 (2014), require verification of ground stability for structures to be erected on or near natural or artificial slopes. The assessment of the seismic slope stability can be performed by a pseudo-static approach or by a dynamic analysis. However, a significant drawback of the pseudo-static analyses is that they tend to be too conservative. In cases where a pseudo-static analysis does not provide the required safety factor, it is advisable to base the assessment on a performance-based design whereby one can use a nonlinear dynamic analysis, for example in finite elements (FE) or finite difference (FD) and estimate the permanent displacements and shear strains in the slope. The assessment can then be based on the computed response against the required performance criteria. This method has been used extensively in soil and rock slopes in seismic areas with different computational solutions such as 2D/3D FE or FD, complex loading and geometry, and advanced constitutive modelling accounting for strain softening due to cyclic loading

and liquefaction among others. See, for example (Kaynia, 2018) for a review of these solutions.

In this study, the more realistic, dynamic analyses of the seismic slope stability are investigated together with a new procedure for determining the cyclic undrained shear strength in slopes.

The work showcased in this article was conducted in conjunction with the design of the Tangenvika railway bridge in Norway, to be constructed by the construction company Implenia for the Norwegian Rail Infrastructure, Bane NOR.

2 ANALYSIS METHOD

To assess the impact of earthquake on slope stability, the dynamics module of Plaxis 2D has been utilized. Three acceleration time histories scaled to the peak acceleration at site were used. Figure 1 shows the time history of Imperial Valley earthquake, 1979. The other two earthquakes were Nahanni (Canada, 1985) and Friuli (Italy, 1976).

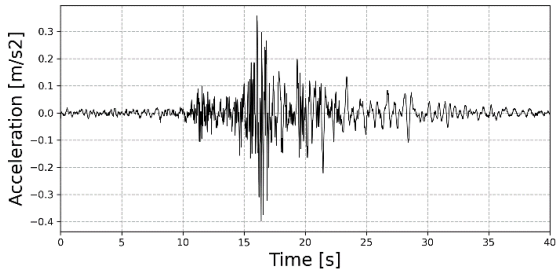

Figure 1. Acceleration time history for Imperial Valley earthquake scaled to peak acceleration at site.

To identify areas with potential stability issues, a seabed mapping was conducted using a multibeam echosounder (MBES). Based on the terrain analysis of this data along the bridge profile and geotechnical considerations, axis 10 was identified as the most vulnerable to earthquake shaking. The analyses related to this location are presented in this article. Figure 2 shows the Plaxis model used for the earthquake analyses of this slope.

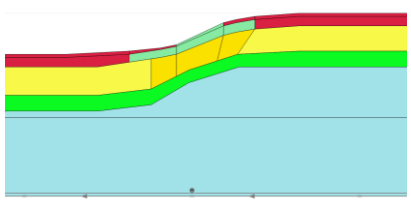

Figure 2. PLAXIS model of slope in axis 10.

To account for both the initial drained stresses in the silt and sand layers due to gravity and the cyclic undrained stresses during the earthquake, a new procedure based on the work of (Andersen, 2015) was used to estimate the shear strength of the soil. The procedure is outlined in the next section. The so-called *Shansep (Stress History and Normalized Soil Engineering properties) MC* model built in Plaxis allows an effective implementation of this procedure in the earthquake analyses.

2.1 Cyclic Shear Strength

Lab tests have shown that undrained cyclic shear strength can be increased in areas where consolidated static shear stresses are acting such as in slopes. The static shear stress will reduce the concurrent cyclic component of additional load. However, the total cyclic shear strength, $\tau_{f,cy}$, which is the sum of the static, τ_a, and cyclic shear component leading to failure, $\tau_{cy,f}$, will increase in most cases. The cyclic shear strength is the peak shear stress that can be mobilized during cyclic loading and is accordingly expressed as (Andersen and Lauritzen, 1988):

$$\tau_{f,cy} = \left(\tau_a + \tau_{cy}\right)_f \qquad (1)$$

Using published data (Andersen, 2015) one can estimate $\tau_{cy,f}$ in Eq. (1) using an interaction diagram as visualized in Figure 3. The intersection of the interaction line and the horizontal and vertical axes are correspondingly drained static shear strength and undrained cyclic shear strength under one-way loading. Using the average shear stress along the slope, the corresponding cyclic shear strength can be estimated from the interaction diagram. See example of the method applied further below.

The *Shansep MC model* introduces a cyclic factor, α, which normalizes the cyclic shear strength, $\tau_{f,cy}$, to the effective vertical stress, σ_v':

$$\alpha = \frac{\tau_{f,cy}}{\sigma_v'} \qquad (2)$$

For non-liquefiable soils, conservative values for the cyclic shear strength, $\tau_{cy,f}$, normalized with σ_v' as a function of Dr have been suggested (Andersen, 2015) which give normalized cyclic shear strength for the interpreted Dr = 40% for the silt and sand layers equal to 0.16.

Further, the estimated friction angle of the sand layer is 34 °, which gives static shear strength of the sand:

$$\tau_f = \sigma_n' \tan(34°) = \sigma_v' \sin(34°) \qquad (3)$$

where σ_n' is the effective normal stress on the failure plane and σ_v' is the corresponding vertical stress. Thus, the normalized static shear strength $\frac{\tau_f}{\sigma_v'} = 0{,}56$.

The average shear stress along the slope is correspondingly:

$$\tau_a = \sigma_v' \sin(\beta) \qquad (4)$$

where β is the angle of the slope.

Using the interaction diagram in Figure 3 and the average normalized shear stress along the slope, $\frac{\tau_a}{\sigma_v'} = 0.18$, one can estimate the normalized cyclic shear strength $\frac{\tau_{cy,f}}{\sigma_{v'}} = 0.11$. Therefore, the total normalized cyclic shear strength along the slope is 0.29 which is considerably larger than the cyclic shear strength without the effect of average shear stress.

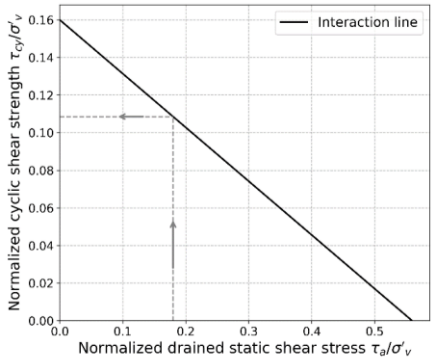

Figure 3. Interaction diagram for cyclic shear strength.

3 CYCLIC SIMPLE SHEAR TESTS

3.1 Laboratory Procedure

To investigate the actual in situ shear strength of the soil at the site and to confirm the selected strength parameters, cyclic direct shear tests (DSS) were carried out at NGI laboratory. The samples were taken from 3.4 m – 3.6 m below seafloor, where the sample quality was deemed best. Based on visual inspection, the material was described as clayey silt interspersed with thin sand layers and sporadic pockets of clay (Figure 4).

Figure 4. Tested specimen.

The DSS-tests were conducted one-way (unsymmetrical) and two-way (symmetrical, i.e., with no application of average shear stress). The unsymmetrical shear tests were intended to investigate the shear strength of the soil in sloping terrain. The equivalent number of stress cycles, *N*, for the design earthquake in the project site is about 5. However, the tests were conducted with additional cycles and increasing packets of higher shear stress to capture its ultimate strength. The experimental program is summarized in Table 1, while details for test ID 4 is given in Table 2.

Table 1. Laboratory programme, DSS cyclic tests.

Test ID	Test type	Depth below seafloor [m]	Consolidation stress [kPa]
1	Two way	3.43	24.0
4	One way	3.53	24.7
5	One way	3.56	24.9

Table 2. Stages of cyclic DSS test 4.

Stages	τ_a [kPa]	τ_{cy} [kPa]	N	$\frac{\tau_a}{\sigma_v'}$	$\frac{\tau_{cy}}{\sigma_v'}$
Cyclic 1	8.6	1.2	5	0.35	0.05
Cyclic 2	8.6	2.5	5	0.35	0.10
Cyclic 3	8.6	3.7	5	0.35	0.15
Cyclic 4	8.6	6.2	5	0.35	0.25
Cyclic 5	8.6	7.4	40	0.35	0.30

3.2 Experimental results

The test ID 4 results are shown in Figure 5. Calculated values for the cyclic factor, α, for all tests are summarized in Table 3.

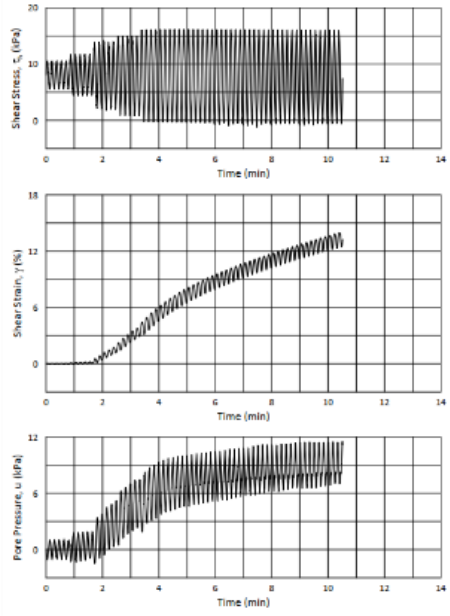

Figure 5. Laboratory results plotted vs time.

Test ID	1	4	5
Cyclic factor	0.33	0.65	1.16

4 RESULTS FINITE ELEMENT ANALYSES

Table 4 provides typical values for deformations and strains along the slope for the Imperial Valley acceleration time history which was found to give the largest response among the three selected earthquakes. Figure 6 and Figure 7 display the contours of the computed deformations and shear strains in the model. The permanent strain in the clay layer is approximately 0.6%, which is below the acceptable limits (Earthquake design at Norwegian Public Roads Administration, 2017). Consequently, the post-earthquake stability can be considered satisfactory.

Table 4. Typical responses in the slope for Imperial Valley time history.

5 CONCLUSIONS

This research has implemented a more realistic approach using nonlinear finite element analyses to investigate slope stability during the design earthquake. An integral aspect of this research was the determination of the cyclic shear strength. Recognizing that the presence of consolidated static shear stress enhances the cyclic strength has proved to be central to the analyses. The conducted laboratory investigations confirmed and further established a notably higher cyclic factor in slopes compared to flat terrains. Overall, these findings reinforce the potential of nonlinear finite element analyses in providing more accurate and realistic assessments of slope stability in earthquake-prone regions.

ACKNOWLEDGEMENTS

This work was made possible through the design contract for the construction company Implenia and the Norwegian Rail Infrastructure, Bane NOR. Their support during this study is gratefully acknowledged. Also, appreciation is extended to the Norconsult colleagues Magnar Myhre, project manager, and Kjetil Kildal, geotechnical discipline leader, for discussions and their collaboration throughout the study.

Appraisal of various measures for liquefaction flowslide mitigation in a mild sloping ground

Évaluation de diverses mesures d'atténuation des glissements de liquéfaction dans un terrain en pente douce

ABSTRACT: Liquefaction-induced flowslides would cause significant damages and casualties as the case of 2018.9.28 incidences of Palu, Sulawesi, Indonesia, where the flowslides occurred immediately after a severe earthquake and led to an extremely-long distance of sliding on mild sloping ground. The conditions that would favour soil liquefaction and the associated flowsliding hence become the focus of the incident. Another issue deserved further attention, however, would be strategy for preventing or mitigating the problem. In accordance, the aim of this study is to apprise the performance and effectiveness of various measures on the mitigation of soil liquefaction and flowsliding. The mitigation measures considered herein include: stone-column (SC), micro-pile (MP), densification (DS), encased stone column (ESC) soil grouting (GT), and groundwater lowering (GL), which are commonly adopted in engineering practice. The performance and effectiveness of the mitigation measures are assessed numerically in terms of their responses in the excess pore pressure generation in soil as well as the lateral deformation of soil deposit due to the excitation of seismic motion. Results generally indicate the SC, ESC, and DS options are more effective in prohibiting the generation of excess pore pressure, and hence in reducing soil liquefaction, than the other options. We also notice the MP, SC, and ESC options would be more effective in preventing the lateral deformation, and therefore in avoiding the flowslide or lateral spread in soil deposit.

RÉSUMÉ: Les glissements de terrain induits par la liquéfaction causeraient des dommages et des pertes importants, comme dans le cas des incidents du 28 septembre 2018 à Palu, Sulawesi, en Indonésie, où les glissements de terrain se sont produits immédiatement après un grave tremblement de terre et ont conduit à une distance de glissement extrêmement longue sur un terrain en pente douce. Les conditions qui favoriseraient la liquéfaction des sols et les glissements d'écoulement associés deviennent alors au centre de l'incident. Une autre question qui mériterait davantage d'attention serait celle de la stratégie visant à prévenir ou à atténuer le problème. Conformément, le but de cette étude est d'évaluer la performance et l'efficacité de diverses mesures d'atténuation de la liquéfaction des sols et des glissements de terrain. Les mesures d'atténuation envisagées ici comprennent: les colonnes de pierres (SC), les micro-pieux (MP), la densification (DS), les colonnes de pierres enrobées (ESC), l'injection de sol (GT) et l'abaissement des eaux souterraines (GL), qui sont couramment adoptées dans pratique de l'ingénierie. La performance et l'efficacité des mesures d'atténuation sont évaluées numériquement en termes de leurs réponses à la génération de pression interstitielle excessive dans le sol ainsi qu'à la déformation latérale des dépôts de sol due à l'excitation du mouvement sismique. Les résultats indiquent généralement que les options SC, ESC et DS sont plus efficaces pour empêcher la génération d'une pression interstitielle excessive, et donc pour réduire la liquéfaction du sol, que les autres options. Nous remarquons également que les options MP, SC et ESC seraient plus efficaces pour prévenir la déformation latérale, et donc pour éviter le glissement ou la propagation latérale dans les dépôts de sol.

Keywords: Mitigation measures; liquefaction flowslide; sloping ground; numerical assessment.

1 INTRODUCTION

Soil liquefaction is the phenomenon associated with strong earthquake which would be of the most catastrophic consequences of earthquake and thus has caused severe damage to the structures. Mainly, liquefaction induced earthquake might cause a significant loss of strength of soil masses with a progressive generation of pore pressure, and thus resulting in large permanent deformation, including

lateral spreading and settlement), and even flowslide failure of soils. Case histories were observed as the Petobo flow failure causing significant movement in a mildly sloping ground due to 2018 Palu-Donggala Indonesia earthquake (Kusumawardani, et al., 2021). Consequently, one of the most important strategy of earthquake-resistant design is to avoid or decrease liquefaction-induced deformations of foundation soils. Ground improvement and soil reinforcement are the most useful methods for improving the strength properties of soils and have been performed in order to avoid or decrease the liquefaction-induced soil deformations and associated damage. For example, the geosynthetics are main materials used for increasing the strength and stability of geotechnical structures (Hosseinpour et al., 2010). Several liquefaction mitigation techniques have been proposed over the years, including densification, grouting, and groundwater lowering. Although, the majority of these methods proves inapplicable or difficult to implement for various reasons and has been based on conceptual understanding or simplified analysis. Accordingly, the mitigation of liquefaction disasters would be a primary concern in engineering practice. Through rigorous finite element analyses, this paper addresses assessment of several liquefaction mitigation measures, including stone-column (SC), micro-pile (MP), densification (DS), encased stone column (ESC), soil grouting (GT), and groundwater lowering (GL), with an aim to provide a clearer understanding on effectiveness of ground improvement methods and to assess the liquefaction-induced soil deformations to acceptable levels for construction.

2 ANALYSIS METHOD

The assessment adopts a numerical tool for all simulations by using OpenSeesPL, which is a graphical user interface for conducting 3D ground-structure finite element analysis (http://opensees.berkeley.edu). A 20-8-node element is assumed, where 20 nodes are for solid translation degree for freedom and 8 corner nodes for fluid pressure. Multi-yield conical surfaces with considering phase transformation are applied for soils. The couple solid-fluid option of the software enables the performance of liquefaction studies. We describe the results of 3D seismic response with considering the behavior of soil in the center and the edge of soil column. In total, 88 simulations were performed to explore different combinations of influence factors, including the original cases (i.e., without any improvement).

Figure 1 indicates a typical soil column of the improved ground with a depth of 30 m, where a periodic boundary condition is assumed for the vertical faces and fix end at the base of column. Due to symmetric, only one half of the soil column is assumed in the numerical analysis. As indicated, the seismic shaking is assigned at the base of the soil column and acting in x-direction.

A liquefaction-prone area at Chuoshui river alluvial fan-delta (CRAFD; Chang et al., 2012) is selected as the target site with a groundwater level of 3.84 m below ground surface, where the log of Borehole W5-3, as shown in Figure 2, is adopted as the soil deposit with improvements by several mitigation measures in current study. It is noticed that the numerical analyses composed of clay and silt layers beneath a deposit of very loose sand to medium which are prone to liquefaction due to seismic shaking. Tables 1 and 2 indicate the assumed material parameters of soil deposit and mitigation as well as geosynthetic measures in numerical simulations.

The input motion of this study adopts the recorded motion at CHY002 station during 1999 Chi-Chi earthquake (M_W = 7.6) of Taiwan. The recorded motion, however, should be scaled to the design earthquake of the site (M_W = 7.1 and a_{max} = 0.308g) based on local building code (MOI, 2011), and then deconvoluted from ground surface to a depth of 30m of the site for OpenSeesPL analysis. Figure 3 shows the deconvoluted input motion for this study (a_{max} = 0.250g).

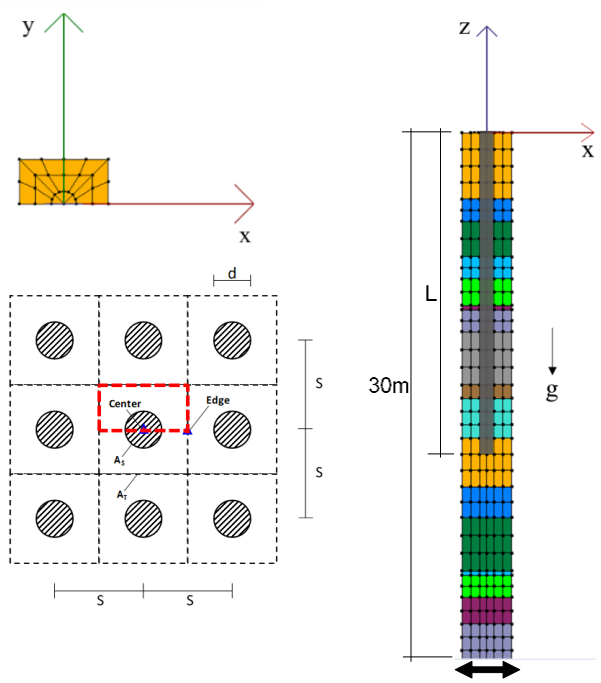

Figure 1. Finite element meshes of representative soil column for numerical simulations.

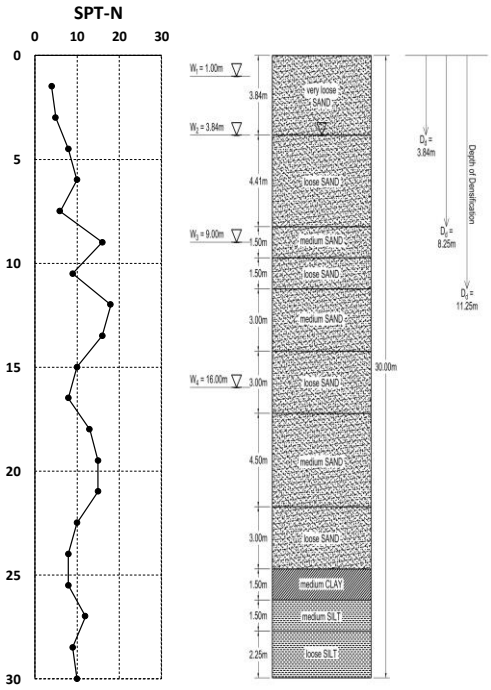

Figure 2. Typical soil/SPT-N profile, based on Borehole W5-3 in CRAFD, for current analysis.

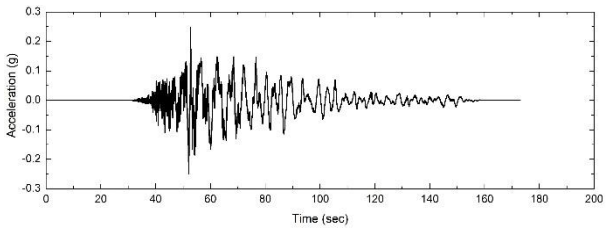

Figure 3. Deconvoluted input motion originally recorded at Station CHY002 (ground surface), in proximity of Borehole W5-3 with a distance < 2 km, during the 1999 Chi-Chi earthquake of Taiwan.

3 ASSESSMENT RESULTS

A comparative study of the seismic performance evaluation of stone-column (SC), micro-pile (MP), densification (DS), encased stone column (ESC), soil grouting (GT), groundwater lowering (GL) is compared with the original deposit (i.e., original ground, OG; without improvement). Typical range of design specifications for each of the options are selected, as indicated in the relevant figures, with varied spacing (s) for SC options, embedment depths (L) for MP options, depth of densification (D_d), thickness of geosynthetic (t) for ESC option, ground improvement ratio (Ir) for GT option, depth of groundwater (W) for GW option.

Table 2. Geosynthetic parameters.

Parameter	Geosynthetic	References
γ_{geosyn}(t/m^3)	0.13	IndoFelt Specification
v_{geosyn}	0.30	Murugesan and Rajagopal, 2006
E (kN/m^2)	1.00×10^6	Tang et al., 2015
k_{geosyn} (m/s)	1.00×10^{-3}	Tang et al., 2015
J (kN/m)	1.00×10^3	Tang et al., 2015
GJ (kN/m^2)	3.85×10^8	For t= 1mm, E= 10^6 kPa
k_{SC} (m/s)	1.00×10^{-2}	
G (kN/m^2)	3.85×10^5	
B (kN/m^2)	8.33×10^5	

Note: γ_{geosyn} = unit weight; v_{geosyn} = Poisson's ratio; E = Young's modulus; k_{geosyn} = permeability of geosynthetic; J = stiffness of geosynthetic; GJ = torsional rigidity; k_{SC} = permeability of stone-column; G = shear modulus of geosynthetic; B = bulk modulus of geosynthetic; Rayleigh damping for geosynthetic is 2%.

3.1 Excess pore pressure generation

For level ground, the computed excess pore pressure at a depth of 7m of deposit are shown in Figure 4. As seen, the SC, ESC, and DS options are more effective in dissipating the excess pore pressure than the other

Table 1. Adopted material parameters for original soil deposit (original ground; OG) and for liquefaction mitigation options of stone-column (SC) and micro-pile (MP).

Parameters	Original Ground (OG)						Stone Column (SC)	Micro Pile (MP)
	Very Loose SAND	Loose SAND	Medium SAND	Loose SILT	Medium SILT	Medium CLAY		
γ (kN/m^3)	16.7	16.7	18.6	16.7	18.6	14.7	18.5	24.5
ϕ (deg.)	29	29	33	29	33	0	33	-
c (kPa)	-	-	-	-	-	37	-	-
ϕ_{PT} (deg.)	29	29	27	29	27	-	27	-
G_r (kPa)	5.5E4	5.5E4	7.5E4	5.5E4	7.5E4	6.0E4	7.5E4	1.4E7
B_r (kPa)	1.5E5	1.5E5	2.0E5	1.5E5	2.0E5	3.0E5	2.0E5	-
K_{soil} (m/s)	6.6E-5	6.6E-5	6.6E-5	1.0E-7	1.0E-7	1.0E-9	-	-
K_{SC} (m/s)	-	-	-	-	-	-	1E-4, 1E-2, 1E0	-
E_r (kPa)	-	-	-	-	-	-	-	3.5E7
ν	-	-	-	-	-	-	-	0.2
σ_{py} (kPa)	-	-	-	-	-	-	-	5.2E4

Note: γ = unit weight; ϕ = friction angle; c = cohesion; ϕ_{PT} = phase transformation friction angle; G_r = shear modulus at a reference effective confining pressure of 80kPa; B_r = bulk modulus at a reference effective confining pressure of 80kPa; K_{soil} = hydraulic conductivity of soil; K_{SC} = hydraulic conductivity of stone-column; E_r = Young's modulus at a reference effective confining pressure of 80kPa; ν = Poisson's ratio; σ_{py} = yield stress.

options. The GT option shows decreasing in excess pore pressure and indicates no soil liquefaction at this depth. The results of excess pore pressure for GL option would be zero. Due to the soil-structure interaction, the excess pore pressure response in soil is oscillating severely by shaking for the MP option.

3.2 Lateral deformation time history

Figure 5 shows lateral deformation time histories computed at the depth of 7m of a mildly sloping ground (i=3deg.). As seen, the MP, SC, and ESC options would be more effective in preventing the lateral deformation than the other options, it is due to the increasing of the stiffness of soil mass. The GT and DS options would increase their inertia and lateral deformations are close or even more than the case of the original ground (OG).

3.3 Lateral deformation profile

Figure 6 shows the lateral deformation profiles of soil deposit with a slightly inclined ground (i=3deg.). Obviously, the MP, SC, and ESC options are most effective in preventing the lateral movement of soil deposits than the other options. The GL option would reduce the lateral movement by lowering the groundwater level down to 9m, however, not as effective as the MP, SC, and ESC options. The DS and GT options would densify or solidify the ground and reduce to some degree the generation of excess pore pressure, however, they tend to amplify the lateral movement as a result of the increase of soil density and inertia force by the shaking.

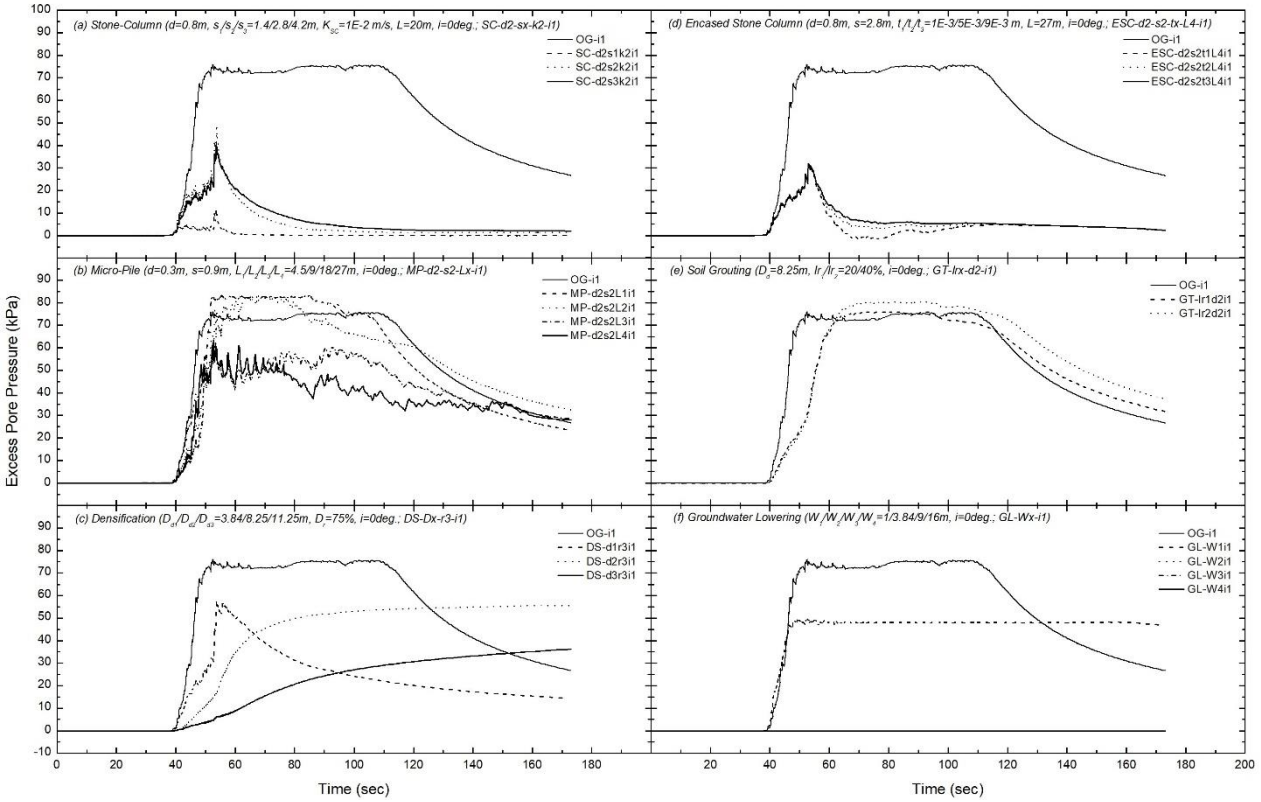

Figure 4. Computed excess pore pressure time histories at a depth of 7m (loose SAND) of the level ground (i=i_1=0deg.) for various liquefaction mitigation options. *(Note: OG – original ground; SC – stone-column; MP – micro-pile; DS – densification; ESC – encased stone column; GT – soil grouting; GL – groundwater lowering).*

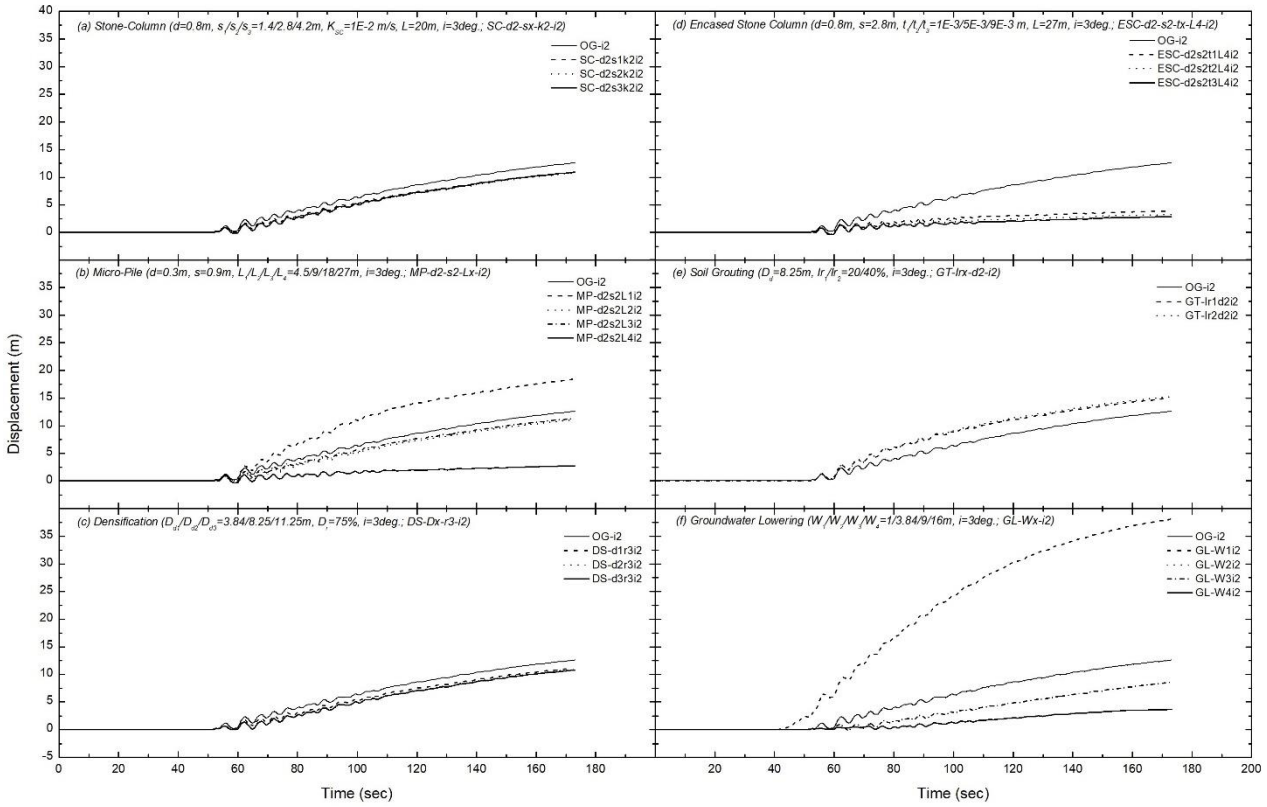

Figure 5. Computed lateral deformation time histories at a depth of 7m (loose SAND) of the inclined ground ($i=i_2$=deg.) for various liquefaction mitigation options. (Note: OG – original ground; SC – stone-column; MP – micro-pile; DS – densification; ESC – encased stone column; GT – soil grouting; GL – groundwater lowering).

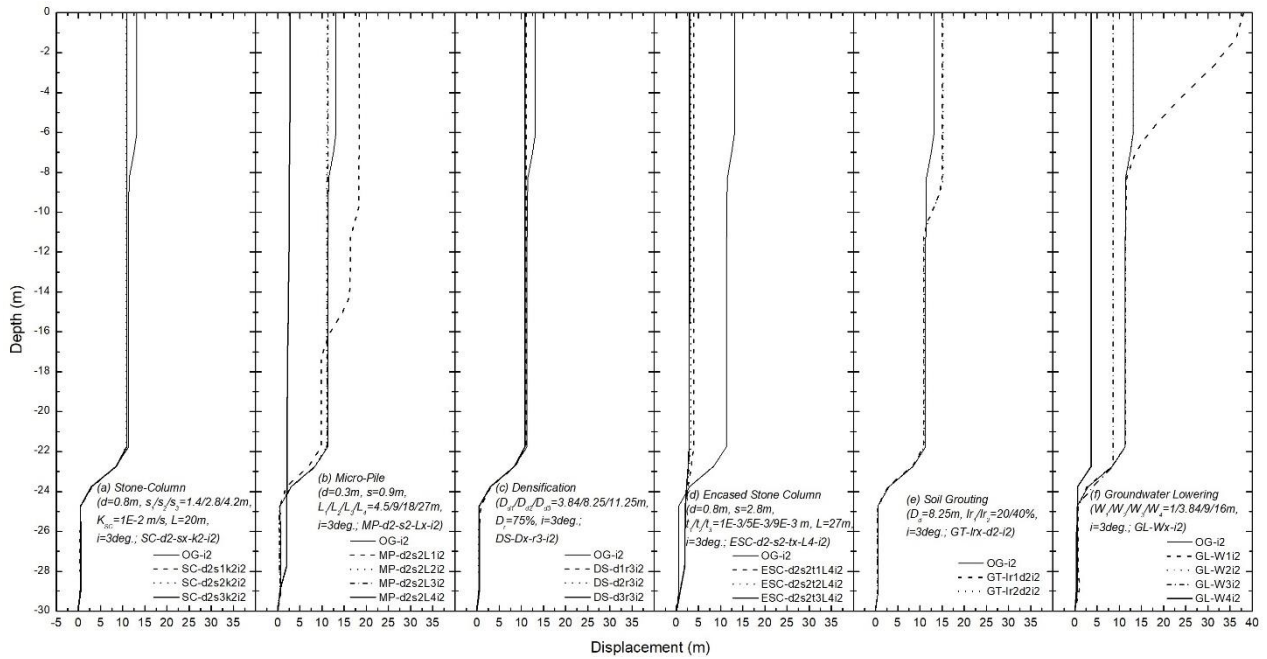

Figure 6. Computed lateral deformation profiles of an inclined ground ($i=i_2$=3deg.) for various liquefaction mitigation options. (Note: OG – original ground; SC – stone-column; MP – micro-pile; DS – densification; ESC – encased stone column; GT – soil grouting; GL – groundwater lowering).

4 CONCLUSIONS

Through a comprehensive numerical assessment of various liquefaction mitigation options, including stone-column (SC), micro-pile (MP), densification (DS), encased stone column (ESC) soil grouting (GT), and groundwater lowering (GL). Some key points and findings of the study are summarized as follows:

- The SC, ESC, and DS options are more effective in dissipating the excess pore pressure than the other options through drainage pathways and increased soil density. The ESC option would be improved soil stability by reinforcing the soil. The encasement provides additional lateral confinement to the stone column, facilitating efficient dissipation of excess pore pressure and enhancing soil stability.
- The GT and GL options would slightly reduce pore water pressure within the soil through soil densification and water table control, respectively. These options contribute to increased soil stability and decreased susceptibility to ground failure during seismic shaking.
- The MP, ESC, DS, and GT options are most effective in preventing the lateral deformation of soil deposits than the other options. They tend to increase the soil density, stiffness, and inertia force by shaking, thereby enhancing stability. The MP option would tend to amplify the lateral movement if the embedment depth is less than the liquefiable layers. The GT and GL options would tend to indirectly influence lateral deformation by stabilizing soil properties, though their direct impact on lateral displacement may vary.

ABSTRACT: The coastal cliffs erosion is a natural process that can lead to unstable occurrences and consequently high risk to the beach users. This paper describes the main solutions adopted at Peneco Beach, Algarve, Portugal aimed to mitigate the risk associated with space usage and access to the beach. Simultaneously, severe structural pathologies were also observed at the beach access stairs determining risk to users and therefore stabilization works were needed. The main goal was to develop solutions that could mitigate the users' risk while being conscious about environmental and aesthetics constrains as well as equipment accessibility restrains. The cliff stabilization solution used pigmented reinforced shotcrete combined with steel rockbolts, while the access stair was rebuilt using reinforced concrete and vertical rockbolts as foundation elements.

RÉSUMÉ: Les falaises côtières se détériorent en raison de l'érosion, qui est un processus naturel, mais qui peut conduire à des occurrences instables et, par conséquent, à un risque élevé pour les utilisateurs de la plage. Cet article décrit les principales solutions adoptées à Peneco plage, en Algarve, Portugal, visant à atténuer les risques associés à l'utilisation de l'espace et à l'accès à la plage. Dans le même temps, ont également été observées de graves pathologies structurelles au niveau des escaliers d'accès à la plage, déterminant le risque pour les usagers et donc des travaux de stabilisation ont été nécessaires. L'objectif principal était de développer des solutions capables d'atténuer les risques pour l'utilisateur tout en tenant compte des contraintes environnementales et esthétiques ainsi que des contraintes d'accessibilité des équipements. La solution de stabilisation de la falaise a utilisé du béton projeté renforcé pigmenté combiné à des clous de sol en acier, tandis que l'escalier d'accès a été reconstruit en utilisant du béton armé et des clous de sol verticaux comme de même de fondation.

Keywords: Coastal cliffs; risk mitigation; rockbolts; shotcrete.

1 INTRODUCTION

Coastal cliffs are areas of natural geological risk of instability due to their sedimentary genesis and exposure to atmospheric and marine agents with consequences for people and property. The risk associated with the instability of cliffs in beaches has been mitigated by several interventions along Portugal's coastline. At Peneco beach, Algarve, the reconstruction of the beach access staircase was implemented, restoring the safety conditions, and mitigating the erosion phenomena of the adjacent cliffs that determine an increased risk for people.

2 REFERENCE SCENARIO

At Praia do Peneco the morphology of the cliffs is a clear expression of the lithologies, as well as the processes and mechanisms of evolution present, mainly due to differential marine erosion. At the cliff face, erosion is accelerated by the intense vegetation that occurs in the place, since the growth of roots helps the opening of discontinuities and the consequent detachment of blocks (see Figure 1).

Figure 1. Cliff before intervention.

The top of the cliff is occupied by hotel and restaurant buildings and viewpoints, where small settlements, displacements and fractures were visible. The scarce presence of drainage and waterproofing devices in the area means that on days of high rainfall, water infiltrates into the existing cracks, dragging finer soil particles, promoting internal erosion phenomena.

The anomalies observed were representative of movements that have been progressively occurring over the years. The area of greatest concern corresponded to the top of the cliff, specifically to the viewpoint where tension cracks were observed in orientation parallel to the slope clearly showing signs of the occurrence of movements in this place.

The beach access staircase presented several structural pathologies caused by differential settlements (see Figure 2). The origin of such pathologies can be related to the lack of drainage devices, and a possible deficient foundation condition. Rainwater made its way to the foot of the cliff, infiltrating under the staircase by dragging particles, causing the observable differential settlements.

Figure 2. Staircase structural pathologies.

In this context, an intervention on cliffs stabilization and staircase reconstruction was considered critical for safety reasons.

3 MAIN CONSTRAINS

3.1 Geological and geotechnical constrains

Based on the Explanatory Report and the Geological Map of Portugal at a scale of 1:50000, sheet 52-B, it is possible to confirm the presence a Miocene unit (M^1) presented as carbonate rocks materializing the cliff (see Figure 3).

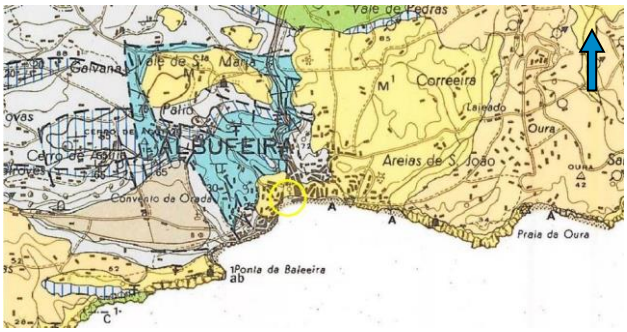

Figure 3. Portugal's Geological Map [sheet 52-B].

Field observation detected the presence of fine sandstones and siltstones, hard and compact, with yellowish tones, materializing metric benches, sometimes combined with centimetric horizons of silts and clays of grey tones (see Figure 4).

Figure 4. Cliff's surface before intervention.

The rock mass along the cliff is stiff and presents fractures that are moderately distant (F3-4). The transversal profiles of cliff can be described as slightly convex, steep slope and with sub-vertical sections, in the most competent rock formations. The cliff profiles are very rough, due to intense fracturing and high density secondary cementation of discontinuities (Marques, 1997).

The geological unit has, in general, a fissure-type permeability, where the circulation of water is essentially through the network of fractures and fissures. Thus, the circulation of groundwater is dependent on the degree of fracturing and weathering of the rock mass.

3.2 Other constrains

Given the location of the cliff, there were no significant constraints for access to the base of the cliff. However, given its height of about 20 m, the proposed solutions determined the need to use light weight equipment that could be operated hanging from a mobile crane.

The stabilisation solutions to be implemented had to use adequate materials considering the particularly aggressive environment due to the proximity to the sea. The interventions were also conditioned by the need to include the execution of a new rainwater drainage system, under the structure of the staircase.

Finally, it is also important to highlight the need to limit the impact of the intervention, especially in terms of the landscape and architectural framework of the proposed solutions always ensuring the indispensable safety conditions and their technical and economic suitability.

4 STABILIZATION SOLUTIONS

To mitigate the risk an intervention on cliffs stabilization and staircase reconstruction was implemented. For the cliffs surface a stabilization solution using rockbolts, geodrains and reinforced shotcrete was considered aiming the mitigation of the phenomena of superficial instability and erosion. Regarding the staircase pathologies a full reconstruction was proposed.

4.1 Cliff intervention

The intervention consisted of application of shotcrete, partially reinforced with metal fibres, and applied in layers with a total thickness of 12 cm. The application of shotcrete with C30/37 class resistance, took place by wet application and with the application of metal fibres, with a minimum dosage of 30 kg/m3, only in the first two layers. In the case of cavity areas, they were pre-filled, also with the application of layers of shotcrete. In the last layer of sprayed concrete, 4cm thick, applied without metallic fibres, a yellow pigment was incorporated for a better landscape integration of the solution (see Figure 5).

Rockbolts were materialized by 36 mm diameter bars, in A500/A550 continuous thread steel, in hot-dip galvanized rod with 85 µm minimum thickness by ISO 1461, placed in holes with a minimum diameter of 116 mm and sealed with cement grout of suitable characteristics. With this process, it was intended to disturb to a minimum the mechanical characteristics of the natural rock during the execution of the works. The diameter of the nails was defined considering a proper sacrificial thickness despite the galvanization.

With a length of 6 m and an inclination of 20º, in addition to fixing the layer of shotcrete, the nails crossed some existing sub-horizontal discontinuity planes near the cliff face. The nails were arranged in an approximate mesh of 3.0m (V) x 3.0m (H), and their position was adjusted during the works according to local needs.

To ensure the internal drainage, preventing the possible generation of hydrostatic pressure in the shotcrete coat, caused by water infiltration, sub-horizontal 4.0 m long geodrains were installed with 50 mm diameter perforated piped and wrapped in TecGeo 300 type geotextile. The gravitational flow of the captured waters is guaranteed because these elements were installed with an upward inclination of 5º with the horizontal.

Figure 5. Cliff's surface after intervention.

4.2 Staircase intervention

Given the severe structural pathologies of the staircase the intervention included its reconstruction executed on top of the existing one. Expanded clay aggregates were used for lightweight filling bellow the staircase concrete structure and rockbolts were used as foundation (see Figure 6).

For a conjoint behaviour of the entire structure, reinforced concrete cross beams were built to ensure a better connection between the various walls, and at the end of these a deep foundation was ensured, materialized by vertical rockbolts sealed in the rock mass.

Given the height of some retaining walls that materialize the staircase, geodrains were installed preventing the build-up of hydrostatic horizontal pressures behind those walls and using the drainage system, constructed bellow the new staircase, to drive those natural waters to the cliff base.

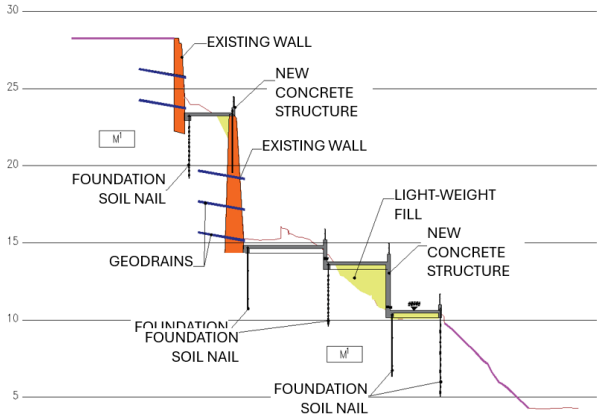

Figure 6. Staircase reconstruction – Cross section (not to scale).

5 MONITORING AND SURVEY PLAN

To monitor any relatively slow sliding movements, inclinometers were installed at the top of the cliff to measure the horizontal deformation of the rock mass. The intervention also provided for an observation plan, which should focus on the conservation and maintenance of the installed systems, to confirm the proper functioning of these structures. To this end, the observation of the intervened cliff will be made through the implementation of the following measures:

- Photographic coverage of the cliff after the intervention has been carried out, with the aim of defining an initial reference situation;
- Periodic photographic coverage in a manner similar to that recorded for the initial reference situation, in order to facilitate its comparison and the detection of any pathologies;
- Periodic reading of the inclinometers installed at the top of the cliff;
- Periodic inspection of the installed drainage systems and verification of their condition.

The information collected within the scope of the measures above described should be evaluated by a technical specialist to continuously validate the suitability of the solutions implemented and the need to carry out maintenance and conservation interventions or confirm the need for future stabilization interventions.

6 MAIN CONCLUSIONS

This article described the main solutions implemented and completed in the summer of 2022, with aim to mitigate the risk associated with the use of space and access to the bathing area at Praia do Peneco, in Algarve, Portugal (see Figure 7). The maintenance of the reinforcement elements and drainage elements installed, namely through the application of the defined monitoring plan, is fundamental to confirm the suitable behaviour of this type of structures and solutions during their lifetime. Special awareness should be considered within the monitoring plan implementation before and after periods of greater rainfall and greater sea agitation.

Coastal cliff erosion phenomenon can cause significant issues for public safety and serious damage to infrastructures. Thus, coastal cliffs stabilization solutions are crucial preventing the evolutive erosion that can lead to a natural disaster.

Figure 7. View after intervention.

ACKNOWLEDGEMENTS

The authors would like to thank the Albufeira City Council, the Owner, for the authorization for the writing and publication of this article. They also consider important to underline that the solutions implemented are the result of teamwork, in which the important role of the companies should be highlighted: GeoAlgar, the entity responsible for the preparation of the Geological and Geotechnical Study and Teixeira Duarte, Engenharia e Construções S.A., the contractor.

A design procedure for high energy rockfall barriers

Conception des écrans pare-blocs à haute énergie

D. García*, L.Molano, G. Torres, D. Freitas
A. Bianchini Ingeniero, Barcelona, Spain

**dg.gordo@maccaferri.com*

ABSTRACT: The design of high energy rockfall barriers is traditionally carried out through trajectory simulations along the slope. The simplest way of designing these structures is comparing the energy level derived from these simulations with the results of the real scale tests according to the European Guideline Document 340059-00-0106 (which substitutes the previous ETAG 27-2008). This EAD is the harmonized document that defines how to test dynamic rockfall barriers and obtain their features (energy, residual height, deformation) in Maximum Energy Level (MEL) and Service Energy Level (SEL). Even though this guideline allows to compare in a reliable way the different barriers, this design procedure has limitations and doesn't consider how the real impact and installation conditions affect the barrier performance. In this paper, we give an overview of the contents of the EAD, and we show a design approach based on the Italian norm UNI 11211:2012, the mentioned EAD and the extensive experience of Maccaferri. Lastly, we will highlight the state of the art related to the foundation design.

RÉSUMÉ: La conception des écrans pare-blocs à haute énergie est traditionnellement réalisée par des simulations de trajectoire le long du talus. La manière la plus simple de dimensionner ces structures consiste à comparer le niveau d'énergie dérivé de ces simulations avec les résultats des essais en vraie grandeur conformément au Document d'Évaluation Européen 340059-00-0106 (qui remplace l'ancien ETAG 27-2008). Ce DDE est le document harmonisé qui définit comment tester les écrans pare-blocs dynamiques et obtenir leurs caractéristiques (capacité d'absorption d'énergie, hauteur résiduelle, déformation) au niveau d'énergie maximal (MEL) et au niveau d'énergie de service (SEL). Bien que ce guide permette de comparer de manière fiable les différentes barrières, cette procédure de conception présente des limitations et ne tient pas compte de la manière dont les conditions réelles d'impact et d'installation affectent la performance de la barrière. Dans cet article, nous donnons un aperçu du contenu du DDE, et nous présentons une approche de conception basée sur la norme italienne UNI 11211 :2012, le DDE mentionné et l'expérience approfondie de Maccaferri. Enfin, nous mettrons en lumière l'état de l'art lié à la conception des fondations.

Keywords: Rockfall protection systems; rockfall barrier; EAD 340059; new design approach.

1 INTRODUCTION

Rockfall dynamic barriers are kits designed to catch rock blocks that can fall from a slope. They are installed far from the detachment area; thus, they are classified as passive protection systems.

These systems can cover large surfaces that could not otherwise be protected with an active system (pinned drapery), they can absorb large impact energies, and they have been tested and certified by a recognised Technical Assessment Body.

1.1 EAD 340059-00-0106

The EAD 340059-00-0106 (hereinafter referred to as EAD) defines a dynamic rockfall barrier as a kit able to stop moving rock blocks on a slope with an energy level greater or equal to 100 kJ.

The kit is made up of:

- Interception structure: made of a principal net, and an optional additional layer usually with a finer mesh.
- A support structure: composed of metallic posts (minimum 4), with a separation distance between 8 and 12 meters.
- Connection components: consisting of metallic ropes, wire rope grips, and/or energy dissipating devices.

The foundation is not considered part of the kit.

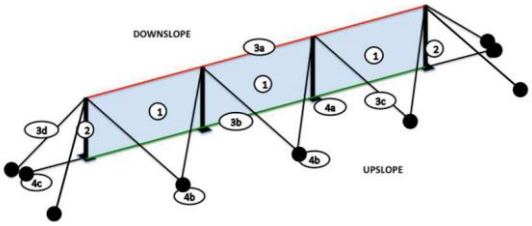

Figure 1. View of rockfall barrier components.

2 ROCKFALL SIMULATIONS

2.1 Input data

The first step to carry out the rockfall simulations in a reliable manner is to obtain the following:

- Geomechanical data: Type and dimensions of the rock blocks.
- Geological data: Type of ground in the hillside to obtain the restitution coefficients.
- Topographic data: To define the most unfavourable section, locate the rockfall detachment area, and choose the optimal location for the bar.

These parameters can be obtained with different degrees of accuracy, which will influence the Safety Factors for the calculations later.

2.2 Rockfall simulations

The rockfall simulations are done through several commercial softwares that rely upon different algorithms. These tools allow the designer to identify the block route and the parameters (velocity, energy, bounce height) at each point. For the numerical analysis, designers should take into account the following (Giachetti & Zotti, 2012):

- It is not advisable to directly use the kinetic energy given by the software, but to calculate it through the mass and translational velocity of the block ($E=1/2\ m \cdot v^2$), to avoid using abnormal data and to apply the corresponding safety factors.
- The rotational kinetic energy accounts for 10-15% of the total energy. Therefore, it can normally be disregarded.
- The statistical analysis allows for a 5% risk. Thus, the trajectories to consider should include the 95% confidence interval.

To validate the simulation, it is recommended to do back testing to check the results and the in-situ evidence, adjusting the restitution coefficients.

3 ROCKFALL BARRIER DESIGN

3.1 Design and safety factors

The EAD 340059 introduces the concepts of Maximum Energy Level (MEL) and Service Energy Level (SEL).

Generally, the MEL design is adopted if the frequency of the rockfalls is low, if individual blocks are expected, if the allowed risk is relatively high or if the maintenance tasks can be done with ease.

SEL design is adopted to reduce maintenance costs, when the allowed risk is low, or when multiple blocks are expected to impact. This criterion is more costly, as it implies the barrier must have a capacity three times higher (SEL = 1/3 MEL), but it enhances the safety of the site, and can be adequate in some cases (i.e. at the entrance of tunnel portals).

3.2 Energy of the barrier

The most important design parameter to determine is the energy level of the barrier, obtained with the following formula:

$$E_{sd} = \frac{E_b}{\gamma_E} \quad (1)$$

where E_{sd} = Block energy.
E_b = Nominal energy of the barrier, according to the EAD 340059.
γ_E = safety factor depending on the design criteria. 1.20 for MEL; 1.00 for SEL; 2.00 if the barrier is shorter than 30 m.

E_{sd} is defined with the classical formula of kinetic energy increased by a safety coefficient ($\gamma_R \geq 1.0$) which considers the human risk.

$$E_{sd} = \left(\frac{1}{2} M_d * {v_d}^2\right) \gamma_R \quad (2)$$

where M_d = Design mass of the block.
v_d = Design velocity of the block.
γ_R = 1.00 for a location of low economic value and easy repair; 1.20 for a location of high economic value and without possibility of repairing.

As per equation number (2); designers must define the design mass and velocity, which are obtained as following:

$$M_d = (Vol_B * \gamma)\gamma_{VOL} * \gamma_\gamma \quad (3)$$

$$v_d = (v_t * \gamma)\gamma_{Tr} * \gamma_{Dp} \quad (4)$$

where Vol_b = volume of the design block.
γ = Unit weight of the block.
γ_{vol} = safety coefficient related to the precision of the design block survey.
γ_γ = safety coefficient related to the evaluation of the unit weight of the rock of the block.
v_t = velocity calculated with the rockfall simulation and considering the 95th percentile of the velocities.

γ_{tr} = safety coefficient related to the reliability of the rockfall simulation.
γ_{Dp} = safety coefficient related to the quality of the topographic survey.

3.3 Height of the barrier

The minimum height of the barrier has to be defined considering the design height, a free zone, and the size of the block:

$$H_b > H_t * \gamma_{Tr} * \gamma_{Dp} + R * \gamma_R + f_{min} \quad (5)$$

where H_b = minimum height of the barrier.
H_t = Impact height of the block simulations, including the 95% confidence interval.
γ_{tr} = safety coefficient related to the reliability of the rockfall simulation.
γ_{Dp} = safety coefficient related to the quality of the topographic survey.
R = radius of the block.
γ_R = safety coefficient on the radius of the block (γ_R> 1.0)
f_{min} = safety zone that cannot be impacted (usually $f_{min} \geq 1.0$)

3.4 Separation distance of the barrier

The minimum distance between the barrier and the structure to be protected is determined as follows:

$$D_A \geq D_b * \gamma_d \quad (6)$$

where D_A = minimum distance between the barrier and the protected zone.
D_b = maximum dynamic deformation of the barrier, measured in accordance with the EAD.
γ_d = safety coefficient related to the energy level adopted during the design (γ_d>1.0 for MEL approach; γ_d=1.0 for SEL approach), the length of the barrier (γ_d>1.0 if the barrier is shorter than 30m) and to barrier-span impacted by the boulder (γ_d>1.0 if the lateral span of the barrier may be impacted)

4 FOUNDATION DESIGN

Even if the EAD does not define the foundations of the barrier as a component of the rockfall kit, these must be appropriately designed, regarding the type of barrier and the type of ground observed at the job site.

This implies that every barrier should have its proper anchoring system.

4.1 Load analysis

During the real scale tests, the suppliers must measure the forces transmitted to the anchors during the impact. Usually, the systems to measure the forces are a data logger connected to different load cells placed on the main foundations of the barrier.

The foundations are divided in 3 categories taking into consideration the worst load for each anchor:

- Post foundations: compression and shear stresses
- Upslope foundations: tensile stress (pull-out)
- Lateral foundations: tensile stress (pull-out)

Table 1 describes an example of the maximum loads in the anchors of the barrier RB 1500, obtained during the MEL crash test. These are the reference values for the design of the anchors, taking into account that this is the worst case scenario and the loads for the SEL test are lower.

Table 1. Forces in barrier RB 1500 during MEL.

Foundation	Type of force	Value
Posts	Compression	226,26 kN
	Shear	157,36 kN
Upslope foundations	Tensile	163,10 kN
Lateral foundations	Tensile	252,60 kN

4.2 Types of anchors

Foundations have to be able to transmit the load to the ground. Deep foundations are normally used in order to guarantee the best performance with a minimum cost. Generally, the anchoring systems are designed as follows:

- Post foundations: steel bars (for rock) or micropiles (usually for loose soil).
- Upslope and lateral foundations: flexible cable anchors (steel bars are not recommended due to the dynamic loads, which can pull the bar in different directions)

All the anchoring systems are considered passive because they start to work only if they are stressed by the impact. They are installed in drilled holes, and they are fully grouted along their entire length in order to develop the maximum anchor-grout and grout-ground friction.

The length and the diameter of the anchors as well as the drilling diameter depends on the design requirements. If the barrier is installed in an uneven terrain, a little concrete plinth can be foreseen to give a flat base for the posts of the fence.

5 CONCLUSIONS

The EOTA published in 2018 the EAD 340059, that replaces ETAG 27-2008 and defines standard procedures to evaluate the rockfall barriers in real scale tests, which allows to obtain the behaviour of the barriers and obtain the ETA and CE marking. Unfortunately, it describes the performance of the barrier in ideal conditions that differ from reality.

We have seen several cases where the consequences of the real installation conditions influence the behaviour of the rockfall barrier when impacted.

To design a rockfall barrier taking into account these factors, a new design approach based on the Italian norm UNI 11211:4-2012 has been defined to design the barriers in Ultimate Limit State and Service Limit State.

Even if the foundations are not considered part of the kit as per the EAD, these elements are crucial in the behaviour of the rockfall barrier. These foundations can dissipate the energy of the impact to prevent problems in other parts of the barrier and to reduce the maintenance costs.

The efforts of the main rockfall barrier suppliers are focused on delivering barriers with the following characteristics:

- Easy to install, through lesser anchors in the plate posts.
- Quick assembly, thanks to premounted elements such as the ring net.
- Effective, through their capability to absorb further impacts in Service Energy Level (SEL).

Calibration of soil water retention parameters based on field measurements

Calibration des paramètres de rétention d'eau du sol basée sur des mesures sur le terrain

ABSTRACT: It is well established that the relationship between soil water content and matric suction (referred to as the soil water retention curve (SWRC)), governs the behaviour of unsaturated soils. While SWRCs are typically measured in the laboratory, it is appreciated that the effects of soil structure can affect the shape of these curves. This paper presents calibration of the soil water retention parameters for an existing instrumented slope in Malaysia using field measurements of matric suction and volumetric water content and fully coupled flow-deformation analysis in PLAXIS. By systematically varying the SWRC parameters based on field measurements, this study attempts to improve the predictions of soil suction using a simplified rectangular soil section. Results from the analyses predicted slightly higher values of matric suction when compared with measured field data. However, the models were able to capture general trends and variations in matric suction in response to rainfall events.

RÉSUMÉ: Il est bien établi que la relation entre la teneur en eau du sol et la succion capillaire (appelée courbe de rétention d'eau du sol (SWRC)) régit le comportement des sols non saturés. Bien que les SWRC soient généralement mesurées en laboratoire, il est reconnu que les effets de la structure du sol peuvent affecter la forme de ces courbes. Cet article présente l'étalonnage des paramètres de rétention d'eau du sol pour une pente instrumentée existante en Malaisie en utilisant des mesures sur le terrain de la succion capillaire et de la teneur en eau volumétrique, ainsi qu'une analyse de déformation-débit entièrement couplée dans PLAXIS. En variant systématiquement les paramètres SWRC en fonction des mesures sur le terrain, cette étude tente d'améliorer les prédictions de succion du sol en utilisant une section de sol rectangulaire simplifiée. Les résultats des analyses ont prédit des valeurs légèrement plus élevées de succion capillaire par rapport aux données sur le terrain mesurées. Cependant, les modèles ont été capables de capturer les tendances générales et les variations de la succion capillaire en réponse aux événements de pluie.

Keywords: Unsaturated soils; slope stability; field monitoring; numerical modelling.

1 INTRODUCTION

Across the world, the effect of climate change and rapid development have increased the risks associated with landslides (Ozturk et al., 2022). In a review of fatal landslide occurrences, Froude & Petley (2018) found that a total of 55 997 fatalities occurred between 2004-2016, with a majority of landslides occurring within the tropics. A country which is particularly susceptible to fatal landslides is Malaysia (Lee et al., 2009). Several studies have attributed rainfall events as the triggering mechanism for landslides in Malaysia (Lee et al., 2009). It is therefore vital to understand the mechanisms for rainfall-induced slope instability.

Tropical humid regions are typically underlain by residual soils (Huat and Toll., 2012) with deep water tables, which result in large portions of the soil profile being unsaturated. Unsaturated soils are characterised by the presence of negative pore-water pressure (referred to as suction) which is related to soil water content through the soil water retention curve (SWRC). Simply put, a reduction in water content increases soil suction which results in an increase in shear strength. Conversely, if water content is increased (as would occur after a rainfall event), suction is reduced which

produces a lower shear strength and factor of safety (FoS).

To understand the behaviour of unsaturated soil subject to transient atmospheric processes, an unsaturated soil slope in Selangor Malaysia, approximately 20 km southeast of Kuala Lumpur was instrumented with suction and volumetric water content sensors. However, the absence of unsaturated soil test results limited the ability to predict the slope behaviour under present and future rainfall scenarios. This paper presents an initial numerical calibration that was undertaken to determine the SWRC parameters based on field-monitored data.

2 SITE DETAILS

The instrumented slope is located in Taman Bukit Mewah, Kajang, Selangor on the west coast of Peninsular Malaysia (2°59'11.7"N 101°47'56.6"E), approximately 20 km southeast of Kuala Lumpur. The location of the site is illustrated in Figure 1 with a cross section of the studied slope in Figure 2. The region chosen for this study has historically seen a vast number of landslides which have resulted in loss of life and severe economic consequences. For context, the location of the 1993 Highland Tower landslide which resulted in 48 fatalities (Jamaludin and Hussein, 2006) has also been highlighted in the figure.

Based on the existing geological maps, the site is underlain by residual granite soil, which occurs widely in Peninsular Malaysia as granites form a major part of the landmass (Singh et al., 2013). Ground investigation was undertaken at the site which indicated that the slope is underlain predominantly by medium brown to greyish brown silty CLAY from 0 to 9m bgl (below ground level), which transitions from being soft to medium stiff to stiff to very stiff below 7.5m.

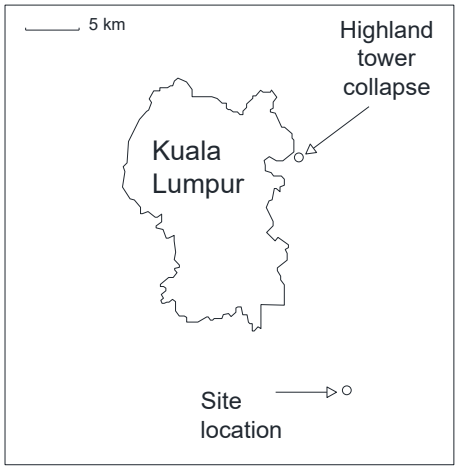

Figure 1. Site location.

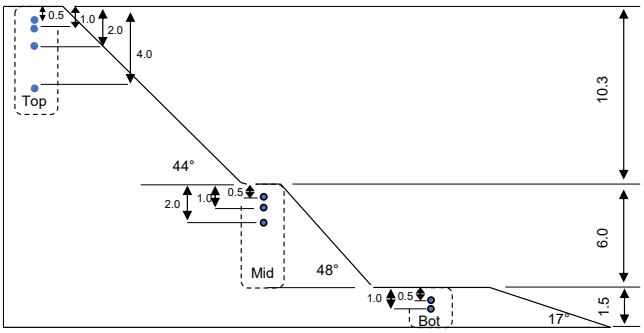

Figure 2. Cross-section of studied slope.

3 FIELD MONITORING

To enable long-term observation of rainfall patterns and hydraulic soil behaviour, a combination of instruments was installed at the selected site. A tipping-bucket rain-gauge, Terros 11 volumetric water content sensors, and Terros 21 soil water potential sensors were meticulously positioned at key locations: the crest, midsection, and toe of the slope. The installation depths are illustrated in Figure 2. By placing sensors at increasing depths within the soil profile, both volumetric water content of the soil and soil suction were measured over time.

4 NUMERICAL MODELLING FOR SWRC CALIBRATION

The soil water retention curve (SWRC) characterises the relationship between soil water content and suction. This relationship is crucial for modelling changes in soil suction, brought about by precipitation which can ultimately lead to the failure of a slope. Laboratory techniques are often used to establish the SWRCs. However, the soil type, initial water content, stress history and method of compaction can influence the shape of this curve which may not be accurately reproduced in the laboratory (Vanapalli et al., 1999).

Hence, this study attempts to derive the van Genuchten (1980) SWRC parameters by comparing the observed soil suction with those predicted through a fully coupled flow-deformation analysis conducted in the finite element program PLAXIS.

For this analysis, a simplified two-layered plane strain rectangular soil model (5 m×10 m) was created to simulate one dimensional infiltration and evaluate consequent changes in soil suction in response to rainfall (Figure 3). The finite element mesh constituted 434 triangular soil elements and 3605 nodes. Hydraulic parameters adopted for numerical modelling are given in Table 1.

The uppermost layer, extending 1.5 m below the top model boundary, represented desiccated surface

near the ground. This layer is known to possess a higher hydraulic conductivity than the underlying layers due to the presence of surficial cracks and plant roots (Toll et al., 2019). Hence, the hydraulic conductivity of Layer 1 representing the desiccated upper surface was adopted from the in-situ infiltration test results reported by Huat et al. (2012) and the hydraulic conductivity of the underlying Layer 2 was considered three orders of magnitude lower than the upper layer as suggested by Md. Rahim (2016) (Table 1).

The conventional Mohr-Coulomb model was used to represent the constitutive relationship of the soil layers. Due to limited testing, the strength properties were considered to be uniform with cohesion, $c' = 1$ kPa and effective angle of shearing resistance, $\phi' = 29^{o}$ based on a single set of consolidated undrained triaxial tests.

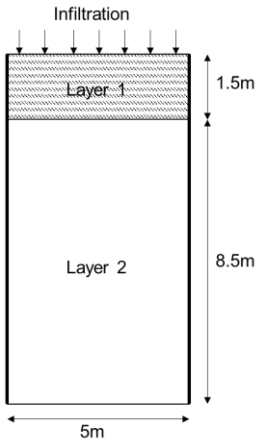

Figure 3. 2D soil model for numerical modelling.

Table 1. Hydraulic model parameters.

Saturated hydraulic conductivity, k_x, k_y (m/s)		1×10^{-5} m/s (Layer 1) 1×10^{-8} m/s (Layer 2)
Van Genuchten (1980) parameters	θ_r	0
	θ_s	0.45
	α (1/kPa)	0.18 (SWRC 1) 0.09 (SWRC 2) 0.154 (SWRC 3)
	n	2.8 (SWRC 1 and 3) 1.9 (SWRC 2)

To establish a representative SWRC for the desiccated surface at 0.5 m depth, upper and lower bound SWRCs were fitted using the van Genuchten (1980) hydraulic model (SWRC 1 and SWRC 2), as shown in Figure 4. The SWRCs for typical residual soils in Malaysia as outlined by Lee et al. (2009) are presented within the figure for context. Between the upper and lower bounds, the van Genuchten model parameters were systematically varied until the model prediction aligned closely with the fluctuations recorded in the field. In the flow-deformation analyses, hourly rainfall recorded between 28 October to 6 December 2021 was imposed as a top infiltration boundary (Figure 3). To simulate 1-D infiltration, the bottom model boundary was set to allow seepage and the left and right boundaries were closed. Initial porewater pressures were generated by assigning an initial degree of saturation, corresponding to the suction observed in the field.

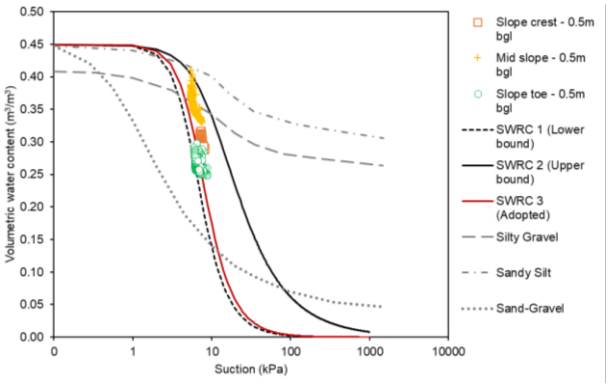

Figure 4. SWRCs plotted from the field measurements at 0.5m depth at the slope crest, mid and toe, and the typical SWRCs for soils found in the Malaysian Peninsula (modified from Lee et al. (2009)).

Figure 5 illustrates the predicted soil suction at 0.5 m depth, compared to the suction values measured at the same depths on the slope crest, mid and toe using 'SWRC 3' parameters. The model using 'SWRC 3' parameters slightly overestimated the suction compared to the onsite measurements. However, it effectively captured the overall trend, timing and magnitude of changes. Over a 922 hour-simulation, the model predicted suction changes between 6 and 11 kPa, while the monitored data showed fluctuations between 5 to 9 kPa. Therefore, with the adopted 'SWRC 3' parameters, the model closely predicted the hydraulic response during infiltration and intermittent dry periods and hence, this hydraulic model can be considered to be representative for this stratum.

It should be emphasised that the results presented in Figure 5, are for a single depth using a simplified rectangular soil model. In reality, the true geometry of the instrumented slope would have influenced infiltration. Additionally, modelling a single rectangular section does not incorporate changes in water content/suction induced by seepage to or from other locations of the slope. Nevertheless, the results provided in Figure 5 provide a useful first estimate of the SWRC which can be incorporated into subsequent slope stability analyses. A similar approach can be adopted in the future studies to calibrate the SWRCs for the underlying strata.

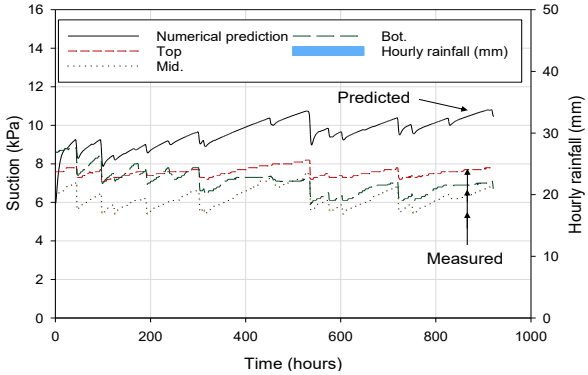

Figure 5. Observed and predicted changes in soil suction between 28 October 2021 to 06 December 2021.

5 CONCLUSIONS

Field monitoring offers an opportunity to calibrate water retention properties of existing unsaturated slopes, with limited disturbance to soil structure which is known to affect the SWRC. In this paper, water content and soil suction measured in-situ were integrated into fully coupled flow-deformation analyses of a rectangular soil section to identify optimal SWRC parameters, unique to the in-situ soil. While numerical simulations predicted slightly higher magnitudes of soil suction when compared to in-situ measurements, the models were able to capture general trends and suction fluctuations in response to rainfall events.

The calibration presented in this study aims only to provide an initial estimate of in-situ SWRC parameters. Using this calibration as a starting point, further analyses are required to accurately model the behaviour of the entire slope.

ABSTRACT: Seismic hazard assessment requires knowledge of regional geological and geotechnical parameters. Shear wave velocity averaged across the upper 30 m of soil (Vs_{30}) is a key parameter for site response studies in earthquake engineering. In the city of Quito, the capital of Ecuador, seismic data are scarce. This paper combines a recently compiled geotechnical database with a Bayesian Kriging technique to generate new soil geotechnical property maps for the city of Quito. The new QUITO/GEO-299 soil geotechnical database contains 299 records of soil geotechnical test results from across the Quito region. These datapoints were analysed using a Bayesian Kriging approach recently developed for generating seismic hazard data for the Kathmandu Valley in Nepal. The resulting Quito Vs_{30} map is compared to the corresponding map created using slope-based proxies implemented in the global Vs_{30} model presented by the U.S. Geological Survey. These new resources are useful for geotechnical engineers working in the Quito region, especially during project planning and preliminary design phases.

RÉSUMÉ: L'évaluation des risques sismiques nécessite la connaissance des paramètres géologiques et géotechniques d'une région. La vitesse moyenne des ondes de cisaillement dans les 30 m supérieurs du sol (Vs_{30}) est un paramètre clé pour les études de réponse des sites dans le domaine de l'ingénierie parasismique. Dans la ville de Quito, la capitale de l'Équateur, les données parasismiques sont rares. Cet article combine une base de données géotechniques récemment compilée avec des techniques de Krigeage Bayésien pour générer de nouvelles cartographies de propriétés géotechniques des sols pour la ville de Quito. La nouvelle base de données géotechniques QUITO-GEO-299 contient 299 enregistrements de résultats d'essais géotechniques du sol dans la région de Quito. Ces points de données ont été analysés à l'aide d'approches bayésiennes de krigeage récemment développées pour générer des données sur les risques sismiques dans la vallée de Katmandou au Népal. La carte Vs_{30} de Quito qui en résulte est comparée à la carte correspondante développée à l'aide d'approximations conventionnelles basées sur les pentes et mises en œuvre dans le modèle global Vs_{30} présenté par l'U.S. Geological Survey. Ces nouvelles ressources sont utiles pour les ingénieurs géotechniciens travaillant dans la région de Quito, en particulier pendant les phases de planification de projet et de conception préliminaire.

Keywords: Shear wave velocity; geodatabases; Bayesian Kriging, Quito.

1 INTRODUCTION

Average shear wave velocity over the upper 30 m of soil at a site (Vs_{30}) is commonly used for seismic microzonation studies. An assessment of the seismic hazard in a region is often carried out using Vs_{30} as a proxy for soil stiffness. (Foti *et al.,* 2018; De Risi *et al.,* 2019). However, due to the high costs associated with Vs_{30} testing, data availability for this parameter is limited especially in low income multi-hazard prone regions. Geospatial analysis of the geotechnical parameters in a region can provide maps of the estimated values such as Vs_{30} without extensive testing. To develop geotechnical parameter maps, an appropriate geospatial model is needed (see Gilder, 2022 and Gilder *et al.,* 2022). Kriging interpolation can be used to develop geospatial maps of various geotechnical parameters, including Vs_{30}, for data-scarce regions (Webster and Oliver, 2007).

A commonly used model for estimating soil Vs_{30} values relies on the topographic information obtained from Digital Elevation Models (DEM) and is currently implemented by the U.S. Geological Survey (USGS). The USGS model uses a slope-based estimation of Vs_{30} to produce estimates without testing (Wald and Allen, 2007; Allen and Wald, 2009). In the case of scarce

measurements (i.e. at few local points within a region), Bayesian Kriging approaches (Omre, 1987; De Risi *et al.,* 2021) can be used to produce a more robust estimation of Vs_{30} compared to the USGS model and may prove to have lower uncertainty compared to Simple or Ordinary Kriging approaches.

In this context, this study developed a Vs_{30} map of Quito, Ecuador, using the data available from a recently developed database (Othman *et al.,* 2023b) and the Bayesian Kriging framework developed by Gilder *et al.* (2022). Quito is in a multi-hazard region highly susceptible to seismic activities due to its location on a 60 km-long fault system (e.g. Vaca *et al.,* 2019). The region is also highly susceptible to rainfall-triggered landslides, debris flows and flooding (e.g. Zapata *et al.,* 2023). The city of Quito can be considered a 'data-scarce' region with respect to geotechnical data (Othman *et al.,* 2023a), and has limited Vs_{30} data available for use in construction design.

2 DATA SOURCES

The required data for the application of the Gilder *et al.* (2022) Bayesian framework for Quito is: (1) the Vs_{30} raster map obtained from the USGS repository (USGS, 2007) used as prior data; and (2) site-specific Vs_{30} data obtained from the open-access geotechnical database 'QUITO/GEO-299' (Othman *et al.,* 2023b) which includes Vs_{30} values and the geographical coordinates of these datapoints.

2.1 The USGS Vs_{30} map

The USGS (2007) open-access map repository contains rasterised global Vs_{30} mosaic maps based on the slope estimation of Vs_{30} using satellite DEM images. Using the data from the USGS raster, a Vs_{30} mosaic map for Quito is constructed, as shown in Figure 1. Using the generated map in Figure 1, the estimated Vs_{30} values for the different sections of the city of Quito can be used within the prediction.

2.2 The Quito geotechnical database

QUITO/GEO-299 database (Othman *et al.,* 2023b) presents comprehensive geological and geotechnical information on the soils of Quito. One of the parameters included in the database is the $Vs_{30,}$ along with the site location coordinates. The total number of available Vs_{30} data is 82 points.

The Vs_{30} data available in the database were reported as found in the source (45 points) or calculated from Vs measurements using CEN (2004) definition (21 points) or extrapolated for data points shallower than 30 m using Boore (2004) method (16 points). Figure 2 shows the location of each Vs_{30} measurement and the value of these measurements compared to the USGS model.

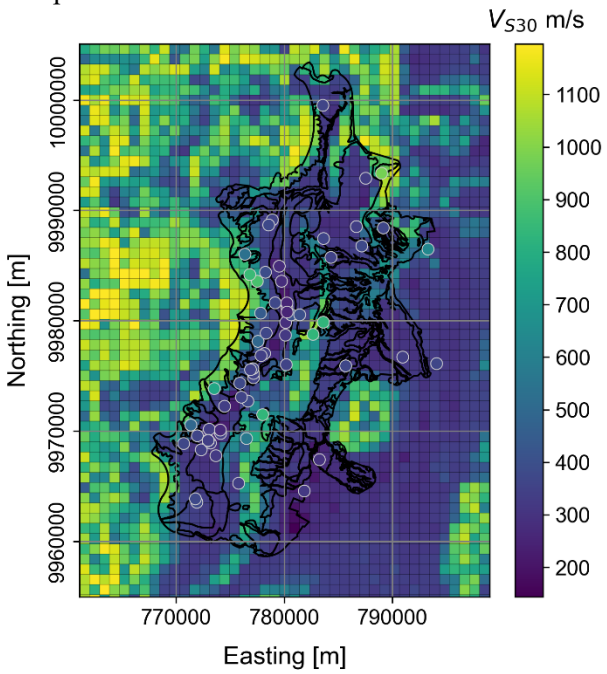

Figure 1. USGS Vs_{30} mosaic map for the Quito area; geology map polygons for the Metropolitan District of Quito (DMQ) from Municipio de Quito (2015).

The slope-based approach used as prior information in this study is known to provide an average overestimation of Vs_{30} with respect to data point measurements (e.g. Stewart *et al.,* 2014). This trend is also found in the area of study comparing the data points from 'QUITO/GEO-299' and the USGS estimates, see Figure 2.

3 ANALYSIS AND RESULTS

The steps described in Gilder *et al.* (2022) were followed: (1) selection of primary and secondary parameters; (2) removal of any bias or cluster from the data (i.e. debiasing or declustering); (3) variable transformation into a normally distributed variable; (4) use the primary variable, estimation of Vs_{30} using Simple Kriging (SK) method; (5) use the secondary variable, identifying the likelihood of the distribution; (6) map updating using the Bayesian method to present the final Kriging map. Based on the methodology described in Gilder *et al.* (2022), the data requires debiasing or declustering depending on the data availability. Histograms of the measured and estimated Vs_{30} are investigated (Figure 3) to determine which option to use. The measured data does not cover the higher values of Vs_{30}. Based on Gilder *et al.* (2022), the data was debiased following 'Option A' of the Gilder *et al.* framework.

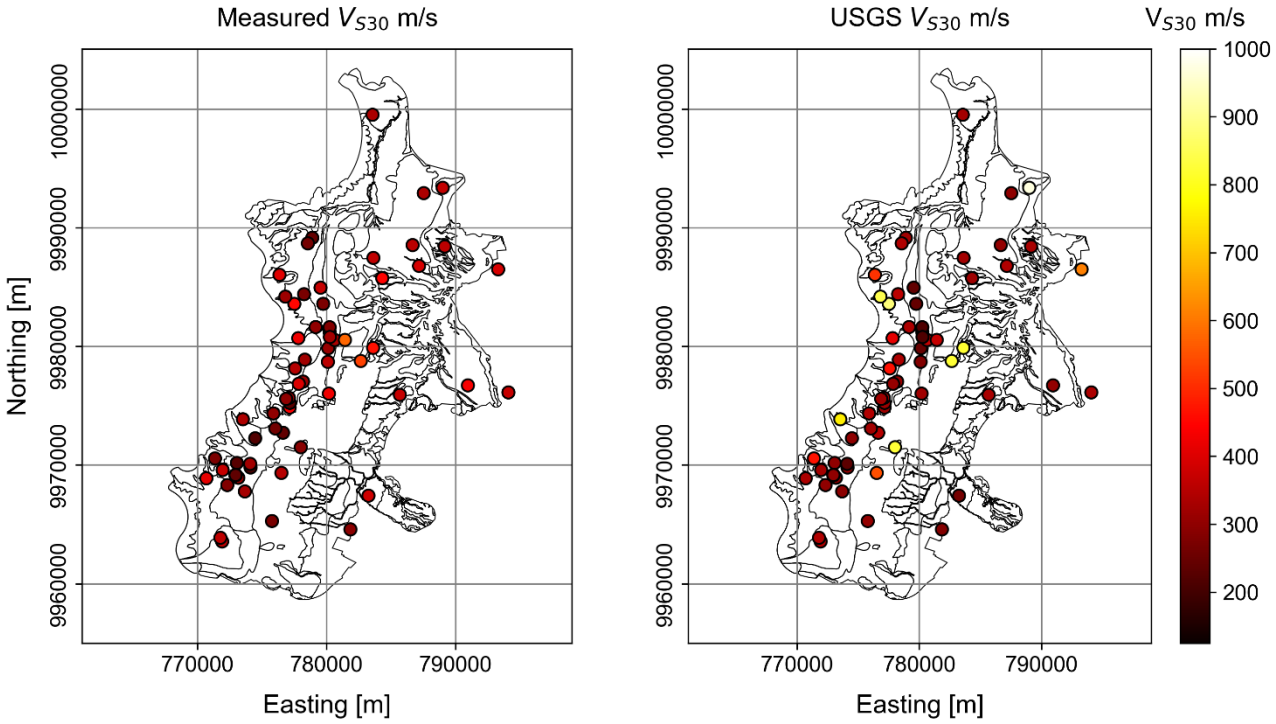

Figure 2. (left) The location and magnitude of each Vs_{30} measurement from QUITO/GEO-299 database compared with (right) values from USGS for the same location; geology map polygons in the DMQ from Municipio de Quito (2015).

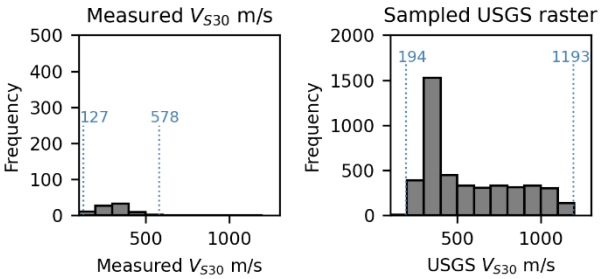

Figure 3. Comparison of the data histogram of the measured versus the sampled USGS raster in the same modelling area.

The updated Vs_{30} map using the Bayesian-Kriging model (Figure 4) shows higher accuracy in the Vs_{30} estimation compared to the map obtained from USGS in Figure 1. This increase in Vs_{30} accuracy is related to the additional information at Vs_{30} points obtained from the QUITO/GEO-299 database. Lower Vs_{30} estimations are observed compared to the USGS map. This outcome aligns with previous studies that suggest the USGS model tends to overestimate Vs_{30}. The updated Vs_{30} map captures differences in the properties of the different surface geology layers (including unconsolidated materials and soils) as described by Othman *et al.* (2023a) and shown in Figure 4.

The red region (*Qal*) in the geological map corresponds to lacustrine, fluvial and marsh deposits which are usually characterised by lower Vs_{30} values than the adjacent geological layer (*Qvi*, in purple) comprising material from pyroclastic flows, silts, lahars and volcanic sands. The Vs_{30} map in Figure 4 shows lower Vs_{30} with respect to the soil categories in the seismic code (ERN 2012).

4 SUMMARY AND CONCLUSIONS

The Bayesian-Kriging framework developed by Gilder *et al.* (2022) was employed to create a new map of Vs_{30} for Quito, Ecuador. Field measurements of Vs_{30} were obtained from QUITO/GEO-299 database (Othman *et al.,* 2023b). The resulting new Vs_{30} map aligns more closely with variations in the geology of the city – distinguishing between more deformable lacustrine soils and stiffer volcanic soils, which are not captured by the slope-based map of USGS or the soil classification of the latest seismic code (ERN, 2012). The new Vs_{30} map captures the difference between the geological formations and variability of this parameter within each formation, providing useful additional information for advanced soil modelling and for guiding future geotechnical investigations in the Quito Metropolitan Area.

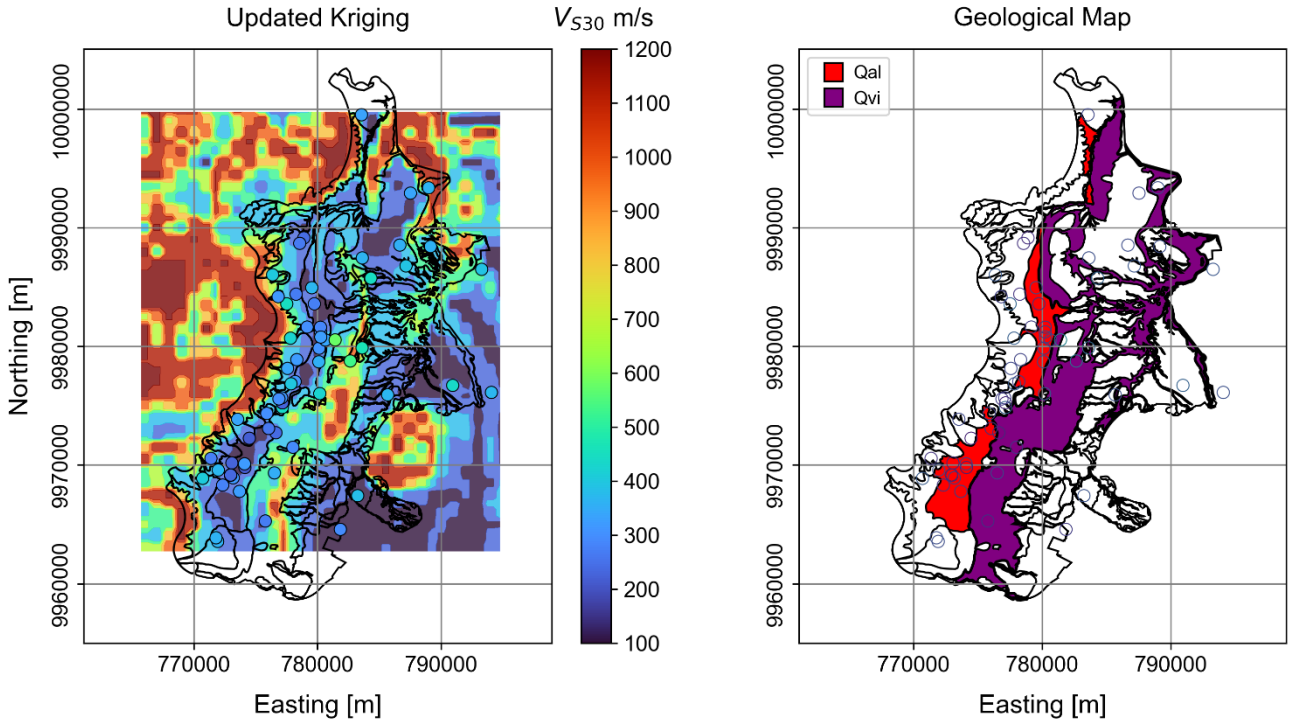

Figure 4. (left) Updated Vs_{30} map using the Bayesian Kriging model compared with (right) the geology of Quito; highlighted geological layers from Othman et al (2023a): Qal – in red – 'Lacustrine, fluvial and marsh deposits with silts and clays, in some sectors interspersed with levels of sand and lapillis from the volcanic centres that surround Quito', Qvi – in purple – 'Pyroclastic flows, silts, lahars; at the base of river-lake sequences sometimes very negligible and streams of volcanic sands (Cangahua formation)' (geological descriptions from Table 2 in Othman et al. 2023a). Geology map polygons in both maps are from Municipio de Quito (2015).

Liquefaction resistance of carbonate sands from cone penetration tests

Résistance à la liquéfaction des sables carbonatés issue d'essais de pénétration au cône

V. Fioravante
Engineering Department, University of Ferrara, Italy
**daniela.giretti@unibg.it*

ABSTRACT: Liquefaction assessment is normally carried out using semi-empirical approaches based on the pioneering study of Seed and Idriss (1982). The methods relate a penetration resistance measured in situ (preferably from cone penetration tests, CPTs) to observed instances of liquefaction and non-liquefaction of sandy deposits. However, the applicability of a simplified approach is questionable for materials which fall outside the range of silica sands and slightly silty sands for which it has been developed and extensively verified against field data. For such cases a more rigorous method is needed. Carbonate sands are well known and documented to behave differently from silica sands: at the same relative density, penetration resistance is generally lower than in siliceous sands, while cyclic laboratory testing indicates higher cyclic resistance. These observations cannot rationally be combined into the commonly used simplified liquefaction procedures. An experimental approach, based on the measured mechanical properties of the carbonate sands, is essential. This paper provides an example of calibration of liquefaction resistance from CPTU for a fill made of dredged carbonate sand, based on centrifuge CPTUs and cyclic laboratory tests.

RÉSUMÉ: L'évaluation de la liquéfaction est normalement effectuée en utilisant des approches semi-empiriques basées sur l'étude pionnière de Seed et Idriss (1982). Les méthodes relient une résistance à la pénétration mesurée in situ (de préférence à partir de tests de pénétration au cône, CPTs) à des instances observées de liquéfaction et de non-liquéfaction de dépôts sablonneux. Cependant, l'applicabilité de l'approche simplifiée est discutable pour les matériaux qui sortent du cadre des sables de silice et des sables légèrement silteux pour lesquels elle a été développée et largement vérifiée contre des données de terrain. Pour de tels cas, une méthode plus rigoureuse est nécessaire. Les sables carbonatés sont bien connus et documentés pour se comporter différemment des sables de silice: à la même densité relative, la résistance à la pénétration est généralement plus basse que dans les sables siliceux, tandis que les tests de laboratoire cycliques indiquent une résistance cyclique plus élevée. Ces observations ne peuvent pas rationnellement être combinées dans les procédures simplifiées de liquéfaction couramment utilisées. Une approche expérimentale, basée sur les propriétés mécaniques mesurées des sables carbonatés, est essentielle. Cet article fournit un exemple de calibration de la résistance à la liquéfaction à partir de CPTU pour un remblai fait de sable carbonaté dragué, basé sur des CPTUs de centrifugeuse et des tests de laboratoire cycliques.

Keywords: Liquefaction; carbonate sand; CPT; centrifuge.

1 INTRODUCTION

There is very little guidance in the literature on seismic liquefaction assessment of carbonate sands. Available information suggests that these materials have crushable grains and can be significantly more compressible than silica sands at the same relative density, resulting in a penetration resistance generally lower, Marioka and Nicholson (2000). However, laboratory testing such as cyclic simple shear or triaxial testing, indicates that, at the same relative density, carbonate sands have a higher cyclic resistance (Hyodo et al. 1998, Marioka and Nicholson 2000, Brandes 2011, Sandoval et al. 2011). These observations cannot rationally be combined into the commonly used simplified liquefaction procedures. This paper provides an example of a liquefaction assessment for a carbonate sand through an uncoupled total stress approach. The assessment compares the resistance to seismic loading to the seismic demand in terms of a factor of safety, FS_{liq}. The pore water pressure generated by seismic loading is computed from the value of FS_{liq}. Referring to a case study of a

hydraulic fill made of dredged carbonate sands, the steps of the assessment are the following:

- Determine seismic loading (cyclic stress ratio) based on site-specific ground response analysis;
- Determine in situ state parameter ψ ($\psi = e - e_{cs}$ where e = current void ratio; e_{cs} = void ratio on the critical state line at the same p', Been and Jefferies, 1985) based on the CPTU data;
- Determine cyclic strength of the sand, at the in situ state, based on laboratory cyclic shear strength tests; and,
- Compare cyclic resistance to the seismic loading to indicate the fill performance. Performance is measured in terms of whether liquefaction is likely or not, quantified by the factor of safety against liquefaction.

This engineering approach should be valid for any material that lies outside of the database of liquefaction case histories for which the NCEER (Youd and Idriss, 2001) approach is appropriate. This includes carbonate sands, as well as silts and tailings. It is also applicable for projects which are considered too complex for the simplified methods to apply.

2 SEISMIC LOADING

The reference case study is a 20 m thick hydraulic fill, made of a carbonate sand, dredged offshore, hydraulically placed and densified by vibrocompaction. The fill is located in the Persian Gulf.

The results of a regional seismic hazard analysis PSHA, indicating reverse and strike-slip earthquakes with moment magnitude of approximately $M_w = 6$, have been used as the basis for selecting and applying bedrock ground motions in the site response models. The number of cycles of loading, wich is mainly influenced by the magnitude, is N = 6, as defined by the PSHA.

The maximum cyclic stress ratio CSR through the depth of the fill has been determined through a series of site-specific dynamic soil response analyses using an uncopled total stress approach and a 1D nonlinear soil response model. Geotechnical and geophysical parameters measured for the calcareous sand fill and underlying geological materials have been used. It's worth noting that the 50 percentile value of the small strain shear modulus in the fill, derived from shear wave velocity measurements, was adopted in the analyses. This is considered appropriate since displacement compatibility is required and it is therefore the average stiffness that determines the cyclic strains. The non linear soil behaviour has been accounted for considering the experimental strain dependent stiffness and damping of the fill's sand.

The analyses output was a profile of maximum cyclic stress ratio, which was then multiplied by 0.65 to convert computed time histories of CSR containing transient peak amplitudes to an equivalent, uniform CSR profile, consistent with laboratory testing.

3 MECHANICAL PROPERTIES OF THE DREDGED CARBONATE SAND

3.1 ZS sand cyclic resistance

ZS sand, described in detail in Giretti et al. (2018a), is a biogenic carbonate sand with a carbonate content higher than 97%. The sand is composed of a major component referred to organigenic and bioclastic origin, clasts of micritic limestones, and minor component of sparry calcite. The prevalent mineral phases are calcite, aragonite and Mg-calcite. The grains are characterised by micro-porosity and fine borings due to action of endolithic algae are present in some cases.

Table 1 reports ZS grain size distribution parameters. Specific gravity, maximum and minimum density (as per ASTM D4254, ASTM D4253) and void ratio are summarised in Table 2. The ASTM procedure for maximum dry density was considered the more suitable to crushable carbonate sands, however the series of determinations carried out highlighted a significant range of variation, confirming the limited reliability of density as reference parameter to characterise carbonate sands.

The critical state line approximation of ZS in the e-$\log_{10}$(p') plane is shown in Figure 1.

To evaluate the cyclic resistance of ZS, many cyclic tests (both triaxial and simple shear) have been performed. The results have been interpreted to define relationships between the cyclic stress ratio CSR ($\Delta\sigma_a/2s'$, where $s' = (\sigma'_v+\sigma'_h)/2$, or τ/σ'_v) and the number of cycles N to cause liquefaction (defined as the condition when the double amplitude axial strain ε_{DA} equals 2.5% or the double amplitude shear strain γ_{DA} equals 5%), for different values of the state parameter ψ.

The cyclic resistance evaluated in triaxial condition has been converted to resistance in a simple shear condition using a multiplier factor (Ishihara et al., 1977, 1985) of 0.7. Data from triaxial tests corrected by this factor, for given values of the state parameter ψ, are compared in Figure 2 to data from cyclic simple shear tests.

Table 1. Grain size distribution parameters of ZS sand.

	D_{10} (mm)	D_{50} (mm)	D_{60} (mm)	U_C (-)	FC (%)	Gravel like (%)
ZS	0.085	0.339	0.474	5.57	7.9	0

Table 2. Index properties of ZS sand.

	γ_{min} (kN/m^3)	γ_{max} (kN/m^3)	e_{max} (-)	e_{min} (-)	G_S (-)
ZS	14.14	17.88	0.95	0.54	2.812

The relationships between the cyclic resistance CSR in simple shear conditions (τ/σ'_v) and N have been used to define relationships between CSR and the state parameter ψ at a given N, as shown in Figure 3. Equation 1, referred to the case of "failure" occurring on the 6th cycle of loading, is also reported in Figure 2.

$$CRR = 0.129 - 0.308 \cdot \psi \qquad (1)$$

This equation has been used to evaluate the *in situ* cyclic resistance as a function of the values of ψ estimated from CPTUs (using a properly calibrated correlation with the cone resistance, see next section).

The results of the cyclic tests have been also used to define a relationship between FS_{liq} and the excess pore pressure build up. For a given applied stress ratio τ/σ'_v, the number of cycles necessary to induce an excess pore pressure $Ru = \Delta u/\sigma'_v$ ranging from 0.1 to 0.95 has been evaluated. The relationship between τ/σ'_v and N for a given Ru value has then been determined. Example of the τ/σ'_v – N – Ru relationships are given in Figures 4a and b.

The FS_{liq} values at N=6 can be computed as the ratio between τ/σ'_v at Ru = 0.95 and τ/σ'_v at lower Ru values. The Ru – FS_{liq} relationships are shown in Figure 5. A unique relationship Ru – FS_{liq} has been found as shown in Figure 5, which can be interpreted with an inverse power law function:

$$Ru = \left(\frac{1}{FS_{liq}}\right)^{6.6} \qquad (2)$$

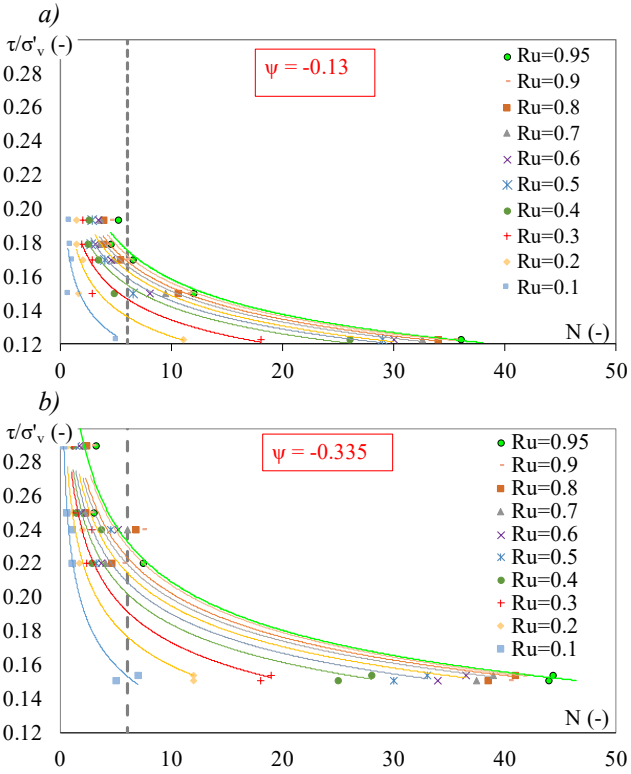

Figure 4. Cyclic stress ratio as a function of the number of cycles for Ru ranging from 0.3 to 0.95: a) ψ = -0.13; b) ψ = -0.335.

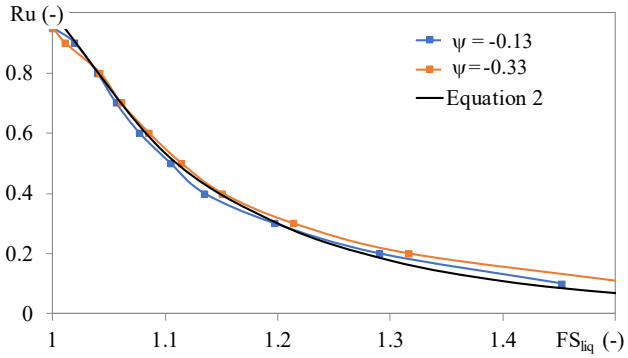

Figure 5. Ru - FS$_{liq}$ relationships.

3.2 Cone penetration resistance in ZS

As described in detail in Giretti et al. (2018b), a significant number of calibration CPTU tests in a centrifuge and in a large calibration chamber have been performed to calibrate correlations between the cone resistance q_t and the state parameter ψ for ZS.

Figures 6 and 7 show typical centrifuge calibration test results of dry and saturated ZS sand over a range of average void ratios (mean value at the end of inflight consolidation). The tip resistance is plotted against the vertical effective stress σ'$_v$, computed accounting for the acceleration field distortion in the centrifuge. Saturated as opposed to dry conditions have a significant effect on the measured tip resistance for ZS sand. Figure 8 shows the same centrifuge data from Figs. 6 and 7 but processed as a normalised tip resistance Q_p vs. to the state parameter, ψ, in which Q_p is:

$$Q_p = \frac{q_t - p}{p'} \quad (3)$$

where p and p' are the total and affective mean stress.

The state parameter is calculated for each Q_p point based on the vertical effective stress, horizontal effective stress from $K_0 = 0.5$, void ratio estimated at that point and a linear critical state line approximation characterised by $\lambda_{10} = 0.296$ and $\Gamma_1 = 1.566$ (see Fig. 1). It's worth noting that in a small scale accelerated model, the vertical effective stress increases significantly from top to bottom of the sample, thus the void ratio also varies through the model. The void ratio profile in the sample can be estimated using the compression coefficients measured in oedometer tests, but maintaining the measured average void ratio (average at the end of the inflight consolidation induced by the augmented gravity fill). The lines of data for dry and saturated conditions in Figure 8 describe two similar relationships, highlighting the significant influence of ψ on tip resistance in sands. Following Jefferies and Been (2006) the relationships have the following Equation:

$$Q_p = k \cdot e^{-m\psi} \quad (4)$$

in which the parameters *k*, *m* are 42 and 5.1 for dry models and 35 and 5.1 for the saturated models.

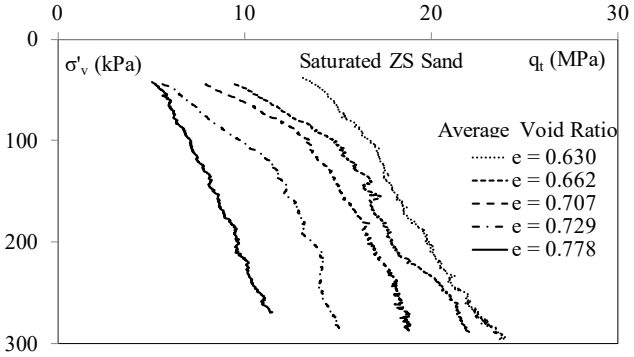

Figure 7. CPTUs in saturated ZS.

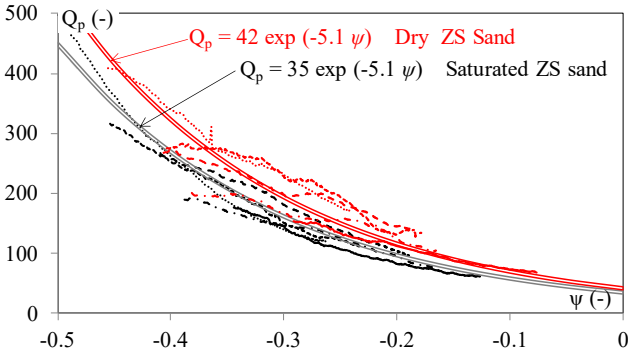

Figure 8. State parameter interpretation of centrifuge tests.

4 LIQUEFACTION ASSESSMENT

The first step of the liquefaction assessment consists in the determination of the in situ state of a sand fill through in situ CPTUs. The CPTU calibration summarised above provides the link between the measured tip resistance and the in situ state parameter. For a large volume of fill in which the in situ state is variable, the definition of a characteristic value for the liquefaction analysis is needed. For liquefaction to be a problem, a certain thickness of fill needs to be loose, and for this reason, 1 m thick layers or depth

increments can be considered. However, only a relatively small portion of a fill needs to liquefy for the overall performance of the fill to be unsatisfactory. The analysis therefore may consider the 20 percentile value of the in situ state in each metre interval. A one metre depth interval provides a good vertical definition of a fill profile in relation to the likely size of foundations and depth of fill. From a liquefaction perspective, a greater depth interval is not desirable as that relatively thin liquefied layers can be problematic.

Figure 9a shows, as an example, a groups of 4 CPTUs carried out in a 25 m x 25 m box of a compacted hydraulic fill made of ZS, and the 20 percentile values in 1 m depth intervals derived from the group. The 20 percentile profile is used to compute the characteristic in situ state parameter by means of the inverse form of Eq. 4, as shown on Figure 9b. For the inversion, an average depth of the groundwater table of 6 m was assumed. Figure 9c presents the comparison between the cyclic strength CRR, derived from the 20 percentile state parameter profiles by means of Eq. 1, with the seismic loading obtained from the site-specific dynamic soil response analysis.

Equation 1 (see also Fig. 2) has been employed to calculate cyclic strength from state parameter for N = 6 cycles. The seismic loading on Figure 9c is 0.65 times the maximum CSR from ground response analysis. The cyclic strength of the compacted fill is clearly well above the cyclic loading, representing a very low risk of liquefaction (or high factor of safety).

The CRR profile in Figure 9c derives from the combination of Eqs. 1 and 4 and can be written as:

$$\mathrm{CRR} = 0.129 - 0.308 \cdot \left(-\frac{1}{m} \cdot ln\frac{Q_P}{k}\right) \quad (5)$$

The ratio between the CSR and CRR profiles in Figure 9c is the factor of safety against liquefaction FS_{liq}, from whose values the pore pressure ratio Ru can be calculated using Eq. 2. The calculated pore pressure profiles for 7 groups of 4 CPTUs are shown on Figure 10. In general, the pore pressure ratio is less than about 0.1, with two locations showing values up to 0.37 in some layers.

These values are low in terms of liquefaction - a range of 0.3 to 0.5 is normally considered to signify the onset of strain softening during seismic loading, while 0.9 is considered liquefaction.

5 CONCLUSIONS

This paper presented an example of a liquefaction assessment for a carbonate sand with reference to a case study of a hydraulic fill made of dredged calcareous, biogenic sands. The two principal ingredients of the assessment are the determination of:

- the in situ state based on CPTU data and a properly calibrated correlation for the fill sand between the cone resistance and the soil state;
- the cyclic strength of the sand, at the in situ state, based on laboratory cyclic shear strength tests.

This assessment procedure has been developed given that carbonate sands lies outside of the range of materials for which the NCEER approach is appropriately applicable.

Core of the procedure is the adoption of the state parameter ψ (Been and Jefferies, 1985) as proper indicator of the state of the fill‘s sand, given that density alone (void ratio or relative density), without stress level, is not sufficient for defining the state of the soil and quantifying its stress-strain-strength behavior. The procedure described allows to assess the satisfaction of performance requirement (such as minimum safety factor against liquefaction) for compacted hydraulic fill on the basis of a directly relevant physical parameter, not affected by i) testing method, ii) the applicability of empirical correlations between cone resistance and liquefaction resistance, iii) potential errors associated with the nature of carbonate sand (e.g. high and variable compressibility and susceptibility to particle crushing).

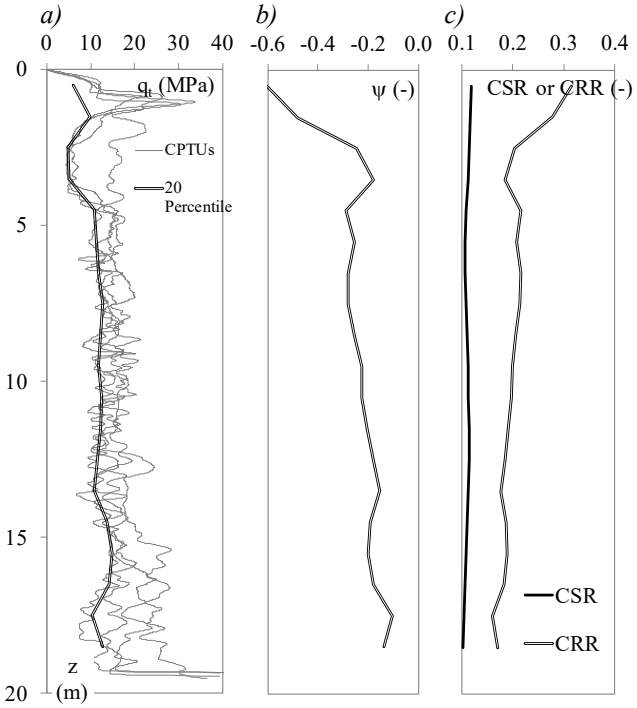

Figure 9. Liquefaction analysis for a group of 4 CPTUs: a) measured q_t profiles and corresponding 20 percentile value; b) characteristic in situ state parameter; c) cyclic resistance and cyclic stress ratio.

ABSTRACT: Seismic Microzonation studies of 3rd Level (SM3) have been performed for the emergency management and the reconstruction of several Municipalities in the eastern flank of Mt. Etna (Southern Italy) hit by the 2018 seismic sequence. The most energetic event (Mw=4.9) occurred on 26th December 2018, causing phenomena of superficial faulting along the Fiandaca Fault (FF), where the most damaged areas are located. In order to define the subsoil model for each seismic homogeneous microzone (SHM) and to perform extensive numerical analyses, intense investigations have been carried out including in situ and laboratory tests. For the estimation of the spatial variability in seismic response, the finite element code PLAXIS 2D has been employed. Moreover, the Hardening Soil model with small-strain stiffness (HS small model), which includes an increased soil stiffness for small strains, has been adopted in order to consider the soil non-linearity. For each SHM, results are presented in terms of acceleration response spectra and amplification factors (AFj). The latter are calculated for three different period intervals linked to the heights of buildings according to the Italian Guidelines and Standards. The results of this work provide important information for the development of urban planning aimed at reducing seismic risk.

RÉSUMÉ: Des études de microzonage sismique de 3e niveau (SM3) ont été réalisées pour la gestion des urgences et la reconstruction de plusieurs municipalités du flanc oriental de l'Etna (sud de l'Italie) touchées par la séquence sismique de 2018. L'événement le plus énergétique (Mw = 4,9) s'est produit le 26 décembre 2018, provoquant des phénomènes de failles superficielles le long de la faille de Fiandaca (FF), où se trouvent les zones les plus endommagées. Afin de définir le modèle de sous-sol pour chaque microzone sismique homogène (SHM) et d'effectuer des analyses numériques approfondies, des investigations intenses ont été menées, y compris des tests in situ et en laboratoire. Pour l'estimation de la variabilité spatiale de la réponse sismique, le code d'éléments finis PLAXIS 2D a été utilisé. De plus, le modèle Hardening Soil with small-strain stiffness (HS small model), qui inclut une rigidité accrue du sol pour les petites déformations, a été adopté afin de prendre en compte la non-linéarité du sol. Pour chaque SHM, les résultats sont présentés en termes de spectres de réponse d'accélération et de facteurs d'amplification (AFj). Ces derniers sont calculés pour trois intervalles de périodes différents liés aux hauteurs des bâtiments selon les directives et normes italiennes. Les résultats de ces travaux fournissent des informations importantes pour le développement d'une planification urbaine visant à réduire le risque sismique.

Keywords: Seismic microzonation studies; amplification factors; FEM analysis.

1 INTRODUCTION

Due to the seismic sequence that began on 23rd December 2018 and hit the eastern flank of Mt. Etna (Southern Italy), 3rd Level Seismic Microzonation studies were performed for several municipalities located in Eastern Sicily (Cavallaro et al. 2022; Grasso and Sammito, 2022). The sequence peaked in the Mw=4.9 seismic event occured on 26th December 2018 after many Mw>2.5 events causing serious damage to unreinforced masonry buildings.

Through intense field activities, the geological and geomorphological setting of the municipalities affected by the sequence was investigated. The physical phenomena govering the site response were studied by the finite element code PLAXIS 2D using

the Hardening Soil model with small-strain stiffness (HS small model).

2 DESCRIPTION OF THE CASE STUDY

Laboratory and in situ tests were performed for the 3rd Level Seismic Microzonation of several municipalities damaged by the 2018 seismic sequence. In this paper, the data collected for the municipality of Trecastagni are taken into consideration (Figure 1).

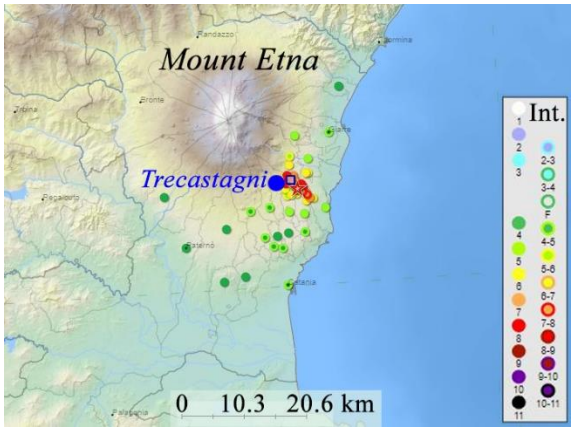

Figure 1. Intensity map. Earthquake of 26th December 2018 (from Rovida et al. 2020; 2022, modified).

To evaluate the local seismic response, laboratory and in situ tests were carried out including n. 8 Boreholes, n. 1 Down-Hole (DH) test, n. 9 Multichannel Analysis of Surface Waves tests (MASW), n. 24 Horizontal Vertical Spectral Ratio Test (HVSR) and n. 1 Direct Shear tests (DST). The shear wave velocities, V_S, obtained from the DH test, are shown against depth in Figure 2. In order to describe the dependence of the shear modulus and damping as a function of the shear strain, it was necessary to refer to dynamic curves from literature (Castelli et al., 2018). The definition of the Seismically Homogeneous Microzones (SHMs) is essential for the construction of the subsoil models (Castelli et al. 2023). Six SHMs were identified in the studied area. The SHMs Map includes also an "Attention zone for active and capable fault" (ACF) (Figure 3).

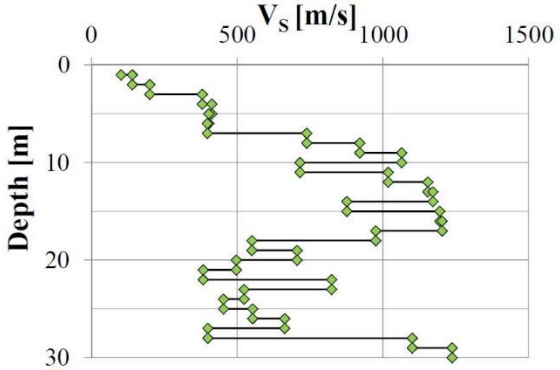

Figure 2. V_S from DH test in the municipality of Trecastagni.

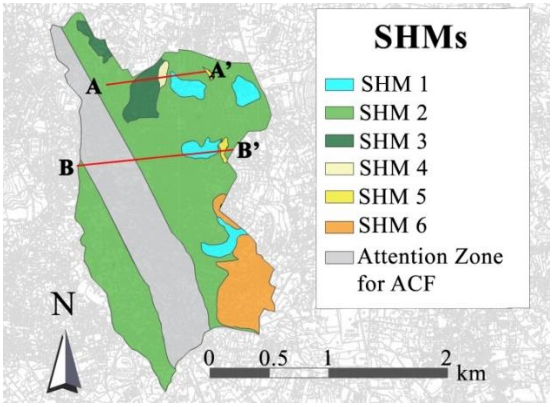

Figure 3. SHMs map with the indication of the studied geological cross-sections.

The main engineering-geological units (*gt-units*), identified by 2 to 4 letter acronyms, are the following: Backfill soil (RI), Silty gravels, gravel-sand-clay mixtures (GM), Coarse scoriaceous products in a predominantly sandy matrix (GW), Well-graded sands and gravelly sands, little or no fines (SW), Cover lithoid (LC), Fractured / altered geological bedrock alternation of lithotypes (SFAL). The 2D subsoil models are based on geological cross-sections that reproduce the geometry of the *gt-units* and the measured V_S from the geophysical tests. As example, the geological cross-sections B-B' is displayed in Figure 4.

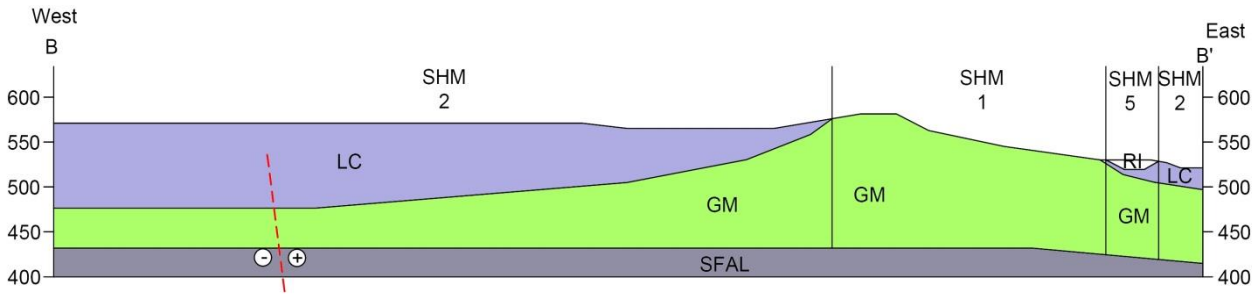

Figure 4. Geological cross-sections B-B'.

3 NUMERICAL MODELLING

For each municipality, the input motions consisted of a set of seven unscaled natural records selected from the European Strong-motion Database (ESM) (https://esm.mi.ingv.it/) to be compatible on average in the 0.1-1.1 s interval of period with the reference response spectrum for Soil Class A and for a return period of 475 year according to the Italian Building Code (NTC, 2018).

Natural records were selected using REXELite, a simplified online version of the computer program REXEL (Iervolino et al., 2009), through the Magnitude-Distance criterion based on disaggregation of seismic hazards (available at http://esse1-gis.mi.ingv.it).

The accelerograms used as input motion for Trecastagni area are listed in Table 1.

Table 1. Natural accelerograms selected as input motion for Trecastagni area.

ID	Mw	R[km]
A.MZ14.HNN.D	6.5	30.6
3A.MZ19.HNE.D	6.5	22.6
IT.CLO.HGN.D	5.9	10.8
IT.MMO.HGN.D	6.5	19.2
IT.SVN.HGE.D	4.9	4.5
IT.SVN.HGN.D	4.9	4.5
IV.T1212.HNN.D	6.5	10.5

The 2D analyses were performed through the finite element code PLAXIS2D using the HS small model.

The mesh was defined by 15-node triangular elements with a size that respects the Kuhlemeyer and Lysmer (1973) condition. With regard to the boundary conditions, the free field and compliant base boundary conditions were considered. The finite element mesh, reproducing the B-B' geological cross section for Trecastagni area, is reported in Figure 5.

The HS small describes the soil stiffness by using three different input parameters at the reference pressure p^{ref}: the secant stiffness in standard drained triaxial test, E_{50}^{ref}, the unloading/reloading stiffness, E_{ur}^{ref}, and the tangent stiffness for primary oedometer loading, E_{oed}^{ref}. To describe the variation of stiffness with strain, two additional parameters have to be considered: the reference shear modulus at very small strain, G_0^{ref}, and the shear strain level, $\gamma_{0.7}$, at which the secant shear modulus, G_S, is reduced to 72.2 % of G_0.

Table 2 reports the input parameters of the HS small model, i.e. for a GM layer, where: γ is the unit weight of soil, m is the power for stress-level dependency of stiffness, c' is the cohesion and φ' is the friction angle.

Table 2. Input parameters for the HS small model.

Symbol	Value	Unit
γ	20	kN/m^3
E_{50}^{ref}	36000	kN/m^2
E_{oed}^{ref}	36000	kN/m^2
E_{ur}^{ref}	108000	kN/m^2
G_0^{ref}	351324	kN/m^2
$\gamma_{0.7}$	0.00018	-
p^{ref}	100	kN/m^2
m	0.51	-
c'	10	kN/m^2
φ'	36	°

4 RESULTS

Once numerical ground response analyses is performed, another key aspect in a SM3 study is the evaluation of the Amplification Factors (AF) (Working Group ICMS 2008, 2011).

They are calculated as the ratio between the integral of the pseudo-acceleration elastic response spectrum of the output motion ($S_{,out}$) and the pseudo-acceleration elastic response spectrum of the input motion ($S_{,inp}$) in a defined interval of period (Pergalani et al., 2019):

$$AF_{T_n} = \frac{\int_{T_a}^{T_b} S_{,out} dT}{\int_{T_a}^{T_b} S_{,inp} dT} \; with \; n = 1,2,3 \qquad (1)$$

where Ta and Tb are the extremes of the defined interval of periods, Tn. The three different range of periods are: T_1= 0.1–0.5 s; T_2= 0.4–0.8 s and T_3= 0.7–1.1 s, in order to cover the fundamental periods of buildings in studied municipalities.

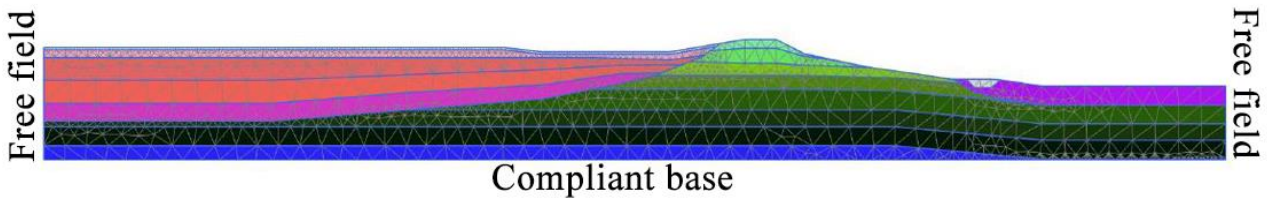

Figure 5. Finite element mesh reproducing the B-B' geological cross section used in numerical analyses for Trecastagni area.

In Figure 6, results are presented in term of response spectrum at the surface, i.e. for a SHM 2, obtained by setting a structural damping of 5%.

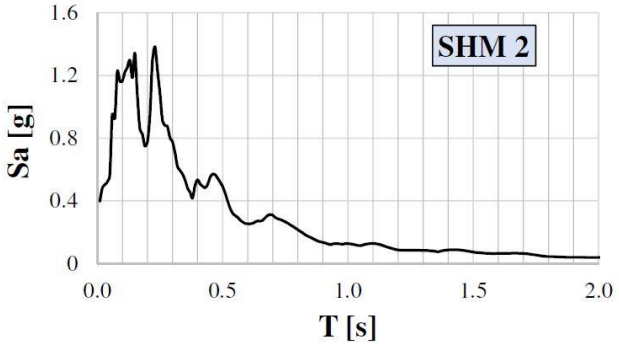

Figure 6. Elastic response spectrum obtained by numerical analyses.

According to the guidelines for Seismic Microzonation studies (Working Group ICMS 2008, 2011), AF factors were determined for each SHM encountered along the cross-sections, as summarize in Table 3. The amplification factors are named according to the related interval of periods: AF0105, AF0408 and AF0711.

Table 3. AF factors for each SHM.

SHM	AF0105	AF0408	AF0711
1	2.43	2.77	2.37
2	1.76	1.61	1.65
3	2.19	1.80	2.48
4	1.62	2.08	2.95
5	2.08	1.83	1.32

5 CONCLUSIONS

In this work, seismic microzonation studies were carried out for several municipalities in Eastern Sicily, after the effects of the 2018 seismic sequence. 2D site response analyses are presented to highlight approaches that could be applied for seismic microzonation studies in similar conditions. Relevant key aspects are reported focusing on a specific case study. Results are presented in terms of amplification factors of spectral acceleration defined according to national guidelines and standards for microzonation studies. The outcome of this paper provides a valuable base in developing urban planning oriented to seismic risk management.

ABSTRACT: Quito, Ecuador, is a rapidly expanding multi-hazard environment at increased risk of rainfall-triggered landslides. In such cities, information on the impact of urbanisation on slopes and rainfall intensity-duration thresholds for triggering landslides can be valuable for resilient urban planning. However, rainfall thresholds are usually generated from empirical landslide data, which is often unavailable. This paper presents an overview of recent stochastic landslide modelling work, enabling regional sensitivity analysis and the development of rainfall thresholds based on tens-of-thousands of physics-based slope stability simulations. Typical landslide-prone communities in north Quito are characterised in terms of degree of urbanisation, slope geometry, soil properties and rainfall scenarios. Soil data came from the new Quito soil geotechnical database and drone mapping successfully resolved slope geometries and more detailed information such as construction materials and slope features. An overview of the modelling methodology is presented. The key findings of the simulation study are that slope cutting, followed by removal of vegetation are the key drivers of slope instability. These findings are discussed in the context of recommendations for land use policy in the studied areas.

RÉSUMÉ: Quito, en Équateur, est un environnement multi-risques en expansion rapide, exposé à un risque accru de glissements de terrain provoqués par les précipitations. Les informations sur l'impact de l'urbanisation sur les pentes et les seuils d'intensité et de durée des précipitations déclencheurs de glissements de terrain peuvent être précieuses pour la planification urbaine. Cependant, les seuils de précipitations sont généralement générés à partir de données empiriques, souvenousat indisponibles. Cet article présente un aperçu des récents travaux de modélisation stochastique des glissements de thterrain, permettant une analyse de sensibilité régionale et le développement de seuils de précipitations basés sur des dizaines de milliers de simulations. Les communautés typiques sujettes aux glissements de terrain du nord de Quito sont caractérisées en termes de degré d'urbanisation, de géométrie des pentes, de propriétés du sol et de scénarios de précipitations. Les données pédologiques proviennent de la nouvelle base de données géotechniques des sols de Quito; la cartographie par drone a réussi à résoudre les géométries des pentes et des informations plus détaillées telles que les matériaux de construction et les caractéristiques des pentes. Un aperçu de la méthodologie de modélisation est présenté. Les principales conclusions de l'étude de simulation sont que la réduction des pentes, suivie de l'élimination de la végétation, sont les principaux facteurs d'instabilité des pentes. Ces résultats sont discutés dans le contexte de recommandations pour la politique d'aménagement du territoire dans les zones étudiées.

Keywords: Slope stability; CHASM; stochastic modelling; urbanisation.

1 INTRODUCTION

Quito, Ecuador is a multi-hazard environment and is subject to the effects of volcanic eruptions, seismic events and rainfall-triggered landslides (cf. O'Rourke and Crespo 1988). Municipal engineers and planners require hazard assessments to support effective disaster risk management practices and policies for today and the future, as urban development continues. Although there is a strong culture of geotechnical testing in the area, a dataset suitable for wide-area landslide hazard assessment was not readily accessible until the recent compilation, publication and statistical analysis of a new database

QUITO/GEO-299 (Hen-Jones et al. 2022; Othman et al. 2023a, b).

The development of this database followed the six-step methodology for data collection and curation in data-scarce regions presented by Vardanega et al. (2023, p.1268-9) summarised as follows: (1) assess the geotechnical-data landscape; (2) make use of local knowledge; (3) understand local practice; (4) undertake data harmonization and cleaning activities; (5) carry-out benchmarking analysis; (6) release the data. The new QUITO/GEO-299 database (Othman et al. 2023a) has enabled physics-based modelling and investigation of landslides in south Quito using the Combined Hydrology And Stability Model, CHASM (Zapata et al. 2023).

In this paper, geotechnical parameter distributions from the database are combined with data on slope geometries, rainfall, and slope features of three hillside communities in north Quito to enable stochastic CHASM modelling of landslide scenarios. The simulation outputs are analysed to find dominant slope instability drivers and rainfall intensity-duration thresholds likely to trigger urban landslides in north Quito. Triggering threshold estimation is usually only possible where landslide inventories are available (e.g., Larsen and Simon, 1993; Guzzetti et al., 2008). Identification of landslide drivers and thresholds can support landslide early warning and resilient land use practice and policy.

2 QUITO LANDSLIDE MODELLING

As part of the Tomorrow's Cities project (see Galasso et al. 2021) Hen-Jones et al. (2024), studied three communities in the northern parts of Quito. A stochastic modelling approach was adopted to allow a wide range of combinations of potential landslide preparatory and triggering factors to be investigated. The following simulation input data was prepared:

1) strata geotechnical properties: soil parameter ranges and distributions were determined from the new Quito geotechnical database, including effective strength parameters, hydraulic conductivity, and unit weight – more information on these geotechnical properties and their fitting parameters can be found in Hen-Jones et al. (2022) and Othman et al. (2023b).

2) natural and urban slope geometry: slope geometry data was derived from drone surveys carried out as part of community participatory activities that had been adapted due to the constraints on field work due to the Covid-19 pandemic. This was successful in capturing detailed information on the heights and angles of cut slopes associated with houses and roads (Hen-Jones et al. 2022). These data were statistically analysed to give distribution parameters for stochastic modelling.

3) urban slope features: drone surveys provided detailed information on house construction materials, urban drainage features and vegetation. Figure 1 indicates how urban slope features are represented in the CHASM urban slope analysis functions developed by Bozzolan et al. (2020). All simulations were run with and without the presence of vegetation.

4) design storms: rainfall intensity and duration ranges were sampled to generate the rainfall inputs that provide the dynamic driver for the hydrological response and stability of each slope in CHASM.

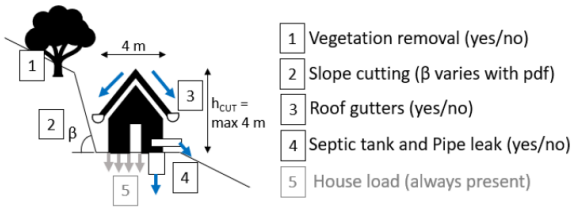

Figure 1. Urban properties of informal housing included in the slope stability analysis (from Bozzolan et al. 2020, used under the terms of the cc-by 4.0 licence).

The parameter ranges in the above four categories were stochastically sampled to generate tens-of-thousands of slope and rainfall scenarios representing the case-study communities. In each case CHASM was used to estimate the minimum slope factor of safety (FoS), where FoS < 1 defined slope failure (i.e. a landslide). CHASM uses Bishop's (1955) method of slices (a limit equilibrium method, LEM) and accompanying hydrological models (Darcy, 1856; Richards, 1931). More details on CHASM can be found in Wilkinson et al. (2002).

Global Sensitivity Analysis (GSA) and Regional Sensitivity Analysis (RSA) of the CHASM input factors and output FoS values were undertaken, allowing the effect of different input parameters on slope stability to be investigated. This analysis was carried out in Matlab using the SAFE Toolbox (Sarrazin et al. 2017; Noacco et al. 2019).

3 URBANISATION SCENARIOS

In this study, the effect of the urbanisation process on slope stability was assessed (Fig. 2) by representing the following stages: (Urb0) the initial plain slope; (Urb1) addition of a road; (Urb2) addition of sparse housing – this situation describes the first North Quito case study community. The other two communities are examples of subsequent urbanisation stages, either: (Urb3) unplanned/informal, high density urbanisation, or (Urb4) planned, low density

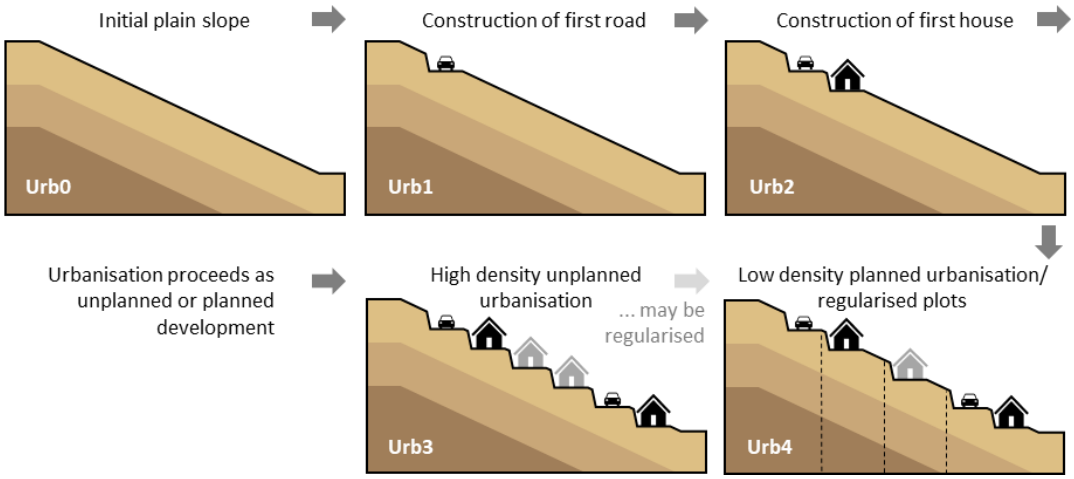

Figure 2. Modelled urbanisation scenarios on the N-S ridges of the Quito Fault System (from Hen-Jones et al. 2024). Urbanisation in east Quito often proceeds downslope from fault ridges or plateaus to lower elevations as the city expands.

urbanisation. Informal settlements often have makeshift drainage, adding to other destabilising factors including deforestation, blockage of natural drainage with solid waste, poor quality construction materials and poor engineering practices (Hen-Jones et al. 2024). Surface drainage features were modelled accordingly, as described in Hen-Jones et al. (2024).

4 RESULTS AND DISCUSSION

Hen-Jones et al. (2024) presents the full discussion of the results of this study. The sensitivity analysis revealed five key input factors dominating slope stability response: natural slope angle, effective cohesion, saturated hydraulic conductivity, height of the water table and rainfall duration. The influence of effective friction angle on slope stability did not feature strongly in the analysis. Given the importance of rainfall duration, rainfall-intensity duration thresholds were developed for north Quito, using the simulation results for all urbanisation stages (Urb0 to Urb4). Often intensity-duration thresholds are developed from smaller empirical datasets (see Table 2) rather than synthetic datasets, and usually presented in the form of Eq. (1):

$$I = a(D)^{-b} \quad (1)$$

where I = rainfall intensity (mm/hr); D = effective rainfall duration (hrs); a and b are fitting parameters. Thresholds were drawn at various percentiles of data capture as presented in Table 1. These can be compared to those from previous studies summarised in Table 2. The ranges of a and b values shown in these tables are broadly comparable but reflect significantly smaller datasets where empirical landslide and rainfall data are concerned (Table 2).

Table 1. Fitting parameters for Eq. 1 rainfall intensity duration thresholds (data from Hen-Jones et al. 2024).

Percentile	*a*	*b*
95	44.52	0.17
99	25.79	0.21
99.5	46.81	0.48
99.9	20.08	0.45
100	20.57	0.77

Table 2. Fitting parameters for I-D thresholds from previous studies.

Reference	Location	*a*	*b*
Larsen and Simon (1993)	Puerto Rico	91.46	0.82
Ahmad (2003)	Jamaica	11.5	0.26
Guzzetti et al. (2008)	Worldwide	6.68	0.52

A comparison of slope failure rates between the different modelled scenarios reveals that the most significant factor driving instability is the act of cutting into the slope (increase in failure rate from 2% to 6% for a plain, vegetated slope, Urb0), also observed in Bozzolan et al. (2020) which investigated the stability of informal housing in the humid tropics. The next most important parameter is the removal of slope vegetation (increase in failure rate from 6% to 13% for a slope with a road cut present, Urb1). Further urbanisation to include an additional road and minimal housing (Urb2) has a negligible effect on the failure rate, the slope stability already having been critically influenced by the initial road cut. When considering vegetated slopes, the unplanned, high density housing scenario (Urb3) gives a significant increase in failure rate compared to the minimal housing scenario (Urb2) of 4%, however, considering bare slopes, the absolute increase is only 1%.

5 CONCLUSIONS

Stochastic simulations have been used to develop I-D thresholds for north Quito, comparing reasonably with past studies. The most important factor affecting stability in the modelled communities is slope cutting, followed by vegetation removal. Analysis supports the importance of revegetation as a landslide management policy and highlights the merit of urban planning for new settlements.

Forensic investigation of quick clay landslide released by construction work at Asak, Norway

Enquête sur un glissement de terrain d'argile sensible provoqué par des travaux de construction à Asak, Norvège

hakon.heyerdahl@ngi.no

ABSTRACT: In November 2016, a quick clay landslide was triggered at Asak in Eastern Norway. The landslide occurred in an area where a landfill was under construction. Six persons worked in the forest downslope of the area at the time of the landslide. Three of these were able to escape from the landslide runout, while three were killed. After the event, NGI investigated the cause of the landslide using available and new information. An important part of the documentation was reconstruction of the landfill work prior to the landslide release, using satellite images and other evidence. The slope geometry previous to the failure was reconstructed, and stability calculations were done based on ground investigations performed outside the landslide area. The performed analyses confirmed that the landfill, although reducing the slope inclination, had resulted in a drastic reduction in the undrained stability. Stability calculations performed with LEM and FEM methods to investigate the probable geometry of the failure plane matched well with field observations.

RÉSUMÉ: En novembre 2016, un glissement de terrain d'argile sensible a été déclenché à Asak, dans l'est de la Norvège. Le glissement de terrain s'est produit dans une zone où une décharge était en construction. Six personnes travaillaient dans la forêt en aval de la zone au moment du glissement de terrain. Trois d'entre elles ont pu s'échapper de l'éboulement, tandis que les trois autres ont été tuées. Après l'événement, NGI a enquêté sur la cause du glissement de terrain en utilisant les informations disponibles et les nouvelles informations. Une partie importante de la documentation a consisté à reconstruire les travaux de la décharge avant le déclenchement du glissement de terrain, à l'aide d'images satellites et d'autres preuves. La géométrie de la pente, avant la rupture, a été reconstituée et des calculs de stabilité ont été effectués sur la base d'études de sol réalisées en dehors de la zone du glissement de terrain. Les analyses effectuées ont confirmé que la décharge, bien que réduisant l'inclinaison de la pente, avait entraîné une réduction drastique de la stabilité non drainée. Des calculs ont été effectués avec les méthodes LEM et FEM pour étudier la géométrie probable du plan de rupture.

Keywords: Landslide; quick clay; investigation.

1 INTRODUCTION

The quick clay landslide at Asak in Eastern Norway occurred on 10 November 2016, around 3:15 pm. There was still daylight at the time of the landslide detachment, and a few eyewitnesses observed the landslide development. Around 5 pm NGI was summoned for assistance by the police and arrived at the landslide site ca. 5:30 pm. Due to wintertime, sunset was around 4 pm and there was no daylight when NGI arrived at the site. Nevertheless, after a short inspection with a rescue helicopter, it could be concluded that the event indeed was a large quick clay landslide, with a high, almost vertical back scarp, and runout covering a large area with remoulded quick clay.

The SAR operation established that six persons working with logging in the forest area downslope of the release area had been trapped by the landslide in the runout area. Three of the workers managed to escape from the landslide. Three others were missing at the time rescue personal and NGI arrived on site and were later declared dead. Two of these persons have yet not been recovered.

The landslide volume was estimated to approximately 350.000 m^3. The runout covered a large area with debris, including liquid remoulded quick clay that collected in the ravines. The debris blocked the downslope creek, floated upstream as well as downstream, crossed and blocked a road, and subsequently followed the creek downslope about 1 km. In this paper, the landslide cause will be discussed.

2 DATA COLLECTION

NGI was appointed by the court to investigate the landslide cause. The work was based on available evidence and on data collected after the landslide.

2.1 Initial evaluation of triggering causes

Many potential triggering causes were evaluated, such as natural triggering by rainfall, pore-water pressure or erosion, as well as human-induced triggering by construction of new buildings at the farm Asak, road construction downslope of the landslide, establishment of an activity park east of the landslide, logging of timber downslope of the landslide, earth works being performed to increase the agricultural area of the farm, and a large mass deposit by a large recycling company just north of the landslide release area. All natural triggering causes, as well as most of the potentially human-induced causes, could after an initial evaluation be eliminated. Erosion in nearby creeks could, e.g., be disregarded due to distance of the creek to the landslide toe, while antecedent rainfall and hydrogeological conditions not in any way were critical. Also, neither the recent construction of a road, new buildings on the farm, the activity park, or activities in a mass deposit next to the landslide release area could have had any direct physical influence of the slope stability. The only remaining activity in the area that could have influenced the slope stability in a negative way was the ongoing landfill performed to increase the area of agricultural land on the farm. Further investigations were therefore concentrated around this activity.

2.2 Satellite images

Images from the Copernicus Sentinel-2 satellite between April 1st and November 17th, 2016, were analysed to map surface changes in the later landslide area prior to the landslide, with the November image being the first image after the landslide event with sufficiently low degree of clouds. These images reveal whether the surface has been changed between the different image acquisitions; that is, whether vegetation has been removed, or soil excavated or filled. Actual topographical changes in the affected area, i.e., whether soil has been excavated or filled, can however not be concluded from these images. The resolution of the imagery is 10 m x 10 m, and only imagery acquired during clear-weather conditions and without snow cover were used. The used images were spread over several months, which means that no exact dates for observed areal changes can be attributed. It is however possible to conclude where on the terrain specific surface changes occurred in the time span between two consecutive images. Figure 1 presents the outline of the landslide release and runout areas, and the interpretation of surface changes based on four satellite images acquired prior to the landslide event.

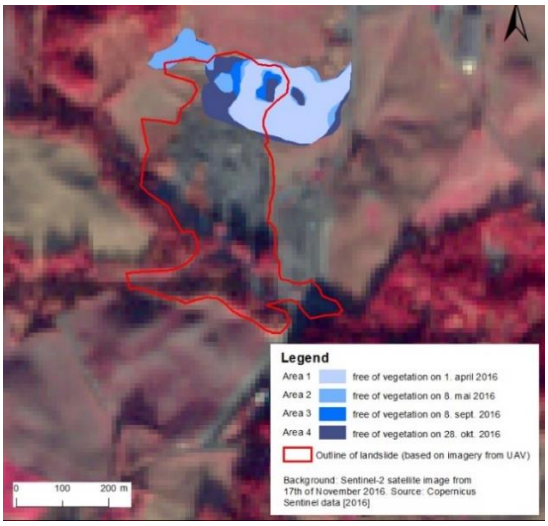

Figure 1. Surface changes interpreted from satellite images.

Zones where the surface had changed between image acquisitions are shown in shades of blue, with the oldest image (in light blue) on top, illustrating the progressive expansion of unvegetated areas into the landslide release area. The large development, indicated by a dark blue shading, shows that practically all the landslide release area was altered during the period ending with the imagery from 28 October, less than two weeks before the landslide.

2.3 Topographic changes

The landslide resulted in large topographic changes in release/runout areas that partly overlap, (Figure 2).

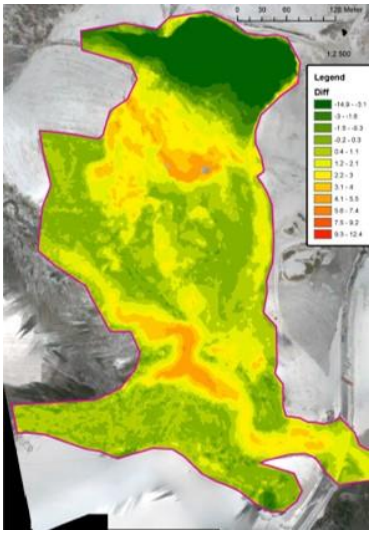

Figure 2. Topographic changes from landslide at Asak. Data before landslide does not include landfill. Map data from www.hoydedata.no.

Data before the landslide does not include landfill under construction. At the steep backscarp of the landslide, the soil surface was lowered by ca. 15 m.

2.4 Field observations

The mapped extent of the landslide (Figure 2) includes both release and runout area, which may be hard to distuingish. Based on field inspections the release area was defined to a limited area in the North. Downslope of this area, it was observed that the landslide had moved on top of the original soil surface. Large slabs of dry crust and landfill had moved down and rotated backwards from their original position, indicating retrogressive behaviour in several steps (Figure 3, Figure 5).

Figure 3. Runout area. Intact slabs have moved downslope and rotated backwards in several retrogressive steps.

The terrain model after the slide showed 5 m thick deposits adjacent to the release area. However, the landfill was not completed in the release area, and caution was taken when defining a the terrain model for subsequent stability analyses.

Landfill thickness was measured on intact slabs in the runout area to > 4 m (Figure 4).

Figure 4. Landfill thickness > 4 m found in runout area.

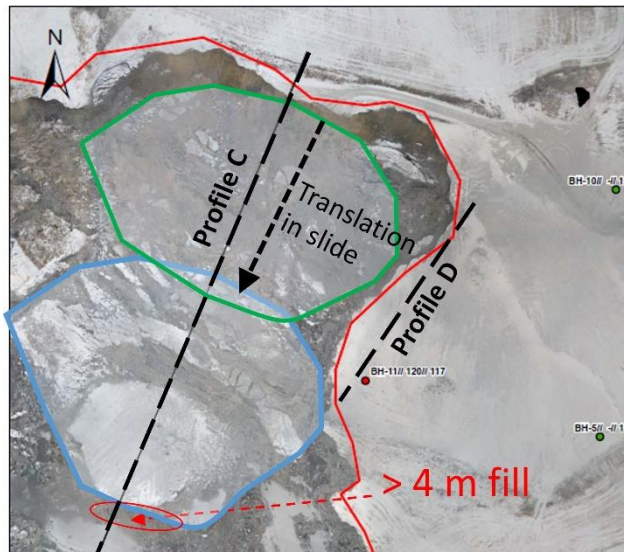

Figure 5. Translation of slabs of soil/fill. Position of soil thickness measurement in Figure 4 is indicated.

2.5 Ground investigations

In parallel with the forensic studies, NGI assisted the authorities with ground investigations and slope stability evaluations around (outside) the landslide area. Soil sampling confirmed quick clay in several bore points (Figure 6), and large amounts of remoulded quick clay were also confirmed in the runout area (Figure 3). Borings within the landslide extent line where performed before the landslide (in the South).

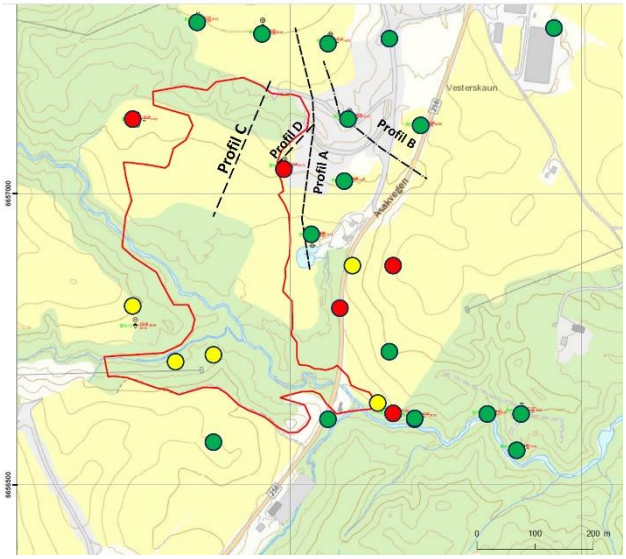

Figure 6. Ground investigations and stability profiles. Red points: QC (quick clay) confirmed by samples. Yellow: QC assumed based on soundings. Green: Not QC, based on soundings and/or samples.

3 EVALUATION OF SLOPE STABILITY

3.1 Slope stability outside the landslide area

East of the landslide scarp, the landfill was finished except from addition of topsoil. Stability profiles were constructed from Lidar data before and after the landslide. Soil parameters and layering were based on samples, total/CPTU soundings, and piezometers. Undrained shear strength of clay from CPTU was interpreted based on Karlsrud et al. (2005). No quick clay was encountered in this part of the slope but found close to the release area (Figure 5). Stability calculations for profile A just east of the landslide scarp and profile B further East showed that the undrained safety factor was reduced by the landfill, but that the safety margin with landfill was sufficient to avoid slope failure, both for drained and undrained conditions.

3.2 Slope stability in the release area

The landfill was built by dumping soil from trucks at a plateau at the top of the slope and pushing the material downslope with a bulldozer. Detailed slope geometry before the landslide release was not known, but reconstructed from topography along the landslide scarp, photos, and field observations. Soil parameters and layering were deduced from ground investigations after the landslide (Figure 6).

For profile C through the centre of the release area, slope stability analyses were performed using LEM and FEM (Figure 7). Results are summarized in Table 1. Undrained safety factor of critical sliding planes drops to values close to critical because of the landfill. Calculations were performed for different assumptions for soil parameters and topography, with similar main conclusions. Drained stability for the long-term situation is however satisfactory.

The failure geometry was validated by FEM analyses in Plaxis (Plaxis bv 2016). Resulting failure geometry (Figure 8) were similar to LEM results (Figure 7). Deep failure planes are critical for the undrained situation, and calculations match with field observation (large backward leaning slabs).

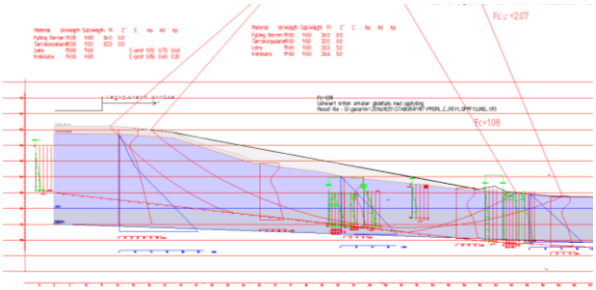

Figure 7. Slope stability C through landslide release area. Drained Fcφ and undrained Fc safety factors shown.

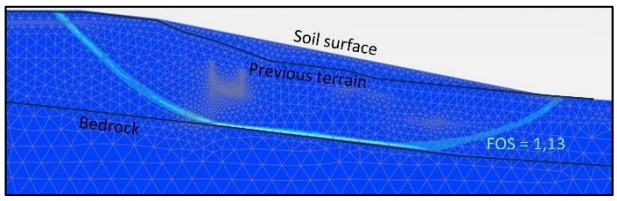

Figure 8. Results from FEM analysis (showing incremental shear strain) for profile C through landslide release area.

Table 1. Undrained safety factor with/without landfill.

Profile	Analysis	Before landfill	With landfill
C	Drained	1.57	2.02-2.07
C	Undrained	1.15-1.23	1.04-1.08 (1.13*)
D	Undrained	1.66-2.51	1.37-1.53

* Results from FEM

4 CONCLUSIONS

The investigation showed that lack of geotechnical design was the root cause of the failure, resulting in a disastrous quick-clay landslide and three fatalities as the consequence. If geotechnical design had been performed, undrained analyses would have shown that stabilising measures were necessary.

ACKNOWLEDGEMENTS

NGI wants to express our gratitude to Police Superintendent Mr. Svenn Roger Gundersen from East Police District, Economic and Environmental Crime Unit, for the opportunity to publish results from the forensic studies of the landslide.

Vulnerability assessment of buildings to landslides: application to Swiss case studies

Évaluation de la vulnérabilité des bâtiments aux glissements de terrain: application à quelques études de cas suisses

ABSTRACT: Natural hazards such as floods, landslides, debris flows, earthquakes, and fires cause many disasters. In Switzerland, from 1972 to 2021, damage from floods, landslides, debris flows, and rockfalls amounted to approximately CHF 300 million annually. Climate change, settlement development, and increasing land use are some of the primary triggers of natural hazards. Permanent landslides generally have a lower probability of producing catastrophic events, but they can lead to structural damage to buildings and infrastructures. The aim of this work is the vulnerability analysis of selected building typologies exposed to the action of permanent landslides. Different building locations on the landslide body were chosen, after making simplifications, and then a vulnerability analysis was carried out on each one to define intensity and resistance parameters. The methodology makes it possible to obtain vulnerability curves depending on the type of building and its position in the landslide body. The method was applied to four case studies in southwest Switzerland: Hohberg Landslide, Converney-Taillepied Landslide, Pont Bourquin Landslide, and La Frasse Landslide. The methodology can be seen as validated since the results of the four case studies are within the range of values used to construct the vulnerability curves.

RÉSUMÉ: Les risques naturels tels que les inondations, les glissements de terrain, les laves torrentielles, les tremblements de terre et les incendies sont à l'origine de nombreuses catastrophes. En Suisse, de 1972 à 2021, les dommages causés par les inondations, les glissements de terrain, les laves torrentielles et les chutes de pierres se sont élevés à environ 300 millions de francs suisses par an. Le changement climatique, le développement de l'habitat et l'augmentation de l'utilisation des sols sont quelques-uns des principaux déclencheurs de risques naturels. Les glissements de terrain permanents ont généralement une probabilité plus faible de produire des événements catastrophiques, mais ils peuvent entraîner des dommages structurels aux bâtiments et aux infrastructures. L'objectif de ce travail est l'analyse de la vulnérabilité d'une sélection de typologies de bâtiments exposés à l'action de glissements de terrain permanents. Différents emplacements de bâtiments sur le glissement de terrain ont été choisis, en utilisant les simplifications nécessaires, puis une analyse de vulnérabilité a été réalisée pour chacun d'entre eux afin de définir les paramètres d'intensité et de résistance. La méthodologie développée permet d'obtenir des courbes de vulnérabilité en fonction du type de bâtiment considéré et de sa position dans le corps du glissement de terrain. La méthode a été appliquée à quatre études de cas dans le sud-ouest de la Suisse : Glissement de terrain du Hohberg, Glissement de terrain de Converney-Taillepied, Glissement de terrain de Pont Bourquin et Glissement de terrain de La Frasse. La méthodologie peut être considérée comme validée puisque les résultats des quatre études de cas se situent dans la fourchette des valeurs utilisées pour construire les courbes de vulnérabilité.

Keywords: Switzerland; landslides; structural harm; infrastructure; vulnerability analyses.

1 INTRODUCTION

Regarding natural hazards, landslides have one of the highest impacts worldwide in terms of loss of life and damage to public or private buildings, infrastructures, agricultural lands and economic activities. Population growth, hence more buildings in at-risk areas, climate change and intensification of land use have only increased the risk in recent years. Consequently, a rise in the frequency and intensity of natural disasters can be expected in the future: melting of glaciers and thawing of permafrost due to climate change threatens to displace vast amounts of soil, rock and stone, seriously endangering settlements and communication routes downstream (Swiss Federal Institute for Forest, Snow and Landscape Research, WLS). This paper focused on developing vulnerability curves in function

of the location and the typology of buildings on the landslide and their application to La Frasse landslide example.

2 METHODOLOGY

2.1 Building parameters

First, it is essential to consider the building locations in the landslide body. Four different building positions on the landslide body were analysed, and are:

A. The crown
B. The lateral edge
C. The middle
D. The foot

Then, buildings were classified according to material and number of floors. Buildings and human lives are the most critical elements in landslide risk assessment. The literature review shows that the main buildings damaged by landslides can be grouped into chalets, residential buildings and villas. Chalets are typical mountain buildings used for both residential and rural purposes. Some of them are entirely made of timber. Others have the first floor built in concrete and the second or third (if there is one) in timber. In this study, the foundations are always considered to be concrete. On the other hand, residential buildings and villas are mainly located at the valley bottom, at the base of the slopes, or in towns, which, in the present work, are small mountain towns composed of several hamlets also located at high altitudes. They are mainly constructed of concrete, stone and masonry. Some of them are built in both masonry and concrete because, as case the study of Lungro (Calabria, Italy) points out, reinforced concrete structures do not always guarantee less landslide damage if they are not accompanied by slope stabilisation measures (Antronico, et al., 2014). On the contrary, if located in a landslide area with specific features, masonry buildings can suffer irrelevant and widespread damage. Table 1 shows the structures analysed in this study and classified by building material and number of floors.

Table 1. Summary of structures vulnerable to landslides.

Building	Material	Number of floors
Chalet	Timber	1
	Timber and concrete	≥ 2
Residential building	Masonry	4
	Reinforced concrete	> 4
Residential villa	Masonry	2
	Concrete and masonry	3

Another critical parameter is the depth of the building foundations. As mentioned by the study of Chen & al 2020, related to the physical vulnerability of buildings affected by slow-moving landslides, the length, width and foundation depth are the three most critical factors that affect the vulnerability. It is highlighted that the higher the ratio of length to width of the building, the more serious the damage to it. Likewise, the shallower the foundation, the more severe the damage will be. Referring to the buildings considered in this work, the foundation's depth can be assumed to be approximately equal to:

- Greater than 1 m for concrete-built mountain chalets
- 1 m or greater than 1 m for residential villas
- Ranging from 2 m to 10 m, to more than 10 m for foundations of residential buildings

2.2 Intensity

"Intensity is the measure of geometrical and/or mechanical parameters, as maximum movement velocity, total displacement, differential displacement depth or volume of the moving mass, kinetic energy per unit area, relate to the destructive potential of a landslide" (Bonnard, et al., 2003). Intensity was quantitatively estimated with equations adapted to the slow-moving landslide. Two equations were used in function of the location of buildings on the landslide. For buildings in A, B or C areas, the impact of the moving mass is not considered because the effect of a slow-moving mass is visible only at the foundation level with subsidence, fractures, ground uplift and building inclinations. In these cases, the simplified intensity equation proposed in this paper refers to the general expression defined by (Li, et al., 2010):

$$I = I_{dyn} \cdot I_{dpt} \quad (1)$$

where I_{dyn} is the dynamic intensity factor and I_{dpt} is the debris-depth factor used to evaluate structures on the body of a slow-moving landslide:

$$I_{dyn} = \frac{1}{16} \cdot (log_{10} C + 0.3)^2 \quad (2)$$

with $C > 5 \cdot 10^{-1}$
where C is the average velocity of the sliding mass in mm/s

$$I_{dpt} = 0.1 \cdot D_{dpt} \quad (3)$$

where D_{dpt} is the debris depth expressed in meters, at the location of the building; considering a slow-moving landslide, the debris-depth also represents the

depth of the failure surface.

For buildings in D areas, the evaluation of landslide intensity refers to the general expression defined by (Kang & Kim, 2015); intensity is expressed as the impact pressure that the slowly moving landslide applies when it strikes structural elements.

$$P_t = \frac{1}{2} \cdot \rho_{df} \cdot g \cdot h + \rho_d \cdot v^2 \quad (4)$$

where ρ_{df} is the mean density of the material, g is the gravity acceleration, h is the height and v is the velocity of the moving mass.

2.3 Vulnerability

In the current and available literature, there are several studies that relate vulnerability and intensity to different parameters concerning landslides and buildings. These are to be considered preliminary to the quantitative study of landslide vulnerability as they must be adapted and calibrated based on actual landslide events or data collections from in-situ investigations. Research in this field is proceeding in this direction in order to refine the methodologies and make them more realistic. The present work mainly refers to four papers which analyse intensity and vulnerability (Li, et al., 2010), (Uzielli, et al., 2014)), (Chen, et al., 2020) (Miteva & Prina Howald, 2022). The vulnerability was analysed on average and is a function of intensity and resistance. Li's model gives the analytical structure, but the resistance formulation is adapted to the case of slow-moving landslides. The model used in this study is shown below, defining vulnerability in the range [0,1]:

$$V = \begin{cases} \frac{2 \cdot I^2}{R_B^2} & \frac{I}{R_B} < 0.5 \\ 1 - \frac{2 \cdot (R_B - I)^2}{R_B^2} & 0.5 \leq \frac{I}{R_B} \leq 1 \\ 1 & \frac{I}{R_B} > 1 \end{cases} \quad (5)$$

Based on Li's model, the proposed resistance formulation considers only structural elements. It is meant as follows: resistance to slow landslide movement for cases A, B and C and impact resistance for case D. Resistance (R) has been replaced by building resistance (R_B) in this work.

In the following formulas, ξfd is the parameter concerning foundation depth, ξcm is the construction material parameter, ξbi is the parameter concerning building inclination, ξnf is the parameter concerning the number of floors, and ξ_{ms} is the parameter concerning the maintenance state.

The resistance index R_B for cases A and C, where buildings are located in the crown and central part of the landslide, respectively, is calculated as follows:

$$R_B = \sqrt[2]{2 \cdot \zeta_{fd} + \zeta_{cm}} \quad (6)$$

The depth of the building foundation has a more significant influence on the building's vulnerability to slow-moving landslides than the construction material of the section above the ground level. This last section is supposed to be an integral part of the building's resistance as it interacts with the foundations by undergoing deformations in relation to its construction material. As the score does not change from one building to another, this factor is worth it. Therefore, the weights assigned to these two factors are 2 for the depth of building foundation (ξ_{fd}) and 1 for the construction material (ξ_{cm}). Table 2 shows the failure surface depth ranges considered in this study.

Table 2. Failure surface depth ranges.

Depth of the failure surface[m]
1.5 to 2
2 to 5
5 to 30
>30

For each failure surface depth range, a score is assigned to the factor concerning the depth of the building foundation. This depends on the foundation depth compared to that of the sliding plane. It will be the greater the shallower the foundation depth compared to that of the failure surface. This procedure is performed for all building materials considered, whose score is shown in Table 3. These scores were given on the basis of the tensile strength of the material.

Table 3. Scores relating to the type of building construction material (tensile strength).

Building	Material	Score
Chalet	Timber	0.6
	Timber and concrete	0.4
Residential building	Masonry	0.2
	Reinforced concrete	0.6
Residential villa	Masonry	0.2
	Concrete and masonry	0.3

The resistance index R_B for case B where buildings are located on the lateral edge of the landslide body, is calculated with:

$$R_B = \sqrt[3]{3 \cdot \zeta_{cm} + 2 \cdot \zeta_{bi} + \zeta_{nf}} \quad (7)$$

The parameters will be weighted according to their influence on the building's resistance capacity. The construction material has a greater influence on the building's vulnerability to slow-moving landslides than the building inclination and number of floors. Therefore, the weights assigned to these three factors are 3 for the construction material (ξ_{fd}), 2 for the building inclination (ξ_{bi}) and 1 for the number of floors (ξ_{nf}). Concerning the construction material parameter, scores assigned according to the type of buildings are the same used in cases A and C previously analyzed. ξ_{bi} is a parameter identifying the building inclination due to the structure's rotation at the boundary between the landslide body and the stable slope. According to the 'Code of Deformation Measurement of Building and Structure' it is possible to calculate the inclination of a building as follows:

$$i = tan\,\alpha = \frac{Y_m}{H} \qquad (8)$$

where i is the inclination of a building, α is the incline angle of the building, ym is the horizontal difference between the top and the bottom, and H is the vertical height of the tilted building calculated from the ground level.

Scores about building inclination are assigned based on threshold values provided by 'The Ministry of Housing and Urban-Rural Development of PRC, 2016'. Buildings with an inclination that exceeds the threshold values are considered dangerous and uninhabitable (Chen, et al., 2020). The present work proposes three inclination classes from very low to very high, shown in Table 4

Table 4. Scores relating to the building inclination.

Height [m]	Threshold value [i_m]	Classes	Score
H≤24	0.01	very low	1.2
24≤H≤60	0.007	medium	0.7
60≤H≤100	0.005	very high	0.1

Where : i<50%(i_m) →very low
50%(i_m)<i<100%(i_m) →medium
i>100%(i_m) →very high

Table 5 shows the scores provided by Li concerning the indicator of the number of floors/height. Four different ranges were distinguished.

Table 5. Scores relating to the number of floors/heights.

Number of floors	Score
1	0.1
2	0.3
3 to 4	0.9
More than 4	1.1

The resistance index R_B for case D where buildings are located at the toe of the slope, is calculated with:

$$R_B = \sqrt[3]{3 \cdot \zeta_{cm} + 2 \cdot \zeta_{nf} + \zeta_{ms}} \qquad (9)$$

The construction material significantly influences the building's vulnerability to slow-moving landslides more than the number of floors and the maintenance state, respectively. Therefore, the weights assigned to these three factors are 3 for the construction material (ξ_{fd}), 2 for the number of floors (ξ_{nf}) and 1 for the maintenance state (ξ_{ms}). The score assigned to the construction material, according to the building considered, can be seen in Table 6. Li's model is adopted for the attribution of this score by adapting it to the case of a moving mass hitting a structure with a certain pressure. These scores were given on the basis of the compressive strength of the material.

Table 6. Scores relating to the type of building construction material (compressive strength).

Building	Material	Score
Chalet	Timber	0.2
	Timber and concrete	0.6
Residential building	Masonry	0.8
	Reinforced concrete	1.5
Residential villa	Masonry	0.8
	Concrete and masonry	1.2

Concerning the indicator 'number of floors/height', the subdivision into four classes is the same as in case B.

The maintenance state describes the change in the building's performance; it is expressed in 5 classes from very poor to very good (Table 7), following the classification proposed by Li, et al.

Table 7. Scores relating to the maintenance state.

Maintenance state	Score
Very poor	0.1
Poor	0.4
Medium	0.8
Good	1.2
Very good	1.5

2.4 Results

Vulnerability curves were developed for each type of vulnerable structure in the four positions chosen in the landslide with the formulas presented above. Figure 1 shows an example of a vulnerability curve. The legend of each curve follows this scheme: Building Type _ Foundation Depth _ Material.

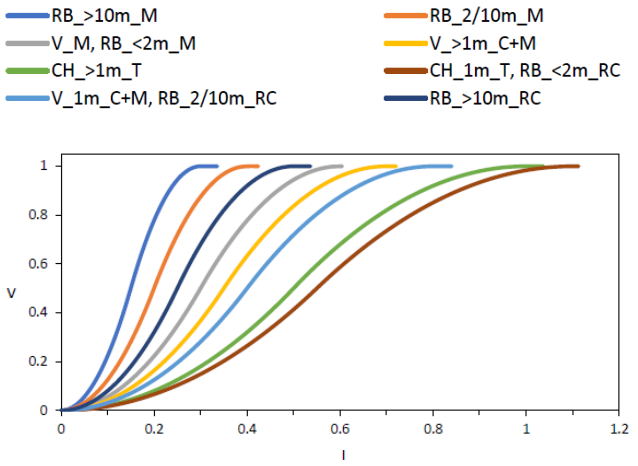

Figure 1. Vulnerability curves for case C when the depth of the sliding surface is between 5 and 30 meters.

3 APPLICATION

The methodology was applied to La Frasse's landslide, located in the Prealps (Vallée des Ormonts) of the Canton Vaud, Switzerland. La Frasse landslide is a huge slide with the toe continuously eroded by the Grande-Eau River. The most active part is the foot of the landslide crossed by the national road RC 705. The total landslide area exceeds 1 km2 with a length of approximately 2000 m oriented NW to SE and a width varying between 500 m in the landslide crown and 1000 m at the toe of the landslide body. Although the total volume of the landslide is approximately 73 million m^3, the volume of the active mass is 42 million m^3 because some portions have been stabilised. The depth of the unstable mass varies between 40 and 80 m, although the depth of the entire landslide reaches 110 m in the central part. The slope has an inclination of 11° in the upper part, reaching 20° in the lower part of the landslide. Concerning velocity, the landslide body could be divided into five main portions shown in Figure 2: Grand Glissement Supérieur, Lobe Sépey, Lobe Aigle, zone+ and zone ++ (Matti, Tacher et Commend 2012).

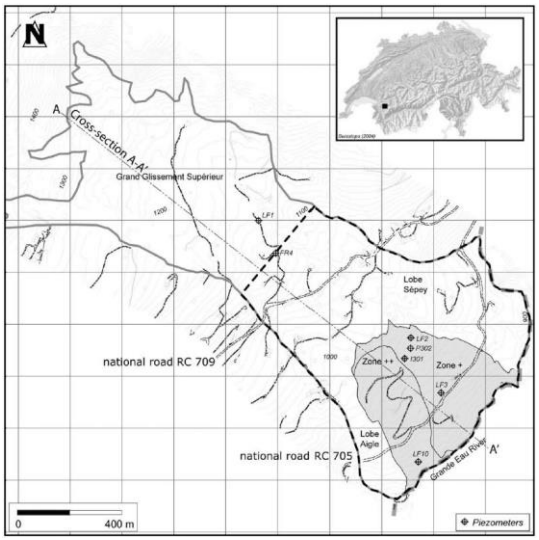

Figure 2. Location of La Frasse Landslide with subdivision in 5 main portions (Matti, Tacher et Commend 2012).

The activity of the La Frasse landslide dates back to 1863 with several reactivation phenomena, especially in the lower part, which occurred in 1910, 1914, 1966, 1981-1982 and 1993-1994. The long-term velocity in the upper and central part of the landslide is not affected by these reactivation events, constantly varying between 10 to 15 cm/year. In the lower part, however, it varies between 20 and 60 cm/year, with the maximum velocity reaching 1 m/week. Monitoring measures such as anchored piles or local pumping platforms, including drainage boreholes, decreased the movement velocity from 60 to 2.4 cm/year. The landslide's global behaviour is not yet wholly secure as near the Cergnat hamlet, and the landslide has been sliding at an average rate of about 13 cm/year for the past 200 years.

The methodology was applied to case C (central part of the landslide). Table 8 shows the data used for the application.

Table 8. Data used in the methodology application for case C, landslide central part.

Building	Height [m]	Velocity [cm/year]
Timber chalet	40	10
Timber & concrete chalet	50	13
Masonry & concrete villa	80	20
Masonry villa		60

The graph concerning case C, with indicators implemented based on the obtained data from the analysis of this case study, is shown in Figure 3.

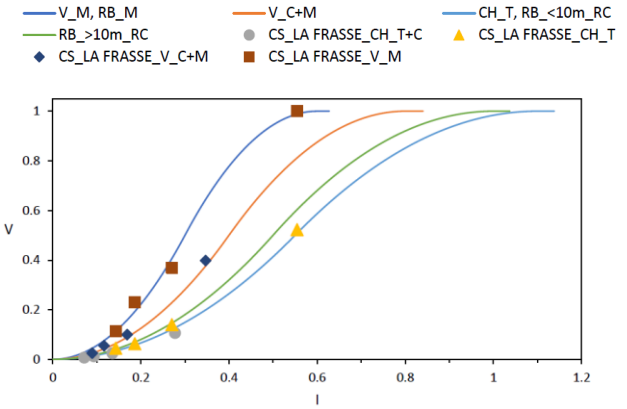

Figure 3. Vulnerability curves and indicators obtained for case C when the depth of the sliding surface is higher than 30 meters.

Since the central part of the landslide body is located in a mountainous area, the buildings considered are timber and concrete-timber chalets, masonry and concrete-masonry villas. In this case, the velocities used to calculate the indicators' vulnerability are relatively low, with a maximum of 60 cm/year. At the same time, the thickness of the landslide body is very high, reaching 80 m concerning the deepest sliding plane. The red square has a vulnerability value equal to 1 because, despite the failure surface being very deep, masonry is the least resistant material to tensile stress compared to concrete and wood. Compared to the red squares, the grey indicators have a considerably lower vulnerability calculated by referring to the higher strength parameters of timber and concrete. In addition, the high depth of the landslide body, relative to the deepest failure surface, and a velocity of more than 1 metre per year give a vulnerability of 1 for masonry buildings (material with the lowest tensile strength of those considered).

4 CONCLUSIONS

Construction in areas affected by more or less stabilised and ancient landslides, or in geologically sensitive sites where stability is a key issue, can lead to situations whose severity is difficult to predict. A minor environmental impact, such as overburdening or rainfall, can cause greater damage due to density, value of buildings and structures exposed, and extent that a small landslide can reach beyond its initial limits. The development of practical methods that consider slope instabilities and their evolution factors in the local planning of risk zones has to be considered. This work may open new perspectives to help spatial planning authorities select the most suitable areas for urbanisation. Furthermore, slope instability specialists should be required in the procedures for obtaining and granting building permits; this would be useful for both builders and local authorities to avoid building in geologically critical areas.

Fire-induced changes in the geotechnical properties of a volcanic soil

Modifications des propriétés géotechniques d'un sol volcanique causées par le feu

L. Iervolino*, D. Peduto, V. Foresta
Department of Civil Engineering, University of Salerno, Fisciano, Italy
**liervolino@unisa.it*

ABSTRACT: Wildfires have been observed to significantly impact hillslope stability through the combustion of vegetation and changes in soil properties, mainly resulting in an increased proneness to post-fire rainfall-induced erosion and debris flows. In this regard, the existing literature on the fire-induced effects on soil properties has yielded divergent results mainly due to the inherent site-specificity that characterizes both wildfire and post-fire soil mobilization phenomena. To shed a light into the post-fire changes in both physical and hydromechanical properties of volcanic soils, an experimental laboratory study was conducted on soil samples collected from the Mt. Saro area in the Sarno municipality (Pizzo d'Alvano massif, Campania region, Italy). Here, a wildfire occurred on March 23, 2022. The experimental campaign pursued the geotechnical characterization of three classes of soil samples i) unburned, ii) wildfire-burned, and iii) laboratory thermally treated. The results unveiled pronounced changes in soil properties under both wildfire- and laboratory-burned conditions. In general, the fire-affected soil showed decreasing values of soil organic matter content, root content by weight, and soil shear strength when compared to the unburned control samples. Conversely, as the severity of the fire increased, we observed increases in soil hydraulic conductivity and cumulative infiltration. These findings can provide novel insights to enhance the comprehension of those processes presiding over post-fire slope instability and erosion in similar geo-environmental contexts.

RÉSUMÉ: Les feux de forêt ont été observés pour avoir un impact significatif sur la stabilité des versants par le biais de la combustion de la végétation et des modifications des propriétés du sol, principalement résultant en une plus grande propension à l'érosion induite par les pluies post-incendie et aux coulées de débris. Cependant, la littérature existante sur les modifications induites par le feu des propriétés du sol a produit des résultats divergents principalement en raison de la spécificité intrinsèque du site qui caractérise à la fois les phénomènes de feu de forêt et de mobilisation du sol après l'incendie. Afin d'éclairer les modifications post-incendie des propriétés physiques et hydromécaniques des sols volcaniques, une étude expérimentale en laboratoire a été menée sur des échantillons de sol prélevés dans la région du Mont Saro, dans la commune de Sarno (massif de Pizzo d'Alvano, région de Campanie, Italie). Dans cette région, un incendie s'est produit le 23 mars 2022. La campagne expérimentale visait à la caractérisation géotechnique des sols distingués en trois classes d'échantillons: i) non brûlés, ii) brûlés par le feu de forêt, et iii) soumis à un traitement thermique en laboratoire. Les résultats ont révélé des modifications marquées des propriétés du sol dans les conditions de feu de forêt et de traitement thermique en laboratoire. En général, le sol affecté par le feu a montré des valeurs décroissantes de la teneur en matière organique du sol, de la teneur en racines en poids, et de la résistance au cisaillement du sol par rapport aux échantillons témoins non brûlés. En revanche, à mesure que la gravité de l'incendie augmentait, nous avons observé des augmentations de la conductivité hydraulique du sol et de l'infiltration cumulative. Ces découvertes apportent de nouvelles perspectives qui renforcent la compréhension de la stabilité des pentes après un incendie et de l'érosion dans des contextes géoenvironnementaux similaires.

Keywords: Wildfires; laboratory testing; slope instability.

1 INTRODUCTION

Wildfires can affect hydrologic slopes response by burning vegetation and inducing changes in soil properties (Certini, 2005). Indeed, several literature studies recognize wildfire-burned watersheds as having an increased susceptibility to rainfall-induced surficial soil failures (e.g., Rengers et al., 2020). In the context of climate change scenarios, in which both frequency and intensity of wildfires are expected to increase, coupled with predicted shifts in precipitation patterns towards more frequent short-duration/high-intensity rainfall events, it is anticipated that the Mediterranean region, and particularly the southern Italy, will experience increasing post-fire surficial failures (Sousa, 2015). Thus, it is important to address

the possible threats that such events can pose to people, property, and infrastructure located downstream of the fire-affected area. In this regard, the geotechnical characterization of burned soil is key in providing quantitative information on post-fire soil behavior, as well as in trying to understand the triggering mechanisms of surficial failures on fire-affected slopes. The literature reveals that the possible fire-induced changes in soil properties are to be considered site-specific since both soil and wildfire characteristics can vary site by site according to local conditions such as geology, topography, and climate (Ulery and Graham, 1993; Certini ,2005).

Fire can impact soil organic matter (SOM) content. SOM may increase, decrease, or not change (Ulery and Graham, 1993). Key role is played by the temperature/duration conditions reached during wildfire, as well as by the types and characteristics of the affected SOM. Moderate to severe fires can permanently alter the grain size distribution (GSD) of the affected topsoil layer (Ulery and Graham, 1993). Similar to SOM, grain size may increase, decrease, or not change, mainly depending on soil type and its mineralogy. Generally, increases in GSD have been attributed with aggregation of fine particles into coarser composite stable particles (Ulery and Graham, 1993; Ketterings et al., 2000).

Although still limited, the existing literature on the effects of fire on soil mechanical properties highlights that the soil-root systems can lose their initial strength post-fire, by lowering the cohesion contribution to soil shear strength (Peduto et al., 2022a, 2022b).

For specific soil types and under certain thermal exposure conditions, soil-water repellency (SWR) may occur at a certain depth along the soil profile, which likely results in a decrease of rainwater infiltration, subsequently increasing the slope susceptibility to flooding and runoff-initiated soil mobilization phenomena (De Bano, 2000). The appearance of SWR in surficial topsoil layers can be related to i) the pore clogging by post-fire residues (e.g., ash, charcoal, burned leaves) (Woods and Balfour, 2006); ii) the temperature gradients experienced along the soil profile (De Bano, 2000). Literature studies suggest that an exposure temperature of 220-250 °C for a duration of 5-7 minutes is ideal conditions for the SWR formation. In contrast, more severe heating conditions (i.e., either longer duration or higher temperature) are reported to destroy either the intrinsic or the fire-induced SWR layer. Indeed, some studies also showed increases in soil infiltration and hydraulic conductivity because of the occurrence of severe wildfires, mainly due to the fire-induced loss of soil structure, attributable to roots and SOM burning (Peduto et al., 2022a, 2022b).

Given the site-specific nature of the possible fire effects on soil properties, this study focuses on the fire-induced changes in the physical and hydromechanical properties of the coarse-grained pyroclastic topsoil covering the Mt. Saro area (Pizzo d'Alvano massif, Campania region, Italy). Here, a wildfire occurred on 23 March 2022 (Figure 1). The slopes of the Pizzo d'Alvano massif are highly susceptible to fast-moving landslides and are also frequently affected by wildfires. Relatively thin pyroclastic soil layers, which derive from the past explosive activity of the nearby Somma-Vesuvius volcanic complex, cover the underlying bedrock (Rolandi et al., 1998).

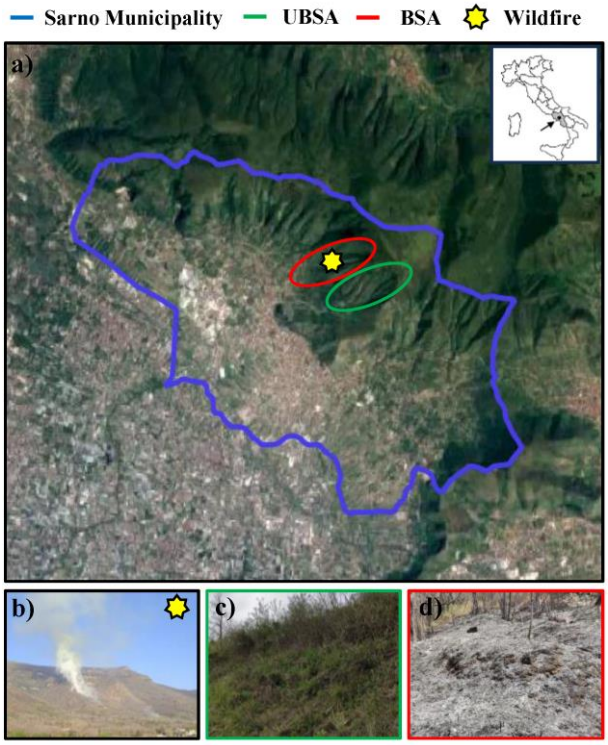

Figure 1. a) Overview of the study area with the indication of the sampling locations (i.e., UBSA: Unburned Sampling Area, BSA: Burned Sampling Area). b) Photo of the active wildfire taken on 23/3/2022. c) Photo of the UBSA. d) Photo of the BSA.

Soil sampling in undisturbed condition was conducted at 0-5 cm depth to limit the analyses to the shallow fire-affected topsoil layer. Both wildfire-burned and unburned soil samples were collected. In addition, laboratory burning treatments were carried out on unburned soil samples. For the purpose of data analysis, three different sample classes were distinguished i) "unburned", ii) "wildfire-burned", and iii) "laboratory thermally treated". Studies such as the one presented here can be useful to investigate mechanisms controlling post-fire erosion/instability slope responses in similar areas and to provide input

data for implementing prediction models and planning *in situ* monitoring systems.

2 EXPERIMENTAL PROGRAMME AND TESTING PROCEDURES

The sampling activity involved both burned (B-j) samples collected within the area affected by the 23 March 2022 fire (i.e., BSA: Burned Sampling Area) and unburned (UB-j) samples collected in the nearby control area (UBSA: Unburned Sampling Area), characterized by similar soil and vegetation conditions (Figure 1). Some of the samples from the UB-j class were also subjected to two different thermal treatments in the laboratory by using a propane burner placed 5 cm above the soil surface for 15- and 30-minutes duration, namely P15-j and P30-j sample classes, respectively.

For each sample class, we investigated the following soil characteristics i) soil grain size distribution (GSD) via particle-size by dry-sieving tests (ASTM D422-63, 2007); ii) root content by weight (RCW) through the procedure proposed by Schuurman and Goedewaagen (1965), iii) soil organic matter (SOM), via loss-on-ignition (LOI) tests (ASTM D7348-08, 2011) and specific gravity (G_s) tests (ASTM D 854, 2014), iv) soil shear strength through direct shear tests in saturated condition (ASTM D3080, 2011), v) soil saturated hydraulic conductivity following the standard method (ISO, 2004), and vi) soil infiltration via mini disk infiltrometer (MDI) tests (Robichaud et al., 2008).

Table 1. Performed laboratory tests and investigated soil properties.

Laboratory Tests	Soil Property
Particle-size by dry sieving	GSD
Schuurman and Goedewaagen (1965)	RCW
G_s and LOI	SOM
Direct Shearing	Shear strength
Constant head permeability	K_{sat}
Mini Disk Infiltrometer	K_{unsat} and infiltration

LOI and G_s tests were carried out to investigate indirectly any fire-related changes in SOM content. Basically, LOI tests involve the destruction by heat (i.e., exposure time of two hours at 550 °C) of SOM. The impact of increasing exposure temperatures on SOM and GSD was assessed. Specifically, LOI, G_s, and sieving tests were carried out on fixed soil material of the UB-j class. The tests were also performed on soil samples from the UB-j class after they were subjected to specific muffle furnace treatments. The latter involved heating soil samples for a duration of 30 minutes at progressively increasing temperatures, ranging from 100 to 600 °C. Direct shear tests were performed on saturated specimens at relatively low vertical pressures (i.e., 2, 10, 20, 30 kPa), given that fire can only affect the very surficial portion of the topsoil layer. To investigate any possible changes in soil infiltration characteristics for different post-burn conditions, we performed MDI tests by using the *Decagon Mini Disk Infiltrometer*.

3 RESULTS

Decreasing LOI and increasing G_s values were found as temperature increased (Figure 2a, 2b). Moreover, a decreasing trend in LOI was observed as G_s increased (Figure 2c). Relatively low LOI values (i.e., relatively high G_s values) are generally associated with low SOM contents (Schulte and Hopkins, 2015).

The obtained results reveal that the SOM decay increased at increasing temperatures, thus burned soil is expected to contain less organic matter than unburned soil.

The structure of the topsoil layer is generally dependent upon SOM content and GSD. By consuming SOM and altering soil GSD, fire can weaken soil structure (Gonzaléz Pérez et al., 2004). This may result in increased bulk density, reduced porosity, and decreased water storage capacity of the soil (Peduto et al., 2022a). Accordingly, along with the removal of ground cover, surface litter, and/or duff, a loss of SOM can significantly accelerate runoff resulting in increased susceptibility to erosion. Moreover, the percentage of soil material passing the 0.15 mm diameter sieve increased as the temperature of exposure increased. This finding could be linked to the thermal-induced weakening and subsequent disaggregation of the pumice particles that are typically found in pyroclastic soils. This statement agrees with past research findings on the topic (e.g., Stoof et al., 2011; Peduto et al., 2022a). Overall, the average RCW was found lower in the fire-affected samples (see table in Figure 3).

Accordingly, we can argue that both the wildfire and the laboratory thermal treatments caused the combustion of the existing soil-root systems and changed their initial characteristics. These findings can be related to the negative impacts of fire on soil shear strength arising from the obtained direct shear tests results (Figure 3). Indeed, a general reduction in the shear strength of B-j and P15/P30-j vs. UB-j samples was found. Notably, the shear strength envelopes exhibited up to almost 50% fire-induced decreases in soil cohesion values with respect to the control unburned samples. In contrast, the effective friction

angle value did not significantly change among the tested sample classes.

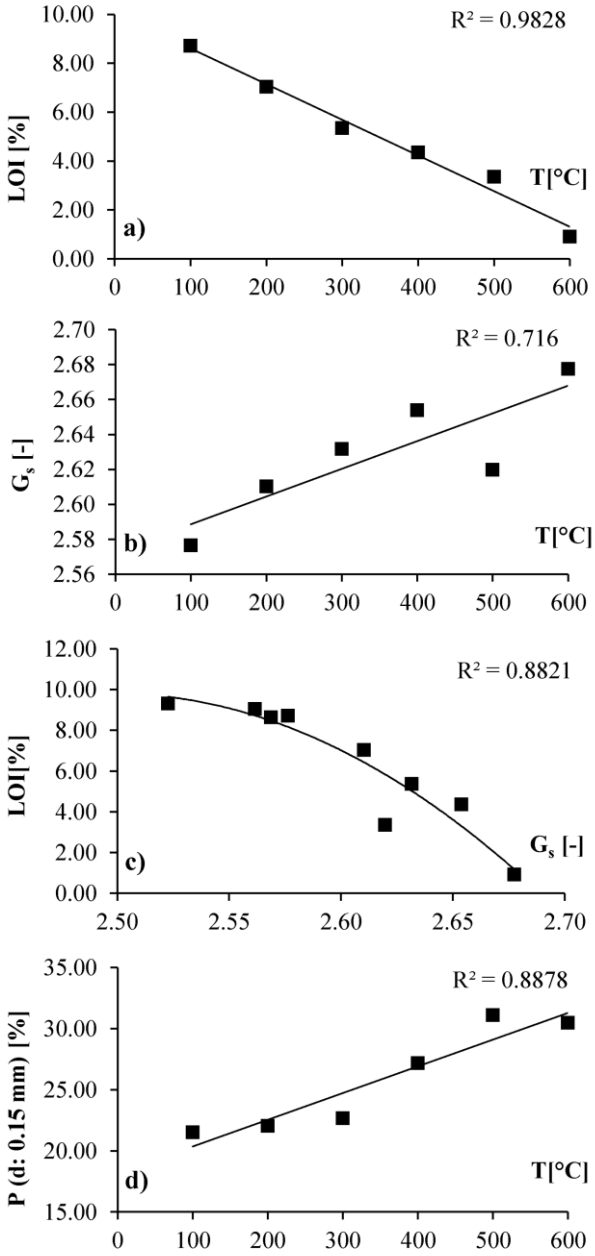

Figure 2. a) LOI, and b) G_s vs. T [°C]. c) LOI vs. G_s. d) percentage of soil passing 0.15 mm diameter sieve vs. T [°C]. The initial soil weight is fixed to 100 g for each heating treatment.

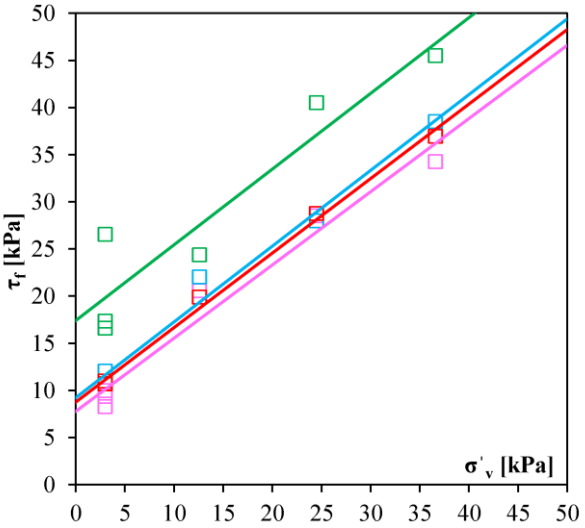
The investigated soils are loose and of pyroclastic origin, in a way that only their root systems and SOM aggregates may provide a cohesive contribution under saturated conditions (Peduto et al., 2022a, 2022b). The results reveal that fire can weaken surficial roots, reducing the associated contribution to the soil shear strength.



SAMPLE	SYMBOL	RCW [g]	c [kPa]	Φ' [kPa]
UB		1.25	17.4	46.0
B		0.09	8.7	45.3
P15		0.15	9.2	44.5
P30		0.12	7.8	46.0

Figure 3. Results from the direct shear tests in terms of shear strength failure envelopes for all the tested soil sample classes. "c" and "Φ'" are the soil cohesion, and the soil effective friction angle, respectively.

From the hydraulic point of view, the tested soil exhibited progressive fire-induced increases in soil cumulative infiltration, in contrast to most literature studies that report the occurrence of SWR (e.g., De Bano, 2000). However, it is worth noting that intensity and persistence of SWR usually differs with fire temperature and duration, vegetation type, soil moisture and texture, as well as time since burning (Huffman et al., 2001).

Overall, since wildfire impacts, vegetation cover, soil texture, and antecedent soil moisture all differ across a burned area, the occurrence and the spatial distribution, depth, and thickness of SWR may also differ considerably (Doerr and Moody, 2004; Woods et al., 2007). Indeed, the spatial distribution of water-repellent soils can range from isolated patches to discrete layers with discontinuities (Jackson and Roering, 2009), to continuous layers (Woods et al., 2007).

Moreover, increases in soil hydraulic conductivity, under both unsaturated and saturated conditions, were observed for fire-affected soil with respect to unburned soil (Figures 4a, 4b). We attributed the increases in both infiltration and hydraulic conductivity to the fire-related development of macropore flow pathways, mainly caused by the combustion of SOM and roots, as well as to alteration of soil GSD. This ends up creating post-fire interface priority flows.

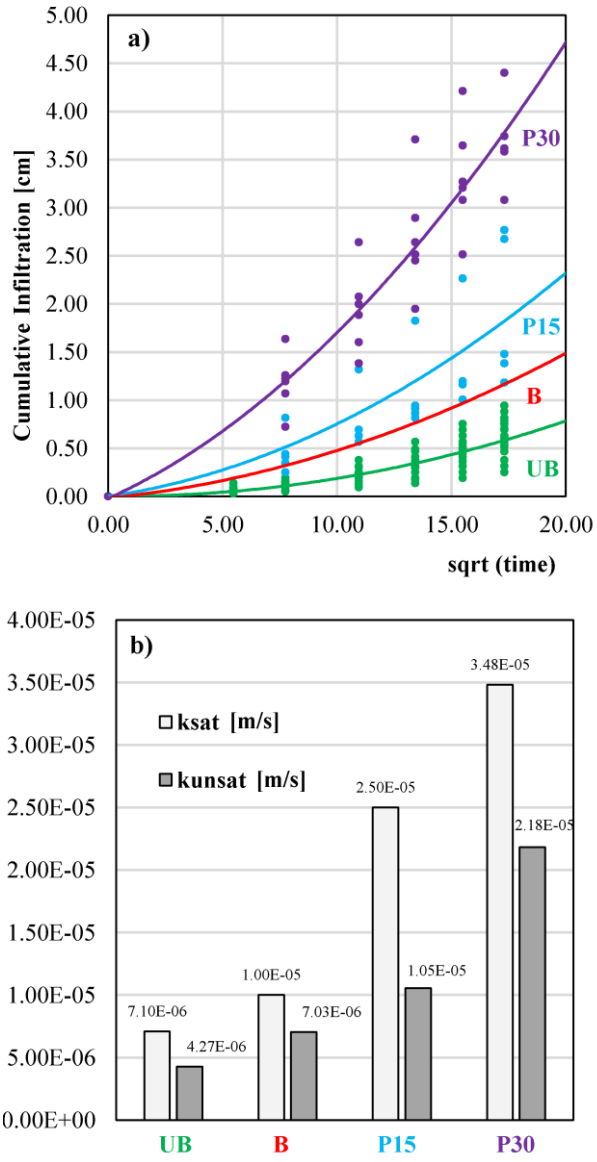


Figure 4. a) Cumulative infiltration vs. sqrt(time), derived from MDI tests. b) Average results in terms of hydraulic conductivity, in both saturated and unsaturated condition (i.e., k_{sat}, k_{unsat}), obtained through soil permeability and MDI tests, respectively.

4 CONCLUSIONS

The experimental results showed changes in the properties of soil sampled in the Mt. Saro wildfire-affected area or treated with laboratory burnings.

In general, the burned soil exhibits decrease in SOM content, RCW, and, consequently, soil shear strength. On the other hand, the increases in soil hydraulic conductivity and infiltration may be linked to the possible formation of macropore flow pathways induced by the burning of roots and SOM. In summary, we found that key role is played by SOM and RCW. By exposing the soil to increasing temperature, a reduction of SOM occurs, along with a possible weakening of the soil root systems, with consequences on both the soil mechanical and hydraulic properties. In turn, this may lead to an increase of the proneness to post-fire surficial soil failures. However, the tests carried out did not consider changes in mineralogy of the burned soil that could have affected GSD, LOI, and G_s.

Although deserving further deepening, the presented results could provide useful information for understanding the initiation mechanisms and assessing the susceptibility to post-fire soil mobilization phenomena.

ABSTRACT: The paper aims to highlight the role of satellite data integrated with conventional monitoring results to support the soil-structure interaction analysis in Structural Health Monitoring (SHM) activities. DInSAR technology is a powerful tool to measure and monitor surface displacements both of ground and structures, without installing sensors or even accessing the structure, with millimetre precision. Using DInSAR data to integrate conventional SHM techniques allows to obtain, from a unique source of data, significant information on many structures, infrastructures, and landslides, detecting potential anomalies and triggering in-situ inspections, with clear benefits in terms of both time and resource management. In this work, results of some remote and contact monitoring techniques, applied in the small medieval village in Southern Italy, considering its complex morphology including underground cavities, have been discussed.

RÉSUMÉ: L'article vise à mettre en évidence le rôle des données satellitaires intégrées aux résultats de surveillance conventionnelle pour soutenir l'analyse des interactions sol-structure dans les activités de surveillance de la santé des structures (SHM). La technologie DINSAR est un outil puissant pour mesurer et surveiller les déplacements de surface du sol et des structures, sans installer de capteurs ni même accéder à la structure, avec une précision millimétrique. L'utilisation des données DInSAR pour intégrer les techniques SHM conventionnelles permet d'obtenir, à partir d'une source unique de données, des informations significatives sur un grand nombre de structures, d'infrastructures et de glissements de terrain, en détectant d'éventuelles anomalies et en déclenchant des inspections in situ, avec des avantages évidents en termes de temps et la gestion des ressources. Dans ce travail, les résultats de certaines techniques de surveillance à distance et par contact appliquées dans le petit village médiéval du sud de l'Italie, en tenant compte de sa morphologie complexe incluant des cavités souterraines, ont été discutés.

Keywords: DInSar; monitoring; resilience of cultural heritage; structural health monitoring.

1 INTRODUCTION

Analyses aimed at forecasting and preventing consequences induced by natural or manmade hazards on existing structures and infrastructures play a fundamental role in risk management activities. Among these, the phenomena of soil instability such as landslides and subsidence phenomena, widespread in geological contexts around the world, can generate considerable damage to existing heritage. Furthermore, historical urban centers are often characterized by cavity systems beneath the foundations or underground stories of masonry buildings, which can also modify the local seismic response (Scotto di Santolo et al., 2015; Piro et al., 2019). The presence in urban area of sectors affected by particular geological conditions has made it necessary to develop innovative monitoring techniques, in addition to conventional methods, in order to develop systems which can be supplied at different scales of analysis, information on the spatial and temporal evolution of current phenomena and their interaction with existing structures and infrastructures.

The integration of data obtained by different sources can be very helpful in understanding the mechanism, the geometry and the kinematic of complex instabilities affecting urban areas. In the past, many researchers demonstrated that the combination of different techniques allows a better understanding

of the instabilities process under investigation (e.g. Pastor et al., 2019). Amongst the complementary techniques that can be employed, satellite monitoring, and more specifically Differential Interferometry Synthetic Aperture Radar (DInSAR), have been widely investigated in recent yearsas a valid response to support structural health assessments, depending by a wide area coverage, millimetric accuracy, non invasiveness and cost-effectiveness of data (e.g. Infante et al., 2019). In addition, PhotoMonitoring techniques, based on Image Processing principles, allows to measure small displacements and deformations of the soil and structure aggregate at the same time, by comparing multi-temporal images of the continuously observed object using high-resolution cameras (e.g. Caporossi et al., 2018).

In this work, the feasibility and effectiveness of the combined use of satellite remote sensing technology and conventional in situ monitoring techniques in the structural health monitoring process for historical structures in Sant'Agata de' Goti village (Campania region, Italy) were evaluated.

2 THE CASE STUDY

The case study is a historic centre of Sant'Agata de' Goti, located in Campania Region, south Italy, resting on a rocky relief between two creeks, where many anthropic cavities, due to tuff quarrying activities, are present. The rock formation constituting the ridge is the Campanian Ignimbrite in its yellow and grey lithofacies, lying on a thin loose layer of pyroclastic soil and a Miocene flysch, Figure 1.

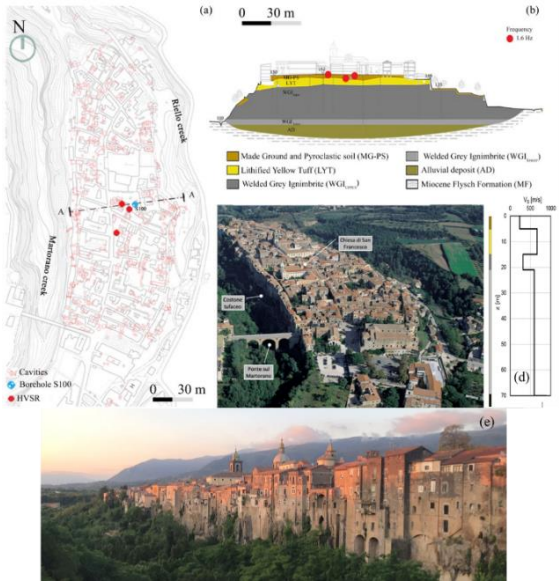

Figure 1. Sant'Agata de' Goti: (a) plan with location of the cavities and in situ tests, (b) A-A geological section, (c) aerial view with attention points; (d) shear wave velocity profile from DH; (e) view from the bridge (modified from Piro et al., 2019).

The western portion of the historic center of Sant'Agata de' Goti was built with rock quarried on site and is perched on tufaceous cliffs, with an often indistinguishable border, as can be observed from the bridge over the Martorano, Figure 2d. The upper portion of the cliffs houses cavities of anthropic origin which due to their position also amplify seismic effects (e.g. Scotto di Santolo et al., 2015; Piro et al., 2019).

The stress relief of the natural slope with the potential genesis of new fissure patterns, the river dynamics associated with the Martorano stream, the progressive alteration of the cortical portion of the promontory subjected to atmospheric agents, and the widespread presence of cavities can be considered overall factors of natural and anthropic risk that may have effects on the overlying inhabited center.

3 SOIL-STRUCTURAL INTERACTION HEALTH MONITORING RESULTS

Aimed to investigate the resilience of historic and cultural heritage, the Soil-Structural Interaction Health Monitoring require, as first step, a preliminary characterization of subsoil geological and geotechnical settings (§ 2). Subsequently, the integrated analysis of conventional and innovative monitoring data, performed also with remote sensing techniques, allows to achieve a validation of the results and to investigate preliminary cause-effect relationship between soil-structure interaction and related building structural behavior.

In the present work the attention is focused to:

- the tufaceous cliff overlooking the Martorano stream, and the corresponding structure including cavities;
- the Church of San Francesco that hosts an archaeological exhibition;
- the bridge over the Martorano stream, the main access to the historic center.

3.1 DInSAR and PhotoMonitoring analysis

Operating X-band Synthetic Aperture Radar sensors of the new generation COSMO-SkyMed satellite have provided long historical archives of motion rates and displacement time-series of whole Sant'Agata de' Goti urban centre, with a spatial resolution of 3x3 m and reduced revisiting time (16 days). In detail, 108 COSMO-SkyMed ascending images in the time-span October 2012–July 2019 and 128 descending images in the time-span February 2012–August 2019 have been processed by means of "Permanent Scatterers Interferometry" (Ferretti et al., 2001) to detect surface deformations of the considered area.

As a results, 'Line Of Sight-LoS' displacement rate maps and historical time series of scatterers identified within the whole urban center have been obtained (Figure 2a). Interferometric products show the occurrence of very slow-moving phenomena, with velocities of about some mm per year. Moreover, looking at the DInSAR scatterers identified above the bridge on Martorano river, a displacement means velocities of few mm/yr have been recorded in the considered period, thus confirming the absence of significant kinematics. As regards the San Francesco Church and palace, in order to analyze structural behavior, DInSAR data at ground level and on top of buildings were preliminarily differentiated, Figure 2b. The first are representative of ground kinematics condition while the second refer to structure deformation (e.g. Infante et al., 2019). Targets discriminated at ground and on top of structure show "LoS" displacement rates lower than 2 mm/year both on the Church and on the surrounding area, thus confirming that area is stable and structures do not show structural problems and deformations.

To evaluate the structure conditions of existing aggregate buildings and cliffs, an innovative remote monitoring system based on the Photomonitoring methodology has been set up (Figure 3). Digital Image Correlation (DIC) is an optical-numerical remote sensing technique that offers excellent opportunities to measure 'full-field' displacements and/or deformations on the surface of the monitored object, both in 2D and 3D.

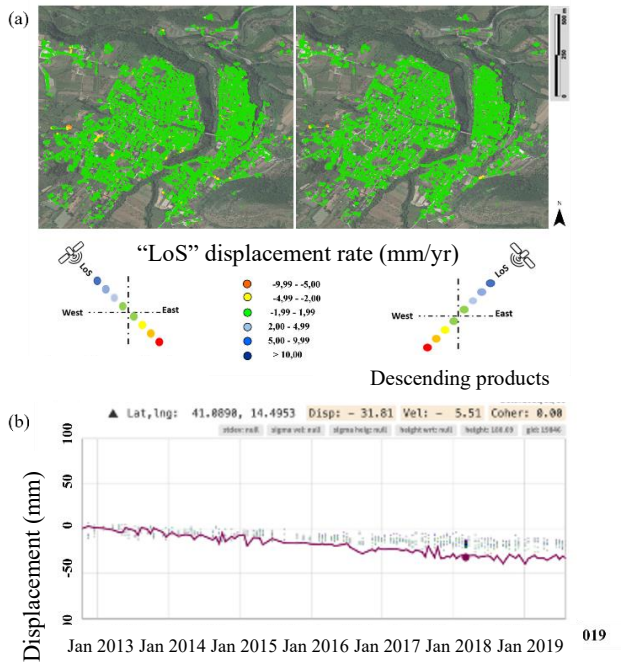

Figure 2. D-InSAR - LoS displacement velocity maps of Sant'Agata dei Goti urban area derived by COSMO-SkyMed SAR images in ascending and descending orbit (a); Displacement time series of significative scatterer identified (b).

This is made possible by comparing, tracing, and consequently, algorithmically correlating frames captured with a high-resolution optical camera at different time intervals. Through techniques based on Image Processing principles, it is possible to measure small displacements and deformations of the tufaceous promontory and building aggregate by comparing multi-temporal images of the continuously observed object using high-resolution cameras.

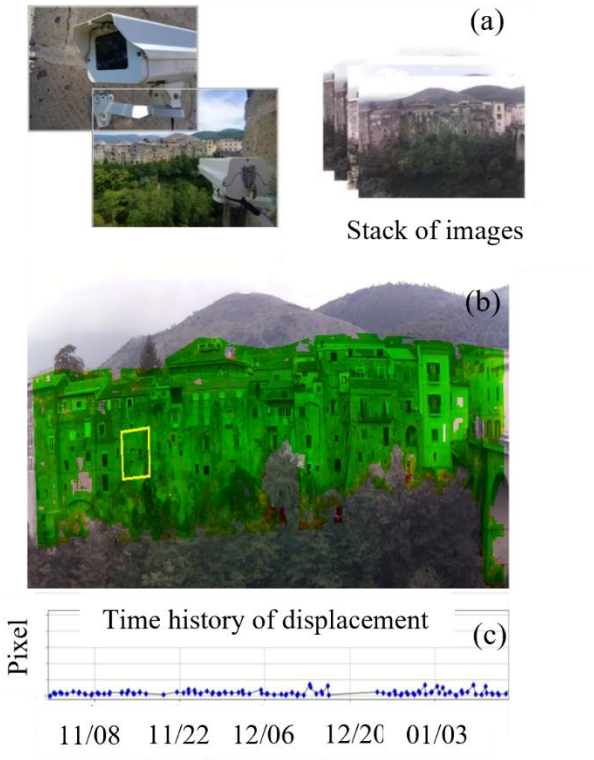

Figure 3. Monitoring of cliff-aggregate buildings movements through Photomonitoring technique: a) set-up and stack of captured images; b) interpretation of sectors; c) displacement time series for yellow area.

3.2 Conventional *in-situ* monitoring

The control and validation of the remote measurements will take place thanks to the installation of instruments on the ground. The wireless monitoring system of the bridge over the Martorano allows the survey, continuously and with high frequency, of the rotations of the bridge piers and cracks as well as the level of the Martorano stream. The system was completed with a total weather station, which allows the main environmental parameters to be recorded to correlate with the deformation behaviour of the structure during the monitoring phase of the work (Scotto di Santolo et al., 2022). In detail, the in-contact tools are:

1. 4 wireless biaxial electric clinometers with built-in temperature sensor, with high acquisition

frequency, located in the piers and abutments of the bridge (Figure 4).

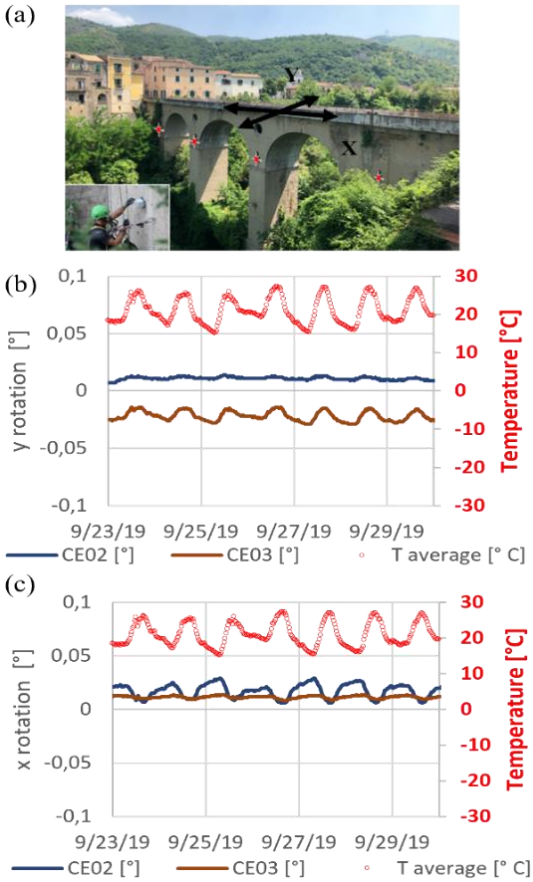

Figure 4 Bridge monitoring set-up (a); time series of air temperature and clinometers rotation in y (b) and x direction (c).

4 DISCUSSION AND CONCLUSION

This work shows the potentiality of remote sensing technique as a complementary tool for the analysis of Soil-Structural Interaction Health Monitoring of a emblematic historical village and its cultural heritage, proving the usefulness of the combination of different techniques. DInSar and Photomonitoring techniques can provide important information about structure conditions and help increase safety and optimize maintenance activities also in sterms of sustainability.

The interpretation process, preliminary includes geological, geotechnical and geomorphological data in determining the type of soil/rock directly interacting with building heritage.

Subsequently, the combined use of multi-source information has enabled performing a comprehensive investigation of structural performance as indicator of a preliminary cause-effect relationship with ground conditions.

The analysis of DInSAR and Photomonitoring displacement time series (Trend Change Detection Analysis) highlighted that no significant deformational trend was recorded, and no differential displacements have occurred, generating angular distortions (drift) consequently on the structures.

These results are confirmed by the stability of static and dynamic terrestrial data acquired in the first half of observation (July 2019 - January 2020): the clinometers integral with the structural elements of the bridge show negligible rotations in x and y direction, with dispersion of values between ± 0,05°, Fig. 4.

As it has been stated above, each of the techniques employed has been useful to understand the health of cultural heritage, considering the interaction with soil starting from the knowledge of geological and geotechnical site conditions.

ABSTRACT: In this paper, we present a study of a large slope failure, which endangered the construction of a bridge, occurred in 24 m deep cutting with a main scarp upper edge extending over 70 m in length. The stability analysis is discussed, with a critical analysis of safety factors, according to the Eurocode. The important place takes the analysis of slope stability during construction, but also the analysis of long-term conditions, back-analysis, in anthropogenic site, conditions that are not completely covered by geotechnical codes. Lessons learned showed, that a design basis in such an anthropogenic environment should ensure an advanced geotechnical characterizations and parametric engineering assessments. Even in such a case, it will be necessary to acknowledge the risk of slope instability by all stakeholders, mainly due to uncertainties associated with a construction of clayey mine spoil heaps and a subsequent mechanical properties heterogeneity of stockpiled soils. The role of geotechnics is inevitable in such "natural" conditions of mine spoil dumps to provide necessary support throughout entire project life cycle.

RÉSUMÉ: On présente l'analyse des conditions de rupture d'une pente, lors de la construction d'un pont. La rupture s'est produite avec une extension de 70m en amont de la pente, avec un dénivelé de 24m. Les études suivent les règles définies par les Eurocodes, et une analyse critique des facteurs de sécurité est faite. L'analyse est faite en prenant en compte le phasage de construction. Ensuite, des études à long terme, en retro-analyse, avec les particularités d'un site anthropique, montrent que ces conditions ne sont pas prises en compte par les règles de calcul : le site est constitué de dépôts des matériaux argileux stériles provenant des mines de charbon. Les conclusions montrent que, dans des sites anthropiques, une importance considérable devra être portée à la caractérisation avancée des sols en place et qu'il est nécessaire que toutes les parties prenantes du projet prennent connaissance des risques encourus. La complexité du site, provenant de l'origine géologique des argiles à fortes hétérogénéité et remaniées lors de dépôts disparates, implique un comportement difficilement prévisible sur le long terme : le rôle et l'implication du géotechnicien, reste fondamentales tout au long de la vie de l'ouvrage .

Keywords: Slope stability; safety factor; anthropogenic site; clayey mine spoil; long term behaviour.

1 INTRODUCTION

As society develops, human activity has an increasing influence on the change of an environment. Mining activities and a subsequent processing of raw materials represent one of the world's biggest waste management challenges with a definite impact on the surrounding environment.

The north-west part of Czech Republic is characterized by the extensive open cast mining of brown coal for several decades. With the progress of open cast mining, overburden spoil material (clays primarily), covering brown coal reserves, is stockpiled in non-engineered manner into large spoil heaps/dumps, several tens of meters in height. These locations represent potential sites for infrastructure projects thanks to an interesting economical aspect. Even if the economic aspects are favourable, technical, and mainly geotechnical issues regarding possible developments represent significant challenge. One such particularity is the acceptance of the risk arising from the "natural" geotechnical conditions of the mine spoil heaps.

2 SPOIL HEAPS SPECIFICS

Vanicek and Vanicek (2008) and Najser (2010) summarized the uniqueness associated with the construction of clayey spoil dumps. During mining,

overburden clays in the form of irregular lumps typically 500 mm in size are stockpiled in large dumps. The total thickness of the layers is generally 20-50 m. The spoil material has a double porosity: the porosity of the clay lumps (primary intragranular) and the pores between the clay lumps (secondary intergranular). The total porosity can reach up to 70%. The clays are stockpiled top-down by free fall from a height of 15-30 m. Although the free fall allows some compaction, the resulting secondary porosity is considerably high, up to 35%. Generally, the loose material has the character of crushed stone material in an embankment with steep slopes of 1:1 (V:H) - 45-degree angle. The properties of the stockpiled material change with time due to increasing height and interaction with water. When the lumpy clays adversely change their mechanical properties due to interaction with water, the original hard clays/claystones change to clays of soft to very soft consistency. Such weakened soils present significant challenges to geotechnical engineering primarily due to significant settlement up to collapse and uneven settlements. Discovering of such altered layers in both vertical and horizontal directions is practically impossible, which greatly inhibits available options for subsoil improvement. Moreover, the progressive transformation from loose to fine-grained matrix with time makes the mechanical modelling of lumpy clays considerably uncertain.

3 CASE STUDY

This construction project including roads construction on the body of an external mine spoil dump was greatly influenced by certain technical challenges that had to be considered in such an anthropogenic environment.

The construction was realized on considerable thicknesses of spoil material, consisting of clayey soils and claystones with the thickness up to 70 m. These are Tertiary lacustrine clays and claystones (Cypress Formation) - kaolin-illite clays with variable minor content of montmorillonite.

During the construction of a bridge structure, a slope failure (landslide) occurred in the cutting with a total depth of approximately 24 m, and length of the main scarp upper edge approximately 70 m (Figure 1). The sliding surface was clearly characterized by a smoothed plane-slip surface with soil displacement of up to 5 m downward at a slope of approximately 45° (Figure 2). The landslide body covered an area of approximately 5000 m2 with a potential soil volume in the landslide of 50000 m3. Observations of the main sliding surface showed an interface of brown and distinctly coloured grey clays, which differentiated largely in consistency. The landslide body negatively affected the construction of the bridge structure and raised many questions about the next steps of the construction due to the geometric constraints of the planned construction. Removal of the landslide body at the bottom was not an option, however works, under increased safety precautions, had to be planned.

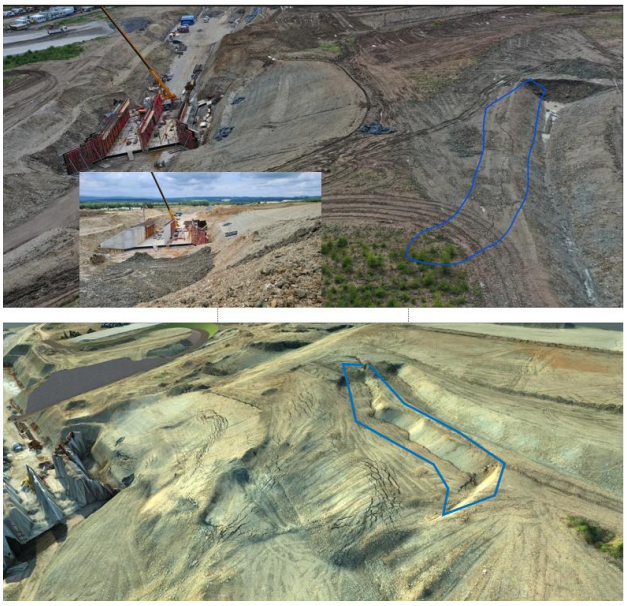

Figure 1. Landslide within 24m deep cutting (upper picture shows a situation before the failure).

Figure 2. Main scarp upper edge of the landslide.

4 BACK-CALCULATION

After the initial measures were taken to minimize the safety risk and based on the results of the daily monitoring, geotechnical assessments of the actual situation as well as back-calculated stability assessments were carried out. It should be paradoxically noted that the slope failure occurred after the construction of the stabilization berm at the toe, following the occurrence of a crack at the crown of the slope cut. Simultaneously, excavation works of soil in the upper part of the cut body were conducted to relief the associated stress just before the slope failure.

The numerical stability analyses results showed that the required theoretical safety factor was achieved in the phase of conducting stabilization measures, after the crack had occurred (Figure 3). Still, the question had arisen as to why the landslide occurred?

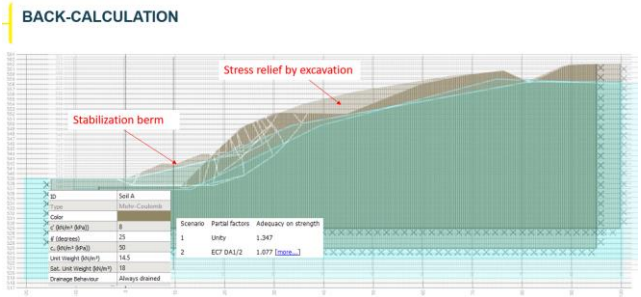

Figure 3. Back-analysis of the failure occurred after the construction of stabilization berm and excavation of upper part material.

The geotechnical back-analysis included parametric studies with different elements of instability. It turned out that a geometric instability element had to be present in the system (model), which was a prerequisite for the occurrence of the slope failure (Figure 4). By including such an instability element in the form of a completely thin layer of soft clay in the body of the landslide, the calculated degree of safety was insufficient, which also confirmed the theoretical possibility of a slope failure. Such calculated representation corresponded well with the site observations.

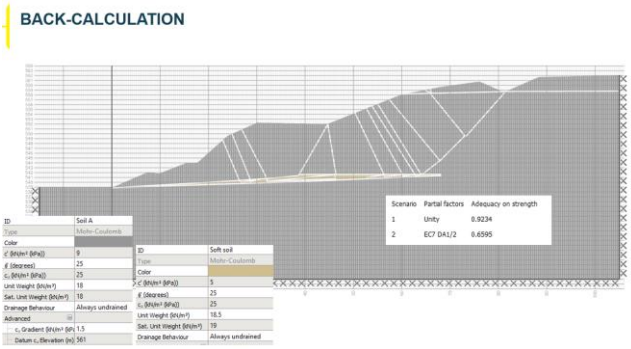

Figure 4. Back-analysis of the failure including an element of instability – 0.5m thick seam of soft soil in the cutting.

5 STATIC PENETRATION TESTS

As part of the investigation of the occurred slope failure, an additional geotechnical investigation by means of static penetration tests was carried out. The results provided detailed information regarding the subsoil profile, showing multiple low-peak locations, at different depths, with very low to low shear strength in the body of the landslide as well as in the wider area outside of the landslide body (Figure 5). These locations were local, very thin clay layers of very soft to soft consistency often only a few cm to a few dm thick. Thus, there was a practical confirmation of the hypothesis arising from the back-calculation, and that is a need for the presence of an element of instability in the system in order to model the theoretical failure. With the help of the interpretation of the static penetration results, the potential basal sliding surface was determined, which was necessary for the planning of remediation measures. The static penetration test results also indicated a random occurrence of very soft to soft clay deposits in locations outside the landslide itself. This confirmed the presence of the geotechnical risk arising from the nature of the spoil heap construction, the unpredictable interaction with water and the consequent change in the mechanical properties of the stockpiled clays.

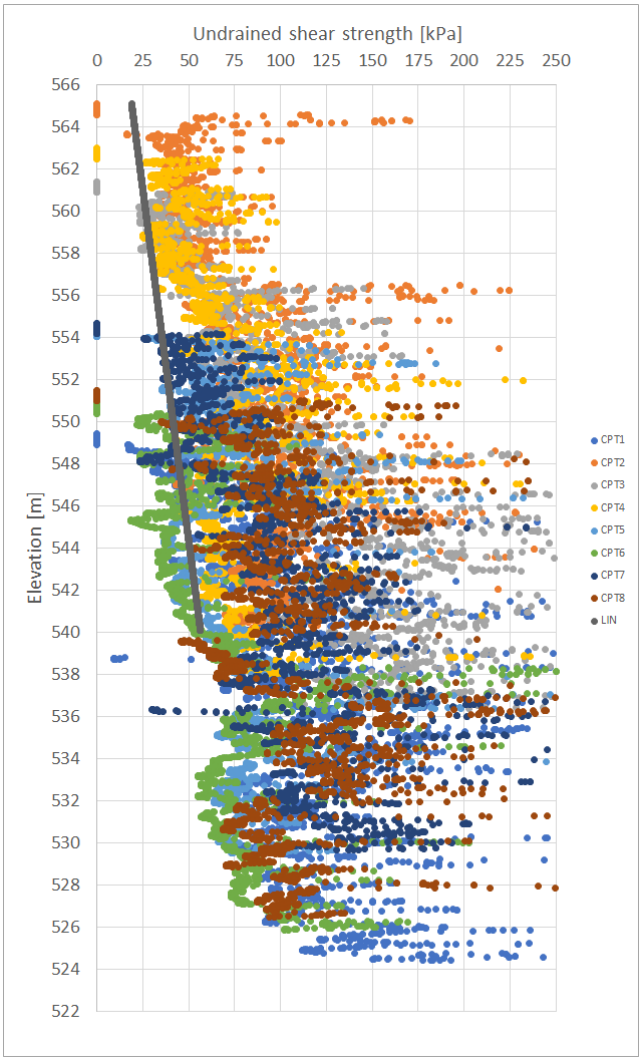

Figure 5. Static penetration test results showing potential basal sliding surface.

6 DISCUSSION

The entire construction site as formed of mine spoil heaps represented geotechnically challenging conditions. The main facts that underlined the geotechnical difficulty were the following:

- Obviously, the geotechnical properties were strongly dependent on the method of the spoil heap construction and in particular, on the interaction of the clay lumps with water long-term
- The construction of the spoil heap was carried out by free-fall of clay-claystone lumps under unknown and time-varying physical and weather conditions, without the classical engineered compaction known from road construction
- Although free-fall during construction allows some compaction, the resulting intergranular - lump porosity reached 35%, which in combination with water interaction varied over the time and created uncertainty to the geotechnical behaviour
- The relocated clay-claystone lumps (excavated and stockpiled) underwent a significant change in stress and depending on the water contact conditions (unknown, highly variable) the expected geotechnical behaviour is between rock type to soft clay type - this represented highly variable geotechnical conditions
- The whole process of stockpiling of clay mine spoil heaps led to an unpredictable alternation/intermixing of softer and stiffer layers/zones that randomly spread across the site
- Despite the site investigation carried out, there had always been uncertainty in the strength parameters and hydrodynamics due to the above facts

7 CONCLUSIONS

The construction site – clayey mine spoil dump represented a critical location predetermined to various forms of instability including slope failures, settlements, irregular groundwater seepage and erosion. Illogically, when the stabilizing measures were conducted, after a tension crack was observed at the crown of the cutting, and with a theoretically increasing factor of safety proved by calculations, a slope failure occurred. Geotechnical design of the 24 m deep cutting in such "natural" environment must ensure an advanced geotechnical characterisation as well as parametric stability assessments including different variables. Nevertheless, in such environments, all stakeholders must acknowledge the acceptance of the geotechnical risk, which would most likely require increased repair and maintenance costs.

ABSTRACT: Earthquake forces can quickly cause vibrations that damage structures, leading to cracks and possible collapse. Buildings designed in accordance with EC8 (Eurocode 8) take into account soil properties based on ground motion amplification data. The use of average shear-wave velocity for the uppermost 30 m soil layers provides the core for soil type classification to determine the appropriate design acceleration response spectrum. On one hand, determining v_{s30} requires detailed investigations, however, lately intensive research has attempted to correlate v_{s30} data with slope and geology. On the other hand, previous results have demonstrated that the amplification of acceleration might differ even for the same soil category determined based on v_{s30}. In this paper v_{s30} is determined from field measurements, also taking into consideration the correlation between slope values and the measured V_{s30} profile. In addition to this result, 1-dimensional response analysis is also performed using STRATA software, obtaining the site-specific acceleration spectrum. The study highlights the importance of seismic site characterization and the usefulness of determining the local site effect.

RÉSUMÉ: Les forces sismiques peuvent rapidement provoquer des vibrations qui endommagent les structures, entraînant des fissures et un éventuel effondrement. Les bâtiments conçus conformément à la norme EC8 (Eurocode 8) prennent en compte les propriétés du sol sur la base des données d'amplification du mouvement du sol. L'utilisation de la vitesse moyenne des ondes de cisaillement pour les couches supérieures de 30 m du sol constitue la base de la classification des types de sol afin de déterminer le spectre de réponse d'accélération de conception approprié. D'une part, la détermination de v_{s30} nécessite des investigations détaillées, mais récemment, des recherches intensives ont tenté de corréler les données de v_{s30} avec la pente et la géologie. D'autre part, des résultats antérieurs ont démontré que l'amplification de l'accélération pouvait différer même pour la même catégorie de sol déterminée sur la base de v_{s30}. Dans cet article, v_{s30} est déterminé à partir de mesures sur le terrain, en tenant également compte de la corrélation entre les valeurs de pente et le profil v_{s30} mesuré. En plus de ce résultat, une analyse de réponse unidimensionnelle est également réalisée à l'aide du logiciel STRATA, obtenant ainsi le spectre d'accélération spécifique au site. L'étude souligne l'importance de la caractérisation sismique du site et l'utilité de déterminer l'effet site local.

Keywords: Site response; local site amplification, slope correlation; ground motion data; response spectrum analysis.

1 INTRODUCTION

The use of average shear-wave velocity for the uppermost 30 m soil layers provides the core for soil type classification, which is crucial for determining the appropriate design acceleration response spectrum. To assess the accuracy of the properties and behaviour of the soil, shear-wave velocity within this specific depth range (uppermost 30 m) is considered to enable the development of a response spectrum that aligns with the expected ground motion during seismic events. This information plays a vital role in designing structures and infrastructure that can withstand and effectively respond to the forces exerted by earthquakes or other ground vibrations (Weatherill et al., 2020, Mori et al., 2020, Thompson et al., 2012, 2014).

In a previous study conducted by Wang and Wang (2015), the focus was on examining the reliability of correlations between measured v_{s30} and estimated v_{s30} through the utilization of a statistical Pearson correlation coefficient (PCC). Furthermore, the accuracy of site classification was assessed by comparing estimated v_{s30} with measured v_{s30}. However, a significant limitation of the proposed correction method by Wang and Wang (2015) became apparent. This limitation manifested in larger relative errors for the depths in the model and an unacceptably large disparity between the curves of estimated v_{s30} and measured v_{s30}, which could potentially be attributed to the presence of interbedded layers with high shear-wave velocities.

Thompson and Wald (2012) conducted additional research that centred around the kriging-with-a-trend approach for mapping v_{s30}. They explored various methods of defining the trend by incorporating abundant v_{s30} measurements in Taiwan, considering geology, topographic slope, or both as potential factors. The aim was to evaluate the accuracy of v_{s30} maps by comparing them statistically to the standard deviation of the residuals. However, it was observed that the geology-based approach was unable to adequately fit the model and thus introduced the highest level of uncertainty in the results.

In a related study, Weatherill et al. (2020) constructed a comprehensive model comprising topographic/bathymetric elevation and a database of 30 m averaged shear wave velocity measurements (v_{s30}). The model incorporated both topography and geology as influential factors. The authors incorporated site amplification functions into the European Ground Motion Model (GMM), which was calibrated based on observed or inferred v_{s30} values derived from European geology and topography models. However, a notable limitation of this research emerged concerning the use of inferred v_{s30} properties such as topographic slope or seismic design code, as well as site class. These factors introduced increased uncertainty in the resulting site amplification estimates.

2 METHOD FOR LOCAL SITE SPECTRA

In this study, the shear modulus was determined through in-situ seismic methods to ascertain the shear wave velocity from two sites. The measurement was carried out by special seismic tool composed by Geomega Ltd. for local (few hundreds of meters long, few tens of meters deep) engineering geological purposes. S waves were triggered by Lightning electromechanical seismic source in every 3 meters along the 459 m (PCS) and 1065 m (KSZ) long sections. The generated seismic signal was 20 s long composed by frequencies 5-200 Hz. Three component geophones were set in an array in 3 m distance, which were used to record S waves' arrivals. Tomographic processing of the results was used to determine the shear wave velocities of the pre-defined 1.5 m size cells along the section. Considering the wave routes initiated from the surface, cells' velocities were modified in order to approximately get the measured arrival times. This inversion method was run in 4 iteration steps in order to decrease the differences between observed and modelled arrival times below the pre-defined threshold. Along the section vertical v_s trends were extracted where additional stratigraphy data were existing.

To enable the selection of appropriate seismic input for nonlinear dynamic analysis, REXEL was utilized for scaling and accurately estimating seismic performance based on the seismic hazard at the location site. This facilitates the proper selection of seismic input and earthquake records using fundamental probabilistic seismic hazard parameters. REXEL, a computer software, allows the construction of design spectra in accordance with Eurocode 8 (EC8). REXEL searches for sets of records for various structural applications, considering soil types, location, peak ground acceleration at the targeted location, and distance (Sgobba, 2019). This process aids in defining the elastic acceleration response spectrum based on the direction of earthquake motion, which can be easily utilized by STRATA, which may include horizontal or vertical components of motion.

Equally, STRATA which is an equivalent linear site response analysis software, was applied in the frequency domain using input motions scaled from REXEL within the time domain to perform random vibration theory (RVT), which enables the randomization of site properties. The 1-dimensional equivalent wave propagation software allows user to input soil layering parameters such as nonlinear properties (soil characteristics), layering thickness, shear-wave velocity, and depth to bedrock. It uses the time series method as a single motion to propagate motions through the site to compute the strain-compatible ground motion at the surface of the site at any depth in the soil column (Kottke, 2012).

Peak ground acceleration (PGA) was used as the primary parameter in the selection of input acceleration records from REXEL, using 0.09 g and soil type C as the intensity parameters to examine the frequency content and intensity relation, which has a significant association with seismic damage.

3 V_S TREND DATA 1-D ASSESSMENT

PCS measurements were carried out in a hilly area located in a tectonically and geomorphologically active area situated between the uplifting Hungarian Mountain Range and the relatively subsiding Danube valley (Ruszkiczay-Rüdiger et al., 2005). Highest point of the measured section is 300 m (asl) and the local relief (maximal height difference) is about 160 m. The area is covered by few meters thick Quaternary and/or late Miocene loess and lacustrine sediment in advance. The main mass of the measured strata consists of loose Oligocene silt, clay to depths down to at least 100 m below surface. Using refraction evaluation method several layer boundaries have been identified. S wave refractions appear at the depths of 3-5 m, 18 m and 45 m depths. Note that in the upper 3 layers (separated by the mentioned boundaries) the S wave velocity is lower than 400 m/s [PCS_1 and [PCS_2]. The P wave refraction based uppermost boundary is at the depth of 8-10 m. This correlates well with the depth where the increase of S wave velocity slows down or even starts decreasing. Based on the slope and geomorphology based v_{s30} map (Kovacs et al. 2023), the measurement site's soil class is B which contradicts the middle of soil class C measured v_s values (275 and 284 m/s). This contradiction can be explained by the active topography of the area: in steady-state the loose sediment would be flattened by preceding erosional processes resulting lower slope and lower predicted v_{s30} (thus may be soil class C), but the intense incision of the Danube river is resulting actively eroding surface with higher slope values and higher predicted v_{s30}.

KSZ measurements were carried out in the western foothills of relatively uplifting Mecsek Mountain (Sebe et al., 2008) which is a structurally and geologically complex shear zone. Surface elevation of the measurement area is 140-148 m (asl), whereas the lowest point in the surroundings is around 110 m (asl). In this measurement site, the two analysed v_s trends reflect significantly different geology. In the vicinity of [KSZ-2] at the depth of 30 m Permian-Triassic sandstone was drilled, however near [KSZ-1] below late Miocene lacustrine sediments (3-12 m) early Miocene strata were present down to the depth of 100 m. The section most likely runs along the edge of the fractured Permian-Triassic strata. S wave refraction method detected a boundary at 13 and 10 m depth (at 580 m and 220 m line distance respectively) which is probably the base of the late Miocene sediments. A deeper boundary reflects the top of a tuffic layer and the basement depth at 32 and 28 m depths. In this case v_{s30} map based on the surface slope provides soil type B that is consistent with the measured average v_s values (364 and 429 m/s). Note that soil type C appears 80 m from the KSZ-1 measurement point.

4 EVALUATION OF STRATA RESULTS

The upper soil layering at site PCS and KSZ in Figure 1 varied to determine the potential causes of the loop before 20 meters and at 40 meters, resulting from the intersection loop in the shear wave velocity profile. To assess the influence of the lower and upper layers of the site, we conducted STRATA analyses at 30, 40, 50, and 80 meters, respectively. For each case, we assumed and varied the bedrock shear wave velocity at 400, 600, and 800 m/s to ascertain the impact on the site results. This was done to rule out the effect on the response spectrum of the sudden jump in applied shear wave velocity (v_s) at bedrock.

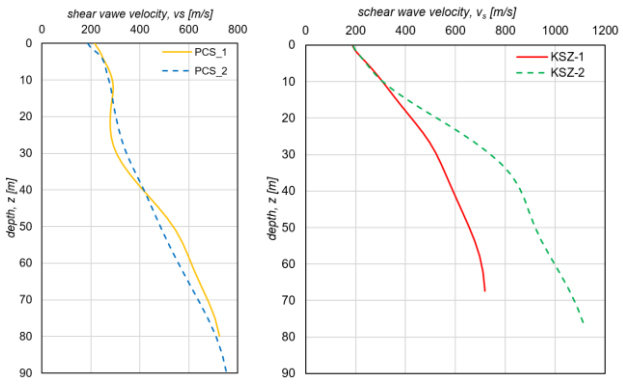

Figure 1. Two v_s trend for both PCS and KSZ location.

Changing the model depth at the two locations had different effects and results, which is in line with the v_s profiles. At PCS locations for all examined model depths, the v_s trends yielded almost identical results, the shape of the response spectra is very similar, their values show a difference mainly on the plateau.

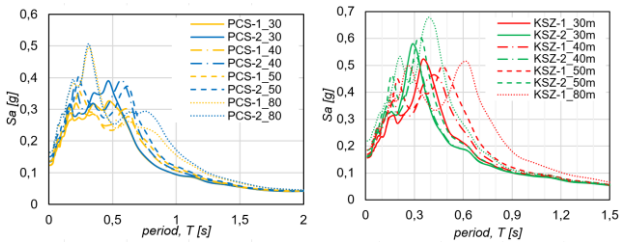

Figure 2. Response spectra for PCS and KSZ site considering two v_s trends and different bedrock depth.

In the case of KSZ sites different model depths, the difference in soil profiles is always apparent, with increasing depth, which is consistent with the fact that in one section the value of v_s increases faster with depth, and thus the average value of v_s, about the

difference between soil profiles as a function of model depth.

5 DISCUSSION

In case of PCS site the PCS-2 curve always gives a higher value at plateau. This fundamentally contradicts the fact that the average shear wave propagation speed determined for that profile is higher ($v_{s.30}$, $v_{s.40}$, $v_{s.50}$), on the basis of which we would expect an inverse ratio. The reason for this can be found in the fact that there is a dip in the PCS-1 v_s profile, which can affect the propagation of the wave towards the surface, in this zone the wave slows down, its amplitude increases, and then the wave accelerates again as it approaches the surface. This pulsation may cause the acceleration values on the plateau to be lower for this profile. The descending branches of the plateaus usually run along the same line, the connection point of the curve belonging to the two profiles is slightly shifted at the depth of 80 m. By increasing the depth of the model, the results given by the two soil profiles change according to almost the same trend. The effect of the depth can be summarized as follows: the average value of the plateau at the first three depths (30-40-50 m) does not change, it is shifting from the two-humped shape more and more towards one hump, within the plateau there is an increase parallel to the period in the case of a smaller depth, a constant for the two intermediate models, a decrease for the 80 m model, and even a marked difference for the latter. The beginning of the descending branch shifts to the right as the depth increases, but there is no significant difference between 40-50 m, and in the 80 m model, the plateau widens and only starts to decrease at a period time of 0.9 s, and it blends into the other curves at almost 2 s, in the case of the 30-40-50 m models it is already 1.2 s after that there is no significant difference.

In case of KSZ sites the shape of the plateau is almost the same for the 2 v_s trends, but in the case of KSZ-1 it is distributed over a larger period-time range than in the case of the KSZ-2 section, and this difference becomes more and more pronounced as the depth increases, the width of the plateau increases to a lesser extent in the KSZ-2 section by increasing the model depth as in the other section. The maximum acceleration value is usually in the very low period time range typical of the KSZ-2 section (depending on the depth T=0.2-0.4s), at the same time the average level of the plateau is almost the same, and in the range of T > 0.5 s, the value is usually smaller than that of KSZ-2, and in some places the difference is very marked, the two curves merge into each other at T = 1-1.6 s.

The effect of bedrock shear wave velocity is examined in case of PCS site, considering bedrock at 40 m, and bedrock v_s varied between 400-600 m/s. According to the calculation results the initial shear wave velocity does not modify the shape of the response spectrum, the run-off conditions, only the acceleration values on the plateau and its surroundings, it scales the ground response in this range. With a lower shear wave velocity, we get a less favorable response, which is in line with the fact that as the value of v_s decreases, the maximum acceleration increases, we get a less favorable effect. According to this result, it is important to really start the response spectrum analysis from the bedrock, and not to consider the range between the soil layers close to the surface and the bedrock with a "degraded" v_s value. Because we saw previously that increasing the depth of the model and taking into account the "real" v_s profile in that range also modifies the shape of the response spectrum, not just scales it. The deeper model is also justified by the fact that the effect is not clear as the model depth increases: it increases in a small period time range, then it decreases a little, but the plateau widens. This effect certainly depends on the soil profile and the accelerograms used.

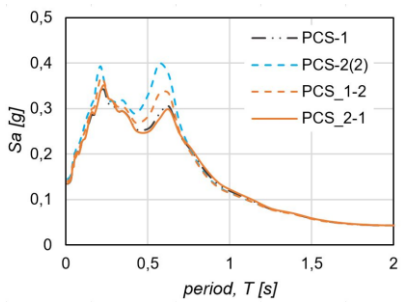

Figure 3. Response spectra for PCS and KSZ site considering two v_s trends and different bedrock depth.

To support the understanding of the results experienced at the different model depths at the PCS site, we made calculations where the layers above and below 14 m were mixed from the two sections (Fig. 3). Accordingly, a calculation was made where the v_s values of the upper 14 m were derived from section PCS-1, in the deeper range from PCS-2 (PCS_1-2) and the reverse of this (PCS_2-1). Both calculations were performed on the 40 m model with v_s 600 m/s at bedrock. The results are somewhat contradictory in terms of which layer is the defining one. As we can see, both versions are close to the PCS-1 profile, PCS_2-1 essentially coincides with it, i.e. according to this, the upper soil zone has no substantial influence here. At the same time, in the case of the other section,

it is closer to this, which would mean that the deeper layers do not have a marked effect either. A deviation is visible in the region of the response spectrum, where the two soil profiles produced a significant difference anyway, but the extent of this does not approach the distance of the two original profiles.

6 CONCLUSIONS

Determining local site spectra plays an important role in seismic design when designing earthquake-resistant structures. Determining $v_{s,30}$ provides insights into the stiffness and amplification properties of the near-surface geology. Based on the slope and geomorphology based v_{s30} map the category of the investigated area can be determined, and a EC8 code spectra can be used. However research conducted in this field applying 1-D STRATA analysis revealed that local site spectra might have higher values than the code spectra (Kegyes-Brassai et al, 2017). This underlines the necessity to evaluate more exactly the amplification potential.

This paper presented two soil profiles at two different sites and the v_s measured trend for each profile. 1-dimensional response analysis was performed using STRATA software, obtaining the site-specific acceleration spectrum. Varying the properties of the soil layering to take into account variability of soil, the mean value obtained for each site response were presented for each profile, PCS-1 and PCS-2, KSZ-1 and KSZ-2. Assuming different measured data local soil spectra were determined for different depth, with different shear wave velocity at bedrock, showing a similar trend in the response, however highlighting clear differences also, such as with increasing depth the plateau widens and the values decrease. Next the effect of the upper and lower layers on the response were also analysed. All the result highlighted that with more in-depth data more precise result can be obtained, and that there is a need for further investigations to be able determine the parameters that have a critical influence on seismic response analysis and the minimum requirement for on-site measurements like the depth, number of v_s-trends, etc. to be able to determine reliable response spectra for further seismic design.

A geotechnical and geophysical characterization of the influence of seasonal variation on railway embankments

Une caractérisation géotechnique et géophysique de l'influence des variations saisonnières sur les remblais ferroviaires

ABSTRACT: Seasonal variation causes the railway embankments in Ireland and the United Kingdom (UK) to experience significant changes in their pore water pressure throughout the year. Most of these embankments were constructed more than a 100 years ago with methods that did not comply with standard compaction methods used in modern embankments. As these embankments form a large portion of the railway infrastructure in the UK, their stability presents a geohazard. With the imminent effects of climate change on unstable seasonal variation in the weather patterns, understanding the behaviour of these embankments becomes even more critical. To understand the influence of such seasonal variation or hydraulic hysteresis, laboratory testing was conducted on clay-based embankment material sourced from an active railway embankment. Firstly, results of field measurements from sensors at the railway embankment are presented. Furthermore, results from shear wave velocity measurements of the material together with suction and moisture measurements are also presented.

RÉSUMÉ: Les variations saisonnières entraînent des changements importants dans la pression de l'eau interstitielle des remblais ferroviaires en Irlande et au Royaume-Uni tout au long de l'année. La plupart de ces remblais ont été construits il y a plus de 100 ans avec des méthodes non conformes aux méthodes de compactage standard utilisées dans les remblais modernes. Étant donné que ces remblais constituent une grande partie de l'infrastructure ferroviaire du Royaume-Uni, leur stabilité présente un géorisque. Avec les effets imminents du changement climatique sur les variations saisonnières instables des régimes météorologiques, il devient encore plus crucial de comprendre le comportement de ces remblais. Pour comprendre l'influence d'une telle variation saisonnière ou hystérésis hydraulique, des tests en laboratoire ont été réalisés sur un matériau de remblai à base d'argile provenant d'un remblai ferroviaire actif. Tout d'abord, les résultats des mesures de terrain effectuées à partir de capteurs situés sur le remblai ferroviaire sont présentés. En outre, les résultats des mesures de vitesse des ondes de cisaillement du matériau ainsi que les mesures de succion et d'humidité sont également présentés.

Keywords: Climate change; embankment stability; shear wave velocity; unsaturated soil; hydraulic hysteresis.

1 INTRODUCTION

Climate change is expected to lead to more frequent and severe weather events, resulting in wetter winters and hotter summers in the UK. For example, over 100 slope failures (significantly higher than usual) were recorded in southern UK in 2000/01 that was recorded as wettest winter on record (Dixon et al., 2008). The failure of these earthworks was attributed to excessive precipitation and a notable increase in saturation, highlighting the vulnerability of these structures to the impacts of extreme weather events. Railway infrastructure development in the UK surged during the industrialization period of the mid to late 19th century. Most of the railway embankments constructed during this pre-regulation era lacked a comprehensive understanding of the geophysical and geotechnical properties necessary for stable embankment design (Skempton, 2017). During construction, the foundations of these embankments were often left unprepared, with topsoil and soft surface deposits left in situ. O'Brien (2007) identified that this practice resulted in dumped clay fills exhibiting a clod-matrix structure, varying from compacted engineered fill to natural clay. The intact

clods could impact the compressibility and shear modulus of the dumped clay, while the remoulded clay matrix influenced permeability and shear strength (Briggs et al., 2017).

The seasonal variation in soil moisture content further influences the volumetric behaviour of embankment material (Briaud, 2013). In the presence of plastic clayey material, seasonal moisture fluctuations pose stability problems for pre-regulation embankments. High-plasticity soils, like soft clays, are more susceptible to excessive shrink-swell behaviour. Soil cracks resulting from clay shrinkage facilitate rainfall infiltration, leading to shallow slides and surface creep (Smethurst and Powrie, 2007). The inadequate compaction of early railway embankments would also have resulted in higher permeability levels and significant permeability fluctuations within the soil. This, in turn, amplifies pore water pressure variability, potentially increasing shrink-swell behavior and accelerating the aging rate (Glendinning et al., 2014). Due to poor compaction, dense vegetation and abundant presence of high-plasticity clays as embankment material, the hazard risk associated with failures of old railway embankments increases significantly with changing precipitation patterns as a result of climate change. Recent studies have employed seismic measurements, for assessing and monitoring the condition of embankments over extended periods (Bergamo et al. 2016). A crucial geophysical parameter derived from such investigations is the shear wave velocity (V_s) of the soil. Laboratory investigations into the impact of varying moisture levels on the mechanical behavior of soil can be conducted through the measurement of V_s using bender elements (Wheelar et. al., 2003). V_s measurements have demonstrated that clayey material exhibits greater sensitivity to changing moisture content (Dong and Lu, 2016). Additionally, higher plasticity in clayey soil has been associated with increased hysteresis (variations in suction within the soil between wetting and drying cycles) during wetting and drying cycles (Gapak and Tadikonda, 2018). Therefore, lab-based V_s measurements provide improved insights into the volumetric behavior of embankment material.

This study presents results from an investigation of the influence of hysteresis on the stiffness response of a clay-based embankment material sourced from an active railway embankment. By using V_s measurements obtained from bender elements, the specimen's stiffness variation with moisture levels is monitored. The moisture levels in the specimen are varied to reflect the suction levels during summer and winter seasons from an instrumented railway embankment.

2 METHODOLOGY

2.1 Materials

All the soil used for testing was collected from boreholes drilled on the Withy Beds embankment in the southeast England, between Effingham Junction Station and Cobham & Stoke d'Abernon (CSD) station. This embankment is part of the New Guildford Railway line. The soil is termed as London Clay. Its material properties are given in Table 1. The maximum dry unit weight and optimum moisture was found using standard proctor compaction method (BS 1377-4:1990). However, the in-situ dry density of the soil was found to be lower at 15 kN/m^3. For a better comparison of the volumetric behaviour of the soil with the in-situ conditions, the test specimen was prepared at the in-situ density with a moisture level of 30%.

2.2 Field instrumentation

Since December 2020, the Withy Beds site has employed different ground sensors, such as 5TE and T21, to capture data on volumetric water content (VWC), temperature, and soil suction. These sensors are located at 5 different locations spaced 66m apart.

2.3 Laboratory experimental setup

A cylindrical specimen was prepared (Dia=102mm and Height = 114mm) with a density of 1800 kg/m^3 at in-situ moisture content. Figure 1 shows the specimen setup for bender element and soil suction measurements. The specimen was fit into an acrylic casing that was fitted with inserts for the benders. MPS-6 tensiometer was embedded into specimen to measure suction. The V_s measurements were obtained using a system having a *Siglent* function generator and *Picoscope* 5000 series oscilloscope. A 10V sinewave was used as the input signal. As the stiffness of the specimen varies throughout the drying and wetting process, the input frequencies were adjusted to ensure that the wavepath-wavelength ratio (L_{tt}/λ) was above 3 at each moisture level (Leong. et al 2005).

Table 1. Geotechnical properties of embankment material.

Parameter	Value
Liquid Limit	60
Plasticity Index	29
Activity (%)	76
Maximum Dry Unit Weight (kN/m^3)	17
Optimum Moisture Content (%)	24
In-situ Moisture Content	30

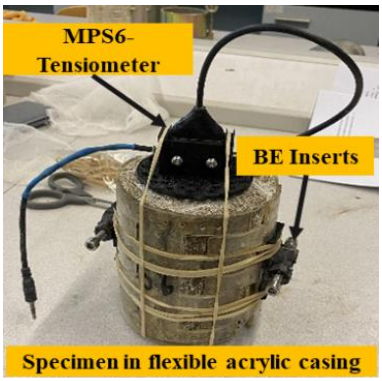

Figure 1. Assembly of specimen with Bender Element (BE) and Tensiometer.

3 RESULTS

3.1 Field measurements

The sensor measurements for soil moisture (VWC) and suction are provided in Figure 2. Averaged results from all five locations are depicted for both sensors. Furthermore, measurements from sensors located at the middle of the instrumentation layout are also provided in Figure 2. This is because the driest conditions were observed at this location with suction measurements exceeding 1000 kPa during the summer of 2022. During this year, high suction and low moisture levels were observed between early March and late October. Another feature of the measurements during the summers is the short-term variation in moisture levels. Due to rainfall events, short term reductions in suction measurements are observed that quickly return to higher values after the soil dries up. Therefore, the soil would likely experience several hysteresis cycles during summer.

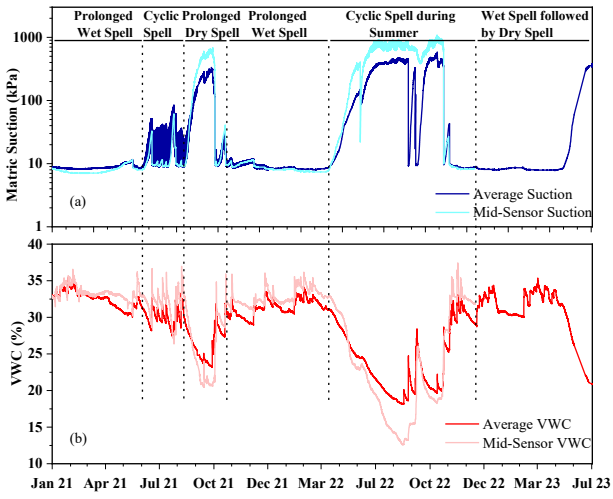

Figure 2. Field measurements, a) Suction Measurements, b) VWC Measurements.
Note: Mid-sensor data was recorded till Dec-2022.

Given the clayey nature of this material, the risk of rainfall induced failure due to crack formation from volumetric instability becomes greater. Consequently, laboratory testing is required to link the influence of hysteresis with the stiffness of the embankment material.

3.2 Laboratory testing

Testing was conducted on a specimen subjected to dry-wet cycles after being prepared at 30% gravimetric moisture content. The soil-water characteristic curve (SWCC) of the embankment clay is given in Figure 3. This curve was plotted using measurements from MPS-6 (up to 1200 kPa) and WP4C Potentiometer (beyond 1200 kPa and up to 75000 kPa). The MPS-6 measurements were obtained from the drying curve of the instrumented cylindrical specimen. The SWCC curve was modelled using the equation proposed by Fredlund and Xing (1994):

$$\theta = \left(1 - \frac{\ln\left(1+\frac{\psi}{\psi_r}\right)}{\ln\left(1+\frac{10^6}{\psi_r}\right)}\right)\left(\frac{\theta_s}{\left[\ln\left(e+\left(\frac{\psi}{a}\right)^n\right)\right]^m}\right) \quad (1)$$

where θ is the moisture content, θ_s is the saturated moisture content, ψ is the suction, ψ_r is residual suction and a, m and n are fitting parameters. Although the curve provides a good fit at suction levels beyond 200 kPa, the MPS-6 tensiometer does not have sufficient resolution for accurate suction measurements at suction levels closer to saturated state. Nevertheless, hysteresis is observed in the MPS-6 measurements on cylindrical specimen as shown by the wetting curve in Figure 3.

Figure 4 illustrates the variation of V_s with moisture content. The selection of a moisture variation range between 20% and 30% for the drying-wetting cycle was based on measurements from the mid-sensor in Figure 2.

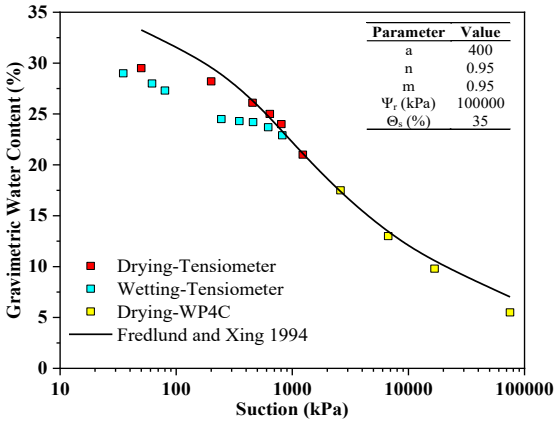

Figure 3. SWCC of embankment material.
Note: Parameters for equation 1 are given in the figure.

This is because the suction measured using MPS-6 tensiometer was approximately 1200 kPa at 20% moisture content, which is slightly higher than the maximum suction measured in the field based mid-sensor. In each drying cycle, the rate of increase in V_s of the specimen becomes higher. This rate of increase becomes evident in driest state where a 5% and 12% increase is observed in V_s at end of each drying cycle after the first cycle.

4 CONCLUSIONS

The influence of moisture variation on poorly compacted embankment material increases the hazard risks associated with embankment failure. These failures are common in old railways due to their clayey nature and insufficient compaction. The current study investigated the influence of moisture variation on stiffness of one such clayey material from an active railway embankment site. Using field-based sensors, soil suction and moisture data were obtained for nearly 30 months from the site. The data illustrated dry periods with episodes of extensive moisture variation during summers. Using laboratory-based testing, hysteresis was observed in the SWCC of the clay. Furthermore, V_s testing exhibited a stiffening influence of the repeated hysteresis. Consequently, the likelihood of rainfall-induced failure increases, primarily attributed to crack formations in the matrix of poorly compacted embankments. This risk is particularly heightened by the potential for seasonal extremes resulting from climate change. To investigate this risk, further studies are required to assess the impact of additional dry-wet cycles on the behaviour of clayey embankment material.

Laboratory assessment of shear strength parameters in sandy soil by lime permeation method and sensitivity analysis from Doi Chang case study

Évaluation en laboratoire des paramètres de résistance au cisaillement dans un sol sablonneux par la méthode de perméation à la chaux et analyse de sensibilité à partir de l'étude de cas de Doi Chang

ABSTRACT: In nature, slopy terrain or loosely compacted soil can have high permeability which can cause rise in groundwater table and may create stability problems. To minimize this phenomenon, hydrated lime slurry permeation can be used. Hydrated lime has been in use for many years. But using lime slurry to treat low shear strength soil can be a solution for slope stability. The purpose of this research is to increase the sand's shear strength by hydrated lime permeation under the influence of constant head. The test samples were obtained by passing through sieve #40 and retained on #200. After 66 days of lime permeation, permeability decreased by 94% and cohesion increased up to 77%. Also, to identify the mineral compounds and analyze the structure of crystalline materials, X-ray Diffraction Method (XRD) was used which showed formation of calcium cations along with the sand silica. The Sensitivity Analysis from Doi Chang mass movement case study (a village in Thailand having active mass movement currently) showed that the increase in cohesion help in the increase in factor of safety by 11.2% even though groundwater level was higher.

RÉSUMÉ: Dans la nature, un terrain en pente ou un sol peu compact peut avoir une perméabilité élevée, ce qui peut entraîner une montée de la nappe phréatique et créer des problèmes de stabilité. Pour minimiser ce phénomène, on peut utiliser la perméation à la boue de chaux hydratée. La chaux hydratée est utilisée depuis de nombreuses années, mais l'utilisation de boue de chaux pour traiter un sol de faible résistance au cisaillement peut être une solution pour la stabilité des pentes. Le but de cette recherche est d'augmenter la résistance au cisaillement du sable par perméation à la chaux hydratée sous l'influence d'une tête constante. Les échantillons de test ont été obtenus en passant à travers un tamis #40 et retenus sur le tamis #200. Après 66 jours de perméation à la chaux, la perméabilité a diminué de 94 % et la cohésion a augmenté jusqu'à 77 %. De plus, pour identifier les composés minéraux et analyser la structure des matériaux cristallins, la méthode de diffraction des rayons X (XRD) a été utilisée, montrant la formation de cations de calcium avec la silice du sable. L'analyse de sensibilité de l'étude de cas du glissement de terrain de Doi Chang (un village en Thaïlande connaissant actuellement des mouvements de masse actifs) a montré que l'augmentation de la cohésion contribue à augmenter le coefficient de sécurité de 11,2 %, même si le niveau de la nappe phréatique était plus élevé.

Keywords: Permeability; lime permeation; cohesion; XRD; sensitivity analysis.

1 INTRODUCTION

Lime treatment by permeation in porous soil is a challenge to let lime particles or soluble cations into the soil. However, pore size of the soil must be larger than the inherent lime particles. When lime is added to a fine-grained soil and intimately mixed, several reactions initiate. Cation exchange and agglomeration-flocculation reactions take place rapidly and produce immediate changes in soil plasticity, workability, and swell properties. A soil-lime pozzolanic reaction may commence depending on the characteristics of the soil being stabilized. The pozzolanic reaction results in the formation of various types of hydrated calcium silicate and calcium

aluminate cementing agents or both. The cementing agents increase strength and durability. Pozzolanic reactions are time dependent, and strength development is gradual but continuous for a long period of time (several years in some instances) (Thompson & Robnett, 1976).

Residual soil or colluvium is the heterogeneous mixture of boulder or granular soil and mixtures of both. The colluvium loses the valuable minerals under leaching such as iron, calcium, aluminum under high rainfall and form lateritic soils and andosols downslope. Many past studies have suggested that permeability in case of In situ residual soil is higher than compacted soil in laboratory and use of lime for high plasticity soils is effective except for organic soil (Townsend, 1985). Grouting by lime slurry with fly ash increased the alkalinity in time, having maximum concentration at 59 days. Also, grouting about 59-64%, hydraulic conductivity was found to decrease (Gabr et al., 1995). The hardening and strengthening of the lime mixture with soil depend on carbonation of the lime. This is likely because of the attachment of the calcite crystals to the surface of aggregate particles. The pore size of the soil is directly involved in the carbonation process (Lawrence et al., 2007).

Dissolving lime in water and intruding saturated lime solution (SLS) containing calcium cations into soil by means of gravity gradient resulted in an increase of 294% in cohesion and 222% in internal friction angle and a decrease of 58% in settlement of specimens (Davoudi et al., 2009).

The sequential permeation of $CaCl_2$ and NaOH solutions into compacted expansive soil resulted in the precipitation of lime in the expansive soil and increased pH level which is important for pozzolanic reactions to effectively reduce plasticity index and swell potential. This is an effective method for lime precipitation for stabilizing expansive soils (Thyagaraj et al., 2012; Thyagaraj & Zodinsanga, 2015).

Another study about the remediation of reactivated landslide used a method to introduce lime slurry into the sheared zone. Just after remediation of 10% of the slip surface by 7% lime, it caused increase in factor of safety from 1.1 to 2.89 after 5 weeks of curing (Moridzadeh, 2019).

X-Ray Diffraction (XRD) test is successful in identifying crystalline minerals such as calcite, illite, quartz, kaolinite and chlorite-serpentine mixed layers. It provides a powerful nondestructive technique for characterizing crystalline materials. It provides information on structures, phases preferred crystal orientation (texture), and other structural parameters, such as average grain size, crystallinity, strain and crystal defects (Moretti et al.,2020).

2 SPECIFIC OBJECTIVES OF THE RESEARCH

- To use lime stabilization to monitor the changes in cohesion and frictional properties of soil.
- To observe the relative changes in soil permeability before and after improvement using lime stabilization.
- To study the changes in soil structure using XRD.
- To perform sensitivity analysis in real case scenario with increase in cohesion.

3 METHODOLOGY

A laboratory set up was arranged using custom made constant head apparatus as in Figure 1. The top two containers contain two separate mixtures of 500 g and 4000 g solutions. The two small constant head containers take solutions to the samples separately. T1, T2 and T3 were passed through 500 g solution whereas T4, T5 and T6 were passed through 4000 g solution. An acrylic waterproof tube was made for testing samples. Altogether 6 sample tubes were prepared to test lime permeation. Samples were obtained from construction site and taken only samples passing #40 and retained on #200. A uniform density was maintained by mild compaction using Proctor for 25 blows at 5 cm each interval. Two solutions were prepared having 500 g and 4000 g for the same volume of water in separate containers. 500 g solution was passed through T1, T2 and T3 whereas 4000 g solution was passed through T4, T5 and T6. Continuous monitoring of the outlet permeability was done to measure and analyse the effectiveness of lime permeation. Samples were taken out at different time intervals to observe strength behaviour. Cohesion and friction angle were measured at different time intervals as in Figure 5 and Figure 6. A direct shear test method was used under drained conditions Also, X-Ray diffraction (XRD) test was done for T5 to see calcium ions within the samples. Finally, a sensitivity analysis was done using the laboratory data to evaluate possible changes in factor of safety in slope stability.

The flowchart shows workflow and varieties of laboratory tests as shown in Figure 2.

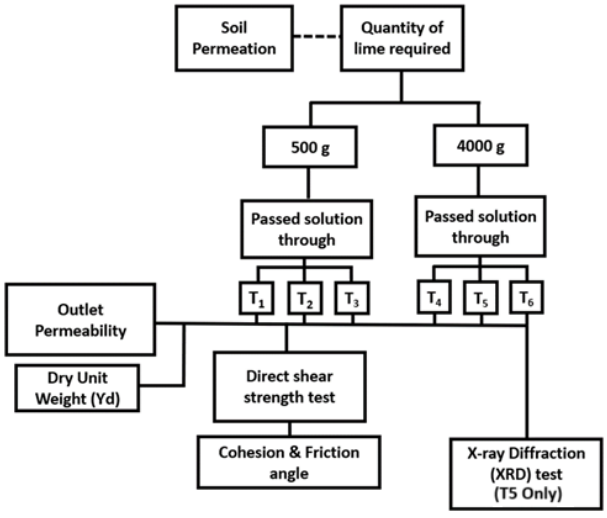

Figure 2. Flowchart of laboratory tests.

5 RESULT AND DISCUSSION

5.1 Unit Weight Variation

Lime water permeation method showed slight gain in the density of the sample i.e. increase in the unit weight of the soil by small percentage from original value. The value from 0.991% to 1.001% was the increased unit weight percentage range from T1 to T6. The result showed increase in unit weight percentage, which was higher in lime solution of 500 g than solution with 4000 g, as in Figure 3 below. 12 days and 66 days had similar results; however, 46 days results were reversed due to uneven flow and irregular permeability during treating.

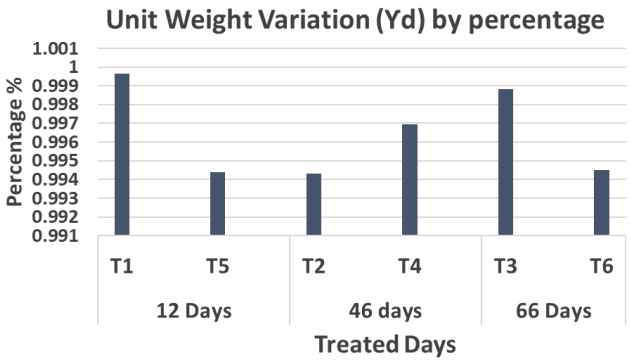

Figure 3. Percentage change in unit weight of the treated soil and its comparison.

5.2 Permeability

The permeability over the period of 2 months (66 days) showed a significant decrease in both 500 g and 4000 g solutions. In the Figure 4, the coefficient of permeability was seen to be slightly higher in 500 g mixture solution than that of 4000 g of solution because of the concentration of the lime particles. Also, as we could see T4 had minimum permeability from beginning due to apparatus misposition of perforated filter or apparatus failure, because of the insufficient permeation, it did not gain enough strength in strength test results. The ups and downs of values in the graph was due to clogging of lime particles. Frequent cleaning of inlet valves and pipes were done. However, this method could not show how much portion of the soil was impermeable and it requires another level of instrumentation or monitoring. The general graph of permeability for all soil samples in different time is in Figure 4 below.

5.3 Strength Test and Analysis

The samples were tested, and friction angle was found to fluctuate slightly lower than beginning as shown in Figure 5. The reduction in friction angle was uniform, which was not much affected by time whereas cohesion was increased exponentially. The friction angle reduction value ranges between 1-5.5% whereas cohesion was increased 0.4% in 12 days, 30% in 46 days and 77% in 66 days of treatment as in Figure 6.

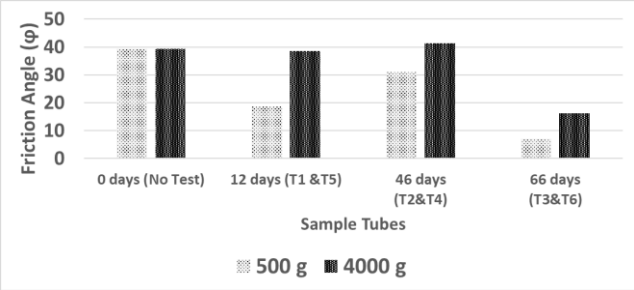

Figure 4. Coefficient of permeability for all samples at two different hydrated lime concentration.

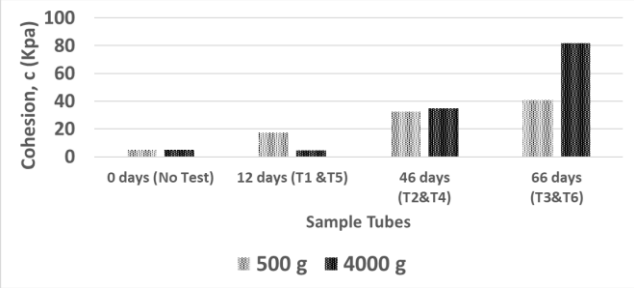

Figure 5. Comparison of friction angle of samples.

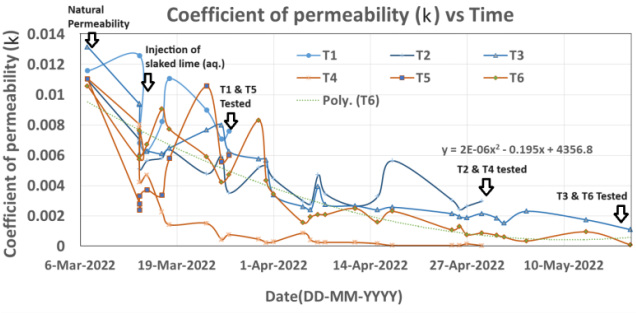

Figure 6. Comparison of Cohesion of samples.

5.4 XRD Test and Analysis

X-Ray Diffraction test was conducted to check the content of lime in compound form or formation of calcium carbonate. A sample tube T5 containing 4000 g solution was tested after 12 days of lime permeation. In a 2D section of the sample tube T5 as in Figure 7, altogether 6 samples were taken out for X-Ray Diffraction test from which Calcite and Quartz crystalline compounds were found. Quartz (SiO_2) is the silica found in sand itself, which had no change unless being mixed by lime particles. Calcite ($CaCO_3$) is the calcium carbonate compound being developed due to lime concentration. The X-ray diffraction was recorded based on reflected light and it is generally called 2θ (2 theta) which gives an angle made between incident and diffracted X-Rays. The result shows higher $CaCO_3$ in the beginning (i.e S51=1.30% and S52=3.46%). However in the middle (i.e S53=0.91%) and last part of the sample got lesser $CaCO_3$ after 12 days of treatment as in Figure 7.

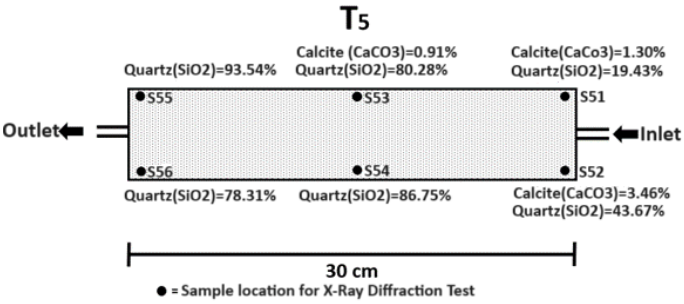

Figure 7. XRD result of T5 sample.

5.5 Sensitivity Analysis

A sensitivity analysis was used to determine the effect of various input parameters on slope stability. The effect of uncertainty or variability in the values of soil parameters could be explored. In this study, cohesion was more dominant parameter than friction angle. From the experiment, it was found that there was no significant change in friction angle values with respect to time; however cohesion was increased over time.

The residual cohesion of soil was found to be 7.84 kPa from a previous study. To check the effect of cohesion parameter in final factor of safety in the Doi Chang case, varying groundwater table and an infinite slope equation was used (Soralump et.al., 2021). In the performed experiment, the cohesion value had increased by 77% over 66 days of lime treatment. Using this cohesion value to simulate safety factor, an 11.2% increment in safety factor was of the unstable slope obtained. This showed that lime treatment would be an effective treatment for unstable slopes with high GWL.

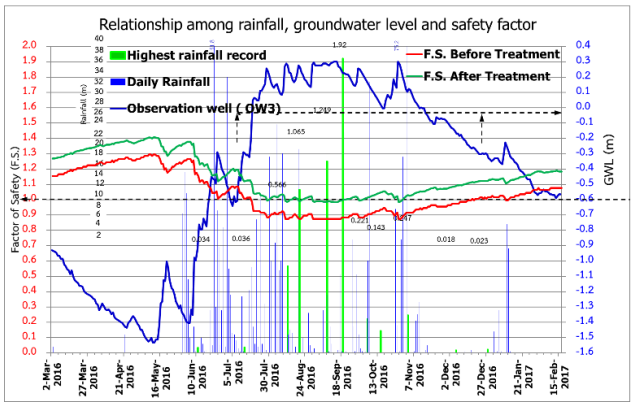

Figure 8. Relationship among rainfall, groundwater, and factor of safety before and after treatment of 66 days of lime permeation.

6 CONCLUSIONS

The lime permeation method is found to be effective for reduction in permeability in fine sand. However, uniform permeation is also a key to strengthen soil within its specimen. It can be greatly expected to have risen in strength where there is higher lime water permeation.

This method also increases cohesion in the cohesionless soil such as sand. However, permeability must be regular and not sudden drop in flow, which might result in the low treatment as in case of T4. Moreover, friction values are not affected much by this method. In case of fiction angle, reduction value ranges between 1-5.5% whereas cohesion was increased 0.4% in 12 days, 30% in 46 days and 77% in 66 days of treatment.

Moreover, presence of Calcium crystals detected by X-Ray Diffraction (XRD) shows successful treatment by lime permeation.

Also, sensitivity analysis for Doi Chang case study shows the cohesion increases by 77% resulting in increase in factor of safety by 11.2% even though high groundwater table is present.

ABSTRACT: The influence of dynamic Soil-Structure-Interaction (SSI) phenomena on the response of structures under dynamic loading is widely recognised. These phenomena are more impactful on structures that are founded on soft soil sites, where soil nonlinearity can prevail. The present study examines this aspect by the means of three-dimensional nonlinear finite element analyses of real-scale free-vibration experiments on a steel frame structure. The structure has outer dimensions of 3×3×5m and is rested on a shallow foundation over a soft soil deposit. The numerical analyses focus on modelling experiments of different magnitude excitation forces, to allow the investigation of the SSI system for a wide strain range. Cyclic nonlinear models, which are typically used in numerical analysis to predict the hysteretic behaviour of soils, can simulate well either the stiffness degradation (G-γ) or the damping evolution (D-γ) with cyclic shear strain. Experimental strong motion data are compared against numerical results of analyses that adopt different G-γ-D curves for the shallow foundation soil. This investigation reveals that the choice of G-γ-D curves affects significantly the SSI free-vibration response, highlighting the importance of modelling the nonlinear behaviour of shallow soil appropriately. It also suggests that prioritising the calibration of the D-γ curve over G-γ is more applicable for most of the modelled experiments.

RÉSUMÉ: L'influence des phénomènes dynamiques d'interaction sol-structure (ISS) sur la réponse des structures soumises à des charges dynamiques est largement reconnue. Ces phénomènes ont un impact plus important sur les structures fondées sur des sols meubles, où la non-linéarité du sol peut prévaloir. La présente étude examine cet aspect au moyen d'analyses par éléments finis non linéaires tridimensionnels d'expériences de vibration libre à l'échelle réelle sur une structure en colonnes d'acier. La structure a des dimensions extérieures de 3×3×5 m et repose sur une fondation peu profonde au-dessus d'un dépôt de sol meuble. Les analyses numériques se concentrent sur les expériences de modélisation des forces d'excitation de différentes magnitudes, afin de permettre l'étude du système ISS pour une large gamme de déformations. Les modèles non linéaires cycliques, qui sont généralement utilisés dans l'analyse numérique pour prédire le comportement hystérétique des sols, peuvent bien simuler la dégradation de la rigidité (G-γ) ou l'évolution de l'amortissement (D-γ) avec la déformation cyclique de cisaillement. Les données expérimentales sur les mouvements forts sont comparées aux résultats numériques d'analyses qui adoptent différentes courbes G-γ-D pour le sol de fondation peu profond. Cette étude révèle que le choix des courbes G-γ-D affecte de manière significative la réponse en vibration libre du ISS, soulignant l'importance de modéliser de manière appropriée le comportement non linéaire du sol peu profond. Elle suggère également que la priorité donnée à l'étalonnage de la courbe D-γ par rapport à la courbe G-γ est plus applicable pour la plupart des expériences modélisées.

Keywords: Dynamic soil-structure interaction; finite element modelling; real-scale experiments; soil nonlinearity; constitutive model calibration.

1 INTRODUCTION

The significant role of soil nonlinearity on the dynamic response of soil-structure-interaction (SSI) systems with shallow foundations has been demonstrated in various studies in the past (e.g. Anastasopoulos et al., 2011; 2014; Gazetas et al., 2013). Most of these

studies focused on large strain problems, where soil plasticity is significantly engaged, however, soil nonlinearity associated with the small strain response has attracted less attention.

In problems dominated by the nonlinearity of soil behaviour at small strains, it is important to consider an appropriate set of stiffness degradation and damping ratio (G-γ-D) curves, due to the very limited linear elastic strains in such soils (e.g. Darendeli, 2001; Vucetic, 1993). Cyclic nonlinear models that are typically used in such analyses can simulate well either the stiffness or the damping curve (Taborda and Zdravkovic, 2012). It has been shown that the accurate prediction of the damping curve should be prioritised in free-field site response problems (e.g. Han et al., 2016; Papaspiliou et al., 2012), however there are no similar studies for SSI problems.

The present study discusses 3D nonlinear finite element (FE) simulations of real-scale free vibration tests on the prototype structure of EUROPROTEAS. Particular emphasis is placed on modelling the soil behaviour, investigating the impact of adopting different calibrations for the G-γ-D curves.

2 EXPERIMENTAL CAMPAIGN

2.1 Structure and experimental set-up

The examined structure is the prototype EUROPROTEAS structure that is 5m tall and 3 x 3m in plan. This frame structure comprises four steel columns (SHS 150 x 150 x 10mm), adjustable steel cross bracing system (L-shape 100 x 100 x 10mm), a reinforced concrete mat foundation (9Mg) and adjustable superstructural mass. Although different structural configurations were examined, the present study refers to one configuration only: a structure braced at all four sides and a superstructural mass of 18Mg (Figure 1).

The wider experimental campaign consisted of free and forced vibration tests (Koronides et al., 2023a), with the present study focusing on the former tests. The free vibration tests involved the application of a pull-out force at 9˚ angle to the horizontal plane on the top slab (Figure 1), via a wire rope tensioned by a pulling hoist. The force was measured in-situ by a load cell and upon reaching the desired magnitude, the wire was instantly cut, enabling the structure to oscillate until it came to rest. In both test types, the force was applied along the NS plane of symmetry of the structure, with reference to the coordinate system shown in Figure 1. The response of the SSI system was monitored by a comprehensive instrumentation that was placed on both the structure and the soil.

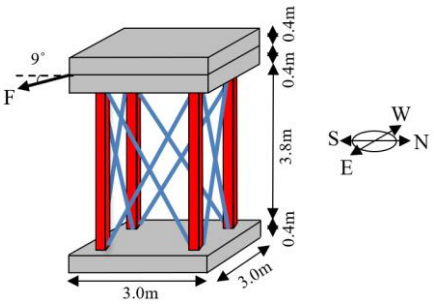

Figure 1. EUROPROTEAS' structural configuration.

2.2 Soil conditions

EUROPROTEAS is located at the TST site, the centre of Euroseistest site, within a valley in Northern Greece. The geotechnical and geological properties of the site are well documented by previous surveys (e.g. D. Pitilakis et al., 2018; K. Pitilakis et al., 1999), with Figure 2(a) and (b) presenting the resulting soil stratigraphy and shear velocity profiles, respectively. The shallow soil layers mainly consist of silty sand and low plasticity clay of very low stiffness, a condition that is anticipated to amplify SSI effects. The geotechnical site characterisation encompassed also resonant column and cyclic triaxial tests for soil samples retrieved from various depths, some of which are indicated in Figure 2(a). These tests produced stiffness degradation and damping ratio curves (G-γ-D) for the corresponding soil layers. The process of projecting the G-γ-D curves from lab conditions to site conditions is described in Koronides et al. (2023a).

Figure 2. (a) Soil stratigraphy, (b) shear wave profiles proposed by (i) K. Pitilakis et al. (1999), (ii) Raptakis et al. (2000) and (iii) Raptakis and Makra (2015).

3 NUMERICAL MODEL

Free vibration simulations were carried out using the Imperial College Finite Element Program (ICFEP) (Potts & Zdravković, 1999). Each simulation consists of three phases: a static phase where the deadloads are applied, a static phase where the pull-out force is

applied, and a dynamic phase where the free oscillation of the structure is computed.

3.1 Problem geometry and boundary conditions

The numerical model simulates only the half of the domain, exploiting the symmetry of the problem. Figure 3 presents the 3D mesh, dimensions and some of the boundary conditions.

The simulated soil domain has dimensions 15 x 7.5 x 6m, which were found to produce neglible boundary effects on the structural response and tolerable effects on the soil response. The 6m deep soil domain is divided into two soil layers (Figure 3a), as identified from the experimental studies, the results of which are shown in Figure 2(a). The domain consists of 20-noded brick elements, the size of which was based on the guidelines of Kuhlemeyer and Lysmer (1973). The corner nodes of the bottom boundary of the soil domain are fully fixed, while all nodes at the plane of symmetry (including the soil, base and top slab and braces) are fixed in the out-of plane (y) direction only. Dashpots and springs (Kontoe, 2006) are applied along the normal and tangential directions on the remaining soil boundary nodes, except those at the ground surface.

The numerical model explicitly simulates the dimensions of the actual structure (Figure 3(b)). The foundation and top slabs are modelled with 20-noded brick elements, while the steel columns and braces with 3-noded beam elements. To establish a moment connection between the columns and slabs, the beam elements of the columns extend into the brick elements of the slabs. The stiffness of the extended beam elements and the damping (ξ) of concrete and steel were calibrated in Koronides et al. (2023a). The remaining structural properties are chosen in accordance with modern regulations (i.e. British Standards Institution, 2004, 2005). All structural elements are assumed to be linear elastic, with their properties, including Young's modulus (E), Poisson's ratio (ν), density (ρ), cross sectional area (A), moment of inertia (I), torsional constant (J) and target Rayleigh damping (ξ), given in Table 1.

The excitation pull-out force (F) is applied at a node of top slab that lies in the plane of symmetry, as shown in Figure 3(a). Two free vibration experiments of 2.9kN and 15.7kN pull-out force are simulated. However, considering that only half of the problem geometry is modelled, half of the above magnitudes was applied in each analysis.

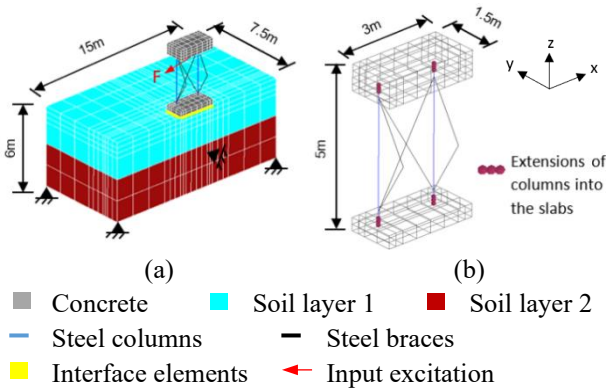

Figure 3. FE mesh, dimensions and some boundary conditions of the simulated experiments: (a) SSI system, (b) Structure.

3.2 Soil-foundation interface model

As discussed by Koronides (2023), field observations as well as strong motion data interpretation indicated permanent gap areas at the interface between the foundation and the soil. These played a crucial role in the response of the SSI system. The gap distribution and the interface model were calibrated by Koronides et al. (2022a, 2023a) against forced vibration measurements. The resulting distribution of permanent gaps is illustrated in Figure 4. Koronides et al. (2023b) demonstrated that during the various experiments carried out in the experimental campaign, temporary detachment and re-attachment of some foundation areas took place. However, they illustrated that for the present experiments, the above foundation behaviour could be reasonably neglected to reduce the computational cost. Therefore, the present analyses assume permanent interface gaps at the positions shown in Figure 4. only. For the interface model, elastic zero thickness interface elements (Day and Potts, 1994) are employed. These are characterised by shear and normal elastic stiffnesses, K_s and K_n, which control the relative elastic displacements between the foundation and the soil. A stiffness value of $K_s=K_n=1E8kN/m^3$ was adopted for the contact area, whereas $K_s=K_n=1E2kN/m^3$ was used for the non-contact area. The reduced interface stiffness of the latter area was shown equivalent to simulating permanent gaps, but at lower computational cost (Koronides et al., 2022b; 2023a; 2023b).

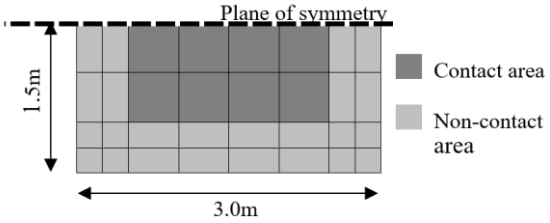

Figure 4. Permanent contact conditions at the soil-foundation interface.

3.3 Nonlinear soil constitutive model

Koronides (2023) showed that for the examined SSI problem, soil nonlinearity extends within a very shallow soil zone. Herein, the first 0.8m of the soil domain is assumed to behave as nonlinear elastic material, while the remaining soil domain is prescribed as linear elastic. Table 2 presents the soil properties of the two layers at very small strains, that were inferred from previous site characterisation studies (Figure 2(b)). A target Rayleigh damping (ξ) of 5% was selected for the linear soil.

Table 2. Small strain soil properties.

	E (MPa)	ν	ρ (Mg/m^3)
Layer 1	100	0.25	2.0
Layer 2	186	0.20	2.1

For the nonlinear soil, the Imperial College Generalised Small Strain Stiffness (IC.G3S) model (Taborda et al., 2016) is used. The model prescribes the G-γ-D curves based on a predefined set of parameters. Figure 5 presents the three different G-γ-D curves, whose effect on the SSI response is investigated herein. These are compared with the reference curves, which were interpreted from resonant column and cyclic triaxial tests.

This type of cyclic models can describe well either the damping or shear stiffness curve, which is deemed the most important consideration on the calibration of the model's parameters. As Figure 5 shows and as highlighted by Taborda and Zdravkovic (2012), if the calibration prioritises the shear stiffness degradation curve (CalibrG), the soil damping is highly underestimated and highly overestimated at the very low and medium strain range, respectively. When, though, the calibration prioritises the damping ratio curve (CalibrD), the model underestimates the soil shear stiffness over the very small to small strain range. To further examine the impact of damping on the SSI response, an additional set of G-γ-D curves that predict a stiffness curve similar to CalibrD, but overestimates damping over a wide range of strains (CalibrDO) is also examined.

The adopted nonlinear constitutive model assumes soil shear stiffness as a function of mean effective stress. This is of paramount importance in SSI problems, where the presence of a structure contributes to a stiffer foundation soil in relation to the free-field conditions, affecting the response of the system.

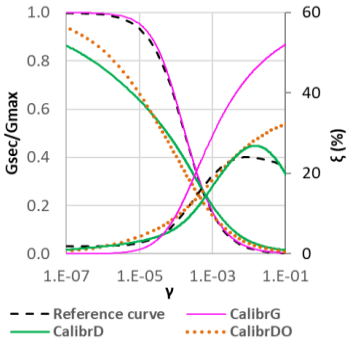

Figure 5. Examined calibrations of stiffness degradation and damping ratio curves.

4 RESULTS AND DISCUSSION

Figure 6 presents acceleration time histories and the corresponding Fourier spectra recorded at the top slab during the free vibration experiments of pull-out forces 2.9 and 15.7kN, as well as the linear elastic prediction. The accelerations were normalised by the magnitude of the pull-out force to allow comparison between different experiments, with any differences being attributed to nonlinear phenomena. The figure demonstrates that when larger pull-out force was applied, the response was more flexible and lower in amplitude. Possible nonlinearities are soil nonlinearity, interface nonlinearity and structural elements' nonlinearity. The latter is assumed negligible due to the weak bending of the structural elements (Koronides, 2023). Also, as shown by Koronides et al. (2022a; 2023a; 2023b), if interface nonlinearity was predominant, it would have led to a smaller interface contact area and, consequently, weaker radiation damping, resulting in motion amplification. This expectation contradicts the observed de-amplification, suggesting that the observed nonlinear phenomena can be predominantly assigned to soil nonlinearity. Figure 6 also demonstrates that a linear elastic analysis overpredicts both the natural frequency and the magnitude of the

SSI response, highlighting the necessity of incorporating soil nonlinearity.

*Figure 7*Figure 7 presents acceleration time histories and the corresponding Fourier spectra inferred from nonlinear analyses that assume different calibrations for the G-γ-D curves. CalibrG analysis predicts a larger natural frequency for both the small and larger strain response (i.e. F=2.9kN and F=15.7kN, respectively) and, most importantly, it strongly overdamps the motion of the system subjected to a larger force (i.e. F=15.7kN, shown in Figure 7b). Conversely, when the calibration prioritises the damping curve, e.g. CalibrD, the analysis accurately predicts the magnitude and frequency of both experimental responses. This observation demonstrates that, in SSI problems, the calibration of the G-γ-D curves should prioritise capturing the experimental damping curve well, accepting the limited consequences of underestimating the shear stiffness curve.The importance of damping in the examined SSI problem is further corroborated by the comparison of CalibrD and CalibrDO results. The two analyses predict similar response frequency, as a consequence of their similar soil stiffness simulation. However, CalibrDO, which overestimates damping, results in response overdamping for both small strain (i.e. F=2.9kN) and larger strain response (i.e. F=15.7kN). Hence, it can be concluded that a seemingly small damping overestimation can lead to significant errors, emphasizing the critical need for accurately simulating soil damping.

5 CONCLUSIONS

Three-dimensional FE simulations of real scale free vibration experiments have been presented. Although the field experiments induced small strains in the soil, soil nonlinearity was important, as indicated by both numerical and experimental data evidence.

Numerical results from analyses that adopt different calibrations for the G-γ-D curves were compared, demonstrating the necessity to simulate the damping behaviour of the soil appropriately. In fact, it is suggested that the calibration of cyclic nonlinear models should prioritise capturing the damping curve, even at the cost of underestimating the stiffness curve.

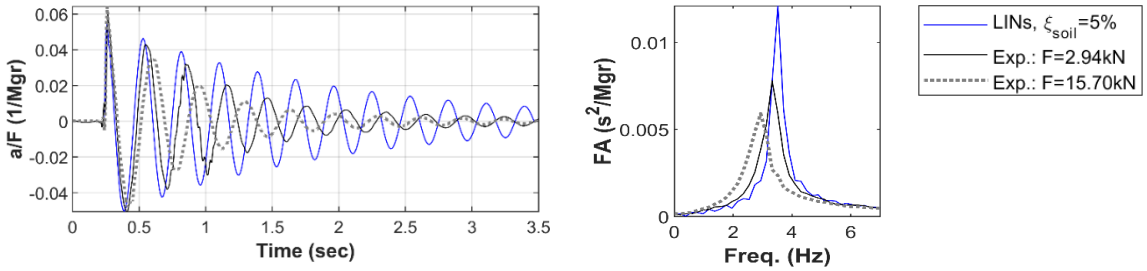

Figure 6. Normalised top slab acceleration time histories and the corresponding Fourier spectra inferred from linear analysis and experimental data.

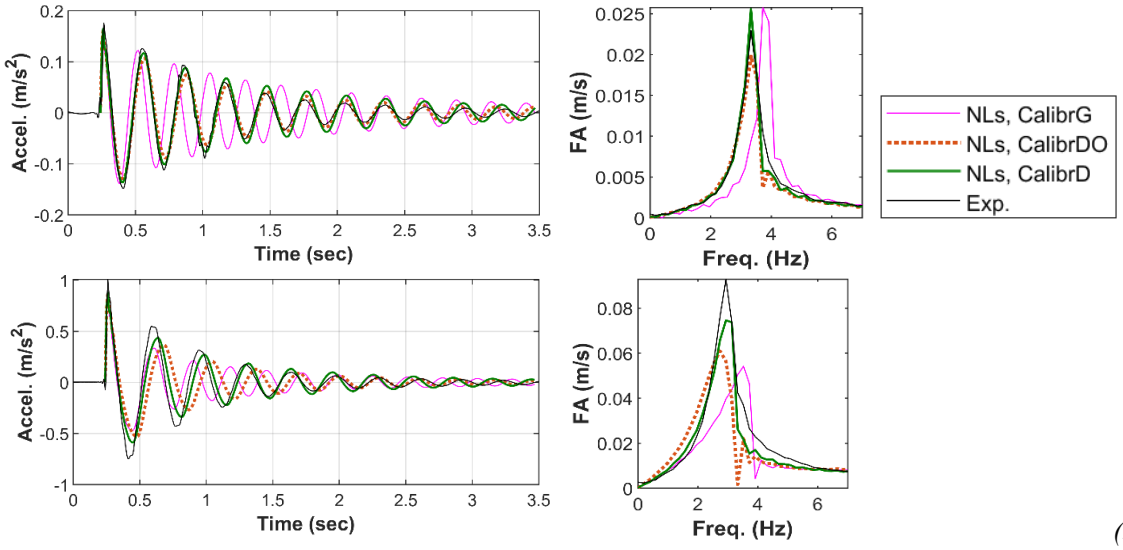

(a) F=2.9kN

(b) F=15.7kN

Figure 7. Top slab acceleration time histories and the corresponding Fourier spectra inferred from experimental data and nonlinear analyses with different calibrations.

The latter conclusion aligns with similar conclusions drawn from free-field site response analyses (e.g. Han et al., 2016; Papaspiliou et al., 2012).

Particle size distribution induced fabric effects on the onset and post liquefaction behaviours of soils

La distribution granulométrique induit des effets de tissu sur le comportement initial et post-liquéfaction des sols

J. Leak*, D. Barreto

**J.leak@napier.ac.uk*

ABSTRACT: Liquefaction in soils is a detrimental phenomenon. Microscale behaviours and their influence on the macroscale response during and after the onset of liquefaction are not well understood. In particular, how contact behaviours effect macroscale properties such as gains in shear strength following the onset of liquefaction. Soil characteristics such as particle size distribution (PSD) are known to have important roles in determining a soils susceptibility to liquefaction. In this study, Discrete Element Simulations (DEM) are undertaken on soils with different PSDs to investigate how contacts at the microscale are influenced by PSD and how this influences the macroscale response. Consideration is given to these behaviours before and after the onset of liquefaction to gain insight into post-liquefaction strength behaviour. Using grading entropy coordinates, it is suggested that the PSD plays a key role in a soils ability to resist liquefaction. Larger grains appear to provide greater stability and an ability gain interparticle contacts post-liquefaction. This greater stability is suggested to come from the grain structure resisting being broken and remade during liquefaction, manifesting in greater isotropy throughout loading. Whereas soils with smaller PSDs are more prone to having their grain structure broken and remade, enabling them to become significantly more anisotropic, this appears to inhibit the ability to regain interparticle contacts.

RÉSUMÉ: La liquéfaction des sols est un phénomène néfaste. Les comportements à l'échelle microscopique et leur influence sur la réponse à l'échelle macro pendant et après le début de la liquéfaction ne sont pas bien compris. En particulier, comment les comportements de contact affectent les propriétés à l'échelle macro, telles que les gains de résistance au cisaillement après le début de la liquéfaction. Les caractéristiques du sol telles que la distribution granulométrique (PSD) sont connues pour jouer un rôle important dans la détermination de la susceptibilité des sols à la liquéfaction. Dans cette étude, des simulations d'éléments discrets (DEM) sont entreprises sur des sols présentant différentes PSD pour étudier comment les contacts à l'échelle microscopique sont influencés par la PSD et comment cela influence la réponse à l'échelle macro. Ces comportements sont pris en compte avant et après le début de la liquéfaction afin de mieux comprendre le comportement en matière de résistance après liquéfaction. En utilisant les coordonnées entropiques de gradation, il est suggéré que la PSD joue un rôle clé dans la capacité des sols à résister à la liquéfaction. Les grains plus gros semblent offrir une plus grande stabilité et une capacité à gagner des contacts interparticulaires après liquéfaction. Il est suggéré que cette plus grande stabilité provienne du fait que la structure des grains résiste à la rupture et à la reconstruction lors de la liquéfaction, se manifestant par une plus grande isotropie tout au long du chargement. Alors que les sols avec des PSD plus petits sont plus susceptibles de voir leur structure granulaire brisée et refaite, ce qui leur permet de devenir significativement plus anisotropes, cela semble inhiber la capacité à retrouver les contacts interparticulaires.

Keywords: Liquefaction; particle size distribution; grading entropy; soil fabric.

1 INTRODUCTION

Susceptibility to liquefaction can be determined with reference to a soils particle size distribution (PSD). Regarding this approach several methods have been proposed (e.g. Tsushida & Hayashi, 1971). The abundance of PSD based susceptibility criteria clearly indicate that a relationship exists between the initiation of liquefaction and grain size. Barreto et. al. (2019) assessed different susceptibly criteria using the grading entropy method proposed by Lőrincz (1986). This study affirmed a clear relationship between the entire PSD (i.e. including fines and gravel content) and liquefaction susceptibility, with reference to the grading entropy stability criteria. Moreover, the study highlighted the benefits of the grading entropy coordinates as a PSD based susceptibility criteria.

There is evidence to suggest that a relationship between PSD and increases in post-liquefaction shear

strength exist also. Whilst aspects such as confining stress, void ratio or relative density, fines content etc, are highly influential, PSD appears to be an important factor in the initiation of liquefaction and its ability to regain its strength following failure, via rebuilding interparticle contacts. It was discussed by Manmatharajan et al. (2023), that amongst varying PSDs, coarser well-graded PSDs showed greater post-liquefaction shear strength, particularly when compared to PSDs with the presence of fines, and poorly graded soils.

It has also been suggested that post-liquefaction shear strength may in part also be related to the orientation in particle fabric. For example, Wang et al (2020) investigated the post liquefaction shearing resistance of gravelly soils and found that the more anisotropic a soil is, the greater the difficulty it exhibits rebuilding shear strength and stable inter-particle particle contacts – leaving the soil vulnerable to secondary liquefaction. This was something also suggested by Otsubo et al. (2022), who stated that soils with a greater inherent isotropic fabric may have the potential to exhibit greater liquefaction resistance.

This study investigates the effect of PSD on the initiation and post-liquefaction contact behaviours of soils. Emphasis is placed on the influence of PSD and fabric behaviours, and exploring the role this plays in the development of liquefaction and a soils ability to regain interparticle contacts following failure. In this work, the entire PSD is assessed using grading entropy coordinates, enabling for the entire PSD to be represented.

2 GRADING ENTORPY

Proposed by Lőrincz (1986), grading entropy condenses the entirety of a PSD to a single point on a Cartesian plane. This is achieved by accumulating the information entropy within each soil fraction to ascertain the total grading curve entropy. The total grading entropy can then be split into two components which form a coordinate pair:

$$S = \Delta S + S_0 \tag{1}$$

where S is the total grading entropy, ΔS is the entropy increment, typically on the y-axis, and S_0 is the base entropy typically on the x-axis. The base entropy (S_0) is a logarithmic mean of the average grain diameter relating to the skewness of the PSD. ΔS is a measure of how much a PSD is influenced by all its fractions and relates to the kurtosis of the PSD.

ΔS and S_0 have normalised counterparts, where $0<A<1$ and $0<B<B_{max}$ 1.41. A is the normalised base entropy and B is the normalised entropy increment, given by:

$$A = \frac{S_0 - S_{0min}}{S_{0max} - S_{0min}} \tag{2}$$

$$B = \frac{\Delta S}{\ln(N)} \tag{3}$$

where N is the number of sieve fractions in the PSD. Whilst grading entropy coordinates may be related to commonly used descriptors, it should be noted that in contrast to these, ΔS, S_0 and A, B involve information about the entire PSD, not just specific particles diameters (e.g., d_{10}, d_{30}, d_{50}, d_{60}) and enables for the direct consideration of both fines and gravel content with no need for additional descriptors. In this study, only the normalised coordinates are used.

3 DEM SIMULATIONS & PSDs

Undrained monotonic DEM simulations were performed using the open-source software YADE. Specimens were randomly generated within cubical periodic boundaries and isotropically compressed prior to triaxial loading under constant volume conditions. A summary of the DEM input parameters is shown in Table 1.

Table 1. DEM Input parameters.

Description	Value
Confining Stress	200 kPa
Poisson's ratio (ν)	0.22
Particle density (ρ)	2650 kg/m^3
Inter-particle friction (μ)	26.6°
Young's Modulus (E)	70 GPa
Unbalanced force ratio	0.0001

These parameters where chosen to represent realistic values that have been measured experimentally by other researchers. Simulations were undertaken on uniform PSDs containing a single fraction, which are shown in Table 2:

Table 2. PSD ranges and entropy coordinates.

ID	Range	A	B
A1	1-2	1	0
A2	0.5-1	0.75	0
A3	0.25-0.5	0.5	0
A4	0.125-0.25	0.25	0
A5	0.0625-0.125	0	0

4 RESULTS

Figure 1 shows the deviatoric stress (q) during the first 5% axial strain (ε_a):

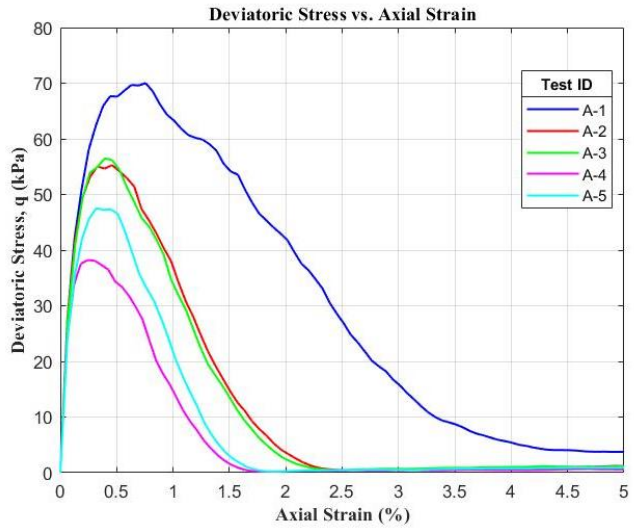

Figure 1. Deviatoric stress during the first 5% axial strain.

In all specimens but A-1, the deviatoric stress increases after the initiation of loading, but immediately reduce to near zero around 1.5% - 2.5% axial strain. Specimen A-1 shows the highest peak stress, followed by A-3, A-2, A-5 and A-4. Generally, as the A-coordinate increases, q_{peak} also increases, highlighting a relationship between stability and grain size. A-1, with the largest grain size, does not drop to a state $q=0$, indicating that it underwent more stable behaviours. Specimens A-2 and A-3 share similar stress relationships, with A-3 experiencing a slightly higher peak stress.

Figure 2 shows the initial mechanical coordination number (Zm_0) plotted with each specimen A-coordinate.

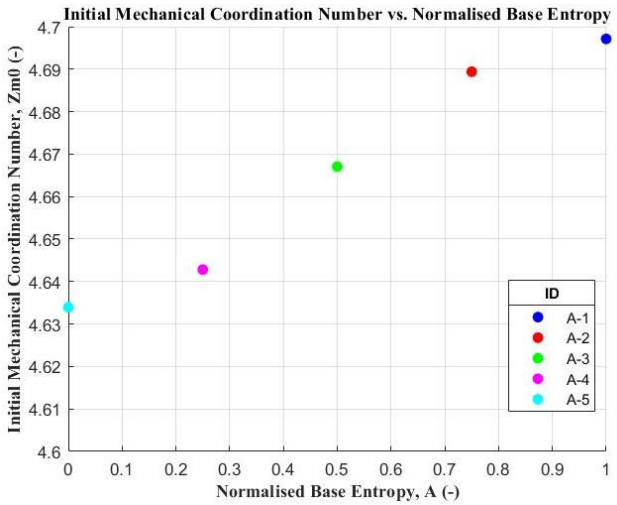

Figure 2. Initial mechanical coordination, Zm_0, number with normalised base entropy, A.

There is a relationship between the Zm_0 and decreasing A-coordinates. In other words, as the PSD decreases the specimens exhibit fewer stable tendencies. Note that these decreases in the Zm_0 align with the decreases in q_{peak} seen in Figure 1. It is suggested that as a result of changing the PSD, the ability for stress transmitting contacts to form is reduced; thus reducing the overall stability of the soil.

In Figure 3, to understand the contact behaviour at the initiation of liquefaction, Zm values corresponding to the minimum mean effective stress (p') in each specimen are plotted against their A-coordinates, i.e. the initiation of liquefaction. The decrease in Zm at the onset of liquefaction follows the same relationship seen in Figure 2, with Zm_0, indicating that the PSD influences stability (by means of particle contacts) during the initiation of liquefaction and this may be an inherent property of different PSDs. Whilst further research is needed, the results presented here may indicate that the threshold coordination discussed by Wen and Zhang (2022), amongst others, may be PSD dependant, at least under monotonic conditions.

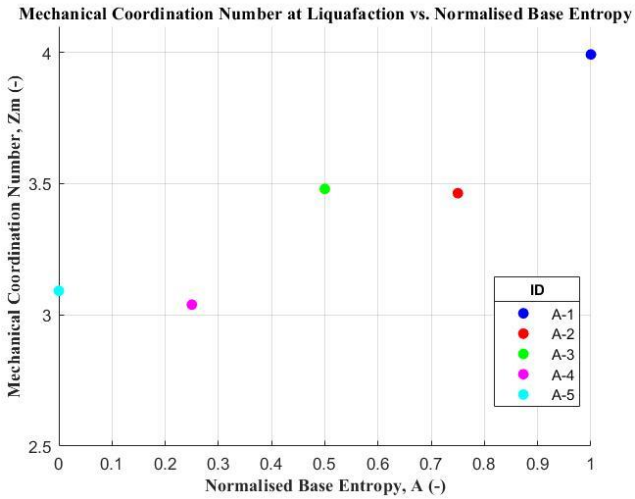

Figure 3. Mechanical coordination number, Zm at the initiation of liquefaction with normalised base entropy, A.

The figures thus far indicate that a correlation exists between the PSD and the stability of a soil during the initiation of liquefaction. This correlation may further be understood with reference to the deviatoric fabric component of the 2nd order fabric tensor (Φ_d), discussed by Satake (1982).

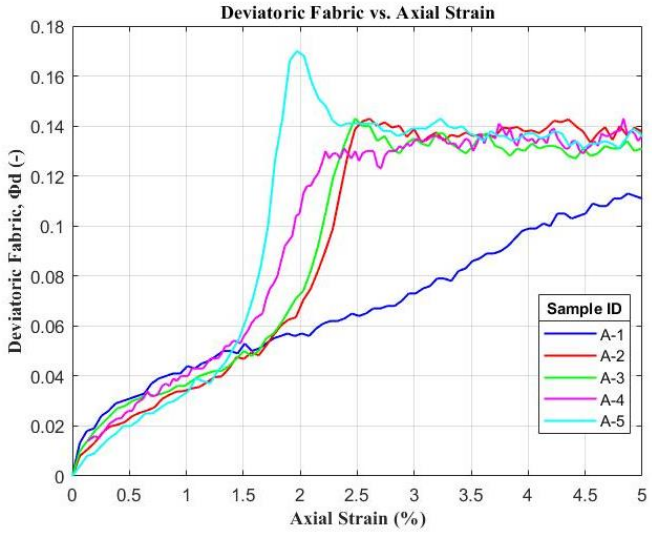

Figure 4. Deviatoric fabric during the first 5% axial strain.

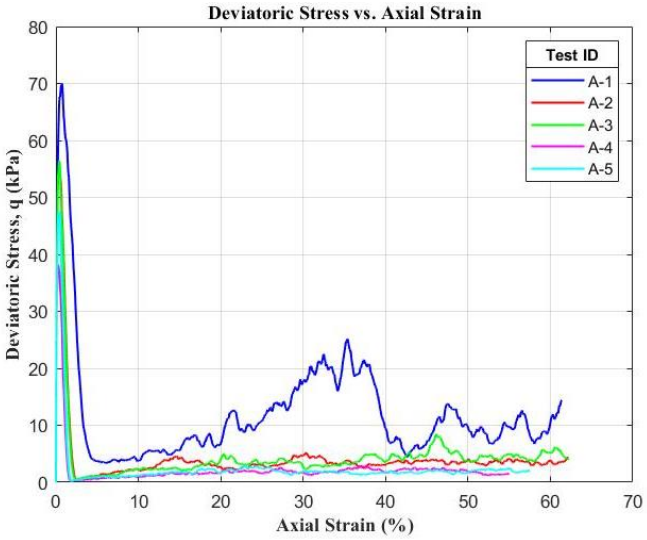

Figure 5. Deviatoric stress vs axial strain to simulation termination (55% - 60% strain).

Specimen A-1 shows a steady increase in Φ_d throughout the first 5% strain. Before q_{peak} at around 0.5% strain, A-1 has the largest Φ_d. In other words, it is the most anisotropic specimen at this point. It is important to note that changes in anisotropy in this work are not due to changes in stress path but are instead a result of changing PSD. A-1 is the most anisotropic specimen up to 1.5% strain. Following failure (2% - 2.5% strain), A-1 shows the lowest values of Φ_d, despite initially showing the largest values of Φ_d prior to failure. Despite this shift, A-1 presents a steadily growing fabric network as strain increases. Other specimens in Figure 4 show the opposite behaviour. They are generally more isotropic prior to failure but following the onset of liquefaction a notable shift in the fabric structure takes place and all specimens (except A-1) rapidly become significantly more anisotropic as their initial fabric was broken.

Figure 5 shows the q-ε_a relationship until a termination strain of 60%. The figure indicates that the initial fabric behaviours are evidently important throughout entirety of loading. Following failure, specimen A-1 exhibits large fluctuations in deviatoric stress indicating that within this specimen, new interparticle contacts were able to be created following failure. Specimen A-1 has been shown to be the most stable PSD throughout this work, which is also indicated by its drop to only around 5 kPa as opposed to near 0 kPa. The fluctuations in stress between 25% - 40% strain highlight the specimens inherent stability, which appears to be related to its ability to retain its grain structure. Whilst other specimens show some slight increases in stress post failure, it is evident that the change in the fabric structure at 2% - 2.5% strain has inhibited these specimens ability to regain interparticle contacts.

5 DISCUSSION AND CONCUSIONS

This work has presented undrained monotonic DEM simulations of 5 PSDs. A relationship has been seen between grain size and stability/resistance to liquefaction. By examining the contact behaviours, it is suggested that larger average grain sizes can greatly increase a soils stability by enabling the soil fabric structure to resist breaking and thus rearrangement, likely as a result of creating strong fabric networks. It was seen in A-1, with the largest grain size, that this specimen steadily increased its contact network following failure. Whereas specimens with smaller grains had their contact network broken, which inhibited their ability to regain contacts following liquefaction.

This also appears to be related to the anisotropy of the grains. Breaking the fabric network made it so that soils which initially showed greater degrees of isotropy become significantly more anisotropic during liquefaction. Whereas A-1, which initially showed the greatest anisotropy, became the most isotropic specimen following failure and was the most stable specimen. These results indicate that anisotropy in soils, resulting from PSD alone, may render soils more susceptible to liquefaction.

ABSTRACT: The catastrophic effects of seismically induced liquefaction recently observed during the Kahramanmaraş sequence (Turkey, 2023) confirmed the need of effective tools for predicting the effects of soil liquefaction on the built environment, to be used at the design stage. The main factors governing the seismic response of buildings founded on liquefiable sandy deposits are nowadays recognised. It is clear that the prediction of the damages depends on the correct estimation of earthquake induced excess pore water pressures Δu within the soil deposit, which cause the loss of soil shear strength and stiffness during the seismic shaking. While in free field conditions there are many models developed in literature able to predict the pore pressure ratio build-up ($r_{u,ff}$) induced by cyclic loading, the correct prediction underneath the footing ($r_{u,st}$) is a rather complex topic, still deserving research insight. By processing published centrifuge tests data, the paper proposes a simple expression of β (= $r_{u,st}/r_{u,ff}$) as a function of some relevant factors affecting the stress state within the liquefiable soil during the seismic shaking, grouped in a single, dimensionless parameter (Ψ).

RÉSUMÉ: Les effets catastrophiques de la liquéfaction induite par un tremblement de terre, récemment observés dans la séquence de Kahramanmaraş (Turquie, 2023), ont confirmé le manque d'outils efficaces pour prédire les effets de la liquéfaction du sol sur l'environnement bâti. La recherche expérimentale des dernières décennies a permis d'identifier les principaux aspects régissant la réponse des bâtiments et la manière dont leur comportement diffère des simples conditions de terrain libre. Il est clair que la prévention des dommages dépend de l'estimation correcte de la surpression de l'eau interstitielle induite par le tremblement de terre Δu dans le dépôt de sol, qui entraîne la perte de résistance et de rigidité du sol pendant la secousse sismique. Alors qu'en condition FF, il existe de nombreux modèles de génération de pression d'eau interstitielle capables de prédire l'accumulation de pression interstitielle induite par une charge cyclique ($r_{u,ff}$), la prédiction correcte sous la fondation ($r_{u,st}$) est un sujet plutôt complexe qui mérite encore d'être approfondi par la recherche. En traitant certaines données d'essais de centrifugation de la littérature, l'article propose une expression simple of β (= $r_{u,st}/r_{u,ff}$) en fonction de certains facteurs pertinents affectant l'état de contrainte dans le sol liquéfiable lors de la secousse sismique.

Keywords: Liquefaction, buildings, pore water pressure.

1 INTRODUCTION

Severe damages induced by soil liquefaction have occurred over time during some important earthquakes around the world (Anchorage, 1964; Niigata, 1964; Kobe, 1995; Kocaeli, 1999; Christchurch, 2010-2011; Emilia Romagna, 2012; Palu, 2018, Turkey, 2023). The effects of liquefaction on structures in these areas were catastrophic, with large settlements and rotations of entire structural complexes, leading to a loss of functionality and operative state. Liquefaction ground failure mechanisms (sand boils and cracks, sand ejecta, ground oscillation, settlements, lateral spreads) are due to the temporary transition of the granular soil from a solid to a fluid state because of the earthquake induced excess pore water pressure (Δu). Despite the experimental research efforts conducted in the last decades by many researchers to explain and understand the factors governing the liquefaction phenomena (cyclic liquefaction, cyclic mobility, and flow liquefaction), major gaps still exist regarding the ability to accurately assess liquefaction effects on the built environment (absolute and differential settlements, tilting, horizontal crack). The catastrophic effects of earthquake induced liquefaction recently observed during the Kahramanmaraş sequence (Turkey, 2023) have highlighted once more that all ground failure mechanisms induced by soil liquefaction are of minor interest in free field (FF), while the attention should be devoted to the built environment (i.e. Dashti et al., 2010a; Baris et al., 2021). As stated by Bray and Macedo (2017), liquefaction induced settlements of shallow founded

buildings are caused by shear (partial bearing failure, SSI induced building ratcheting) and volumetric strains (localized sand ejecta, sedimentation, and consolidation phenomena), that combine differently in time.

Figure 1. Example of liquefaction effects on a structure, with large settlements and tilt (Turkey 2023).

The relative relevance of these mechanisms depends on the characteristics of the earthquake motion, depth and thickness of liquefiable layer and building features (Dashti et al., 2010a, b).

This is the reason why the well-known semi-empirical procedure set out to compute the free field post liquefaction re-consolidation settlements (Zhang et al., 2002), usually gives only a rough prediction of the true building settlement. If we consider only the (minor) component linked to the post liquefaction volumetric strains, buildings settle more than the soil in free field conditions, even though is observed in many experiments (Dashti et al., 2010a-b; Bray and Macedo, 2017, Mehrzad et al., 2018) that the pore pressure ratio r_u ($r_u=\Delta u/\sigma'_v$) under them ($r_{u,st}$) is lower than in free field conditions ($r_{u,ff}$). This is due to the difference in the stress state underneath the foundation, linked to the higher vertical stresses ($=\sigma'_{v0}(z)+\Delta\sigma'_v(z)$) and the pre-existing static shear stresses. While in FF condition many excess pore water pressure generation models are nowadays available (Chiaradonna and Flora, 2020, Mele et al., 2022), the correct prediction of the pore pressure ratio underneath the foundation ($r_{u,str}$) is a rather complex topic still deserving research insight. Generally, the pore pressure ratio underneath the structure $r_{u,st}$ is expressed as a portion of the ones in free field $r_{u,ff}$:

$$r_{u,st}(z) = \beta \cdot r_{u,ff}(z) \qquad (1)$$

with $\beta \leq 1$. The knowledge of β is the key point for the estimation of the stress field underneath shallow founded structures and of the linked effects (i.e, vertical settlements, loss of bearing capacity). Experimental evidence (Dashti 2010 a,b, Bray and Dashti 2014, Bilotta et al, 2019, Ntritsos and Cubrinovsky, 2022) highlighted that β is a function of the foundation geometry, the applied load, the depth and thickness of the liquefiable layer, the presence of a non-liquefiable crust, and the seismic demand. Furthermore, $r_{u,st}$ is also affected by the partial drainage phenomenon within the soil volume under and near the building foundation caused by the fact $\Delta u_{,st} \neq \Delta u_{,ff}$.

Based on the results of a wide numerical study, Karamitros et al (2013) confirmed that the ratio between $\Delta u_{,st}/\Delta u_{ff}$ (named A in Figure 2), computed at a representative depth z under the footing, is lower than one, and it is coupled with the normalized seismic settlements (ρ_{dyn}/B). For large settlements ratio, Karamitros et al. (2013) suggest using the conservative value A=0.8 (Figure 2).

Since these indications are mostly based on numerical results, it is extremely relevant to verify them experimentally. To this aim, the paper collects several published centrifuge tests results, checking the effects of all the relevant factors, eventually proposing a simple expression of β as a function of them.

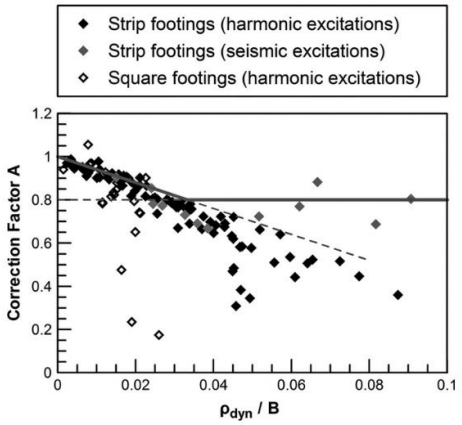

Figure 2. Dependence of the parameter A on the normalized dynamic building settlements (Karamitros et al. 2013) computed at a depth z=D+B, where D and B are respectively the depth and the width of the foundation.

2 EXPERIMENTAL MEASUREMENTS OF THE LIQUEFACTION INDUCED EXCESS PORE WATER PRESSURE

The performance of buildings founded on liquefiable soils has been investigated via centrifuge tests by many authors. In this paper, the well documented centrifuge tests carried out by Dashti (2009, 2010a, 2010b) and Bertalot and Brennan (2015) have been considered and processed.

Dashti (2009, 2010a, 2010b) tested three different (single degree freedom) elastic flexible structures (BLDG A,B and C, Figure 3) placed on a rigid mat

foundation of dimensions B×L loaded with realistic earthquake motions (see Table 1). The water table is at the depth D=1m below the ground level. The names of the tests reported in Table 1 report the thickness of the liquefiable Nevada Sand layer (H_L) and its relative density (i.e., T3-30 has H_L= 3m and Dr=30%). In test T3-50silt, a silty layer has been placed above the liquefiable layer.

The input motions are a scaled version of the ground motions recorded during the Kobe earthquake (1995) and the Chi-Chi event (1999). The objective was to analyse the dynamic response of structures with different degrees of liquefaction, using 'moderate' and 'large' events with different peak base accelerations. (Table 1).

The centrifuge tests carried out by Bertalot and Brennan (2015) involved four rigid square footings with different applied loads (30, 60, 90, and 130 kPa) placed on loose liquefiable sand deposits (Figure 4). The models had 15 m deep deposits of clean sand with a top loose liquefiable layer (Dr=40%) and a bottom dense layer (Dr=80%). The liquefiable layer thickness varied in each model. The input motion chosen was the 2010 Maule earthquake (Table 1).

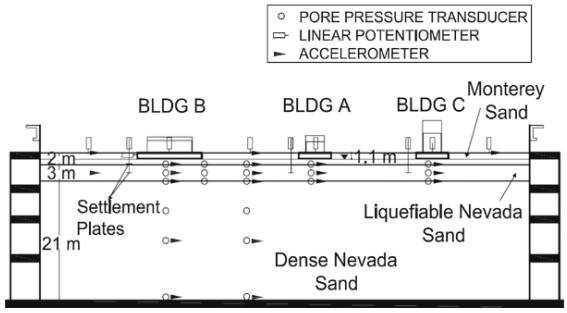

Figure 3. Section of the model used in the centrifuge tests (Dashti et al. 2010a).

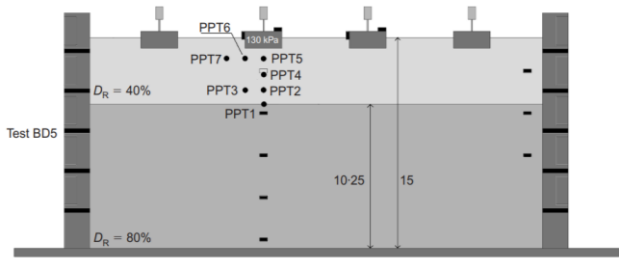

Figure 4. Section of the model used in centrifuge test BD5.

Table 1. Literature centrifuge tests.

Test	a_g (g)	H_L (m)	N_{eq}	q (kPa)	B (m)	L (m)
*T3-30	0.19 - 0.55	3	12-25	80-130	6-12	9-18
*T3-50	0.13 - 0.55	3	12-25	80	6	9

^BD5	0.6	4.75	20	120	2.75	2.75
^BD7	0.6	6.75	20	90	2.75	2.75

(*) Dashti et al. (2009-2010a, b) and Karimi and Dashti (2016)
(^) Bertalot and Brennan (2015)

In all centrifuge tests (Table 1), the excess pore water pressures induced by the imposed seismic demand at different depths under the structures have been measured and compared with the values at the same depth in FF conditions. The following considerations can be drawn to comment the overall results:

- at a given time and depth, $\Delta u_{st} \neq \Delta u_{ff}$;
- if liquefaction is attained, its triggering under the building generally happens at the bottom of the liquefiable layer with a certain time-delay compared to FF conditions (Figure 5);
- the shaking duration has an effect on the proportionality between $r_{u,st}$ and $r_{u,ff}$ (i.e. on β). In particular, when the soil liquefies in FF and $r_{u,st}$<1, the longer the shaking duration the higher the value of β;
- for the given constant stratigraphy, the values of $r_{u,st}$ are mainly affected by the foundation geometry and applied load (as sketched in Figure 6).

3 PROCESSING OF EXPERIMENTAL DATA

For all the selected centrifuge tests (Table 1), the ratio β (eq. 1) has been computed. As previously mentioned, it depends on all the parameters previously reported (i.e., foundation geometry and loads, characteristics of the dynamic action). Therefore, an attempt has been herein done to group them in a single, dimensionless parameter (Ψ) in such a way to correlate it directly to β. A possible form for Ψ is:

$$\Psi = \frac{5 \cdot \left(\frac{\Delta\sigma'_v}{\sigma'_{v0}}\right)^{0.8} \cdot D_r}{\left(a_g \cdot N_{eq}\right)^{0.5}} \qquad (2)$$

where $\Delta\sigma'_v$ is the effective vertical stress increment induced along the foundation axis at each depth z by the building load, $\sigma'_{v,0}$ is the lithostatic effective vertical stress at the same depth, N_{eq} is the equivalent number of cycles, a_g [g] is the non-dimensional peak ground acceleration.

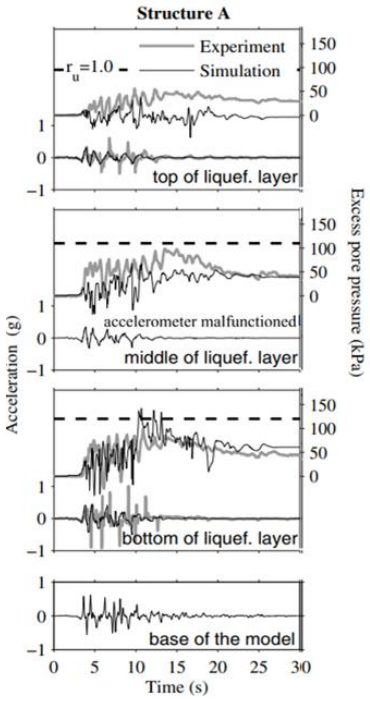

Figure 5. Centrifuge test T3-30, large event (Dashti et al. 2010a): comparison between excess pore water pressures measured under the structure A (at the top, bottom, and middle height of the liquefiable layer).

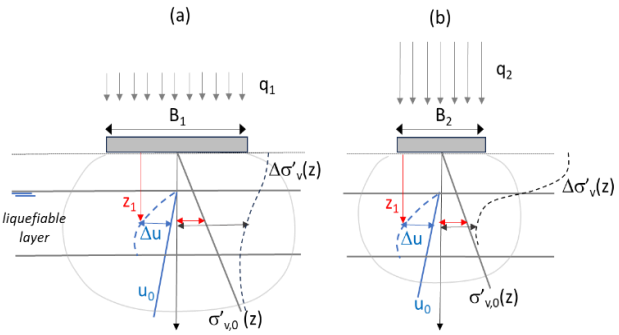

$$r_{u,st\,(z1,a)} < r_{u,st\,(z1,b)}$$

Figure 6. Sketch of the combined effect of the applied loads q and of the foundation width B on the excess pore water pressure ratio underneath the structure ($r_{u,st}$).

Figure 7 reports the experimental values of β as functions of Ψ.

Even though the data show some scatter, likely because of the simple expression adopted for Ψ (eq. 2), they confirm that the pore pressure ratio, underneath shallow founded buildings, differs from the one measured in free field conditions (i.e., β≤1). A clear trend can be also observed: as the parameter Ψ gets larger, the value of β (= $r_{ust}/r_{u,ff}$) clearly decreases. In other words, higher applied loads and/or larger foundations (both increasing the ratio $\Delta\sigma'_v/\sigma'_{v,0}$), and/or seismic actions with lower energy (i.e., with smaller values of N_{eq} and/or a_g) reduce the values of β and therefore of the pore pressure increment ratios underneath the foundation, in comparison to the free field values.

The experimental results also show that the simple indication of β=0.8 by Karamitros et al. (2013), regardless of the seismic actions and of the foundation properties and loads, is a bit oversimplified and can be unnecessarily conservative for Ψ≥1.5.

As a preliminary proposal to overcome this possible excessive overconservativeness, in this paper a simple yet conservative enveloping of the experimental data is proposed:

$$\beta = e^{-0.25\Psi} \qquad (3)$$

Valid for 0≤Ψ≤7, which covers a large part of the possible cases of engineering interest. For values of Ψ>7 it is reasonable to consider β=0.

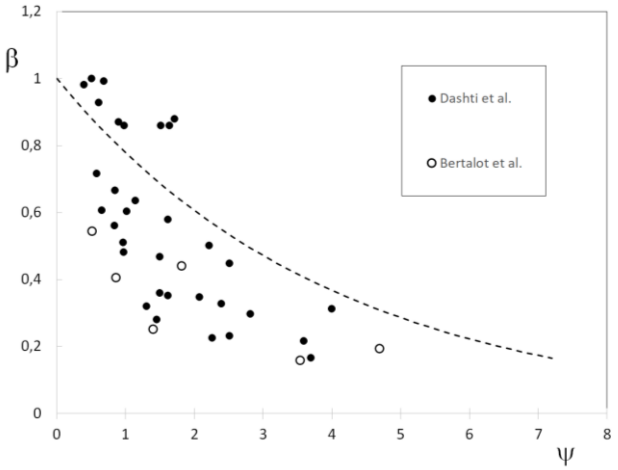

Figure 7. Experimental values of β (β=$r_{u,st}/r_{u,ff}$) measured in centrifuge tests (Table 1) as functions of the dimensionless parameter Ψ (eq.2).

4 NUMERICAL STUDY

A 2D numerical study has been carried out to check the validity of the proposed approach, starting from a simulation of T3-30 (Large P.I. event), and increasing the liquefiable thickness (H_L) to test the goodness of the relationship even deeper. The numerical study has been carried out with the code PLAXIS adopting the PM4Sand soil constitutive model for the liquefiable soil layer. The PM4Sand constitutive parameters (Table 2) have been calibrated on the results of

experimental data (VELACS project, Arulmoli K. 1992). The comparison between the pore pressure ratio time histories recorded (at z=3.5m) during the centrifuge test T3-30 test (Port Island PI large event, characterized by a PGA of 0.55g) and the ones computed by the numerical model (FF condition in Figure 8a, and underneath the structure in Figure 8b), confirm the effectiveness of the numerical model to capture the complex stress state induced by the seismic shaking within the soil volume.

After the calibration of PM4SAND, the numerical study has been extended considering the PI large event and the structure A founded on larger liquefiable soil (i.e., $3<H_L<6$ m). The numerical results in Figure 9, in terms of pore pressure ratio, highlighting how $r_{u,st}$ values. The volume affected is not only that located directly underneath the structure but also that beyond the edges of the structure due to the presence of the shear stresses; as it would be expected, the peak values of r_u in the two adjacent layers at high densities do not exceed values of 0.2-0.3.

Table 2. Calibrated PM4Sand model parameters.

PM4Sand Parameters	Nevada sand			Monterey sand
	Dr 40%	Dr 60%	Dr 90%	Dr 86%
G_0	524	710	1053	1092
hp_0	0.028	0.11	0.008	0.56
pA	101.3	101.3	101.3	101.3
e_{max}, e_{min}	0.78-0.51			0.81-0.51
n_b	0.5	0.5	0.5	0.5
n_d	0.1	0.1	0.1	0.1
ϕ_{cv}	33	33	33	33
ν	0.3	0.3	0.3	0.3
Q	9.5	9.5	9.5	10
R	1.4	1.4	1.4	1.5

The values of β (= $r_{u,st}/r_{u,ff}$) numerically computed at different depths have been reported in Table 3 and compared with the ones given by eq. 3. The numerical results are physically consistent (β_{Num} decreases for increasing values of the parameter Ψ), and β_{Num} is always lower than β_{Comp}, confirming the reasonable conservativeness of eq. (3).

Table 3. Comparison of β derived from eq. (3) and from the numerical analyses.

Ψ	β_{Num}	β_{Comp} (eq. 3)
0.17	1.00	0.96
0.34	0.60	0.92
0.41	0.70	0.90
0.60	0.50	0.86
0.80	0.60	0.81
0.98	0.55	0.78
1.20	0.52	0.74
1.60	0.40	0.67

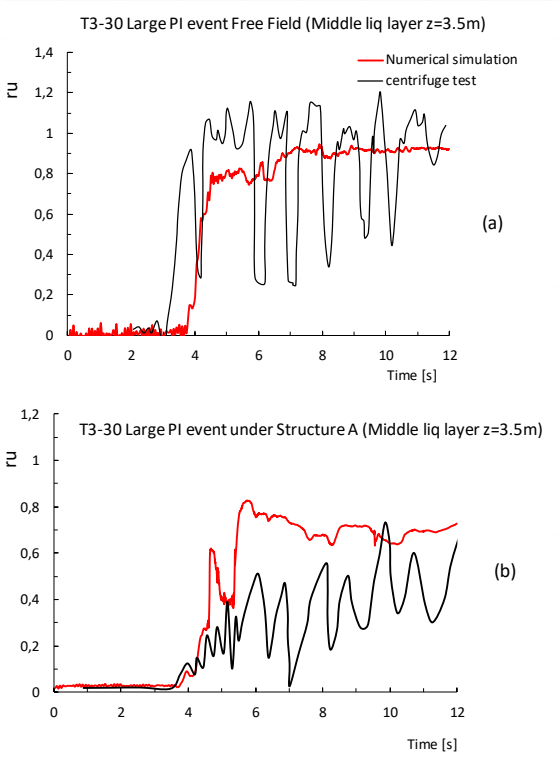

Figure 8. Comparison between the pore pressure ratio time histories recorded during T3-30 test (PI large event) and the numerical results (a: FF condition, b: underneath the structure A) at a depth z=3.5.

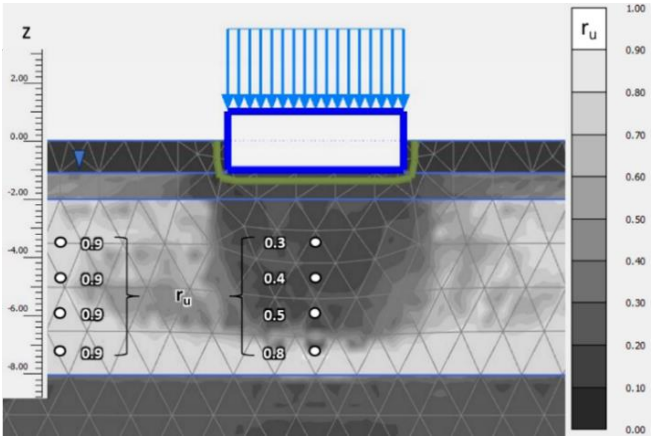

Figure 9. Peak values of the pore pressure ratio computed in the 2D numerical analysis of this work.

5 ACKNOWLEDGEMENTS

This study was carried out within the RETURN Extended Partnership and received funding from the European Union Next-GenerationEU (National Recovery and Resilience Plan – NRRP, Mission 4, Component 2, Investment 1.3 – D.D. 1243 2/8/2022, PE0000005).

6 CONCLUSIONS

Published centrifuge tests have been processed to provide an insight into the prediction of the pore pressure ratio $r_{u,st}$ caused by the seismic excitation of soil layers under shallow founded structures, expressing it as a function of the free field value $r_{u,ff}$ (relatively simply to compute) as $r_{u,st}=\beta \cdot r_{u,ff}$. Even though the considered data set does not cover the whole possible range of values of the involved variables, it is wide enough to conclude that for loose to medium dense soils the parameter β mainly depends on the foundation geometry and loads, as well as on the characteristics of the dynamic action. In this work, these factors were successfully grouped in the non-dimensional parameter Ψ (eq. 2). Figure 7 confirms that β depends on Ψ, allowing to derive a simple relationship between β and Ψ (eq. 3) which can be easily adopted to get a conservative estimate of the excess pore water pressure underneath shallow founded buildings ($r_{u,ff}$).

ABSTRACT: Collapsing gully as an erosional landform with a high sediment transfer rate is causing various hazards. Although it is widely acknowledged that the granite residual soil (GRS), especially its disintegration, plays a critical role, the quantitative characterizations of its disintegration behavior and the underlying mechanism remain to be revealed. In this study, laboratory disintegration tests were performed using a self-developed apparatus on natural GRS collected at various depths. The disintegration process was quantitatively traced through two types of parameters, namely disintegration ratio and disintegration rates. The disintegration behavior of natural GRS is classified accordingly. It is revealed that soil disintegration was triggered by cementation damage upon soaking which broke up the soil aggregates and reduced soil stability. In addition, previous studies overestimated the effect of particle composition on the disintegration of soil. This study provides quantitative characterizations of the disintegration behavior of GRS.

RÉSUMÉ: L'effondrement d'un ravin en tant que relief érosif avec un taux de transfert de sédiments élevé entraîne divers dangers. Bien qu'il soit largement reconnu que les sols granitiques résiduels (GRS), en particulier dans leur désintégration, jouent un rôle critique, les caractérisations quantitatives de leur comportement de désintégration et le mécanisme sous-jacent restent à révéler. Dans cette étude, des tests de désintégration en laboratoire ont été effectués à l'aide d'un appareil développé par nous-mêmes sur du GRS naturel collecté à différentes profondeurs. Le processus de désintégration a été suivi quantitativement à travers deux types de paramètres, à savoir le taux de désintégration et les taux de désintégration. Le comportement de désintégration du GRS naturel est classé en conséquence. Il est révélé que la désintégration du sol a été déclenchée par des dommages de cimentation lors du trempage, qui ont brisé les agrégats du sol et réduit la stabilité du sol. De plus, des études antérieures ont surestimé l'effet de la composition des particules sur la désintégration du sol. Cette étude fournit des caractérisations quantitatives du comportement de désintégration du GRS.

Keywords: Granite residual soil; disintegration; collapsing gully; microstructure; classification.

1 INTRODUCTION

A collapsing gully (CG) is an erosional landform (Xu, 1996) situated above the granite crust with a high sediment transfer rate. In 2005, a national-scale field investigation was performed by the Ministry of Water Resources of China and it is shown that more than 239,100 CGs exist in the south of China (Liang et al., 2009). As one of the most devastating types of soil erosion, CG is believed to be associated with different types of hazards, including soil and water loss, farmland degradation, infrastructure damage, and even loss of life. Specifically, Liang et al. (2009) indicated that the CGs in the south of China have resulted in the loss of more than 60 Mt of soil and 380,000 hectares of farmland, as well as a financial loss of more than 200 million Renminbi. The potential threat of CG has been long realized and researchers have characterized CG including its distribution (Xu, 1996), formation (Luk et al., 1997; Lin et al., 2015), classification (Zhong et al., 2013), development process (Lin et al., 2015), and controlling factors (Deng et al., 2018). However, in recent years, the number and the affected area of CGs still increased remarkably. This phenomenon is likely to be caused by a lack of firm understanding of its formation mechanism. Given that most of the CGs are found to occur in thick granite regolith, granite residual soil (GRS) therefore plays an important role in the formation mechanism serving as material for the CG. GRS is the in-situ product of parent rock weathering and has been studied extensively. The consensus is that this type of soil has fundamentally different geotechnical properties from

common sand and clay because of their difference in forming history (Liu et al., 2022). Despite the extensive studies performed on residual soil, little attention has been paid to the relationship between the geotechnical behavior of GRS and the development of CG. Among all aspects of geotechnical properties, disintegration referring to the crumbling of soil into small fragments and particles when a soil sample is immersed in water is believed to be tightly related to the formation of CGs because it involves soil–water interactions (Shit and Adhikary, 2020). Currently, the systematic information regarding the disintegration of GRS is still to be obtained, perhaps hindered by the limited apparatus available for soil disintegration tests. The test method for rock disintegration has been standardized by the American Society of Testing Methods (ASTM) but this is not the case for soil and only several researchers have performed disintegration tests either qualitatively or semi-quantitatively. For example, Shit and Adhikary (2020) performed disintegration tests on soil collected from a gully erosion area in India. The soil blocks were placed on a metal mesh underwater and the ultimate number of entirely disintegrated soil fragments was chosen to calculate the resistance to disintegration of soil. This method provides qualitative information on soil disintegration but cannot trace the disintegration process of soil quantitatively.

In response, this study investigates the disintegration of GRS collected at different depths quantitatively using a self-made apparatus. The disintegration process was quantitatively traced and three parameters are proposed to reflect soil disintegration rate. In addition, the disintegration rate is correlated to particle composition and shear strength parameters. This study improves the understanding of the soil-water interaction of GRS and the formation of CG.

2 MATERIALS AND METHODS

A typical CG area is selected at Jiangmen in Guangdong Province, China. In Jiangmen city, the total soil erosion area is estimated as 1225.82 km^2 which accounts for ~13% of this city's total area. This study focused on a CG near the Longmen (LM) reservoir (Figure 1), which is one of the largest CGs in this area. The studied CG was found to influence more than 10^5 hectares of farmland, 233 hectares of fishpond, and the safety of a minimum of 4000 local people. Unfortunately, the scale of this CG is still progressing.

A typical weathering profile has been established in this area and the sampling has occurred within the range of residual soil. This study uses a Mazier triple-tube core barrel to collect soil samples continuously from 0.3 to 12 m deep. This method can retrieve undisturbed residual soil which is sensitive to external disturbance. Table 1 lists the variations of clay content and shear strength parameters with depth and more details of soil properties of the studied soil are provided by Liu et al. (2022).

Figure 1. Photograph of CG.

Table 1. Soil index properties.*

Sampling depth (m)	w (%)	Clay content (%)	c' (kPa)	φ' (°)
0.3	40.90	48.7	23.4	26.6
1.3	39.40	42.4	26.3	27.2

12	35.83	10.2	27.1	36.4

*Note: w is the water content; c' and φ' are the effective cohesion and internal frictional angle, respectively.

The disintegration of residual soil is investigated using a purpose-built disintegration test apparatus (Figure 2). The soil specimen (cutting-ring sample, 61.8 mm in diameter and 40 mm in height) placed on a metal frame was immersed in distilled water. Upon the onset of soil disintegration, the produced fragments fall downward through the mesh of the plate. Concurrently, the mass variation of the sample was recorded by a digital dynamometer whose readings were output in real-time to a computer. A digital single-lens reflex camera was used to photograph the morphology of the specimen in the course of disintegration. The disintegration tests were terminated at either complete sample disintegration or a duration of 24 h. This study uses the disintegration ratio R_d and equivalent disintegration rates (v_I, v_{II}, and v_{III}) to quantitatively trace the disintegration process of GRS and the calculation is:

$$R_d = \frac{G' - G}{G' - G_0} \times 100\% \quad (1)$$

$$v_{\mathrm{I}} = \frac{R_{d10}}{t_{R_d=10\%}} \quad (2)$$

$$v_{\mathrm{II}} = \frac{R_{d30} - R_{d10}}{t_{R_d=30\%} - t_{R_d=10\%}} \quad (3)$$

$$v_{\mathrm{III}} = \frac{R_{d50} - R_{d30}}{t_{R_d=50\%} - t_{R_d=30\%}} \quad (4)$$

In Eq. (1), G_0 is the total weight of the float and metal plate. G is the nominal weight of the specimen as a function of time t, which is directly given by the reading of the dynamometer. G' is the initial value of G at $t = 0$. R_{d10}, R_{d30}, and R_{d50} are disintegration ratios of 10%, 30%, and 50%, respectively, and $t_{Rd=10\%}$, $t_{Rd=30\%}$, and $t_{Rd=50}$ is time needed to reach the above R_d values.

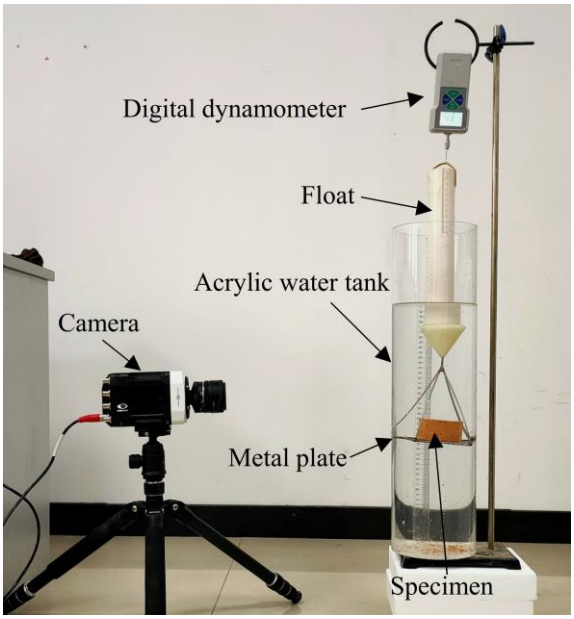

Figure 2. Adopted apparatus for disintegration test.

3 TEST RESULTS AND DISCUSSIONS

The disintegration behavior of natural GRS samples at different depths is given in Figure 3. Figure 4 gives typical photographs of the soil samples during the disintegration process. In addition, the relationships between the soil disintegration rates with the clay content and shear strength parameters are given in Figure 5.

It was found that the soils from a depth of 0.3 m and 1.3 m showed similar disintegration behaviors characterized by rapid climb of R_d to 100% within 5 min. The deeper soils (2 m and 3 m deep) also displayed complete disintegration (R_d = 100%), and the disintegration rate was generally high. Notably, these two samples show a temporary stop of disintegration, with the value of R_d being approximately constant. The GRS soil from the depth of 4.0–8.0 m disintegrated consistently over time but the disintegration rates gradually declined at the end of disintegration with the value of v_{III} being lower than 1%/min. The GRS at a depth of more than 10 m showed incomplete disintegration and the ultimate R_d was ~60%; a disintegration ratio of 100% has not been obtained even after 24 h.

The disintegration of GRS explains the occurrence of the CG. Upon heavy rainfall, the soil becomes rapidly saturated which degrades the cementation of surface soil. Therefore, the soil disintegrated into smaller fragments and particles, which were the major sources of colluvial deposits. These colluvial deposits were then transported to the LM reservoir.

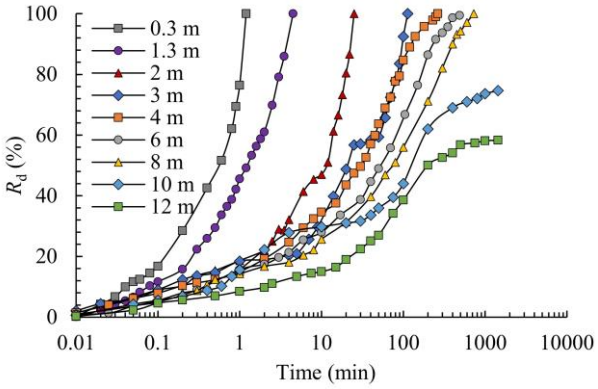

Figure 3. R_d–t curves for GRS from various depths.

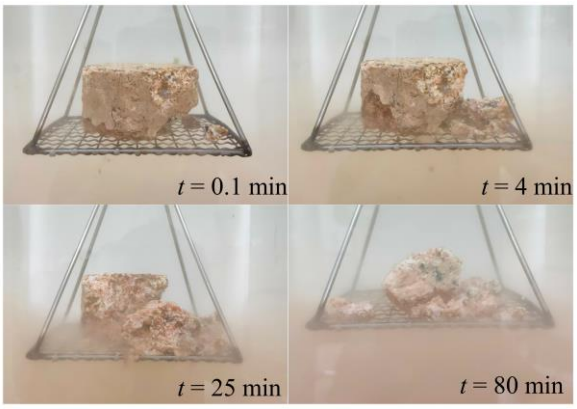

Figure 4. Photograph of the disintegration process.

In this study, a two-level classification system is adopted for soil disintegration. The soil was first classified according to the ultimate R_d value as completely disintegrative (R_d = 100%, type I) or incompletely disintegrative (R_d < 100%, type II).

Subsequently, the soil was further termed as stable (subtype A), incremental (subtype B), or rapid (subtype C) according to R_d–t curve shape. For type A, R_d increases stably to 100% and the disintegration rate reduces gradually. For type B, R_d increased incrementally to 100% and the ultimate time is approximately 100 min. For type C, R_d increased sharply to 100%. The combination of these two-level features produces a more reasonable classification. For example, GRS at 0.3 m deep was classified as I-C indicating the complete and rapid disintegration.

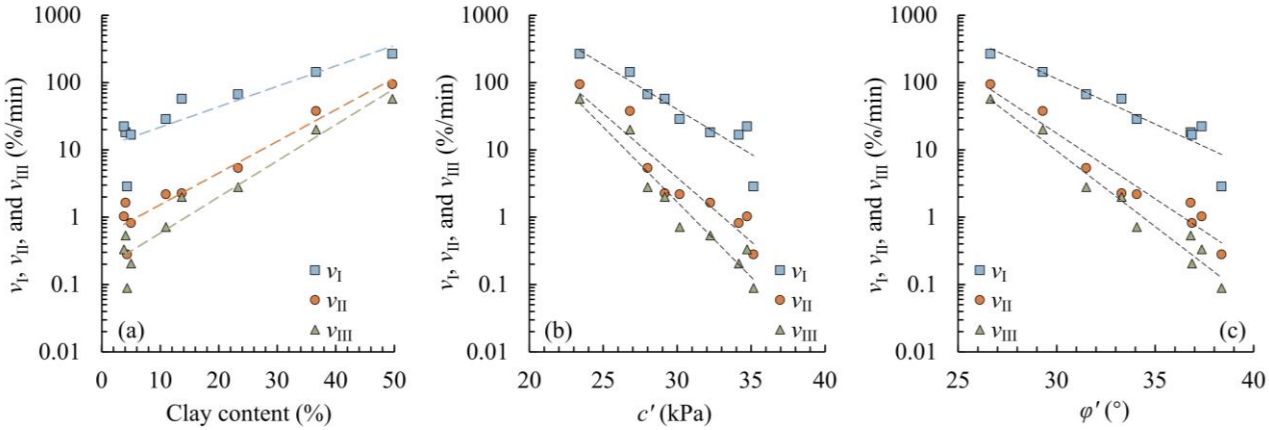

Figure 5. Correlations between disintegration rates and (a) clay content, (b) c', and (c) φ'.

Interestingly, the present results indicate that a higher clay content of GRS corresponds to less stable disintegration behavior. This is counterintuitive because of the higher interparticle forces within clays compared to the case of sand. This phenomenon shows that the particle composition may not be the dominant controlling factor of soil disintegration. It is also revealed that soils having higher c' and φ' are less disintegrative. It should be clarified that the shear strength of natural GRS is predominantly controlled by the interparticle cementation which binds the soil particles and forms larger aggregates. However, immersion of soil in water may damage the cementation and trigger disintegration.

4 CONCLUSIONS

This study presents the disintegration behavior of natural GRS collected from various depths. The GRS displays obvious disintegration when immersed. In addition, the disintegration of soil is affected by the soil depth, with the shallow soil showing less stable behavior. Different from the previous understanding, the particle composition was not a critical controlling factor at least for natural GRS; instead, the cementation among soil particles play critical roles.

ABSTRACT: The city of Ravenna (Italy) is worldwide famous for the well-preserved late Roman and Byzantine architecture with eight buildings protected by UNESCO as part of the World Heritage Site "Early Christian Monuments of Ravenna". Climate change effects have increased the site vulnerability to natural hazards, in particular flooding and subsidence, two phenomena often strictly interrelated. The topic has been addressed with reference to the complex of Santa Croce in Ravenna (Italy), an emblematic case of the main hydrogeological and water-related threats affecting the city monuments. A recent geotechnical campaign and a new piezometric monitoring system helped to gain information on the local subsoil and on the drainage system, permanently operating in the area in order to maintain it dry; the 3D geometry of the complex was obtained by integrated geomatic techniques (mainly laser scanning and photogrammetry). The paper aims at presenting the main geotechnical issues affecting the site stability and its long-term preservation.

RÉSUMÉ: La ville de Ravenne (Italie) est mondialement connue pour son architecture de la fin de l'ère romaine et byzantine remarquablement préservée, avec huit bâtiments protégés par l'UNESCO dans le cadre du site du patrimoine mondial "Monuments du christianisme primitif de Ravenne". Les effets du changement climatique ont accru la vulnérabilité du site face aux risques naturels, notamment les inondations et l'affaissement, deux phénomènes souvent étroitement liés. Le sujet a été abordé en référence au complexe de Santa Croce à Ravenne (Italie), un cas emblématique des principales menaces hydrogéologiques et liées à l'eau affectant les monuments de la ville. Une récente campagne géotechnique et un nouveau système de surveillance piézométrique ont permis d'obtenir des informations sur le sous-sol local et sur le système de drainage fonctionnant en permanence dans la région afin de le maintenir sec; la géométrie en 3D du complexe a été obtenue grâce à des techniques géomatiques intégrées (principalement scanner laser couplé à un relevé photogrammétrique). L'article vise à présenter les principaux problèmes géotechniques affectant la stabilité du site et sa préservation à long terme.

Keywords: Historic site; Ravenna; Santa Croce church; land subsidence; drainage system.

1 INTRODUCTION

Ravenna (northern Italy) is renowned for its rich history, cultural heritage and stunning Byzantine mosaics that adorn its churches and monuments. As a UNESCO World Heritage Site, Ravenna boasts eight early Christian monuments that testify its significance during late Roman and Byzantine periods. However, these ancient historic sites face severe natural hazards that threaten their conservation. Being situated in a low-lying area, only few kilometres from the Adriatic Sea shoreline, the city is constantly prone to flooding. High tides, storm surges and heavy rainfalls - whose frequency is rapidly increasing as effect of climate change - can produce potentially significant damages to ancient sites and monuments, which have been historically subjected to relevant phenomena of land subsidence and are therefore located well below the current mean sea level. In order to mitigate such geohazards and preserve Ravenna's cultural treasures, numerous efforts have been made through many conservation and restoration projects, starting from an in-depth study of their current situation and thus devising possible solutions (Santangelo et al., 2022; Bertolini et al., 2023; Marchi et al., 2023a; Franzoni et al., 2023). Any conservation program aiming at safeguarding monuments and mosaics from environmental degradation and the impact of natural hazards should start from a diagnostical analysis trying to connect "root" causes to the effects on the structure (Gottardi et al., 2015; Bertolini et al., 2022; Marchi et al., 2019; Marchi et al., 2022a, Marchi et al. 2022b; Marchi et al., 2023b).

The paper addresses the steps taken to analyse, from a geotechnical point of view, the "state of health" of the archaeological site of the Santa Croce Church in Ravenna, encompassing the visual analysis of its decay due to the effects of natural and anthropic land subsidence with the preliminary results of a recent

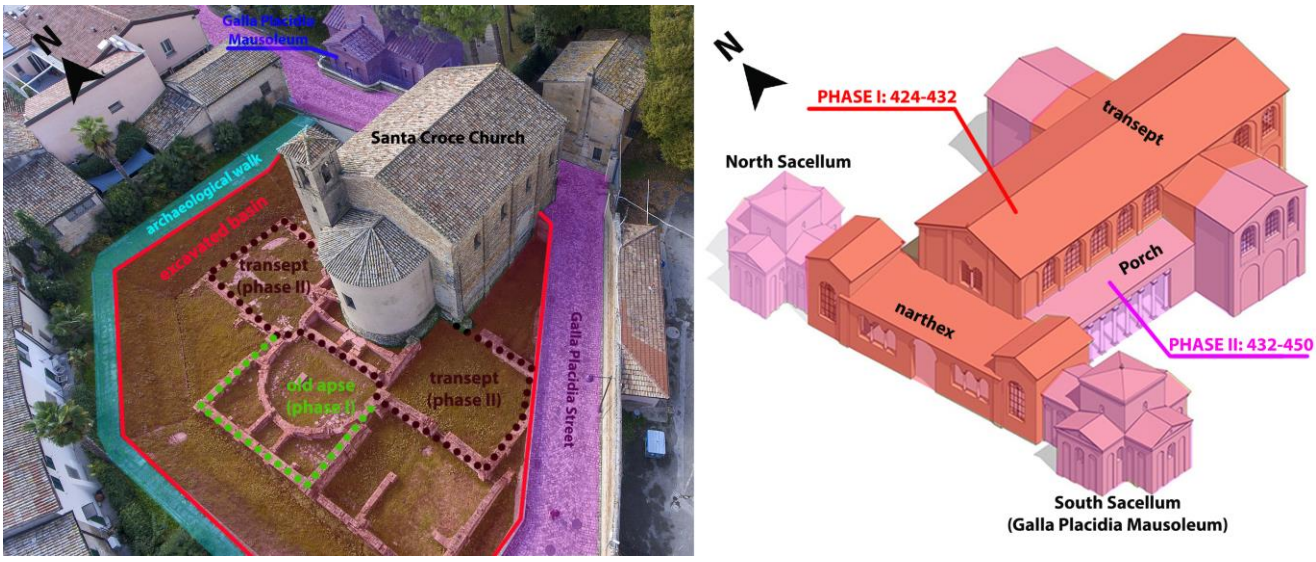

Figure 1. On the left, a bird's eye view of the area under study, with the excavated basin containing the archaeological remains and the Church. On the right, reconstruction of the geometry of the church at the end of the placidian era (modified from Cassanelli et al. (2013)).

geotechnical campaign investigating the local stratigraphy and the piezometric regime acting in the shallow aquifers as induced by a previously installed drainage system.

2 THE ARCHAEOLOGICAL SITE OF THE SANTA CROCE CHURCH

The archaeological site of Santa Croce is located in a buffer zone of the UNESCO early Christian monuments of Ravenna, adjacent to the world-famous San Vitale Basilica and Galla Placidia Mausoleum. While the two latter monuments are in good conservation conditions and are open to the public, the Santa Croce site appears in a partially abandoned state and is currently not accessible to visitors. The Church of Santa Croce, in ancient times, was a three-nave building preceded by a long portico (narthex) at the ends of which probably opened two symmetrical chapels (*sacellum*). The only surviving chapel is the south one, the so-called Mausoleum of Galla Placidia. The church was likely built in two phases on the structures of a roman *domus,* of which beautiful floor mosaics are preserved on site. The first church configuration dates back to the period between 424 and 432 A.D., constructed by the will of the roman empress Galla Placidia, and was followed by an enlargement between 432 and 450, precisely with the addition of two chapels and small adjacent porches next to the aisles, configured for funerary purposes (Figure 1, right). The early Christian church had a rich mosaic and stucco decorations, almost entirely lost today, similar in splendor to that still observable in the south *sacellum*. The old placidian church has been almost entirely reconstructed in time. In particular, at the beginning of the 17th century, the church front was set back and separated from the south chapel to make space for the Galla Placidia road today bordering two sides of the site. Concurrently, the apse has been demolished and reconstructed, in smaller dimensions, in correspondence of the old transept, considerably reducing the length of the church nave (Figure 1, left). In the 18th century, a bell tower, still observable today, has been added at the side of the apse.

2.1 Past and present hazards affecting the site

After the World War II, the economic recovery increased the need for fluid withdrawal from the subsurface. The exploitation of the Quaternary multiaquifer system underneath the Ravenna city centre and of new on-shore and off-shore gas reservoirs, increased the subsidence rate of the area from few millimetres/year (natural land subsidence rate before 1950) up to a peak value of ~80 mm/year recorded in the period 1972-73 (Carbognin et al., 1984). The cumulated subsidence in proximity of the Santa Croce site has been estimated ~1.3 m between 1897-2002, as a result of the superposition of natural and anthropic subsidence effects (Teatini et al., 2005), leaving evident signs of a marked decline in the urban and natural environment.

In the period between 1970 and 1980 the Santa Croce site was subjected to an important archaeological campaign aiming at bringing to light the archaeological stratification in the area. A basin was therefore excavated on three of the four sides of

Figure 2. On the left, scheme of the drainage system operating in the area. On the right, a picture taken during the drying procedures required following the basin's flooding caused by the malfunction of the two submersible pumps in 2021.

Figure 3. Pictures highlighting the different types of deterioration to the masonry structures and to the earthen slope of the basin, caused in time by the operating drainage system.

the church up to a depth of ~3.7m from the current street level (at ~1.5 m a.m.s.l) (Figure 1, left). The phreatic water level in the area is consistently located at ~1.5 m below the actual ground level; thus, to perform the excavation and maintain the archaeological remains in dry conditions a drainage system had to be set in place. A scheme of the drainage system, still in operation, is shown in Figure 2 (left). A perforated horizontal PVC tube (red line in Figure) bordering two sides of the excavated basin channels the water from well P1 through P2 and C1 to a buried concrete tank (indicated with a blue dot in Figure 2, left) containing two submersible pumps. The pumps lift the drained water to the street level and release them in the public sewer (light blue line in Figure 2). The subsequent piezometric lowering in the shallow aquifer initially produced new settlements in the overall site containing the church structure, the archaeological remains in the excavated basin and the private buildings standing at the site borders. Moreover, the lack of maintenance to the drainage system caused over the past years the progressive obstruction of the drainage pipes by soil particles. From a recent site inspection, the water still drained by the pumps flows along the soil surface, on a shallow trench self-created above the pipes (blue arrows in Figure 3, left), producing continuous shallow erosion and local instabilities. Despite the underpinning works operated in 1985 to the masonry remains in proximity of the tank, the negative effects of the continuous water withdrawal appears to have never stopped. In fact, the area in proximity of the concrete tank is clearly the most affected by settlements, as visible in all the close by masonry archaeological structures in

the south side of the church and in the deformation of the slope (Figure 3, right and left, respectively). Furthermore, occasional malfunctioning of the pumps in the past caused multiple flooding of the area with subsequent damages to the archaeological remains and to the roman mosaics (Figure 2, right).

2.2 The 2022 geotechnical investigation campaign and site monitoring

Funded under the European research program Horizon 2020, SHELTER (Sustainable Historic Environments holistic reconstruction through Technological Enhancement and community-based Resilience) project aims to increase the resilience of cultural heritage and reduce its vulnerability to natural and anthropic hazards through the elaboration of disaster risk management plans and protocols of intervention. The archaeological area of Santa Croce was selected as emblematic case study because it incorporates all the preservation issues characteristic of coastal, low-land, historic cities.

In 2022, among many other investigations, a geotechnical campaign was carried out, aiming at investigating the local soil stratigraphy and characteristics, together with the piezometric conditions in the area, as induced by the drainage system. Two piezocone penetration tests (CPTu), one seismic cone penetration test (SCPTu), one dilatometer test and three corings (two continuous and one destructive drillings) were executed in the area. Under a 5.5 m thick anthropic fill (unit R), rich in archaeological remains, the deposit turned out to be a succession of highly permeable aquifers (units U1 and U3) and low-permeable aquitards (units U2 and U4), up to the maximum investigated depth (~ 45 m) (Figure 4).

A piezometric monitoring system was thus installed in the site with the aim of recording in situ pore water pressure (pwp) data in the shallowest aquifers at different distances from the buried tank. As expected, the greatest dropdown in piezometric head is registered in PZ3, installed in the first aquifer and located in proximity of the pumps (Figure 5). The effects of the drainage system seem to reduce with distance in fact, PZ1, 50 m far from PZ3, has a higher piezometric head (with a difference of ~ 0.2 m). The deeper aquifer (monitored by PZ2) is only marginally influenced by the drainage conditions and tends to the undisturbed water level, located ~1.4 m below the street level (as measured locally at pumps shut down).

Various geomatics techniques were also integrated to create a highly detailed 3D model of the Santa Croce site (Bitelli et al., 2021). These geometrical data will support the creation of a seepage Finite Element (FE) model able to accurately reproduce the pwp distribution in the 3D system of aquifers as a consequence of the drainage currently in operation and to reproduce the effect of possible, more effective, solutions. Piezometric observed data will be used for a suitable calibration of the FE model parameters.

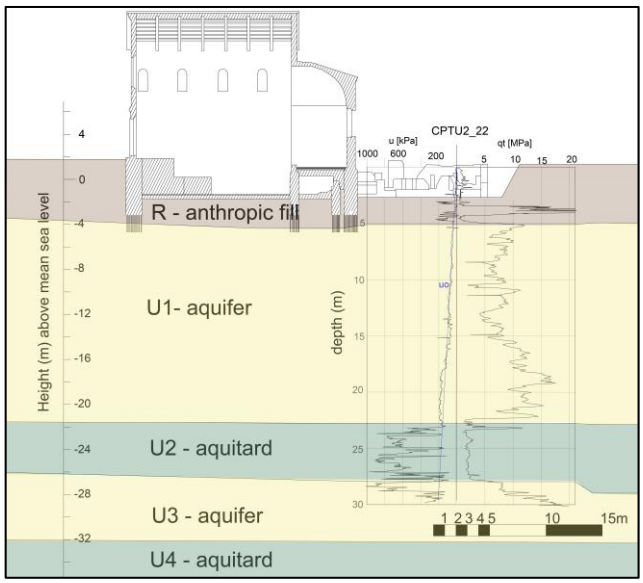

Figure 4. Soil stratigraphy in the investigated area with superimposition of the q_t and u profiles from a CPTU.

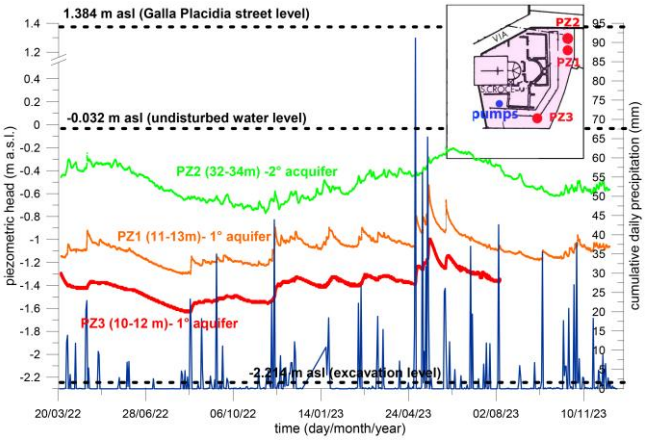

Figure 5. Piezometric head trends with time measured in PZ1 (1st aquifer), PZ2 (2nd aquifer) and PZ3 (1st aquifer).

3 CONCLUSIONS

The paper focuses on the precarious conditions and the number of hazards affecting the archaeological area of Santa Croce. This scrutiny has brought to light their significant implications to the preservation of such invaluable historic site. Diligent care and increased vigilance are required in order to effectively mitigate the associated risks, thereby enabling the safeguarding and future accessibility of the entire complex. The extensive field campaign conducted, coupled with the initial findings from on-site monitoring, represents a

valuable analysis of the current geotechnical situation. These findings not only shed light on the existing context but also pave the way for the formulation of well-informed management strategies essential for the preservation and sustainable use of the site. In this perspective, multiple solutions can be proposed to ensure an optimal control of the groundwater conditions in the area. Among them, a re-efficiency of the old drainage system in use or the design and implementation of a new dewatering system (e.g., well-points), able to guarantee spatial uniformity of pore pressure distribution and lower hydraulic gradients in the area.

ACKNOWLEDGEMENTS

ABSTRACT: The coastal cliffs on the north coast of the São Miguel Island, between Capelas and Rabo de Peixe parishes, due to its geology, composed by alternated fractured basaltic lava flows with breccia and/or unconsolidated pyroclastic deposits, are naturally predisposed to rock falls. Sea waves, meteorological agents and the anthropogenic activity that takes place near the cliffs are the main factors responsible for the erosive dynamics, with estimated retreat rates of up to 0.40 m/year. In this context, the urban settlements closest to the coastline are cyclically affected by landslides and rock falls. These geomorphological processes are responsible for the retreat of the cliffs, with the consequent loss of land, buildings and roads. Calhetas parish, in the municipality of Ribeira Grande, is one of those places that has recently been most affected by geomorphological instability. Since February 2023, a reactive phase of the cliff has been underway, with a consequent retreat of its crest. This paper describes the process that has affected this sector of São Miguel Island coast in recent years, with a particular focus on the phase that is currently underway. Displacements data are presented, obtained by fixed marks, as well as the measures that have been taken to mitigate the risk to the population. Finally, a discussion is presented on the solutions that are considered most appropriate for the problem.

RÉSUMÉ: Les falaises côtières de la côte nord de l'île de São Miguel, entre les paroisses de Capelas et Rabo de Peixe, en raison de leur géologie, composée d'alternances de coulées de lave basaltique fracturées avec des brèches et/ou des dépôts pyroclastiques non consolidés, sont naturellement prédisposées aux chutes de pierres. Les vagues de la mer, les agents météorologiques et l'activité anthropique qui se déroule à proximité des falaises sont les principaux facteurs responsables de la dynamique érosive, avec des taux de retrait estimés jusqu'à 0,40 m/an. Dans ce contexte, les agglomérations urbaines les plus proches du littoral sont cycliquement touchées par des glissements de terrain et des éboulements. Ces processus géomorphologiques sont responsables pour le retrait des falaises, avec pour conséquence la perte de terrains, de bâtiments et de routes. La paroisse de Calhetas, dans la municipalité de Ribeira Grande, est l'un des endroits les plus touchés récemment par l'instabilité géomorphologique. Depuis février 2023, une phase réactive de la falaise est en cours, avec pour conséquence un retrait de sa crête. Cet article décrit le processus qui a affecté ce secteur de la côte de l'île de São Miguel au cours des dernières années, avec un accent particulier sur la phase en cours. Les données de déplacements sont présentées, obtenues par notes fixes, ainsi que les mesures qui ont été prises pour atténuer le risque pour la population. Enfin, une discussion est présentée sur les solutions considérées comme les plus appropriées au problème.

Keywords: Geological risks; geomorphological instabilities; volcanic coast; cliff instability; coastal protection.

1 INTRODUCTION

The coastline of São Miguel Island, between the parishes of Capelas and Rabo de Peixe, has a morphology characterized by steep cliffs with heights between 10 and 20 m. From a geological point of view, these cliffs are made up of alternations of volcanic materials with different mechanical characteristics.

Maritime agitation, meteorological agents, and human activity that develop in the vicinity of these cliffs are mainly responsible for erosion dynamics, with estimates of the average retreat rate reaching 0.40 m/year (Borges, 2003).

Since the urban centres are located close to the crest of these cliffs, cyclically these villages are affected by retreat processes leading to the loss of land, buildings, and streets. The parish of Calhetas is one of these locations that periodically is affected by crises of geomorphological instability.

In February 2023, another geomorphological crisis began, and until December 2023, there have been several episodes of instability, three of greater dimensions and others of lesser importance.

During this crisis, some measures were implemented to mitigate the risk for the local

population. As part of this initiative, six pairs of marks were placed along two alignments of tension cracks that developed parallel to the crest of the cliff. These marks aimed to assess the rock mass kinematics and try to understand the dynamics of the process. The objective is, proactively, to anticipate potential cliff retreats and, consequently, promptly alert the population to ensure their safety.

2 CASE STUDY

2.1 Location and geological settings

The Azores archipelago is located at the triple junction between the Eurasian, African, and North American tectonic plates. Being recent volcanic islands, their rock formations are generally unaltered, and the soils are little altered. The cliffs present in São Miguel Island coastline between Capelas and Rabo de Peixe are characterized by being steep and made up of sub-horizontal layers of pomitic pyroclastic deposits without effective cohesion and/or by alternations of basaltic lava flows fractured with clinker.

The cliff under analysis in this study delimits the parish of Calhetas to the north and is around 20 m high, with a sub-vertical slope, with some of the strata partially suspended. The lower half of the cliff, geologically, is made up of soft formations, namely a level of pumice of trachytic nature, with interspersed ash of the same nature with variable thickness. The upper half is formed by lava flows of a basaltic nature (s.l.) with clinker intercalations. Finally, a small layer of surface soil (vegetable soil and/or landfill) can be seen. All these formations have varying thicknesses along the length of the cliff (Figure 1).

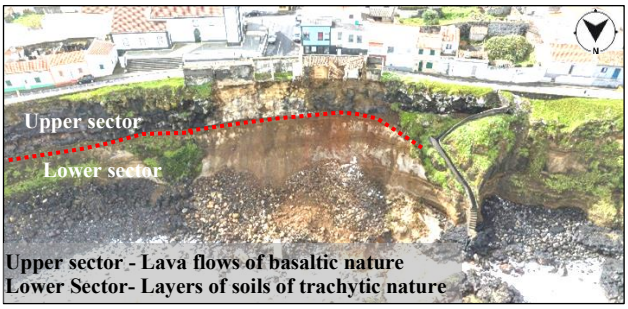

Figure 1. Geological constitution of the cliff at Calhetas.

In this sector of the coastline, close to the crest of the cliff and parallel to it, there are two streets with houses on the south side and some more scattered buildings on the north side over the crest of the cliff. With the inevitable progression of the cliff retreat process, the number of houses on the north side of the streets is increasingly reduced. Recently, the streets themselves have started to be threatened, restricting their use.

The erosion process in question consists of an intermittent phenomenon in time and space due to the intrinsic characteristics of the materials that constitute the cliffs and the action of triggering agents such as wave action, windstorms, intense precipitation, earthquakes, and anthropogenic actions (Di Crescenzo et al., 2021).

At the time of the beginning of this crisis, as the site was not being monitored, it was not possible to attribute any more intense meteorological phenomenon or any major anthropogenic action to trigger it, attributing its beginning to the progressive process of deformation of the massif and consequent increase in stress.

According to Borges (2003), who carried out quantitative studies of coastal retreat rates for the island of S. Miguel in the period between 1955 and 1999, the sector under analysis in this document points to values of average coastal retreat very heterogeneous cliff, varying between 0.1 m/year and 0.4 m/year.

Geologically, this cliff has a high propensity for the occurrence of these instability processes, considering that the base of the cliff is made up of material that is easily erodible by the action of the sea. So, periodically, the overlying basalt flows stay in cantilever. Furthermore, the alternation of basaltic flows with clinker levels, which are also quite erodible, leads to situations where the overlying strata also stay unsupported.

2.2 Description of occurrences

The current crisis began on February 2, 2023, at 8:00 pm, having destabilized an extension of the cliff measuring around 30 m and causing a retreat, which, in some places, reached 5 m (Figure 2).

In this episode, one of the affected buildings lost its back façade. It is important to note that the affected buildings were already vacant since the 2016-2017 crisis, except the structure located further west, which remained in use once it was a small warehouse.

After the first episode, the cliff became unstable again on March 1st, this time in a sector immediately to the west of the previous one, reaching a length of around 16 m and causing a retreat of around 2 m.

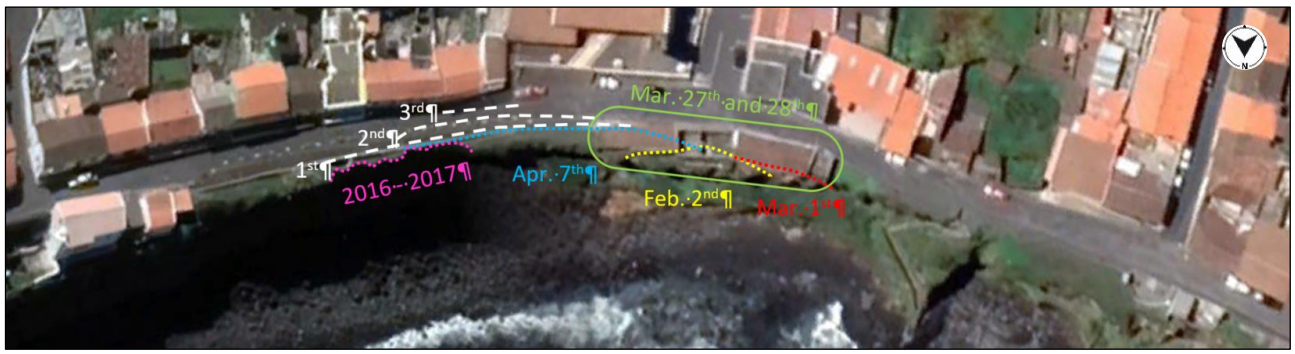

Figure 2. Affected areas on the Calhetas cliff: the alignment of existing cracks (dashed), the unstabilised areas (dotted) and the demarcation of demolished buildings / those affected by this crisis (continuous). Google Earth image (June 2022).

After this reactive phase, following a recommendation previously made by the Regional Laboratory for Civil Engineering, the four buildings located in the affected sector were demolished on the 24th, 27th, and 28th of March. This operation was done to relieve the load over the cliff and reduce the mass expected to become unstable once the cracks between the buildings and the adjacent sidewalk continued to evolve.

A few days before the demolitions began, it was found that the first and second alignment of cracks parallel to the coastline, already identified in 2016-2017, reactivated on the sidewalk and in the street pavement, resulting in an increase in the opening and the extension to the west of cracks. Furthermore, a new alignment of cracks further back was detected, the third (3rd) (Figure 2).

In March, the 2nd alignment (Figure 2) was located between 4.2 m and 6.2 m from the cliff crest, and the 3rd alignment was 1.6 m further back, thus compromising around 2/3 of the traffic lane.

On the night of April 7th, a few days after the demolitions had concluded, the cliff became unstable again. The sector now unstable was located immediately east of the initial one. With a length of around 50 m, it reached a retreat of 5 m in the sector of the demolished buildings (Figure 3).

Figure 3. The cliff after the instability of April 7.

After the instability of April 7th, the crest of the cliff retreated to the 1st alignment, becoming the 2nd alignment 2 to 3 m from the crest.

3 RISK MITIGATION MEASURES

3.1 Protection measures adopted

After the 2016-2017 crisis, when the retreat of the cliff reached the outer face of the road's guard wall, and the 1st and 2nd alignment of cracks appeared (Figure 2) parallel to the crest of the cliff, it was recommended that automobile circulation should be restricted on the affected extension of the road (70 m). It was also recommended to avoid activities or the presence of people and goods in the affected area until the 2nd crack alignment. For this purpose, it was suggested the placement of physical barriers like metal fences or blocks on the pavement. In addition, it was recommended the visual monitoring of the cliff quarterly, or after an abnormal worsening of weather conditions, to check for any retrogressive evolution of the site. In the case of activity, it was suggested the implementation of a monitoring system based on instrumental techniques to allow the detection of ground movements before the occurrence of instabilities. Although no movement was visually detected in the rock mass, marks were installed in the affected area, and the site was monitored for two years. Due to the movement being in its early stages or the limited accuracy of the total station used, no activity was detected, leading to monitoring discontinuation.

During the current crisis, and after the reactivation of the 2nd alignment and the emergence of the 3rd, it was recommended to increase the extension of the prohibited area for car traffic. This closure was extended to the west around 100 m, and in width, besides the entire sidewalk, 2/3 of the traffic lane was closed in the most critical area.

In May, after the crisis calmed down, six pairs of markers were placed along the two remaining crack alignments (2nd and 3rd) to evaluate its evolution weekly (Figure 4).

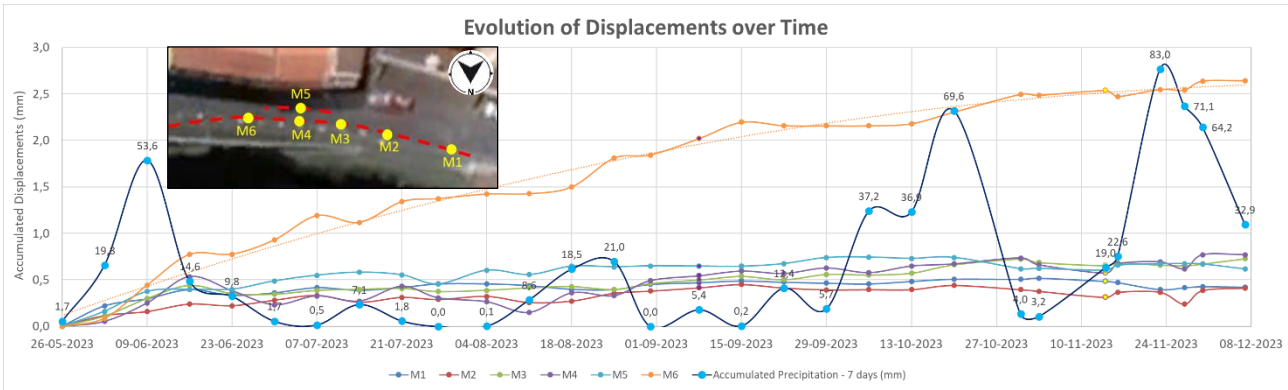

Figure 4. Evolution of the marks installed in the monitored cracks and precipitation.

3.2 Proposed solutions

To avoid the continued retreat of the cliff, it will be necessary to protect its base, which is made up of soft strata, as well as the stabilization of the overlying basalt flows that are fractured. For the lower sector, a rockfill prism adhering to the cliff can be done, which could serve as a base or foundation for the stabilization solution in the upper sector. Therefore, two possible solutions are proposed for the upper sector: one involves constructing an embankment along with small containment structures, while the other entails the installation of a reinforced concrete curtain anchored and nailed to the cliff.

At present, the authorities have granted a contract for the construction of a berm breakwater (a reshaping structure) for the base of the coastal cliff, without taking into account the solution to be implemented for the upper part. Even though the solution adopted isn't the one suggested, it has the advantage of needing smaller stones in the armour layer, making the construction process easier. Furthermore, although the project defines a reshapable berm, this intervention allows the execution of the solutions thought for the stabilization of the upper part of the cliff. Indeed, the breakwater has a wide stable crest, with a 15 to 23 m width.

In any case, until the entire cliff is protected and stabilized, new construction or rehabilitation should not be permitted on both sides of the street. Furthermore, it is essential to consider the necessity for new rehousing and relocation of structures, especially on the north side of the street.

4 CONCLUSIONS

The cliff that delimits the urban core of the parish of Calhetas to the north is cyclically plagued by crises of geomorphological instability.

The retreat of the cliff crest is the outcome of a natural process known as 'differentiated coastal erosion, occurring within various strata along the coastline.

In general, the occurrence of this type of phenomenon arises from the actions of different agents (e.g., high precipitation, intense maritime agitation, earthquakes, and vibrations resulting from human activity). Typically, there is a time interval of the order of hours or days between the request and the cliff's response to the action of the triggering agents in the rock mass.

During the current phase of the process, monitoring tension cracks near the crest of the cliff suggests that the mass rock does not react responsively to precipitation episodes, although, in the beginning, it seemed otherwise. Currently, this part of the cliff seems to have entered an inactive dormant state.

As this is a natural and irreversible process, there are two options: stabilization of the cliff or vacating the area near the ridge as the process progresses. In the latter case, proactive measures are necessary to minimize the exposed value. For this purpose, territorial planning tools are essential. Because both options have very high associated costs, each situation has to be viewed on a case-by-case basis. Regardless of the option adopted, it is essential to define clear policies to minimize losses and not create false expectations for the population.

Prediction program for slow moving landslides

Programme de prédiction des glissements de terrain à déplacement lent

R. Marte*, H. Ramoser
Institute of Soil Mechanics, Foundation Engineering and Computational Geotechnics, Technical University of Graz, Austria

**roman.marte@tugraz.at*

ABSTRACT: The deformation behaviour of large, slow moving landslides is often governed by rainfall characteristics. Whereas the average deformation rate per year of such landslides is often in the range of some mm to several cm, permanent deformation measurements for instance by means of permanently installed chain inclinometers show a far wider range of deformation rates especially after dry or very wet periods. If in addition to chain inclinometers, a weather station and permanent measured pore water gauges in the slip zone are installed one can identify in many cases a strong correlation between strong rain fall events, a time-delayed increase of the pore water pressure in the slip zone and simultaneously to this, an increase of the deformation rate of the landslide. So, based on these data, a good understanding of the above-mentioned correlation can be obtained. In this paper a newly developed analytical model which couples the relation between rainfall characteristics and the development of pore water pressures in the slip zone on one hand and the deformation behaviour of the slope on the other will be presented. The code allows a partition of the landslide in different sections to consider the often-observed time delayed deformation behaviour over the length of large landslides. The interrelation of shear resistance in the slip surface and deformation rate is defined by a logarithmic constitutive law. The calibration of the model is done by means of the above-mentioned permanent measurement data of precipitation, pore water pressures and deformation measurements.

RÉSUMÉ: Le comportement de déformation des grands glissements de terrain à déplacement lent est souvent régi par les caractéristiques des précipitations. Alors que le taux de déformation moyen par an de ces glissements de terrain est souvent compris entre quelques mm et plusieurs cm, les mesures permanentes de la déformation, par exemple au moyen d'inclinomètres à chaîne installés en permanence, montrent une gamme beaucoup plus large de taux de déformation, en particulier après des périodes sèches ou très humides. Si, en plus des inclinomètres à chaîne, une station météorologique et des jauges permanentes de l'eau interstitielle sont installées dans la zone de glissement, on peut identifier dans de nombreux cas une forte corrélation entre de fortes chutes de pluie, une augmentation différée de la pression de l'eau interstitielle dans la zone de glissement et, simultanément, une augmentation du taux de déformation du glissement de terrain. Ainsi, sur la base de ces données, une bonne compréhension de la corrélation susmentionnée peut être obtenue. Cet article présente un nouveau modèle analytique qui associe la relation entre les caractéristiques des précipitations et le développement des pressions d'eau interstitielle dans la zone de glissement, d'une part, et le comportement de déformation de la pente, d'autre part. Le code permet de diviser le glissement de terrain en différentes sections afin de prendre en compte le comportement de déformation souvent observé avec un décalage dans le temps sur la longueur des grands glissements de terrain. L'interrelation entre la résistance au cisaillement dans la surface de glissement et le taux de déformation est définie par une loi constitutive logarithmique. L'étalonnage du modèle est effectué à l'aide des données de mesure permanentes susmentionnées concernant les précipitations, les pressions de l'eau interstitielle et les mesures de déformation.

Keywords: Landslide; creep; inclinometer; pore water pressure; deformation rate.

1 INTRODUCTION

The deformation behaviour of large, slow moving landslides are often governed by rainfall and/or snow melting but sometimes also by man-induced processes. Such slow moving landslides (SMLS) are a common phenomenon in Alpine regions and their origin is often connected with erosion processes by glaciers during the last Ice Age, when steep mountain slopes have been left after the melting of the glaciers about 10.000 to 15.000 years ago. As a consequence, some of these steep mountain slopes developed to instable and large landslides, with low deformation rates in mm to cm per year and low factors of safety (FOS) (Marte & Hofmann 2020).

When infrastructure such as motorways, tunnels, railway tracks, water power plants, snow water storages on mountain slopes or constructions with a severe damage potential in general are endangered by such SMLS, an extensive assessment of the deformation behaviour, safety aspects as well as the

future behaviour of the slope is required (Leroueil, 2001; Hungr, 2016). Typical questions are (Marte, 2019):

- What is the expected deformation behaviour of the SMLS which needs to be considered for the life cycle of the objects?
- What is the "FOS" of the SMLS and how does it influence endangered objects?
- What are circumstances which could lead to a sudden failure of the SMLS?
- Is a sudden failure of the SMLS predictable and what is a proper observational instrumentation?
- What kind of remediation measures are applicable – what are their effects and their costs?

To work out proper answers for such questions geological survey (field work and subsoil exploration) and extensive measurement campaigns (e.g. inclinometer, geodetical, ground water resp. pore water measurements, installation of a weather station) are generally implemented (Ausweger, 2018, Marte & Hofmann, 2020). Based on results and data from this investigation geological, geotechnical and calculation models are developed. SMLS show in many cases complex geometrical and geological boundary conditions, a long history and often large movements in past as well as sometimes different triggers which govern the deformation behaviour. For such complex landslides – in many cases only simplified calculation models which prove to be valid only for some of the questions and aspects above, are available. Therefore a critical interpretation of calculation results is essential.

Improved calculation models allow a direct comparison of calculation results with measured data, which also allow a calibration of the most important input data. When for instance a calculation model delivers deformation (rate) and/or pore water pressures in the slip surface as results, this data can directly be compared to measurement data (Ausweger, 2018). On the other hand, a calculated FOS is a number which cannot be measured or controlled directly in the field, at most a change in FOS can be quantified indirectly by a change of deformation rate of the SMLS.

In the next chapter a new developed analytical model which couples the relation between rainfall characteristics, the development of pore water pressures in the slip zone and the deformation behaviour of the slope is presented. The model is calibrated on the bases of measured deformation and pore water pressure data over a longer period of time.

2 MODEL FOR SLOW MOVING LANDSLIDES

The presented model has been developed for SMLS, which are mainly triggered by rainfall (and snow melting) events. The primary input data therefore are precipitation data from a weather station (or artificial rainfall data for future events). The model is a combination of a hydrogeological model and a simple mechanical creep model (Leinenkugel, 1976). The hydrogeological model allows the calculation of pore water pressures along the slip zone over time as a function of the rainfall data. The mechanical creep model is used to calculate the deformation rate of the slope as a function of time and of pore water pressures in the slip zone.

2.1 Model description

The analytical model is based on the infinite slope model with an expansion that the SMLS is subdivided into several blocks, with the active earth pressure *Ea* at the upper end and a mobilisation function for the earth resistance *Er* at the lower end of the SMLS as shown in Figure.1 and Figure 2. The whole slope is split up into multiple finite blocks. Each block is a trapezoid with a vertical height at the lower end t_1, a vertical height at the higher end t_2 and a horizontal length l (Figure 1).

Additionally the inclination α of the slip plane is given. With that the geometry of each block is determined.

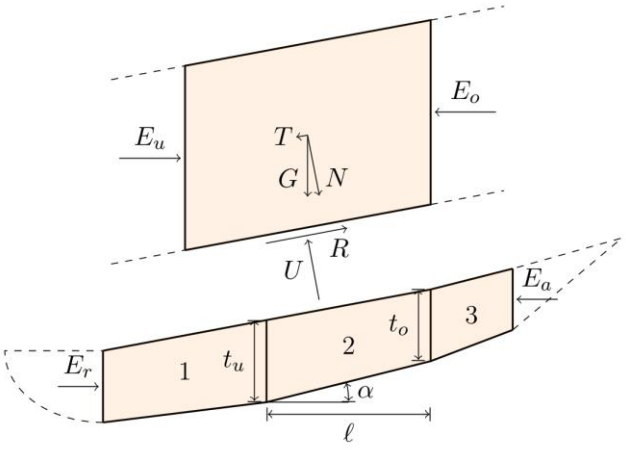

Figure 1. Model basics.

The model in the longitudinal section is shown in the lower part of Figure 1. A material is assigned to each block. The most important properties of the material are the weight γ to calculate the dead load *G* and with the geometrical data *N*, and *T* the normal and tangential component of *G*. Further input data are the friction angle Φ, the stiffness *E* and the creep index *Iv*.

The creep index *Iv* is a value that stems from the model after (Leinenkugel, 1976). The forces acting in the blocs are shown in the upper part of Figure 1:(*R* … shear resistance in the slip surface; *Eu* and *Eo* … Earth pressure at the lower and upper end of the bloc; *u* pore water pressure in the slip surface and *v* average deformation rate in a bloc). The number of blocs as well as the inclination of the surface and slip surface of each single bloc in the model is chosen individually for each SMLS. In the actual version the bloc stiffness is modelled by a Young's Modulus *E*, and the Poisson ratio is chosen ν=0, so the mechanical model can be seen as 1D model.

In this model the main mechanism that controls the deformations and velocity of the slope are the pore water pressures in the slip plane as well as the characteristics of the earth resistance and the mobilization function at the lower end respectively. A change in the pore water pressure results in a change of shear resistance and further on the velocity.

Each block has 5 degrees of freedom in the model. The general velocity of the block, the earth pressure force and the displacements on the the lower and upper side . The system of equation is split into 5 equations for the 5 degrees of freedom. The central equation (1) is the relationship between the changing forces at one block and the change of velocity:

$$(\Delta E_o - \Delta E_u) * \cos\alpha + \Delta u * \frac{l}{\cos\alpha} * \tan\phi - \tau_0 * I_v * \ln\left(\frac{v_i}{v_{i-1}}\right) * \frac{l}{\cos\alpha} = 0 \quad (1)$$

The first term describes the change of the earth pressure forces on the end of the blocks in direction of the slip plane. The second term describes the change of the resisting force in the slip plane due to a change of the pore water pressure. The last term describes the change of the resisting force due to the change of velocity whereas I_v is the creep index according to Leinenkugel (1976).

The second leading equation formulates the change of the length of each block by ($\Delta S_o - \Delta S_u$) the difference in displacements at the upper and lower end of a bloc) due of the changes of stress in the blocks ($\Delta E_{o,i}$, $\Delta E_{u,i}$) This is approximated with Hook's law:

$$(\Delta S_o - \Delta S_u) * \frac{\cos\alpha}{l} * E - \frac{1}{2}\left(\frac{\Delta E_u}{t_1} + \frac{\Delta E_o}{t_2}\right) = 0 \quad (2)$$

The third major equation describes the relationship between the change of displacements of the blocks in direction of the slip plane and the velocity of each bloc:

$$v_i * \Delta t - \frac{\Delta S_o + \Delta S_u}{2\cos\alpha} = 0 \quad (3)$$

And the last two field equations connects the change of earth pressure and change of displacements between two consecutive blocks:

$$\Delta E_{o,b} = \Delta E_{u,b+1} \quad (4)$$

$$\Delta S_{o,b} = \Delta S_{u,b+1} \quad (5)$$

To finish the system of equations two boundary equations are necessary. For the bottom boundary a mobilization function that combines the displacements of the lowest joint with an according earth pressure.

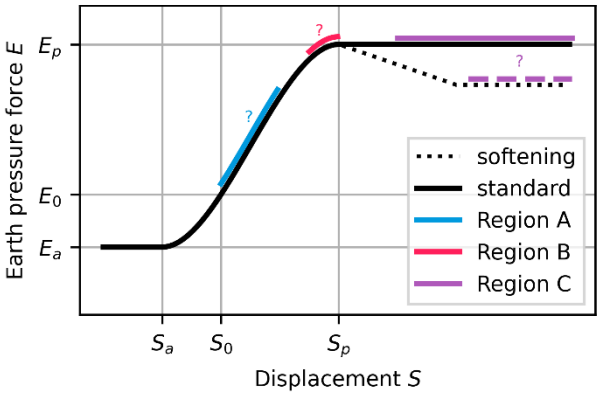

Figure 2. Mobilization Function for Er.

The mobilization function (Figure 2) is approximated as a polynom of third order that ranges from the active earth pressure E_a at the lower bound to the passive earth pressure E_p at the higher bound with a horizontal tangent at each point. The respective displacements s_a, s_0 and s_p in Figure 2 are calibration parameters of the model. The starting point on this function is another important initial parameter of the model and is understood as a representation of the history of the landslide. Region A (blue) in Figure 2 as starting point for the simulation shows a young SMLS with only small deformation in the past whereas Regions B and C show a SMLS with significant deformation in the past. Region C indicates two scenarios, one without softening and one with softening behaviour at large deformation.

In Figure 3 the principles of the hydrogeological model are presented for one single bloc which can be understood as a tank-like element. There are two types of such tank-like elements. The standard type that is modeled after the blocks in the Geomechanical Model and a source area element. The standard element takes the geometric properties of the block like the length, height and inclination. Other material properties like porosity *n*, saturation *Sr* and hydraulic conductivity *kf*

are added in the model to model the discharges through the block. Other properties are tuning factors for the amount of infiltration and influx that flows into the block from the sides. These elements are thought as 1m wide. The source area element, which describes the catchment area above the landslide, on the other hand has the same material and infiltration properties but has only an area and an inclination as geometric properties. In difference to the standard elements the source area element has two different flows out. One is the flow above the slip surface into the next bloc-element. To calculate the outflow into a 1 m wide bloc element the width of the bottom of the source area is given. The other outflow is below the slip surface that flows out of the system and does not inflence the behaviour of the SMLS anymore.

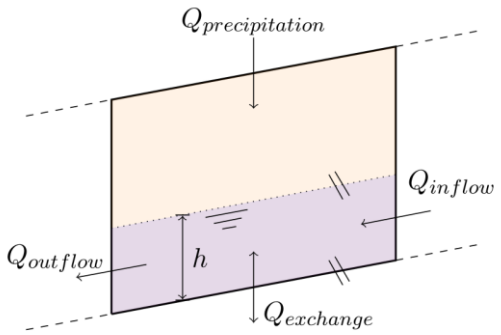

Figure 3. Hydrogeological Model.

Qprecipitation, Qinflow, Qoutflow respectively Qexchange in Figure 3. show water input and output in one bloc element.

So the model simulates a cascade of bloc elements in the direction of the slope. With the input of precipitation data the volume of water as well as a fictive water level in the elements, the flow between the elements and the pore water pressure in the slip surface is simulated. The cascade starts with the source area element from which the first flow to the top most block element is simulated. Further on an inflitration into each bloc element occur over the surface. At the bottom of the slope the discharges just flows out of the system.

For the simulation an initial water level is assigned for each element. This water level is then calculated into a volume with the length of the block, the porosity and the degree of saturation of the material.

Now every time step this volume is updated with the given flows between the elements and the infiltration over the surface and the new water level is calculated. As the system is a linear system of equations the whole calculation can be written in matrix form and solved with common linear system of equation solvers. The pore water pressures for each elemement are then saved as input for the Geomechanical Model.

2.2 Initial values and calibration parameters

To calculate the system a number of initial values have to be chosen. The initial velocity of all the blocks needs to be given together with the past displacement of the bottom block in order to initialize the mobilization function. With the initial earth resistance at the bottom block and the active earth pressure at the top most block an initial distribution of earth pressures along the slope is calculated. By multiplying the calculated earth pressures with the respective joint heights the initial forces Eo and Eu can be calculated in each joint. These earth pressures are then used to calculate an initial total resisting force in the slip plane that results from the earth pressure forces and the weight of the block. With these information the system can be calculated.

The calibration of the model, i.e. the determination of the major input data is done by comparing the calculation results for a certain time period respectively the rain fall data for this period with available measurement data from permanent pore water pressure measurements (PW-gauges) as well as data from chain inclinometer(s). Main input data are adjusted until a proper curve fitting of calculated and measured data are achieved. In Figure 4 measurement data from a case history, which are used to calibrate the model for this SMLS are shown exemplarily. The programming code for the model is written in Python 3.

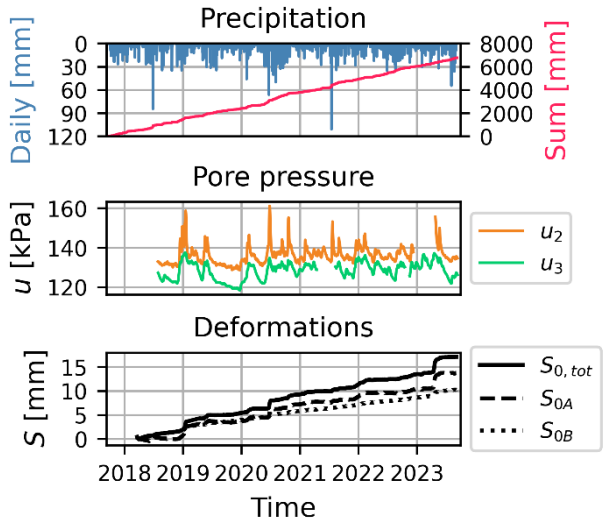

Figure 4. Measurement data for calibration of the model for a case history. Upper figure: Daily and cumulated precipitation data; Central figure: Measured pore water pressures in two points along the slip surface; Lower figure: Results (displacements) from an inclinometer measurement in different depths of the landslide.

3 CASE STUDY WITH ARTIFICIAL DATA

To present the general capacity of the model, Figure 5 shows the results of an artificial data set. A slope model with three blocks and a sinus shaped rainfall distribution over a time period of three years is modelled. The earth pressure Er at the lower end is assumed to start with earth pressure at rest E_0 at time zero. The infiltration of water in the slope is assumed in this simplified example only from the catchment area above the highest bloc of the landslide.

The results of pore water pressures in the slip surface show in accordance to the modelled sinus shaped rainfall distribution also a sinus shaped distribution over the year, with highest and temporary first peaks in the topmost bloc where the water inflow occurs first. The deformation curves for the different blocs show the highest deformation (rates) in the uppermost bloc and the lowest deformation (rates) in the lowest bloc where earth resistance is the highest and increases with further deformation.

This can also be seen in the lowest chart of Figure 5, where the earth pressure development over the three years is presented. On the upper end of the model the earth pressure remain on the level of the active earth pressure (red line). On the lower end the earth resistence increase with ongoing deformation according to the mobilization function as shown qualitively in Figure 2.

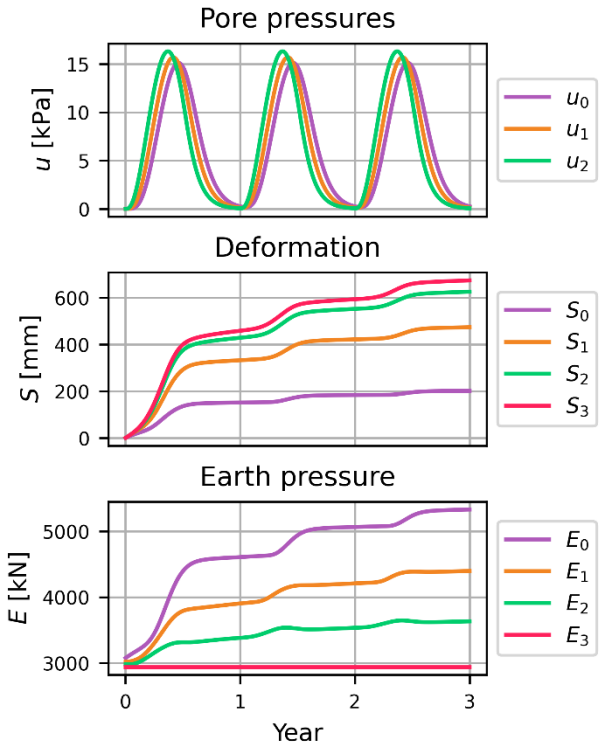

Figure 5. Calculation results for an artificial example.

It also can be seen that the same amount of pore water pressure peaks over the years lead to a decrease in ΔE over the time because of an increasing earth resistence with time. ΔE means the change of earth pressure in the bloc joints. E_3 in figure 5 is the constant active earth pressure at the upper end of the landslide, E_0 is the earth resistance (accorting to the moblization function) at the lower end of the landslide. E_1 and E_2 ar the earth pressures in the bloc joints of the model. This demonstrates the influence of the landslide history.

The application of the model for real case histories show on the one hand the applicablity and sgnificant improvements by the model compared to classical models with only discussing FOS. On the other hand the effort to get measurement data from chain inclinometers and permanent pore water pressure measurements in the slip surface as well as the challenge of a reliable calibration of the model specially for complex boundary conditions needs to be mentioned.

4 CONCLUSIONS

In this paper a combined hydrogeological-geomechanical model for slow moving large landslides is presented. For this type of landslides, the analytical model allows the simulation of the dependency of precipitation characteristics, time delayed pore water pressure developments in the slip surface and as consequence changes in the deformation rates. For slow moving landslides the model can be understood as supplement to classical analytical models which allow the calculation of FOS only. Assumed a successful calibration of the model is done, the prediction of further deformation behaviour as function of possible future rainfall events can be simulated. The model also is a good supplement for warning and alert plans, based on pore water pressure and deformation measurements, because a much deeper understanding of the deformation behaviour of the landslide is possible. Further developments of the model are necessary to simulate the influence of stabilization measures – such as anchors, dewatering measures but also the effect of pumping storages with changing water tables at the toe of such a SMLS.

ABSTRACT: Tailings storage facilities present a global and growing challenge for mining companies. The management of tailings, which are the by-products of the mine processing plant, requires careful attention due to the potential risks they pose if the storage facility were to collapse. Such incidents can result in severe and lasting damage to the environment in downstream areas. Therefore, it is crucial to continuously monitor the structural stability of these facilities to ensure the safety and sustainability of active mining sites and legacy mines. This paper introduces a novel approach where muon tomography is employed to analyse the internal density structures of tailings dams. This work was conducted at the Prominent Hill Mine site in South Australia. We introduce an innovative method and technology for examining the internal density distribution of tailings storage facilities using muons, a natural source of radiation that can create X-ray-like scans of large structures. Muon technology provides a unique opportunity to provide insights into the inner structure of tailings storage facilities and potentially serves as a foundation for future research on developing early warning systems for detecting structural changes.

RÉSUMÉ: Les installations de stockage de résidus représentent un défi mondial et croissant pour les sociétés minières. La gestion des résidus, qui sont les sous-produits de l'usine de traitement minier, nécessite une attention particulière en raison des risques potentiels qu'ils posent en cas d'effondrement de l'installation de stockage. De tels incidents peuvent entraîner des dommages graves et durables à l'environnement dans les zones en aval. Il est donc crucial de surveiller en permanence la stabilité structurelle de ces installations afin de garantir la sécurité et la durabilité des sites miniers actifs et des mines existantes. Cet article présente une nouvelle approche où la tomographie muonique est utilisée pour analyser les structures de densité internes des barrages à résidus. Ce travail a été réalisé sur le site de la mine Prominent Hill en Australie méridionale. Nous introduisons une méthode et une technologie innovantes pour examiner la distribution de densité interne des installations de stockage de résidus à l'aide de muons, une source naturelle de rayonnement capable de créer des balayages de grandes structures semblables aux rayons X. La technologie des muons offre une opportunité unique de mieux comprendre la structure interne des installations de stockage de résidus et sert potentiellement de base à de futures recherches sur le développement de systèmes d'alerte précoce pour détecter les changements structurels.

Keywords: Tailings storage facilities; tailings wall monitoring; muon tomography; muography.

1 INTRODUCTION

Tailings Storage Facilities (TSF) are subject of long-term monitoring for stability and liquefaction assessments. Some remote monitoring capability for TSF is currently available with detection systems such as extensometers, LIDAR, total station, taseometers, and seismic sensors. However, their range and coverage of detection area are limited. Furthermore, background noise that inhibits detection ability, radiation licences that create barriers to deployment, and significant energy consumption of the systems either increase cost or restrict the longevity and flexibility of deployment.

The use of muons, naturally occurring particles from space, that impact a site and penetrate through hundreds of metres of rock with well-characterised frequency and direction, has long been considered a potential means to scan large volumes of matter.

Muons are continually being created by high-energy cosmic rays arriving from interstellar space and colliding with Earth's atmosphere at altitudes of about 15 kilometres. The average muon flux at sea level is about 1 muon per square centimetre per minute. The rate at which a muon loses energy as it interacts with matter is proportional to the density of the material it travels through.

Initially explored in 1955 to estimate tunnel overburden in the Snowy Mountains in Australia (George, 1955); detector capabilities have since greatly improved permitting mineral exploration (Bryman et al. , 2015), volcano monitoring (Nagamine et al., 1995), tide/tidal wave detection (Tanaka et al., 2022) and even mapping of corridors inside pyramids (Procureur et al., 2023).

In this paper we demonstrate a world-first use case of muon tomography in the context of TSF.

2 METHODOLOGY

The core detection unit is a 'telescopic' muon detector with several plastic scintillators that emit light when struck by a muon. This light is then received by mounted single-pixel silicon photomultipliers (SiPMs) (Krishnan et al., 2020). By utilising optically isolated sub-detectors within a panel plane, the arrival direction of intersecting muons can be estimated geometrically. The telescopic detectors provide angular coordinate uncertainty of less than five degrees within a field-of-view of order 17 × 17 degrees per pointing.

Two or more telescopic detectors are arranged along the embankment of a TSF to provide a limited 3D stereoscopic resolution of the muon flux detected across the extent of the embankment. Each detector observes multiple pointings over the course of several weeks to determine the muon flux as a function of angle across a TSF embankment (shown in Figure xxx). The observed muon flux depends on the elevation angle of observation and the opacity (or projected surface density), which is directly proportional to the muon path length inside the TSF embankment material and to the density of the material itself. Using at least two observation points separated by a known distance provides a stereoscopic 3D constraint on the material within overlapping fields of view.

The stand-alone telescopic muon detector system is solar powered with data transferred over 4G and can work independently of the mine power and communications infrastructure, easing many overheads and permissions from the host site.

Numerical simulations using the PUMAS library (Niess, 2022) and the Pyrate software package (Scutti, 2022) have been used to establish a relation between measured muon flux and observed opacity. This relation, which includes the correction for the elevation of observation, is used to convert the measured muon flux into observed opacity.

Assuming a geometry where the TSF can be subdivided into N 3D sub-blocks with uniform density ρ_j, the opacity Λ_i relative to a given muon path i inside the TSF is the sum of the products of individual path lengths Δl_{ij} and densities ρ_j for each sub-block j.

Simplifying assumptions about the interactions of muons with the medium of the TSF embankment are as follows. (1) Muons travel in straight lines for the energy ranges that predominate the ambient muon flux. (2) Muons are attenuated at a rate (Λ_i) proportional only to the density of the medium traversed (ρ_j) and distance traversed (Δl_{ij}) given as:

$$\sum_{j=1}^{N} \Delta l_{ij} \rho_j = \Lambda_i \qquad (1)$$

The basis of our adopted algorithm for 3D Muon Tomography is that of the Lines-Of-Sight (LOS) of different detectors intersecting common cells in the 3D block model space and by comparing observed LOS opacities against those computed by equation 1. The computed LOS opacity uses a 3D regular grid traversal algorithm (Figure 1) through an a priori discretised geological model of densities.

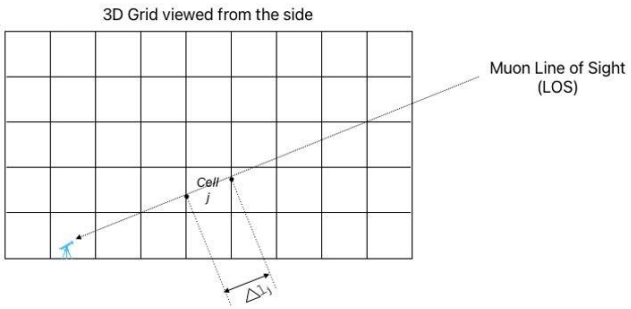

Figure 1. 3D Regular Grid Traversal Algorithm; with the opacity along a muon's line of sight (LOS) computed using equation 1.

The algorithm aims to find the density distribution of the medium traversed (ρ_j) such that equation 2 is minimised:

$$\left\| \Lambda_i - \left(\sum_{j=1}^{N} \Delta l_{ij} \rho_j \right) \right\| \qquad (2)$$

The algorithm developed to solve equation 1 is based on a Monte Carlo Markov Chain (MCMC) approach. Starting with an a-priori discretised geological model of densities to populate the initial guess for values of the image precomputed segment lengths of muon trajectories for the action, and reconstructed opacities derived from the observed muon events, an iterative method stochastically perturbs the image - one randomly selected cell at a time - looking to minimise equation 2.

This approach allows for geological constraints to be applied to the evolution of the model during its convergence (Guillen et al., 2004). The ability to use geological constraints is an advantage the MCMC approach offers over approximate imaging methods such as SIRT (Ren and Kalscheuer, 2020).

3 SURVEY

The Prominent Hill copper-gold mine is located approximately 640 km northwest of Adelaide in northern South Australia. Prominent Hill has one TSF impounded within the Integrated Waste Landform (IWL), shown in Figure 2. The TSF is a singular, circular facility containing tailings generated from processing ore from the open pit and underground mines. It has a diameter of 1750 m covering an area of about 2.4 km^2.

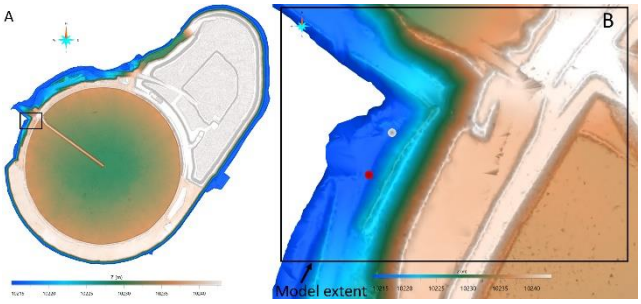

Figure 2. Topography surfaces generated from LiDAR data (blue colours are low elevations, white colours are high elevations) for: (A) the entire Prominent Hill tailings storage facility (black box shows the location of the scanned region), and (B) the scanned region zoom in, with the two telescopic detector deployments as the white and red dots.

Construction of the TSF has been ongoing, with five embankment lifts occurring since commissioning in 2009. The TSF embankment is a minimum 60 m wide waste rock dump rising 25 m high. On the tailings side of the embankment, a filter zone made up of finer waste rock, typically 3 m wide, was built concurrently with a 6m clay liner adjacent to the tailings.

Three detectors (seen in Figure 3) were used to monitor the region of interest identified in Figure 2. The primary and secondary detectors were telescopes used to scan the region dynamically. These detectors are placed approximately 10 m from the beginning of the rise, spaced 50 m from each other. The third reference detector was a simple muon counter recording the background rate.

The primary and secondary detectors were powered by an independent solar array with a single communication link used for data transfer and power distribution. Data acquisition and 4G gateway then arbitrated the data from all three detectors and forwarded data to the cloud.

Figure 3. Two muon detector telescopes mid-installation (note not their final placements), with the background muon counter as the small black box at its base.

Each detector observed multiple pointings over the course of nearly ten days to determine the muon flux as a function of angle across the TSF embankment.

The muon flux, detected across the extent of the embankment was converted to an opacity using an open-source muon physics transport engine, PUMAS (Niess, 2022). Regions in which opacities, or equivalently projected surface densities, had intersecting sightlines were then inverted to produce a 3D apparent density using the MCMC algorithm. These discrete points were then kriged to create a 3D volumetric apparent density, as shown in Figure 4.

The results of the muon-derived apparent densities, post-kriging, are found to be a distribution heavily skewed to the expected wall material density, with the 10th and 90th percentile found at 1.64 g/cm^3 and1.82 g/cm^3, respectively. While there are some outliers with unrealistically high apparent densities (over 10.0 g/cm^3), these make up a very small proportion of the scanned volume (0.3 per cent of the scanned volume falls between 3.0 g/cm^3 and 10.2 g/cm^3) and are numerical artefacts.

As shown in Figure 4, relatively high apparent densities (between 1.8 g/cm^3 and 2.2 g/cm^3) are robustly detected although their cause remains unclear. We suspect these values correspond to cemented backfill and basement waste which has been confirmed to have been used to build the TSF in the observed

direction of the telescope. Apparent densities estimated from muon tomography have tended to be slightly higher (median of 1.68 g/cm^3) compared with the measured value (1.495 g/cm^3).

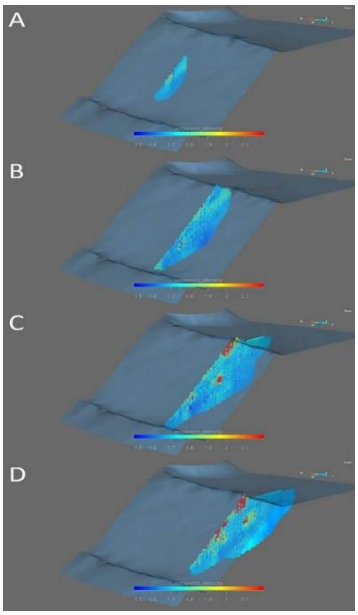

Figure 4. Apparent densities kriged throughout the scanned volume, shown as a progressive slice from North (A) to South (D). Cooler blue colours indicate low apparent densities, warmer red colours indicate high apparent densities. The transparent blue surface is the topography of the TSF. Note that only the rock fill embankment has been scanned.

4 CONCLUSIONS

Although only a limited area of the Tailings Storage Facility was scanned in this short deployment the utilisation and efficacy of muons for cheaply scanning large volumes, with no site disruption or installation requirements is clear. Muon technology provides a unique opportunity to provide insights into the inner structure of tailings storage facilities and potentially serves as a foundation for future research on developing early warning systems for detecting structural changes.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the support of the Prominent Hill mine in facilitating the trials, particularly Antoinette Stryk. mDetect recognises the valuable ongoing support of the Swinburne University of Technology, with special thanks to David Smoors for technical efforts. This work was made possible by the Australian Commonwealth Government's Advanced Manufacturing Growth Centre, AMGC, grant number C259.

Liquefaction resistance of TP-Lisbon sand: A comparison between cyclic triaxial and cyclic direct simple shear tests

Résistance à la liquéfaction du sable TP-Lisbon: Une comparaison entre les essais triaxiaux cycliques et cisaillement simple direct cycliques.

ABSTRACT: Soil liquefaction is one of the most complex phenomena characterised by the rapid loss of the strength and stiffness of soil. In the laboratory, the liquefaction resistance can be assessed by different testing procedures, involving axisymmetric and plain strain conditions. This paper addresses an experimental comparison between the results of cyclic triaxial and cyclic direct simple shear testing. The tests were conducted using a historically liquefiable sand from the city centre of Lisbon, denominated as TP-Lisbon sand. Findings showed a higher liquefaction resistance for axisymmetric conditions (cyclic triaxial tests) than plane strain conditions (direct simple shear tests). Therefore, a method to transform the results derived from either cyclic triaxial or direct simple shear is proposed. This method provides a reliable prediction of liquefaction resistance derived inversion and rotation of principal stresses in a single approach.

RÉSUMÉ: La liquéfaction des sols est l'un des phénomènes les plus complexes et instables, se caractérisant par une perte rapide de la résistance et de la rigidité du sol. En laboratoire, la résistance à la liquéfaction peut être évaluée par différentes procédures d'essai, impliquant des conditions axiales symétriques et de déformation simple. Cet article aborde une comparaison expérimentale entre les résultats des essais triaxiaux cycliques et des essais de cisaillement simple direct cycliques. Les essais ont été réalisés avec un sable historiquement liquéfiable du centre-ville de Lisbonne, sable TP-Lisbon. Les résultats ont montré une plus grande résistance à la liquéfaction dans des conditions axysy axisymétriques métriques (essais triaxiaux cycliques) par rapport aux conditions de contrainte pure (essais de cisaillement simple). Par conséquent, une méthode de transformation des résultats obtenus par des essais triaxiaux cycliques ou de cisaillement simple est proposée. Cette méthode permet de prédire la résistance à la liquéfaction en prenant en compte l'inversion et la rotation des contraintes principales au sein d'une seule approche.

Keywords: Liquefaction; laboratory testing; cyclic characterisation; sands.

1 INTRODUCTION

Liquefaction phenomena is characterised by the rapid loss of the strength and stiffness of soil due to the pore pressure build-up during cyclic or monotonic loading. Effective stress tends to zero during liquefaction due to the generation of pore pressure build-up (Ishihara, 1993). Around the world, liquefaction has seriously damaged a number of infrastructures. In Portugal, local liquefaction-induced damage dates from 1344, 1531, 1755 and 1909 when distant and local intraplate earthquakes (with a magnitude between 6.0 and 8.5) struck the Portuguese onshore mainland, mainly affecting the greater Lisbon area (Jorge, 1993). Therefore, the characterisation of the cyclic behaviour of liquefiable soils of Lisbon centre is essential to prevent damage and possible collapse of buildings and infrastructure in this region due to earthquake-induced liquefaction.

This paper presents the results of the liquefaction resistance characterisation of TP-Lisbon sand using cyclic triaxial tests (CTx) and cyclic direct simple shear tests (CDSS). TP-Lisbon sand was collected in a site locally denominated as 'Terreiro do Paço', located in the historical centre of Lisbon (Molina-Gómez & Viana da Fonseca, 2021). The experimental program focuses on the assessment of the effects of the inversion and rotation of principal stresses. A method to assess and compare these effects is proposed herein, proposing an estimation from a single approach. This method provides a reliable unification of both CTx and CDSS results to characterise the liquefaction resistance of TP-Lisbon sand.

2 MATERIALS AND METHODS

2.1 Description of TP-Lisbon sand

TP-Lisbon sand is an alluvial granular soil with origin in the late Quaternary, which has sedimented next to the Tagus River in the historical centre of Lisbon. This site is named by locals as 'Terreiro do Paço', (that in English means courtyard palace). The buildings surrounding this relevant historical spot correspond to old heritage Pombalino masonry buildings (Couto et al., 2020). The samples of TP-Lisbon sand were collected within the scope of geotechnical exploration for the construction of the Lisbon blue line tunnel of 'Metropolitano de Lisboa'. These samples were collected in a site investigation located into the 'Praça do Comércio', specifically at the coordinates 38º42'26.6"N–9º8'13.4"W (Molina-Gómez & Viana da Fonseca, 2021).

The specific gravity of solid particles (G_s), the minimum void ratio (e_{min}) and the maximum void ratio (e_{max}) are shown in Table 1. The parameters of the particle size distribution are also exposed in Table 2, including the mean diameter (D_{50}), the coefficient of curvature (Cc), the coefficient of uniformity (Cu) and the fines content (FC). The particle size distribution of TP-Lisbon sand is depicted in Figure 1. The unified soil classification system (USCS) classifies the TP-Lisbon sand as poorly graded (SP), with low values for Cu and Cc.

Table 1. Physical properties of TP-Lisbon sand.

Parameter	Value
Gs	2.66
e_{min}	0.64
e_{max}	1.01
D_{50} (mm)	0.21
Cu	1.69
Cc	1.13
FC (%)	2.21

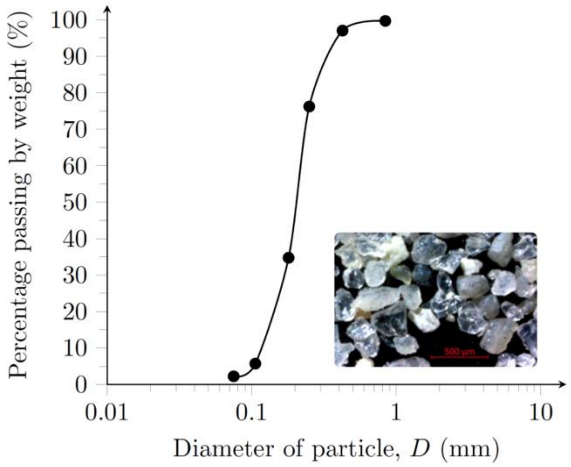

Figure 1. Particle size distribution of TP-Lisbon sand.

2.2 Testing devices and experimentation

The experimental programme for assessing the liquefaction resistance of TP-Lisbon sand involved an advanced testing programme in the laboratory involving cyclic triaxial (CTx) and cyclic direct simple shear (CDSS) tests. CTx and CDSS apparatuses allowed for the inversion and rotation of principal stresses, respectively. Therefore, the comparison between the results of both types of tests provided a comprehensive characterisation of cyclic behaviour and liquefaction resistance of TP-Lisbon sand.

The CTx apparatus featured a traditional triaxial cell equipped with a submersible load cell with a capacity of 1 kN. Cyclic loading was applied using a servo-actuator, consisting of a hydraulic piston for displacement or load control, with a frequency ranging between 0.001 and 2 Hz. A precise regulation of cell pressure and back-pressure was achieved using a pair of Pressure/Volume Controllers manufactured by Global Digital Systems (GDS). These controllers allowed for the automated increment of both pressures during the saturation and consolidation phases. To ensure reliable contact between the top cap and the hydraulic piston during cyclic loading, a rubber V-ring was employed to guarantee the inversion of principal stresses during the cyclic testing (Cordeiro et al., 2022; Molina-Gómez et al., 2023).

An advanced and fully automatic simple shear apparatus manufactured by Willie Geotechnik was employed. The equipment features two high-quality servomotors for vertical and horizontal loading, two local LVDT transducers to measure vertical and horizontal displacements and a multi-axis load cell. It enables static and cyclic tests under both strain and stress control by a SGI configuration. The SGI configuration comprises a series of stacked copper rings to maintain a constant cross-sectional area while allowing for shear distortion of the specimen. The cyclic loading was applied under constant volume conditions, ensuring an invariant height of the specimen through active control based on the vertical displacement reported by local LVDT. Constant volume tests are equivalent to undrained shear tests (Dyvik et al., 1987).

In this study, the following testing procedures were implemented for both CTx and CDSS tests. All samples were reconstituted to achieve a Dr of 50% using the dry pluviation method. This method was adopted due to its capability to replicate the initial fabric of alluvial soil deposits (Quinteros & Carraro, 2023). The samples were saturated by flushing carbon monoxide and de-aired water (Viana da Fonseca et al., 2021). The full saturation condition was confirmed through bender element tests by reporting P-wave

velocity values higher than 1482 m/s are needed to ensure the full saturation of the soil (Astuto et al., 2023). After saturation confirmation, the samples were consolidated for a mean effective stress (p'_0) of 50 kPa and effective vertical stress (σ'_0) of 80 kPa for CTx and CDSS tests, respectively. The soil samples were sheared using different cyclic stress ratio (CSR) combinations at a frequency of 0.1 Hz.

3 RESULTS AND DISCUSSION

3.1 Description of TP-Lisbon sand

Figure 2 shows the liquefaction resistance curves for TP-Lisbon sand derived from the results obtained from 5 CTx and 5 CDSS tests. These curves were derived by a power law that correlates the number of cycles liquefaction onset (N_L) for each CSR. N_L was identified when double axial strain exceeding 5.0% for CTx tests and double shear strain exceeding 7.5%.

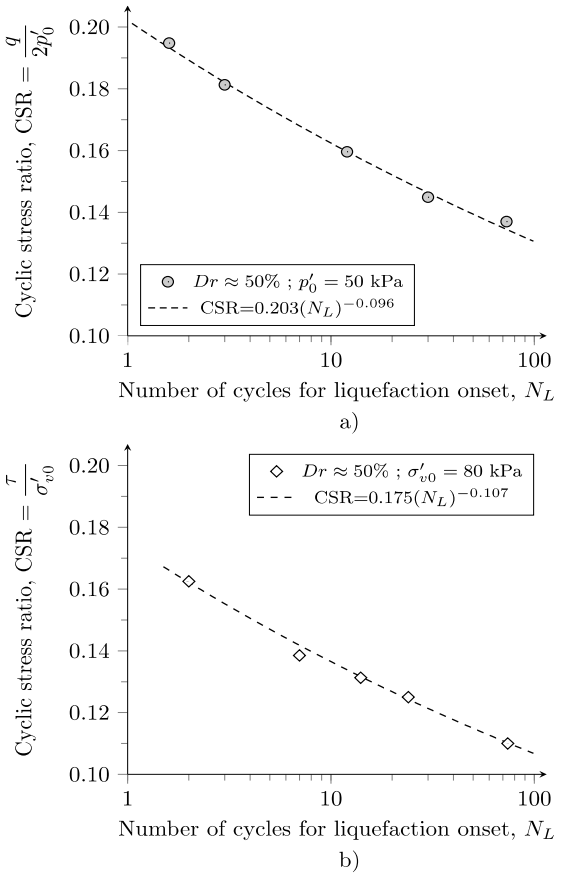

Figure 2. Liquefaction resistance curves: a) CTx results; b) CDSS results.

Experimental results in Figure 2 revealed that inversion of principal stresses (i.e. CTx tests) leads to a higher liquefaction resistance than rotation of principal stresses (i.e. CDSS tests). However, Figure 2 shows that the liquefaction resistance curves for TP-Lisbon sand are parallel, independently of the testing condition. The CTx and CDSS results have been contrasted (Giretti et al., 2018; Nong et al., 2021). Although the loading differences, these results can be correlated using a correction coefficient (*Cr*), which transforms liquefaction resistance from isotropic triaxial testing into liquefaction resistance in simple shear conditions:

$$CSR_{SS} = Cr \cdot CSR_{CTx} \quad (1)$$

Diverse authors (Castro & Poulos, 1977; Finn et al., 1971; Ishihara et al., 1985) demonstrated that *Cr* is a function of the lateral earth pressure coefficient at rest (K_0). Equation 2 presents a *Cr* correlation for TP-Lisbon sand.

$$Cr = \frac{2 + 3K_0}{4} \quad (2)$$

This correlation was obtained by adjusting the experimental results by the least-square method, obtaining a correlation coefficient $R^2 = 0.92$. For normally consolidated sands, K_0 is reasonably estimated by the approximation $K_0 = 1\text{-}\sin\phi_{cv}$ (Jaky, 1944). Molina-Gómez & Viana da Fonseca (2021) found that the friction angle at constant volume (ϕ_{cv}) of TP-Lisbon sand is 34º. Hence, *Cr* is equal to 0.83. Figure 3 demonstrates that the results obtained from both test types are associated since they fall into a single liquefaction resistance curve after applying the *Cr* transformation.

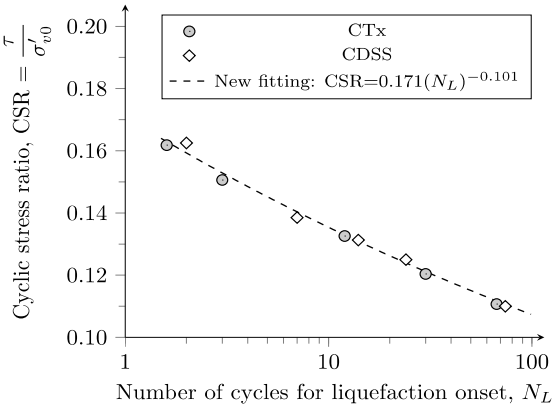

Figure 3. Transformed liquefaction resistance curve.

Figure 3 shows a good agreement between CTx and CDSS after results transformation. Hence, by using the *Cr* transformation, it is possible to compare the liquefaction resistance estimated by both testing procedures, providing a robust basis for cross-referencing their results and facilitating a more

comprehensive understanding of cyclic behaviour of TP-Lisbon sand.

4 CONCLUSION

This paper has presented a comprehensive characterisation of the liquefaction resistance of the TP-Lisbon sand using CTx and CDSS testing. Experimental results showed that the inversion of principal stresses leads to higher resistance than the rotation of principal stresses. This disparity between the two testing conditions can be overcome by introducing the correction coefficient, *Cr*. The transformation provided by *Cr* allows for a reliable approach, which provides a valuable approach to compare and understand the liquefaction resistance of TP-Lisbon sand under different stress paths.

ABSTRACT: The regional road no. 2-2ª is the only access to Ribeira Quente parish on the island of São Miguel (Azores). This road is approximately 5.5 km long and runs along the Ribeira Quente valley, with slopes that, in some cases, reach 450 m in height and with very steep gradients. The geology is very complex, with basaltic (*s.l.*) and trachytic (*s.l.*) lava flows, welded and non-welded ignimbrites, fall and flow pumice deposits, and slope deposits. Due to their geological, morphological, and hydrological characteristics, normally associated with episodes of intense and/or prolonged rainfall, the slopes often become unstable, isolating the population of Ribeira Quente parish from any kind of assistance by land. An example of this was the disaster that occurred on October 31, 1997, which left 29 people dead. Given the above, various consolidation works were carried out on the road's slope, of different types, namely: alteration of geometry, installation of external and internal drainage systems, ditches, application of shotcrete with nailing, and a semi-tunnel. This work presents the different interventions carried out along this regional road, as well as those that are planned to minimize and mitigate geomorphological risks. The aim is also to illustrate and emphasise the fact that any stabilisation solution needs to be properly dimensioned and have a maintenance plan after its implementation to guarantee its full functionality.

RÉSUMÉ: La route régionale n.° 2-2ª est le seul accès à la paroisse de Ribeira Quente sur l'île de São Miguel (Açores). Cette route, d'une longueur d'environ 5,5 km, longe la vallée de Ribeira Quente avec des pentes qui, dans certains cas, atteignent 450 m d'altitude et des dénivelés très importants. La géologie du site est très complexe, avec des coulées de lave basaltique (*s.l.*) et trachytique (*s.l.*), des ignimbrites soudées et non soudées, des dépôts de ponce de chute et de coulée et des dépôts de pente. En raison de leurs caractéristiques géologiques, morphologiques et hydrologiques, normalement associées à des épisodes de précipitations intenses et/ou prolongées, les pentes deviennent souvent instables, isolant la population de la paroisse de Ribeira Quente de toute forme d'assistance par terre. La catastrophe du 31 octobre 1997, qui a causé la mort de 29 personnes, en est un exemple. Compte tenu de ce qui précède, divers travaux de consolidation ont été réalisés sur le talus de la route, de différents types, à savoir: modification de la géométrie, installation de systèmes de drainage externes et internes, fossés, application de béton projeté avec clouage et un semi-tunnel. Ce travail présente les différentes interventions réalisées le long de cette route régionale, ainsi que celles qui sont prévues pour minimiser et atténuer les risques géomorphologiques. L'objectif est également d'illustrer et de souligner que toute solution de stabilisation doit être correctement dimensionnée, et disposer d'un plan d'entretien après sa mise en œuvre, afin de garantir sa pleine fonctionnalité.

Keywords: Geomorphological risks; slope instabilities; road protection; Azores.

1 INTRODUCTION

As a result of its volcanic-tectonic setting, the Azores archipelago has a wide variety of soils with different mechanical characteristics. The existence of slopes made up of volcanic deposits with different physical, mechanical, and hydrogeological characteristics are themselves predisposing factors to the occurrence of geomorphological instability processes, namely landslides, with consequences for people and property. Rainfall is one of the main factors triggering landslides in the Azores, as the increase in water in the materials leads to a decrease in shear strength, which can occur through the decrease in apparent cohesion (in unsaturated soils) or an increase in neutral pressures in the potential slip surface due the rise of the water table (Amaral, 2010 and Amaral *et al.*, 2010).

The regional road no. 2-2ª (E.R. 2-2ª), in the Ribeira Quente parish, on São Miguel Island (Azores), is flanked by slopes ranging in height from a few metres to approximately 450 meters, some with steep inclines. These slopes have a complex geological

constitution, ranging from basaltic (*l.s.*) and trachytic (*l.s.*) lava flows, welded and non-welded ignimbrites, pomitic pyroclastic deposits of fall and flow and gravitational deposits. Given the above, these slopes are highly prone to slope movements, particularly landslides and debris flows, which are usually associated with heavy and/or prolonged rainfall.

Over time, numerous episodes of heavy precipitation have triggered slope movements, resulting in the blockade of the road, often at multiple locations. This, in turn, isolates the local population, cutting off access to assistance by land. The most notable event took place in 1997, when 29 people died in the Ribeira Quente parish, and the most recent was in June 2023. Therefore, it has become imperative to intervene geotechnically along this road. The carried-out interventions aimed the improvement of safety conditions; however, if they are not supported by geological and geotechnical studies and maintenance actions, they risk not being functional in the long term. This article presents some slope consolidation works carried out at Ribeira Quente Road. In addition, the aim is to illustrate why any stabilisation solution must be the subject of a study, which supports the project, and must also include a long-term maintenance plan, which must be adhered to guarantee the functionality of the solutions.

2 STUDY AREA

The E.R. 2-2ª access road to the Ribeira Quente parish, in the Ribeira Quente valley, is one of the areas most affected by slope movements in the Azores archipelago. This road is the only access route to the parish.

The existing water lines in the Ribeira Quente valley, as well as the presence of concave morphologies expressed in the slopes, with continuity upstream, represent flow channels favourable to the mobilisation of debris flows.

Considering the susceptibility of this location to the occurrence of slope movements, Marques (2013), based on the work carried out by Marques et al (2009), produced a map of susceptibility and propagation of slope movements for the municipality of Povoação, including the Ribeira Quente parish (Figure 1).

From this map, it can be seen that this road is very vulnerable to geomorphological instability processes. Based on this information, which justifies the phenomena that have occurred in this location, it became imperative to implement actions to minimise some of the most serious situations, intending to improve safety conditions for passers-by. It is important to emphasise that these measures do not completely eliminate geomorphological risk (as we can see in the most recent situation), but only contribute substantially to reducing it.

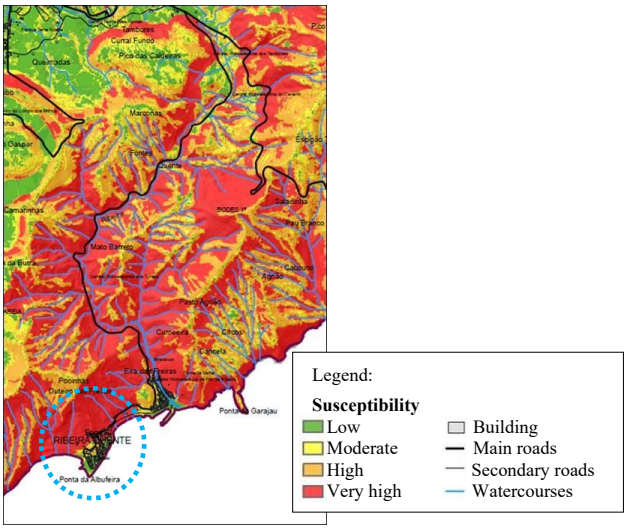

Figure 1. Map of susceptibility and propagation of occurrence of slope movements for the Ribeira Quente valley, outlined in blue (adapted from Marques, 2013).

3 RISK MITIGATION MEASURES

In recent years, 15 sites along the E.R. 2-2ª (Figure 2), which had been identified as critical, have been intervened. The risk mitigation measures to be implemented are: (1) re-profiling the slope, (2) a retaining wall with a ditch at the end, (3) construction of a semi-tunnel, (4) removal of rock blocks and (5) metal nets with nails and sometimes with shotcrete. This paper will present only 4 of the 15 sites intervened, corresponding to sites 4, 5, 12 and 14 (Figure 2), taking into account their representativeness in the overall context of the interventions.

Site no. 4 corresponds to a slope about 20 metres high and is made up of intercalations of trachytic pyroclastic deposits of different grain sizes. The intervention carried out at this site involves altering the geometry of the slope, softening its slope, and creating a bench at approximately half height (Figure 3).

The slopes adjacent to the E.R. 2-2ª usually have water levels. Evidence of this can be seen in the numerous springs and waterfalls that can be seen along the road. Despite this, no deep drainage system, such as sub-horizontal drains, has been installed at site no. 4. Thus, on the face of the slope, it is possible to observe signs of internal erosion caused by the outflow and accumulation of water, as well as gullies due to surface run-off (Figure 4 on the left). Apparently, no geological and geotechnical study or global stability analyses have been carried out on the slopes to be re-profiled to ascertain which tilt gives them stability.

Indeed, there have already been several surface geomorphological instabilities on the face of the re-profiled slopes. At site no. 6 (Figure 4 on the right), there was a superficial geomorphological instability on the face of the re-profiled slope.

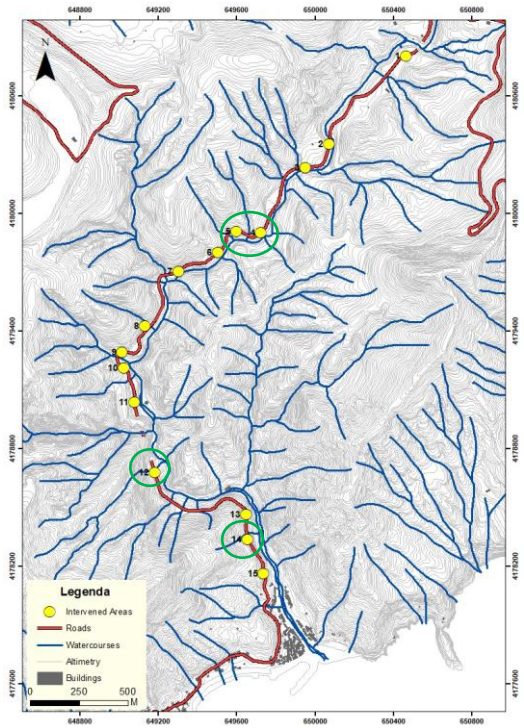

Figure 2. Location of the sections of the intervened areas. In green circles, the indication of the four sites presented in this work.

Figure 3. Site no. 4 - Slope re-profiling.

Figure 4. Site nº. 4 - Erosion on the slope face (on the left). Geomorphological instability at site no. 6 (on the right).

At site no. 5, a retaining wall was built with a ditch at its back, aiming to collect a large part of the material mobilised from upstream, preventing it from reaching the regional road platform (Figure 5). Over time, this measure has proved to be effective, as there have been several reports of these structures intercepting material that was heading towards vehicles travelling on the E.R. 2-2ª. However, these are measures that need to be maintained, in this specific case by removing the material that is trapped inside the ditch, so that it remains operational, a situation that does not always occur, as is the case at site no. 7 (Figure 5 on the right).

Figure 5. Site no. 5 – Waiting wall with ditch (on the left). Site no. 7 – No maintenance (on the right).

The slope adjacent to site no. 12 is 400 metres high. Taking into account the difficulty of implementing stabilisation measures there, a semi-tunnel was built, approximately 200 m long (Figure 6).

Figure 6. Site no. 12 – Semi-tunnel.

The length initially planned for the semi-tunnel was greater than that actually built. The initial extension was justified by the geological and morphological characteristics of the adjacent slopes. A heavy rainfall event in June 2023, which led to several landslides, debris flows, and debris avalanches, demonstrated

this. In fact, in this event, the most serious situation occurred on the slope adjacent to the section of the semi-tunnel that was chosen not to be intervened on (Figure 7). The unstable material was deposited at the entrance of the semi-tunnel, causing its interruption and, once again, leaving the population of the Ribeira Quente parish isolated for a few hours.

Finally, the last site presented (site no. 14) corresponds to the application of nailing, metal mesh and shotcrete (Figure 8).

Figure 7. Geomorphological instability, of debris avalanche type, on the slope adjacent to the semi-tunnel.

Figure 8. Site no. 14 - Application of nailing, metal mesh and shotcrete.

4 CONCLUSIONS

The Ribeira Quente valley, where the E.R. 2-2ª is located, is one of the places that has been most affected by slope movements. The wide variety of volcanic materials, combined with adverse weather conditions, promotes the occurrence of different types of slope failures, with different modes of mobilisation and destructive potential, which is why risk mitigation measures have been taken.

The stabilisation solutions implemented in the sectors identified as most critical were conditioned by the geology and morphology of the slopes adjacent to the E.R. 2-2ª. These measures aim to minimise the geomorphological risk of this road and its passers-by, although they will not eliminate it completely. The solutions involved re-profiling the slopes, building retaining walls with a ditch at the end, constructing a semi-tunnel, removing rock blocks, and the application of metal nets with nails, sometimes with shotcrete.

Throughout the document, it was possible to see the importance of a prior study of the site to be intervened, with geological and geotechnical studies, as well as global stability analyses. In addition, all the works carried out require periodic maintenance, with cleaning and removal of debris, in order to guarantee their effectiveness. It should be noted that the main problems were observed in the places where the stabilisation solution involved slope re-profiling, with the occurrence of surface ruptures. Furthermore, places where retaining walls were built with a ditch at the end found a lack of cleaning of the ditches where the unstable deposits were trapped in that structure.

Effect of bentonite permeation on the fabric and strength of Ottawa Sand

Effet de la perméation de la bentonite sur la structure et la résistance du Sable d'Ottawa

D. Mourtada, G.A. Jaoude*
Lebanese American University, Byblos, Lebanon
**grace.aboujaoude@lau.edu.lb*

ABSTRACT: This work aims to assess how the application of bentonite for soil liquefaction mitigation influences the soil fabric. Soil fabric controls the mechanical response of the soil through the interlocking forces between its particles. This is quantified using small-strain stiffness modulus G_{max}. Maintaining or increasing G_{max} is as important as increasing the cyclic resistance in any proposed mitigation measure against soil liquefaction. Previous studies have shown the effective use of bentonite in loose Ottawa sand samples for liquefaction mitigation using dry-mixing and permeation sample preparation techniques. However, resonant column tests on bentonite-treated dry mixed Ottawa Sand samples showed a decrease of the small strain stiffness modulus (G_{max}) and thus a decrease in the shear strength of the treated soil compared to that of clean Ottawa Sand samples. This work investigated the effect of permeation on the small-strain stiffness of bentonite-treated loose Ottawa sand samples. Static triaxial tests and bender element tests on these samples showed that bentonite-treated sand samples at least maintained the same shear strength and small-strain stiffness moduli as those of clean sand samples. This work proves the effectiveness of the use of the permeation method using bentonite as a non-disruptive liquefaction mitigation technique.

RÉSUMÉ: Ce travail vise à évaluer comment l'utilisation de la bentonite pour atténuer la liquéfaction des sols influence la structure du sol. La structure du sol contrôle la réponse mécanique du sol grâce aux forces d'imbrication entre ses particules. Ceci est mesuré par le module de module de cisaillement à petite déformation G_{max}. Le maintien ou l'augmentation de G_{max} est aussi important que l'augmentation de la résistance cyclique dans toute mesure d'atténuation proposée contre la liquéfaction du sol. Des études antérieures ont montré l'utilisation efficace de la bentonite dans des échantillons de sable meuble d'Ottawa pour atténuer la liquéfaction en utilisant des techniques de préparation d'échantillons par mélange à sec et par perméation. Cependant, les essais sur colonne résonante sur des échantillons de sable d'Ottawa mélangés à sec et traités à la bentonite ont montré une diminution du module de cisaillement à petite déformation (G_{max}) et donc une diminution de la résistance au cisaillement du sol traité par rapport à celle des échantillons de sable d'Ottawa propres. Ce travail a étudié l'effet de la perméation sur la rigidité à faible déformation d'échantillons de sable d'Ottawa meuble traité à la bentonite. Des essais triaxiaux statiques et des essais d'éléments de flexion sur ces échantillons ont montré que les échantillons de sable traité à la bentonite conservaient au moins les mêmes modules de résistance au cisaillement et de rigidité à faible déformation que ceux des échantillons de sable propre. Ce travail a prouvé l'efficacité de l'utilisation de la méthode de perméation utilisant la bentonite comme technique d'atténuation non perturbatrice de la liquéfaction.

Keywords: Bentonite; bender element; static triaxial testing; small strain stiffness modulus; soil fabric.

1 INTRODUCTION

Laboratory experiments have proven that the addition of 3% and 5% of plastic fines (bentonite) to sand increases the cyclic resistance by an order of magnitude in comparison to clean sand (El Mohtar et al., 2013; Haldavnekar et al., 2003). While extensive research has been conducted to study the effect of bentonite on the cyclic resistance of clean Ottawa Sand, the literature still lacks comprehensive information regarding the influence of bentonite on the fabric and strength of Ottawa Sand. El Mohtar et al. (2008) used the dry mix method to prepare sand mixtures with 3 and 5% bentonite (by mass of bentonite) and conducted static triaxial and resonant column tests to study the behaviour of the small strain stiffness modulus (G_{max}) during flushing and hydration, back saturation, and consolidation stages. Results showed that the G_{max} sharply drops after flushing the dry mixed samples with water. This was explained by the formation of a weak soft lubricant layer around the sand particles that is prevented from swelling due to contact stresses. As a consequence, the interlocking forces between the sand particles are

disturbed, hence, decreasing the G_{max}. During the consolidation stages at effective stress of 50 kPa, the G_{max} increased with time to values below those observed for clean sand samples. Moreover, El Mohtar et al. (2013) found that the yield stress friction angle of 3% and 5% dry mixed sand with bentonite samples decreased from 23° for a clean sand to 18° and 17°, respectively. The implications drawn from these findings suggested that the dry mix method altered the fabric of the sand and reduced the interlocking forces between the sand particles.

In this study, bentonite was introduced into a sand sample by permeation in an attempt to best represent the method that would be used on site. Bender element tests were performed on two types of samples: clean Ottawa Sand and permeated Ottawa Sand with 2% bentonite (by dry mass of sand). Samples were prepared at low relative densities (<35 or 40%). G_{max} values were obtained during the flushing and hydration (for clean sands), aging (for permeated samples), and over a range of consolidation stresses (50-300 kPa). Finally, strength properties were obtained following the shearing stage.

The results of the bender element tests were used to investigate the impact of the permeation method on the G_{max} and its correlation with the stress level. The preliminary findings provide insights on the effect of the selected laboratory sample preparation method on the fabric and strength of treated sand.

2 EXPERIMENTAL PROGRAM

2.1 Materials

The sand used for this study is Ottawa Sand C 778; a uniform clean fine to medium sand (D_{50}=0.4mm and C_u=1.7), having a specific gravity G_s=2.65, and minimum and maximum void ratios e_{min}=0.48 and e_{max}=0.78. The bentonite used is a commercial bentonite from Fisher Scientific finer than 0.075 mm. SPP (sodium pyrophosphate decahydrate) is used to decrease the yield stress and viscosity of the bentonite grout during permeation.

2.2 Sample preparation

Clean sand and permeated clean sand with 2% bentonite (by dry mass of sand) samples were prepared and tested. The clean sand samples were used as the reference samples to examine the effect of bentonite permeation on the fabric and the shear strength of the sand.

The clean sand samples were prepared directly on the triaxial machine. Ottawa Sand was air pluviated at zero drop height using a funnel to produce a loose sample with relative density below 35%. After assembling the samples and confining them at 25 kPa, CO_2 was flushed through the sample at a small rate for 15 mins to replace the air voids. Then, three pore volumes of distilled deaired water were flushed at a low gradient of 8 mL/min from the bottom to the top of the sample to achieve initial partial saturation while preventing the disturbance of the sand particles.

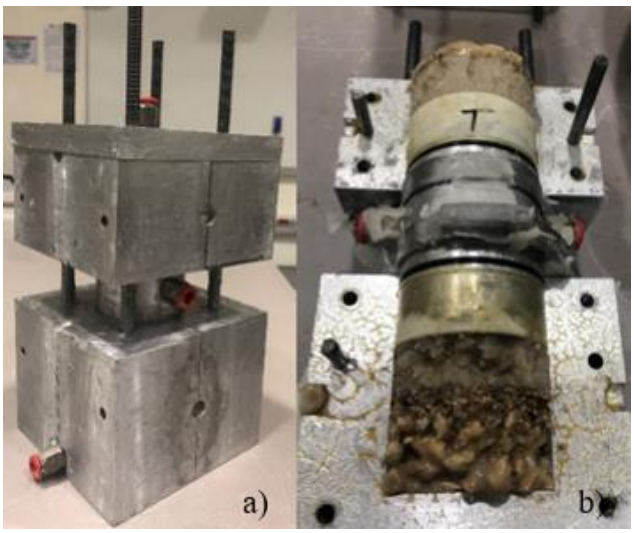

Figure 1. a) 3-way split mold b) Permeated sample after disassembly.

The permeated samples were prepared in a 3-way split mold, shown in Figure 1(a), that was first proposed by El Mohtar & Rugg, (2011). Due to impracticalities in performing the permeation process on the triaxial setup since cohesionless samples grouted with uncemented materials would collapse under their own weight, the mold provides adequate confinement to the sample during permeation. First, filter materials were first placed at the bottom of the mold consisting of a 20 mm layer of fine aggregates (diameter >4.75 mm) and a 20 mm layer of course sand (1.2>diameter>1.75 mm) to ensure a uniform permeation. A 10 mm layer of Ottawa Sand was placed above the filter material to allow for trimming any caking that would occur during the permeation process. Then, Ottawa Sand was air pluviated into the central section of the mold at zero drop height to achieve a relative density with a range of 33-42%. The properties of the clean sand and permeated samples are presented in Table 1. After air pluviation, another 10 mm layer of Ottawa Sand was placed on top of the central mold again for trimming purposes. Finally, a 20 mm layer of filter material was placed on top to prevent the sand from piping out of the mold during flushing and permeation. The CO_2 and distilled deaired water flushing procedures were done similar to the clean sand specimens. Bentonite suspensions with water to bentonite ratio of 8.55, equivalent to 2

Table 1. CS and PM sample properties.

bentonite by dry mass of sand, and 0.5% SPP by mass of bentonite were prepared using a high shear mixer. The permeation process was done at 8 mL/min and pressures below 100 kPa after 3 pore volumes of distilled deaired water were flushed into the sample. All the flushing and permeation procedures were done using a peristaltic pump (see setup in Figure 2). Permeation stopped when the pressure build-up reached a steady state or when sufficient amount of bentonite escaped from the top outlet of the mold. After that, the mold was kept still for 72 hours to allow the bentonite to swell and hydrate before disassembling the mold and placing the sample on the triaxial machine for testing.

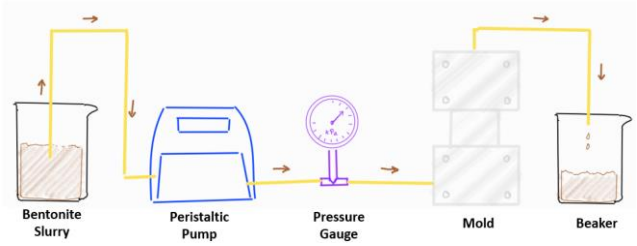

Figure 2. Permeation setup.

2.3 Static triaxial and bender element testing

A VJTech static triaxial machine was used to conduct consolidated undrained triaxial tests on both the clean sand and permeated specimens. First, a flushing and hydration stage for the clean sand samples and an aging stage for the permeated samples at a confinement of 25 kPa were done to ensure that the bentonite fully swells and hydrates for additional 72 hours. Second, back saturation begins to fully saturate the samples and reach a Skempton's B>0.95 (Black & Lee, 1973). The back pressures during this stage ranged between 500 and 600 kPa. Third, isotropic consolidation stages were done at effective pressures of 50, 75, 100, 200, and 300 kPa. Finally, undrained shearing was conducted to find the shear properties of the samples.

A VJTech bender element system embedded in the triaxial machine was used to fire S-wave signals from the top piezoelectric element placed in the top cap of the sample to the bottom piezoelectric element placed in the bottom cap of the sample. The travel time required for the S-wave to reach the bottom of the sample was used to calculate the shear wave velocity, knowing the height of the sample beforehand. The travel time was found using the peak-to-peak method. The small strain stiffness modulus (G_{max}) was calculated using equation (1):

$$G_{max} = \rho {v_s}^2 \quad (1)$$

where, ρ is the bulk density (Mg/m^3) of the sample and v_s is the shear wave velocity (m/s). Since bender element testing is non-destructive, it was conducted throughout the aging and consolidation stages of the triaxial testing at pulse frequencies 15 kHz, 10 kHz, and 5 kHz and amplitude 12 mV to study the behaviour of G_{max} and compare the values between the clean sand and permeated specimens.

3 RESULTS

3.1 Effect of flushing and hydration/aging on G_{max}

Figure 3 shows the behavior of G_{max} during the flushing and hydration period of clean sand (CS) samples and during the aging period of permeated (PM) samples. The data corresponding to these samples is representative of other tested samples. The clean sand sample shows a sudden rise in G_{max} after flushing the sample with water due to the increase of bulk density (ρ) and G_{max} remains constant after flushing because there is no change in the soil fabric with time. The permeated samples were prepared in the 3-way split mold and kept undisturbed for 72 hours for the bentonite to hydrate and to be able to disassemble the samples without it collapsing. After disassembling the samples (see Figure 1(b)), they were placed on the triaxial machine and confined at 25 kPa. Bender element signals were fired throughout the 72 hours of confinement. The permeated specimens showed almost a constant behavior of G_{max} with time. This is because the time needed for the bentonite to fully hydrate in the pore space is between 36 and 72 hours as discussed in El Mohtar (2008) and after that amount of time, no significant change in the soil fabric is observed.

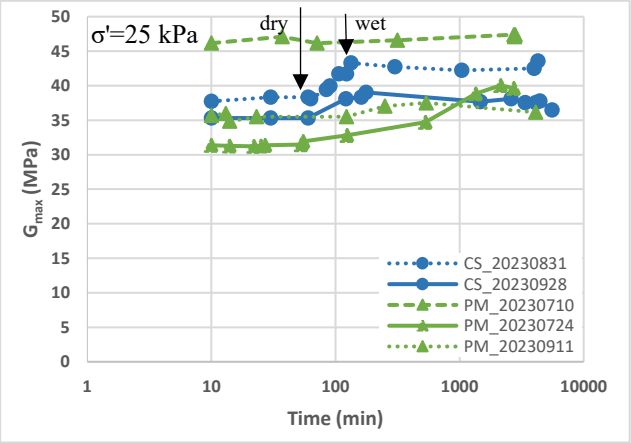

Figure 3. Gmax monitoring throughout the flushing and hydration/aging stages of CS and PM samples.

3.2 Effect of consolidation on G_{max}

Figure 4 shows the G_{max} results during the staged consolidation phases performed at 50, 75, and 100 kPa effective stresses. One clean sand sample (CS_20230928) was only consolidated at 50 kPa effective stress to obtain shearing results at this effective stress for at least one clean sand sample. The initial data point of each data set indicates the G_{max} value at the end of the flushing and hydration/aging stages. The curves indicate that the G_{max} values increase after dissipating the excess pore pressure and remain almost constant throughout the primary consolidation stage. The data also shows that the G_{max} exhibit greater values under higher effective stresses as can also be seen in Figure 5, where G_{max} increases linearly with effective stress during consolidation. This can be attributed to the increase of interlocking forces between the sand particles at higher confining stresses.

It can also be seen in Figure 4 that the G_{max} values of the permeated samples increase to values equal or slightly higher than those observed for the clean sand samples prepared at a loose state. These results suggest that unlike the dry mix method, the permeation method does not form a weak lubricating layer of bentonite coating around the surface of sand particles but instead, the grouted bentonite slurry fills the void space between the sand particles without affecting the frictional forces between the sand particles. Although the permeated samples were prepared using the same procedure, there was a slight difference in the G_{max} values between them. This can be attributed to the slight variation of properties of the samples (relative density and bentonite content).

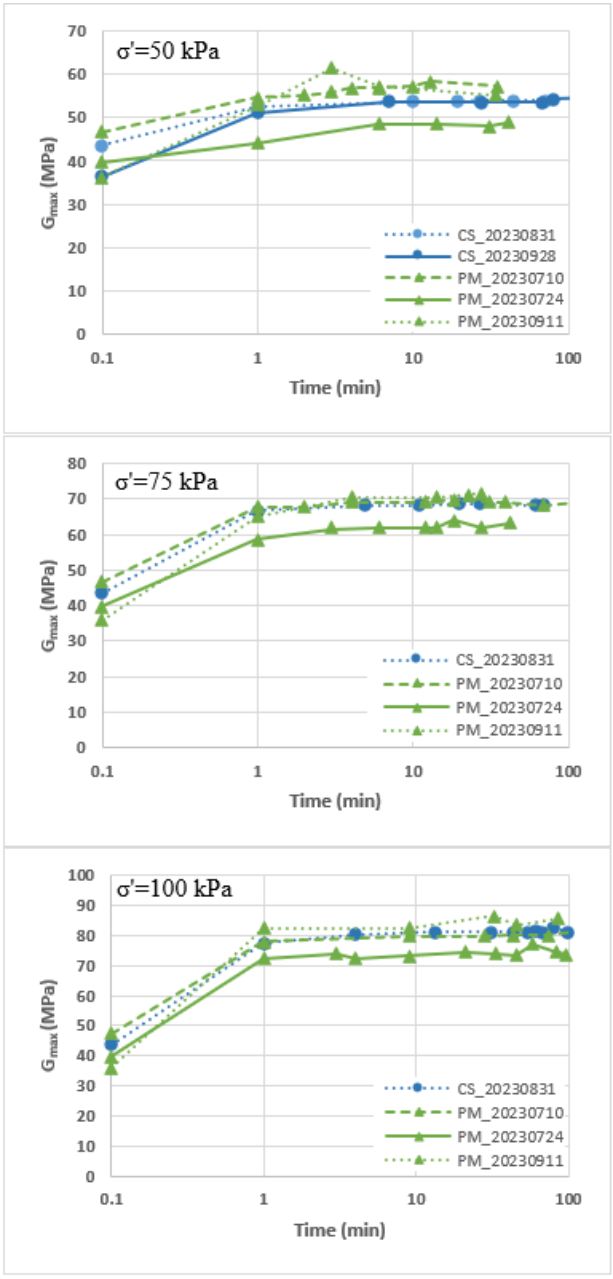

Figure 4. G_{max} monitoring throughout staged consolidation stages at 50, 75, and 100 kPa effective stresses.

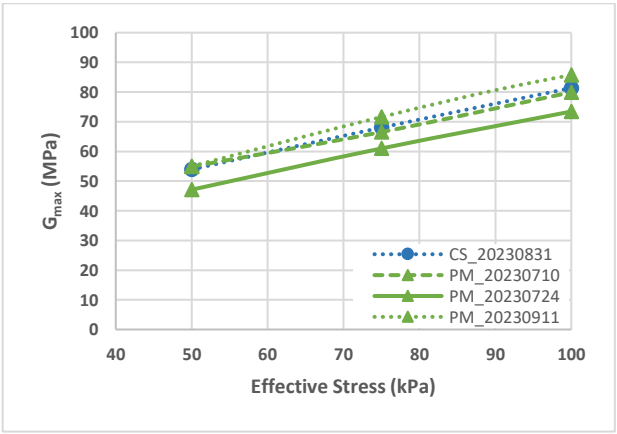

Figure 5. G_{max} versus effective confining stress.

3.3 Effect of bentonite permeation on shear strength

The shearing results of the 2% permeated specimens were consistent with those in the literature stating that the permeated specimens do not show a true undrained instability state (UIS) point, which is the point at which a loose or a medium loose sand start showing a tendency to liquefy and flow (Rugg et al., 2011). The yield stress friction angles were found at the corresponding UIS at the location of the initial change of slope in the stress-strain curves as shown in Figure 6. The yield friction angles were found using the Mohr's circle method. As reported in Table 2, for the permeated sand, the UIS friction angle is equal to that of the clean sand (19°). At the critical state, the permeated sand has a critical friction angle of 33°, which is almost equal to that of the clean sand (32°). Consistent with the literature, the results indicate that the shear strength of the sand samples is not affected by the permeation grouting of bentonite.

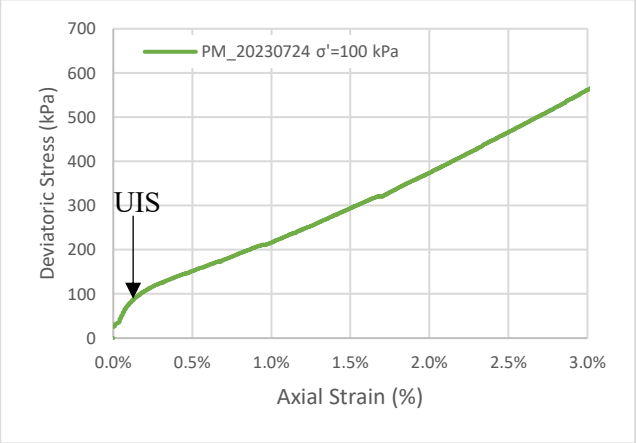

Figure 6. Consolidated Undrained Deviatoric Stress versus Axial Strain showing UIS.

Table 2. Yield and Critical Friction Angles of 0 and 2% bentonite-sand samples.

Shear Strength Parameter	**%Bentonite**	
	0%	**2%**
Yield Stress ϕ'	19	19
Critical State ϕ'	32	33

4 CONCLUSION

These results offer interesting insights on the different effects of laboratory sample preparation methods to introduce bentonite into a sand medium. In this study, preliminary results show that the fabric and the strength of Ottawa Sand, represented by G_{max} and friction angles, are not detrimentally affected by the bentonite in the pore space introduced through the permeation method. More samples need to be tested to reach a wide comparison between the fabric of the clean sand and the permeated samples in order to pave the way for onsite bentonite permeation applications.

Mapping the 3D effect for slope stability analyses of quick clay slopes

Cartographie de l'effet 3D pour les analyses de stabilité des pentes en argile rapide

ABSTRACT: Industry quite often utilizes 2D limit equilibrium analyses to check the stability of sensitive and quick clay slopes. However, such analyses fail to capture the post peak reduction in undrained shear strength of these clays. In this work, finite element modelling with an appropriate constitutive model, capable of capturing strain softening, was used to compare 2D analyses against 3D analyses. Different slope widths were analysed, and results demonstrated that the width of the 3D model controls the width of the failure surface and thus also the factor of safety. The effect of strain softening was studied by means of simulations with and without strain softening. To emphasise the importance of considering spatially varying undrained shear strengths for strain softening clays, results from simulations with constant undrained shear strength were compared to ones with spatially varying undrained shear strengths. The analyses were used to develop a map for 3D effect factors for various kinds of idealized slopes with varying width, slope angle/height and undrained strength profiles.

RÉSUMÉ: L'industrie utilise assez souvent des analyses d'équilibre limite en 2D pour vérifier la stabilité des pentes en argile sensible et argile rapide. Cependant, de telles analyses ne parviennent pas à capturer la réduction post-pic de la résistance au cisaillement non drainé de ces argiles. Dans ce travail, la modélisation par éléments finis avec un modèle constitutif approprié, capable de capturer l'adoucissement sous contrainte, a été utilisée pour comparer les analyses en 2D aux analyses en 3D. Différentes largeurs de pentes ont été analysées, et les résultats ont démontré que la largeur du modèle 3D contrôle la largeur de la surface de rupture et donc aussi le coefficient de sécurité. L'effet de l'adoucissement sous contrainte a été étudié au moyen de simulations avec et sans adoucissement sous contrainte. Pour souligner l'importance de la prise en compte des résistances au cisaillement non drainé variant spatialement pour les argiles subissant un adoucissement sous contrainte, les résultats des simulations avec une résistance au cisaillement non drainé constante ont été comparés à ceux avec des résistances au cisaillement non drainé variant spatialement. Les analyses ont été utilisées pour élaborer une carte des facteurs d'effet en 3D pour divers types de pentes idéalisées avec une largeur variable, un angle/une hauteur de pente et des profils de résistance au cisaillement non drainé variables.

Keywords Quick clay; landslide; softening; 3D FEM.

1 INTRODUCTION

Soft sensitive clays like Norwegian quick clays undergo strain-softening under undrained loading, posing risks of catastrophic failure in slopes. Accurate modelling of slope stability (safety factor) is crucial. The progressive failure mechanism in strain-softening clays may reduce stability compared to non-softening materials with the same peak undrained shear strength. While two-dimensional studies explored the reduction (Fornes & Jostad, 2017 suggested 20%, Rødvand et al., 2022 found no significant reduction), the impact in three dimensions remains unclear. Current two-dimensional analyses don't fully represent the true three-dimensional nature of slope stability, and the effect of strain softening in three dimensions is not well-understood. This work aims to quantify strain-softening effects on three-dimensional stability using PLAXIS 3D V21 and the NGI-ADPSoft model for quick clay softening behaviour.

2 NUMERICAL & CONSTITUTIVE MODEL

This section describes the methodology employed in creation of the 3D quick clay slope model in PLAXIS

3D. The choice of constitutive model to capture the behaviour of the quick clay is explained.

2.1 Numerical model of slope

PLAXIS 3D V21 (2021) facilitated the creation and analysis of the 3D boundary value problem (BVP), referred to as the model. The model utilized 10-noded tetrahedral elements with second-order interpolation for displacements. Figure 1 outlines the dimensions of the 3D quick clay slope model, meshed with fully fixed bottom and laterally fixed boundaries against horizontal movement. The slope width (W) varied (H, 2H, 3H, 6H) to evaluate 3D effects, while the slope height (H) remained constant at 50 m. Note that Figure 1 models only half the slope width, exploiting symmetry. Although slope and clay layer depth influence 3D effects, this work concentrates on softening behaviour, maintaining constant depth and slope inclination for consistency. Once a trend is established for the selected slope geometry, previous work (Jostad & Lacasse, 2015) suggests that the same trend would extrapolate to other slope angles and depths.

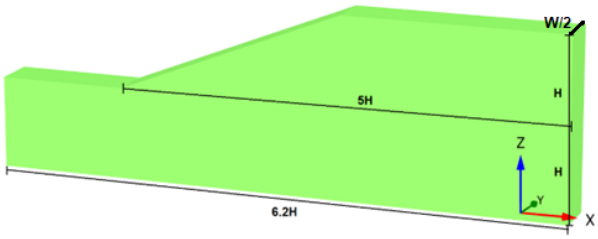

Figure 1. PLAXIS 3D model of the idealised quick clay slope.

2.2 Constitutive model: NGI-ADP Soft

NGI-ADP, an elastoplastic anisotropic shear strength-based model (Grimstad et al., 2012; PLAXIS V21, 2021), is used for capacity, deformation, and soil-structure interaction analyses under undrained loading of clay. It incorporates anisotropy based on the ADP framework (Bjerrum, 1973), where "A" is active, "D" is direct shear, and "P" is passive. Formulated for 3D stress states, NGI-ADP aligns undrained failure shear strengths and strains with experimental results, employing a translated Tresca criterion (Grimstad et al., 2012) and elliptical interpolation. With nine parameters directly obtainable from lab and in-situ testing, NGI ADP-Soft, an extension of NGI ADP, is capable of modelling undrained strain-softening behaviour, making it ideal for sensitive quick clays with distinct strain-softening beyond peak shear strength.

The focus of the work as discussed earlier was to study 3D effects in an ideal model with and without softening. Hence, material parameter values for the NGI ADP-Soft model were picked for a typical quick clay after Karlsrud's Bjerrum lecture (2010). Table 1 tabulates the material parameters; these parameters replicate the strains softening of the quick clay. Analyses conducted without softening used the same material parameters as in Table 1, barring the fact that residual strength was equal to 100 % of the peak strength. For constant undrained strength acrosss slope a value of 35 kPa was used. To study the effect of spatial variation of undrained strength on quick clay slope stability, an undrained shear strength of 20 kPa was assumed at the surface and assumed to linearly increase at a rate of 3 kPa/ unit depth.

Table 1. Material parameters used for quick clay.

Parameter		Value
Gur/su^A	Initial stiffness	300
$S_u^A ref\ (kPa)$	Reference active shear strength	35 kPa or varying with depth
$s_u{}^{DSS} / s_u{}^A$	Normalised DSS strength	0.59
$s_u{}^P / s_u{}^A$	Normalised passive strength	0.27
$s_{ur}{}^A / s_u{}^A$	Normalised residual active strength	0.1
$s_{ur}{}^{DSS} / s_u{}^A$	Normalised residual DSS strength	0.059
$s_{ur}{}^P / s_u{}^A$	Normalised residual passive strength	0.027
$\gamma_p{}^C\ (\%)$	Shear strain at peak in triaxial compression	0.6
$\gamma_p{}^{DSS}\ (\%)$	Shear strain at peak in DSS	0.7
$\gamma_p{}^E\ (\%)$	Shear strain at peak in triaxial extension	0.8
$\gamma_r{}^C\ (\%)$	Shear strain at residual state in triaxial compression	20
$\gamma_r{}^{DSS}\ (\%)$	Shear strain at residual state in DSS	20
$\gamma_r{}^E\ (\%)$	Shear strain at residual state in triaxial extension	20
$c1$	Shape parameter	1
$c2$	Shape parameter	1
v_u	Poisson's ratio, undrained conditions	0.495
$\gamma_{tot}\ (kN/m^3)$	Total unit weight	19.5

2.3 Simulation Methodology

Failure was achieved by load increments combined with indirect displacement control using the arc length

method. The standard phi/c strength reduction method cannot be used for a strain-softening material. The gravity increase method after Swan & Seo, (1999) was employed where gradually gravity loading was applied keeping other material properties constant until the slope became unstable. FoS was defined as the ratio of gravity at failure to actual gravity on earth. It was observed that shear force peaked at failure and eventually reduced as PLAXIS reduced gravity to maintain equilibrium. The analyses were continued 10 steps beyond failure, thus assuring that global failure had occurred rather than a local instability.

3 RESULTS OF NUMERICAL ANALYSIS

This section discusses in detail numerical simulation results for the ideal 3D quick clay slope. Strain softening constitutive model was used to describe the behaviour of the quick clay layer. However, no regularisation technique was used so the results would be mesh dependent. The FoS normalised by ratio of undrained shear strength to total stress at base of the slope ($\gamma H = 19.5 \times 50 = 975$), reduced as element sizes reduced as tabulated in Figure 2 and did not reach steady state indicating that results are discretisation sensitive and mesh regularisation techniques have to be employed while using a softening-based model, but this is out of scope of this work. A particular mesh discretisation was chosen and used in all the analysis to ensure consistency.

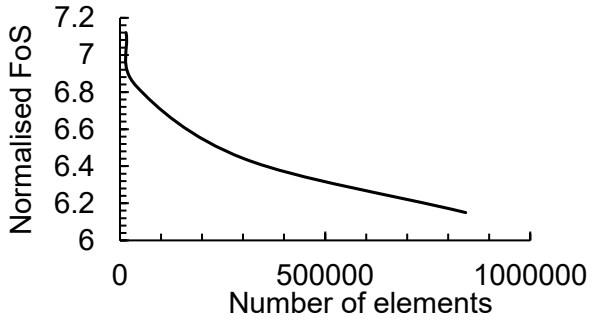

Figure 2. Effect on element size on factor of safety.

3.1 Effect of softening

The 3D model in Figure 1 simulated slope stability with and without softening effects for various widths: H (equal to slope height), 2H, 3H, and 6H, maintaining a 30 cm element size. Figure 3 displays normalized FoS for different widths, with the x-axis representing the inverse width ratio. To ensure accurate 3D effects, 2D cases were simulated in PLAXIS 3D with the same discretization error (Figure 3). The FoS decreases with wider slopes, and softening causes an 82 % drop with respect to analysis without softening. Conclusively, softening effects are comparable in 2D and 3D, consistent across varying slope widths.

3.2 3D effects with constant undrained shear strength

The model in Figure 1, featuring varied widths, maintained a constant undrained shear strength of 35 kPa across sensitive clay. Figure 4 depicts the 3D effect factor on the y-axis, representing the ratio of the factor of safety for a specific slope width to the factor of safety for a 2D plane strain model. Please note that the factor of safety at H/W=0 is 2D plane strain model factor of safety. The 3D effect factor peaked at around 90 % for narrow slopes and drops below 10 % for H/W < 0.17 (widths greater than 6H). Softening increased 3D effect factors compared to scenarios without softening. Results from PLAXIS 3D, with and without softening, are compared with Jostad and Lacasse (2015) results (b/w color scale), showing a similar trend. However, PLAXIS calculations exhibit lower 3D factors even without softening for steeper slopes (b represents the slope ratio of horizontal/vertical and d is ratio of depth to rock to height of slope, H/H here). This difference could stem from discretization variances, including the element types used in Bifurc3D and PLAXIS 3D (Zhang et al., 2013). Jostad and Lacasse (2015) used Bifurc3D, an in-house NGI development, employing isoparametric 20-noded brick elements, while PLAXIS 3D uses 10-noded tetrahedral elements.

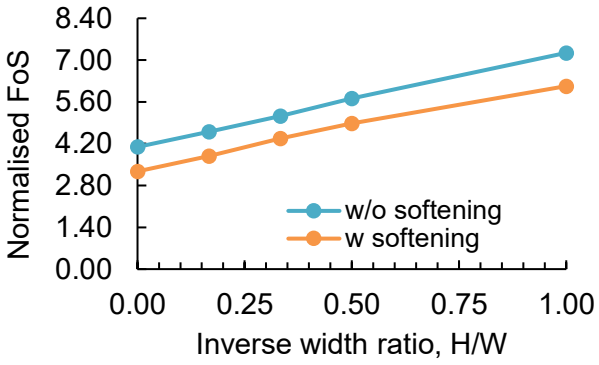

Figure 3. Variation of 3D FoS with width of slope with and without softening.

3.3 3D effects with varying undrained shear strength

To analyse the impact of varying undrained shear strength on the 3D effect factor, simulations were conducted with and without softening, where the undrained shear strength across the sensitive clay increased linearly with effective stress at a rate of 3

kPa/unit depth in m, starting at 20 kPa. Figure 5 illustrates the variation of the 3D effect factor with the inverse width ratio, showing an immediate reduction in the 3D effect as soon as a variation in undrained shear strength is considered. The case with softening exhibits higher 3D effect factors than the case without softening. A maximum 3D effect factor of 1.27 is observed for a narrow slope (H/W = 1). The 3D effect factor for a narrow slope (H/W = 1) with varying undrained shear strength with depth is 1.47 times lower than the 3D effect factor for the same slope with constant undrained shear strength. For slopes with widths larger than 6H (H/W = 0.166), the 3D effect factor with softening ranges between 1.05 and 1.07.

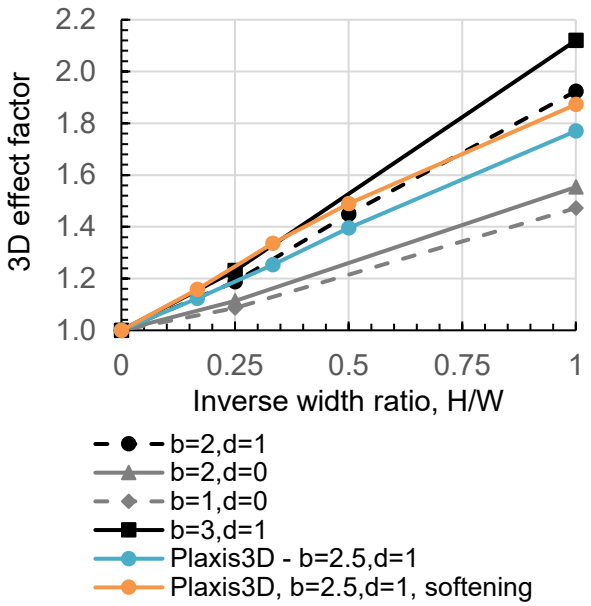

Figure 4. Variation of 3D effect factor with width of slope with and without softening for constant undrained shear strength (Jostad & Lacasse, 2015).

4 CONCLUSIONS

Wider slopes (width > 6 times height) can rely on 2D plane strain analysis due to reduced 3D effect with increasing undrained shear strength. For narrow slopes (width < 6 times height), significant 3D effects may occur, necessitating accurate 3D modeling. In cases where 3D modeling is impractical, scaling the 2D factor of safety using 3D effect factors is feasible, but attention to slope geometry is crucial. The impact of boundary conditions on softening along model edges is under study. The extent of influence is being studied by ensuring that softening to be predominant in the middle of the slope by having higher undrained strengths along slope edges.

ABSTRACT: The evaluation of failure planes on rock slopes is always a great challenge, because of limited accessibility and natural hazards a failing cliff face could pose. Designing of retaining or protecting structure requires very specific data: maximal size and mass of rock that can dislocate from the slope, the highest point on the rock face of failure occurrence, depth of alteration, and a yearly estimate of volume and weight of fallen rocks. Often the devices and methods used for determining the aforementioned information may seem simplistic or disproportionately small in order to extrapolate to a large surface of rock slope, but many of them have proven to be efficient over time. One such method is the stereographic projection of discontinuities. This allows predicting the failure type based on determined pole density of the orientation of the discontinuity sets, that will be extensively explained in the paper. This study is based on results collected from two of the most spectacular mountain roads of Romania: the Transfagarasan highway, once described as the "best driving road in the world" by a famous british TV show, and the Transalpina, which may be less conspicuous, but is officially the highest road of the country. The paper highlights similarities and differences between resulting input data for consolidation and maintenance works.

RÉSUMÉ: L'évaluation des plans de rupture sur les pentes rocheuses est toujours un grand défi, en raison de l'accessibilité limitée et des risques naturels qu'une falaise défaillante pourrait poser. La conception d'une structure de soutènement ou de protection nécessite des données très spécifiques: taille et masse maximales de roches pouvant se disloquer de la pente, point le plus élevé de la paroi rocheuse où se produit une rupture, profondeur d'altération et estimation annuelle du volume et du poids des éboulis. Souvent, les dispositifs et les méthodes utilisés pour déterminer les informations susmentionnées peuvent sembler simplistes ou disproportionnellement petits pour pouvoir être extrapolés à une grande surface de pente rocheuse, mais plusieurs d'entre eux se sont révélés efficaces au fil du temps. Une de ces méthodes est la projection stéréographique de discontinuités. Cela permet de prédire le type de défaillance en fonction de la densité de pôles déterminée par l'orientation des ensembles de discontinuités, qui sera expliquée en détail dans l'article. Cette étude est basée sur les résultats recueillis sur deux des routes de montagne les plus spectaculaires de Roumanie: l'autoroute Transfagarasan, autrefois décrite comme la « meilleure route du monde » par une célèbre émission de télévision britannique, et la Transalpina, qui est peut-être moins visible , mais c'est officiellement la route la plus haute du pays. Le document met en évidence les similitudes et les différences entre les données d'entrée résultantes pour les travaux de consolidation et de maintenance.

Keywords: Rock slope failure; stereographic projection; compressive strength of rocks; Carpathian mountains geology.

1 INTRODUCTION

There are several recently published studies that investigate rock failures. Lagarde et al. (2023) applied a hidden Markov machine learning model to seismic data, revealing the temporal evolution of cracks prior to a major rockslide event in the Swiss Alps. After prolonged linear increase of the crack cumulative number, an S-shaped crack rate pattern occurred in the day before the rockslide. Total crack boundary length was described as the key factor controlling failure plane evolution immediately before mass movement. The study conclusions indicated that cracks should be treated as 2-D, rather than 1-D objects, and that slope failure can be driven predominantly by internal rather than external processes. Sečanj et al. (2019) presented preliminary rockfall susceptibility assessment based on remote

sensing and automated kinematic analysis for the steep slopes above the Town of Omiš. Their results of the spatial kinematic analysis and with the calculation of Kinematic Hazard Index, show that the most critical parts on the slopes for the occurrence of possible instability mechanisms can be identified. Resulting rockfall susceptible areas, unstable blocks and probable instability mechanisms on the investigated slopes provide the input data that can be used to determine critical areas for further deterministic slope stability analysis, as well as for rockfall hazard and risk assessment.

2 INVESTIGATION METHOD

Stereographic projection is the classical approach for the analysis of rock discontinuities. The concept and the graphical methods are widely used in rock engineering education to illustrate the orientation of planes of discontinuity and occurrence of failures. Described in Rock Slope Engineering by Hoek and Bray (1974), stereographic projection is a technique used to represent and analyze 3-D orientation data in a 2-D format. In this projection, a reference sphere is employed, with its equatorial plane positioned horizontally and its orientation fixed relative to the north. Among various projection methods, the equatorial projection is the preferred choice for plotting and analyzing discontinuity data in most cases. Equal area stereonets find particular utility in structural geology because they eliminate statistical bias when dealing with large datasets. They ensure that area preservation is maintained, meaning that, for instance, each 2-degree polygon on the stereonet possesses the same area. In structural geology, it is customary to consider the stereonet as a lower-hemisphere projection because all structural elements are assumed to be inclined below the horizontal plane.

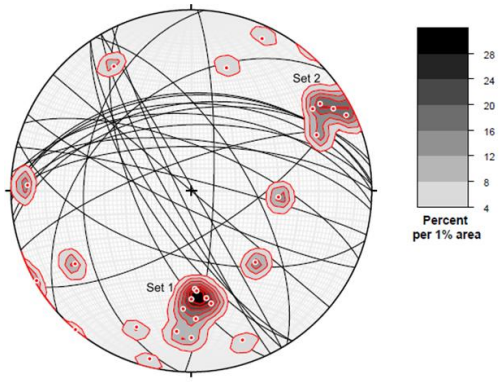

Figure 1. Plot of poles and great circles on stereonet (Schmidt) (km 132+760-132+860).

When representing a plane, such as a discontinuity surface, its intersection with the lower half of the reference sphere delineates a distinctive line on the stereonet (Wylie & Mah, 2004). This line typically takes the form of a circular arc known as a "great circle." Accurately plotting this great circle requires knowledge of both the dip direction and dip angle. The software Steronet v. 11 was used to plot the structural geology data (Allmendinger et all.2012, Cardozo & Allmendiger, 2013). Data collection in the field was done taking into account the ISRM 1981a guidelines.

2.1 Overview and geological conditions

Both studied areas are situated in the South Carpathians. The Transfagarasan was built in in the 1970s as a strategic military route, connecting Transylvania and Wallachia. The investigated areas are high above a steep valley. Excavation of rock slopes involved heavy blasting. Since 2009, the Transalpina has held the title of Romania's highest paved road, reaching an elevation of 7,037 feet (2,145 meters) above sea level at the Urdele Pass. Stretching for 92 miles (148 kilometers), the road meanders from Novaci in the southern region to Sebeș in the northern part, as it navigates its path through the magnificent Parâng Mountains within the Southern Carpathians. Throughout the ages, it has played pivotal roles in facilitating trade, communication, and transportation.

The geological structure of the South Carpathians is very complex, with an intricate pile of tectonic nappes, overthrusted from west eastward. The lithology consists of metamorphic rocks, mainly gneisses and mica schist (Mutihac,1990).

2.2 Transfagarasan

On the Transfagarasan three road segments were investigated. In the highest one (km 124+754-124+855), two sets of discontinuities were separated with mean dip direction and inclination of 052.6°/45.6°, respectively 063°/71°. The lithology is formed by mica schist, with irregular blocks and maximum block size of 5 m^3. The discontinuity spacing is moderate to wide, with medium persistence. In the middle segment (km 125+000-125+215), three sets of discontinuities were identified. The first discontinuity set is given by schistosity, with mean dip direction of 346.6° and inclination of 71°. The second and the third set of discontinuities have mean dip direction and inclination of 274.4°/61.4°, respectively 244.6°/64.8°.

Figure 2. An overview of the first segment on Transfagarasan (km 124+754-124+855). Notice the steep mountain slope, protected by a rock shed in the most dangerous area.

The lithology is formed by gneisses and mica schist, with the maximum block size of 7 m^3. At the lower end of this segment, there is a fault, with the fault zone, affected by parallel, close to moderate spaced discontinuities, with medium persistence. The fault zone is dump, but with no free water observed (rating IV). The filing material consists of saturated sand and clay. The fault does not seem to play an important role in overall slope stability; however it provides some small to medium blocks.

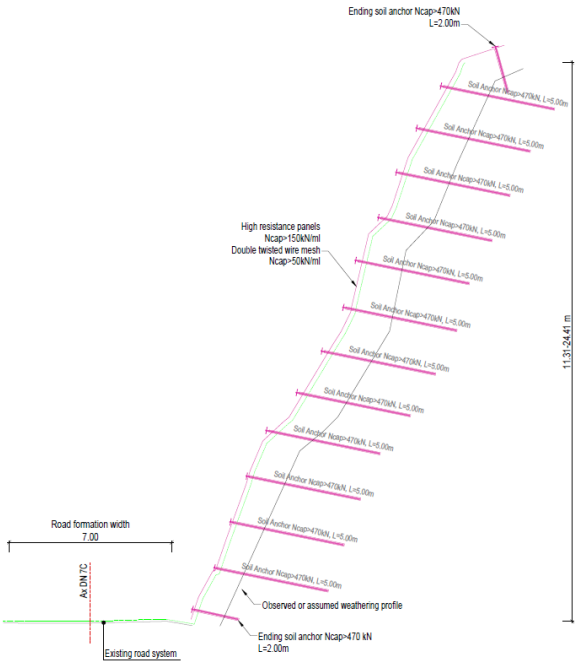

Figure 3. Observed or assumed weathering profile for the highest segment between km 124+754-124+855 on Transfagarasan Highway.

In the lowest segment (132+590-132+860), two set of discontinuities were identified, with mean dip direction and inclination of 358.3°/55° and 240.4°/75°. The lithology is formed by gneisses and sericite chlorite schist, mica schist, with the maximum block size of 3.36 m^3. The lower part of the segment is more affected by blasting, providing in general, small to medium blocks. This area is particularly unstable. A contour of the observed or assumed weathering profile for the highest segment between km 124+754-124+855 can be seen in Figure 3, together with the chosen retaining and protection systems.

2.3 Transalpina

On Transalpina six road segments were investigated. On the first segment (km 80+500-81+000) the lithology consists of gneisses with subordinate pegmatites, migmatites and amphibolite. The outcrop was a quarry not long ago. The slope face is at an angle between 45-60°. On the southern side of the quarry, there is an old magmatic intrusion. The schistosity plane dips towards NE, at 30-50°. Apart from the plane of schistosity, there are two sets of discontinuities dipping towards S and SW at 70-80°. Many discontinuities have at least 3 m persistence. The outcropping rocks are in general from fresh to slightly weathered, apart from the rocks at the top, that are moderately weathered. The maximum block size observed in the quarry is 20 m^3, but this is very likely the result of blasting. Most of the blocks are below 2 m^3 in volume. The maximum falling height is about 40 m.

The second segment (km 88+500-89+000) consists of fragmented and moderately altered gneisses. The rocks are highly affected by tectonics, and possibly blasting, with discontinuities dipping at high angles either towards E or W. The schistosity plane dips at 30-40° towards W. Because of the numerous discontinuities the maximum block size is below 1 m^3. The maximum falling height is 15 m.

The third segment (km 91+000-91+800) consists of mica schist followed by gneisses. Most rocks are moderately weathered, with the depth of weathering extending beyond 5 m. The are large blocks slipped over each other and precarious stabilized by vegetative cover. The lack of outcrops made it impossible to take compass reading. The maximum block size that reached the road is 2 m^3. In this area, there is a real risk of triggering a landslide, involving large blocks if any intervention is made without a careful planning.

The fourth road segment (km102+750-103+000) consists of slightly weathered gneisses and subordinate pegmatites. The weathered zone is below 2 m. The maximum block size is quite small 0.5 m^3. The schistosity plane dips towards SW, at 30-50°.

Apart from that, there is a set of discontinuities dipping almost at 90°, either towards NNE or SSW. Between km 102+950-102+980, the schistosity plane daylights on the slope face.

The fifth road segment (112+000-114+000) consists of slightly weathered gneisses and scree. At km 112+210, the slope face is almost vertical, with large unstable block. We were able to make only a small number of compass readings. The slope face with unstable scree, could fail in favourable conditions, but the size of blocks is small.

The sixth road segment (km 126+000-128+000) comprises areas with scree, with rock fragments caught in an argillaceous matrix (km 126+260-126+355; 127+330-127+240; 127+505-127+640) and areas with steeper slopes with mica schist and gneisses (km 126+490-127+020). The area with scree is in places protected with old gabions. This area is prone shallow circular failure. The area with steep slope is protected by an old wire mesh, which is broken in places, because of falling rocks, and inadequate wire mesh.

Figure 4. Closed spaced discontinuities on Transalpina favouring wedge failure. The slope is protected by a wire mesh that is teared-off in places.

2.4 Compressive strength

Estimation of the compressive strength of the rocks was done by uniaxial compressive strength (UCS) and point load test. The UCS of gneisses and amphibolite was between 68-165 MPa, and for mica schist 50-130 MPa. For some moderately weathered mica schist from Transalpina, the UCS was as low as 20 MPa. The moderately weathered rocks had UCS value well below the slightly weathered or fresh rocks.

3 CONCLUSIONS

The lithology of both area is very similar consisting of metamorphic rock, dominated by mica schist and gneisses. The Transfagarasan section belongs to a different tectonic unit, Supragetic Nappe, whereas Transalpina section belongs to Getic Nappe (Mutihac,1990). Transalpina section seems more affected by tectonics, with old igneous intrusions, folding and faulting. As a result, Transalpina section appear to be more affected by weathering. The discontinuity spacing is smaller on Transalpina, resulting in smaller falling block size. Wedge failure type predominate in both areas, but on Transalpina section, circular failure is likely on slopes covered by scree.

Although not part of the projects budget, the investition in these protection systems would have benefitted from using monitoring equipment that may have been installed in the slopes to measure displacements, strains, stresses or water pressure over time.

Geotechnical seismic site characterization of deep alluvial sand sites in the South Iceland Lowland

Caractérisation géotechnique sismique des sites de sables alluviaux profonds dans les basses terres du sud de l'Islande

ABSTRACT: Thick deposits of post-glacial sediments are widely found along the coastline and close to main riverbeds in South Iceland. This work studies the feasibility of using a joint inversion of dispersion and ellipticity curves to characterize deep alluvial sand sites in the South Iceland Lowland. For this purpose, MASW (Multichannel Analysis of Surface Waves), small-aperture MAM (Microtremor Array Measurements) and MHVSR (Microtremor Horizontal-to-Vertical Spectral Ratio) field tests were conducted at selected locations along the Markarfljót River. The results provide the V_S profiles of the tested sites down to bedrock level at 120–190 m depth, along with the fundamental frequency (f_0) of the soil strata. Furthermore, simple correlations between f_0 and bedrock depth are evaluated against the measurement results, in order to identify suitable relationships for preliminary assessment of bedrock depths based on MHVSR measurements in South Iceland.

RÉSUMÉ: D'épais dépôts de sédiments post-glaciaires sont largement répandus le long du littoral et à proximité des principaux lits des rivières du sud de l'Islande. Ce travail étudie la faisabilité de l'utilisation d'une inversion conjointe des courbes de dispersion et d'ellipticité pour caractériser les sites de sable alluvionnaire profond dans les basses terres du sud de l'Islande. À cette fin, des tests sur le terrain MASW, MAM à petite ouverture et MHVSR ont été menés à des endroits sélectionnés le long de la rivière Markarfljót. Les résultats fournissent les profils V_S des sites testés jusqu'au niveau du substrat rocheux à 120–190 m de profondeur, ainsi que la fréquence fondamentale (f_0) des strates du sol. De plus, des corrélations simples entre f_0 et la profondeur du substrat rocheux sont évaluées par rapport aux résultats de mesure afin d'identifier les relations appropriées pour une évaluation préliminaire des profondeurs du substrat rocheux sur la base des mesures MHVSR dans le sud de l'Islande.

Keywords: Non-invasive site characterization; shear wave velocity; bedrock depth; South Iceland Lowland.

1 INTRODUCTION

The South Iceland Lowland is characterized by strike-slip earthquake activity and a geological environment shaped by volcanism and glacial impacts. Thick deposits of post-glacial sediments, resulting from repeated glacial outburst floods and accumulation of volcanic-originated materials, are widely found along the South Iceland coast and close to main riverbeds. The local soils are mostly normally consolidated coarse-grained basaltic materials and are often loosely compacted due to a rapid sediment build-up in catastrophic events.

This work focuses on an area along the Markarfljót River in South Iceland, between the Markarfljót Bridge and the Landeyjar Harbor (Figure 1a). The area is close to the eastern boundary of the South Iceland Seismic Zone (SISZ). The soil deposits along the glacier fed river primarily consist of sand and sandy gravel and were mainly created in outburst events. The river is highly dynamic with the river mouth moving in a cyclical pattern along a few-kilometre wide part of the coastline. It carries an estimated 100,000–200,000 m^3 of sand to the coastal zone annually (Pétursson et al., 2020).

Borehole logs for a site around 4.5 km east of the current study area indicate layers of sand and gravel down to a depth of 80 m and unspecified sedimentary layers down to 168 m. The borings were terminated before reaching competent bedrock. Seismic refraction surveys conducted in the 1970s (Mott MacDonald and Línuhönnun, 2004) further showed thick sediment formations in the area. The minimum sediment thickness was estimated as 40–50 m near the farm Kross, ca. 12 km west of the current study area. The depth to bedrock was then found to increase towards east, reaching up to 250 m near the farm Bakki, 2-3 km west of the Markarfljót River. No data exists for the sites considered in this work.

Non-invasive methods, specifically Multichannel Analysis of Surface Waves (MASW), Microtremor Array Measurements (MAM) and single-station microtremor measurements, are used to evaluate the shear wave velocity (V_S), depth to bedrock (H) and fundamental frequency (f_0) for selected sites within the area. Subsequently, simple equations relating f_0 and H are evaluated against the results to identify suitable correlations for preliminary assessment of bedrock depths for deep soil sites in South Iceland.

2 SITE CHARACTERIZATION

The surface wave tests in the Markarfljót area (Figure 1a) consisted of four MASW arrays (at S1–S4), two small-aperture MAM arrays (at S1 and S4) and single-station measurements at several locations, including S2 and in the vicinity of S3. This section provides an overview of the data acquisition (DAQ) and analysis. A more comprehensive description is given in Olafsdottir et al. (2023).

2.1 In-situ data acquisition

The MASW data was acquired using an array of twenty-four 4.5 Hz vertical geophones (receiver spacing of 0.5–2 m) and a 6.3 kg sledgehammer to generate the impact load. Repeated shots were collected along the same survey line whilst changing the receiver spacing, source offset and shot position. The MAM measurements were conducted using four Lennartz 5 s seismometers, each coupled with a Reftek digitizer. The seismometers were arranged in triangular-shaped arrays (circumradius of 12 m and 24 m) whose centroid was located at the midpoint of the respective MASW array. The single-station measurements at locations S2, S2b and S3a–d by the bridge and along the river (Figure 1a) were conducted using ETNA 2 accelerographs. As prior studies have recommended against the use of accelerometers for HVSR analysis (e.g., Guillier et al., 2008), the data acquisition was repeated at stations S1 and S1a using the ETNA 2 accelerographs and the resulting MHVSR compared (Figure 1b). The results show that comparable H/V ratios were obtained with both instruments, which is considered to support the use of the ETNA 2 accelerographs in this work.

2.2 Evaluation of f_0, V_S and H

The MHVSR (Microtremor Horizontal-to-Vertical Spectral Ratio) technique was used for evaluation of f_0. For each site, the three-component record (duration 50–100 min) was split into 50 s windows. The Fourier spectra of each component was smoothed using the Konno-Ohmachi function (with b = 40) and the H/V-ratio subsequently obtained by dividing the geometric mean of the horizontal spectra by the vertical spectrum. The resulting MHVSR curves are given in Figures 1b–e.

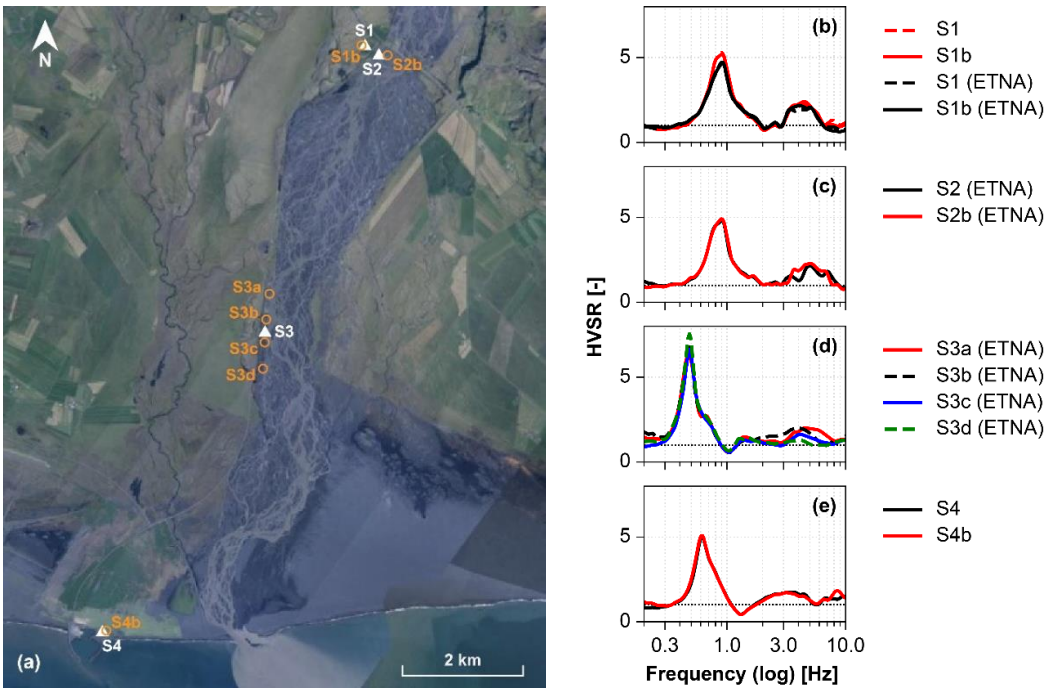

Figure 1. (a) Aerial image of the survey area along the Markarfljót River showing the test site locations. S1-S4: Evaluation of S-wave velocity profile, fundamental site frequency and depth to bedrock. S1b, S2b, S3a-d, S4b: Evaluation of fundamental site frequency. (b-e) Lognormal-median MHVSR curves for individual measurement stations.

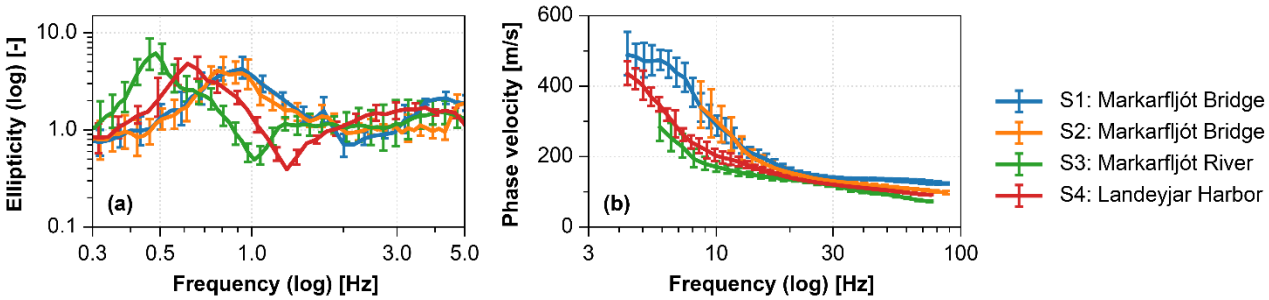

Figure 2. Experimental R-wave (a) ellipticity and (b) dispersion curves for sites S1-S4.

A joint R-wave dispersion-ellipticity inversion was used to evaluate V_S and H for sites S1–S4. The dispersion curve (DC) for each site was obtained from the active-source (MASW) and, where available, the passive-source (MAM) data. Each MASW shot gather was processed using the dispersion tool in MASWaves (Olafsdottir et al., 2018). The MAM data was processed using the MSPAC toolbox in Geopsy (Wathelet et al., 2020), with the 50–60 min recordings split into 12.5–15 min windows and each sub-record processed separately. An average DC (Figure 2b) was finally obtained by binning the dispersion data within log-spaced frequency bands.

The RayDec technique (Hobiger et al., 2009) was used to evaluate the R-wave ellipticity (Figure 2a), with the recorded microtremors split into 8–10 min windows. For S1 and S4, the ellipticity curves specified as inversion targets were obtained using the recordings of the central stations of the MAM arrays. For S2, a single-station measurement was conducted at the location of the MASW survey. The HVSR curves for stations S3a–d show limited variability (Figure 1d), thus indicating small variations in soil stratigraphy for the 1.2 km segment between S3a and S3d. Hence, the ellipticity for site S3 was estimated as the average ellipticity of S3b and S3c.

The inversion was conducted as described in Olafsdottir et al. (2023) using the Dinver module in Geopsy (Wathelet et al., 2020). The layer thicknesses and V_S in each layer were treated as unknowns to be established by the inversion, whilst the mass density was fixed as 2000 kg/m^3 and the Poisson's ratio confined to the range of 0.2–0.5 in lack of site-specific data. The inversion scheme was initiated five times with 75,000–90,000 models sampled in each initiation.

Following each inversion initiation, 100 models were randomly selected from the subset of sampled models whose dispersion-ellipticity misfit (m) fulfils $m \leq 1.25m_{min}$, with m_{min} being the minimum misfit value. The resulting collections of inverted velocity profiles, along with the associated ellipticity and dispersion curves, are shown in Figure 3 (sites S1, S2) and Figure 4 (sites S3, S4). Figure 5 illustrates the variation of the sediment V_S down to bedrock level and within the upper-most 30 m. Also shown is the lowest misfit model for each site.

The analysis points to a broadly similar velocity structure at all four sites along the river. Specifically, for the sandy and gravelly sediments, the developed velocity profiles indicate an increase in V_S from 70–130 m/s at surface to around 350–600 m/s.

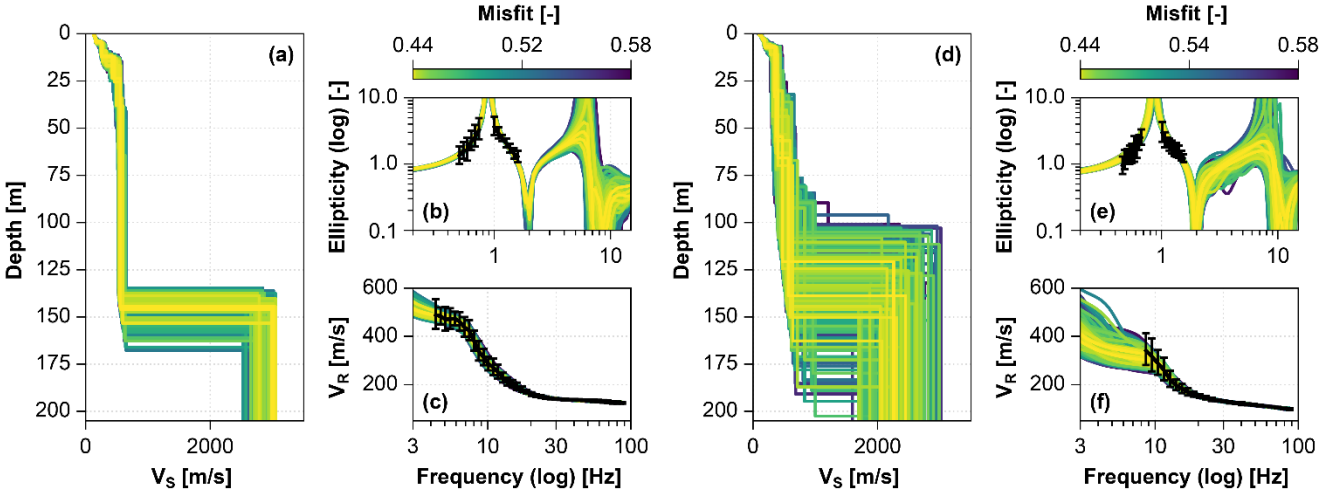

Figure 3. Joint dispersion-ellipticity curve inversion for Markarfljót Bridge sites (a-c) S1 and (d-f) S2. (a,d) Set of V_S profiles whose misfit values fulfil $m \leq 1.25m_{min}$. The associated theoretically computed ellipticity (b,e) and dispersion (c,f) curves are compared to the experimental data points specified as inversion targets.

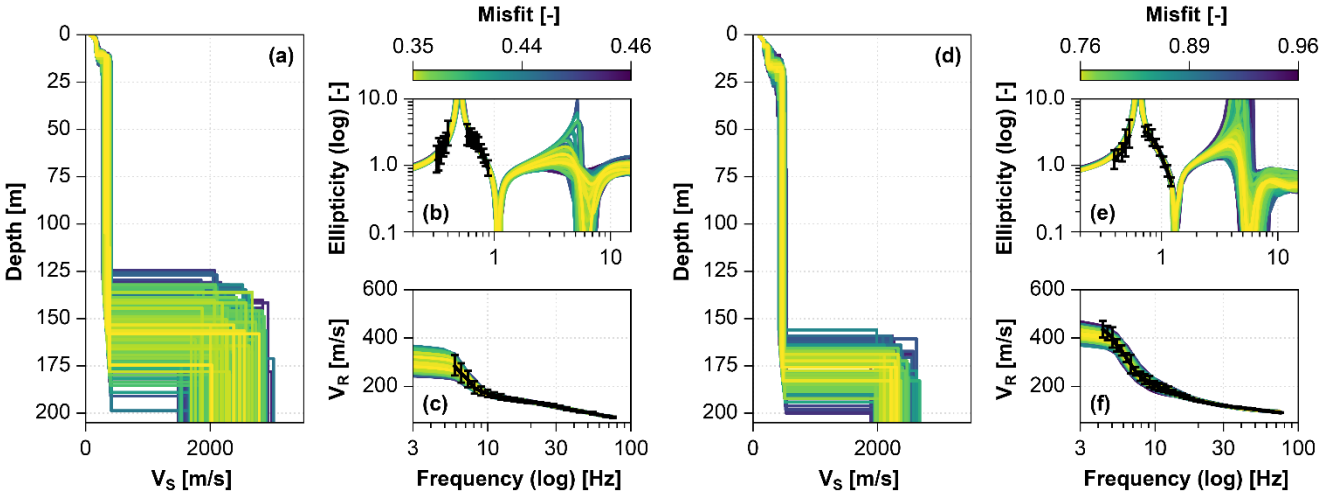

Figure 4. Joint dispersion-ellipticity curve inversion for (a-c) Markarfljót River site S3 and (d-f) Landeyjar Harbor site S4.

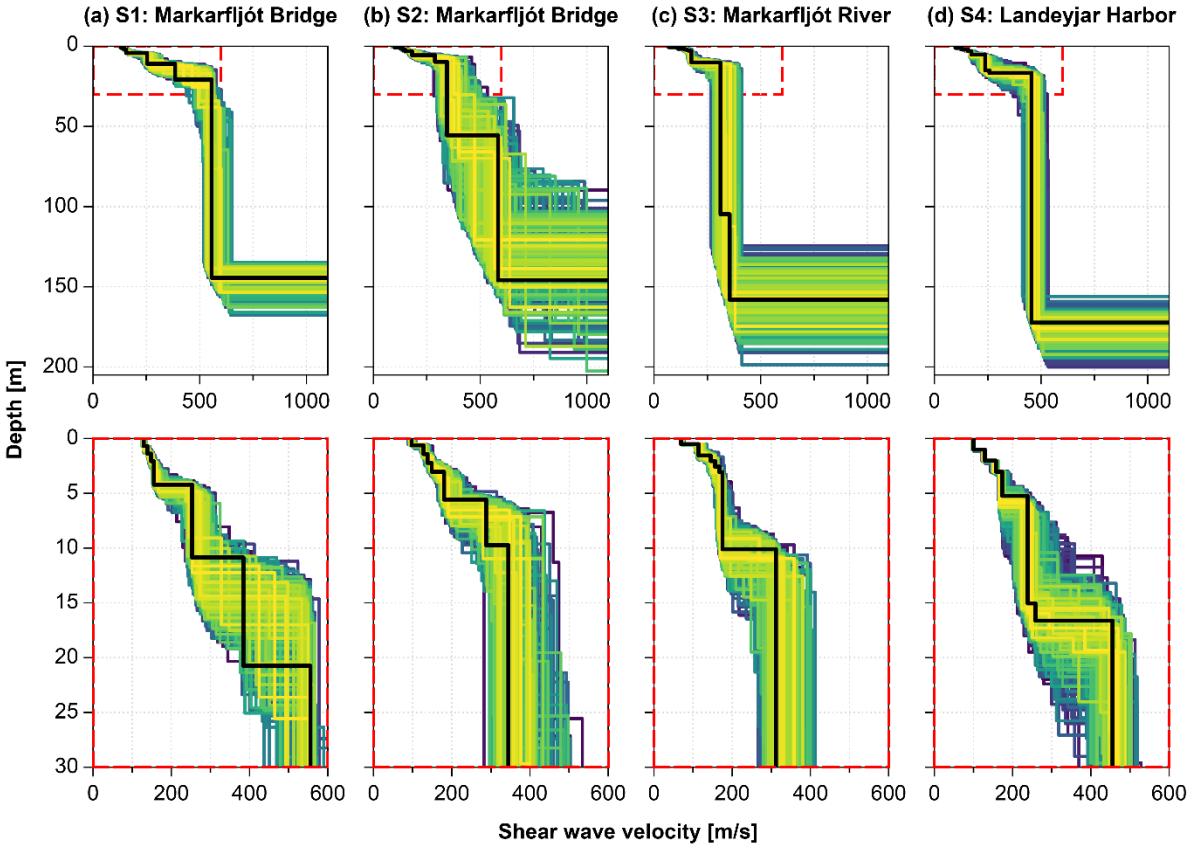

Figure 5. Variation of the sediment shear wave velocity predicted for sites (a) S1, (b) S2, (c) S3, and (d) S4 down to bedrock level (upper row) and down to a depth of 30 m (lower row). The colour scale used for each site refers to the misfit values in Figures 3 and 4. The lowest misfit shear wave velocity profile for each site is shown as a black line.

The strong impedance contrast at a depth of around 120–190 m is interpreted as depth to bedrock. However, the predicted bedrock velocity (>2000 m/s) may be affected by the uncertainty of the obtained data at depth. The time-averaged V_S for the top-most 30 m ($V_{S,30}$) is found to be in the range of 230–320 m/s. Down to bedrock level, the time-averaged V_S ($V_{S,H}$) is estimated as 290–480 m/s. Sediment thickness well exceeding 100 m is in line with available information on the Markarfljót area. It is noted that depth to bedrock was only retrieved at four locations. However, based on the results in Figure 5, a picture of increasing sediment thickness from north towards the sea emerges. Measurements at additional locations along the river are, however, required to conclude on this point.

The inversion results for the two sites by the Markarfljót Bridge (S1 and S2, Figures 3 and 5ab)

reveal a significantly more variation within the set of S2 V_S models as compared to those for S1. This is both observed in the predicted location of the sediment-bedrock interface, which is much better constrained for S1 than S2, as well as in the velocity estimates, particularly at depth. The observed difference is attributed to the narrower frequency range of the S2 dispersion curve, which results in a wider frequency gap between the right flank of the ellipticity peak and the experimental DC, as compared to that of S1. The lower surficial V_S for S2 (Figures 5ab) is consistent with prior expectations, as the surficial soil at S1 consisted of slightly compacted gravel whilst it was loose basalt sand at S2.

The results in Figures 4 and 5cd present a comparable trend for sites S3 and S4, as previously described for S1 and S2. Particularly, the lack of low-frequency components in the S3 DC (which results in a gap in the experimental data at 0.9–5.9 Hz) leads to increased difficulties in constraining the depth to bedrock. The effects of the lack of low-frequency DC components are also observed in the velocity estimates at depth, which are slightly less constrained at S3 than at S4. As shown in Figure 2b, the S3 DC presents the lowest phase velocity values out of the four experimental DCs, thus suggesting a somewhat softer surficial soil profile than at the other sites. However, the lack of data to constrain the theoretically computed DCs below 6 Hz is considered to affect the reliability of the velocity estimates for S3 at depth, possibly biasing the inverted V_S estimates to lower values and thereby also affecting the predicted bedrock depth. It would, therefore, be of value to gather MAM data at S3 in order to extend the experimental DC to lower frequencies. Consequently, the current estimate of the depth to bedrock and the corresponding value of $V_{S,H}$ for site S3 are considered more uncertain than those for S4.

3 SIMPLIFIED ESTIMATE OF H

In lack of site-specific measurements of velocity profiles or deep borehole logs, simple relationships providing a link between f_0 and H may be used to estimate depth to bedrock (or engineering bedrock) based on MHVSR measurements without inversion. Power-law regression models, i.e., $H = a \cdot f_0^b$, have been proposed by many authors, with the regression parameters a and b reflecting regional and geological characteristics. Thus, local calibration using data from multiple sites is required.

Assuming a one-dimensional soil model consisting of a soft sedimentary layer above bedrock, Eq. (1) relates f_0 and the average V_S of the sedimentary layer ($\overline{V}_S$) with H following a quarter-wavelength approach (Lachetl and Bard, 2011). A value of $\overline{V}_S$ = 300 m/s has previously been suggested to estimate sediment thickness based on measurements of f_0 (Nelson and McBride, 2019):

$$H = \frac{\overline{V}_S}{4 f_0} \quad (1)$$

Figure 6 compares the measurement results (i.e., MHVSR estimates of f_0 and the depth to bedrock level established based on the joint inversion) with values computed using Eq. (1) with $\overline{V}_S$ in the range of 200–600 m/s. For the softest site (S3), $\overline{V}_S$ = 300 m/s is found to provide an estimate of H that is consistent with the measured values. However, for S1, S2 and S4 a value of 300 m/s would lead to a significant underestimation of the depth to bedrock, with a $\overline{V}_S$ value in the range of 400–500 m/s seeming more appropriate. These results are consistent with the estimated $V_{S,H}$ for the four sites, i.e., around 300 m/s for S3, 410–420 m/s for S2 and S4, and up to 480 m/s for S1. This further correlates with the $V_{S,30}$ for the respective sites, which was estimated at around 230 m/s for S3 but showed values in the range of 260–280 m/s for S2 and S4 and exceeding 300 m/s for S1.

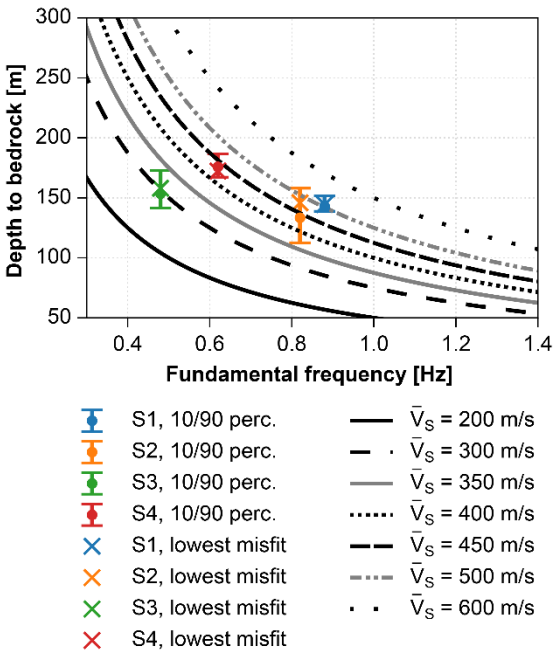

Figure 6. Comparison of measured values of depth to bedrock and values computed using Eq. (1) with $\overline{V}_s$ in the range of 200–600 m/s. For each site, the measured values are given as the 10th to 90th percentiles of the inverted bedrock depths (error bars) and the depth indicated by the lowest misfit velocity profile (crosses).

4 CONCLUSIONS

This study points at a joint dispersion-ellipticity inversion as a feasible method to retrieve the V_S distribution and depth to bedrock at deep soil sites in the South Iceland Lowland. For the conditions described here, a composite use of MASW and small-aperture MAM is further found highly beneficial to reduce the frequency gap between the experimental dispersion and ellipticity data, thus providing a more refined estimate of the sediment V_S and depth to bedrock. The bedrock depths estimated in this work are in line with available information on the wider Markarfljót area. However, existing data is limited to a few surveys, thus, comparison with direct measurements, e.g., deep boreholes, is considered beneficial for further verification of the results.

The results suggest that the quarter-wavelength approach (Eq. (1)) with $\overline{V}_S$ in the range of 300–500 m/s could be used for initial assessment of bedrock depths in the area based on MHVSR measurements of f_0. However, this study only includes data from four sites along the Markarfljót River. Further verification based on data from a larger number of sites is therefore required before general conclusions can be drawn. Future steps may also include calibration of power-law regression models relating f_0 and H to describe the local characteristics.

ABSTRACT: It is recognised that site effects have a great impact on seismic ground motion characteristics and this can lead to higher structural damage. Lisbon has a moderate to high seismic risk due to its historical seismicity, socio-economic importance and dense urbanisation. Furthermore, its geological setting is characterised by a complex lithostratigraphic structure, complex buried and surficial morphologies, shear wave velocity inversion and weathered rock layers. To assess the seismic site effects in Lisbon, a site response numerical analysis was performed along a profile characterised by the presence of a topographic relief and slightly inclined layers, considering the available geotechnical and geophysical data and the two types of seismic action defined in the Portuguese Annex of Eurocode 8. The results are shown in terms of amplification factors and acceleration response spectra at selected points. The physical phenomena governing the site response were also investigated by comparing 1D and 2D numerical analyses. At the top of the crest, an amplification factor equal to 3 was estimated within the period range of 0.05-2.50 s, which is related to bidimensional topographic effects.

RÉSUMÉ: Il est reconnu que les effets de site ont un grand impact sur les caractéristiques du mouvement sismique du sol ce qui peut accroître les dommages structurels. Lisbonne présente un risque sismique modéré à élever en raison de sa sismicité historique, de son importance socio-économique et de son urbanisation dense. De plus, son contexte géologique se caractérisé par une structure lithostratigraphique complexe, morphologies complexes enterrées et superficielles, l'inversion de la vitesse des ondes de cisaillement et des couches rocheuses altérées. Pour évaluer les effets sismiques du site à Lisbonne, des analyses numériques de la réponse des sites est réalisée le long d'un profil caractérisé par la présence d'un relief topographique et de couches légèrement inclinées, en tenant compte des données géotechniques et géophysiques disponibles et des deux types d'action sismique définis dans l'Annexe Portugais de l'Eurocode 8. Les résultats sont présentés en termes de facteurs d'amplification et de spectres de réponse d'accélération à certains points. Les phénomènes physiques qui sont responsables de la réponse du site sont également étudiés en comparant les analyses numériques 1D et 2D. Au sommet de la crête, un facteur d'amplification de 3 a été estimé entre 0.05 et 2.50 s, liés aux effets topographiques bidimensionnels.

1 INTRODUCTION

Since the combination of the many geological features of Lisbon's geological setting (Figure 1) increases the potential of site effects related to an earthquake, it is essential to identify and quantify them to delimit the areas of highest local hazard and contribute to long-term urban planning and seismic risk mitigation.

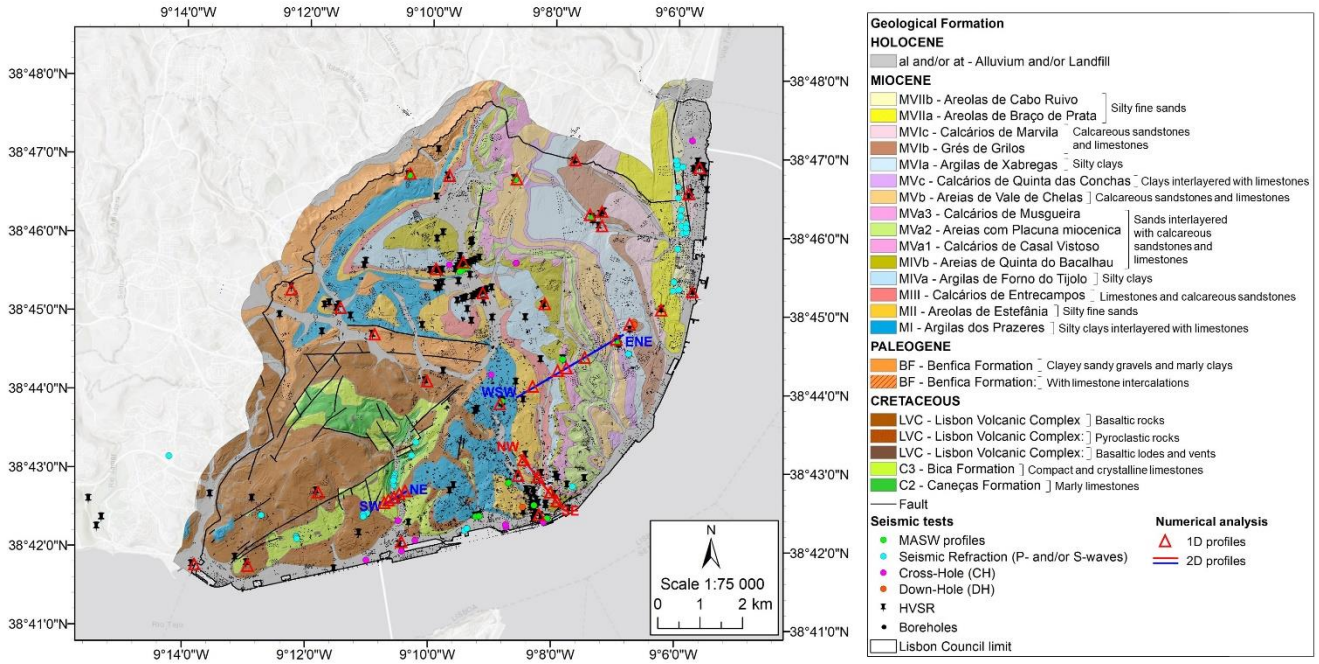

Figure 1. Geological map of Lisbon County (adapted from Almeida, 1986), displaying the spatial distribution of available geotechnical and geophysical data. The NW-SE profile is also identified with a red line.

This paper presents the results of numerical analyses carried out along a NW-SE profile characterised by topographic relief, slightly inclined layers and S-wave inversion. The profile was drawn based on the geological cross-section provided by Almeida (1986). The subsoil model was defined considering all the available geotechnical and geophysical data (see Figure 1), while the two types of reference spectra corresponding to seismic action type 1 (*AS1*) and seismic action type 2 (*AS2*) (return period of 475 years) defined in the Portuguese Annex of Eurocode 8 (IPQ, 2010) were considered to select two sets of seven accelerograms compatible with the reference spectral shapes. Figure 1 shows all of the 2D profiles that were modelled as well as the 1D analyses that were performed. However, due to limited space, the study focuses on the NW-SE profile.

The 1D numerical analyses were performed using STRATA (Kottke and Rathje, 2008), while the 2D analyses were carried out using LSR2D (www.stacec.com), with both employing an equivalent-linear viscoelastic approach. The 1D simulations were performed considering the same soil properties and input motions as the 2D response analysis. The compliant (elastic) base boundary condition was applied in both the 1D and 2D analyses. In 2D analysis, the free-field condition is applied to the lateral boundaries, leading them to operate as a system capable of absorbing reflected waves that would otherwise be artificially reintroduced into the model.

2 GEOTECHNICAL PROFILE

The NW-SE profile is characterised by a significant topographic variation, with the presence of a crest at 90 m a.s.l. and an adjacent shallow valley with a width of 95 m and filled by sediment of thickness around 15 m (Figure 2). Below the Miocene layers, the geological bedrock is composed of Cretaceous formations, including basalt rocks from the *LVC* and limestones from the *C3* and *C2* formations (Figure 1).

The shear wave velocity (V_S) of each geological unit was estimated through the site-specific V_S-depth equations developed for the Lisbon area (Oliveira et al., 2023), considering the average depth of each layer. The bedrock depth was calibrated to numerically reproduce the resonant frequencies measured through the noise (*HVSR*) measurements. Poisson's ratio (υ) was not directly measured in any geological formations. The Poisson's ratio was set at $\upsilon = 0.49$ for saturated soil, $\upsilon = 0.35$ for unsaturated soil and $\upsilon = 0.30$ for rocks (Oliveira et al., 2023).

The non-linear decay and damping curves computed for gravel soils by Rollins et al. (1998) were considered to describe landfill deposits and *MVa* complex (MVa3, MVa2 and MVa1 formations) behaviour due to their heterogeneous composition that can be comparable with gravel soil. The Darendeli (2001) curves were assigned to the alluvial deposit, *MIVb*, *MIVa*, *MII* and *MI* formations. The *LVC* behaviour is described by the Schnabel et al. (1972) curves and a linear viscoelastic behaviour was set for the *MIII*, *C3* and *C2* formations with damping D = 1%.

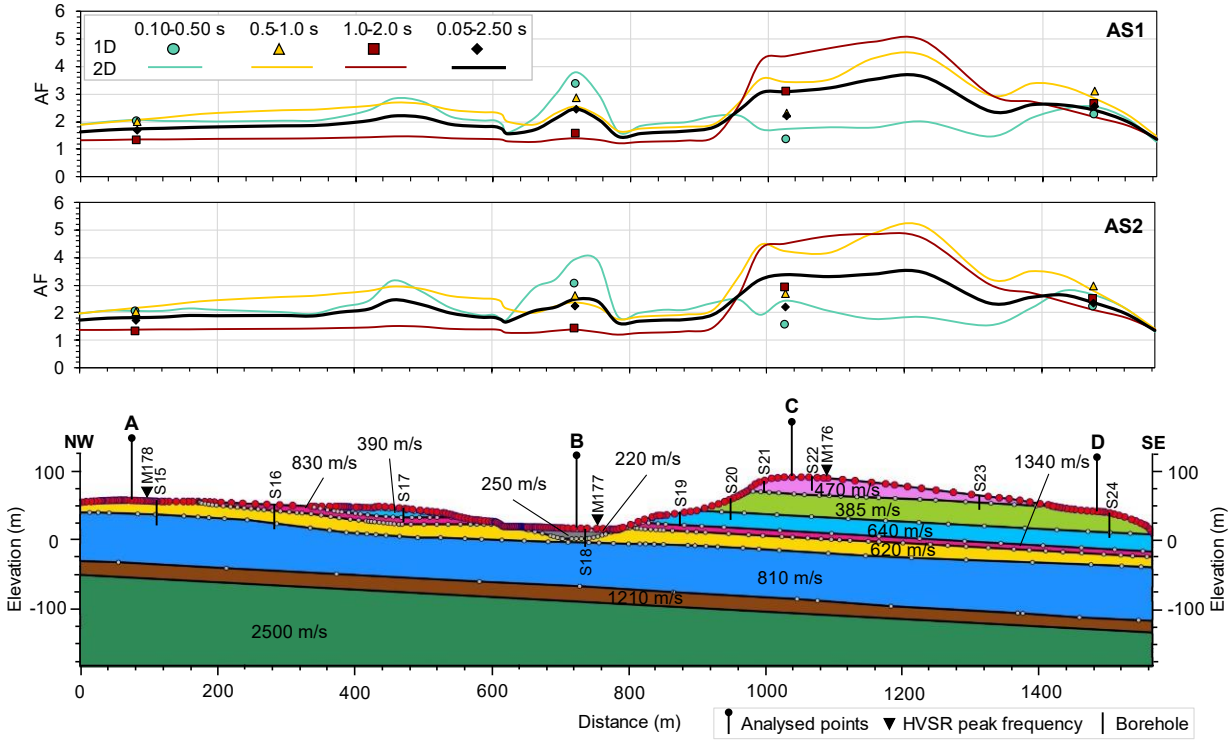

Figure 2. NW-SE profile: median total amplification factors (AF_{2D}) computed in the four period ranges T = 0.1–0.5 s; 0.5–1.0 s; 1.0–2.0 s; 0.05–2.50 s for AS1 (top) and AS2 (bottom) compared to the values computed through 1D seismic response analyses (AF_{1D}) along the verticals A, B, C and D. The geological formations are coloured according to Figure 1.

3 RESULTS AND DISCUSSION

Figure 2 shows the median AF_{2D} total amplification factor variation computed for periods 0.1–0.5 s, 0.5–1.0 s, 1.0–2.0 s and 0.05–2.50 s along the NW-SE profile, with the 2D response normalised by the input.

In the range 0.1–0.5 s the maximum amplification factors (*AFs*) occur in the middle of the valley (B). Conversely, at the top of the crest (C), the peak amplification factor (*AF*) occurs in the range 1.0–2.0 s. When the *AF* for the 0.1–0.5 s and 0.5–1.0 s period ranges are compared to the 1.0–2.0 s range in correspondence with the alluvial deposit (B), the expected dependence of *AFs* on the frequency and magnitude of the input motions is confirmed. On the other hand, a lower dispersion is associated with the outcropping stiff layers (e.g., A). Higher *AFs* occur in the intermediate to lower period ranges in correspondence of A and D for both *AS1* and *AS2*. At the top of the crest (C) and the centre of the valley (B), an *AF* of ~3-3.4 and ~2.5 are computed in the 0.05–2.50 s range, respectively. The comparison between the 2D median response spectra and median input spectra substantially confirms that the amplification takes place essentially for the periods lower than 0.5 s in the valley (B), more significant in *AS1*, and for the periods higher than 0.5 s at the top of the crest (C), observed in both *AS1* and *AS2* (Figure 3). The amplification takes place essentially for the periods higher than 0.3 s for *AS1* and for the periods lower than 0.3 s for *AS2* in A. The amplification is essentially observed for the periods higher than 0.1 s in D. Spectral accelerations as high as 13–20 $m.s^{-2}$ appear at B in the 0.3–0.5 s period range for *AS1* and *AS2*; on the contrary, the spectral acceleration is lower than 10–12 $m.s^{-2}$ at A, C and D in the whole period range.

To investigate the 2D physical phenomena that govern the local response, Figure 3 compares the 1D and 2D median response spectra for A, B, C and D, reporting the 2D/1D spectral ratios. 2D effects are noticed in B between 0.2 s and 0.4 s for *AS1* and *AS2* (peaks of the 2D/1D ratio), related to the valley effect and basin configuration; here the 2D analyses are ~1.2 (*AS1*) and ~1.3 (*AS2*) the amplitudes of ground motion predicted by 1D simulations (Figure 3). These effects are responsible for ground motion amplification in the 0.1–0.5 s period range mentioned above.

In C, clear 2D effects are observed in 0.5–1.0 s and 1.0–2.0 s ranges for *AS1* and *AS2*, evidencing the topographic effects related to the crest. In this case, the 2D analyses return ~1.5 (*AS1*) and ~1.6 (*AS2*) the amplitudes of ground motion predicted by 1D simulations (Figure 3). With reference to A and D, 1D and 2D computations are much closer for both *AS1* and *AS2*. The slight 2D effects are related to the buried morphology (i.e., inclined layers), leading to a residual

amplification factor. In this case, the amplification is mainly due to stratigraphic effects, which are well-predicted by 1D seismic response analysis (Figure 3).

According to the EC8 recommendations, the topographic amplification factor for ridges with crest width significantly narrower than base is 1.4 for slope angles $i > 30^{o}$ and 1.2 for gentler slope angles ($15^{o} < i < 30^{o}$) (CEN, 2004). In this study, the slope angle of the crest is roughly 20º and the maximum topographic amplification factor varies between 1.4 and 1.5, slightly higher than the EC8 recommended values.

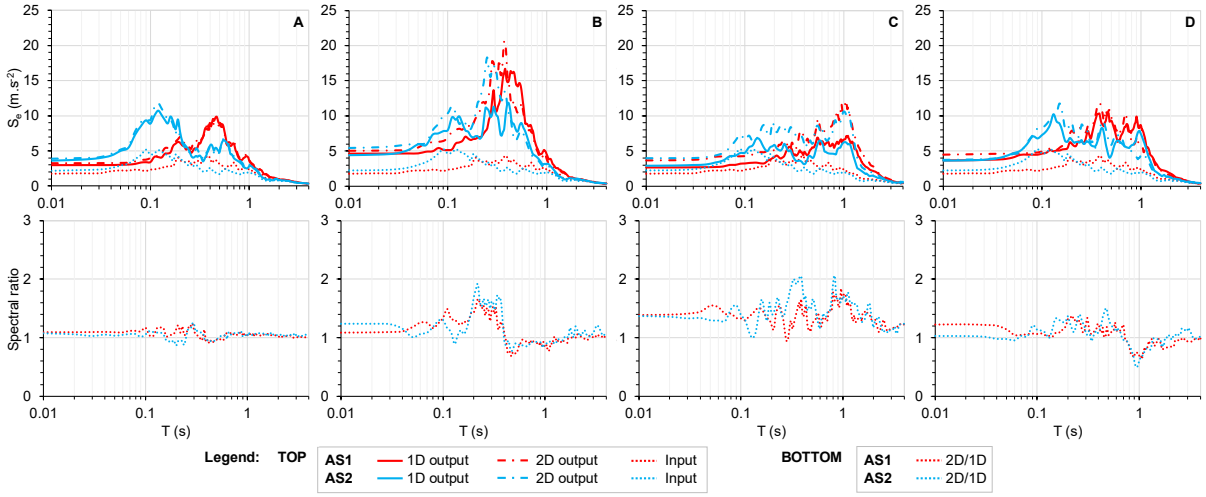

Figure 3. Response spectra (ξ = 5%) (top) and spectral ratios (bottom) from the 2D and 1D numerical analyses computed at points A, B, C and D for AS1 (red) and AS2 (blue).

4 CONCLUSIONS

This analysis shows that in an urban area like Lisbon, assessing seismic site effects is essential to mitigate the impact of a seismic event.

The presence of large topography differences, such as a crest and a valley filled with alluvial deposits, causes the observed valley and topographic effects. There are also slight 2D effects related to the buried morphology (i.e., inclined layers). Ground motion is aggravated by 2D site effects by a factor of 1.2-1.6 when compared to 1D prediction. The topographic amplification factors obtained at the top of the crest are 15% to 25% higher than the EC8 suggested values.

This methodology can be applied to quantify the impact of 2D effects in other parts of the city.

Expansive and collapsible soil behaviour under the Revised Soil Classification System

Compportement des sols gonflant ou affaissants selon le Système Révisé de Classification des Sols

R. Ortiz-Hernández*, E. Rojas-González
Universidad Autónoma de Querétaro, Santiago de Querétaro, México
**raforther@gmail.com*

ABSTRACT: Identifying expansive and collapsible soils is crucial for geotechnical engineering. Grain size distribution and Atterberg limits help identify such soils, and the Revised Soil Classification System enhances this identification. It primarily introduces a new testing protocol for the liquid limit of soils using various fluids. When assessing the plasticity behaviour of these soils under different levels of chemical stabilization, it is evident that the concentration of the stabilizing agent linearly reduces expansion or collapse potential. However, the liquid limit's behaviour under varying pore fluid chemistry and stabilizing agent concentration follows a non-linear trend.

RÉSUMÉ: L'identification des sols expansifs et pliables est cruciale pour l'ingénierie géotechnique. La distribution granulométrique et les limites d'Atterberg aident à identifier ces sols, et le système révisé de classification des sols améliore cette identification. Il introduit principalement un nouveau protocole de test de la limite de liquidité des sols utilisant divers fluides. Lors de l'évaluation du comportement plasticité de ces sols sous différents niveaux de stabilisation chimique, il est évident que la concentration de l'agent stabilisant réduit linéairement le potentiel d'expansion ou d'effondrement. Cependant, le comportement de la limite liquide selon la chimie du fluide interstitiel et la concentration de l'agent stabilisant varie suit une tendance non linéaire.

Keywords: Expansive soils; collapsible soils; geotechnical characterization; soil classification.

1 INTRODUCTION

In geotechnical engineering, certain soils pose risks during infrastructure construction. These include expansive and collapsible soils. Qualitatively identifying these soils based on their index properties is crucial in engineering practice to prevent costly foundation repairs resulting from misidentification.

Expansive soils alter their volume with changing saturation levels, expanding when saturated and contracting during desiccation (Zepeda, 2004). They are primarily characterized by their mineral composition, with clay minerals like smectite and illite being significant (Mitchell & Soga, 2005). The relationship between clay mineralogy and their position on the Casagrande Plasticity Chart has been established (Okkels, 2019).

Figure 1 illustrates that montmorillonite clay and illite fall above the A-Line (distinguishing clays from silts) and below the U-Line (indicating empirical clay behavior), classifying them both as "high plasticity clay," CH, under the Unified Soil Classification System (USCS). The primary difference between them is the value of the plasticity index (PI).

Collapsible soils remain stable under dry conditions but experience significant volume changes (shrinkage) when saturated under the same load (Ali, 2011). Indications of a collapsible soil include low volumetric weight and a high void ratio. The relationship between its dry volumetric weight and liquid limit (LL) (Rezaei et al., 2012) or the void ratios under natural conditions and at the LL (Denosov, 1951) has been established.

In soil classification advancements, the "Revised Soil Classification System (RSCS)" has been developed. It involves a review of the test protocol regularly used in the USCS to describe the fractions controlling the soil's mechanical and hydraulic behavior (Park & Santamarina, 2017). The RSCS is summarized graphically in the flow diagram presented in Figure 2.

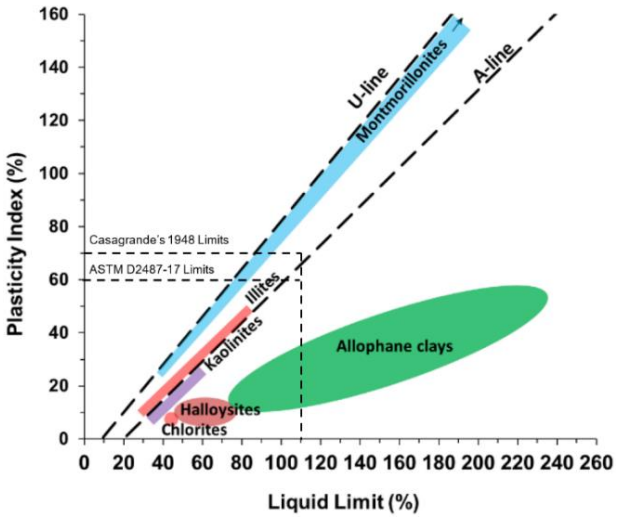

Figure 1. Fine-grained soils plasticity chart with mineralogy zones (adapted from Okkels, 2019).

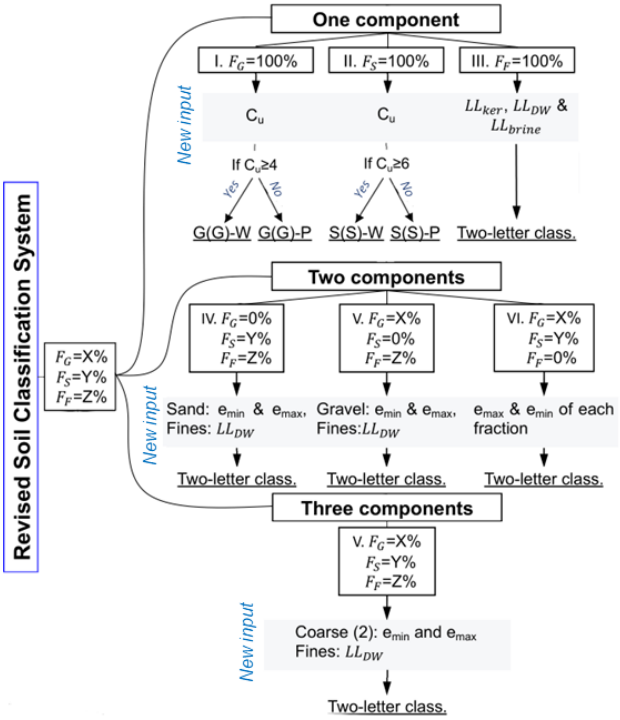

Figure 2. RSCS workflow (adapted from Castro et al, 2023).

For soils where the fine fraction influences the soil's mechanical and/or hydraulic behavior, the RSCS advises analyzing this fraction using the LL with various fluids. The LL is preferred due to its consistency, repeatability, and absence of segregation or edge effects (Jang & Santamarina, 2017).

The RSCS recommends using specific testing fluids: deionized water, enhancing double layer effects; kerosene, affecting van der Waals forces; and 2 M NaCl brine, causing the collapse of the diffuse double layer (Jang & Santamarina, 2017; Castro et al., 2022).

These fluid-based limits help establish relationships that express specific soil properties. The deionized water to brine water ratio denotes pore fluid permittivity, while the kerosene to brine ratio defines fluid electrical conductivity. These relationships lead to the determination of a new parameter called "Electrical Sensitivity" (Jang & Santamarina, 2017):

$$S_E = \sqrt{\left(\frac{LL_{dw}}{LL_{brine}} - 1\right)^2 + \left(\frac{LL_{ker}}{LL_{brine}} - 1\right)^2} \quad (1)$$

where S_E is the electrical sensitivity, LL_{dw} (%) is the deionized water LL, LL_{brine} (%) is the 2 M NaCl brine LL and LL_{ker} (%) is the kerosene LL.

When LL ratios are less than 1, their reciprocals are used to maintain a positive value in equation (1). To address density variations between kerosene (2) and deionized water and salt concentration in brine (3), these corrections are applied as outlined in Jang and Santamarina (2017):

$$\left.\frac{LL_{ker}}{LL_{brine}}\right|_{corr} = \frac{LL_{ker}}{LL_{brine}} \frac{1 - c_{brine}\frac{LL_{brine}}{100}}{G_{ker}} \quad (2)$$

$$\left.\frac{LL_{dw}}{LL_{brine}}\right|_{corr} = \frac{LL_{dw}}{LL_{brine}} \left(\frac{1 - c_{brine}\frac{LL_{brine}}{100}}{G_{ker}}\right) \quad (3)$$

where c_{brine} is the concentration of NaCl brine (mol/L) and G_{ker} is the specific gravity of kerosene.

The electrical sensitivity is a function of particle size, shape, mineralogy, surface, and edge charges, these in turn have an effect in the hydraulic conductivity, compressibility, and shear strength of the soil (Jang and Santamarina, 2016).

The electrical sensitivity and corrected brine LL are used in the RSCS Plasticity chart (Figure 3a), while the corrected LL ratios are depicted on a new electrical sensitivity chart (Figure 3b).

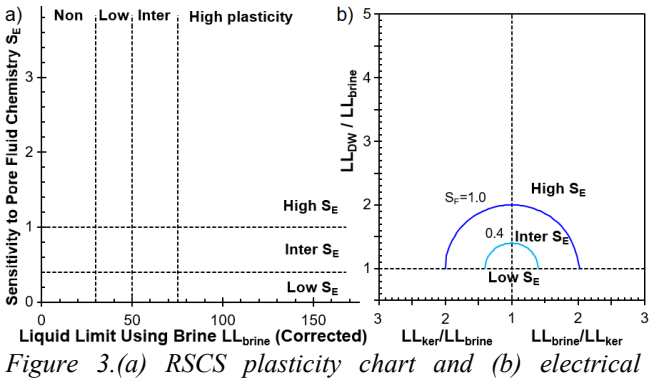

Figure 3.(a) RSCS plasticity chart and (b) electrical sensibility chart.

Tests using this new protocol reveal that soils with expansive minerals like montmorillonite exhibit high

plasticity with brine and an elevated electrical sensitivity. These findings group them into distinct sectors on the Plasticity Chart and Electrical Sensitivity Chart (Figure 4).

As of now, collapsible soils have not undergone this testing protocol, and thus, their position on the Plasticity and Electrical Sensitivity Charts remains uncertain.

This research aims to correlate a soil's expansive or collapsible behavior with its electrical sensitivity parameter due to the lack of knowledge regarding how special soils behave in various pore fluid conditions, both natural and when stabilized.

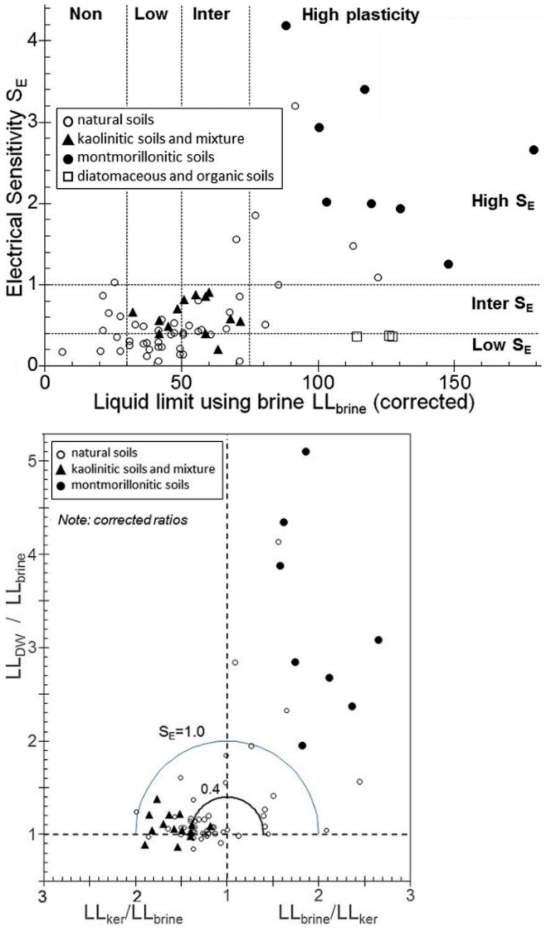

Figure 4. Soil mineralogy clusters in the RSCS plasticity and electrical sensitivity charts (adapted from Jang and Santamarina, 2017).

2 EXPERIMENTAL PROGRAM

The experimental program involved assessing a soil's expansion or collapse potential under natural conditions and applying a stabilizing agent at 3% and 5% concentrations while measuring electrical sensitivity. Additional tests for specific surface and specific gravity of soil solids were conducted to monitor material property changes.

The soil was dry sieved with a #200 sieve and dried at 60°C to prevent soil chemistry alteration (ASTM, 2010) before conducting expansion/collapse and LL tests.

The expansion potential was assessed using ASTM D4546-14 A-Method, while the collapse potential was determined following the ASTM D5333-12 standard. In both tests, the material was remolded to match the natural unit weight and water content reported by Verdín (2022) for expansive soil and Fonseca et al. (2014) for collapsible soil.

The electrical sensitivity parameter was calculated using the corrected LL ratios of the material with deionized water, reagent-grade kerosene, and 2 M NaCl brine using equations (2) and (3). The LL was determined using the fall cone method (BSI, 1990) and adjusted based on the fluid's concentration or specific gravity. To prevent material contamination, a fresh sample was used for each LL test and not reused between tests.

The 2 M NaCl brine is prepared by dissolving 117 grams of NaCl reagent in one liter of deionized water. Electrical sensitivity was calculated using the EGEL KAUST's spreadsheet for RSCS soil classification. Specific surface assessments for soils in their natural state and two stabilization levels were conducted with the "methylene blue" test (Santamarina et al., 2002), and the specific gravity of soil solids was determined following ASTM D854-10 standard.

3 RESULTS AND DISCUSSION

Chemical stabilization agents at 3% and 5% were employed, aligning with established practical geotechnical engineering ranges (Barma & Dash, 2022; Basma & Tuncer, 1992). Chemical stabilization was chosen due to its effectiveness in altering soil index properties, as other stabilization methods yielded less significant changes.

The soils used in these tests were previously identified as having expansion potential (Verdin, 2022) or collapsible behavior (Fonseca et al., 2014). Both soils primarily consist of fine particles. Key properties of the natural condition materials are detailed in Table 1.

Based on this data, both soils fall into the RSCS classification as F(F) soils, where the fine fraction governs the soil's mechanical and hydraulic characteristics. As a result, it's necessary to establish the LL of the materials using deionized water, kerosene, and brine as stated in the RSCS flowchart of Figure 2. The outcomes of the corrected LL tests are presented in Table 2, and their placement on the RSCS

Plasticity and Sensitivity Charts is depicted in Figure 5.

Expansion test results and electrical sensitivity data are displayed in the top section of Table 3, while potential collapse results and electrical sensitivity are presented in the lower section of the same table.

Table 1. Soil properties under natural conditions.

Material	Fractions			Atterberg Limits	
	G (%)	S (%)	F (%)	LL (%)	PL (%)
Expansive soil	0	16	84	76	39
Collapsible soil	0	3	97	63	39

Material	SUCS	Gs	Se (m²/g)
Expansive soil	CH	2.48	300
Collapsible soil	MH	3.15	27

Data obtained from Verdin (2022), Fonseca et al (2014) and the authors. G is Gravel, S is Sand, F is Fines, LL is Liquid limit, LP is Plastic limit, Gs is specific weight of soil solids, Se is specific surface.

Table 2. Liquid limits of soils under natural conditions and two stabilization levels in different pore fluid chemistry, electrical sensitivity and RSCS classification.

Material	LL_{dw} (%)	LL_{ker} (%)	LL_{brine} (%)	S_E	RSCS
Exp + 0%	67	41	46	0.47	F(F)-LL
Exp + 3%	66	46	46	0.32	F(F)-LI

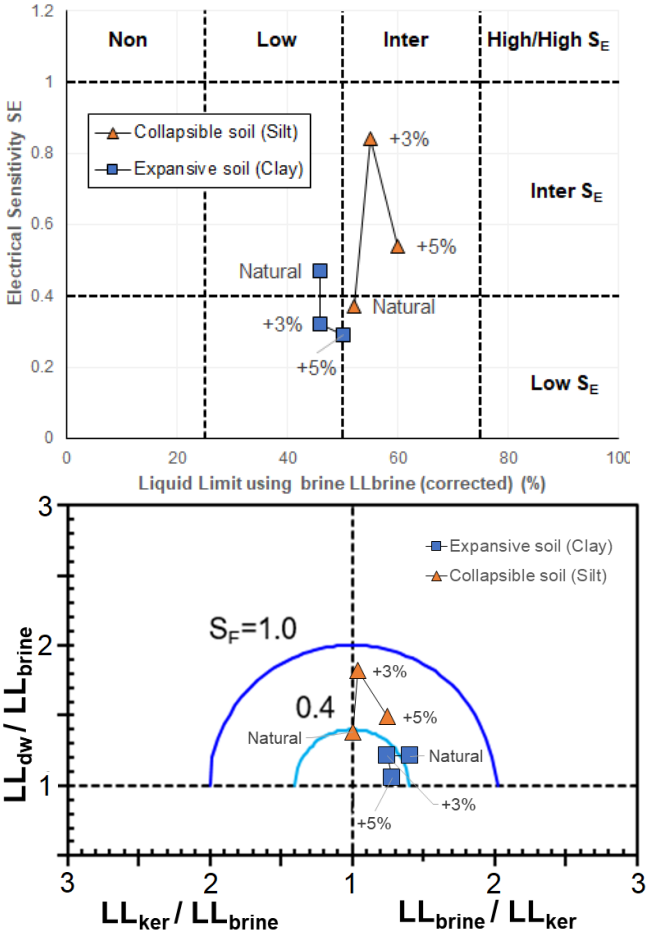

Figure 5. Evolution of the behaviour of expansive and collapsible soils in the RSCS plasticity and electrical sensitivity charts.

In the RSCS Plasticity Chart, expansive soils show that it has a natural low brine plasticity and low electrical sensibility, at a 3% stabilization agent concentration the soil presents a reduced electrical sensibility but no change in its brine plasticity, at a 5% stabilization the electrical sensitivity keeps decreasing but it presents an increase in brine plasticity. This effect could be attributed to the change lime produces on the ionic concentration of the soil and its effects on the double layers (Barman & Dash, 2022).

In collapsible soils, plasticity increases with greater stabilizing agent concentrations, however, in terms of electrical sensitivity there is a significant peak at a 3% concentration and a sharp decrease at 5%. The increase in deionized water and brine plasticity can be attributed to the microstructural mechanisms of hydration, surface deposition and shallow infilling of cementitious materials in the silt clusters (Basma and Tuncer, 1992).

In the Electrical Sensitivity Chart, expansive soils exhibit increased permittivity at 3%, followed by a reduction at 5%, with increased conductivity. Collapsible soils show reduced permittivity at 3% but increased permittivity at 5%.

No linear behavior was observed for both treated expansive or collapsible materials in both Plasticity and Electrical Sensitivity charts, so more experiments on higher concentrations are needed to establish a possible trendline, however these concentrations are purely for research purposes as these might be economically unfeasible for real-life applications.

In the complementary soil solid density measurements, the addition of the stabilizing agent increased the soil specific density, affirming a physical-chemical change in the soil's particles. As for specific surface, both lime and cement reduced the soil surface area with increasing concentration. Notably, the decrease in the collapsible silt surface area while the LL in both deionized and brine fluid increases during chemical stabilization suggests the presence of a distinct mechanism in the LL test, depending on the material's particle size and mineralogy, as noted by Sridharan and Prakash (2000).

During experimentation with the collapsible silt, an intriguing phenomenon occurred. It underwent a cementation reaction with both deionized water and brine, leading to an exothermic reaction with a temperature rise of 20°C, ultimately solidifying into a hard mass. To conduct the LL test, continuous stirring and fluid addition were essential to cool the mixture and prevent the formation of a non-workable paste.

Although the stabilization of these soils is a physical-chemical reaction that tends to continue to evolve over time, no significant change in LL results was recorded during the testing period of 14 days.

4 CONCLUSIONS

In the expansive soil, lime concentration inversely impacts expansion, with electrical sensitivity following a linear trend. However, brine plasticity exhibits a decreasing-then-increasing pattern.

For the collapsible soil, increased cement concentration reduces collapse potential. Electrical sensitivity displays a non-linear trend, while plasticity in brine rises with cement concentration.

In both cases, complementary tests reveal that chemical stabilization increases solids density and diminishes their specific surface area.

For establishing material expansive using RSCS, it's advisable to utilize its electrical sensitivity as a control parameter. However, for collapsible soils, finding a suitable control parameter remains challenging.

A potential issue with this new system is the contamination of soil samples with kerosene and brine. Proper disposal and treatment of test residues need to adhere to environmental regulations, a capability not commonly found in standard soil mechanics laboratories.

ACKNOWLEDGEMENTS

We extend our gratitude to National Council of Humanities, Science and Technology (CONAHCyT) for their support in this research through the Graduate Scholarship Program. We also appreciate the assistance provided by the academic and student community of the Department of Research and Graduate Studies at the Autonomous University of Querétaro. ABSTRACT: This research article explores an innovative method for predicting rockbursts using Machine Learning (ML) algorithms. The study utilizes a decision tree (DT) algorithm and tests two distinct approaches: (1) utilizing a DT model for each rock type (DT-RT) and (2) developing a single DT model (Unique-DT) for all rock types. The dataset comprises 210 records from China, Canada, the United States, Japan, and Italy and includes five input variables for training and testing. The effectiveness of the DT models is compared to other ML algorithms, including Random Forest (RF) and Gradient Boosting (AdaboostM1). The results show that the Unique-DT model performs well and has an F1 score of 0.65 in predicting rockburst conditions. Although RF and AdaboostM1 with F1 (0.66) outperform the Unique-DT model slightly, the Unique-DT model is recommended due to its superior ease of use, effectiveness, and accuracy.

RÉSUMÉ: Cet article de recherche explore une méthode innovante pour prédire l'éclatement des roches à l'aide d'algorithmes d'apprentissage automatique. L'étude utilise un algorithme d'arbre de décision (DT) et teste deux approches distinctes: (1) l'utilisation d'un modèle DT pour chaque type de roche (DT-RT) et (2) le développement d'un modèle DT unique (Unique-DT) pour tous les types de roches. L'ensemble de données comprend 210 enregistrements provenant de Chine, du Canada, des États-Unis, du Japon et d'Italie et inclut cinq variables d'entrée pour la formation et les tests. L'efficacité des modèles DT est comparée à d'autres algorithmes de ML, notamment Random Forest (RF) et Gradient-Boosting (AdaboostM1). Les résultats montrent que le modèle Unique-DT est performant et a un score F1 de 0.65 pour prédire les conditions d'éboulement. Bien que RF et AdaboostM1 (F1 = 0.66) soient légèrement plus performants que le modèle Unique-DT, ce dernier est recommandé en raison de sa facilité d'utilisation, de son efficacité et de sa précision supérieure.

1 INTRODUCTION

Underground activities, such as mining, railway, and road constructions, are intricate geotechnical works. This complexity can be partly attributed to the limited understanding of the subsurface, which makes underground constructions challenging due to the variability of the geology. Although underground operations at depths of 2000 m have become increasingly common, and efforts have been made to perfect underground constructions, uncertainties still arise occasionally. These uncertainties can lead to the waste of resources such as time, money, and properties, and even loss of life. It is important to address these uncertainties in order to minimize risk and improve outcomes in underground construction. One such uncertainty is the instability of rock mass, caused by factors including the type of rock, its strength, and brittleness. External conditions also contribute to the instability of the rock mass (Askaripour et al., 2022; Meng et al., 2017; Owusu-Ansah et al., 2023). These include dynamic disturbances, the magnitude of in situ stresses, and the order of excavation (Owusu-Ansah et al., 2023).

Rockburst is regarded as a form of rock mass failure in deep excavations involving hard and brittle rocks subjected to high-stress conditions (Askaripour et al., 2022; Lu et al., 2018; Meng et al., 2017; Owusu-Ansah et al., 2023). Rockburst is defined as the sudden and intense movement, accompanied by rock failure, in underground spaces under high-stress conditions. It transpires due to overburdening the rock mass (unaltered, brittle rock) when the stresses exceed the material's compressive strength (Dietz et al., 2018; Kidybiński, 1981; Owusu-Ansah et al., 2023; Xu and

Yu, 2016). Since rockburst is an unforeseen phenomenon, it presents a range of issues including loss of life, property damage, and in some instances, financial and temporal setbacks. Therefore, comprehending this phenomenon and determining its triggers is critical to prevent such vulnerabilities. This paper applies a rockburst intensity or rockburst conditions (RBC) grading system, consisting of four predetermined classes built on rock displacement, damage, and failure characteristics, as demonstrated in Table 1 (Blake & Hedley, 2003; Liu et al., 2023; Owusu-Ansah et al., 2023; Russenes, 1974; Zhou et al., 2012, 2021). The prediction of rockburst mechanisms has been extensively researched over the years. Numerous authors have produced thoughtful and profound works that demonstrate successful outcomes.

Table 1. Classification of rockburst intensities.

Rockburst Condition	Failure Characteristics
None	No sound of rockburst and rockburst activities.
Light	The surrounding rock is deformed, cracked, or rib-spalled, there is a weak sound, and no ejection phenomenon.
Moderate	The surrounding rock is deformed and fractured, and there is a considerable number of rock chip ejections, loose and sudden destruction, accompanied by crisp cracking, and often presented in the local cavern of surrounding rock.
Strong	The surrounding rock is busted severely, and suddenly thrown out or ejected into the tunnel, accompanied by a strong burst and roaring sound, air spray, and storm phenomena, with continuity that rapidly expands to the deep, surrounding rock.

Recent studies on the application of Machine Learning (ML) algorithms for predicting rockburst have revealed notable effectiveness when given sets of input and output data from earlier rockburst cases. This success confirms their capability. Thus, the objective of this paper is to explore the use of decision trees (DT), a type of ML algorithm, to determine rockburst conditions in diverse rock types. The objective is to create a distinctive model that can competently forecast rockburst conditions, irrespective of the type of rock. Two decision tree-based methods have been developed and assessed using performance metrics. Moreover, ML algorithms, specifically Random Forest (RF) and AdaBoostM1, are used for comparison (Owusu-Ansah et al., 2023). The study relies on a rockburst dataset and a pre-defined four-level classification scale (see Table 1).

2 METHODOLOGY

The decision tree is an ML algorithm used for both classification and regression tasks. It is a tree-like model, where each internal node represents a test on an attribute, each branch represents the outcome of the test, and each leaf node represents a class label or a numeric value. The algorithm works by recursively splitting the data based on the most important attribute at each level of the tree, thus forming a decision path from the root of the leaf node.

This paper focuses on the implementation of decision trees (J48) with a nominal classification method. The R statistical environment, in conjunction with the Rweka package, is utilized to execute various algorithms throughout this study. A cross-validation technique with a K-fold value of 10 is implemented for validating the results.

Two decision tree approaches, DT-RT, and the Unique-DT, are utilized to forecast rockburst conditions. The former predicts rockburst conditions for each rock category using three distinct models, namely Igneous (IG), Metamorphic (MT), and Sedimentary (SD). The latter utilizes all datasets (210 occurrences) to predict rockburst conditions, thereby reducing analysis work and increasing accuracy. Both approaches aim to enhance the efficiency of the algorithm in predicting rockburst conditions. The alternative technique employs RF and AdaboostM1 algorithms to predict rockburst conditions by using a dataset that comprises 210 records. The goal is to create a comparison of performance metrics with other approaches.

2.1 Data characterization and evaluation

The rockburst condition database comprises 210 records from studies conducted by multiple authors. Table 2 summarizes the data distribution by rock category.

Table 2. Rock category distribution.

Rock category	Number of records
Igneous	103
Metamorphic	58
Sedimentary	49

The database comprises five input variables used for predicting rockburst conditions: depth, elastic

energy index (EEI), Brittle Index BI — (σ_c/σ_t), Stress Index SI — (σ_θ/σ_c), and Rocktype exclusively for Unique-DT approach. With σ_c, σ_t, and σ_θ denoting uniaxial compressive strength, tensile strength and maximum tangential stress. To evaluate model performance, the metrics employed are F1-score (F1) and Accuracy (ACC). The F1-score is regarded as a superior metric for evaluating the classifier's performance when compared to the standard accuracy measure. Accuracy represents the percentage of correctly placed data points. In both cases, the closer the metric value is to one, the better the prediction. Furthermore, a sensitivity analysis (relative importance) (Cortez & Embrechts, 2013) was also performed on the two DT approaches. The aim was to identify the pertinent input variables that contribute to the prediction of rockburst conditions.

3 RESULTS AND DISCUSSIONS

The performance metrics for the models are presented in Table 3. The DT algorithm trained to predict metamorphic rock type exhibited the best F1 score (0.74) and accuracy (0.86), demonstrating superior performance compared to the trained model for sedimentary rock type, which performed the poorest. This difference may be ascribed to the intricate geological material and the scarcity of data.

Table 3. Metrics for Algorithms.

Algorithms	**Metrics**	
	F1	**ACC**
DT-IG	0.62	0.81
DT-MT	**0.74**	**0.86**
DT-SD	0.35	0.72
Unique-DT	*0.65*	*0.82*
RF	*0.66*	*0.83*
AdaboostM1	*0.66*	*0.82*

NB.: Best Value in Bold and Italics are comparison values

The Unique-DT model, which covers all rock types, exhibited promising performance with an F1 score of 0.65 and an accuracy of 0.82. It must be emphasized that the two other DT-RT models (for IG and SD prediction) demonstrated poorer performances than the Unique-DT. Additionally, when comparing the performance metrics of RF and AdaboostM1, they were found to be similar to the Unique-DT, with RF showing a slight advantage based on ACC metric. The study indicates that the Unique-DT model presents a viable approach over other ML algorithms for predicting rockburst conditions.

Figure 1 summarizes the relative importance of model attribute, illustrating that the elastic energy index (EEI), with a percentage of 36.13%, has the greatest impact on the Unique-DT model. Additionally, Depth (25.84%), Brittle index (BI = 16.13%), and Stress Index (SI = 13.85%) are other input variables with a significant impact in rockburst prediction. The influence of the variables on rockburst due to the rock type varies among the three DT-RT models. The DT-RT model's significance in sedimentary research highlights EEI (43.01%) as the primary factor, followed by Depth (21.19%), BI (18.71%), and SI (17.09%). Similarly, the IG and MT models prioritize BI (27.37%) and SI (32.21%), respectively, with EEI ranking second in importance for both.

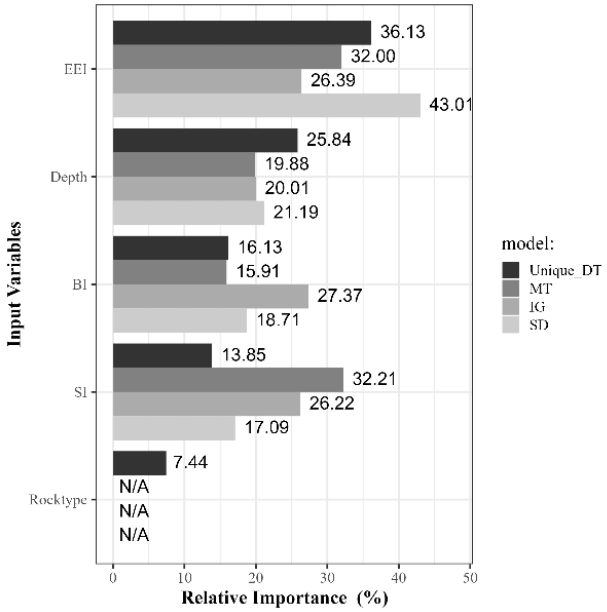

Figure 1. The relative importance of the two DT approaches for predicting rockburst condition.

These findings are consistent with previous studies on predicting rockburst conditions, stressing the significance of accurately identifying underlying factors by closely examining input data. It is worth noting that all models prioritize the elastic energy index (EEI), which aligns with the method presented by Owusu-Ansah et al. (2023) and Xu and Yu (2016) for predicting rockburst based on this index.

4 CONCLUSIONS

This paper proposes a novel model integrating rock type datasets to predict rockburst conditions using Machine Learning (ML) algorithms such as Decision Tree, Random Forest (RF), and AdaboostM1. Training and testing were conducted on a dataset comprising

210 records with 5 input variables, revealing that the Unique-DT model outperforms individual DT models for each rock type (DT-RT), achieving a promising F1 score of 0.65. RF and AdaboostM1 slightly outperformed Unique-DT with F1 scores of 0.66.

However, due to its simplicity and effectiveness, the unique-DT model is advised for rockburst prediction.

Based on this work, some future research should concentrate on improving the proficiency of ML models. Two viable approaches to explore are feature engineering which examine the formation of new features, or the transformation of existing features, to better capture the underlying patterns in rockburst conditions and hybrid models that integrate data-driven ML approaches with physics-based models. These hybrid models have the potential to improve prediction accuracy by leveraging the strengths of both approaches.

To summarise, this study highlights the potential of machine learning algorithms, specifically decision trees, in forecasting rockburst conditions by taking into account variables such as depth, elastic energy index, and rock strength parameters. Future research should focus on further enhancing the performance of machine learning models in this area.

ABSTRACT: The study proposes an integrated approach using Artificial Intelligence (AI), satellite imagery analysis, and Machine Learning (ML) to address the global challenge of slope instabilities. It emphasizes the importance of comprehensive risk assessment frameworks, particularly focusing on Early Warning Systems (EWS) and decision-making tools. By structuring risk assessment around the hazard-exposure-vulnerability-damage model, the study aims to provide a systematic approach to slope instability management, especially in transportation networks. Additionally, the research evaluates ML algorithms, namely, Multiple linear Regression (MR) and Artificial Neural Networks (ANN), for displacement prediction, highlighting their promising performance while identifying areas for refinement in data preprocessing and model optimization. MR and ANN models consistently achieved high performance, with determinant coefficient (R^2) values of 0.93. This indicates that the model can explain approximately 93% of the variance in the target variable, reflecting strong predictive capability. Despite minor variations in other metrics, such as Mean Absolute Error, Mean Squared Error, and Root Mean Squared Error, the R^2 values remained consistent, emphasizing the robustness of the model in predicting displacements.

RÉSUMÉ: L'étude propose une approche intégrée utilisant l'intelligence artificielle (IA), l'analyse de l'imagerie satellitaire et l'apprentissage automatique (ML) pour relever le défi mondial des instabilités de pente. Elle souligne l'importance de cadres d'évaluation des risques complets, en mettant particulièrement l'accent sur les systèmes d'alerte précoce (SAP) et les outils de prise de décision. En structurant l'évaluation des risques autour du modèle danger-exposition-vulnérabilité-dommages, l'étude vise à fournir une approche systématique de la gestion de l'instabilité des pentes, en particulier dans les réseaux de transport. En outre, la recherche évalue les algorithmes de ML, à savoir la régression linéaire multiple (MR) et les réseaux de neurones artificiels (ANN), pour la prédiction des déplacements, mettant en évidence leurs performances prometteuses tout en identifiant les domaines à affiner dans le prétraitement des données et l'optimisation du modèle. Les modèles MR et ANN ont constamment atteint des performances élevées, avec des valeurs de coefficient déterminant (R^2) de 0,93. Cela indique que les modèles peuvent expliquer environ 93% de la variance de la variable cible, ce qui témoigne d'une forte capacité de prédiction. Malgré des variations mineures dans d'autres mesures, telles que l'erreur absolue moyenne, l'erreur quadratique moyenne et l'erreur quadratique moyenne racine, les valeurs R^2 sont restées cohérentes, soulignant la robustesse des modèles dans la prédiction des déplacements.

Keywords: Slope instability; artificial intelligence.

1 BACKGROUND

Slope instabilities, involving both natural and human-induced processes that alter slope shape, composition, or stability, give rise to a variety of potentially disastrous outcomes, including landslides, debris flow, rock falls, and avalanches (Casagli et al., 2016; Stavrou et al., 2011). These events pose significant threats to individuals, infrastructure, and the environment. Addressing these risks requires ongoing monitoring and the implementation of risk reduction measures. Various methodologies, including remote sensing techniques and Machine Learning (ML), have been explored to comprehend and mitigate slope instabilities (Casagli et al., 2016, 2023; Hammar-Klose & Thieler, 2001; Kuhn & Prüfer, 2014; Mihalić et al., 2015; Nhu et al., 2020; Owusu-Ansah, 2020; Segoni et al., 2018; Stanchev et al., 2013). This work

uses ML algorithms to develop predictive models for slope movement detection and stability level classification. The goal is to optimize these models to predict slope movement and classify stability levels accurately. Integrating satellite image analysis and AI algorithms offers promising opportunities for automating processes and enhancing decision-making in slope instability monitoring and risk assessment, addressing the urgent need for effective disaster risk reduction frameworks.

2 METHODOLOGY

The proposed framework integrates AI with satellite imagery to assess highway service levels by utilizing ML to detect slope movements and categorize them into four classes (A-D), with A representing the lowest risk and D indicating the most unstable conditions, through analysis of Interferometric Synthetic Aperture Radar (InSAR) data.

This framework specifically focuses on developing predictive models capable of detecting slope movements using InSAR data, which captures vertical and horizontal displacements on both road infrastructure and surrounding slopes. The data is segregated into two parts: one depicting displacements on the road infrastructure and the other showcasing displacements on slopes adjacent to it. This study particularly concentrates on the vertical displacements observed on the slopes, deliberately excluding other data sources to minimize noise.

The source dataset encompasses 5079 records of displacement values and dates spanning a 7-year period (2016-2023). To streamline the exploration of this dataset, a five-moving window technique is employed to transform it into a new dataset (training dataset) comprising five columns. This curated dataset is more manageable for analysis and serves as the foundation for model training. Table 1 and

Table *2* delineate the step-by-step process involved in processing the source dataset into the training dataset.

This report outlines an experiment for predicting slope movement, where data from the last four slope movements, specifically vertical displacement measurements, were condidered as inputs to forecast the subsequent movement (Next stage).

Table *2* illustrates the sampling strategy for the training data, providing insight into the methodology employed for model training and prediction.

2.1 Machine learning algorithms

The present study employs a data-driven approach to forecast displacements, utilizing two ML algorithms, namely Artificial Neural Network (ANN) and Multilinear Regression (MR). These algorithms were executed in the R statistical environment (Venables et al., 2024), employing the rminer package (Cortez, 2010). Under both algorithms, cross-validation (5-fold) was implemented for training and validation purposes.

The entire procedure was repeated five times (5 runs) for generalization.

2.2 Model evaluation

The complexity of ML algorithms poses a significant challenge, which can be addressed by evaluating the algorithms based on three primary criteria: accuracy, computational efficiency, and interpretability (Owusu-Ansah et al., 2022). To ensure accuracy, a set of metrics such as Mean Absolute Error (MAE), Mean Square Error (MSE), Root Mean Square Error

(RMSE), and determination Coefficient (R^2) are considered.

The smaller or closer MAE, MSE, and RMSE are to zero, the higher the accuracy of the predictive model. Similarly, a higher R^2 value indicates greater accuracy of the model. These metrics play a crucial role in assessing the algorithm's efficacy, so their importance must be recognized.

3 RESULTS

This section summarizes the results obtained from predicting the next stage using ANN and MR algorithms. The focus is on accuracy metrics, with *Table 3* presenting performance metrics for both iterations and algorithms. R^2 indicates a strong correlation, while low values of MAE, MSE, and RMSE emphasize their usefulness in predicting the next stage based on the preceding four stages and time intervals.

This study analyzed the correlation between experimental results and predicted outcomes using two ML algorithms. The correlation analysis, shown in Figure 1, indicated a promising overall performance. Metric values in Table 3 indicate that the results for both ML models perform well and similarly.

Accordingly, additional data pre-processing and the inclusion of other variables are being considered in further experiments aiming to develop more robust models.

Table 3. Models performance evaluations based on MAE, MSE, RMSE, and R^2.

Models	MAE	MSE	RMSE	R^2
MR (stage-MR)	2.19	8.14	2.85	0.93
ANN (stage-ANN)	2.19	8.14	2.85	0.93

4 REMARKS

This study offers valuable insights into the predictive performance of Machine Learning (ML) algorithms for displacements. While the overall analysis shows promising results, there is a need for further refinement in data preprocessing techniques and model optimization to enhance prediction accuracy and reliability.

Correlation analysis, illustrated in Figure 1, reveals consistent and favorable performance trends for both ML algorithms, underscoring their effectiveness. The comparable metric values between the two algorithms suggest consistent performance.

Overall, this study contributes to advancing our understanding of ML-based displacement prediction and suggests avenues for future research, such as exploring additional input variables and refining model optimization techniques, to improve predictive outcomes for practical applications across various domains.

Stabilization of excavation slopes between km 0+000 and km 2+000 of the EN337, in the municipality of Vouzela

Stabilisation des pentes d´excavation entre le km 0+000 et le km 2+000 de l´EN337, dans la commune de Vouzela

F. Paulino*, E. Fernandes, A. Dinis
Geovia, S.A., Lisbon, Portugal

**fpaulino@geovia.pt*

ABSTRACT: With this paper it is intended to present a case study referring to the cut slopes that occur between the kilometric points 0+000 and 2+000 of the EN337 national road, whose stabilization is within the scope of the intervention foreseen for the infrastructures and municipal equipment which were affected by the great fire that occurred in Portugal's Centre region. This fire, which broke out in June 2017, affected around 75% of the area in the municipality of Vouzela, having burned around 85% of the forest area, causing 8 deaths, losses of more than 8 million euros in agriculture and 4,75 million euros in infrastructure and municipal equipment. The occurrence and characteristics of this type of fire was aggravated by the extreme phenomena (fire) associated with climate change. It is assumed that the elimination of the vegetation area had the immediate consequence of aggravating the phenomena of the local geological formations (fracturing), thus increasing the risk of rock falls onto the road.

RÉSUMÉ: Cette communication entend présenter une étude de cas de pentes coupées qui se produisent de long de 2 km de l´EN337, conformément à l´intervention prévue par les infrastructures et équipements municipaux touchés par le grand incendie dans la région Centre. Cet incendie, qui s´est déclaré en juin 2017, a touché environ 75% de la superficie de la commune de Vouzela, ayant brûlé environ 85% de la superficie forestière, causant 8 morts, des pertes de plus de 8 millions d´euros in infrastructures et équipements municipaux. La survenue et les caractéristiques de ce type d´incendie ont été aggravées par les phénomènes extrêmes liés au changement climatique. Il est supposé que la suppression de la zone de végétation a eu pour conséquence immédiate d´aggraver les phénomènes des formations géologiques locales, augmentant ainsi les risques de chutes de pierres sur la route.

Keywords: Slopes; fire; deaths; climate; risk; rehabilitation; rock fall.

1 INTRODUCTION

As a consequence of the large fire which occurred in the municipality of Vouzela in June 2017, and the deforestation that has followed, the existing slopes' vulnerability to the erosive processes was increased. Ultimately, this led to the decrease of the slopes' stability in the affected area which. This paper's case study corresponds to the EN337 cut slopes that are present between km 0+000 and 2+000, and it is based on the slope stabilization project elaborated by this paper's authors (Elsamex, 2019).

Based on surface recognition, it was found that the existing geology at the site essentially comprise granite rock with degrees of alteration varying essentially between slightly weathered to moderately weathered (W2) and moderately altered (W3) and slope deposits, formed by the alteration of the rock mass, chaos of boulders and topsoil.

By analysing the existing situation, it was verified the existence of zones of block chaos at different heights of the slope and areas of outcrop of the rock mass that were slightly weathered and highly jointed, giving rise to discontinuity planes unfavourable to stability.

In order to reduce the increased risk of falling rock blocks, stabilization solution were defined for it, which include measures to prevent falling rock blocks and consolidation of the rock mass also prevents rockfalls, namely:

- Controlled removal of rock blocks;
- Application of mortared stone wall;
- Application of rockbolts;
- Installation of triple torsion wire mesh (Figure1);
- Installation of HEA panels (High Energy Absorption Panel) (Figure 2).

2 GEOLOGY

According to the explanatory notice on sheet 17-A (Viseu) of the Geological Chart of Portugal, the area under study is characterized exclusively by the presence of magmatic rocks, more specifically by Hercynian granitoids. The identified granitoid facies was framed within the deformation features of the surrounding rocks, taking as a reference the 3rd phase of Hercynian deformation, with which the granites of the region are related. Therefore the granites present in EN337 are late to post-tectonic (relative to D3). In relation to mineralogical composition, they are considered as granites with 2 micas.

Figure 1. View of the slope showing the heavily fractured rock mass at a high elevation with potential for instability.

3 SURFACE RECOGNITION AND DESCRIPTION OF THE EXISTING SITUATION

In order to accurately describe the existing conditions, a geological survey was performed between the kilometric points 0+000 and 2+000 of the EN337 road. The referred survey concerned the cut slopes that are present on the right side of the road.

The weathering grade of the rock mass, according to what was observed, varies essentially between little altered (W2) and moderately altered (W3) along the slope.

Between km 0+950 and 0+980, the rock massif is visible only at a height of around 10m, in a sub vertical structure (Figure 1). The massif appears much fractured, with loose blocks of medium large size with potential for instability.

Between approximately km 1+020 and km 1+090, a scenario similar to the previous one was observed, with the difference that the outcrop of the granite outcrop is visible from area adjacent to the road, i.e., it emerges at a higher elevation, low, extending in height (Figure 2).

To support the work developed, a topographic survey was carried out using a drone. This allowed a perception not only of the position and size of the blocks, as well as, the elevation at which the rock blocks are located in relation to the EN337 (Figure 3).

Figure 2. Slope featuring loose blocks with kinematic potential.

Figure 3. General aerial view of the site under study.

4 STABILIZATION SOLUTIONS

The controlled removal of rock blocks becomes necessary due to different facts, namely:

- Proximity to the road;
- Location at great heights, allowing the gain of kinetic energy;
- Subvertical slope of the massif where the rock blocks are located;
- Degradation of local friction conditions at the base of the blocks, due to weather or fires.

The recommended solutions include measures to prevent the potential fall of blocks along the slope, particularly in areas where highly fractured granite emerges, and active measures to consolidate the slope in areas of the granite mass with unfavourable discontinuity planes.

The application of triple-twist metal mesh (Figure 4) was defined for areas of the granite massif that present simultaneously a low degree of alteration and a high degree of fracture, which could consequently imply the detachment of blocks of different dimensions and subsequent fall to the road.

The solution for applying HEA panels (Figure 5) was defined only for areas where the isolated removal of blocks is unfeasible, due to steeper slopes and more significant slope heights. This solution aims to maintain rock blocks of considerable size in their position.

With the purpose of consolidating rock masses in areas where unfavourable joint planes are present, it was recommended to install localised rockbolts in exposed granitic masses with a low weathering grade (Figure 6). With its application, it was intended to prevent further development of the existing failure's surfaces and therefore increase stability.

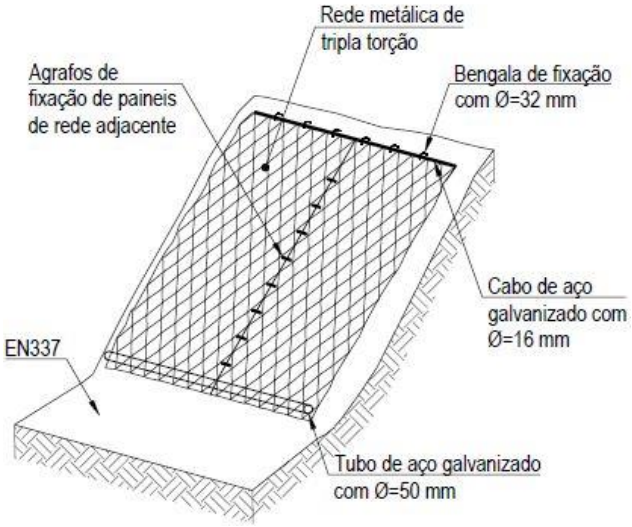

Figure 4. Triple twist wire mesh fastening diagram.

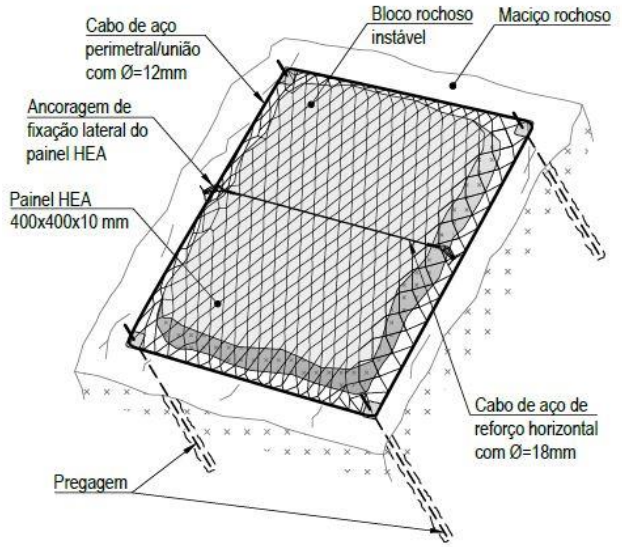

Figure 5. HEA panel fixing diagram.

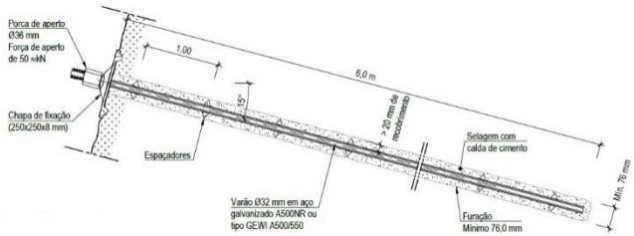

Figure 6. Rockbolt detail.

5 IMPLEMENTATION SOLUTIONS

Below, some photographs of the on-site works carried out within the scope of the solutions implemented are presented (see Figures 7 to 9).

Figure 7. Application of triple twist net and nailing in excavation slope.

Figure 8. Application of HEA panels and nailing in excavation slopes.

Figure 9. Application of punctual nailing in excavation slopes.

6 CONCLUSIONS

Following the large fire, which occurred in the municipality of Vouzela in June 2017, and the consequent deforestation, thus accelerating the erosion process and increasing the instability of slopes the need arose to carry out of the Execution Project for "Stabilization of Excavation Slopes of EN337 between km 0+000 and km 2+000".

In order to reduce the increased risk of falling rock blocks, stabilization solutions were defined, which include measures to prevent falling rock blocks and consolidate the rock mass, namely:

- Application of specific nails;
- Installation of metal mesh and triple twist;
- Installation of HEA panels (High Energy Absorption panel).

Triple wired mesh was applied in the most critical areas, whose locations comprised: i) Slopes that present clear signs of instability; ii) The steepest slopes and; iii) The higher slopes. In these areas, in addition to the triple wire mesh, it is also recommended to apply HEA panels whenever large and loose rock blocks are present.

ACKNOWLEDGEMENTS

The authors are grateful for the documentation support provided by municipality of Vouzela.

ReSist - A municipal policy to increase awareness on seismic risk

ReSist - Une politique municipale pour accroître la sensibilisation au risque sismique

ABSTRACT: Lisbon has a dense urban occupation with more than half a million inhabitants, not accounting for the daily commutes of workers and students who enter the municipality, which increases this value up to 70%. Since most of the national economic and political decision-making centres are in Lisbon, the emergency response could be constrained in case of a high-impact event. The risk factor is further aggravated due to an old building stock. Considering this context, a municipal program was implemented to assess and promote seismic resilience. Within the scope of the ReSist framework, the City Council intends to carry out assessment campaigns aiming at achieving seismic resistance of the city's buildings and infrastructures. Implementing these targeted actions can accelerate the achievement of the United Nations 2030 Agenda for Sustainable Development, particularly the goal nr. 11 - to make cities and communities inclusive, safe, resilient, and sustainable, while improving people's well-being. Several studies and risk mitigation activities are being conducted by several action plans in different sectors, bringing together stakeholders from academic and research institutions, national administration entities, professional orders and associations, real estate, consultancy and insurance companies, and citizens. Dissemination strategies and workshops were also promoted, to raise awareness and prepare civil society for a seismic event.

RÉSUMÉ: Lisbonne présente une occupation urbaine dense, avec une population de plus d'un demi-million d'habitants, sans compter les déplacements quotidiens des travailleurs et des étudiants qui entrent dans la municipalité, augmentant ainsi cette valeur jusqu'à 70%. La plupart des centres de décision économique et politique nationaux se trouvent à Lisbonne. En cas d'événement à fort impact, la réponse d'urgence pourrait être entravée. Ce risque est exacerbé par un parc immobilier vieillissant. Dans ce contexte, un programme municipal a été lancé pour évaluer et promouvoir la résilience sismique. Dans le cadre du projet ReSist, le conseil municipal prévoit une évaluation rapide de la résistance sismique des bâtiments et infrastructures de la ville. La mise en œuvre de ces actions peut accélérer l'atteinte des objectifs de l'Agenda 2030 des Nations Unies pour le développement durable, en particulier l'objectif 11 de rendre les villes et les communautés inclusives, sûres, résilientes et durables, tout en améliorant le bien-être des habitants. Plusieurs études et mesures d'atténuation des risques sont menées dans le cadre de plans d'action et de formations impliquant divers secteurs, réunissant des acteurs issus d'établissements académiques, d'entités administratives centrales, d'ordres et d'associations professionnelles, d'entreprises immobilières, de cabinets de conseil et d'assurances, ainsi que des citoyens. Des stratégies de diffusion et des ateliers visant à sensibiliser et à préparer la société civile à un événement sismique ont également été promus.

Keywords: ReSist program; seismic resilience; retrofitting; inter-municipal communities.

1 INTRODUCTION

Lisbon's high exposure to active seismogenic sources, combined with the high population density in an urban context and the services located here, make the city extremely vulnerable to the impacts of earthquakes, also leading to a very high-risk factor.

It is recognized that the intense rehabilitation of buildings recorded over the past decade has improved the general conservation state of the city's buildings. Nonetheless, these might not have considered the necessity to maintain or reinforce the structure's resistance to damage during a near-future seismic event. Furthermore, according to the most recent

census data (INE, 2021), 60% of existing houses were built prior to seismic-resistant regulations, which coincidentally are in the most populated areas. In 1958, Portugal introduced its first design codes that explicitly included seismic provisions (RSCCS, 1958).

The context presented above led to the necessity of defining and applying a local strategy leading to the creation of the ReSist Program, a municipal program aiming at the promotion of seismic resilience to the private and municipal buildings and municipal urban infrastructures.

2 FRAMEWORK

The ReSist Program stems from the need to respond to the various programs and strategies of the city as part of a broader effort to promote Lisbon's seismic resilience.

Given the importance of the subjects approached by the program, in June of 2021 the Lisbon City Council unanimously approved it and set up a Project Team with the mission of implementing and monitoring the execution of the municipal program. In addition to the permanent members, the team has the support of the Advisory Structure (AS), the Technical-Scientific Council (TSC), and an Inter-municipal Technical Structure (ITS). The AS is composed by municipal technicians representing different services, while the TSC is composed by external entities or individuals with expertise in this domain, whose function will be the guidance and optimisation of the actions to be developed. The most recent addition to the project team was the establishment of the ITS (which is ongoing), aims to share knowledge and good practices between other municipalities through the intermunicipal communities.

2.1 ReSist Project main goals

The project is based in specific main goals materializes in 47 actions to be implemented, which will be presented generically throughout this article:

- Methodology development to define the criteria and tools to support preventive inspection and seismic vulnerability assessment to private and public buildings;
- Tools to support the prior control of urban planning operations and the subsequent execution of successive inspection actions;
- Submission of proposals for incentives or support, particularly at a technical level, to encourages owners to promote technical inspection in order to identify vulnerabilities and, therefore, adopt measures to buildings structural reinforcement;
- Development of information platform for monitoring purposes and to inform citizens;
- Development of methodologies and support tools that allow the assessment of the seismic vulnerability of the city's infrastructures (road network, artworks and sewage);

2.2 ReSist base vectors

These ReSist actions will be developed according to three base vectors (Figure 1).

2.2.1 Knowledge and modelling infrastructure

This vector frames the actions regarding acquisition, compilation, and data processing to define the most vulnerable areas in the city. A seismic resistance index of the private and public buildings and infrastructures will be proposed, as well as the definition of models and actions to enable the adoption of mitigation, prevention, and adaptation measures.

2.2.2 Society engagement

This vector comprises actions regarding the creation of municipal incentive programs aimed at involving private owners to provide technical or financial support in the inspection and reinforcement of the structural safety of private buildings.

Communication strategies and actions for the involvement of society are also included, as well as the participation in research and development projects.

The establishment of external partnerships will help guide the actions to be materialized.

2.2.3 Regulation and supervision

This vector integrates actions regarding the update of municipal regulations and territorial management instruments, procedure optimization, project quality evaluation, and the definition of standards that will regulate municipal inspection actions.

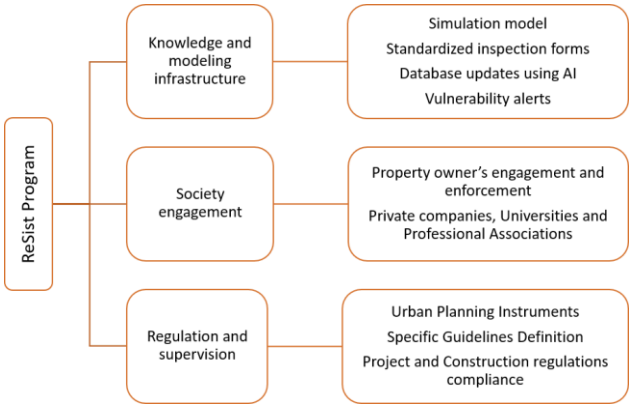

Figure 1. Base vectors of the ReSist Program.

3 RESULTS AND DEVELOPMENTS IN PROGRESS

3.1 Knowledge and modeling infrastructure

3.1.1 Development of seismic vulnerability assessment methodologies

The prompt assessment of the seismic vulnerability of the building stock was conducted by Instituto Superior Técnico (IST) and led to the production of a macroscale risk map for identify the most vulnerable areas and the early damage assessment. It also allowed the development of a methodology for assessing the seismic resistance of single buildings on a microscale approach. This methodology includes a visual inspection of the buildings to determine its typology, structural irregularities, and state of conservation. Posterior work will involve an information update about retrofitted buildings. The municipal building inspection program was conducted along 100 inspections realized in residential and equipment buildings, in close collaboration with Gebalis, an entity that manages municipal neighbourhoods. The sample selection considered the different architectural and structural typologies, intending to replicate the results obtained in the buildings evaluated by those with identical construction characteristics. (Figure 2). Using this methodology we were able to asses around 1600 buildings.

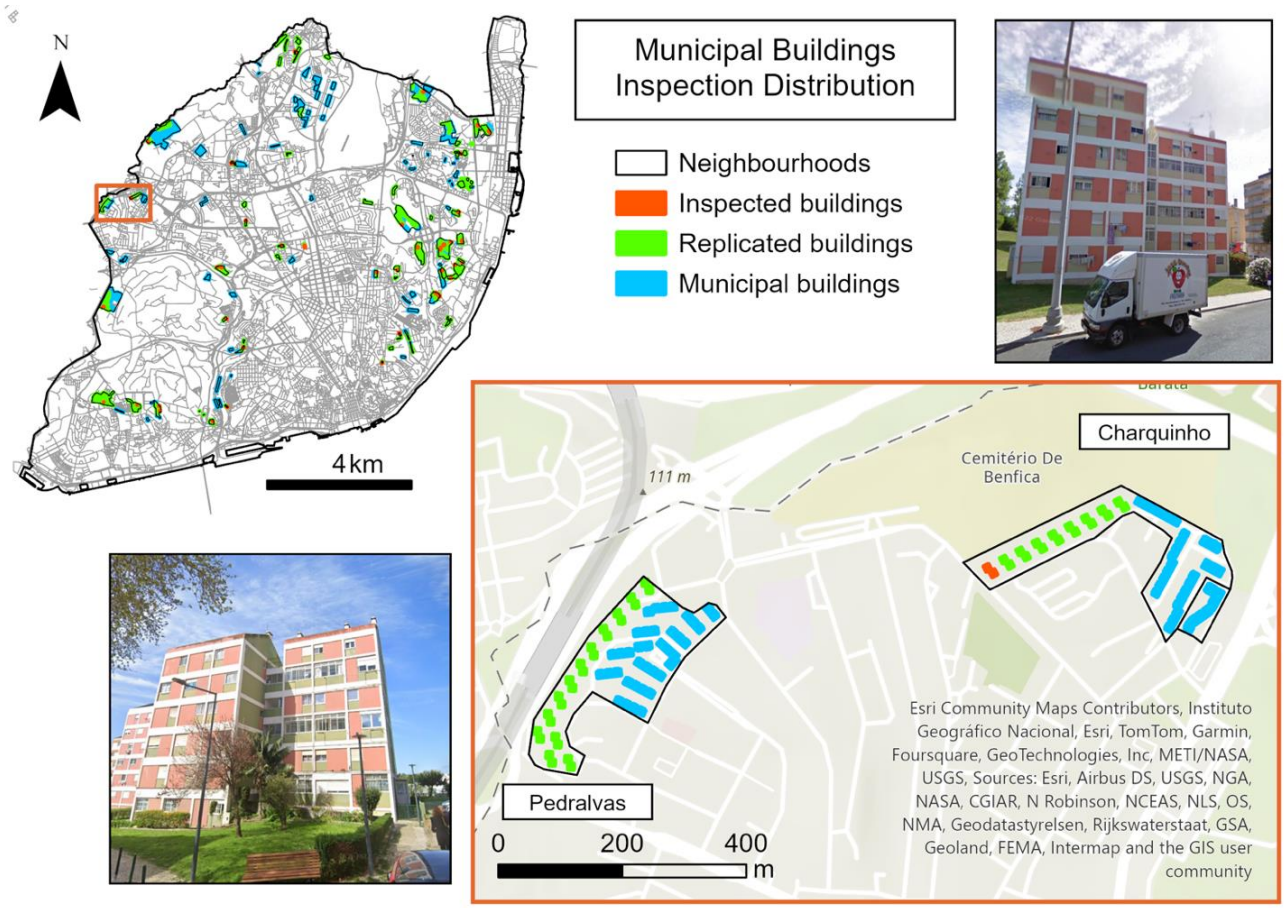

Figure 2. Map of Lisbon with distribution of municipal neighbourhoods. Example of building replication based on construction characteristics, in the Pedralvas neighbourhood based on an inspection made in the Charquinho neighbourhood.

The production and map updating, namely the geotechnical map of Lisbon and the natural and anthropic risks map available in Lisbon Master Plan, respectively, are taking place in parallel with other work, such as identifying complementary sources of information to supplement the gaps in the databases.

Other actions include a soil liquefaction and cyclic mobility study in partnership with the National Laboratory of Civil Engineering (LNEC), and the development of an application for managing inspection processes.

3.1.2 Development of a data management application

The development of a mobile application can standardize inspection surveys by allowing field technicians to do them based on observation. On the other hand, the LxReSist website will allow citizens to get relevant information about where they live according to the inputs they provide (Figure 3).

Process digitalization and incorporation into databases facilitates access to archived information.

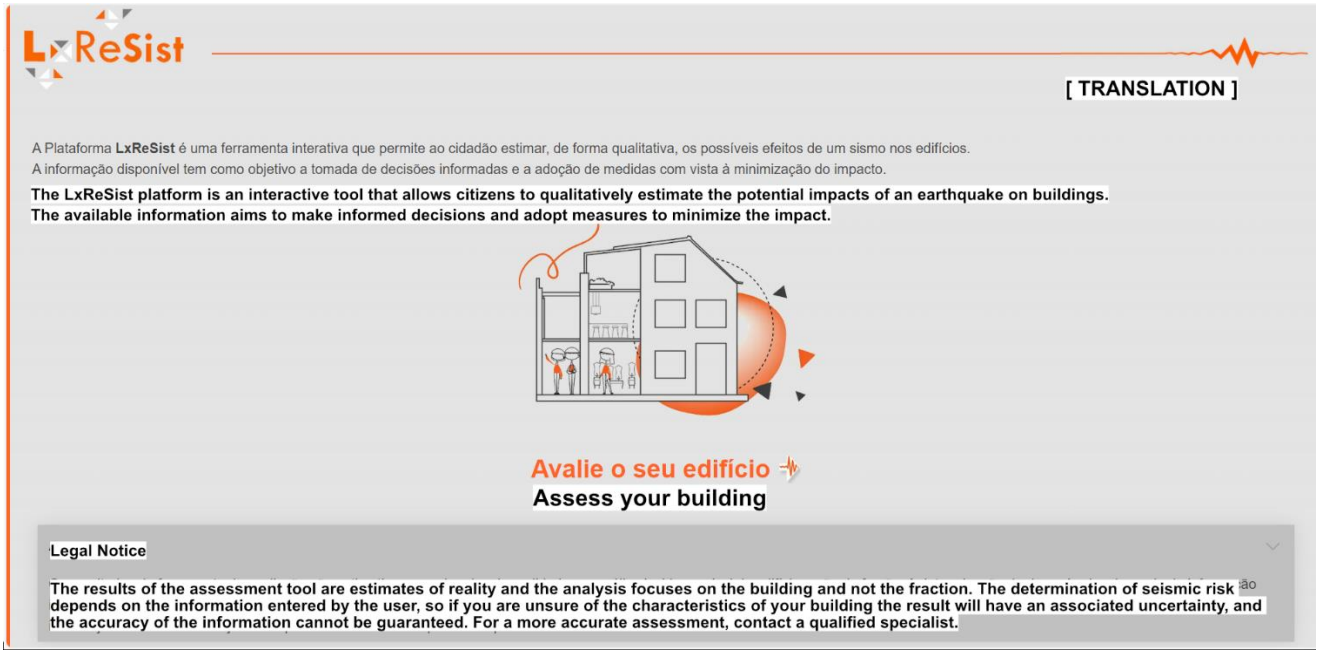

Figure 3. LxReSist platform front page.

3.2 Society engagement

Since its first public presentation in March 2022, the project team attended several events. The ReSist Journeys were developed and divided into three cycles: an Explanatory Cycle, a Capacitation Cycle, and a Training Cycle, with a total of 1183 participants. The explanatory and capacitation cycles reached diverse target audiences, while the training cycle was aimed at engineers, architects, designers and technicians in the inspection area. At the same time, some actions were carried out in schools, reaching a total of 2461 students (Figure 4), and others where 200 teachers participated.

Dissemination actions directed to the general population allowed the acquisition of skills that will lead to more efficient reactions when confronted with an earthquake, and these should be held periodically to sustain their desired effect. Concerning technical personnel, raising awareness of good practices will lead to the definition of better projects and safer buildings, with the help of methodology guides in development. Still within the scope of sharing good practices, the involvement of other municipalities located in the regions north to east of Lisbon and south of the Tagus basin is of great significance for everyone involved.

Figure 4. Actions developed in schools.

Communication strategies involved the production of several materials such as emergency kits for the students, roll-ups, flyers, as well as short and informative videos. Other dissemination and training actions are being developed, and the “Do it yourself” initiative is under expansion to raise public awareness (Figure 5).

As part of the intervention programs, the feasibility of installing gas seismic valves in new constructions is under review in partnership with the Gas Technological Institute (ITG) and General Direction of Energy and Geology (DGEG).

Figure 5. Flyer developed as part of the "Do it yourself" program. Adaptation of the original Portuguese flyer to show the icons designed and the main titles.

3.3 Regulation and supervision

In the context of standard development, a proposal for the structure and content to be included in the seismic vulnerability assessment report (RAVS) was prepared, and a procedural flow was developed to support urban management. In April 2023, the delivery of the RAVS (Figure 6) was introduced during the approval phase of the Architectural Project to ensure that structural safety is considered at an early stage of the urban licensing process.

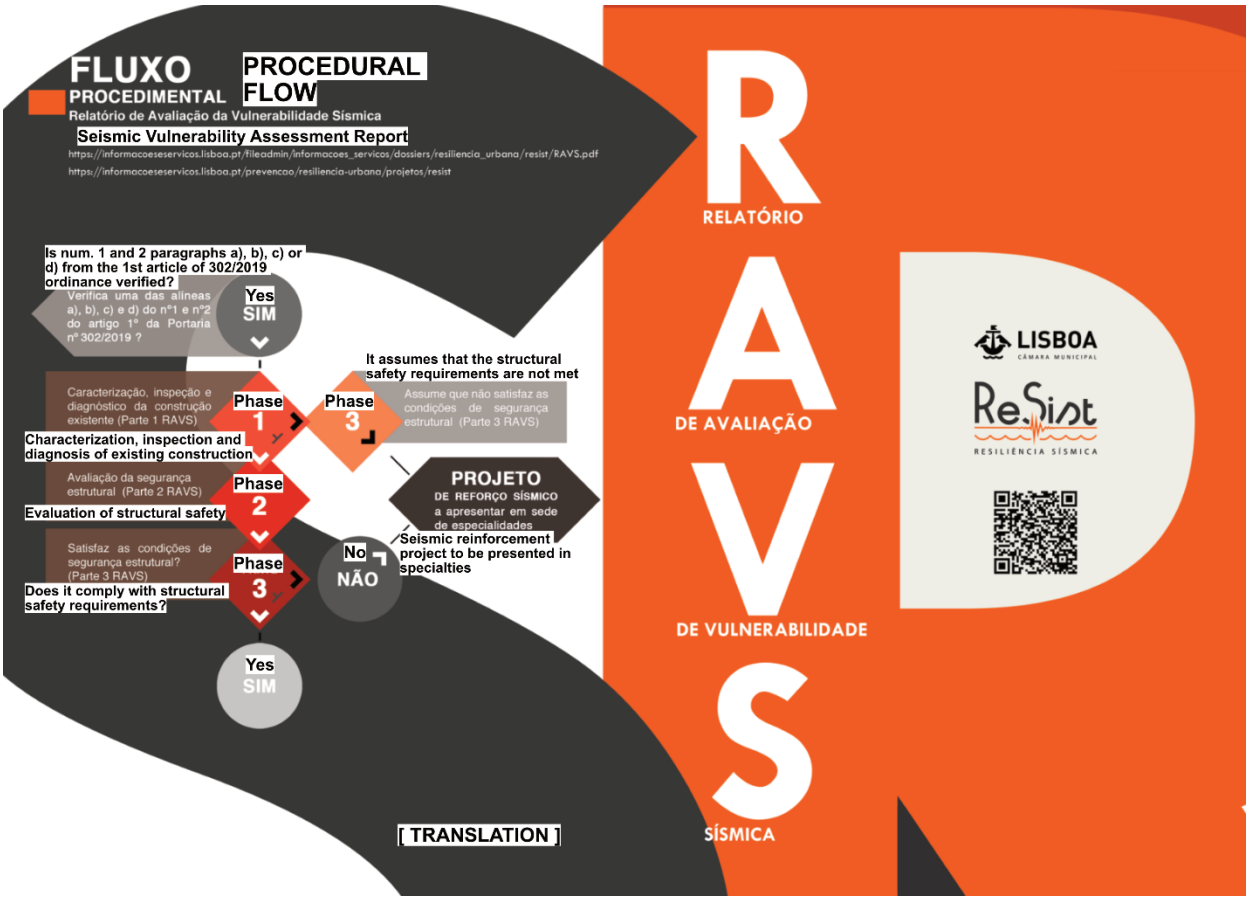

Figure 6. Seismic vulnerability assessment report: application and procedural flow (translation).

The regulation of the occupation of priority road axes and the operationalization of emergency plans are being developed with the Municipal Civil Protection Service and the Fire Department (RSB). To assess the viability and maintenance of the functionality of the road axes identified in the emergency plans, considering the collapse of the building stock after an earthquake, the development of a building collapse model (ÉRRE LRB, 2022), was contracted which will later be crossed with the sewage infrastructures. This measure also aims to identify the axes of access roads to critical infrastructures where seismic reinforcement intervention should be prioritized. The results will also lead to the definition of evacuation routes and definition of meeting points for population, serving as a support tool for planning actions.

Measures to be implemented in territorial management instruments require specific standards to be included in their regulation, accessible through the "Planning a Resilient City" guide.

4 CONCLUSIONS

The program's implementation relies on a governance model that emphasizes centralized management and coordination, with the ability to facilitate communication between municipal organic units, leading to flexibility and effectiveness in management. It combines technical knowledge with political and social engagement, appropriate regulation, incentive allocation, and technical support, which materialize the three fundamental aspects of the program.

ACKNOWLEDGEMENTS

The project presented in this article is grateful for the support provided by the partners and their availability to cooperate whenever required by the project team. Mónica Amaral Ferreira is grateful for the Foundation for Science and Technology's support through funding UIDB/04625/2020 from the research unit CERIS.

ABSTRACT: As part of the Lisbon Multihazards Citizens Observatory, which is integrated in the AGEO Project - Platform for Atlantic Geohazard Risk Management, Lisbon Municipality has developed a platform to receive information by citizens - Citizen Observatory. The platform's interface, aiming to simplify the report, is based on graphic content and uses simple language, enabling ordinary citizens to give information about situations related with geotechnical risk in Lisbon. This solution allows citizens to play an active role in risk management systems and facilitates the monitoring of situations in which Lisbon Municipality technicians have increased difficulties due to lack of access. Ultimately, it allows Lisbon Municipality to anticipate problems that may arise in some parts of the city, such as settlements in buildings, enabling a proactive response and not a reactive one, as it happens today. In addition to the platform, educational contents were also developed aiming to raise population's awareness to geological risks, allowing the implementation of preventive measures.

RÉSUMÉ: Dans le cadre de l'Observatoire Citoyen Multirisques de Lisbonne, intégré à la Plateforme AGEO pour la Gestion du Risque Géohazard Atlantique, la municipalité de Lisbonne a développé une plateforme pour recevoir des informations des citoyens - l'Observatoire Citoyen. L'interface de la plateforme, visait à simplifier le rapport, est basé sur un contenu graphique et utilise un langage simple, permettant aux citoyens de donner des informations sur des situations liées au risque géotechnique à Lisbonne. Cette solution permettra aux citoyens de jouer un rôle actif dans les systèmes de gestion des risques et facilitera le suivi des situations où les techniciens de la Municipalité de Lisbonne rencontrent des difficultés accrues en raison du manque d'accès. En fin de compte, cet outil permettra à la Municipalité d'anticiper les problèmes qui pourraient survenir dans certaines parties de la ville, comme les affaissements dans immeubles, permettrant une réponse proactive et non réactive, comme c'est le cas aujourd'hui. En plus de la plateforme, des contenus pédagogiques ont également été développés visant à sensibiliser la population aux risques géologiques permettant la mise en œuvre de mesures préventives.

Keywords: Citizens observatory; geotechnical risk; educational contents; AGEO app.

1 INTRODUCTION

The Atlantic region is exposed to a range of low-probability/high-impact events and various hazard risk scenarios, which, due to the low likelihood of occurrence and/or the high cost of mitigating actions, lack the level of preparation for effective monitoring and response. It is in this context that the AGEO Project emerges. The aim was to implement several citizen observatories pilots aiming to test a new form of engagement between civil society and local authorities for geohazards-related local capacity building, also encouraging the local use of innovative Earth observation products and services provided by European data infrastructures.

Lisbon is located at the confluence of the Tagus River with the Atlantic Ocean, which gives the city a prominent geostrategic position, but also a high exposure to natural and climatic hazards, such as earthquakes, tsunamis, coastal and urban floods, landslides, and an increasing occurrence of extreme weather events. The city presents a high population density and hosts most of the government and services buildings, which, in case of a disruptive event, could directly impact the decision chain. Many of these city buildings, as well as the infrastructures, are aged, so urban improvement is required to reduce the impact of natural phenomena.

Lisbon is already preparing for other threats by integrating responsive services which increase

efficiency, but developments are required to have a more effective planning for larger, more severe events brought on by geohazards and climate changes. Considering this, it is fundamental to prepare the society to better respond to disasters and to guarantee that citizens, properly oriented towards a problem, can provide valuable data about a specific event in their area of residence and play an active role in risk management systems.

This was the proof of concept demonstrated in the Lisbon Pilot, managed by the Lisbon Municipality, on the behalf of AGEO Project, which addresses seismic risk, urban floods, landslides, and geotechnical risk, and has the particularity of being developed in an urban context.

One of the key objectives of a Citizen Observatory is to assure citizen engagement, building awareness and involving specific groups of stakeholders, from the common citizen to specialized professionals. To achieve that, it is critical to provide the appropriate means for active citizens to participate. One of the easiest ways is to create a direct information channel for citizens, allowing them to easily communicate events related with natural risks or geohazards, when they witness one. In the Lisbon pilot, this communication channel was materialized in a mobile application, considering the different levels of expertise and accessible to everyone by smartphone.

The stakeholder groups were selected considering their respective area of activity and ability to promote efficient monitoring of risk situations. In this case, local civil protection groups, municipal services (firefighters, sewage and pavement brigades), the scientific community, schools, senior university students and scout groups were involved.

Using the app, the citizens can report geohazards events easily and, in this way, play an active role in risk management systems, allowing for a more informed decision, and ultimately contribute to the implementation of proactive measures rather than reactive responses in terms of risk management.

2 COMMUNICATION STRATEGY / PUBLIC AWARENESS

Given that geological hazards constitute a type of risk whose concept not all people understand and are not aware of the relevance that such risks may have on their daily routine, it was considered necessary to develop an easy and direct communication strategy, which in this case began with the creation of the project's mascot, RISKA (Figure 1), a geologist who travels around the city of Lisbon, and became the communication identity of the Lisbon Pilot.

Figure 1. RISKA, the Lisbon pilot mascot.

Using RISKA, several communication materials were developed to support the work with stakeholders, particularly with educational community, such as flyers, posters, tray napkins with crosswords about AGEO and other games, bookmarks, rulers and keychains (Figure 2). These materials were distributed through several dissemination actions carried out in Lisbon schools, in which around 2500 students participated.

Figure 2. Educational Contents.

Aiming the engagement of the common citizen, a partnership with Delta Cafés (portuguese coffee company) was promoted, resulting in a campaign carried out to disseminate the AGEO Project through sugar packets distributed in the city of Lisbon (Figure 3). For this purpose, 10 layouts were developed regarding the risks managed by the Lisbon Pilot.

Figure 3. Two examples of sugar packets.

In addition to these materials, other contents were developed, including educational videos, in which RISKA explains, teaches and alerts to some of the daily problems that occur in the city, explaining how to prevent them and how to react in different situations. The videos are available on Youtube and at the Lisbon Municipality web page (https://informacoeseservicos.lisboa.pt/prevencao/resiliencia-urbana/projetos/ageo).

Given the diversity of the target audience, it was decided that communication on social media should be informal, explanatory, educational and with low

technical complexity, for easy understanding by the general population. Social networks, such as Facebook and Instagram, were widely used as communication platforms and more than 50 posts related to specific days were published during the Project (https://www.facebook.com/ageoatlantic; https://www.instagram.com/ageoatlantic).

3 LISBON AGEO APP

To assure citizen engagement and obtain as much data as possible, the Lisbon pilot developed a mobile application, accessible to everyone in every smartphone, available in iOS and Android formats, through which citizens can report situations related to geological risks, in particular earthquakes, landslides, floods, and geotechnical risk in the city of Lisbon, in a straightforward and standardized manner.

However, reporting geohazard events can be a tricky task. As the primary goal is to receive inputs from the biggest audience possible, the main target user is the regular citizen, that is, people with no technical expertise in the matters concerned. Still, it is expected that even a non-specialized citizen, if effectively directed, can provide meaningful and information about the witnessed events, allowing technical staff to analyse the reported data and to take better and informed decisions, even before visiting the site. This will optimize risk management systems and allow more informed decision-making, ultimately contributing to the implementation of proactive measures rather than reactive.

Taking these aspects into consideration, careful thought was put into the design of the geohazard reporting app, developing mock-ups of the app's user interface, and idealizing the user flow experience.

As the need for an easy, fast and low-cost implementation solution was evident, it was decided to use the technology available in Lisbon's spatial data infrastructure. Among the various applications available in the ESRI software, the ArcGis Survey 123 solution stood out, as it is free of access, it does not require any registration from the user and is accessible from the AppStore and Google Play. So, before using the AGEO application, citizens must install ArcGis Survey 123 on their mobile device, available on the Lisbon Municipality page.

3.1 Designing the user interface and application workflow

To provide a visual overview of the expected user interface for the report app, a set of mock-ups were developed. The layouts were designed focusing on the expected user experience and intending to provide an easy way to use and a visually attractive interface, with graphic buttons that facilitate the user's perception of the required information.

After installing the platform, the user has access to the interface. The main steps of the application workflow while reporting an event are:

A. Choosing the type of event to report.

In this step, the user is presented with a grid of graphic buttons representing the different types of events (Figure 4). An option of "Other events" was added, to facilitate the usage by those citizens who don't know which event to choose or are not comfortable in identifying the specific event type.

B. Taking photos of the event and providing some additional descriptive info.

C. Defining the location and date of the event and indicating the major elements at risk (people, animals and/or assets).

To define the location, the user can choose to use the device location info or, manually, pick the correct location in an interactive map available.

D. Reporting specific event information.

In this step, the user will be presented with distinct interfaces, according to the event type, helping the user provide meaningful information about the event.

Careful consideration was taken when defining the input interfaces for the user to provide information about the event, favouring self-explanatory graphic buttons that allow him to visually interpret what is expected and quickly report the information. When asking for measurement units, scales of measure with physical objects were provided so the citizen could easily visualize and identify the correct amount, even if he is not used to the standardized unit measuring systems. For instance, when asking the user to indicate the volume of land mass displaced in a landslide event, a graphic scale using vehicles was used, as shown in Figure 5. The flow of a report ends with Submission.

Figure 4. Graphic buttons representing the event types.

Figure 5. Examples of the interfaces for step D for two event types: subsidence and landslides.

In complement to reporting events, the citizen can check all the reported events through the app. Using a map-based interface, the user can download the information related with the events reported in each location. Filtering or ordering the reported events by type of event or occurrence date is also available.

3.2 Dealing with the reported data

Reports made by citizens via the AGEO App are always received by The ReSist team of Lisbon Municipality, which is focused on the urban resilience sector. Once the reports have been received, they are forwarded to the services responsible for dealing with each situation. In addition, if there are people at risk (a situation that can be flagged directly in the app), the report is automatically sent to the municipality's fire department occurrence management system, in order to ensure that the rescue services can act more quickly. All communication between the app and the services, including reporting to the regiment, is based on ESRI technology and it is always possible to locate the incident.

While considering individually each of the reported events, it can be hard to envision if the driving forces behind it are of geological nature or if they are related to some other site-specific circumstances. But when the reports are analysed altogether, evidence of more complex and systemic "problems" can emerge.

This ability to globally analyse the reports of several occurrences spatially related is one of these great advantages behind multihazards citizens' observatories (Figure 6). Despite that, if a concerned citizen reports a hazard of any kind, local governments and authorities must assure that no immediate security concerns are in place and must take measures to correct any reported damages.

To achieve this, it is fundamental to guarantee that the reported information reaches the local authorities responsible for the first response operations, in case of an emergency and/or the services responsible for the maintenance of public space. With this objective in mind, Lisbon municipality is implementing an automatic workflow that forwards the information reported by the citizens to the adequate entities according with the circumstances reported through the geohazards report app.

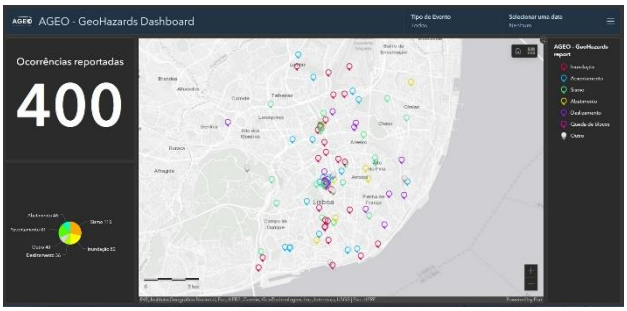

Figure 6. Dashboard for reports visualization and global analysis (data reflects simulated occurrences).

4 CONCLUSIONS

As part of the Lisbon Multihazards Citizen's Observatory, which is integrated in the AGEO Project – Platform for Atlantic Geohazard Risk Management, Lisbon Municipality developed a communication strategy based on a mascot called RISKA. Educational contents were also developed aiming to raise the population's awareness to geological risks and allowing the implementation of preventive measures.

To receive information by citizens a platform was developed. The platform's interface aimed to simplify the report using simple language and based on graphic content, to enable ordinary citizens to give information about situations related with geohazards in Lisbon. The simplicity of the app and the visual presentation of the screens had an excellent receptivity by the test public. This solution will allow citizens to play an active role in the risk management system and will facilitate the monitoring of situations in which Lisbon Municipality technicians have increased difficulties due to lack of access. Ultimately, this tool will allow Lisbon Municipality to anticipate problems that may arise, such as settlements in buildings, enabling a proactive response and not a reactive one, as it happens today.

The implemented proof of concept allowed to demonstrate that a citizen properly aware of a certain problem can contribute to a more efficient risk management in the city of Lisbon.

ACKNOWLEDGEMENTS

The authors would like to thank to all the municipality technicians that supported the tasks developed, as well as the stakeholders who participated in the several dissemination actions and who introduced the AGEO app in their daily work.

This work has been undertaken in the framework of the INTERREG Atlantic Area AGEO Project (EAPA_884/2018 – AGEO)

An early warning procedure based on coupling short-time weather forecasting and numerical slope analysis

Un système de early warning basé sur le couplage prévision météo à court-terme - analyse numérique du comportement de la pente

ABSTRACT: Rainfall-induced debris flows and avalanches represent an impending hazard in some densely populated areas of Campania Region, Italy, which are mantled by loose air-fall volcanic ashes. The development of reliable early warning systems is then a strong need. The studies that have been carried out in the last twenty years, which include the long-lasting monitoring of some well instrumented slopes, have allowed to obtain a good knowledge about the hydraulic and mechanical properties of these soils. A further step should be now the assessment in real time of their response to expected rainfall aimed at setting up reliable early warning systems. A procedure that exploits the available short-term weather forecasts and a numerical analysis of the potential slope response to rainfall based on field monitoring of the initial conditions, is proposed.

RÉSUMÉ: Les coulées de debris induites par les précipitations représentent un risque permanent dans certaines zones densément peuplées de la Region Campanie, en Italie, qui sont caractérisées par des couvertures de cendres volcaniques lâches de déposition aérienne. Le développement de fiables systèmes de early warning est donc un impératif. Les études qui ont été conduits dans les vingt dernières années, qui ont inclus la surveillance à long terme de quelques pentes bien instrumentées, ont permis de obtenir une bonne connaissance du comportement hydraulique et mécanique du sol. Une nouvelle étape maintenant devrait être l'évaluation en temps réel de leur réponse aux précipitations prévues, dans le but de développer des fiables systèmes de early warning. Dans cet article on propose un processus qui utilise les prévisions météo à court-terme disponibles et l'analyse de la réponse potentielle de la pente aux précipitations sur la base de la surveillance sur site des conditions hydrauliques initiales.

Keywords: Unsaturated volcanic ash; rainfall forecasting; field monitoring; numerical analysis.

1 INTRODUCTION

Sudden and destructive rainfall-induced debris flows and avalanches represent an impending hazard in some densely populated areas of Campania Region, Italy, which are mantled by loose air-fall volcanic ashes. The development of reliable early warning systems is then a strong need. The studies which include in depth hydraulic and mechanical characterization of the soil and long-lasting monitoring of some well instrumented slopes, have allowed to obtain a good knowledge about the properties (Lampitiello, 2004; Nicotera et al., 2015; Dias et al., 2022) and behaviour of these soils (Comegna et al., 2016; Picarelli et al., 2020; Pirone et al., 2023). In order to protect people and infrastructure, a further step should be now the assessment in real time of their response to expected rainfall aimed at setting up reliable early warning systems. This paper describes a novel procedure based on the numerical analysis of the potential slope response to expected rainfall in the next hours by exploiting official weather forecasts and data provided by field monitoring, which can provide the initial hydraulic conditions. Here, first, the soil properties and the numerical model employed, with a focus on model validation, are presented; then, in order to assess if the proposed approach can be effectively used within early warning systems, results of some blinded analyses carried out in a monitored site in Campania, are shown.

2 THE INVESTIGATED AREA AND THE MAIN SOIL PROPERTIES

The proposed approach is applied in the area of Pagani (SA), 35 km South-East from Naples, in a site where some debris flows have occurred in the past. The stratigraphic setting consists of a 2 m deep succession of thin air-fall pyroclastic soil layers covering a

fractured carbonate bedrock (Santo et al., 2021). Bottom upward in the considered section (Figure 1a), the succession includes 20–60 cm thick silty sands (C1), overlaid by brown silty sands rich in pumices (A2), which have a thickness of 30–130 cm. The top soil consists of a highly weathered vegetated volcanic ash (A1); its thickness spans from 20 to 80 cm, with a mean value around 35 cm. The average slope angle is 35°.

The instrumentation consists of four tensiometers and four TDR probes installed in pairs at the same depth (Figure 1a). Matric suction and volumetric water content are being measured hourly since November, 2020. The site is also equipped with a rain gauge that records rainfall every ten minutes.

The pyroclastic cover is partially saturated over the entire year. Figure 1b shows the grain-size curves obtained from a number of samples; the curves fall within the envelopes of the pyroclastic soils of the whole Lattari chain (Santo et al. 2021) and of the Faito Mt. test site (Pirone et al., 2023). Considering that the Mt. Faito soils have the same geological history, stratigraphy and porosity as the Pagani soils, here we have assumed also the same friction angle (Table 1). The hydraulic properties have been obtained by processing field data collected at the Pagani test site and are summarized in Figures 2a, b. The solid lines in Figure 2a show the Water Retention Curves (WRCs) obtained by interpolating hourly field data, provided by tensiometers and TDR probes over the first part of the year 2021, by the Van- Genuchten model (crossed lines).

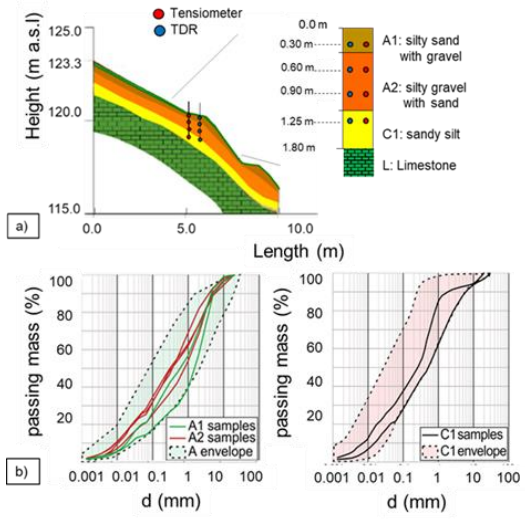

Figure 1. a) Longitudinal section of the slope, simplified stratigraphic soil profile, the instruments installed in the Test Site; b) Grain-size curves of soils A1, A2 and C1 along with the envelopes of the other samples collected on Lattari Mts.

Table 1. Mean physical and mechanical properties of soils sampled in Mt. Faito (γ_d: dry unit weight; n: soil porosity; φ':friction angle at critical state).

Soil	γ_d (kN/m^3)	n (-)	φ' (°)
A1	7.70	0.70	38.4
A2	8.19	0.65	38.4
C1	7.35	0.70	35.4

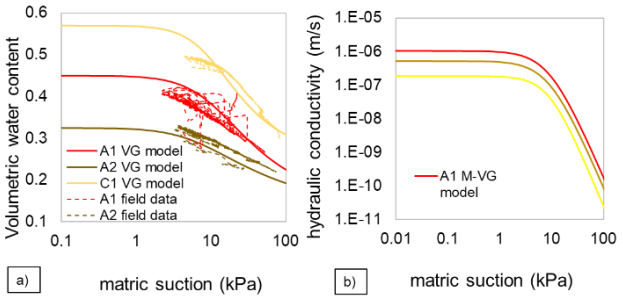

Figure 2. a) WRCs of single layers, as adopted in the analysis, compared to field data; b) HCs of single layers. In the figure M-VG means Mualem Van Genuchten.

The corresponding Hydraulic Conductivity curves (HCs, Figure 2b) have been obtained according to the modified Mualem-Van Genuchten function (Mualem, 1976). For what concerns the saturated permeability of layers A2 and C1, it has been assumed to be equal to the average value measured at the Monte Faito test site through constant head permeameter tests. Finally, the saturated permeability of layer A1 has been taken as a calibration parameter for the numerical model, adopting the value that best replicates the in-situ measurements of suction and water content.

3 RELIABILITY OF THE NUMERICAL ANALYSIS

The hydraulic slope response to precipitation has been investigated by means of the Richards' equation implemented in the FEM code SEEP/W using the WRCs and the HCs (Figs. 2a-b).

The longitudinal slope section shown in Figure 1a has been modeled through a mesh with element sizes of 0.05 m. In order to test the model's effectiveness, the effects of some rainy events recorded from winter 2021 to winter 2022, have been simulated by applying at the upper boundary the hourly rainfall measured by the rain gauge installed at the Test Site and neglecting evapotranspiration. The numerical simulations focus solely on rainstorm duration, adopting hourly time steps. The matric suction values measured in the pyroclastic cover before rainstorms have been assigned as initial conditions. It is useful to outline that the initial suction retains a memory of the slope's past hydraulic history. In all the analyses, the lower

boundary and the edges of the domain have been modeled as potential seepage faces, which keep null flux for pore pressure < 0 kPa, and convert the boundary condition to a head-type, with the total head, H, equal to the y-coordinate (which means assuming u = 0 kPa) when u > 0 kPa. Several numerical analyses have been carried out as the saturated hydraulic conductivity of layer A1 varies in the range of $5{\cdot}10^{-7}$ - $5{\cdot}10^{-6}$ m/s, which represents a reasonable interval of variation for the hydraulic conductivity of pyroclastic soils. The value of $1{\cdot}10^{\wedge-6}$ m/s resulted in the lowest mean error, *e*, defined as the difference between the measured and calculated value. Field vs calculated values of matric suction and volumetric water content at depths of 0.30 m and 1.25 m during four selected rainfall events are plotted in Figure 3 along with the values of *e* and of standard deviation of *e*, noted as dev.st (*e*). The good match between recorded and calculated values, which are characterized by *e* lower than 1 kPa for matric suction and equal to 0.015 for average volumetric water content, is encouraging. However, as expected, a greater standard deviation has been calculated for the topsoil (0.30 m) due to the difficulty to replicate the complex phenomena related to the soil-atmosphere interaction by means of this simple numerical model.

This indicates that, in principle, both the numerical approach and the soil properties used in the analysis allow to properly predict the slope response to rainfall.

4 THE PROPOSED EARLY WARNING PROCEDURE

The proposed procedure has been tested using the weather forecast provided by 3Bmeteo.com for April 16, 2023, rainfall, made 48h and 24h before respectively, i.e., on April, 14, and April, 15. Calculated and measured values of matric suction and volumetric water content are plotted in Figures 4a-d. Figures 4e and f, in turn, show the factor of safety (FS) calculated by uploading the predicted suction distribution in the code SLOPE/W that implements the limit equilibrium method (LEM). The contribution of matric suction to shear strength has been obtained through the equation proposed by Vanapalli et al. (1996). The critical shear surface has been determined by imposing the entry and exit option. The minimum thickness of the zone, within which the sliding surface may develop, has been set at a depth of 0.5 m based on evidence. The safety factors corresponding to rainfall forecast 48h and 24h before the selected day (April, 16) are compared to the safety factors determined under the rainfall that has been actually recorded.

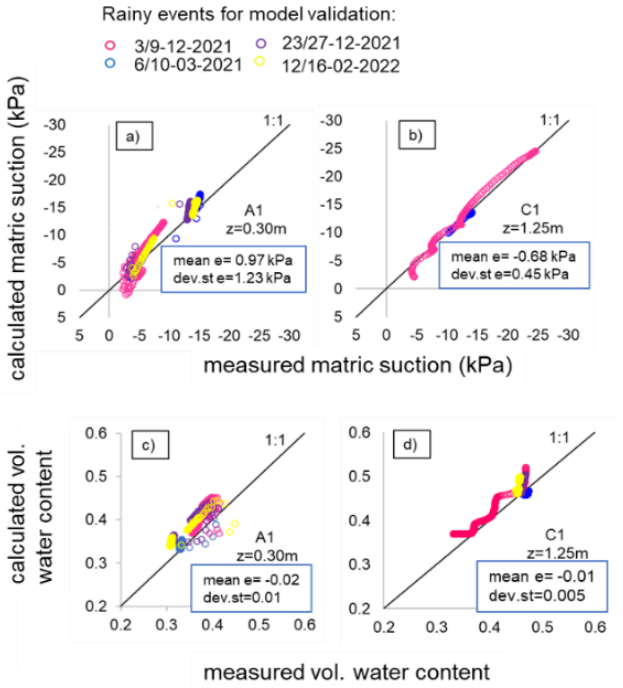

Figure 3. a), b) Measured vs calculated values of matric suction at depths of 0.30 m and of 1.25m; c), d) volumetric water content at the same depths.

As field readings show, almost the entire soil cover is subjected to suction decrease due to both the amount of rainfall and the high hydraulic conductivity of the soil in such a wet period. It is worth noting that suction at 0.30 m continues to increase even after rainfall stops. The corresponding factor of safety (FS) along with the critical slip surface are shown in Figures 4e and 4f. The maximum thickness of the involved soil body is 0.90 m (within the soil A2), and FS reflects the suction trend of the uppermost half part of the pyroclastic cover.

The daily rainfall forecasted 48h and 24h before April, 16, were 19 mm and 35.2 mm respectively, less than the value that was actually measured at the Test Site (42 mm). The analysis shows that rainfall forecast 24h before can provide a better prediction of the hydraulic slope response (Figure 4b,d), leading to FS values closer to those that have been determined under the recorded rainfall (Figure 4f). In contrast, the rainfall forecast 48h in advance underestimates the decrease in matric suction by providing FS values about 40% higher (FS=1.50 against FS=1.22) than those calculated for the actual rainfall distribution (Figure 4a, c, e). Since the capability to correctly assess the suction distribution from measured rainfall appears to be quite good (Figure 3), these results show that, at the moment, a major problem concerns the reliability of weather forecast, which strongly depends on the selected time interval in advance.

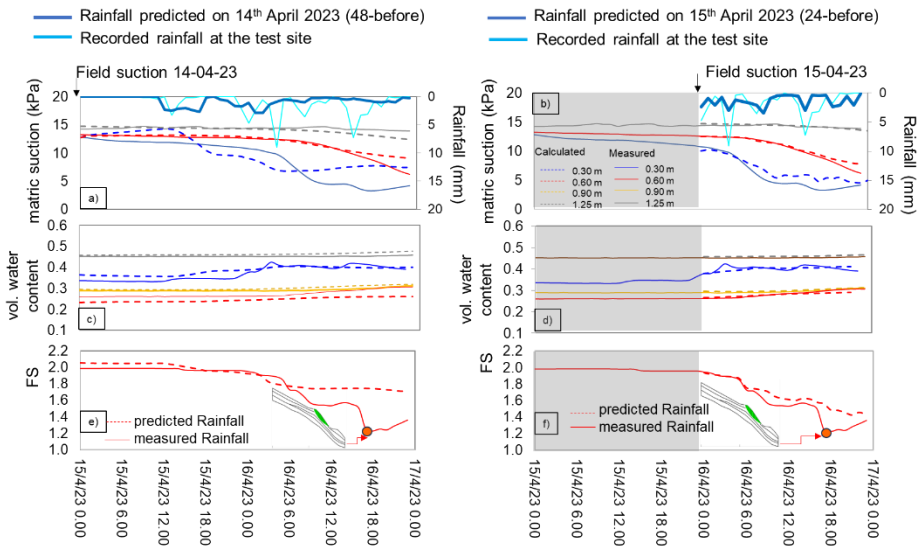

Figure 4. a), b), c), d) Measured (solid line) and predicted values (dashed line) of suction (a and b) and of volumetric water content (c and d) on April, 16, 2023, based on rainfall forecast 48 h and 24h in advance; e), f) safety factor, FS, calculated from measured and forecasted Rainfall along with the picture of critical slip surface determined for FS corresponding to measured Rainfall.

5 CONCLUSIONS

A numerical procedure for early warning of fast flow-like rainfall-induced landslides in unsaturated pyroclastic soils based on weather forecast and field monitoring of the initial soil conditions, is being tested in an area susceptible to slope failure. The first results are encouraging showing that the reliability of the approach strongly depends on a correct forecast of the rainfall amount and distribution. At the moment, further in-depth analyses are needed to have a clear understanding about the reliability and effectiveness of the procedure proposed.

Ground investigation methods used in high-speed railway for mitigation of dissolution features risk in chalk

Méthodes d'études de sol utilisées dans les chemins de fer à grande vitesse pour atténuer le risque de dissolution dans la craie

ABSTRACT: Chalk is known to have a potential risk for natural cavities (solution features) and documenting the location and nature of these geohazards is important to infrastructure projects. North Chilterns Area, one of the five projects within the HS2 Main Works Civils Contract, C23 includes cuttings, embankments and viaducts which will be designed and constructed in the formation of Chalk. The risk of presence of dissolution features in this area is high, either as infilled features near formation level in cuttings and embankments or void or infilled features, being present immediately below the toe of foundation piles, along their shafts, or below shallow footings. This paper discusses the risk from dissolution features for selected high-speed railway assets and presents the approach to investigate their presence based on various ground investigation methods, which were employed on the project. These include LiDAR surveys, surface geophysics (electromagnetic, electrical resistivity, microgravity surveys), intrusive ground investigation (boreholes, CPT probing), use of borehole cameras and downhole surveys. The limitations and advantages of these methods are discussed, highlighting the importance of the combined interpretation of ground investigation data to design appropriate mitigation works.

RÉSUMÉ: La craie est connue pour présenter un risque potentiel de présence de cavités naturelles (phénomènes de dissolution); ainsi, documenter l'emplacement et de la nature de ces aléas géologiques est important pour les projets d'infrastructure. La région de North Chilterns, l'un des cinq projets parmi le Contrat HS2 section C23, comprend des déblais, des remblais et des viaducs qui seront conçus et construits dans la craie. Le risque de présence d'éléments de dissolution dans cette zone est élevé, soit sous forme de cavités remplies près du niveau de formation dans les déblais et les remblais, soit sous forme de zones vides ou remplis, étant présentes immédiatement sous la base des pieux de fondation, le long de leur longueur, ou sous des semelles de foundation peu profondes. Cet article discute le risque de dissolution pour certains actifs de ligne de chemin de fer à grande vitesse et présente les démarches pour évaluer leur présence sur la base de diverses méthodes d'études de sol, qui ont été utilisées dans le cadre du projet. Il s'agit notamment des relevés LiDAR, de méthode géophysique de surface (relevés électromagnétiques, de résistivité électrique, de microgravité), d'études de sol intrusives (forages, sondages CPT), de l'utilisation de caméras de forage et de relevés géophysiques de fond. Les limites et les avantages de ces méthodes sont discutés, soulignant l'importance de l'interprétation combinée des données des diverses études de terrains pour soutenir la prise de décision et concevoir des travaux d'atténuation appropriés.

Keywords: Chalk; dissolution features; ground model; geohazard.

1 INTRODUCTION

The High Speed Two (HS2) project is a High-Speed Railway Line currently under construction in the UK. Phase 1 of HS2 runs between London and Birmingham across the English Midlands. This scope is part of the HS2 Main Works Civils Contract C23, awarded to Eiffage Keir Ferrovial Bam (EKFB) JV in partnership with the design JV of Arcadis Setec COWI (ASC). The North Chilterns Area (NCA) section covers an approximate length of 11km; of which approximately 8km is underlain by Chalk bedrock, namely Lewes Nodular Chalk, Holywell Nodular Chalk, New Pit

Chalk, Zig Zag Chalk and West Melbury Marly Chalk. This section of the route is the subject of this paper, as the chalk bedrock has an inherent risk of dissolution features and chalk mining features. These features present a risk to the project and require a strategic and coordinated approach to investigation, risk assessment and treatment.

2 GEOLOGICAL CONTEXT

Dissolution features are a common geohazard in karst geology and occur when slightly acidic rainwater is allowed to infiltrate into calcium carbonate rich bedrock, such as chalk. Features may occur in a variety of forms, as illustrated in Figure 1.

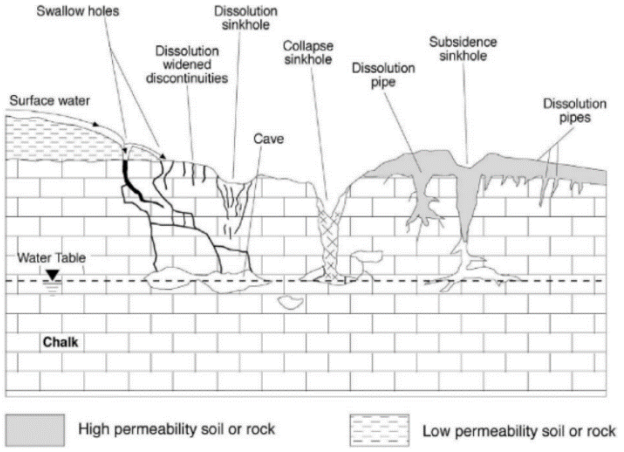

Figure 1. Schematic cross-section of common dissolution feature types (Lord et al, 2002).

Typically, these dissolution features present themselves as localised undulations in the bedrock profile at the interface of the chalk, which are infilled by loose superficial materials. Across the NCA section of the route, these superficial materials generally comprise cohesive Head deposits or Clay with flints.

Risk also exists associated with chalk mining. Historically, chalk was mined and used for spreading on heavy clays or in agricultural lime production, therefore the risk of chalk mines is particularly prevalent in areas where clay overburden is present, which covers most of the study area. It should be noted however in the works undertaken to date that chalk mining features have not been identified across the NCA route.

3 GROUND INVESTIGATION STRATEGY

3.1 Detailed design investigations

An initial phase of ground investigation works was undertaken across the NCA package as part of the detailed design phase. This generally included a suite of boreholes, CPTs and trial pits. As these were undertaken as part of the detailed design, they were not specifically targeted to investigate potential dissolution features. It was determined that these investigations should be undertaken as part of the construction programme to expedite the design works and subsequent approval processes.

However, as part of the detailed design investigation works, a preliminary programme of surface geophysics was undertaken. This comprised microgravity, electromagnetic and electrical resistivity surveys and covered approximately 52% of the total development footprint. The purpose of these works was to inform a preliminary qualitative assessment of the possible extent of dissolution features at each asset, in order that the targeted investigation works during the construction phase could be undertaken.

3.2 Dissolution features investigations

Given the risk of dissolution features extends over an area approximately 8km long, careful planning was required to optimise the ground investigations. This was particularly relevant to ensure best value was obtained from intrusive investigations. A phased approach was adopted utilising ground profiling and geophysics in advance of committing to intrusive investigations. The general phasing and rationale is summarised in Table 1.

Table 1. Summary of ground investigation phases.

Stage No.	Technique (s)	Rationale
1	Phase 1 Geophysics and LiDAR	Preliminary qualitative assessment of risk per asset
2	Phase 2 Geophysics	100% earthworks footprint coverage to identify anomalies for targeted intrusive GI
3	Dynamic probing / boreholes	'Ground truthing' of geophysical anomalies to identify features of concern.

3.3 Geophysical Surveys

The success of surface geophysics across this alignment was aided by the characteristics of the land; as this was largely open pasture uninterrupted by significant development and/or services, these works have yielded generally good results.

Three key geophysical techniques have been adopted. Electromagnetic and electrical resistivity surveys were utilised; these are generally reliable to 3-4mbgl and are therefore most useful in areas of shallow overburden. The focus of the geophysical works was microgravity surveying which is generally

reliable to 20-25mbgl and can therefore identify most features of concern; this technique was specified to cover 100% of the development footprint.

The results of the geophysical surveys were reviewed to identify areas where the results indicate a varying response of the surrounding ground (Figure 2).

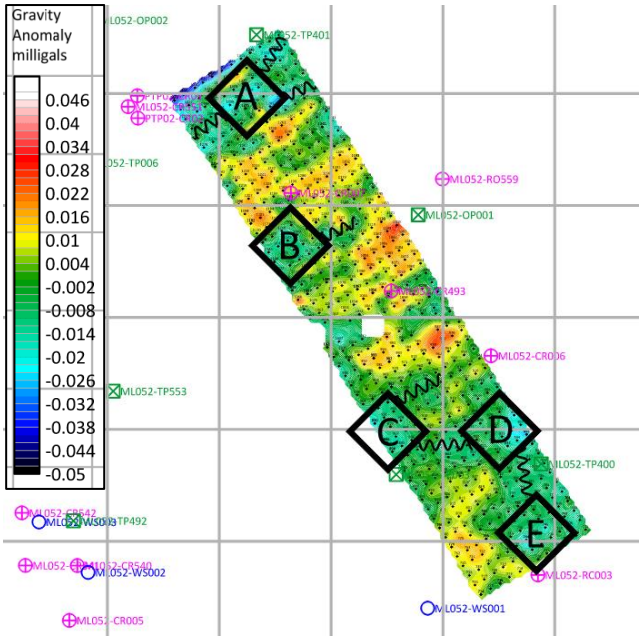

Figure 2. Interpreted microgravity results showing features of concern.

3.4 Targeted intrusive investigations

Where features of concern were identified from the Phase 2 geophysical surveys, intrusive investigations were scoped and targeted to these features as a means of 'ground truthing' the anomalies.

The intrusive investigations comprised a linear array of 9no. dynamic probing positions spanning the direction of the perceived feature of concern at 1.5m centres. The purpose of these was to identify perceived changes in in-situ density at the interface of the chalk materials that may indicate a possible dissolution feature. Following this, a rotary open-holed borehole with down-hole televiewer was targeted adjacent to the dynamic probing positions to confirm the geological interpretation of the probing results. An example of the distribution of these positions is presented in Figure 3.

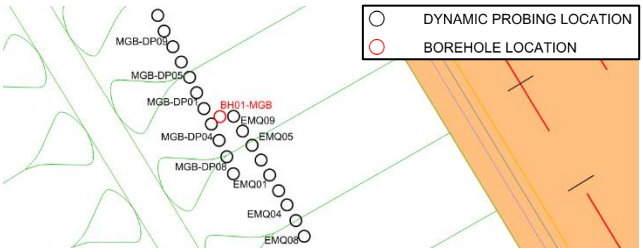

Figure 3. Distribution of intrusive GI at feature 'MG-B / EM-Q'

3.5 Interpretation of results

A review of the findings of the intrusive works was undertaken to assess the features of concern. The stratigraphy determined from the detailed design investigation was firstly superimposed onto the dynamic probing logs to determine the chalk interface profile/level. The probing results were then reviewed to identify zones of low blow counts, which was defined as three or more consecutive results with blow counts between 0-3.

An analysis of the data showed that between 15-25% of the geophysical anomalies could be correlated to solution features; the others could be attributed to other geological reasons including naturally occurring loose zones or localised boulders within the superficial deposits. The overriding principal of the interpretation of these results was to 'prove the negative', i.e., where a feature could not be proven, some interpretation had to be provided as to why the geophysical anomaly was recorded. This analysis fed into a feedback loop with the geophysics review to refine these assessments for each subsequent asset.

Following initial interpretation of the dynamic probing logs, a rotary-open holed borehole with down-hole televiewer was scheduled adjacent to these positions to allow a visual assessment of the chalk and verify the ground model assumptions (see Figure 4).

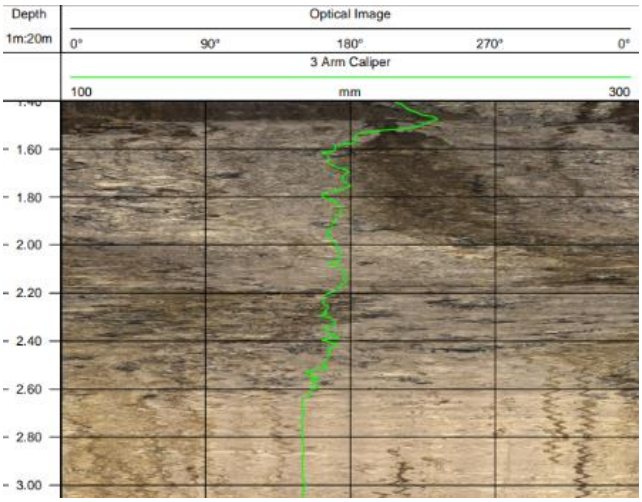

Figure 4. Extract from televiewer log from feature 'MG-B / EM-Q' showing overburden/chalk interface.

An example of an interpreted row of dynamic probing logs for feature 'MG-B' is presented in Figure 5. Characteristically, each of the perceived features identified a zone of low blow counts at chalk interface. Also apparent was a shallower zone of low blow counts within the superficial materials; interpreted as propagated loose material above the feature at an approximate draw angle of ~45-60° away from the edge of the feature.

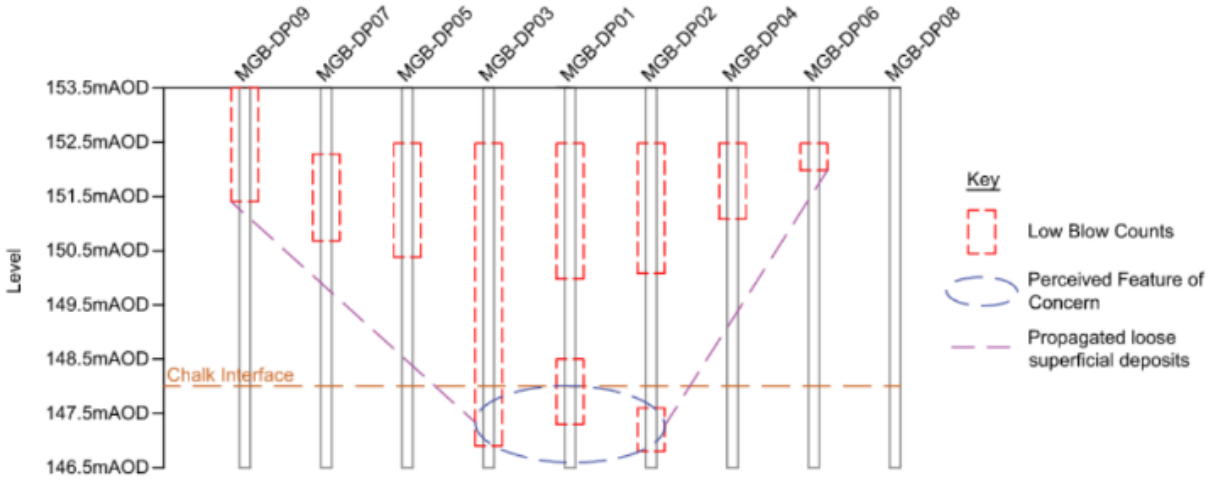

Figure 5. Interpretation of dynamic probing results at feature 'MG-B'.

3.6 Investigation strategy per asset type

The investigation strategy and sequence detailed in the foregoing sections describes the process adopted for earthworks assets (i.e., embankments and cuttings), with Small Dean South Embankment being used as a case study. These earthworks assets account for the majority of the development; however a number of structural assets including viaducts and underbridges are present across the alignment which have adopted a slightly different investigation approach.

The investigation requirements for each structural asset have been determined on an individual basis. To use Small Dean Viaduct as an example, it was determined that due to the relatively small footprint of the abutment foundations as well as significant programme constraints at this asset, Phase 2 geophysical works were replaced with an array of dynamic probes at 1.5m centres across the abutment footprints. The advantage of this approach was that the programme was expedited. No features of concern were identified from these works.

4 RISK ASSESSMENT AND TREATMENT

Where features of concern were identified by investigation, a risk assessment was undertaken to determine if treatment was required. The strategy determined that features were only deemed to require treatment where they were below the high-speed railway or were within the support zone for earthworks/foundations.

4.1 Rock cover ratio assessment

An initial risk assessment was undertaken on features of concern to determine if a suitable rock cover thickness was present above the feature so as to not present a risk to the development. This used a modified version of guidance for treatment of coal mine workings (R.J Piggot and P. Eynon, 1978). For the purposes of the risk assessment, Class 1A1 granular materials to be filled as part of 'excavate and replace' at the formation of earthworks assets were considered to contribute to this competent cover thickness, given the stringent control over the parameters of the placed materials.

As part of this risk assessment process, it was identified that a zone of uncertainty existed between the depth range of geophysical surveys and the depth of features considered to be tolerable within the design. This was particularly relevant to features relating to historic chalk mining (i.e., deeper than the chalk interface level) and is illustrated in Figure 6. This inherently led to some residual risk in the assessment.

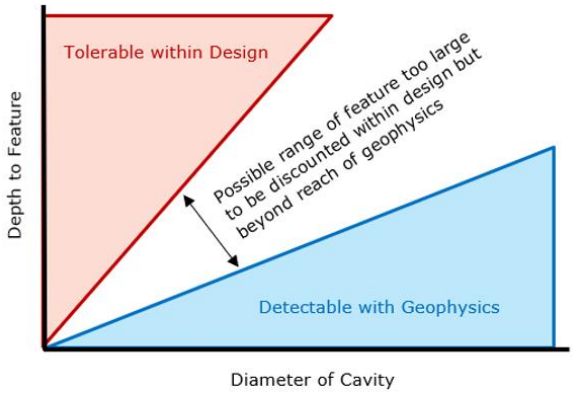

Figure 6. Schematic relationship between feature size and geophysics range.

The rock cover assessment method shown in Figure 7 utilised existing studies regarding collapse mechanisms in chalk (Z.E. Jeffrey et al, 2020, C.N. Edmonds, 2008, T. Waltham, 2008). The relationship was developed considering a conical failure mechanism for chalk grades A-D.

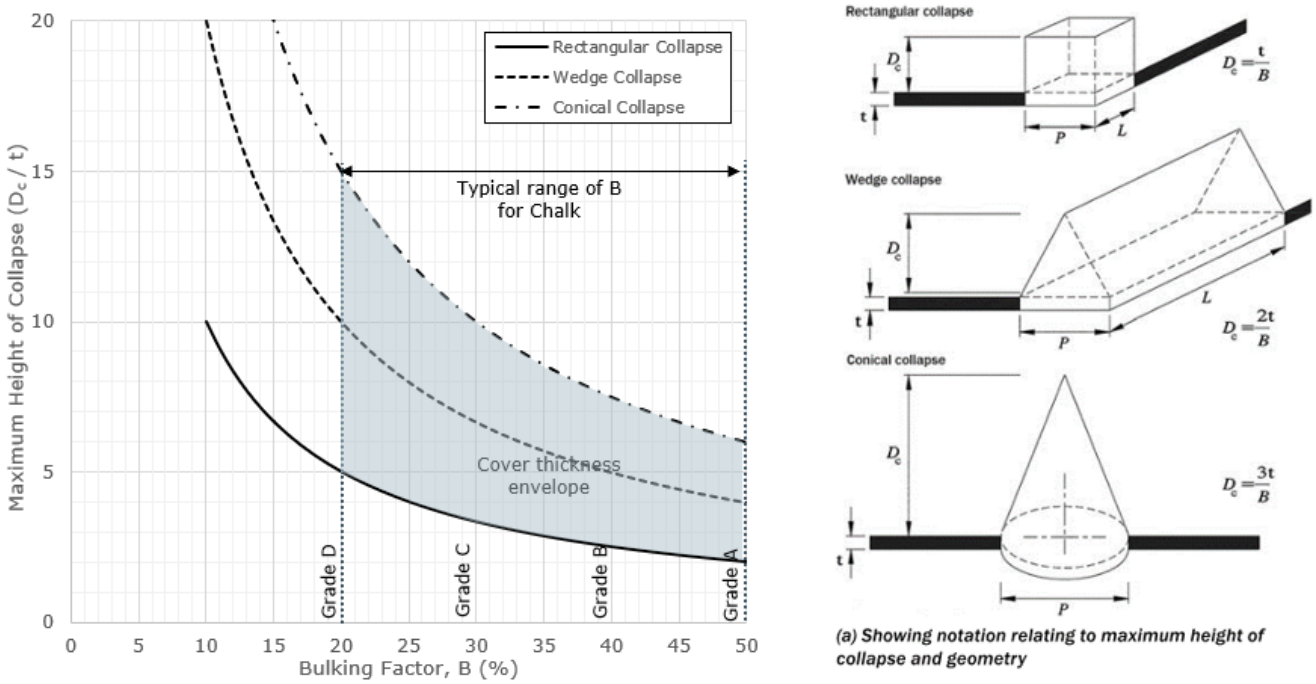

Figure 7. Modified cover assessment method for chalk grades A-D (after Piggot and Eynon, 1978).

This assessment model gives relationships for the cover thickness for each chalk grade, as summarised below:

$$Grade\ A = 6t \quad (1)$$

$$Grade\ B = 7.5t \quad (2)$$

$$Grade\ C = 10t \quad (3)$$

$$Grade\ D = 15t \quad (4)$$

Where *t* is the ratio of feature size versus the thickness (m) of competent cover materials above.

4.2 Treatment Options Hierarchy

Within the overarching strategy, a hierarchy of treatment options was developed between the designer and the contractor which informed the extent of the ground investigations required (see Table 2).

Where the depth to the base of the feature was sufficiently shallow (≈6m below earthworks formation level), the excavate and replace solution was seen as the preferred option, as by nature, this could be implemented under a semi-observational approach. This could therefore minimise the scope of intrusive ground investigations as the extents of the feature could be confirmed during treatment.

Grouting techniques were considered to be less effective at shallow depth due to the complexity of the method in comparison to excavation and replacement. For treatment to depths greater than 6m, grouting would be considered on a case-by-case basis considering the need for additional investigation works and regulatory requirements.

Table 2. Hierarchy of treatment solutions.

Solution	Prog-ramme	Cost	Residual Risk
1. Sufficient cover – no physical treatment	Very low	Very low	Low
2. Excavate & Replace using Class 1A1 fill / concrete plug	Low	Moderate	Very Low
3. Drill and Grout (cavity infill) or compaction grouting	High	Moderate / High	Low
4. Spanning / bridging solutions	Low	Low	Moderate

5 TREATMENT IMPLEMENTATION

To illustrate the application of the investigation, risk assessment and treatment strategy detailed within this paper, the implementation of the site works at Small Dean South Embankment is discussed below.

Within the first 500m of the asset, 3no. features of concern were identified, each at the interface of the chalk deposits. Of these, one was situated outside of the support zone for the high-speed railway and embankment therefore did not require treatment. The

two remaining features ('MG-B / EM-Q' and 'EM-S') required treatment by excavate and replace.

Figure 8 below shows the excavation to the base of the feature at 'EM-S'. The depth and extent of the feature extended far beyond what was anticipated. It was therefore concluded that the intrusive investigation works at 'EM-S' identified only the outer edge of the feature. This further reinforced the benefit of implementing the excavate and replace under a semi-observational approach. For 'MG-B / EM-Q', the extent of the feature correlated well to the interpretation of the dynamic probing results.

Figure 8. Excavation to base of feature at 'EM-S'.

As part of the backfilling of the feature, a concrete plug was installed at the approximate interface of the natural chalk level. This was to provide an impermeable interface to prevent further long-term deterioration of the chalk, bearing in mind that the mechanism for the initial creation of these features is through infiltration of slightly acidic rainwater. The installation of this concrete plug is shown in Figure 9.

Figure 9. Installation of concrete plug at 'EM-S'.

6 CONCLUSIONS

This paper discusses the approach to the ground investigation, risk assessment and treatment of chalk dissolution features covering an approximate length of 8km of high-speed rail development.

Given the extensive area within which these geohazards exist, the systematic phasing of investigations, firstly comprising geophysics then including targeted intrusive works, has allowed the risk to be effectively managed whilst optimising the extent of the intrusive investigations and programme.

The development of a treatment options hierarchy and tailoring of the investigation strategy per asset type (i.e., cutting / embankment / structure) has further allowed optimisation of the investigation scope. Further, the implementation of excavate and replace earthworks solutions under a semi-observational approach for earthworks assets has allowed the scope of intrusive investigations to be reduced significantly.

ABSTRACT: Differential settlement is one of the key causes of damage to buildings on liquefiable soil deposits. Although important technical developments in geotechnical earthquake engineering have provided significant insights into the performance of buildings on liquefiable soil, the current solutions for the mitigation of the associated damages are based on expensive mat foundations. While buildings with isolated footings are unexpensive, they are more susceptible to differential settlements. Differential settlement can not only make a building unusable and irreparable, but also introduce large stresses into a building that can result in damage and collapse of the superstructure. The main objective of this work is to investigate the key parameters that influence building differential settlements and tilting through nonlinear effective stress fully-coupled dynamic numerical simulations in PLAXIS-2D®. In this paper, 1-bay and 2-bays buildings on a mat foundation will be compared with an equivalent building on isolated footings.

RÉSUMÉ: Le tassement différentiel est l'une des principales causes de dommages aux bâtiments sur des dépôts de sols liquéfiables. Bien que d'importants développements techniques dans l'ingénierie géotechnique sismique aient fourni connaissances significatives sur la performance des bâtiments sur des sols liquéfiables, les solutions actuelles pour atténuer les dommages associés reposent sur des coûteuses fondation en radier. Alors que les bâtiments avec des semelles isolées sont peu coûteux, ils sont plus susceptibles aux tassements différentiels. Le tassement différentiel peut non seulement rendre un bâtiment inutilisable et irréparable, mais également introduire de grandes contraintes dans un bâtiment qui peuvent entraîner des dommages et l'effondrement de la superstructure. L'objectif principal de ce travail est d'étudier les paramètres clés qui influencent les tassements différentiels et l'inclinaison des bâtiments par simulations numériques dynamiques, non linéaires, contraintes effectives et entièrement couplées dans PLAXIS-2D®. Dans cet article, les bâtiments à 1 et 2 travées sur une fondation en radier seront comparés à un bâtiment équivalent sur des semelles isolées.

Keywords: Effective stress analysis; liquefaction; differential settlements; isolated footings.

1 INTRODUCTION

Earthquake-induced liquefaction can lead to significant damage in buildings and huge economic and social costs to communities. Although important technical achievements in liquefaction mitigation have been accomplished in the last decades in the field of earthquake geotechnical engineering, significant damage still occurs in seismic areas around the world.

Settlements and tilting of structures that are not supported by deep foundations are the main types of liquefaction-induced damage (Yoshimi and Tokimatsu, 1977; Acacio et al., 2001) and, due to that, several methodologies have been developed to study the performance of buildings with shallow foundations on liquefiable soil deposits (Yoshimi and Tokimatsu, 1977; Liu and Dobry, 1997; Karamitros et al., 2013; Millen et al., 2018; Viana et al., 2018). These methodologies have been based on field observations, centrifuge experiments, numerical simulations, or a combination of them.

The ability to easily vary key parameters within a numerical simulation has led to several new approaches to estimating the settlement of raft foundation buildings (Karamitros et al., 2013; Bray and Macedo, 2017). These new approaches have focused on the settlement of buildings with strong mat foundations while buildings with isolated footings, which represent a large part of the European building stock, are more susceptible to differential settlements.

This work intends to analyse the performance of isolated footings compared to mat foundations to start investigating more complex systems and provide key insights for extending the existing methods to estimate settlements in the future. This comparison was performed in PLAXIS-2D a finite element software, through nonlinear dynamic soil-structure interaction effective stress analyses.

2 DESCRIPTION OF THE NUMERICAL MODEL

Two identical soil profiles were modelled using two different buildings, one with a mat foundation (Building 1) and the other with isolated footings (Building 2) as shown in Figure 1. Both buildings were modelled considering 1-bay (with two columns) and 2-bays (with three columns).

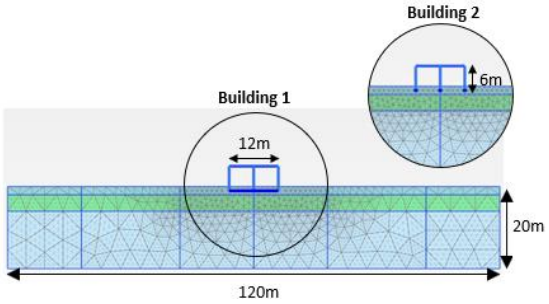

Figure 1. Numerical model with mat foundation and isolated footings for 2-bays buildings.

The finite element sizes were defined using the automated meshing algorithm selecting a 'Fine' mesh. Additionally, mesh refinement was adopted below the building. The soil profile was 20 m deep and the total model width was 10 times the building width, the lateral boundaries were tied together and the base boundary was a compliant base (absorbing) where the Northridge-01 motion in Figure 2 was entered as a horizontal displacement. This motion was recorded at the LA-Baldwin Hills station and was obtained from the NGAWest database. A scale factor of 1.22 was used to achieve a PGA of 0.612g to fit the acceleration response spectra of the selected ground motion with the acceleration response spectra of the reference seismic design action defined by the Portuguese National Annex to Eurocode 8 (PNAEC8) for the Greater Lisbon region.

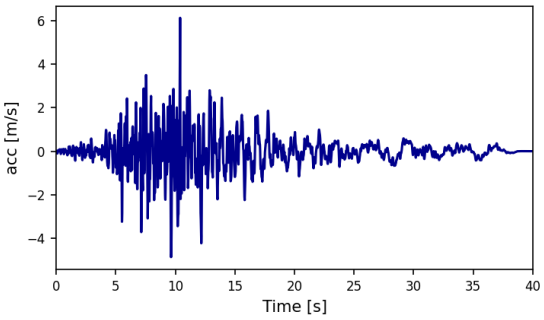

Figure 2. Input motion time series.

The soil profile consisted of a top layer of 2 m thick clay (L1), a 4 m thick liquefiable sand (L2) and a 14 m thick clay on the bottom (L3). The ground water table was set at 2 m. Prior to the dynamic loading phase, soil layers were modelled using the Hardening Soil (HS) constitutive model for the definition of initial stress states and the subsequent structural loading phases. The soil model for the liquefiable layer was switched to the PM4Sand constitutive model when the dynamic loading phase started. The parameters defining the HS model for the soil layers are listed in Table 1. Rayleigh damping was set at 2% at 0.5 Hz and 10 Hz to mitigate numerical instability. The type of calculation used in PLAXIS was a dynamic analysis with consolidation.

Table 1. Input parameters of the HS model.

Parameter	L1	L2	L3
H (m)	2	4	14
γ (kN/m^3)	15.6	19.6	20.2
e_0	0.70	0.65	0.60
E_{50}^{ref} (kN/m^2)	108x10^3	99x10^3	540x10^3
E_{oed}^{ref} (kN/m^2)	108x10^3	99x10^3	540x10^3
E_{ur}^{ref} (kN/m^2)	324x10^3	296x10^3	1620x10^3
m	1.0	0.5	1.0
c_{ref}	40	0	200
ϕ	0	33	0
k (m/s)	1x10^{-7}	1x10^{-5}	1x10^{-9}

The liquefiable layer was also assigned the additional PM4Sand properties of relative density of D_r=50%, normalised shear modulus of G_o=611, and contraction rate parameter, h_{po}=0.25 (Boulanger and Ziotopoulou, 2017). The contraction rate parameter was calibrated by performing numerical element tests using the subroutines provided by the authors of the PM4Sand model and adjusting the parameter to obtain a cyclic resistance ratio (CRR) of 0.126 for 15 cycles (15 cycles represent an earthquake with a magnitude of 7.5). The CRR value was estimated based on the relative density.

The height of the structure was 6 m and the bay length was 6 m, resulting in a total building width of 12 m. The beams and columns of the building were 0.45 m × 0.45 m. The foundation was located at a depth of 1 m. The footings of building 2 were 1 m length. A distributed load of 59.3 kN/m was applied in the beams and no self-weight or load was added to the columns and foundation elements. The structural elements were modelled as 'Plate' elements, which can only simulate elastic behaviour. They were modelled with the provided dimensions and a Young's modulus of 28 GPa. The secant-to-yield stiffness of the beams and columns was modelled according to the proposal of Haselton et al. (2016), which reduces the gross stiffness to simulate the effect of cracking and accounts for the axial force level. The secant-to-yield stiffness of the members considered was 50% of their gross stiffness. The interface between the base of the foundation elements and surrounding soil was fixed.

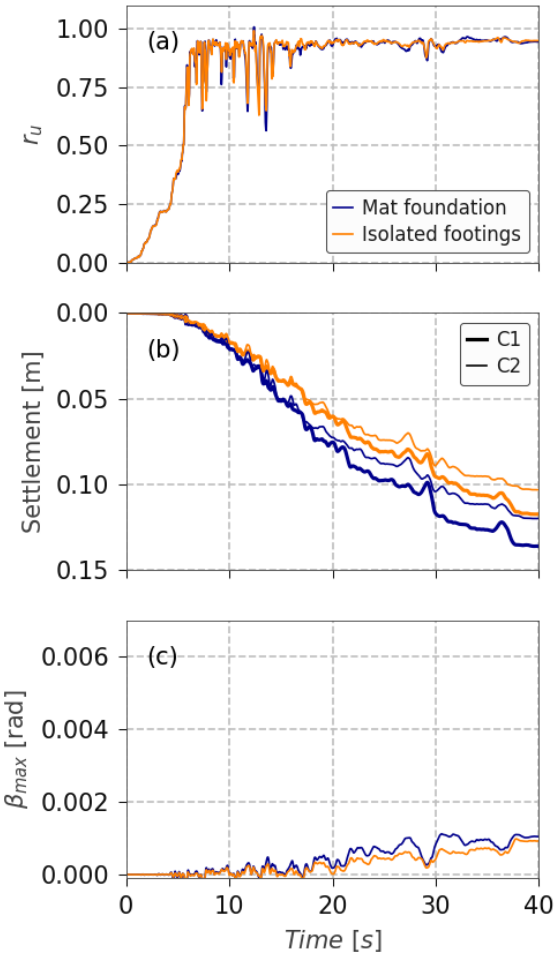

Figure 3. Comparison between the two 1-bay buildings numerical models: (a) excess pore pressure ratio in the middle of the liquefiable layer in free-field; (b) settlements at columns; and (c) maximum angular distortion.

3 RESULTS

1-bay and 2-bays buildings were modelled to analyse two different configurations of buildings, with mat foundation and isolated footings.

Figure 3 presents the results obtained from 1-bay building models and Figure 4 from 2-bay buildings model. In Figure 3(a) and Figure 4(a), the pore pressure ratio in the middle of the liquefiable sand layer for free-field conditions is shown. In both cases the pore pressure build up reached a state of total liquefaction at near 6 seconds.

When 1-bay buildings were modelled, Figure 3(b) shows that the total settlements in the building with mat foundation are higher when compared with the building with isolated footings, but the maximum angular distortion is similar using both types of foundations as observed in Figure 3(c).

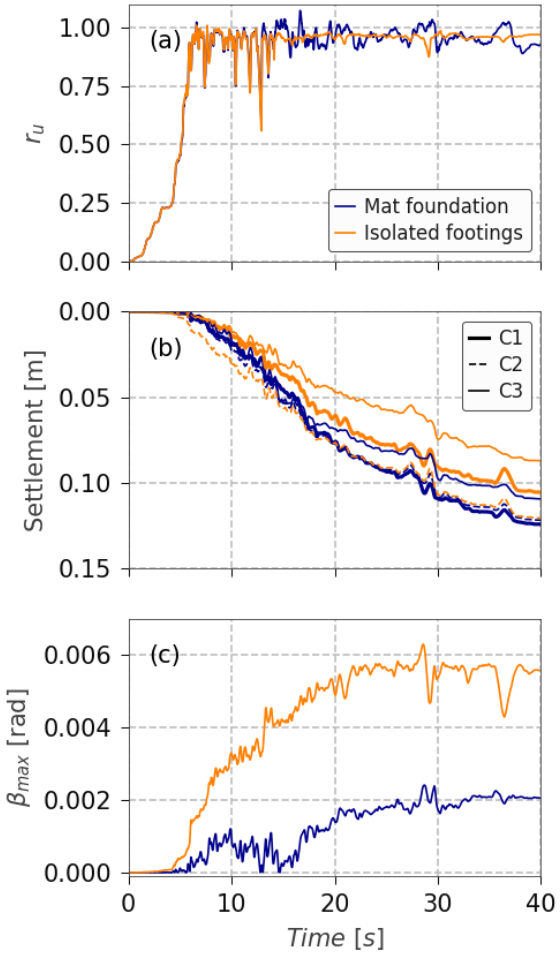

Figure 4. Comparison between the two 2-bay buildings numerical models: (a) excess pore pressure ratio in the middle of the liquefiable layer in free-field; (b) settlements at columns; and (c) maximum angular distortion.

When 2-bay buildings were modelled, Figure 4 (b) shows that the total settlements in the building with the

mat foundation are higher in the external columns (1 and 3) but almost the same in the central column when compared with the building with isolated footings. When the mat foundation was used the column on the left and the central column settled the same and more than the column on the right. When isolated footings were used the central column settled more than the external columns. Also, Figure 4 (c) shows that the maximum angular distortion is much greater when isolated footings were used.

If both buildings, 1-bay and 2-bays buildings, with mat foundation are compared, the external columns had more settlements when 1-bay building was modelled. Regarding the buildings with isolated footings, the external columns also had more settlements when 1-bay building was modelled.

A recent simplified approach (Bray and Macedo, 2017) that was developed for structures with mat foundation was used to estimate the settlements and compare them with the maximum settlement from numerical analyses. Foundation settlements of 0.024 m and 0.021 m were obtained for mat foundation buildings with 1-bay and 2-bay respectively. These settlements are very low when compared with the numerical results. If the simplified approach is used just considering the load in each footing, average values of 0.119 m and 0.140 m were obtained for buildings with 1-bay and 2-bay respectively. These settlements are similar with the numerical results.

4 CONCLUSIONS

This work provides the first key insights for extending the existing methods considering more complex systems such as buildings on shallow isolated footings. The numerical models presented in this paper allowed to observe the difference between total settlements and differential settlements when mat foundations and isolated footings are used. The results also showed the importance of considering the number of footings in the settlements of a building. The future analyses to complement this work should include additional parameters to quantify the mechanisms related to isolated footings, such as stiffness of the building and footing spacing.

ABSTRACT: The erection of protective structures is necessary to ensure the safety of infrastructure facilities such as roads and railways as well as settlement areas. Especially for rockfall protection structures, foundations in the form of micropiles are often used to transfer dynamic or impact-like loads into the subsoil. In addition to the requirements regarding the installation, the demands for a durable and sustainable foundation design of such structures have increased in recent years. In the course of a research project, a micropile system that can meet these requirements has been developed. It consists of a hollow bar that can be installed in a self-drilling manner and additionally has a corresponding durability due to a factory-applied resin coating. The advantages of such a system are the simple and fast installation process, which can be carried out with a wide range of equipment. This allows the system to be installed in areas that are difficult to access, as it is the case with protective structures. In addition, the resin coating has a high wear resistance in order to withstand the rough installation process during rotary percussive drilling and ensures the required corrosion protection layer for a durable geotechnical element. On the one hand, this paper presents findings from investigations on current corrosion protection methods for micropiles. On the other hand, the developed micropile system is introduced, which has already been tested and validated in a series of field tests. In addition, ongoing developments such as spacers and post grouting possibilities are presented.

RÉSUMÉ: La mise en place d'ouvrages de protection est nécessaire pour assurer la sécurité des infrastructures telles que les routes et les voies ferrées, ainsi que des zones d'habitation. En particulier pour les ouvrages de protection contre les chutes de pierres, des fondations sous forme de micropieux sont souvent utilisées pour transférer des charges dynamiques ou des charges d'impact dans le sous-sol. Outre les exigences relatives à l'installation, les demandes de conception de fondations durables pour de telles structures ont augmenté ces dernières années. Dans le cadre d'un projet de recherche, un système de micropieux capable de répondre à ces exigences a été développé. Il s'agit d'une barre creuse qui peut être installée de manière autoperceuse et qui présente en outre une durabilité correspondante grâce à un revêtement en résine appliqué en usine. Les avantages d'un tel système sont la simplicité et la rapidité du processus d'installation, qui peut être réalisé à l'aide d'un large éventail d'équipements. Cela permet d'installer le système dans des zones difficiles d'accès, comme c'est le cas pour les structures de protection. En outre, le revêtement en résine présente une résistance élevée à l'usure afin de supporter le processus d'installation brutal pendant le forage rotatif à percussion et assure la couche de protection contre la corrosion requise pour un élément géotechnique durable. D'une part, cet article présente les résultats d'études sur les méthodes actuelles de protection contre la corrosion pour les micropieux. D'autre part, il présente le système de micropieux développé, qui a déjà été testé et validé dans une série d'essais sur le terrain. En outre, les développements en cours, tels que les entretoises et les possibilités de post-encastrement, sont présentés.

Keywords: Rockfall-protection, durability, micropiles, impact-like loads.

1 FOUNDATION OF ROCKFALL PROTECTION STRUCTURES

Protective structures such as rockfall protection nets are an essential part of Austrian railways and roads and along settlement areas. Due to the topography, such structures are necessary and are currently becoming more frequent due to the effects of climate change. Rockfall protection structures can be designed in different forms and variants (Bergmeister, 2009). In addition to dam structures (Mölk & Hofmann, 2018), rockfall protection nets are often erected, as shown in Figure 1. These consist of a superstructure formed by posts and a net placed in between.

Figure 1. Rockfall protection net next to a support road of a railway line.

The (inclined) posts are connected to an appropriate foundation (e.g. slab) and can also be supplemented – depending on the energy level – by an additional upstream and downstream cable. Therefore, next to counterweights, micropiles are necessary for the foundation of protective structures in order to transfer the cable forces into the subsoil and to ensure the load-bearing capacity of the post foundations. Consequently, these are to be installed in the surrounding subsoil along the axis of the protective structure, which means that they are installed in mostly inaccessible areas.

As an installation method either solid rod systems or self-drilling systems can be used. The first are installed by means of a cased drilling with the advantage of a wide range of usability and the disadvantage of low performance in installation and correspondingly high costs. The second type can be installed easier and therefore offers a quite high performance under the constraints of the location of these structures.

2 CORROSION PROTECTION MEASURES & MICROPILE DCP-SBZ

In order to ensure the necessary (or expected) durability and the planned service life (ÖNORM B 1997-1-, 2021 & ONR 24810, 2017), appropriate corrosion protection of the micropiles is required. This generally applies to all buildings and structures, although protective structures usually have a shorter service life. A large part of the structural elements can be examined for damage of degradation in the course of visual tests and inspections. The foundation elements, however, are installed within the subsoil and therefore cannot be inspected visually. For this reason, attention must be paid to the corrosion protection of the tension elements.

Typical corrosion protection measures for micropiles are defined in the respective regulations (e.g. ÖNORM EN 14199, 2015) and have recently been specified more comprehensively in ÖNORM B 4456 (2021). Within this Austrian standard, a distinction is made between single corrosion protection (SCP), double corrosion protection (DCP see Figure 2 bottom) and material related corrosion protection (MCP). The first – and most frequently used SCP – can be further subdivided into sacrificial corrosion allowance (STA), coating corrosion protection (CCP), zinc corrosion protection (ZCP see Figure 2 top right) and grout cover protection (GCP see Figure 2 top left).

Figure 2. Types of corrosion protection, top left: grout cover protection (GCP), top right: uinc corrosion protection (ZCP) and double corrosion protection (DCP).

In the course of a research project (DAT, 2022), improvements on the corrosion protection of micropiles used as a foundation of protective structures has been investigated. The results of this project are described below and show a first basic concept while the field testing and application if given in chapter 3.

The basic concept was to develop a permanent and durable micropile, that fulfils both the requirements

for durability and load-bearing capacity and also offers easy installation. A system based on a self-drilling tensile element was used as the basis for this, which was supplemented by an appropriate coating to ensure durability. This corrosion protection system is based on the DCP, which is widely used for pre-stressed anchors (ÖNORM EN 1537, 2015) and other tensile elements, but is not yet used for self-drilling elements such as micropiles and soil nails. A schematic structure of an initial prototype is shown in Figure 3.

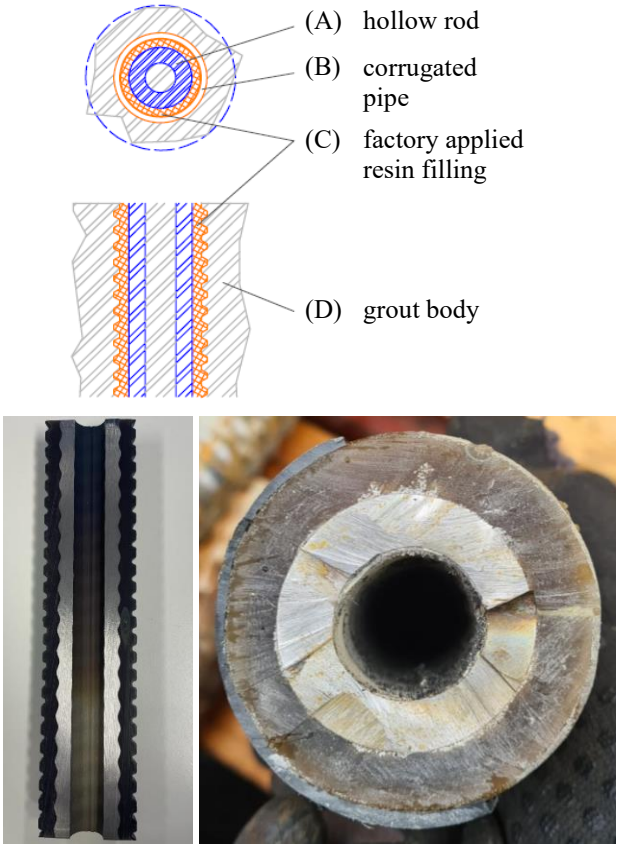

Figure 3. Developed double-corrosion-protection self-drilling tension element (DCP-SBZ), top: schematic, bottom: longitudinal and sectional cross section.

Rotary driven micropiles – using a hollow rod (A in Figure 3 top) – represent one of the cheapest installation methods in terms of equipment, making this system particularly suitable for the use in inaccessible areas. To prevent corrosion and furthermore fulfil the requirements of a planned service-life of more than 30 years, the metal rod was supplemented with a corrosion protection similar to a double corrosion protection DCP. However, this could not be achieved by using a cement-filled corrugated pipe (B in Figure 3 top), as it would not withstand the impact and abrasiveness due to the rotary percussive installation process. Consequently, the cement was replaced by a resin body (C in Figure 3 top) with a thickness of 4 to 7 mm depending on the shape of the rod.

The first results of this development have shown that a uniform and full-surface coating of the metal rod (see Figure 3 bottom) can be achieved during manufacturing, providing a continuous corrosion protection barrier.

3 FIELD TESTING, APPLICATION AND FURTHER DEVELOPMENT

In a series of field tests (DAT, 2022), investigations were carried out to determine whether the applied resin layer can withstand the installation process of rotary percussive drilling. These were carried out under a wide range of geological boundary conditions, from compact rock to soft, uncompacted fills and boulder dumps. The aim was to determine the applicability of the system and the influence of the subsoil on the installation. Figure 4 shows the installation process of aforementioned micropiles in a slope using a mounting carriage on an excavator.

Figure 4. Installation of DCP-SBZ (self-boring tensile element) micropiles for testing purposes.

These tests and a subsequent deinstallation of the micropiles showed, that over a large part of the pile length both the resin body and the corrugated pipe were still intact. On the one hand, micropiles installed were pulled out of the subsoil before the grout body hardened (Figure 5 left) and, on the other hand, the micropiles were uncovered after hardening (Figure 5 rigth) and the performance of tensile load tests.

In addition to the condition of the corrosion protection, a comparison of the load-bearing capacity with classic micropiles was also carried out. This showed no significant difference in either the load-deformation behaviour or the load-bearing capacity.

With respect to the corrosion protection only the head area near the drilling bit and in the area of fittings and joints small damages were observed when test bodies in (gravely and sandy) soil were exhumed after installation. These damages can be attributed to entrapment of coarse-grained fractions. However, such damage can be eliminated by further developing drill bits and also coupling devices, which provide protection for the transition zones.

Figure 5. Examples for exhumed micropiles.

The concept described and tested shows the development of a new type of micropile, which has considerable advantages due to the resin-based corrosion protection barrier and the simple self-drilling installation process. These range from the low installation effort to ensuring the required durability due to the double corrosion protection. The disadvantages at present are the high costs – due to the expensive resin that has to be used – and the fact that the application of the corrosion protection layer results in a significant increase in weight, which limits the handling by the site personnel.

Furthermore, the concept of this micropile additionally offers the possibility of post grouting (due to the core of the hollow rod), which can lead to an increase in the load bearing capacity and subsequently to a reduction in the required pile lengths. In addition to cost savings, this can result in a reduction in installation time, which can be a clear advantage given the difficult installation conditions for protective structures, as mentioned above.

Furthermore, this micropile system can also be used in other areas of geotechnics in addition to rockfall protection nets. Particularly in the construction and installation of soil nailing, the use of this type of system can create a permanent and therefore sustainable form of construction for cuttings and slope stabilisation.

4 CONCLUSIONS

This paper gives a brief insight into developments in the field of the foundation of protective structures through the use of micropiles.

A new type of micropile was presented, which is based on the application of a corrosion protection barrier to self-drilling tensile elements. The required corrosion protection can be ensured by a resin coating, which is factory-applied to the metal rod and therefore offers an easy and well-known installation process. This layer offers sufficient strength and abrasiveness to allow rotary percussive installation even in coarse-grained soils.

This article shows that there is a comprehensive potential for optimisation and improvement in the field of protective structures. Such developments are necessary to ensure the requirements for durability and thus a sustainable operation of the infrastructure, while still guaranteeing sufficient safety of the structures. Taking into account the increase in climate change-related effects, it can be assumed that there will be an increased need for such constructions in the future.

Landslide susceptibility map of the southern slope of the municipality of Odivelas using the AHP method

Carte de susceptibilité aux glissements de terrain du versant Sud de la municipalité d'Odivelas à l'aide de la méthode AHP

ABSTRACT: The Laboratório Nacional de Engenharia Civil has produced a Landslide Susceptibility Map (LSM) of the Southern Slope of the municipality of Odivelas. Regarding the Portuguese legislation in force for the prevention of risks in potentially unstable areas, the main goal of this map is to support the ongoing urban planning on the site (155 ha), occupied by illegal constructions. Based on the information obtained about the characteristics of the ground in the study area, as well as on the consulted bibliography, six conditioning factors for landslides were selected, which in order of decreasing importance are as follows: slope, soil thickness, lithology, curvature, land use, and aspect. For each factor, classes with different degrees of susceptibility were used. The Analytic Hierarchy Process (AHP), a multicriteria analysis method, was used to structure, hierarchise and calculate the weights of those factors. Using these weights and the degrees of susceptibility assigned to the classes of each factor, a landslide susceptibility index was calculated, whose values and a susceptibility scale consisting of five classes have allowed generating the LSM.

RÉSUMÉ: Le Laboratório Nacional de Engenharia Civil a réalisé une Carte de Susceptibilité aux Glissements de Terrain (CSGT) du Versant Sud de la commune d'Odivelas. Concernant la législation portugaise en vigueur pour la prévention des risques dans les zones potentiellement instables, l'objectif principal de cette carte est de soutenir l'aménagement urbain en cours sur le site (155 ha), occupé par des constructions illégales. Sur la base des informations obtenues concernant les caractéristiques du terrain dans la zone d'étude, ainsi que sur la bibliographie consultée, six facteurs conditionnant les glissements de terrain ont été sélectionnés, qui par ordre d'importance sont les suivants: pente, épaisseur du sol, lithologie, courbure, l'utilisation du terrain, et l'exposition. Pour chaque facteur, des classes présentant différents degrés de susceptibilité ont été utilisées. L'Analytic Hierarchy Process (AHP), une méthode d'analyse multicritère, a été utilisée pour structurer, hiérarchiser et calculer les poids de ces facteurs. En utilisant ces poids et les degrés de susceptibilité attribués aux classes de chaque facteur, un indice de susceptibilité aux glissements de terrain a été calculé, dont les valeurs et une échelle de susceptibilité composée de cinq classes ont permis de générer la CSGT.

Keywords: Urban planning; unstable areas; conditioning factors; analytic hierarchy process; susceptibility mapping.

1 INTRODUCTION

To watch out and reduce risks in areas with potentially unstable slopes and contributing to the safety of people and property, Portuguese legislation has, since 2008, included them in a group of areas that are subject to special protection. The area shown in Figure 1 (approximately 155 ha), known as the Southern Slope (SS) of Odivelas, falls into this category. In a previous period, between the beginning of the 1960s and the end of the 1980s, most of this area was occupied by illegal construction. To proceed with its urban redevelopment it is intended to apply to the competent Portuguese regional authority for the detachment of the areas where potentially unstable slopes are low enough not to put urban occupation at risk. It was in this context that the National Laboratory for Civil Engineering and Odivelas Town Council signed a scientific and technical cooperation agreement to produce the Landslide Susceptibility Map (LSM) here presented.

Based on the geomorphological, geological-geotechnical and hydrogeological information obtained in the study area and on the bibliography collected and analysed, six conditioning factors for the mass movements of the SS of Odivelas were selected, which in descending order of importance are as follows: slope, soil thickness, lithology, curvature, land use, and aspect. Each of these factors was assigned various classes with different degrees of susceptibility. In order to structure, prioritise and calculate the weights for each factor, a multi-criteria analysis method, called the Analytic Hierarchy Process (AHP) was used (Saaty, 1980). Based on the

weights obtained for each factor and the degrees of susceptibility assigned to the classes of each factor, the landslide susceptibility index, I_S, was calculated for the square cells (or pixels) of 5 m side, into which the study area was divided. Considering the I_S value calculated for each cell and the five classes of susceptibility used (very high, high, moderate, low and very low), the areas of the LSM where the probability of landslides occurring is similar were generated.

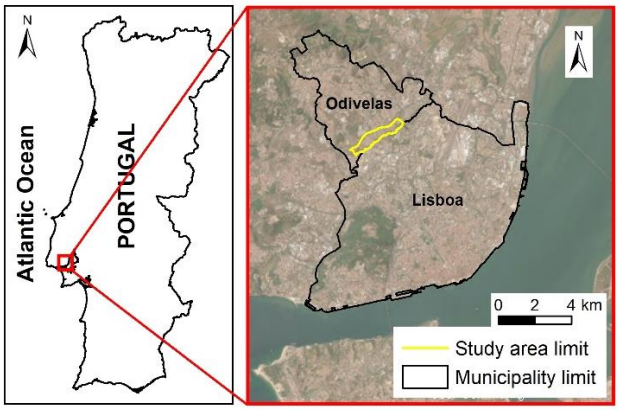

Figure 1. Location of the Southern Slope of Odivelas.

2 CHARACTERISTICS OF THE SOUTHERN SLOPE OF ODIVELAS

The SS of Odivelas is located on a very steep slope, which varies, in less than 500 metres, between plane areas (slope < 5%), to the north and steep areas (slope ≥ 50%), to the south. The areas occupied by these two classes are the most expressive compared to the others (5-15%, 15-30% and 30-50%). This morphology is due to the presence of a monoclinal structure, which dips moderately (10º to 25º) towards the SE, and the occurrence of lithologies (conglomerates or limestones) that are more competent at the top than in the concave part, where sandstones and claystones occur. The plane areas are occupied by the alluvium deposited by a local river, which has, approximately, the same orientation as the SS of Odivelas, i.e. SW-NE.

The geological-geotechnical and hydrogeological characterisation of the SS of Odivelas has been carried out on the basis of surface geological reconnaissance and, mainly, using information obtained from the following site investigation: i) 174 boreholes, of which 144 were located in the study area and the rest in the immediate vicinity, ii) 15 pits, iii) 8 seismic refraction profiles, and iv) 3 electrical resistivity profiles. Seventeen inclinometer tubes and 41 piezometers were installed in the boreholes to monitor the occurrence of horizontal ground displacement and groundwater level fluctuations.

From a geological-geotechnical point of view, the subsoil has been classified into two units. The superficial formations correspond to backfill, alluvium, colluvium and bedrock with a number of blows of the Standard Penetration Test (N_{SPT}) less than 30. The total thickness of these formations varies between 0 m, when the bedrock outcrops, and 18.2 m. The bedrock formations, individualised according to lithology and/or N_{SPT}, are as follows: a) sandstones and claystones, with $30 \leq N_{SPT} < 50$, b) claystones, siltstones and marls, with $N_{SPT} \geq 50$, c) clayey sandstones and marls, with $N_{SPT} \geq 50$, and d) fractured limestone and compact calcareous marls.

The variations in the groundwater level measured in the piezometer were less than 3 m for about 85% of the total, so there were no significant variations in the subsoil hydrogeological regime.

3 SELECTED CONDITIONING FACTORS FOR LANDSLIDES

The selection of conditioning factors to the occurrence of landslides in the SS of Odivelas took into account the provisions of the current Portuguese legislation, according to which "(...) at least (...) slope, slope aspect, slope curvature (cross-sectional profile), lithology and vegetation cover/land use should be considered. In addition, other relevant factors such as soils, superficial formations, Wetness Index and geological structure can be used.". Moreover, eight internationals (Jade and Sarkar, 1993; Irigaray et al., 2007; Jiménez-Perálvarez et al., 2009; Thanh and De Smedt, 2012; Faria and Fialho, 2013, Souza and Sobreira, 2014, Torres et al., 2015; Guedjeo et al., 2017) and four Portuguese (Garcia, 2002; Zêzere, 2002; ANPC, 2009; Policarpo, 2012) studies, were also considered. The selected conditioning factors are shown in Table 1. The legislation dealing with the "delimitation of areas of slope instability" does not establish classes for conditioning factors, so the classes shown in were defined on the basis of the authors' experience, knowledge of the geological-geotechnical characteristics of the study area and the bibliography consulted.

Based on the classes assigned to each conditioning factor, the corresponding factor maps were generated (Figure 2). All the maps were calculated or converted to raster format, with 5x5 m^2 cells, using ArcGIS 10.2.

Table 1. Selected conditioning factors and their classes.

Factor	Classes
Slope (%)	≥ 50; 40 – 50; 30 – 40; 15 – 30; < 15
Soil thickness (m)	≥ 5.0; 3.0 – 5.0; 1.5 – 3.0; < 1.5
Lithology	Backfill, alluvium, colluvium (superficial units) and bedrock with N_{SPT} < 30; Bedrock, or bedrock with a covering < 1.5 m
Curvature	Cc / Cv; Cc / P; Cc / Dv; P / Cv; P / P; P / Dv; Cx / Cv; Cx / P; Cx / Dv; HP
Land use	Built-up area; Agricultural area; Tree and forest area; Herbaceous and shrub area; Special infrastructure area
Aspect	North; East; West; South; HP

Cc – Concave; Cx – Convex; Cv – Convergent; Dv – Divergent; P – Planar; HP – Horizontal Plane.

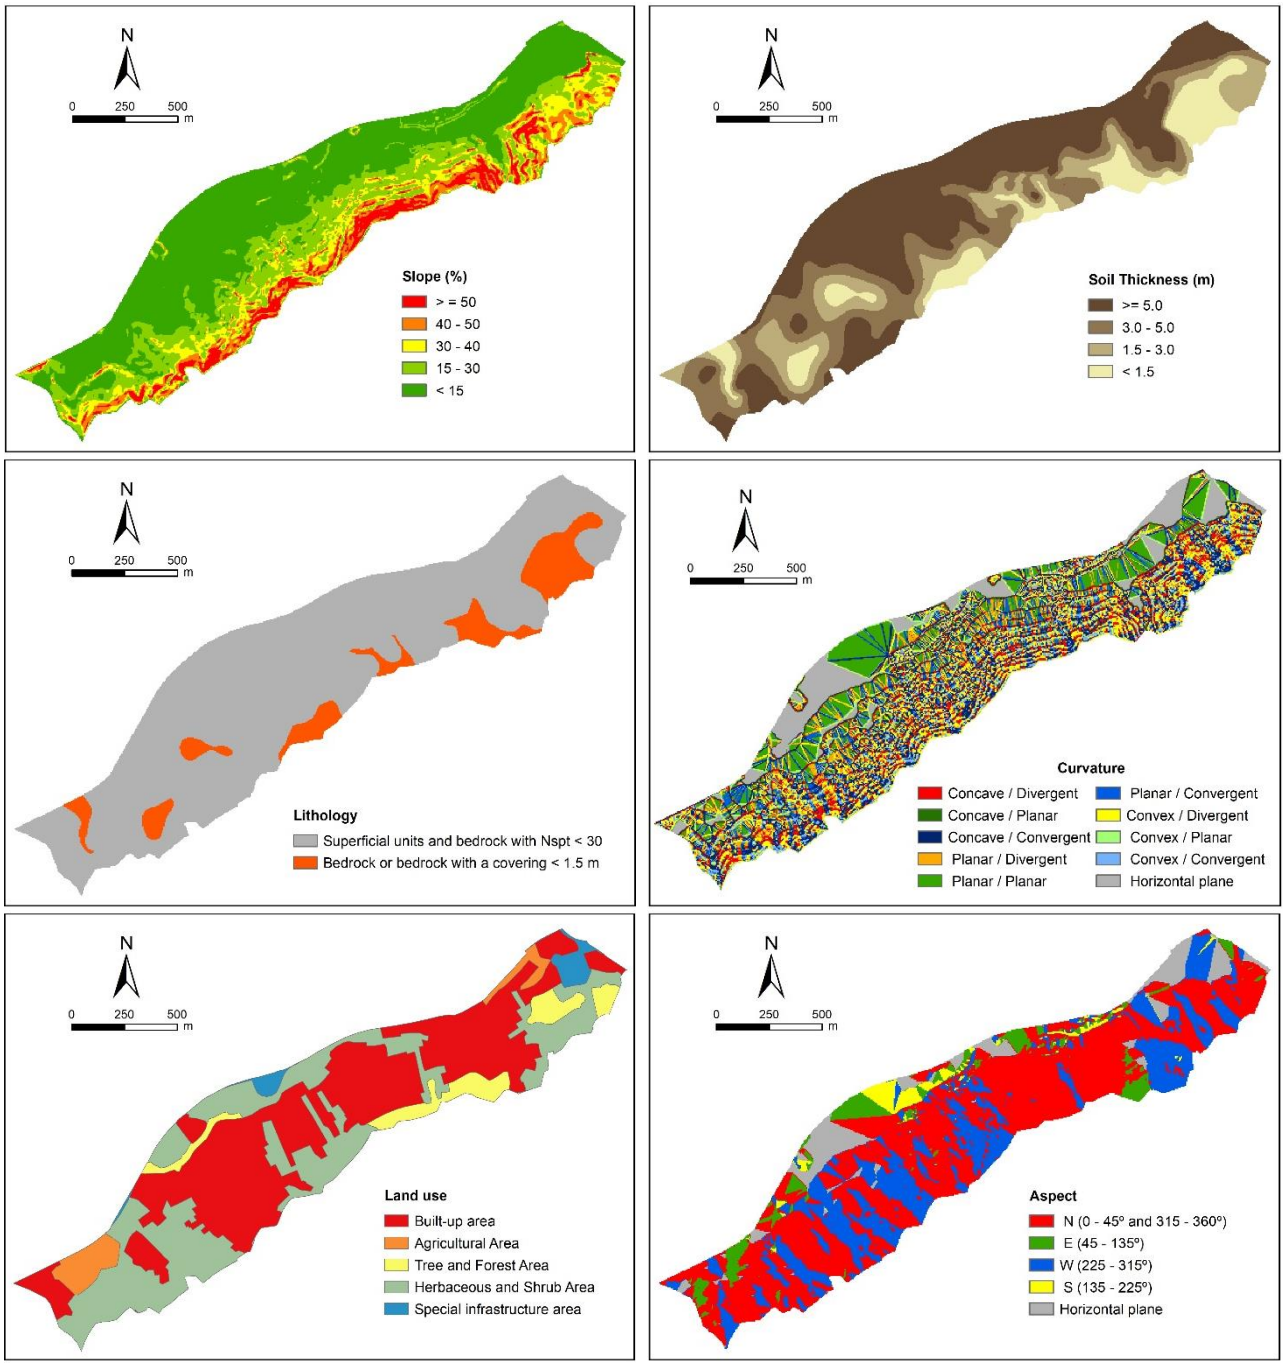

Figure 2. Conditioning factor maps used in the Southern Slope of Odivelas.

4 SUSCEPTIBILITY INDEX TO LANDSLIDES IN THE SOUTHERN SLOPE OF ODIVELAS

The methodology adopted for the calculation of the index of susceptibility, I_S, in the SS of Odivelas comprised two stages.

In the first stage, the AHP allowed to evaluate the weights (W_1 to W_6) of the six conditioning factors, which were used to calculate the susceptibility index, I_S (LNEC, 2018, Roque et al., 2023). The weights obtained were: W_1 = 48.902% for "Slope", W_2 = 20.367% for "Soil thickness", W_3 = 11.775% for "Lithology", W_4 = 8.155% for "Curvature", W_5 = 7.514% for "Land use", and, lastly, W_6 = 3.287% for "Aspect".

In the second stage, to each class listed in Table 1, some of which were regrouped into one class, was assigned a degree of susceptibility, $G_i(F_i)$, as shown in Table 2. These degrees vary between a minimum value of 1 (corresponding to the lowest susceptibility) and a maximum value of 5 (corresponding to the highest susceptibility). The degrees of susceptibility were assigned taking into account the relative importance of the classes in terms of ground movements. The full range of susceptibility degrees was only applied to the "Slope" factor. In the "Soil thickness", "Curvature" and "Aspect" factors, the range of values was between 1 and 4 and in the "Lithology" and "Land use" factors between 1 and 3.

Table 2. Degrees of susceptibility $G_i(F_i)$ assigned to the classes of each factor (F_i).

F_i	Class	$G_i(F_i)$	F_i	Class	$G_i(F_i)$
Slope	≥ 50%	5	Curvature	Cc / Cv or Cc / P	4
	40 – 50%	4		Cc / Dv or P / Cv or P / P	3
	30 – 40%	3		P / Dv or Cx / Cv	2
	15 – 30%	2		Cx / P or Cx / Dv or HP	1
	< 15%	1			
Soils thickness	High (≥ 5 m)	4	Land use	Built-up or agricultural area	3
				Tree and forest area	2
	Moderate (3 – 5 m)	3		Heraceous and shrub area or special infrastuctrures area	1
	Low (1.5 – 3 m)	2			
	Superficial (< 1.5 m)	1			
Lithology	Backfill, alluvium, colluvium (superficial units) and bedrock with N_{SPT} < 30	3	Aspect	N (0 – 45º and 315 – 360º)	4
	Bedrock or bedrock with a covering < 1.5 m	1		E (45º – 135º) or W (225º – 315º)	2
				S (135º – 225º) or HP	1

Cc – Concave; Cx – Convex; Cv – Convergent; Dv – Divergent; P – Planar; HP – Horizontal Plane.

Using the weights, W_i, obtained for each factor, F_i, and the degree of susceptibility, $G_i(F_i)$, assigned to each class of F_i, the I_S was calculated through the weighted sum of the weights W_i and the degrees of susceptibility $G_i(F_i)$, as follows:

$$I_S = \sum_{i=1}^{6} W_i \, G_i(F_i), \qquad (1)$$

with $\sum_{i=1}^{6} W_i = 1$ e $0 < W_i < 1$ $(i = 1, \cdots, 6)$

The minimum and maximum values that I_S can take are 1.00 and 4.30, respectively.

5 LANDSLIDE SUSCEPTIBILITY MAP OF THE SOUTHERN SLOPE OF ODIVELAS

The Landslide Susceptibility Map (LSM) of the SS of Odivelas (Figure 3) was obtained by dividing the study area into square cells of 5 m side and calculating the susceptibility index, I_S, value for each cell. As mentioned before, I_S varies between a minimum of 1.00 and a maximum of 4.30.

The ArcGIS 10.2 Natural Breaks classification method was applied to the distribution of I_S values in the cells of the study area, in order to obtain five classes, which corresponding to the same number of classes of the applied susceptibility scale: very high, high, moderate, low and very low. Areas represented by the same class are considered to be of the same order of magnitude in terms of susceptibility to landslides.

In the areas classified as very low (29.7 ha, 19%) to low (68.6 ha, 44%) susceptibility classes, the ground is generally plane or slightly sloping, with poor drainage and with the possibility of flooding. The hazard of ground movement in areas belonging to these classes is very low, making them favourable for

land use. In areas of moderate susceptibility (31.2 ha, 20%), the hazard of ground movement is low, although occasional interventions in existing buildings may be required to reduce the risk. Future local interventions must be carried out in such a way as not to affect the existing ground stability, in order to keep the risk at an acceptable level. In the areas of high susceptibility (16.7 ha, 11%), the anthropogenic interventions that were observed have increased the hazard of ground movement, given the existing geological-geotechnical and geomorphological conditions, which are not favourable to the occupation of these areas. In areas that have already been built on, local interventions may be necessary to reduce the risk and new building should not be allowed. Urban occupation of areas with very high susceptibility (9.0 ha, 6%) should clearly be avoided, as the hazard of ground movement is very high. The ground movements that have already occurred in the SS are almost always in this susceptibility class, as shows Figure 3. In built-up areas, intervention may be necessary to reduce the risk.

These results show that the areas of very low to moderate susceptibility represent approximately 83% of the total area. In these areas, the hazard of ground movement was considered to be acceptable and did not pose its occupation by people and goods at risk.

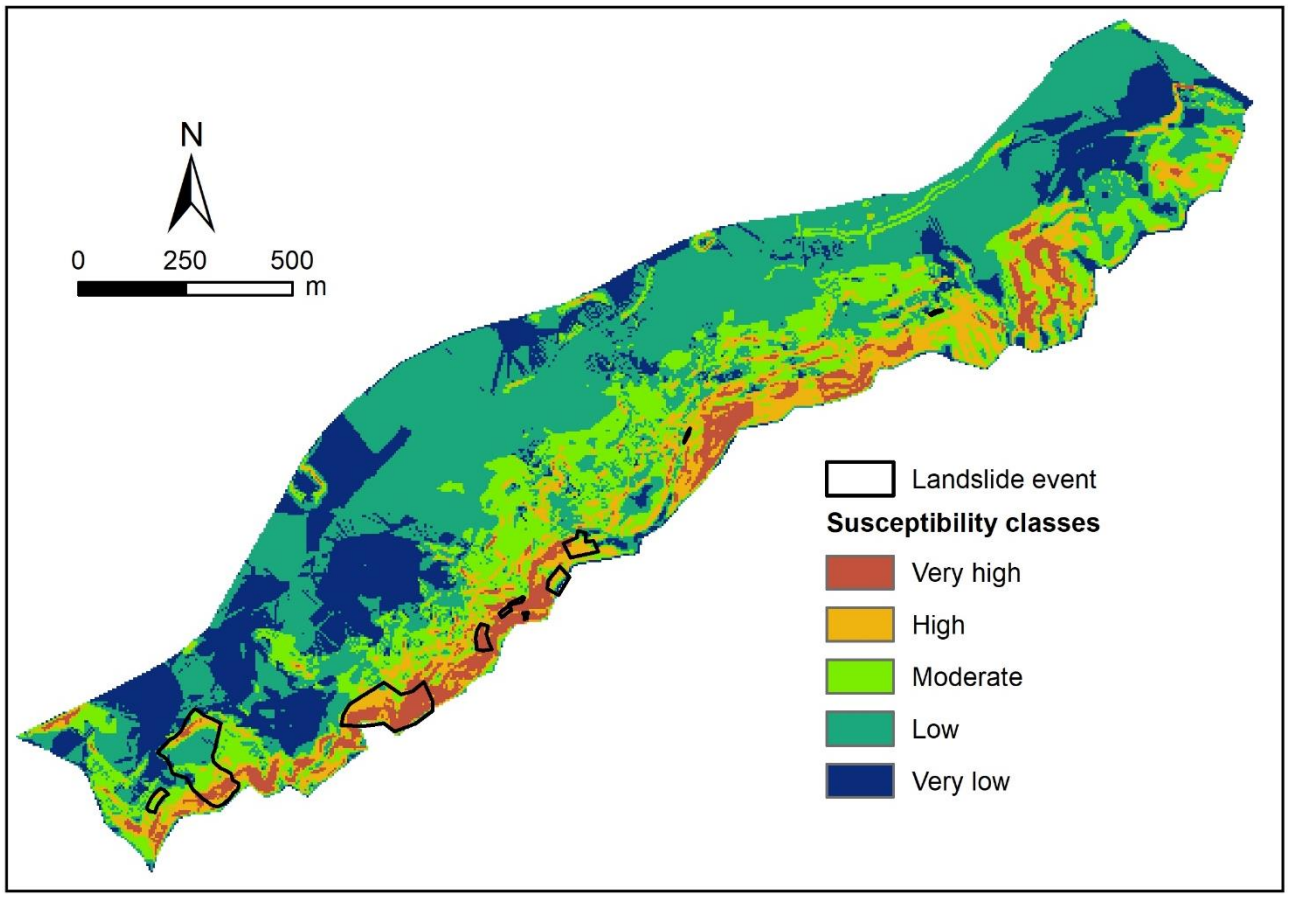

Figure 3. Landslide Susceptibility Map of the Southern Slope of Odivelas with depiction of past landslide events.

6 CONCLUDING REMARKS

Under current Portuguese legislation, the SS of Odivelas is classified as an area of potentially unstable slopes where the risks to the safety of people and property must be safeguarded and reduced. For Odivelas Town Council to proceed with the urban redevelopment of the SS, which has been occupied by illegal constructions since the early 1960s, it is necessary to apply to the competent Portuguese authorities for the de-annexation of areas where the hazard of ground movement occurring is acceptable. It was with the aim of mapping the areas of the SS of Odivelas that comply with this requirement, that the study presented in this communication was developed.

The obtained Landslide Susceptibility Map (LSM), based on six conditioning factors to landslides (slope, soil thickness, lithology, curvature, land use, and aspect) and a susceptibility scale with five classes (very high, high, moderate, low and very low), shown that the areas of very low to moderate susceptibility represented around 83% of the SS. In these areas, the risk to urban occupation was considered acceptable.

ACKNOWLEDGEMENTS

The authors are grateful to the Odivelas Town Council for permission to use and disseminate the work carried out to produce the Landslide Susceptibility Map of the Southern Slope of Odivelas.

ABSTRACT: In unsaturated shallow deposits, rainfall infiltration is the most common cause of landslides. This paper focuses on landslides involving coarse-grained soils and, in particular, analyses the mechanisms that cause the evolution of slides into flow-slides. This study provides an alternative explanation for the initiation of these phenomena, suggesting that they may result from a combination of two unstable processes: the first occurring when the soil is still in the unsaturated regime, the second taking place when full saturation is reached. This hypothesis is based on the analysis of the numerically observed response of an ideal infinite slope to rainfall events. Beyond illustrating the initiation of the unstable process, the study investigates its causes and provides an analytical criterion for capturing the onset of the instability and monitoring local slope stability.

RÉSUMÉ: Dans les dépôts peu profonds non saturés, l'infiltration des pluies est la cause la plus fréquente des glissements de terrain. Cet article se concentre sur les glissements de terrain impliquant des sols à gros grains et, en particulier, analyse les mécanismes qui causent l'évolution des glissements en glissements d'écoulement. Cette étude fournit une explication alternative pour l'initiation de ces phénomènes, suggérant qu'ils peuvent résulter d'une combinaison de deux processus instables: le premier se produisant lorsque le sol est encore dans le régime non saturé, le second se produisant lorsque la saturation complète est atteinte. Cette hypothèse est basée sur l'analyse de la réponse observée numériquement d'une pente infinie idéale lors d'événements pluvieux. Au-delà de l'illustration de l'initiation du processus d'instabilité, l'étude examine ses causes et fournit un critère analytique pour capturer la zone d'instabilité et surveiller la stabilité locale de la pente.

Keywords: Flow-slides; triggering mechanism; infinite slope; water infiltration; stability criterion.

1 INTRODUCTION

Rainfall-induced landslides are natural hazards that cause large numbers of casualties and economic losses every year. Due to the continuous climatic and environmental changes, the landslide risk has been increasing over time, especially that posed by extremely rapid movements, such as flow-slides. In recent years, failure and propagation mechanisms of flow-slides have been widely studied (Wang and Sassa, 2001; Olivares and Damiano, 2007, Cascini et al, 2010). These phenomena generally involve coarse-grained soils and are often triggered by the unstable soil behaviour under undrained conditions.

This study investigates the triggering mechanism of flow-slides and provides an alternative explanation for their initiation. According to this interpretation, flow-slides can stem from the combination of two instabilities: the first occurs in the unsaturated regime and leads to a rapid transition from unsaturated to saturated conditions; the second originates from the first one and occurs under undrained conditions. This interpretation is supported by the results of the numerical study presented in the following section, concerning the effects of water infiltration in an ideal infinite slope.

2 CASE OF STUDY

The study was conducted by analysing the response of an ideal infinite slope to rainfall events. The slope consists of an unsaturated cover 1.2 m thick, resting on a rigid and impervious bedrock inclined at 30° to the horizontal (Figure 1). The material is a lightly over-consolidated coarse-grained soil with low plasticity fine fraction (soil unit weight γ=19 kN/m^3).

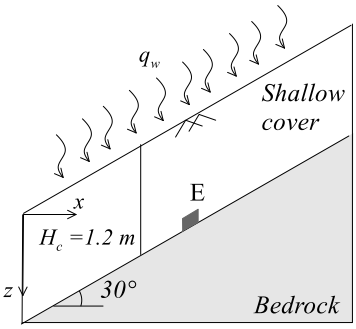

Figure 1. Ideal infinite slope.

The hydro-mechanical soil behaviour is described by combining the WR2-Unsat model (Rotisciani et al., 2021) and the Van Genuchten water retention model. The suction of 10 kPa is uniformly distributed within the shallow cover. Such value is typically observed during rainy seasons in the Campania region, where landslides evolving into flow-slides are frequent.

2.1 Constitutive laws for solid and fluid phases

The WR2-Unsat model is a single-surface hardening plastic model developed by extending the WR2-model (Boldini et al., 2019) to unsaturated conditions. The model is formulated in terms of Bishop's effective stress σ_{ij}': $\sigma'_{ij} = \sigma_{ij} + S_r\, s\, \delta_{ij}$, where σ_{ij} is the net stress, S_r the degree of saturation, s the matrix suction and δ_{ij} the Kronecker delta. The model can reproduce the main features of the mechanical behaviour of structured unsaturated soils under monotonic loading paths.

The model formulation presented below is a simplified version since it neglects *i*) the influence of the Lode angle on the yield surface, which is assumed to be circular in the deviatoric section, *ii*) the terms in the hardening law describing the destructuration phenomena since the shallow cover consists of an uncemented soil.

The yield surface F delimiting the elastic domain follows the expression proposed by Bigoni and Piccolroaz (2004):

$$-Np_c\sqrt{(\Phi - \Phi^{\mathrm{m}})\,[2(1-\alpha)\Phi + \alpha]} + q = 0 \quad (1)$$

where Φ is defined as: $\Phi = p'/p_c$, p' and q are the mean effective and deviatoric stress invariants, α, m and N define the shape of the curve in the stress invariants plane, and p_c is the hardening variable.

In the elastic domain, the material behaviour is hyperelastic, and the evolution laws of the stiffness moduli with effective stress are a function of the dimensionless parameters n_e, k, and g and the reference pressure p_a.

In the q-p' plane, the plastic potential function G follows an equation similar to the one adopted for the yield surface:

$$-N_g\hat{p}_c\sqrt{\left(\Phi_g - \Phi_g^{m_g}\right)\left[2\left(1-\alpha_g\right)\Phi_g + \alpha_g\right]} + q = 0 \quad (2)$$

where Φ_g is defined as: $\Phi_g = p'/\hat{p}_c$, $\hat{p}_c$ identifies the dimension of the G-locus passing through the current stress state, α_g, m_g, and N_g control the shape of the curve in the q-p' plane. In the deviatoric section, G always coincides with F.

The yield locus changes in size with the development of plastic strains and/or any variation in saturation. The isotropic hardening law is given by:

$$\dot{p}_c = p_c\left[\frac{1}{\lambda^*}\dot{\varepsilon}_v^p - b\dot{S}_r\right] \quad (3)$$

where $\dot{\varepsilon}_v^p$ is the volumetric plastic strain rate, $\dot{S}_r$ the increment of the degree of saturation, λ^* is the modified compression index evaluated in the bi-logarithmic compressibility plane, and b controls the mechanical effects induced by the variations of the degree of saturation.

The non-hysteretic uncoupled retention behaviour is described by the well-known Van Genuchten Water Retention Curve (WRC):

$$S_r = S_{r,res} + \frac{(1-S_{r,res})}{[1+(\alpha_w\, s)^{n_w}]^{m_w}} \quad (4)$$

where α_w, n_w and m_w control the shape of the curve and $S_{r,res}$ defines the residual degree of saturation.

The set of constitutive parameters adopted in the numerical study is listed in Table 1. The model was calibrated based on the literature data related to silty sands following the procedure described in Rotisciani et al. (2023). The selected class of materials is the one most involved in landslides evolving into flow-slides.

The yield surface has a distorted shape in the q-p' plane with the stress ratio at the maximum deviatoric stress η_p equal to 0.9 (Figure 2). The plastic potential function coincides with the ellipse of the Modified Cam Clay model, where N_g defines the slope of the Critical State Line (CSL) in the q-p' plane. The WRC is characterized by a low air-entry value, small slope, and negligible residual degree of saturation. The curve adopted is the one typically observed in coarse-grained soils (Rotisciani et al., 2014).

2.2 Wetting-induced instability

The effects of water infiltration were investigated, focusing on a soil element located at the base of the shallow cover (element E in Figure 1). This area is generally the first to be involved in the instability mechanism. Water infiltration was modelled by imposing an inflowing water flux of constant intensity, keeping unchanged the geostatic total stresses. Figure 2 shows the wetting-induced stress path in the q-p' plane. The reduction in suction leads to a reduction in the isotropic stress component under constant deviatoric stress. The test ends before reaching the CSL, suggesting no shear failure occurs.

Figure 3 shows the evolution of the pore water pressure u_w and volumetric strain ε_v with the water ratio e_w, defined as the ratio of water to solid volume. The simulation ends before attaining full saturation. The similarity of the curves u_w-e_w and ε_v-e_w suggests a mutual interaction between the two variables. Indeed, in water-content controlled tests, the degree of saturation and the volumetric deformations are interdependent: the increase in S_r causes the volumetric collapse of the solid skeleton, which in turn provokes a further increase in the saturation level. This process can give rise to an instability mode, as is the case here.

The instability is pointed out by *i*) uncontrolled increase of u_w and thus S_r that prevents the injection of further water volumes; *ii*) continuous changes in volume of the solid skeleton that reveals the inability of the soil to sustain the applied loadings.

Table 1. Constitutive parameters.

Elastic parameter		F and G shape parameters		WRC parameter	
Par.	Value	Par.	Value	Par	Value
n_e	0.5	α	0	α_w	0.2 kPa^{-1}
p_a	1 kPa	m	2	m_w	0.23
k	6666.7	N	1.1	n_w	1.3
g	5000	α_g	1	$S_{r,res}$	0.073
		m_g	2		
		N_g	1.33		

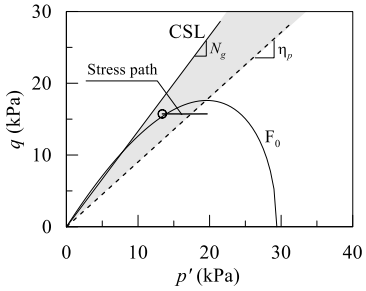

Figure 2. Wetting-induced stress path.

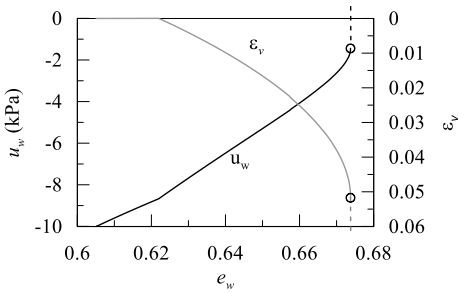

Figure 3. Evolution of pore water pressure and volumetric strains with water ratio.

It is important to note that the final stress state lies within the undrained failure domain coloured by pale grey in Figure 2. The latter is included between the straight lines with slope η_p and N_g (Rotisciani et al., 2021). This outcome reveals the possibility that the observed instability triggers a second instability, once attained full saturation. The latter can occur, provided that the soil yields under undrained conditions.

3 STABILITY CRITERION

The numerical results show the onset of an unstable process when the soil is still in the unsaturated regime. This instability mode is due to the strong coupling between solid and fluid phases and manifests as an uncontrolled growth of u_w, S_r, and ε_v. When the instability takes place, the combined effect of the volumetric collapse and the rapid increase in pore saturation prevents carrying on the injection of water volume. Therefore, the onset of the instability can be found by imposing the condition:

$$\dot{e}_w \leq 0 \tag{5}$$

Taking into account the definition of e_w, Eq. (5) can be rewritten in the form:

$$-\frac{\dot{e}_w}{1+e} = S_r\dot{\varepsilon}_v - n\dot{S}_r \geq 0 \tag{6}$$

where e is the void ratio, n the soil porosity, and $\dot{\varepsilon}_v$ the volumetric strain rate. The latter can be deduced by expressing the constitutive laws in the stress-based form:

$$\dot{\boldsymbol{\varepsilon}} = \left[\boldsymbol{C^e} + \frac{1}{H}\left(\frac{\partial G}{\partial \boldsymbol{\sigma'}} \otimes \frac{\partial F}{\partial \boldsymbol{\sigma'}}\right)\right]\dot{\boldsymbol{\sigma}}' + \left[\frac{1}{H}\frac{\partial F}{\partial p_c}\frac{\partial p_c}{\partial S_r}\frac{\partial G}{\partial \boldsymbol{\sigma'}}\right]\dot{S}_r \tag{7}$$

where $\boldsymbol{C^e}$ is the elastic compliance matrix, $\partial F/\partial \boldsymbol{\sigma'}$ and $\partial G/\partial \boldsymbol{\sigma'}$ are the partial derivative of F and G with respect to $\boldsymbol{\sigma'}$; $\partial F/\partial p_c$ is the partial derivative of F with

respect to p_c, H is hardening modulus defined as: $H = -\frac{\partial f}{\partial p_c}\frac{p_c}{\lambda^*}\frac{\partial G}{\partial p'}$.

Taking into account the imposed boundary conditions ($\dot{q} = 0$; $\dot{p} = 0$), $\dot{\varepsilon}_v$ is given by:

$$\dot{\varepsilon}_v = \left(C_{pp}^e - \frac{\lambda^*}{p_c}\frac{\partial F}{\partial p'}/\frac{\partial F}{\partial p_c}\right)\left(\frac{ds}{dS_r}S_r + s\right)\dot{S}_r + b\lambda^*\dot{S}_r \quad (8)$$

where the term $(ds/dS_r\, S_r + s)\dot{S}_r$ defines the increment of p', C_{pp}^e is equal to the inverse of the bulk modulus K. Substituting Eq (8) in Eq (6), the latter becomes:

$$\left[\left(\frac{1}{K} - \frac{\lambda^*}{p_c}\frac{\partial F}{\partial p'}/\frac{\partial F}{\partial p_c}\right)\left(\frac{ds}{dS_r}S_r + s\right)\dot{S}_r + b\,\lambda^*\dot{S}_r\right]S_r - n\dot{S}_r \geq 0 \quad (9)$$

By dividing for $\dot{S}_r$ (that is greater than 0) and placing:

$$n_{lim} = \left[\left(\frac{1}{K} + \frac{\lambda^*}{p_c}\frac{\partial F}{\partial p'}/\frac{\partial F}{\partial p_c}\right)\left(\frac{ds}{dS_r}S_r + s\right) + b\lambda^*\right]S_r \quad (10)$$

Eq. (9) can be simplified in the following form:

$$n \leq n_{lim} \quad (11)$$

where n_{lim} is the threshold porosity separating stable to unstable states.

The validity of the stability criterion (Eq. (11)) was checked by monitoring the evolution of n and n_{lim} in the above mentioned wetting test (Figure 4). The injection of water volume causes *i*) a small reduction in soil porosity due to the collapse of the solid skeleton; *ii*) a significant increase in n_{lim} taking place when full saturation is approached. According to the proposed criterion, the simulation ends when n is equal to n_{lim}.

4 CONCLUSIONS

The study inspects the stability of an ideal infinite slope during rainfall events, focusing on a soil element located at the base of the shallow cover. The numerical results show that the instability *i*) can occur before full saturation is reached, *ii*) manifests itself as an uncontrolled growth of soil strains and hydraulic variables, and *iii*) takes place when n=n_{lim}. These results suggest an alternative mechanism for the activation of flow-slides, according to which the rapid transition from unsaturated to saturated conditions is the triggering factor of the instability. Such instability can lead to a flow-slide, provided that *i*) the soil yields under undrained conditions and *ii*) the stress state is within the undrained failure domain.

Innovations in liquefaction mitigation: Modelling the mechanical cyclic behavior of biocemented soils

Innovations dans l'atténuation de la liquéfaction: Modélisation du comportement mécanique cyclique des sols biocimentés

Z.N. Sahlab*, D. Terzis, L. Laloui

ABSTRACT: Liquefaction remains a major geotechnical hazard in seismically active zones. Traditional mitigation methods while effective, frequently have significant environmental and economic impacts and may not be suitable for existing structures. Biogeotechnical methods, notably Microbially Induced Calcite Precipitation (MICP), offer a sustainable alternative. Experiments reveal that MICP enhances liquefaction resistance, even at low calcite contents. However, the lack of models capturing this behavior hinders the design and adoption of these techniques. This study presents Hujeux-BC, a mechanical constitutive model for the cyclic behavior of biocemented soils. It independently incorporates the main characteristics of biocementation, densification and interparticle bonding. This is done by modifying the materials elastic parameters and relative density, as well as the addition of a bonding parameter. Using the measured calcite content and change in shear wave velocity, the model is able to simulate the cyclic behavior of biocemented soils. Notably, in an undrained cyclic direct simple shear (DSS) test, the model can simulate the porewater pressure generation, accurately estimating the number of cycles needed to trigger liquefaction. This accuracy and the model's straightforward calibration process provide a powerful tool for designing and optimizing MICP-based mitigation techniques, leading to more targeted and sustainable solutions.

RÉSUMÉ: La liquéfaction demeure un risque géotechnique majeur dans les zones sismiques. Les méthodes d'atténuation traditionnelles, malgré leur efficacité, ont des impacts environnementaux et économiques et ne conviennent pas toujours aux structures existantes. Les méthodes biogéotechniques, comme la Précipitation de Calcite Induite par Microbes (MICP), représentent une alternative durable. Les essais montrent que la MICP augmente la résistance à la liquéfaction, même à faible teneur en calcite. Cependant, l'absence de modèles constitutifs adéquats limite leur adoption. Cette étude introduit Hujeux-BC, un modèle constitutif pour le comportement cyclique des sols biocimentés. Il intègre séparément les caractéristiques principales de la biocimentation : la densification et la liaison entre particules. Ceci est fait en modifiant les paramètres élastiques du matériau, la densité relative, et en ajoutant un paramètre de liaison. En se basant sur la teneur en calcite et la vitesse des ondes de cisaillement, le modèle reproduit le comportement des sols biocimentés. Notamment, dans un essai cyclique non-drainé de cisaillement simple il permet de simuler la génération de la pression interstitielle, estimant le nombre de cycles nécessaires pour déclencher la liquéfaction. Cette précision, et la calibration simple des paramètres du modèle, en font un outil essentiel pour optimiser les techniques basées sur la MICP, menant à des solutions plus ciblées et durables.

Keywords: Liquefaction; biocementation; constitutive model; cyclic loading.

1 INTRODUCTION

Despite our increased understanding of liquefaction and the developed prevention methods, recent earthquake events highlight that liquefaction remains a threat to infrastructure (Cubrinovski et al., 2012), emphasizing the ongoing need to explore liquefaction mechanisms and preventative measures.

Traditional mitigation methods such as compaction, drainage, and grouting while effective, are often costly and invasive making them unsuitable for many existing structures. The need for more environmentally conscious, low-cost and non-invasive methods is therefore ever-present (Towhata, 2008). Biogeotechnical methods have emerged as a possible solution for this persistent hazard, particularly Microbially Induced Calcite Precipitation (MICP).

To assess the effectiveness of MICP based techniques, a combination of experiments and models is essential. Numerous experiments were conducted to observe the dynamic behavior of biocemented sands showing that biocementation greatly increased the liquefaction resistance, with highly cemented soils

becoming virtually un-liquefiable (Montoya et al., 2013; Sasaki and Kuwano, 2016; Zamani et al., 2021; Lee et al., 2022). Yet, the shortage of models for biocemented soils' cyclic behavior limits the technique's widespread use.

This study introduces Hujeux-BC, a cyclic elastoplastic constitutive model for biocemented soils. The model is based on the Hujeux (1985) cyclic model framework and integrates the observed changes in behavior of biocemented soils under both monotonic and cyclic loading. This is done by the addition of new biocementation parameters that are calibrated through the measured calcite content and the change in the shear wave velocity.

The model uniquely considers biocementation's mechanical effects, densification and inter-particle bonding, separately which enables it to simulate the bond degradation and the lasting densification impact of biocementation independently making it a valuable tool for studying the long-term behavior of biocemented sands subjected to repeated cyclic loading.

The following sections present the model formulation and performance in simulating an undrained cyclic DSS test on biocemented soils at varying cementation levels under different Cyclic Stress Ratios (CSR).

2 MODELLING FRAMEWORK

2.1 Theoretical background

The model development draws from observations of the physical mechanisms that govern the behavior of biocemented soils under both monotonic and cyclic loading. The main characteristics of the monotonic mechanical behavior of biocemented soils as detailed in numerous review papers (Terzis and Laloui, 2019; Fu et al., 2023) can be summarized as: i) increased soil stiffness, ii) increased soil strength and softening post peak, iii) dilatant behavior. Experimental data consistently attribute this behavior to two mechanisms: i) densification and ii) interparticle bonding(Nafisi and Montoya, 2018; Harran et al., 2023). Densification occurs due to the presence of calcite in the pore space which can be easily determined through acid washing or thermos-gravimetric analysis among other methods. Bonding on the other hand is more difficult to quantify. While it can be detected using advanced techniques like scanning electron microscopy or X-ray micro-tomography, it remains difficult to accurately identify the "active" bonds. Alternatively, these bonds can be estimated using indirect methods such as the shear wave velocity V_s (Nafisi and Montoya, 2018).

The cyclic behavior of biocemented has been investigated through different laboratory and scaled model tests where it was found that even low levels of cementation result in a dramatically increased liquefaction resistance (Montoya et al., 2013; Sasaki and Kuwano, 2016; Zamani et al., 2021; Lee et al., 2022). These studies identify the effects of biocementation on the cyclic behavior as: i) increased resistance, ii) reduced porewater pressure generation, iii) increased stiffness and iv) delayed onset of liquefaction. These observations align with the change in behavior under monotonic loading implying that the physical mechanisms inducing these changes are the same.

2.2 The effects of biocementation

2.2.1 Densification

A densification parameter for the elastic behavior is introduced as:

$$\xi_{den} = \frac{\rho_{cc}(G_s + eSr) + m_{cc}(G_s - Sr)}{\rho_{cc}(G_s + eSr)} \qquad (1)$$

where G_s is the specific gravity, Sr is the degree of saturation, e is the untreated void ratio, $m_{cc} = \frac{m_c}{m_s}$ is the calcite content, and $\rho_{cc} = \frac{\rho_c}{\rho_s}$ is the calcite density ratio.

The effect of densification on the yield surface is introduced through the parameter ψ_{den} expressed as:

$$\psi_{den} = \exp\left(\frac{e - e^*}{\lambda}\right) \qquad (2)$$

here, λ is the coefficient of compressibility obtained as the slope of the critical state line (CSL) in the $v - \ln(p')$ plane.

2.2.2 Bonding

The effect of active calcite bonds on the elastic behavior is obtained through the change in shear wave velocity and is estimated as:

$$\xi_{bon} = \frac{(V_s^2)^*}{V_s^2} = \frac{(V_s + \Delta V_s)^2}{V_s^2} \qquad (3)$$

where V_s^* and V_s are the shear wave velocities before and after calcite precipitation.

The effect of bonding on the yield surface is introduced through the parameter ψ_{bon} expressed as:

$$\psi_{bon} = \left(\psi_{bon_0}\right)^R \quad (4)$$

where ψ_{bon_0} is the initial degree of bonding and R is a debonding function given by:

$$R = \exp\left(-\omega \cdot \varepsilon_v^p\right) \quad (5)$$

Here, ω is the debonding rate and ε_v^p is the plastic volumetric strain. This expression was inspired by the work of Koliji et al. (2010) on structured soils since it was observed that their evolution during loading closely resembles that of biocemented soils.

3 MODEL FORMULATION

The model presented in this study is based on the work of Hujeux (1985) where the full elasto-plastic relationships are described. The following presents the changes due to biocementation.

The effect of biocementation on the elastic moduli is expressed as a combination of the densification and bonding parameters into a cementation factor CF_E given by:

$$CF_E = \xi_{den} \cdot \xi_{bon} \quad (6)$$

The elastic moduli are then expressed as:

$$K(p') = CF \cdot K_{ref}\left(\frac{p'}{p_{ref}}\right)^n \quad (7)$$

$$G(p') = CF \cdot G_{ref}\left(\frac{p'}{p_{ref}}\right)^n \quad (8)$$

where K_{ref} and G_{ref} are the reference bulk and shear moduli, p_{ref} is the mean effective pressure at which the moduli were estimated, p' is the current mean effective pressure, and n is an elastic exponent.

The change in the yield surface is done through the mean pressure at the critical state p'_{cs} which governs the strength response of the soil. p'_{cs} evolves to:

$$p'_{cs}{}^* = CF_S \cdot p'_{cs} \quad (9)$$

where $CF_S = \psi_{den} \cdot \psi_{bon}$ is the cementation factor for strength.

4 MODEL PERFORMANCE

The model's performance was tested against a series of undrained cyclic DSS tests conducted by Lee et al. (2022) on Ottawa sand F65 with light cementation levels.

The model was calibrated on the untreated results to determine the main model parameters and then the biocementation parameters were estimated from the reported calcite content and change in V_s. The results shown in Figure 1 align well with the experimental ones, accurately simulating the trends and the cycles needed to reach an excess pore water pressure (r_u) value of 0.95, highlighting the model's potential in predicting liquefaction under cyclic loading. Using the same model parameters calibrated on the tests shown in Figure 1, the model was used to simulate tests at all of the cyclic stress ratios used in the experiment to construct the CSR – N curves for the untreated soil and the two selected cementation levels shown in Figure 2. The simulated curves closely match the experimental ones for high CSRs but underestimate the cycles to liquefaction for lower CSRs. Given the inherent variability of cemented soils, however, the results offer a reasonable estimation showcasing the model's potential for evaluating MICP based mitigation techniques.

5 CONCLUSIONS

This study introduces the Hujeux-BC model, tailored for biocemented soils, that integrates biocementation's effects using the calcite mass content and shear wave velocity as input parameters. The model uniquely represents densification and inter-particle bonding independently, giving it the potential to simulate the long-term soil behavior as bonds degrade. When benchmarked, the model effectively mirrored biocemented soils' response under cyclic loading, particularly producing accurate CSR – N curves for biocemented soils at different levels of cementation.

Despite the complexities involved in modelling biocemented soils, this study shows that by using the reference, untreated state of sands as a starting point and incorporating parameters that reflect the densification and bonding effects, the cyclic behavior of biocemented sands can be understood and replicated, and as experimental observations increase, model calibration can be improved leading to a more robust framework.

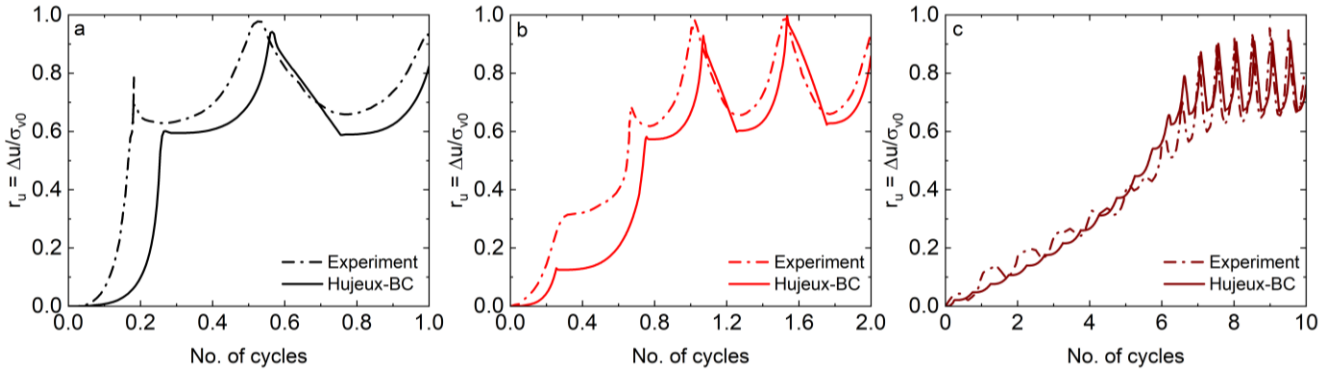

Figure 1. Comparison between experimental and simulations results for an undrained cyclic DSS on MICP-treated sands using Hujeux-BC a) untreated, b) $m_{cc} = 0.14\% - \Delta V_s = 16\ m/s$, c) $m_{cc} = 0.43\% - \Delta V_s = 36\ m/s$ (experimental data from (Lee et al., 2022)).

ABSTRACT: Dealing with foundation soils that are likely prone to liquefaction, or at least cyclic mobility during Ultimate Limit State earthquakes, some relevant uncertainties may arise in selecting appropriate remedial schemes. While it is a most common practice to consider soil improvement works, in some practical scenarios such ordinary policy may result in unreasonable choices under both engineering and economical points of view. A typical case is the design of spread foundations or buried caissons of limited size, in moderately liquefaction prone soils. A case history is discussed in this contribution, related to a touristic infrastructure installation in a reclaimed area, at the seashore of Northern Adriatic Coast, Italy. Ordinary free-field, one-dimensional liquefaction analyses have been compared with results from numerical models based on Flac3D, implementing P2PSand constitutive model (Cheng and Detournay, 2021), capable of reproducing pore pressure build up. The seismic response has been predicted and maximum displacements as well as design stresses for the structure have been evaluated; consequently, the Performance Based Design Approach has allowed to assess the minimum countermeasures required, ensuring an appropriate safety level even without the need of huge soil improvement works.

RÉSUMÉ: Dans le cas de sols susceptibles à la liquéfaction, ou au moins à la mobilité cyclique en cas de séisme à l'état limite ultime, certaines incertitudes pertinentes peuvent survenir lors de la sélection des programmes de remédiation appropriés. Bien qu'il soit courant d'envisager des travaux d'amélioration du sol, dans certains scénarios pratiques, cette politique ordinaire peut aboutir à des choix déraisonnables d'un point de vue technique et économique. Un cas typique est la conception de fondations étalées ou de caissons enterrés de taille limitée, dans des sols modérément sujets à la liquéfaction. Dans cet article est explique un cas type, lié à une installation d'infrastructure touristique dans une zone de remise en état, au bord de la mer au nord de la côte Adriatique, en Italie. Les analyses de liquéfaction unidimensionnelles ordinaires en champ libre ont été comparées aux résultats numériques du logiciel Flac3D, en mettant en œuvre le modèle constitutif P2PSand (Cheng et Detournay, 2021), capable de reproduire l'accumulation de la pression interstitielle. La réponse sismique a été prédite et les déplacements maximaux ainsi que les contraintes de conception pour la structure ont été évalués; par conséquent, l'approche de méthodes de conception fondées sur la performance a permis d'évaluer les mesures minimales requises, afin de garantir un niveau de sécurité approprié même sans la nécessité d'énormes travaux d'amélioration du sol.

Keywords: Liquefaction phenomenon; performance design.

1 INTRODUCTION

The liquefaction phenomenon is a quite common issue concerning the reduction or the loss of soil stiffness and strength caused by earthquake shaking.

It takes place in loosely packed, water-saturated sediments at or near the ground surface. Liquefaction occurring beneath buildings and other structures can cause major damage during earthquakes.

Therefore, in order to mitigate the liquefaction hazards several techniques have been implemented. The ordinary methods include vibroflotation, compaction grouting, stone columns. The objective is to improve the strength, the density of the soil so that soil skeleton will not collapse under rapid loading and possibly improve the drainage characteristics of soils.

These common practices, in some scenarios, may result in unreasonable choices under both engineering and economical points of view. This is the case for lightweight buildings. In this respect, this proceeding provides a case history in which a different approach has been adopted based on Performance Design Approach. Following this procedure, as done by many researchers such as Murashev, Keepa et Tai, (2015) and Liu, Macedo et Candia (2021), the soil is not improved while the structure is designed to resist the

effects of liquefaction, in terms of internal forces due to settlements.

The evaluation of those settlements, in the state of practice still largely involves using empirical procedures developed to calculate post-liquefaction consolidation settlement in the free-field. This approach cannot possibly capture shear-induced and localized volumetric induced deformations in the soil underneath shallow foundations. Two dimensional or three dimensional soil structure interaction nonlinear effective stress dynamic analysis can provide a reliable estimates of building movement. Lopez-Caballero and Farahmand-Razavi (2008), Shakir and Pak (2010), Adrianopoulos et al. (2006), Dashti and Bray (2013), and Karimi and Dashti (2016a,b) perform numerical analysis in this field.

2 CASE STUDY

The effect of liquefaction on ancillaries, lightweight buildings, related to a touristic infrastructure installation in a reclaimed area, at the seashore of Northern Adriatic Coast, Italy, will be examined in this study.

At this purpose, several numerical analyses were carried out, starting from stratigraphic column model and comparing it with simplified models. The stratigraphic column was compared with a subsequent two-dimensional model under free-field conditions. And finally, the influence of the light building on the soil layer was analysed.

The aims of the seismic numerical analyses are, therefore, to:

- check the triggering of the phenomenon and compare the results obtained with the results of the empirical methods;
- assess the interaction between the liquefaction phenomenon and the foundation structures, in terms of maximum displacement and stresses acting on the foundation.

2.1 FLAC3D analysis: procedure

Analyses were carried out with the Flac3D finite difference code, implementing the 'P2PSand' constitutive model (Cheng and Detournay, 2021). The model is specially formulated and calibrated to reproduce main experimental evidences of the liquefaction phenomenon. It defines the deformability of the material, in terms of shear modulus, as a function of relative density by means of the following expression:

$$G = G_0 \, P_{atm} \left(\frac{p'}{P_{atm}}\right)^{0.5} \qquad (1)$$

$$G_0 = g_0 \left(D_R + C_{D_r}\right) P_{atm} \left(\frac{p'}{P_{atm}}\right)^{0.5} \qquad (2)$$

where, for clean and uniform sands, it is possible to assume: $g_0 = 1240$ e $C_{D_r} = 0.01$ ($P_{atm} = 101.3\ kPa$).

The main calibration parameters of the constitutive model are the relative density D_R and the shear modulus multiplier g_0. These parameters were calibrated to reproduce the design shear modulus along depth.

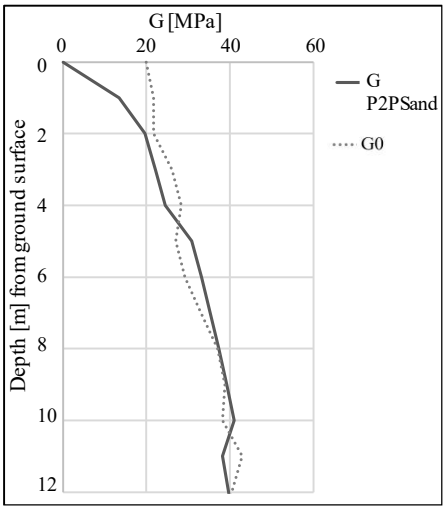

Figure 1. Calibration of shear modulus with P2PSand model.

The stratigraphy at the site can be modelled by four geotechnical units, defined as “R”, “A”, “B” and “C”. The liquefaction prone sandy sediments of geotechnical units R and A are modelled with the P2PSand constitutive model. Whereas Mohr-Coulomb model is used for geotechnical units B and C. The bottommost meter at the base of the model is modelled as elastic material in order not to have input wave distortion or noise in the application of seismic stress.

The main geotechnical input parameters are reported in Table 1 and Table 2. Water table is 2m below the ground surface.

Table 1. Geotechnical input parameters: P2PSand.

Unit	z [m]	γ [kN/m³]	φ [°]	Dr [%]	Vs [m/s]
R	0 ÷ 5	19	30	30	125
A	5 ÷ 10	19	30	35	161

Table 2. Geotechnical input parameters: Mohr-Coulomb.

Unit	z [m]	γ [kN/m³]	φ [°]	c' [kPa]	E [MPa]
B	10 ÷ 29	19	25	5	25
C	29 ÷ 39	20	33	30	70

REXEL, the database provided by ITACA, was used to define the seismic input: seven seismocompatible and spectrum-compatible accelerograms.

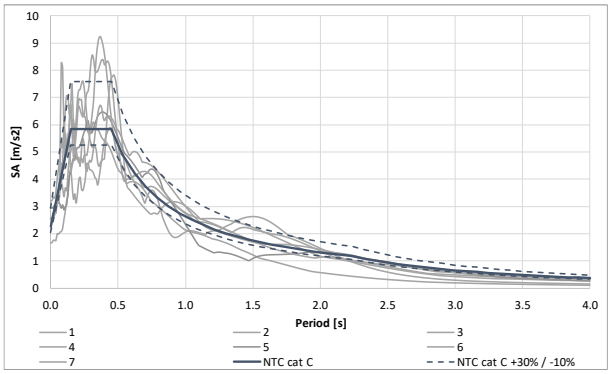

Figure 2. Response spectra of accelerograms extracted from REXEL. Comparison with NTC2018 spectrum.

The boundary conditions imposed on lateral sides of the numerical model are of the free-field kind. They consist of inserting a small column of soil at the extremes of the model to prevent both the distortion and the reflection of the seismic waves.

At the base of the model the following conditions were applied:

- The compliant base boundary conditions, which are implemented with independent dashpots in the normal and shear directions. They dampen the seismic wave, preventing its reflection within the model;
- the design velocity history, applied as time-dependent tangential stress:

$$\tau(t) = -\rho\, V_s\, v(t) \qquad (3)$$

where ρ and V_s are the density and shear wave velocity of the soil at the base of the model. v(t) is the seismic velocity diagram, obtained by integrating the deconvoluted design accelerograms.

The potential for liquefaction can be assessed by analysing the R_u coefficient, defined as the ratio of pore pressure increment Δu to geostatic vertical effective stress:

$$R_u = \frac{\Delta u}{\sigma'_{v0}} \qquad (4)$$

Soil is considered not subject to liquefaction if R_u<0.95.

The calculation phases implemented in the model are as listed below:

1. Initialisation of the geostatic stress state with the Mohr-Coulomb constitutive model;
2. Application of the P2PSand constitutive model on the geotechnical units R and A;
3. Dynamic analysis by applying the history of τ(t) of the 7 design accelerograms at the base of the model.

2.2 1D model: stratigraphic column

The numerical model is defined by a column with planimetric dimensions 2.0 m x 2.0 m (X and Y axes), and a height of 40.0 m (Z axis).

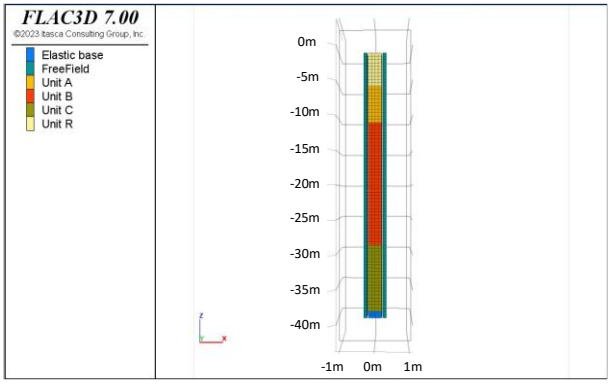

Figure 3. 1D model.

Figure 4, on the left, illustrates the 7 profiles of the R_u envelopes with depth, related to the 7 design accelerations; the profiles are sampled at the centre of the column. On the right, shows results from a common empirical approach (Robertson, 2009) for CPTus conducted in the same site. The factor of safety (F_s) against liquefaction is assessed by CRR (Cyclic Resistance Ratio) and CSR (Cyclic Stress Ratio) ratio.

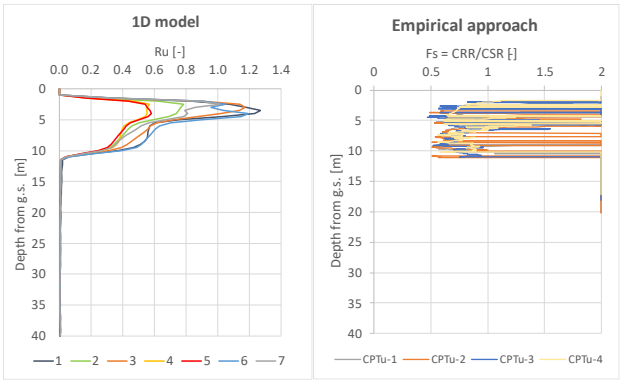

Figure 4. Results from numerical model (left) and empirical approach (Robertson, 2009).

It is noticeable that, by the empirical approach, geotechnical Unit R and A are prone to liquefaction (F_s <1), while the 1D model indicates probability of liquefaction just for Unit R, associated with a R_u>0.95 factor.

2.3 2D model: free field

The numerical model is defined by a two-dimensional block with planimetric dimensions 40.0 m x 0.5 m (X and Y axes), and a height of 40.0 m (Z axis).

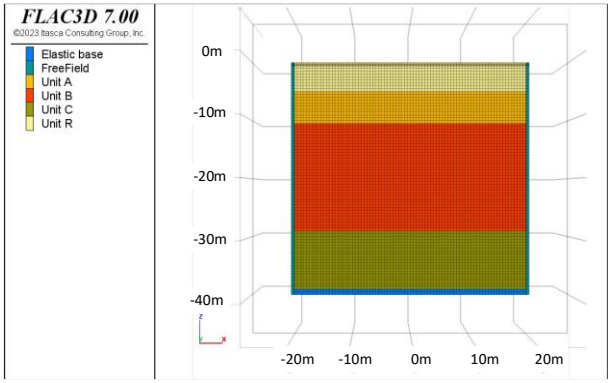

Figure 5. 2D model in free field conditions.

The 2D free field model confirm results observed in 1D model: soil belonging to unit R, as shown in Figure 6, when subjected to the seismic design stresses, induced by accelerograms 1, 3, 6 and 7, is liquefiable.

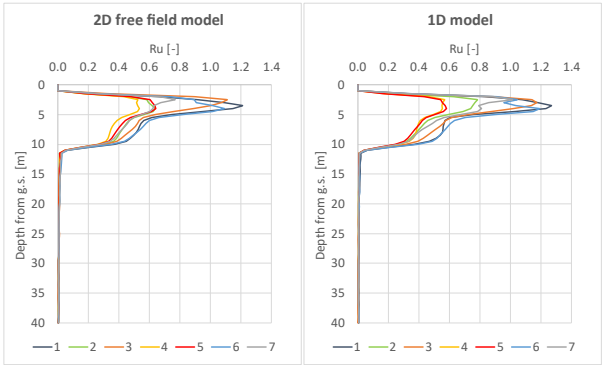

Figure 6. Comparison of free field 2D model (left) and stratigraphic column (right).

2.4 2D model: interaction with the shallow foundation

Based on free-field analyses, which reveal the occurrence of the liquefaction phenomenon, it is deemed necessary to further investigate the problem by modelling the on-site condition associated with the presence of some light buildings.

The building slab dimensions are B=9.5m and H=0.6m. It is modelled with elastic solid elements, having a specific weight equal to that of concrete (γ=25 kN/m^3), and a stiffness 20 times that of the surrounding soil (E=300 MPa).

The presence of the superstructure is simulated with elastic solid elements of equivalent weight and stiffness equal to that of the surrounding soil. The load due to the superstructure is 7.1 kPa, corresponding to an equivalent specific weight of 23.6 kN/m^3.

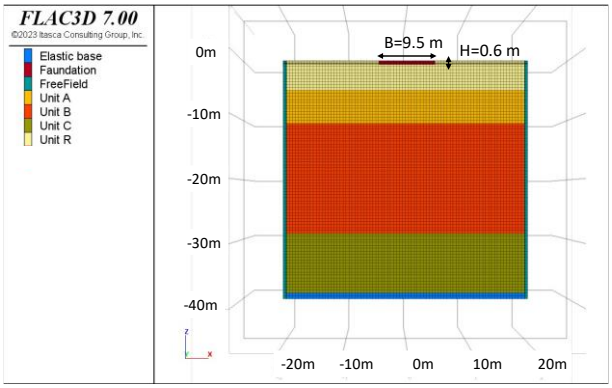

Figure 7. 2D model with shallow foundation.

In addition to the stages previously mentioned, three further stages run before phase 3: i) modelling the foundation slab; ii) applying the loads coming from the superstructure; iii) resetting the displacements before carrying out the dynamic analysis.

Obtained R_u profiles with ancillary building are compared with free-field profiles.

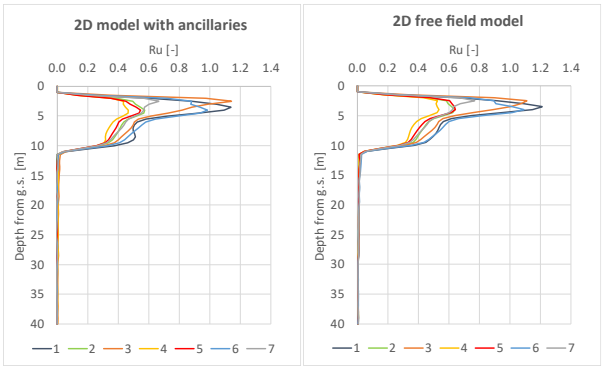

Figure 8. Comparison of model with ancillaries (left) and free-field model (right).

The presence of the building reduces the maximum value of R_u: this result is consistent with the fact that the building load increases the effective stresses near the foundation, reducing R_u ratio.

The results of the analysis in terms of displacement histories, associated with accelerogram 3, are shown in Figure 9. The upper Figure shows the vertical displacements of: the left end side of the foundation, in green; the point at the centre, in brown; and the right end side, in red. While the bottom one shows the horizontal displacements, which are uniform within the slab, which behaves as a rigid body.

The maximum horizontal displacement, experienced during the earthquake, is of the order of ± 5cm. While the residual one is close to 1 cm. To the contrary, vertical settlements tends to increase with

time, gathering some millimiters at mid axes as residual values.

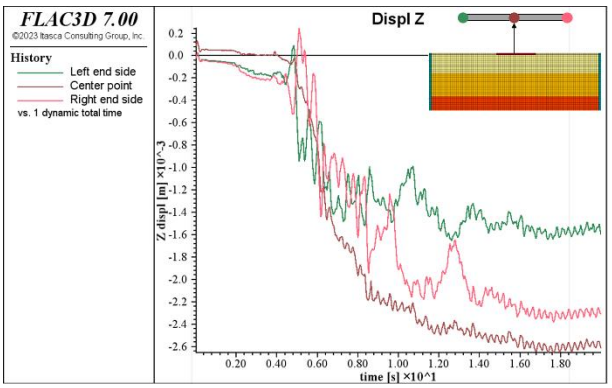

Figure 9. Time history of vertical displacements - accelerogram 3.

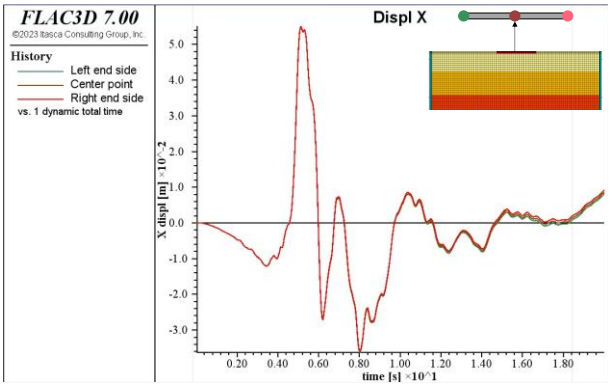

Figure 10. Time history of horizontal displacement - accelerogram 3.

The profile of the seven vertical displacements along the slab, associated to the design accelerations, are shown in Figure 11:

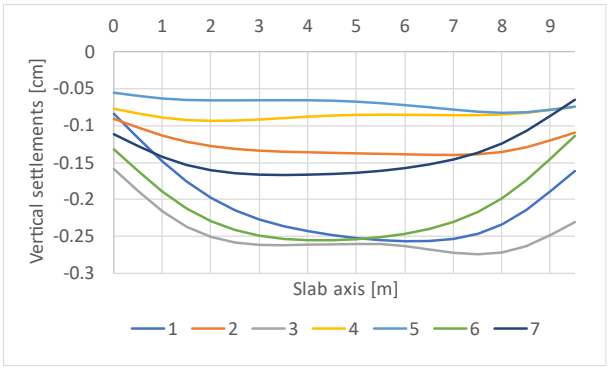

Figure 11. Vertical settlements along the slab.

The maximum vertical displacement is of the order of 0.27cm, associated with accelerogram 3. While the maximum differential settlement is of the order of 0.2cm associated with accelerogram 5.

Considering that the liquefaction phenomenon occurs without leading to excessive horizontal displacements and settlements, it has been decided to design foundations in such a way as to resist the additional stresses induced by liquefaction with a Performance Based Design approach.

2.5 Performance based design approach

The structure should be designed to resist the effects of liquefaction.

As a result of the analyses, the profiles of the horizontal minimum and maximum σ_{xx} stresses and the shear σ_{xz} stress acting in the slab elements were obtained.

Hence, the maximum bending moment and shear force were computed. These actions have to be added to the static design actions of the foundation as an additional loading condition due to soil liquefaction. In this way, the designed foundation will be able to resist to the envelope of the maximum expected deformations coming from the liquefaction phenomenon.

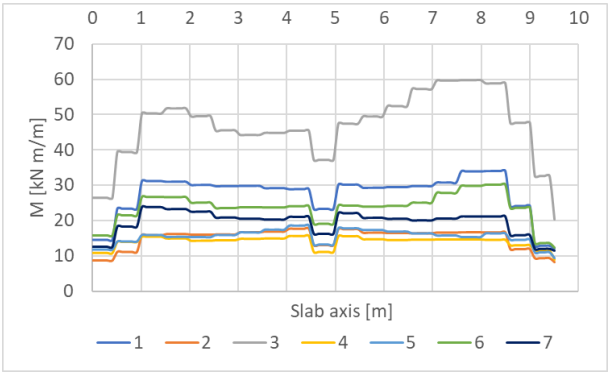

Figure 12. Bending moment along the slab.

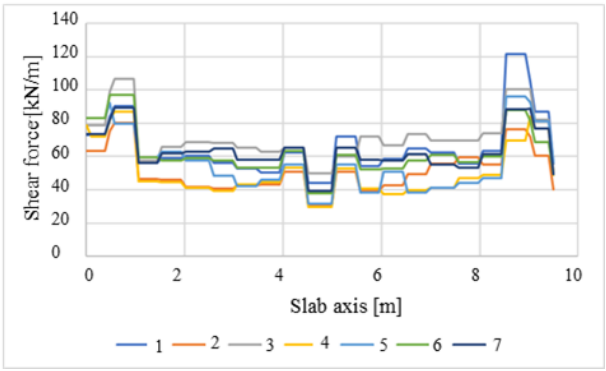

Figure 13. Shear force along the slab.

These supplementary actions, in the current project, are moderate. This is due to shallow setting of the foundation and to an R_u factor not far above unity.

Horizontal and vertical displacements of the foundation, due to the liquefaction phenomenon, are therefore compatible with design requirements.

3 CONCLUSIONS

FLAC 3D analyses confirmed the risk of soil liquefaction in same soil region where conventional calculations, based on empirical correlation, reported these issues.

However, such numerical approach is providing a relevant added value represented by a more accurate prediction of soil and foundation deformations occurring during seismic event. Such additional result is very important in the light of a Performance Based Design approach. In fact, according to this approach, the design of the foundation has the purpose to resist the effects of liquefaction in terms of deformations and supplementary actions, that are the results of the FLAC 3D analyses.

In the authors' opinion, such improvement in analysis results well counterbalances the increased efforts in terms of computational time and analysis complexities.

A further output of the numerical analysis, not dealt with in this contribution, is the evaluation of the increase of water pressures at the interface between foundation and soil. In case such overpressures may cause instability problems, such as uplift, appropriate countermeasures could be reliably assessed.

Effects of temperature, pore fluid composition and rate of shearing on the residual shear strength of soils

Effets de la température, de la composition du fluide interstitiel et de la vitesse de cisaillement sur la résistance résiduelle des sols

ABSTRACT: The residual shear strength is a crucial parameter in the post-failure behaviour of landslides. Many studies have shown that this parameter depends on the rate of shearing according to the normal stress and soil composition. Some researchers have shown that the composition of the pore fluid, which in landslide shear zones is typically an aqueous solution containing various dissolved ions, also can affect the residual shear strength. Smectites, in particular, can exhibit dramatic strengthening upon exposure to a concentrated salt solution. Few researchers have begun to evaluate the residual shear strength while also controlling the temperature during testing. Results demonstrated both strengthening and weakening upon heating, depending on soil composition. Owing to the coupled nature of hydraulic, thermal, chemical, and mechanical processes in soil, coupled effects also are expected; however, these effects are largely unexplored. We performed ring-shear experiments on pure clays and natural soils to obtain some insight into these coupled effects. We observed, for instance, that the effect of temperature fades away as the rate of shearing increases or the clay fraction decreases. We also observed some relationship between the shear rate effect and pore fluid composition. Understanding coupled processes in soils remains challenging; however, experiments may help improve our understanding of field-scale events, such as landslide reactivation and runout upon complex changes in boundary conditions.

RÉSUMÉ: La résistance résiduelle est un paramètre crucial dans le comportement post-rupture des glissements de terrain. De nombreuses études ont montré que ce paramètre dépend de la vitesse de cisaillement en fonction de la contrainte normale et la composition du sol. Chercheurs ont montré que la composition du fluide interstitiel, qui dans les zones de cisaillement est généralement une solution aqueuse contenant divers ions dissous, peut également affecter la résistance résiduelle. Les smectites, en particulier, peuvent montrer une augmentation considérable de la résistance si elles sont exposées à une solution saline concentrée. Peu de chercheurs ont commencé à évaluer la résistance résiduelle tout en contrôlant également la température pendant les tests. Les résultats ont démontré un renforcement ou un affaiblissement sous des températures élevées, en fonction de la composition du sol. En raison de la nature couplée des processus hydrauliques, thermiques, chimiques et mécaniques dans le sol, des effets couplés sont également attendus; cependant, ces effets sont largement inexplorés. Nous avons réalisé des expériences de cisaillement annulaire sur des argiles pures et des sols naturels pour obtenir un aperçu de ces effets couplés. Nous avons observé, par exemple, que l'effet de la température s'estompe lorsque la vitesse de cisaillement augmente ou que la fraction d'argile diminue. Nous avons également observé une certaine relation entre l'effet de la vitesse de cisaillement et la composition du fluide interstitiel. La compréhension des processus couplés dans les sols reste difficile; cependant, des expériences peuvent aider à améliorer notre compréhension des événements à l'échelle du terrain, tels que la réactivation des glissements de terrain et leur propagation lors de changements complexes des conditions aux limites.

Keywords: Residual shear strength; rate effect; thermo-hydro-mechanical coupling; chemo-mechanical coupling; clay.

1 INTRODUCTION

The residual shear strength is the minimum resistance that a soil can offer to shearing under a given effective normal stress (Scaringi and Di Maio, 2016). It is typically the only available resistance in regular landslide shear zones after large displacements and has been found to depend on the mineral composition of the solid skeleton as well as on that of the pore fluid (Di Maio, 2004; Di Maio and Scaringi, 2016). The residual shear strength also depends on the rate of shearing, and exhibits rate-strengthening, rate-weakening, or rate-neutral behaviours mainly according to the soil's mineral composition and grain-size distribution (Tika et al., 1996; Scaringi and Di Maio, 2016; Duque et al., 2023). Recent experiments

have demonstrated a dependence of the residual shear strength on the soil temperature during shearing (Loche and Scaringi, 2023). The residual shear strength and its controlling factors have been receiving increasing attention from researchers owing to the importance of this parameter in the behaviour (reactivation, runout) of landslides moving on clay-bearing shear zones. Understanding such behaviour has become even more critical under the ongoing, rapid climatic changes that many clay-rich regions are experiencing worldwide (Scaringi and Loche, 2022).

Here, we report on some recent ring-shear experiments that we conducted to begin quantifying how the aforementioned factors can condition the available shear resistance in the residual condition.

2 MATERIALS AND METHODS

2.1 Materials

We used commercial clays (kaolin, bentonite) as well as a number of natural soils in our experiments. Specifically, we used a Malaysian kaolin containing 46% of kaolinite and 48% of muscovite in dry weight. This kaolin exhibited a liquid limit of 63% and a plastic limit of 40%, with a granulometric clay fraction of 28% (< 2 μm), consistent with the typical large size of kaolinite stacks. Consequently, it had an activity of 0.82 and was classified as MH (inorganic, elastic silt) in the USGS classification. Further details on this material can be found in Duque et al. (2023).

The other commercial clay was a Ca-Mg bentonite named B75 and extracted from a deposit in the Czech Republic, containing 85% of montmorillonite and exhibiting a liquid limit and a plastic limit of 217% and 51%, respectively. Through sieve-sedimentation analysis, a clay fraction of 61% was evaluated, conferring the material an activity of 2.7 and resulting in a CH (fat clay) denomination in the USGS classification. Further details on this material can be found in Roháč et al. (2020) and Sun et al. (2022).

Additionally, samples of natural landslide soil (denominated A31, A68, A69, and A71) taken from the Melamchi catchment in Nepal were used. This Himalayan area experienced many landslides during a large-scale disaster in 2012. Owing to the limited accessibility of the site to heavy machinery, sampling was done using manual tools, down to depths of 0.5–1 m. The samples exhibited different index properties and mineral compositions. In general, they were characterized by low clay fraction (< 20%) and plasticity (< 20%), and by a dominance of kaolinite among the clay minerals. To explore the role of the clay component in determining the controlling factors of the residual shear strength, reconstituted samples (using distilled water or a concentrated NaCl solution) were prepared only from the fine fraction through successive sieving (< 125 μm, < 62 μm, < 20 μm).

2.2 Ring-shear device with temperature control

A Bromhead-type ring-shear device was employed (Wykeham Farrance, now Controls group). The device consists of a rotating base lined with a roughened brass porous platen, accommodating an annular sample 5 mm deep and 30 mm wide (outer diameter: 100 mm; inner diameter: 70 mm; area: 40 cm^2; volume: 200 cm^2). A top cap, also lined with a roughened porous platen, transfers the normal load to the sample and is prevented from rotating by two load cells contrasting a torque arm bolted to the cap.

The device was modified to gain control of the temperature of the water bath in which the sample is immersed. This was done by placing a closed water circuit made of a heat-conductive pipe, connected to an external thermostatic bath. Monitoring of the device's water bath was ensured by a thermocouple transmitting data to a computer, which was also receiving data from the device's controller (two load cells to determine the shear force and one sensor to monitor vertical displacements). Notably, we recorded a significant difference between the temperature measured in the device's bath and that set in the thermostatic bath owing to insufficient insulation of the device; therefore, we were unable to explore temperatures above ~55 °C even though we could reach ~90 °C in the thermostatic bath. The procedure for temperature-controlled experiments is described in Loche and Scaringi (2023). A sketch of the experimental setup is shown in Figure 1.

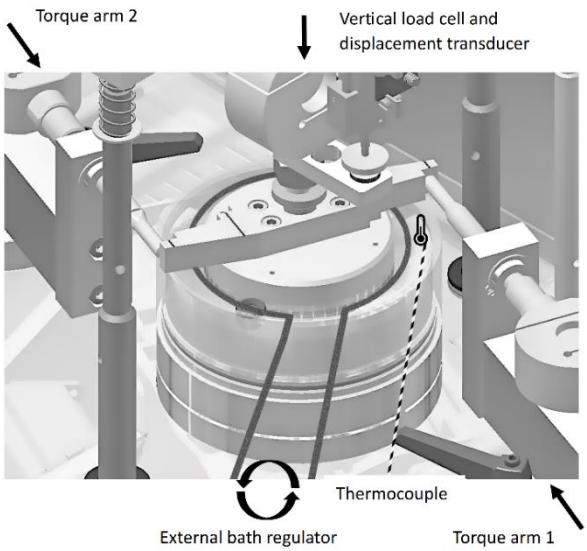

Figure 1. Sketch of the modified ring-shear device for temperature controlled experiments.

To evaluate the effect of the pore fluid composition we compared results using a conventional testing procedure (samples reconstituted with distilled water and immersed in a bath of distilled water during the whole test) with those evaluated on samples reconstituted with a concentrated (1 mol/L) NaCl solution and sheared while immersed in a bath of the same solution. The quality of the distilled water was ensured by measuring its electric conductivity (<1 µS/cm at 20 °C).

Finally, to evaluate the effect of the rate of shearing, we conducted experiments under various rates, exploiting the entire range available in the device. To preserve a smooth shear surface for as long as possible, we preferred a single-stage over a multi-stage procedure (Tiwari and Marui, 2004). We followed the protocol described by Stark and Eid (1994) to minimise the lateral friction by ensuring sample thicknesses above 4 mm before the start of the shearing phase. This required successive stages of consolidation with addition of material and overconsolidation to a normal load of 600 kPa prior to shearing under 50–150 kPa (i.e., OCR ≥ 4).

3 RESULTS AND DISCUSSION

The major role of the pore fluid composition in controlling the residual shear strength has been demonstrated extensively in various studies (see Di Maio and Scaringi, 2016). This was done with reference, in particular, to the role of inorganic salt solutions under landslide stress levels and very slow shearing (50–200 kPa; 0.005–0.018 mm/min). Less attention has been devoted to the coupled effect of pore fluid composition and rate of shearing. In Figure 2, we show an example of result using samples of kaolin, where the rate-strengthening behaviour and the (negligible) weakening effect of the salt solution are both visible. These effects are consistent with knowledge from the literature (Di Maio and Fenelli, 1994; Scaringi and Di Maio, 2016). Some enhanced rate-strengthening can be noticed in the samples in salt solution, but this is heavily masked by the wide error bars, which prevent a statistically-significant conclusion. The result suggests that a more refined device is necessary for a multivariate analysis.

More extensive studies on the shear-rate effects are reported in the literature, with a stress on the roles of the normal stress and mineral composition of the solid skeleton, that is, without specific attention to the influence of pore fluid composition and temperature. Nevertheless, important insights have been gained, for instance, concerning the predominant rate-strengthening behaviour of pure clays and clay-rich soils under rates of shearing corresponding to very slow to rapid landslides (Scaringi and Di Maio, 2016; Duque et al., 2023). Notably, under much larger displacement rates, shear-rate weakening is systematically observed independently of the soil nature. Various reasons for this phenomenon have been put forward, which entail frictional, acoustic, and thermo-chemical weakening mechanisms (Hu et al., 2018; Scaringi et al., 2018; Deng et al., 2020).

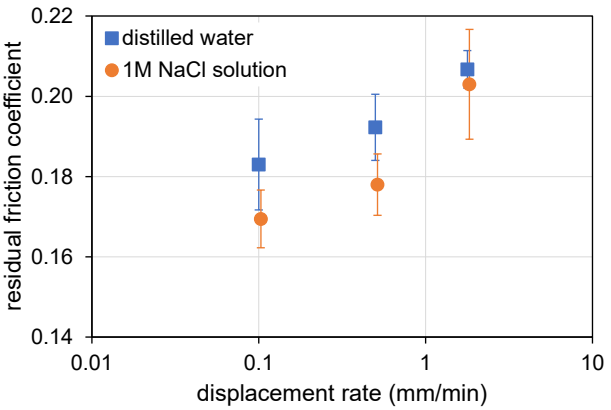

Figure 2. Residual friction coefficient (residual shear strength divided by the normal stress) of kaolin samples, prepared with and tested in a bath of distilled water or 1M NaCl solution, sheared under various displacement rates at 20 °C. The values correspond to the slopes of regression lines with zero intercept obtained from tests under 50, 100, and 150 kPa of normal stress (one test per normal stress). The error bars inform on the variability of the friction coefficient with the normal stress.

The effect of temperature on the residual shear strength of two pure clays was highlighted by Loche and Scaringi (2023), where considerations on a possible shear rate – temperature coupled effect were made, and implications in terms of possible changes in (shallow) landslide mobility under climate change were discussed. In Figure 3, a key result obtained on bentonite is reported, showing important strengthening upon heating during slow shearing (0.018 mm/min), which fades away upon faster shearing (0.5 mm/min) as the rate-strengthening behaviour dominates over the temperature-dependent one. This may be related to a change in the mode of shearing, from laminar to transitional or turbulent as the rate increases, which may result in a much less temperature-sensitive material. In fact, while laminar shearing is dominated by face-to-face interactions of clay particles, controlled by physico-chemical forces that are markedly sensitive to temperature, in a turbulent shearing condition, where particle arrangement is more chaotic, a role of pore fluid viscosity should prevail, which however varies little in the explored range of temperatures.

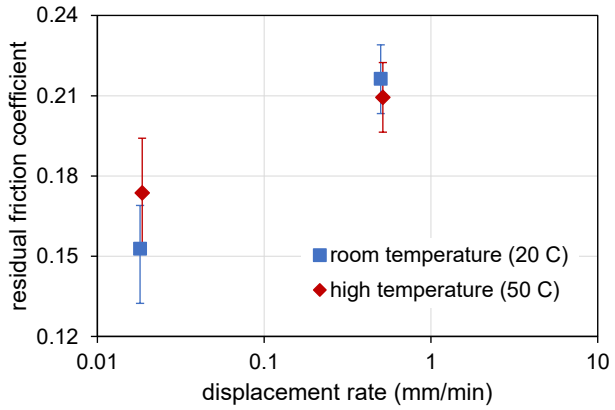

Figure 3. Temperature effects in ring-shear experiments on bentonite samples under various normal stresses, shear rates, and temperatures.

The experiments we conducted on natural soil, mainly aimed at identifying possible temperature effects, pointed out the crucial role of clay minerals in determining such effects, as evidenced by experiments carried out on the finest fraction of the samples. Figure 4 suggests that this can be evidenced by changing the cut-off grain size of the material submitted to the experiments. Obviously, by doing so, interpretation of field behaviours on the basis of experimental results becomes more difficult. However, in case of clay-enriched shear zones, it seems reasonable to hypothesise an enhanced role of the finest soil fraction in the process of shearing and in determining its controls.

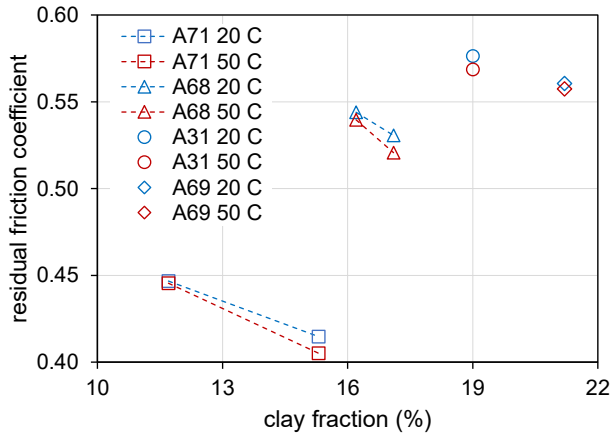

Figure 4. Temperature effects in ring-shear experiments on natural soil samples, sieved to enrich them in clay fraction. The experiments were conducted under 50–150 kPa of normal stress and 0.1 mm/min of rate of shearing.

4 CONCLUSION

We reported on ring-shear experiments aimed at evaluating the effects of pore fluid composition, temperature, and rate of shearing on the residual shear strength of various soils under stress conditions that are relevant in soil landslides. While many more experiments are needed to draw meaningful conclusions, we argue that the aforementioned effects should be studied comprehensively because coupled effects may arise. Furthermore, the role of grain size and/or mineralogical clay fraction, as well as that of the normal stress should be considered. Moreover, to study these effects, precise and accurate device setups providing highly repeatable results are essential to ensure that statistically significant conclusions can be reached.

Sand stabilization with colloidal silica for protection from liquefaction caused by dynamic loads

Stabilisation du sable avec de la silice colloïdale pour la protection contre la liquéfaction causée par les charges dynamiques

ABSTRACT: Dynamic loads may cause liquefaction of the saturated sandy soil. The colloidal silica grouting is the most advanced and effective sand stabilization method. Higher permeability of the colloidal silica gives the method an advantage over other soil stabilization methods. Due to its water-like density and viscosity, the highly dispersive colloidal silica with the particle size less than 15 nm (up to 15-30 nm) is capable to penetrate into sands of various grain size. It forms gel in soil pores after being mixed with activator, thereby stabilizing the soil. The paper presents results of the study on gel time, permeability properties and dynamic strength of sand against concentration of the colloidal silica and sand density. It has been obtained that with increasing colloidal silica content and activator concentration, as well as with increasing temperature, the gel time significantly reduces. The defined and therefore recommended for use colloidal silica concentration ranges from 5% to 10%, which provides gel hardening within 10 days at the activator concentration of 1-2%. It has been found that dynamic strength of sand increases by 1.5-5 times when sand is grouted with minimum concentration of 5%. The performed study has shown that the colloidal silica concentration of 5% is sufficient for stabilizing the soil subjected to earthquakes of the intensity up to 9 (on the base of MSK-64 scale). The dependency of gel time on concentration resulted from the study can be applied in design practice. Due to its permeability, colloidal silica is a promising material for strengthening clayey or silty sand.

RÉSUMÉ: Les charges dynamiques peuvent provoquer la liquéfaction du sol sableux saturé. Le jointoiement de silice colloïdale est la méthode de stabilisation du sable la plus avancée et la plus efficace. Une perméabilité plus élevée de la silice colloïdale confère à la méthode un avantage par rapport aux autres méthodes de stabilisation du sol. En raison de sa densité et de sa viscosité semblables à l'eau, la silice colloïdale hautement dispersive avec une granulométrie inférieure à 15 nm (jusqu'à 15-30 nm) est capable de pénétrer dans des sables de différentes granulométries. Il forme du gel dans les pores du sol après avoir été mélangé avec un activateur, stabilisant ainsi le sol. L'article présente les résultats de l'étude sur le temps de gel, les propriétés de perméabilité et la résistance dynamique du sable contre la concentration de la silice colloïdale et la densité du sable. Il a été obtenu qu'avec l'augmentation de la teneur en silice colloïdale et de la concentration de l'activateur, ainsi qu'avec l'augmentation de la température, le temps de gel diminue considérablement. La concentration de silice colloïdale définie et donc recommandée pour une utilisation varie de 5% à 10%, ce qui permet un durcissement du gel en 10 jours à la concentration d'activateur de 1-2%. Il a été constaté que la résistance dynamique du sable augmente de 1,5 à 5 fois lorsque le sable est jointoyé avec une concentration minimale de 5%. L'étude réalisée a montré que la concentration de silice colloïdale de 5% est suffisante pour stabiliser le sol soumis à des séismes d'intensité jusqu'à 9 (sur la base de l'échelle MSK-64). La dépendance du temps de gel sur la concentration résultant de l'étude peut être appliquée dans la pratique de la conception. En raison de sa perméabilité, la silice colloïdale est un matériau prometteur pour renforcer les sables argileux ou limoneux.

Keywords: Ground improvement; colloidal silica; gelling time; dynamic strength.

1 INTRODUCTION

The earthquake hazard of more than 25 % of the Russian territory is classified as high. Sandy water-saturated soil of these regions is most liable to liquefaction. The dynamic strength improvement of liquefiable sands is necessary to use these soils as base of structures. However, the traditional grout improvement techniques (such as cement, microfine cement, epoxy or silica grouting) are often not applicable due to poor penetrability of materials into the granular soils (Semkin and Ibragimov, 2016).

The colloidal silica can be used for stabilizing saturated sand and protecting it against liquefaction. The advantage of the method is high penetrability of

colloidal silica. It is capable to penetrate into granular soil due to solution's finely dispersed particles of less than 15 nm in size and its density and viscosity are close to water. Soil stabilization is result of colloidal silica gelling caused by activator.

However, well-known laboratory tests on colloidal silica application have been conducted at a room temperature ~20˚C which differs from the natural soil temperature of 0-10˚C.

The article presents results of laboratory analysis of gel time and permeability of colloidal silica at the temperature ranging from 20 to 25°C and close to a natural temperature range from 0 to 10°C. The results of dynamic strength analysis of soil grouted by colloidal silica are presented. The optimal colloidal silica concentration on the basis of gel time, permeability and dynamic strength of the stabilized soil is determined.

2 METHODS

2.1 Gel time in relation to the temperature

The dependency of gel time on colloidal silica content at different the temperatures was studied in laboratory. For the purpose, a colloidal silica sol was taken with initial concentration of $K_{initial}$ = 30%. Gel time was analyzed at the temperature range from 5 to 25 ˚C. To maintain the required temperature, colloidal silica mixtures were prepared in a refrigeration chamber equipped with temperature controllers.

Series of tests were performed with:

- Colloidal silica concentration of 2.5, 5, 10 and 15%;
- *NaCl* activator concentration of 0.25, 0.5 1 and 2%;
- The temperature of 5, 10 and 25˚C.

Each test was repeated at least three times.

Testing technique was as follows:

At the first stage, NaCl was introduced into a desired volume of distilled water, thoroughly mixed until the required concentration of the activator was reached.

At the second stage, the required volume of colloidal silica was introduced into the *NaCL* solution, thoroughly mixed, hermetically sealed in the glass container and left at rest until the gelation started.

At the third stage, the gel was visually examined. A stage of the hard gel formation, at which no deformations of gel surface were observed, was taken as a gel time.

2.2 Permeation of colloidal silica

Permeation of colloidal silica was studied in tests on filtration soil properties, when soil was saturated with distilled water or colloidal silica of various concentrations. A series of test on medium and fine sands was carried out at:

- Colloidal silica concentration of 0, 2.5, 5, 10 and 15%;
- The temperature of 5; 10 и 25˚C;
- Minimum (I_D=0), medium (I_D=0,5) and maximum (I_D=1) density degree of sands.

Each test was repeated at least three times.

The components were kept at a given temperature in the refrigerator chamber for at least a day for further experiments. Testing and processing of results were carried out in accordance with the stationary filtration mode scheme prescribed by GOST 25584-2016.

2.3 Dynamic strength of soils grouted with colloidal silica

Dynamic triaxial test (Voznesensky, 1997) was used for assessing strength of sandy soil grouted with colloidal silica. Strength characteristics under dynamic loading were estimated for both grouted and clean sand. The tests were performed via GDS ELDYN (Figure 1).

Figure 1. Dynamic triaxial test system GDS ELDYN.

Tests were performed on medium and fine sands (Figure 2) at:

- Initial void ratio e=0,7; 0,6 and 0,5;
- Colloidal silica concentration of 5, 10 and 15%.

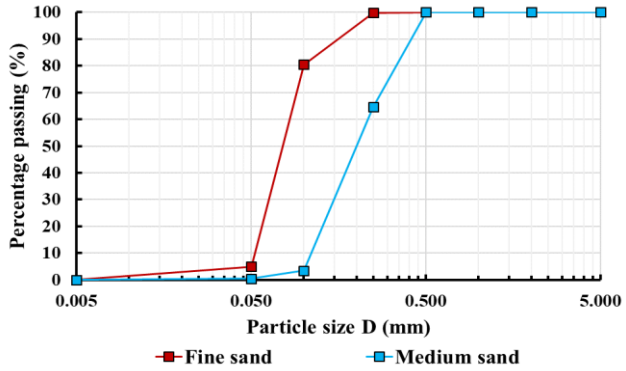

Figure 2. Cumulative curve of the grain size distribution.

Each test involved the following sequences:

At the first stage, a specimen was prepared in a special split mold by tamping dry soil in layers.

At the second stage, the specimen was grouted with colloidal silica through the bottom side (Figure 3) under the pressure of 10 kPa. When the specimens became saturated, the molds were removed and specimens were kept at rest until the gel stabilized.

At the third stage, after gel stabilization, the specimens were placed under water to prevent contact with the air and they were left so to gain strength.

Figure 3. Saturation device.

At the fourth stage, the specimens were loaded under anisotropic consolidation at a given initial stress and then were subjected to dynamic loading. The tests were repeated at least six times with a shear stress taken depending on soil strength. The dynamic load was applied until the specimens failed.

Changes in cyclic resistance ration *CRR* of specimens were assessed with a method of equivalent cycles. A critical number of cycles N_{cr}, at which the specimens failed, was determined for each test and a relation $CRR = f(N_{cr})$ was then generated.

3 RESULTS

Gel time. It has been defined that minimum colloidal silica SiO_2 concentration is 5%, inasmuch that with minimum temperature of 5 ˚C and minimum activator concentration of 1 % it was possible to fix moment of gelation within the optimum waiting period (Figure 4). At lower concentration, gel time increases significantly and gelation in laboratory conditions has not fixed.

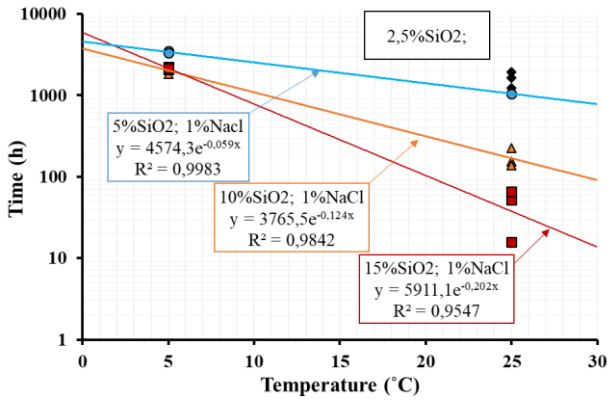

Figure 4. The relationship between gel time and temperature at activator concentration of 1%

Concentration of colloidal silica has a significant effect on its permeability. As the concentration increases from 0 to 15%, the hydraulic conductivity of sands decreases by average 2 times regardless of sands density, particles distribution and temperature conditions. It was observed, that for the concentration of colloidal silica $C_{SiO2} \leq 5\%$ the difference in the rate of colloidal silica delivery and water infiltration was less than 10%. This indicated the high permeability of low-concentrated grout (Figure 5).

The temperature drop by *5* times lowered the rate of grout delivery by 1,2 – 2,2 times, whatever density and particle distribution of sand were.

The hydraulic conductivity of sand decreased by 1,8 – 3,6 times with the increasing density degree I_D from 0 to 1. In this case, the influence of the density degree of medium sand was more significant than that of fine sand due to the pore size and the roundness of the particles of the soils considered (Figure 5).

Dynamic strenght of soils grouted with colloidal silica. Figure 6 shows the results of dynamic triaxial tests on fine sand (6a, 6b) and medium sand (6c, 6d) at different concentration of colloidal silica. It was observed that strength properties of fine sand increased significantly as compared to medium sand. Grouting smaller fractions was approximately 55% more effective.

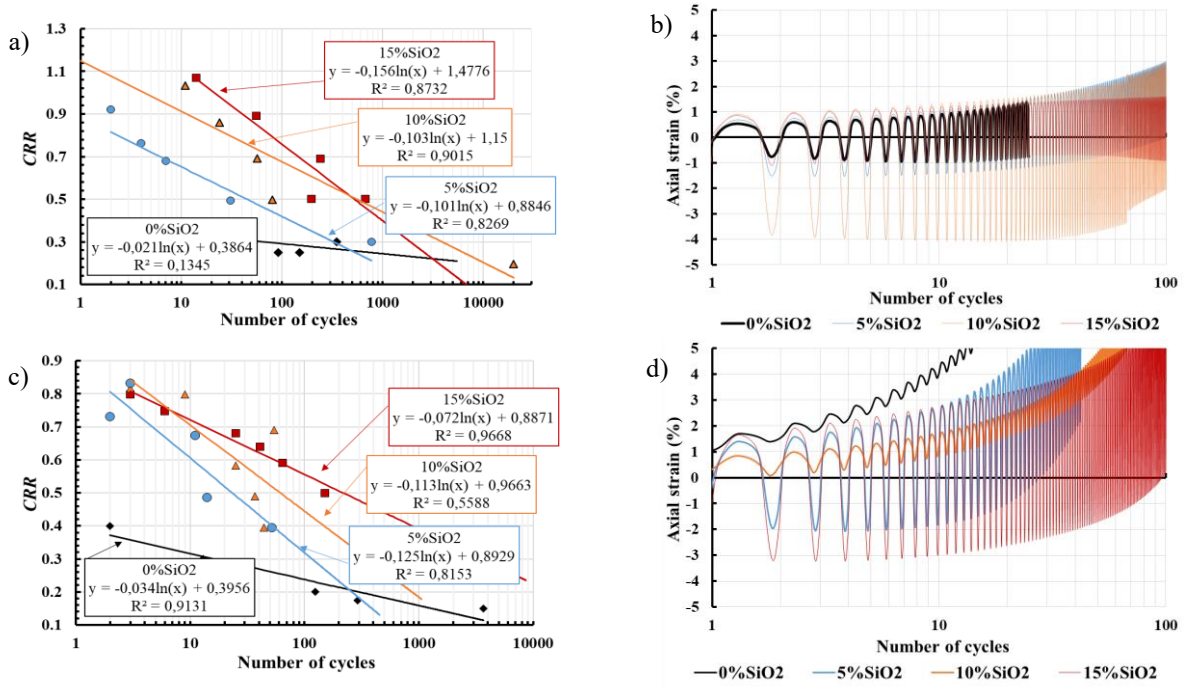

Figure 6. Results of dynamic triaxial tests: a - cyclic resistant ration (CRR=0,6) of fine sand (e=0,7) versus a number of loading cycles; b – fine sand axial strain under cyclic loading for different concentration of colloidal silica SiO_2 ; c- cyclic resistant ration (CRR=0,6) of medium sand (e=0,7) versus a number of loading cycles; d - medium sand axial strain under cyclic loading for different concentration of colloidal silica SiO_2.

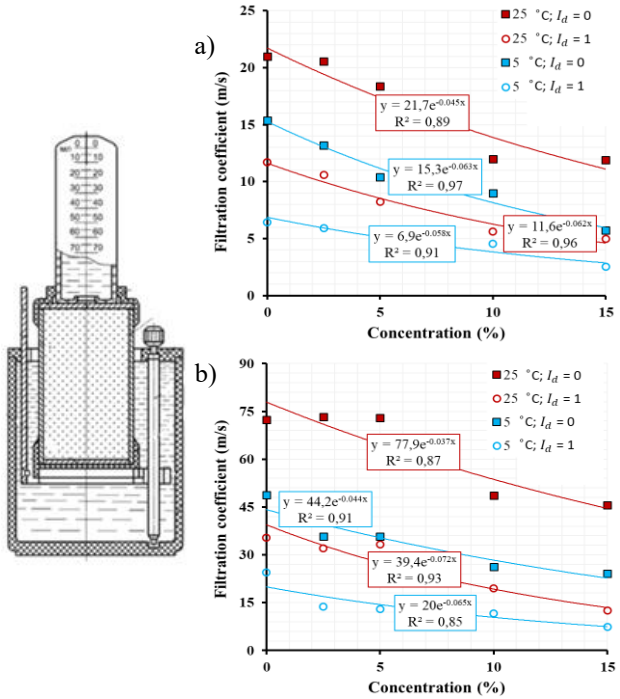

Figure 5. Installation scheme for testing filtration of sand at a constant pressure level: permeability of colloidal silica versus concentration in fine sand (a) and in medium sand (b).

On the base of regression analysis the following empirical dependence was proposed:

$$CRR = a_1 \lg N + a_2 \lg C_{SiO_2} + a_3 \qquad (1)$$

where, N – a number of dynamic triaxial loading cycles; C_{SiO_2} – concentration of the colloidal silica; a_1, a_2, a_3 – empirical coefficients derived from tests.

Overall, based on the total results published (Gallagher, 2002, 2009; Sharafutdinov and Kuznetsova, 2023), it can be noted that 5% colloidal silica content is enough to protect sandy soil from earthquakes with intensity up to 9 (on MSK intensity scale). However, most existing studies do not make a direct correlation between soil density and minimum colloidal silica concentration required. A content of 5% colloidal silica was defined for particular sands (including particle roundness, mineralogy etc.) and, therefore, could not be recommended for practical application (Figure 7).

Moreover, most existing publications assess the influence of colloidal silica content on stiffness and deformation of soil specimens prepared in laboratories. The benefits of colloidal silica grouting needs to be studied more thoroughly in-situ.

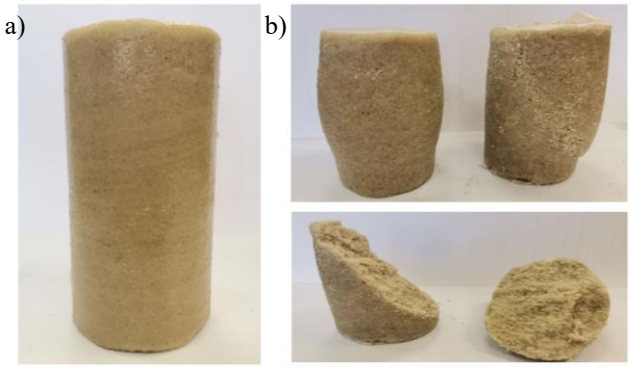

Figure 7. Specimens of sand grouted with colloidal silica: before (a) and after (b) dynamic testing.

4 CONCLUSIONS

Minimum concentration of colloidal silica needed to stabilize soils was defined as 5%, since with this concentration gel formed at minimum temperature of 5 ˚*C* and minimum activator concentration of 1%.

The permeability of colloidal silica has a significant influence on stabilization process. The research performed by the authors shows that with concentration of colloidal silica increasing from 0 to 15% its permeability reduces by 2 times. It is obvious that activator influences the results. While permeating, the colloidal silica forms gel and a real size of the grouted area is changing (Gallagher, 2007). Nevertheless, for the concentration of colloidal silica $C_{SiO2} \leq 5\%$ the difference in the rate of colloidal silica delivery and water infiltration is less than 10%. This indicates the high permeability of low-concentrated grout.

Temperature conditions are also of great importance. Notwithstanding the density degree of sand, hydraulic conductivity reduces by average 1,2-2,2 times when temperature falls by 5 times (from 25 ˚C to 5 ˚C). This factor should be taken into account when soil massive is grouted with colloidal silica in-situ.

On the base of the study performed, relations for estimating soil stiffness with regard to the concentration of colloidal silica, sand density and particle size distribution has been derived. Overall, based on the total results received, it can be noted that 5% colloidal silica content is enough to stabilize sandy soils, protecting them from dynamic impact. Strength properties of grouted fine sands are better if compared with medium sands. Grouting of fine fractions gives approximately 55% more effective results. The cyclic resistance ration can be estimated with relation (1), depending on concentration of the colloidal silica. However, the resulting empirical coefficients may be subjective, which requires additional research.

The performed study on gel time, permeability of colloidal silica and dynamic stiffness of sandy soil allows authors to conclude with carefulness that 5% concentration of colloidal silica may be recommended for grouting soils subjected to dynamic loading including seismic impact. According to the authors, benefits of colloidal silica grouting needs to be studied more thoroughly in-situ.

ABSTRACT: Long-term landslide monitoring is essential for understanding landslides and implementing mitigation strategies. Case studies in Brazil and the UK used automatic systems for this purpose. In Brazil, since 2013, a geotechnical sensor system has been monitoring soil movement, water pressure, and rainfall. In the UK, a project since 2012 has been using various instruments to monitor a highway's slope slippage. Both systems allow for early warnings and corrective actions. The current paper will also discuss the challenges and advantages of implementing such systems and also show the benefits of using the right instruments to provide long term monitoring of unstable assets in different regions and contexts.

RÉSUMÉ: La surveillance à long terme des glissements de terrain est essentielle pour comprendre ces phénomènes et mettre en œuvre des stratégies d'atténuation. Des études de cas au Brésil et au Royaume-Uni ont utilisé des systèmes automatiques à cet effet. Au Brésil, depuis 2013, un système de capteurs géotechniques surveille les mouvements du sol, la pression interstitielle et les précipitations. Au Royaume-Uni, un projet utilise divers instruments depuis 2012 pour surveiller le glissement de pente d'une autoroute. Les deux systèmes permettent des alertes précoces et des actions correctives. Le présent document exposera également les défis et avantages de la mise en œuvre de tels systèmes et montrer également les avantages de l'utilisation des bons instruments pour assurer le suivi à long terme des actifs instables dans différentes régions et contextes.

Keywords: Geotechnical monitoring; instrumentation; observational method; inclinometers; piezometers.

1 INTRODUCTION

Continuous monitoring systems aid risk management by understanding landslides and enabling timely responses to reduce casualties. They enhance risk reduction strategies and ensure infrastructure safety by using advanced technology for data acquisition and analysis. Monitoring enables informed decisions and timely interventions to mitigate landslide impacts.

Long-term monitoring of landslides is essential in regions like UK and the Brazil for understanding their dynamics and implementing mitigation measures. Both countries have adopted automatic systems for this purpose. For instance, a project in Lancashire, UK, initiated in 2012, employs ShapeArrays, water level recorders, rain gauges, and tiltmeters to monitor slope movements on a highway. Likewise, in Campos de Jordão, Brazil, a geotechnical sensor system has been operational since 2013, gathering real-time information on soil movement, water pressure, and rainfall. This system aids in early warnings and taking timely corrective actions. The current paper will expose the challenges and advantages of both long-term monitoring case studies.

The objective of the paper is not to provide an analysis and description of the failure mechanisms, or to undertake a back analysis of the data, but to stress the benefits of using the right instruments to provide long term monitoring of unstable assets in different regions and contexts.

2 UK CASE STUDY – SOUTHBOUND HIGHWAY

The United Kingdom has an extensive road network totalling approximately 400,000 km. The Strategic Road Network of England is the economic core of the country's road network and is made up of motorways and major A-roads, with a length of over 15,000 km. 80% of these (approx. 13,000 km) are comprised of cuttings and embankments.

An ageing infrastructure (mostly built in the 1960s and 1970s) and an increased volume of traffic (up approximately 80% between the 1980s and the early 2000s) have continuedly contributed to the deterioration of a significant number of geotechnical assets along the network.

The site presented in this paper is in Lancashire, United Kingdom and comprises a cutting approximately 250m long along the Southbound carriageway of a dual carriageway road part of the Strategic Road Network. The cutting features a sheet piled retaining wall spanning approximately 90m at the toe of the slope, raising approximately 1m above ground level, with a layer of rockfill behind it.

A ground investigation campaign was carried out in the Summer of 2011 which was used to install monitoring along the slope, comprised of piezometers and inclinometers. Initial readings of inclinometers were taken end of September 2011. In a manual monitoring campaign carried out early January 2012, cumulative displacements of up to 80mm had already been recorded, with a shear zone clearly identified in all the instruments. As it can be seen in Figure 1, the inclinometer measurements allow not only to understand the cumulative displacement of the slope, but also the rate of displacement and the width of the "shearing zone" within the soil; in the case of Figure 1, it is apparent how the soil deformation is concentrated within a "band" which is approx. 3m thick.

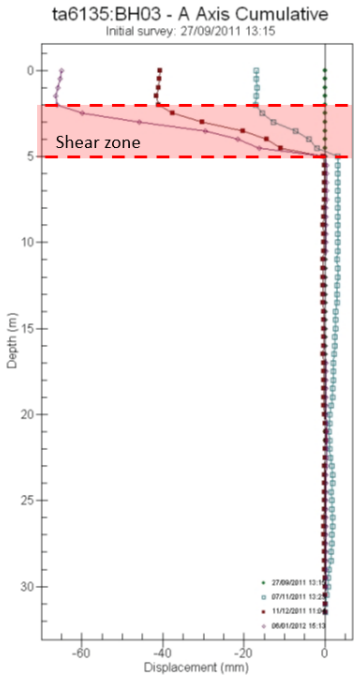

Figure 1. Manual inclinometer results for BH03 Jan/2012.

2.1 Automation monitoring

In April 2012, given the rate of displacement and the fact it wasn't possible to traverse the inclinometer casings with an inclinometer probe due to excessive bending, the slope monitoring was automated with ShapeArrays (Figure 3) and water level recorders. To complement this, a rain gauge was also installed on site in June 2012 and wireless tiltmeters were installed on the sheet pile wall in August 2012 (Figure 2).

Figure 2. Wireless tiltmeter in a sheet pile wall.

Data was collected using four independent networks of dataloggers connected via radio link. On each network, a main hub with a mobile network modem allows for remote data collection, with data being made available to the asset owner automatically via a web-based data visualisation and analysis platform.

Figure 3. Automatic inclinometers (ShapeArray) installation.

Since the installation of the automated monitoring in 2012, displacements have been registered up to a maximum of 995mm downslope, with an average displacement of ~86mm/year (Figure 4).

Based on the continuous monitoring of the asset, over the last 10 years, the client was able to assess the stability of the slope, implement any required safety measures, and guarantee the safety for the road users throughout the year.

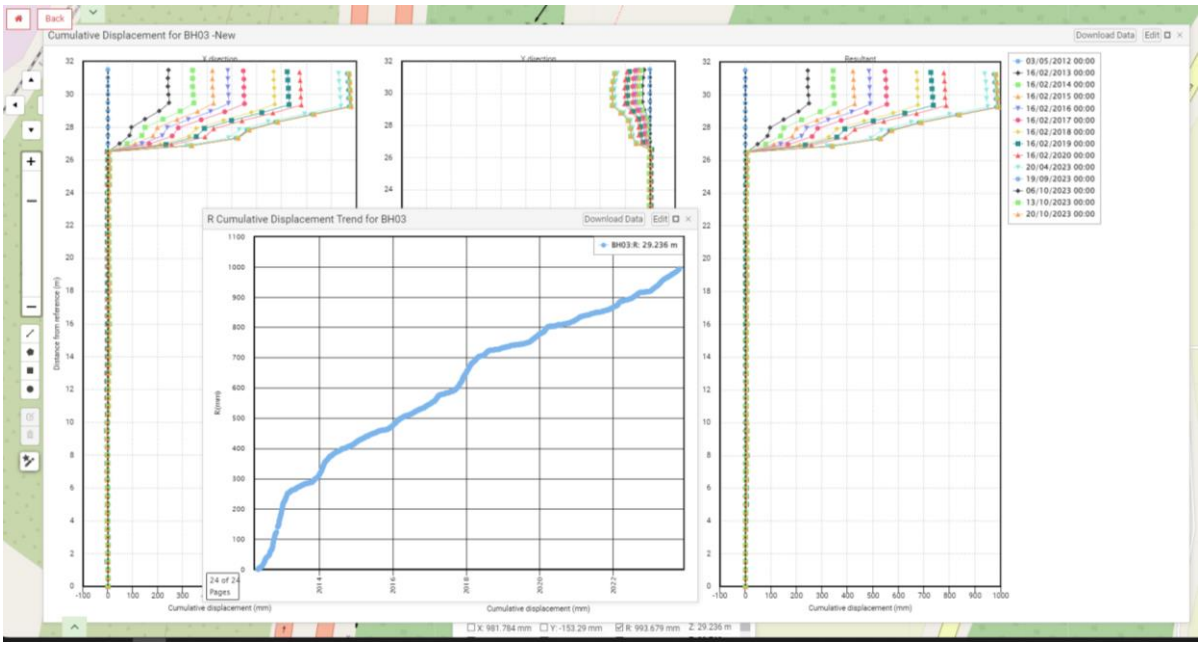

Figure 4. Cumulative displacement at BH03 in October 2023 and cumulative displacement trend.

The automation of the site allowed the monitoring to continue without costly re-drilling works, with increased frequency of data acquisition if/when required, reducing the presence of staff on site with only one/two maintenance visits throughout the year required to keep the system running.

Figure 5 shows how the thickness of the soil "band" interested by the deformations has been keeping consistent during the monitoring period. This kind of information could crucially inform the back analysis and the (consequent) optimisation of the maintenance strategy and maintenance interventions on the slope.

The slope stability analysis and any potential stabilisation/remedial works have been and are being carried out by a specialist engineering consultancy employed by the client. The authors are not involved in this process.

Recently, works were carried out to improve the drainage along the slope and the sheet pile wall was extended North for approximately 100m. The client and the engineering consultant are now assessing the impact of these works in the overall stability of the slope.

Over the years some of the equipment (mainly piezometers) started failing, which prompted the client to consider a refurbishment of the monitoring system. The ShapeArrays continued performing over the years, even when measuring significant deformations over very short lengths.

Due to the rate of movement over the years, manual data acquisition with an inclinometer probe and the required additional works to keep the monitoring going would render this option unsustainable. The ability to retrofit ShapeArrays into existing inclinometer casings that had suffered extreme bending proved to be a game changer for this project, allowing the monitoring of the slope to continue without costly additional works or disturbance of the slope with heavy drilling equipment.

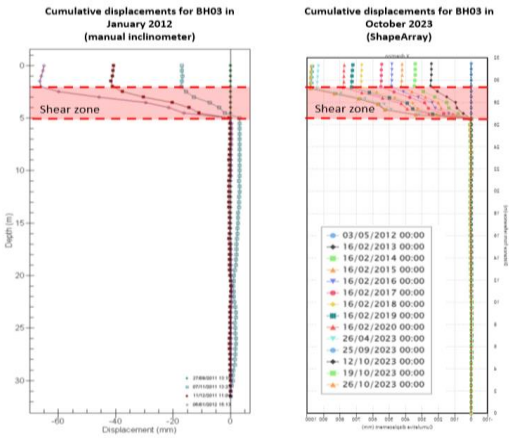

Figure 5. Comparison of cumulative displacement profiles between Jan/2012 and Oct/2023.

3 BRAZIL CASE STUDY – CAMPOS DO JORDÃO PILOT PROJECT

Brazil annually contends with floods and landslides affecting over 4 million people across 14,000 highly susceptible areas. During the rainy season (December-March), catastrophic events claim lives and cause substantial damage. In January 2023, flooding and landslides in São Paulo killed 65 and displaced 3,500. In the previous year, Petropolis saw 235 fatalities and 4,000 displaced due to intense rainfall. Despite recognizing the importance of geotechnical instrumentation, its inadequate implementation persists.

In 2013, a pilot project was initiated to monitor a slope in São Paulo, Brazil, using two ShapeArray inclinometers and two vibrating wire piezometers. The fully automated system has been operational for around 10 years with hourly data collection. The project aims to:

- Establish a remote monitoring system.
- Measure key variables.
- Ensure reliable, continuous data delivery.
- Enhance risk management in an area prone to landslides.

3.1 Geometric, geological, and geotechnical characterization

The slope is about 50m long and 10m wide from the top to its base. The water table varies between 2m from the surface at the base of the slope and about 5m at the top of it (Figure 6).

The stratigraphy obtained through the boreholes provided indicates the existence of a surface landfill stratum (brown clay silt) and an underlying layer with low, predominantly clayey resistance characteristics (Gray organic clay with 1 to 2 blows Nspt), followed by a saprolite soil (young residual soil) to saprolite (transition from residual soil to altered rock) typical of tropical regions.

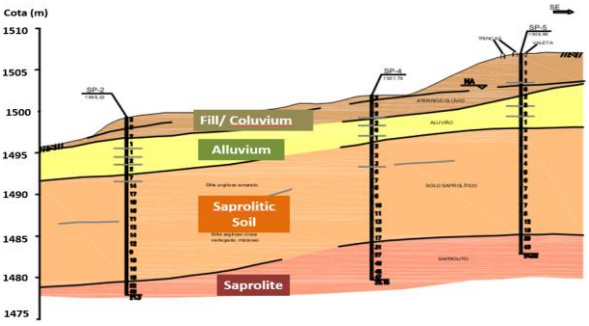

Figure 6. Geological profile of the study area (from top to bottom – Fill/Coluvium, Alluvium, Saprolitic soil, Saprolite.

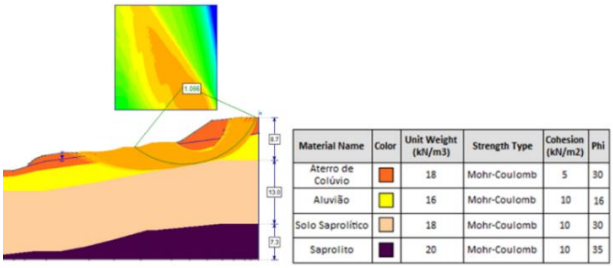
Before installation, a Morgenstern-Price Method limit equilibrium analysis assessed slope stability (Figure 7). Despite moderate steepness, geological and hydrogeological factors favour mass movement. The analysis highlighted the importance of the alluvial layer (yellow layer in Figure 6 and Figure 7) in slope stability, with its characteristics directly influencing the overall safety factor. Rupture surfaces with safety factors near 1 are concentrated in this layer, indicating deeper landslide potential. Furthermore, stability worsens with heavy rainfall and loads on the upper slope. This limit equilibrium analysis was useful to understand the potential failure mechanism and define the instrumentation plan such as: type of instruments, location and data collection frequency.



Material Name	Color	Unit Weight (kN/m3)	Strength Type	Cohesion (kN/m2)	Phi
Aterro de Colúvio		18	Mohr-Coulomb	5	30
Aluvião		16	Mohr-Coulomb	10	16
Solo Saprolítico		18	Mohr-Coulomb	10	30
Saprolito		20	Mohr-Coulomb	10	35

Figure 7. Results of the stability analysis (Morgenstern-Price Method - FS [1 to 1.5]. Material names translation from top to bottom: Fill/Colluvium, Alluvium, Saprolitic soil, Saprolite).

3.2 Instrumentation plan

The instrumentation project involved integrating two ShapeAccelArrays (SAAs) and two vibrating wire piezometers at a geological site. They were strategically placed based on-site features. A detailed assessment identified critical factors including horizontal displacements and pore pressures. Two SAAs (18m and 22m) measured displacements at various depths, while two piezometers (at 5m and 8m depths) monitored pore pressures. The data collection occurred at one-hour intervals.

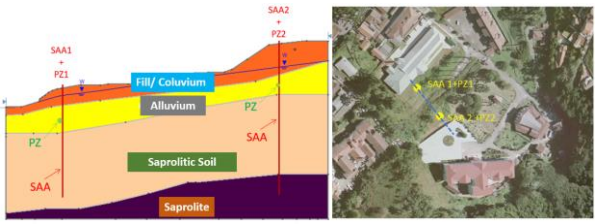


Figure 8. Cross-section with the location of the instruments (from top to bottom – Fill/Coluvium, Alluvium, Saprolitic soil, Saprolite.

As illustrated in Figure 8 there was a concern about anchoring the automated inclinometers in competent locations of the saprolitic or saprolite layers. The piezometers in the middle of the alluvial layer to verify the possible change in the pore pressure regime in this soft clay soil were identified as critical in the limit equilibrium stability analysis.

3.3 Analysis and data interpretation

It is important to note that although the monitoring has been taking place since 5/10/2013, there is a gap without data due to the lack of project funding funds that prevented the data from continuing to be transmitted, being only kept in the physical datalogger. However, due to the frequency adopted, the datalogger's ring memory was filled every three months, and the older data were overlaid as new data were collected. Continuous data collection resumed in July 2022. Even so, after diagnostic tests and sensor integrity checks, the equipments remain in good working condition.

Automated inclinometers demonstrate displacements in the shallowest strata of colluvium and alluvium. In SAA1, a clear-cut surface is defined about 3.5 m from the surface, while for SAA2, this surface is delineated from the surface 6 m, as illustrated in Figure 9. The results are consistent with the geological profile of the site, showing a creep phenomenon (Figure 11) that mobilizes slowly the surface layer of colluvium and part of the alluvium due to its characteristics of magnitude and velocity (1mm/year), with the latter showing more variation of around 2mm in periods of greater rainfall (Figures 9B and 10B).

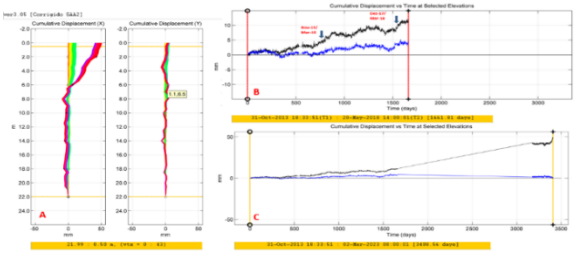

Figure 9. A) Cumulative displacements in the X (preferred direction of displacement) and Y axes of SAA2; B) Cumulative displacements in X (black) and Y (blue) axes over time at 1.0m depth, emphasizing acceleration during heavy rainfall; C) Cumulative displacements in X (black) and Y (blue) axes over time at 1.0m depth from 2013 to 2023.

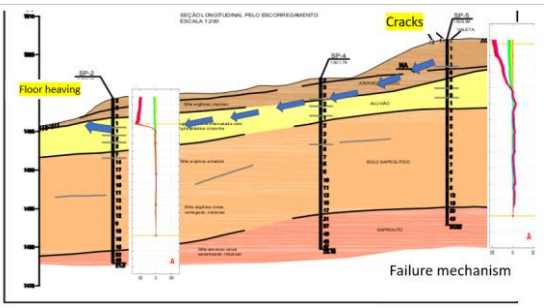

Figure 10. Illustration of the cumulative displacements in both ShapeArrays (left/right) according to the geological profile and installation site. Pathologies (cracks at the top and school floor heaving at the bottom). Location of vibrating wire piezometers and assumed position of the water table (NA) according to piezometric results. Understanding of the failure mechanism. (blue arrows).

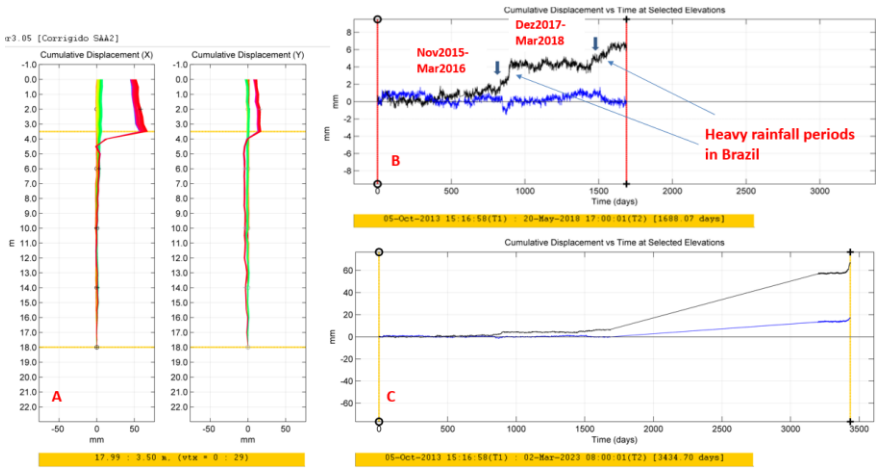

Figure 11. A) Cumulative displacements in the X (preferred direction of displacement) and Y axes of SAA1; B) Cumulative displacements in X (black) and Y (blue) axes over time at 3.5m depth, emphasizing acceleration during heavy rainfall; C) Cumulative displacements in X (black) and Y (blue) axes over time at 3.5m depth from 2013 to 2023.

3.3.1 Vibrating wire piezometers

The vibrating wire piezometers had a brief operational period due to technical issues. Data collected during this time was accurate. PZ1 and PZ2 showed consistent values with assumed groundwater levels from geotechnical investigations (Figure 12). Despite the short period, PZ1 detected minor variations during the initial high rainfall period (Nov/2013 to Mar/2014), indicating increased pore pressures during peak rainfall and subsequent decrease. This is likely due to colluvium layer saturation, increasing self-weight and loading on adjacent alluvium layer.

Barometric variations may also influence these changes.

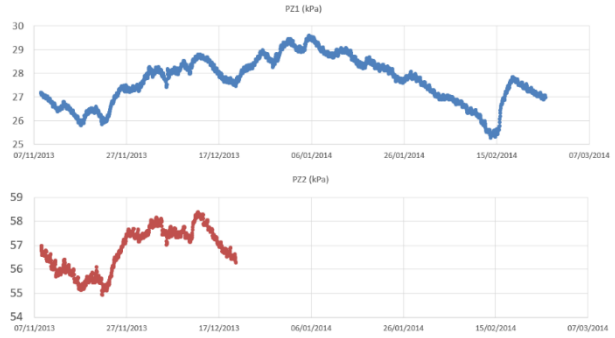

Figure 12. Pore pressure data recorded by vibrating wire piezometers (while operational).

3.3.2 Rain gauges

Rain gauge data from CEMADEN, a governmental institute tracking environmental data and natural disasters nationwide, was integrated with geotechnical monitoring from the pilot project. This enhanced landslide risk forecasting by correlating rainfall with soil stability. The data reveals annual rainfall and temperature patterns over 30 years (Figure 13), aiding in identifying regional wettest/driest and hottest/coldest periods.

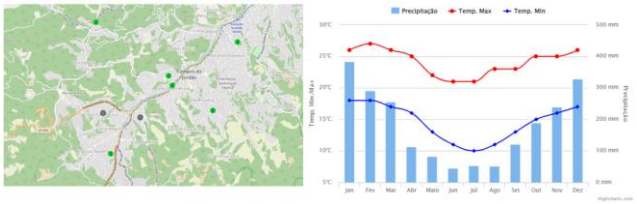

Figure 13. Left- Rain Gauge location (Green circles); Right - the average behaviour of rainfall (blue histogram) and temperature (min-blue line/max- red line) throughout the year at Campos de Jordão city– Source: CEMADEN.

4 CONCLUSIONS

1. Geological Behaviors in Brazil and the UK: Despite similar monitoring principles, distinct geological responses and context were observed.
   - Brazil: Revealed slow, 'creep' type landslide characterized by discrete movements.
   - UK: Showed high-magnitude displacements and faster landslide evolution.

2. Role of Automated Monitoring: Automated systems efficiently correlate rainfall with displacement rates, crucial in both cases.
   - Correlation with Rainfall: established over multiple seasonal cycles, illustrates the critical role of prolonged and intense rainfall as triggers for landslides.

3. Decision-making between Manual and Automated Monitoring: Hinges on project-specific factors.
   - Cost-effectiveness of Automation: Automated monitoring emerged as more cost-effective despite challenges faced (importation fees and taxes in the Brazilian case)

4. Integration of Geotechnical and Meteorological Data: Enhances effectiveness of preventive and corrective actions.
   - Improvement in Data Collection: Facilitates better correlation with rainfall, surpassing limitations of manual methods.

5. Challenges and Maintenance: Vulnerability of instruments and financial constraints emphasize the need for ongoing management.

6. Importance of Integrated Data for Understanding Geological Events: Integration of geotechnical and meteorological data crucial for comprehending slope stability dynamics.
   - Advancement in Research: Enables further exploration of rainfall, infiltration, and soil suction dynamics, expanding understanding of slope stability.

7. Contribution to Risk Management and Future Projects: Insights gained contribute significantly to risk management in slope stability, informing approaches for future projects in different regions and scenarios.

Assessment of geotechnical properties using optimisation methods

Évaluation des propriétés géotechniques par des méthodes d'optimisation

M. Stãnciucu*, I. Mircea
University of Bucharest, Romania
**stanciucumihaela@yahoo*

ABSTRACT: The paper presents the results of the complex geotechnical evaluation of two sites situated on the alluvial plain of the Dâmbovita River in Bucharest, Romania, where geotechnical investigations were completed with the geophysical survey. Despite short distances between sites, the results illustrate significant variabilities of sedimentary layers and consequently of geotechnical properties. To obtain local representative correlations, we applied in the first instance several well-known formulas, but the degree of fitness was inferior. In the second stage, we developed several evolutionary polynomial regression algorithms (EPR), a method of solving optimization problems, when the objective function is nonlinear. The new predicted values were analyzed using statistical parameters and residual analysis. Thus, we obtain new formulas for each layer, allowing more precise correlations of geotechnical and geophysical parameters inside the sedimentary alluvial structure, by reporting to the relations proposed in the literature.

RÉSUMÉ: L'article présente les résultats de l'évaluation géotechnique complexe de deux sites situés sur la plaine alluviale de la rivière Dâmbovita à Bucarest, en Roumanie, où les études géotechniques ont été complétées avec l'étude géophysique. Malgré de courtes distances entre les sites, les résultats illustrent des variabilités significatives des couches sédimentaires et par conséquent des propriétés géotechniques. Pour obtenir des corrélations représentatives locales, nous appliquons en premier lieu plusieurs formules bien connues, mais le degré de fitness était très faible. Dans un second temps, nous avons développé plusieurs algorithmes de régression polynomiale évolutive (EPR) qui est une méthode de résolution de problèmes d'optimisation, lorsque la fonction objective est non linéaire. Les nouvelles valeurs prédites ont été analysées à l'aide de paramètres statistiques et d'analyses résiduelles. Ainsi, nous obtenons de nouvelles formules pour chaque couche, permettant des corrélations plus précises des paramètres géotechniques et géophysiques à l'intérieur de la structure alluviale sédimentaire, par rapport aux relations proposées dans la littérature.

Keywords: Evolutionary polynomial regression; alluvial deposits; lacustrine.

1 INTRODUCTION

The two sites we refer to (A and B, North and South) are located in the alluvial plain at small distances from the canalized course of the Dâmboviţa River the middle of Bucharest City.

In this research we considered three of the superficial layers, starting from the surface of the terrain, as:

(I) the upper cohesive (7-9m thickness) composed mainly on silty clays;

(II) the middle noncohesive, consisting of sands and fine gravel of 13-30m thickness with thin cohesive intercalations, and

(III) the deeper lacustrine clays, which were partially opened on 15m to 40m.

On each site geotechnical investigations (boreholes and laboratory analyses) were executed in tandem with geophysical survey works (cross-hole and down-hole).

2 CURRENT CORRELATIONS

Estimation of the density layers based on geotechnical usual practices is a very difficult task in case of under consolidate cohesive and noncohesive sedimentary deposits.

In consequence, realistic assessment of relative density through correlation with various in situ investigation results represent the only path to evaluate this important geotechnical parameter. One of the very few such correlations is given by Mayne and Schneider, (1999), which evaluates the relative density of soils ρ (g/cm^3) as a function of shear wave velocities Vs (m/s) and depth z (m):

$$\rho = 0.85\, log(V_s) - 0.16\, log(z) \qquad (1)$$

We apply this correlation for both sites A and B, but the fitting of results with measured data is poor considering the coefficient of correlation $0.2 \leq R^2 \leq 0.3$, fact that may be visually observed also in Figure 1.

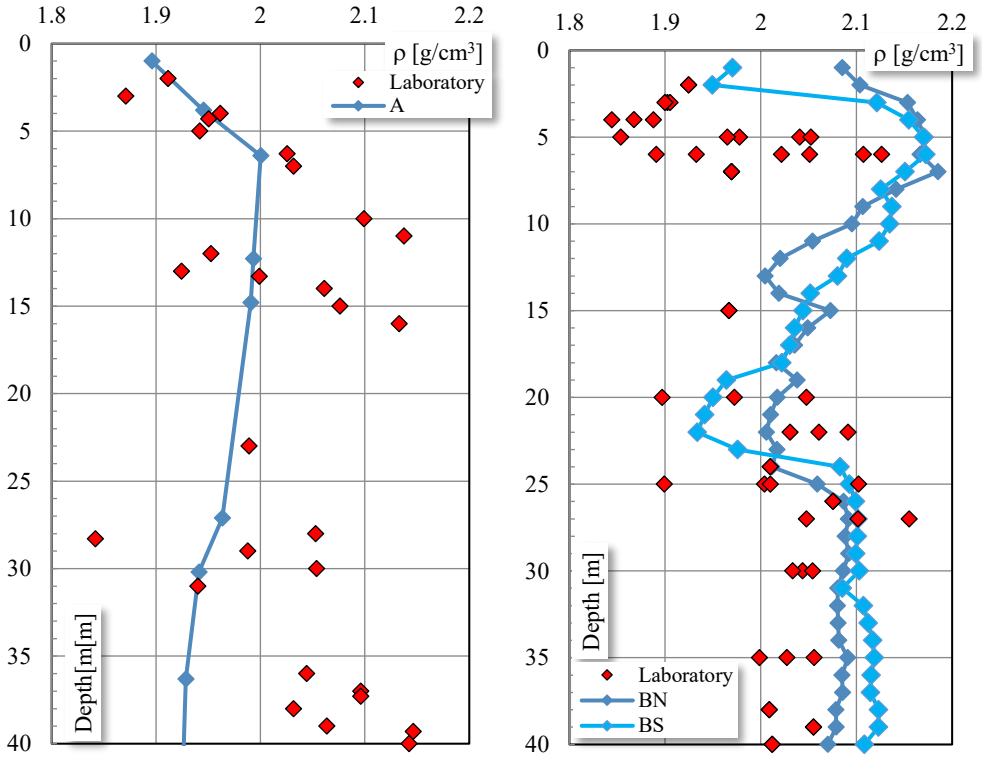

Figure 1. Variation in depth of measured and calculated values of relative density of soils, formula (1).

3 EPR MODEL CONSTRUCTION

3.1 Theoretical frame of EPR models

The mathematical model proposed for this paper is based on evolutionary polynomial regression (EPR) which is a method intensely used in geotechnics in order to find polynomial structures with an output-dependent variable Y and a set of independent variable X (Clegg et al, 2005; Keramati et al, 2014; Rezania et al, 2009).

The function can be written as:

$$Y_{N\times 1} = F(\alpha_{1xk}, X_{N\times m}) \quad (2)$$

where F is a function that will be determined using input – output data and $\alpha_{1\times k} = [a_0\ a_1\ a_2\ \dots\ a_n]$ is a vector with $k = n + 1$ parameters. For a matrix of inputs considered as $X_{N\times m} = [X_1\ X_2\ \dots\ X_m]$ and a matrix of exponents whose elements can take values within user–defined bounds, $E_{n\times m}$, can be defined n vectors whose elements are products of independent inputs X as:

$$Z^i_{N\times 1} = X_1^{E(i,1)} \cdot X_2^{E(i,2)} \cdot \dots \cdot X_m^{E(i,m)}, \quad i = 1, \dots, n \quad (3)$$

Thus, a matrix equation results:

$$Y_{N\times 1}(\alpha, Z) = Z_{N\times k} \times \alpha^T_{k\times 1} \quad (4)$$

where $Y_{N\times 1}(\alpha, Z)$ is the least squares estimate vector of the N target values.

To successfully determine the optimal values of the exponents, the genetic algorithm is recommended. This algorithm represents a method of solving optimization problems, especially when the objective function is nonlinear. The process consists of generating a population of individuals who are used as parents to produce a new generation through mutations and crossover techniques. The algorithm is used to obtain an equation that ensure the best possible fit of the data. Then, adjustable parameters a_i, $i = 0, 1, \dots, n$, can be determined by the linear square's method. The estimated equation of regression will be evaluated using the determination coefficient expressed as:

$$R^2 = \frac{\sum_i (\hat{y}_i - \bar{y})^2}{\sum_i (y_i - \bar{y})^2} \quad (5)$$

where $\hat{y}_i$ is the estimated value of the output of the process, y_i is the value of a dependent variable and $\bar{y}$ is the mean of the variable y. As R^2 it increases with the inclusion of several variables, the coefficient of determination is adjusted accordingly:

$$\bar{R}^2 = \frac{n-1}{n-p} R^2 - \frac{p-1}{n-p} \quad (6)$$

where n is the number of observations and p is the number of independent variables.

Another statistically important parameter is the residual standard error which is a measure used to assess the precision of the predictions. Regression testing consisted of studying the dispersion analysis, the *F - test* of global significance and the t-test. Thus, if *Significance F* has a value lower than the established significance threshold, then the null hypothesis of the statistic F is rejected. Also, for the *t - test*, a value of *P-value* lower than the significance threshold leads to the rejection of the nullity hypothesis (Clocotici, 2007). Residue analysis assumes the validity of an error normal distribution. This can be verified by studying the diagrams predicted values – residues, $(\hat{y}_i\ ,\ d_i)$, $i = 1, \dots, n$, where the normalized residuals d_i is given by (Montgomery et al., 2003; Pimpan and Suwattee, 2009):

$$d_i = \frac{e_i}{s(e_i)} \tag{7}$$

in which $e_i = y_i - \hat{y}_i$ and $s^2(e_i)$ is the dispersion of the residue e_i, $i = 1, \dots, n$.

If there is an observation i with a large standardized residual ($|d_i| > 3$) then that observation is a potential outlier and can be excluded from the data set or analyzed in another subject of interest.

3.2. EPR models used for geotechnical data

In the next step, several EPS models have been developed and analyzed according to the procedure described above for all three layers, on both sites.

For the upper cohesive layer (I), the EPR model is given in Eq. 8. Specific values of the coefficients $a_{i, i=0,1,2..6}$, as the statistical parameters of regression model are exposed in Table 1 (Figure 2).

$$\rho = a_0 + a_1 \frac{{V_s}^2}{z} + a_2 \frac{1}{z^2 {V_s}^2} + a_3 \frac{1}{z} + a_4 \frac{V_s}{z^2} + a_5 \frac{V_s}{z} + a_6 z V_s \tag{8}$$

Table 1. Regression coefficients and statistical parameters for layer (I), Eq. 8.

4 CONCLUSIONS

Depositional and spatial variability of recent alluvial deposits of the rivers could often mislead the assessment of geotechnical and geophysical parameters based on general correlation equations available in the literature. For this reason, the establishment of such particular relationships at the local scale of a geological or geomorphological formation is an important task in order to obtain precise and reliable results of investigations. Regardless of the quality, the amount or the diversity of investigations, the accuracy and the representativeness of such correlations are strongly influenced by the mathematical tool used for this purpose.

In this paper we examined geotechnical and geophysical investigations of two sites situated on the alluvial plain of Dâmboviţa River, Bucharest City. For the assessment of relative density based on shear wave velocity we elaborated an EPR model for every layer of the geological structure.

Using the genetic algorithm tool and the multidimensional linear regression method, equations were obtained that accurately describe the mathematical relationship of one of the most important geotechnical parameters (ρ) for every specific encountered layer. Finally, this may lead to a more precise approach in such regions where general relations are not relevant to the field situation

In these new EPR models statistical parameters extended between the limits exposed in Table 4, proved to be much appropriate than the well-known correlation formula ρ - Vs used in such situations.

Due to the fact that the accuracy of all mathematical models depends among other attributes, on the volume and density of the data used, it appears that it would be of scientific interest to elaborate a communitarian database associated with large geological and geomorphological units, in order to obtain a proper and realistic assessment of geotechnical parameters, which are the most important key parameters of serious and safe design of all civil or industrial projects.

Comparative assessment of liquefaction susceptibility of unconsolidated deposits

Évaluation comparative de la sensibilité à la liquéfaction des dépôts non consolidés

M. Stãnciucu*, I. Dogaru
University of Bucharest, Romania
**stanciucumihaela@yahoo.com*

ABSTRACT: Liquefaction may be considered one of the most dangerous physical-geological processes associated with the seismic hazard that affects almost all granular deposits as the fine ones, of low plasticity. The triggering mechanism depends on many factors that vary in space and time and may be clustered into three classes: two related to the soil properties (general settings of soil layers and geomechanical features) and one defined by earthquake characteristics. In this frame, determining the cyclic resistance of soils through in situ tests becomes an important and sensitive issue in assessing liquefaction susceptibility. This paper presents the evaluation of this seismic characteristic through several semiempirical correlations based on the most important in situ test: the Standard Penetration Test, executed on one of the most vulnerable structures which are the Holocene sedimentary alluvial deposits encountered all over the world in the proximity of every river or stream.

RÉSUMÉ: La liquéfaction peut être considérée comme l'un des processus physico-géologiques les plus dangereux associés à l'aléa sismique qui affecte presque tous les dépôts granulaires comme les plus fins, de faible plasticité. Le mécanisme de déclenchement dépend de nombreux facteurs qui varient dans l'espace et le temps et peuvent être regroupés en trois classes: deux liées aux propriétés du sol (paramètres généraux des couches de sol et caractéristiques géomécaniques de ses) et une définie par les caractéristiques sismiques. Dans ce cadre, la détermination de la résistance cyclique des sols par des essais in situ devient un enjeu important et sensible dans l'évaluation de la sensibilité à la liquéfaction. Cet article présente l'évaluation de cette caractéristique sismique à travers plusieurs corrélations semi-empiriques basées sur le test in situ le plus important: Test de Pénétration Standard, qui a été réalisé sur l'une des structures les plus vulnérables qui sont les dépôts alluviaux sédimentaires holocènes rencontrés partout dans le monde à proximité de chaque rivière ou ruisseau.

Keywords: Liquefaction, cyclic resistance, alluvial deposits.

1 INTRODUCTION

Presently, assessment of liquefaction susceptibility may be performed in several different ways (Anwar et al, 2016), either through: (i) probabilistic methods which evaluate the probability of liquefaction (PL), which is a quantitative measure of the severity of this possible phenomenon; (ii) artificial neural networks (ANN) which are conceptual models that estimates the relationships between the earthquake characteristics and the soil with liquefaction potential or, more common, (iii) deterministic methods which provide an alternative verdict of "liquefiable" or "un-liquefiable" based on the computed values of the safety factor against liquefaction (Fsliq).

In this paper we will approach the third method of research and we will assess the factor of safety against liquefaction (Fs_{liq}) as defined by Ishihara (1993) and Seed and Harder (1990):

$$Fs_{liq} = \frac{CRR}{CSR} = \frac{CRR_{7.5}MSF}{CSR} K_\sigma K_\alpha \qquad (1)$$

where the significance of terms is: *CRR* - cyclic resistance ratio; $CRR_{7.5}$ - cyclic resistance ratio for an earthquake with 7.5 magnitude; *CSR* - cyclic stress ratio induced by the seismic shake; *MSF* - magnitude scaling factor; K_s - overburden stress correction factor and K_a - correction factor for sloping ground.

Due to the fact that the estimation of both *CRR* and *CSR* may be done through numerous semiempirical correlations with in situ test results, we chooses to perform comparative calculations based on the investigations results of three formulas of Standard Penetration Test (*SPT*), which is not only the older in situ test, but also the most widespread.

2 GENERAL FRAME OF THE SITE

The triggering mechanism of liquefaction depends on (Youd and Perkins, 1978): (i) factors related to geo-mechanical properties of soil: grain size distribution (percent of fines-*FC*, median diameter - D_{50}) and properties derived from it (hydraulic conductivity, plasticity of fines), relative density - *Dr*, frictional skills of soils; (ii) factors related to general settings of deposits: depth of the layer, thickness, overburden pressure, confining stress, nature of bed and roof layers, underground water level, and (iii) factors related to earthquake characteristics: magnitude, peak ground acceleration, intensity and duration, the distance from epicenter. In this view, alluvial layers, especially the newest Holocene ones, are the most prone to this very damaging phenomenon (Giardini et al, 2013; Ranguelov et al, 2007).

The site we refer to is located at the plain of Danube river, at short distances (less than 100km) from one of the stronger European seismic areas - namely Vrancea Seismic Zone. The specific sedimentary structure for this fluvial system consists mainly in cross-laminated fine sands, silts and mud with thin peat lenses, alternated with massive fine sandy silts and gravel bars. On selected site, these Holocene deposits in fluvial facies extend from surface to 80m up to 120m depth, and have been investigated by eight geotechnical boreholes situated at distances that do not exceed 50m one from other, in continuous rotary dry drilling system, with temporary metal casing protection, due to the fact that the water table level is very close to the terrain surface.

3 THE SUITABLE ASSESEMENT METHODS

3.1 Determination of CSR

CSR is defined as the average cyclic shear stress induced by shear waves normalized by the initial vertical effective stress (Seed and Idriss, 1971), or "the seismic demand on a soil layer" (Youd et al., 2001) is usually expressed using the well-known formula:

$$CSR = 0{,}65\left(\frac{a_{max}}{g}\right)\left(\frac{\sigma_v}{\sigma_v'}\right)r_d \qquad (2)$$

where the significance of terms is: a_{max} - maximum horizontal ground surface acceleration, g (m/s^2) - gravitational acceleration, σ_v (kPa) - total overburden pressure at depth z (m), σ'_v (kPa) - effective overburden pressure at depth z and r_d (-) is the stress reduction factor. The latest term, r_d, may be obtain through several analytical methods (Liao and Whitman, 1986; Idriss, 1999; Cetin et al, 2004). In this application we used the relation of Youd et al. (2001), as follows:

$$\begin{aligned} r_d &= (131 - z)/131, \text{ for } z \le 9.15\text{m};\\ r_d &= (44 - z)/37, \text{ for } 9{,}15\text{m} \le z \le 23\text{m};\\ r_d &= (93 - z)/125, \text{ for } 23\text{m} \le z \le 30\text{m};\\ r_d &= 0{,}50, \text{ for } z \ge 30\text{m} \end{aligned} \qquad (3)$$

3.2 Determination of CRR

The calculations of CRR were performed through three deterministic methods, all based on SPT resistance, expressed as functions of corrected and normalized values $(N_1)_{60}$ and of clean sand corrected N-value $(N_1)_{60cs}$.

(I) In the first set of relations Seed et al. (1984) and Youd et al. (2001) expressed the cyclic resistance ratio for an earthquake with 7.5 magnitude, based on the following equation:

$$CRR_{7.5} = \frac{1}{34-(N_1)_{60cs}} + \frac{(N_1)_{60cs}}{135} + \frac{50}{[10(N_1)_{60cs}+45]^2} - \frac{1}{200} \qquad (4)$$

According to Youd et al. (2001), $(N_1)_{60cs}$ may be obtained as a function of fine content (*FC*) from:

$$(N_1)_{60cs} = \alpha + \beta(N_1)_{60} \qquad (5)$$

in which for $FC \le 5\%$, $\alpha = 0$ and $\beta = 1.0$; for $5\% < FC < 35\%$, $\alpha = exp\left[1.76 - \left(\frac{190}{FC^2}\right)\right]$ and $\beta = \left[0.99 + \left(\frac{FC^{1.5}}{1000}\right)\right]$, and finally, for $FC \ge 35\%$ $\alpha = 5.0$ and $\beta = 1.2$.

(II) In the second set of relations, Idriss and Boulanger (2004) express $CRR_{7.5}$ from equation (6):

$$CRR_{7.5} = exp\left(\frac{(N_1)_{60cs}}{14.1} + \left(\frac{(N_1)_{60cs}}{126}\right)^2 - \left(\frac{(N_1)_{60cs}}{23.6}\right)^3 + \left(\frac{(N_1)_{60cs}}{25.4}\right)^4 - 2.8\right) \qquad (6)$$

in which $(N_1)_{60cs}$ has been calculated based on Idriss and Boulanger (2008), formulas (7).

$$(N_1)_{60cs} = (N_1)_{60} + \Delta(N_1)_{60}$$
$$\Delta(N_1)_{60} = exp\left(1.63 + \frac{9.7}{FC+0.01} - \left(\frac{15.7}{FC+0.01}\right)^2\right) \qquad (7)$$

(III) Finally, Japanese Bridge Code-JR (1990) attests that $CRR_{7.5}$ is affected by the median diameter of grain size distribution curve (D_{50}) as follows for $0.05\text{mm} \leq D_{50} \leq 0.6\text{mm}$ (8):

$$CRR_{7.5} = 0.0882\sqrt{\frac{(N_1)_{60cs}}{\sigma'_v+0.7}} + 0.255log\left(\frac{0.35}{D_{50}}\right) + R_3 \quad (8)$$

in which dimensionless coefficient $R_3=0$ for $FC<40\%$ and $R_3=0.004FC-0.16$ for $FC \geq 40\%$.

In this third calculation, $(N_1)_{60cs}$ has been used based on Idriss and Boulanger (2008) formulas.

4 RESULTS

In the first instance, we performed a single calculation of CSR as described in paragraph 3.1., considering a value $a_{max}=0.30g$, according to Romanian Seismic Code, for the depths where simultaneously grainsize distribution tests and SPT tests has been made.

We continued by applying the three variants of calculation of $CRR_{7.5}$ as described in paragraph 3.2. After normalization of SPT values, with the aim of calculation of the equivalent clean-sand corrected blow count $(N_1)_{60cs}$, we applied the relations (5) and (7), which proved to offer similar results on the first 10m, and slightly to significant different from 10m to 30m depth.

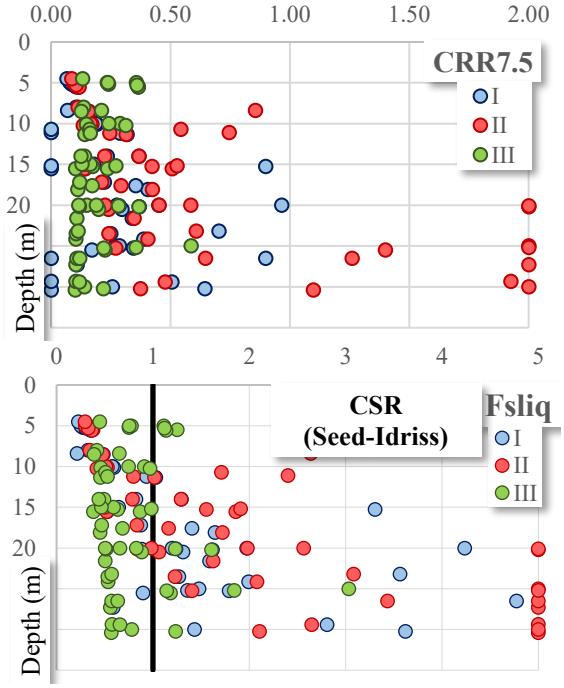

Figure 1. Comparative assessment of variation in depth of $CRR_{7.5}$ (up); factor safety against liquefaction according to Seed-Idriss (down).

In the following, we applied relations (4), (6) and (8), considering an event of magnitude 7.5, for which consequently the magnitude scaling factor is $MSF=1$, and a value of $K_\alpha=1$ for level ground. As for overburden stress correction factor K_s, we applied recommendations of Youd et.al (1996). The results are graphically presented in Figure 1.

In second instance, we recalculate CSR according to Eurocode 8, Part 5 and reevaluate the main parameter Fsliq through relations (4), (6) and (8), in the same conditions. The results are graphically presented in Figure 2, in which the differences ΔFsliq is given by the formula:

$$\Delta Fs_{liq} = Fs_{liq}^{Seed-Idriss} - Fs_{liq}^{Eurocod\ 8} \quad (9)$$

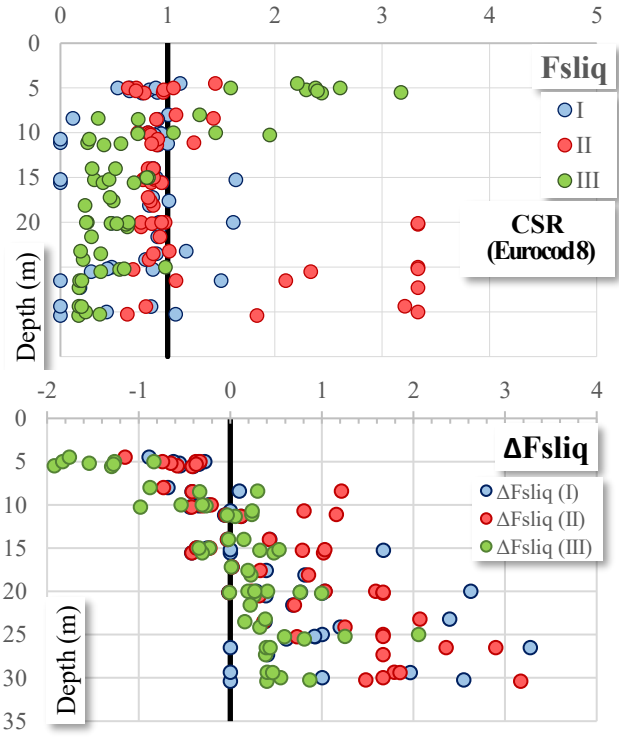

Figure 2. Factor safety against liquefaction according to Eurocod 8 (up); differences ΔFsliq between calculations (down).

5 CONCLUSIONS

A. Regarding the comparative calculation of the cyclic resistance ratio (CRR):

- as is presented in Figure 2 (up), the procedure II, Idriss and Boulanger (2004), provide the most overrated values compared to the other two set of results, while the Japanese Bridge Code-JRA (1990) - procedure III, offers the most conservative results;

- these ranges of values conducted at a safety profile against liquefaction mainly secure bellow 15m depth, according to procedures (I) and (II), while relations (III) extend the unsafety of the ground up to 30m depth;
- consequently, authors consider that procedures (I) or (II) are more suitable for shallow foundations, and procedure (III) is more appropriate for deep foundations.

B. Regarding the comparative calculation of the cyclic shear stress (CSR):

- the range of values resulting from Seed and Idriss formulas (Eq. 2) is strongly decreasing in depth and in consequence, the values Fsliq will directly increase in the same direction;
- on the other hand, the evaluation of CSR according to Eurocod 8 is influenced primarly by the fines percents and subservient by depth; this dependency makes that for the same set of data, the values Fsliq will decrease in the depth for most calculations;
- differences between these two procedures of calculation of CSR (Eq. 9), drive to large differences in term of factor of safety, wich varies $-2 < \Delta Fsliq < 3$, with prevalent negative values recorded above the depth of 15m (Figure 2 down).

ABSTRACT: Airport infrastructure plays a crucial role in regional and national economies, as well as during emergencies such as after major earthquakes. However, its functionality remains vulnerable to disruption caused by secondary earthquake effects, such as soil liquefaction. Hence, assess the risk posed to airport facilities by these phenomena becomes paramount for ensuring airport resilience and preparedness in the face of seismic events. This study, introduces a practical and rapid assessment tool for the risk analysis of airport infrastructure located in liquefaction-prone areas. Focusing on the Nestos delta in Greece, where the Kavala International Airport (KVA) is placed, a new methodology is proposed, which combines geological and remote sensing data to assess and map liquefaction susceptibility at local scale. The results reveal that a significant section of KVA's runway and taxiways are located on highly susceptible soils of abandoned meanders. Using FEMA's HAZUS methodology the study quantifies the impacts of liquefaction for a given seismic scenario. The analysis estimates a 49% probability of liquefaction for the highly susceptible class, with ground settlements predicted to reach 30cm. The results of the liquefaction hazard analysis are used for the risk assessment of the airport infrastructure, estimating a total direct loss of €22,2 million. The analysis is validated using datasets from three international airports that sustained extensive seismic damage in the past. This research serves toward safeguarding airport infrastructure in liquefaction-prone regions.

RÉSUMÉ: Les infrastructures aéroportuaires jouent un rôle crucial dans les économies régionales et nationales, ainsi que lors de situations d'urgence comme après des tremblements de terre majeurs. Cependant, sa fonctionnalité reste vulnérable aux perturbations causées par les effets secondaires des tremblements de terre, tels que la liquéfaction du sol. Par conséquent, évaluer le risque que ces phénomènes font peser sur les installations aéroportuaires devient primordial pour garantir la résilience et la préparation des aéroports face aux événements sismiques. Cette étude présente un outil d'évaluation pratique et rapide pour l'analyse des risques des infrastructures aéroportuaires situées dans des zones sujettes à la liquéfaction. En se concentrant sur le delta du Nestos en Grèce, où se trouve l'aéroport international de Kavala (KVA), une nouvelle méthodologie est proposée, qui combine des données géologiques et de télédétection pour évaluer et cartographier la susceptibilité à la liquéfaction à l'échelle locale. Les résultats révèlent qu'une partie importante de la piste et des voies de circulation du KVA est située sur des sols très sensibles de méandres abandonnés. À l'aide de la méthodologie HAZUS de la FEMA, l'étude quantifie les impacts de la liquéfaction pour un scénario sismique donné. L'analyse estime une probabilité de liquéfaction de 49 % pour la classe très sensible, avec des tassements au sol qui devraient atteindre 30 cm. Les résultats de l'analyse du risque de liquéfaction sont utilisés pour l'évaluation des risques de l'infrastructure aéroportuaire, estimant une perte directe totale de €22,2 millions. L'analyse est validée à l'aide d'ensembles de données provenant de trois aéroports internationaux qui ont subi d'importants dommages sismiques dans le passé. Cette recherche sert à sauvegarder les infrastructures aéroportuaires dans les régions sujettes à la liquéfaction.

Keywords: Liquefaction; airports; runways; risk analysis; remote sensing.

1 INTRODUCTION

Earthquakes pose a significant threat to vital infrastructure and communities, as they can induce damage due to ground shaking and ground failure. A common form of failure is soil liquefaction, a phenomenon in which granular material transforms

from a solid state into a liquefied state, as a result of decreased effective strength and increased pore pressure during seismic shaking (Youd, 1973). Generally, liquefaction occurs in fluvial and coastal regions and filled land areas, that contain shallow layers of low density, saturated and granular sediments (Youd and Hoose, 1978; Holzer, 1998; Tinsley et al., 1985). Ground settlement and cracking, lateral spreading and foundation failure caused by soil liquefaction have led to extensive damage to transport infrastructure and other lifelines in the past.

Airports are one of the most critical infrastructure, especially in the aftermath of devastating natural disasters, as they play a pivotal role in emergency response and recovery efforts. Previous seismic events in Niigata (Japan) in 1964, Loma Prieta (USA) in 1989, Nisqually (USA) in 2001, Tohoku in 2011 and the most recent one in Turkey-Syria in 2023 revealed the vulnerability of airports to both ground shaking and secondary earthquake effects like soil liquefaction. These factors can lead to damage and disrupt the normal operation of the airport. In particular, runways, taxiways, and ramp areas are susceptible to sinking or shifting, similarly to roadways, leading to substantial discontinuities or pavement cracking. Moreover, air traffic control, navigation, piping and fuel storage facilities, may incur damage from ground deformation or differential settlement. Given that most of the airport infrastructure has low tolerance to deformations, such damage can impede the transport of people and supplies, and result to destructive effects on the regional economy (Grogan and Vallerga, 2000). Therefore, it is crucial to have a comprehensive understanding of liquefaction mechanisms and their impact on airport environments, for ensuring that efficient mitigation measures are taken.

This paper introduces a practical and rapid tool for facilitating the risk analysis of airport infrastructure located in liquefaction prone areas. A new methodology is proposed for local-scale liquefaction assessement and mapping, which combines geological data and remote sensing techniques. This is applied on the Nestos delta in Greece, where the Kavala International Airport (KVA) is located. The results are utilised to estimate the permanent ground displacement (PGD), such as vertical displacements and lateral spreadings, due to liquefaction. Subsequently, PGD is used as the intensity measure for the risk analysis of the infrastructure. The liquefaction susceptibility and vulnerability assessment are validated using datasets from Oakland, King County (USA) and Hatay (Turkey) international airports.

2 METHODOLOGY

Considering the significant influence of depositional processes on the susceptibility of sediments to liquefaction, we have developed a methodology that enables the identification of surface geological units prone to liquefaction. This method involves creating a geomorphologically oriented map by integrating geological and remote sensing data, as outlined in the study by Taftsoglou et al. (2022). This procedure includes four phases (Figure 1).

In phase 1 geological and historical maps of the area, orthophotos and satellite images are collected in order to examine the geological formations and the geomorphological evolution of the plain. By combining these layers of information with the local topography (DEM) the mapping of geomorphological features is conducted in phase 2. Geomorphological formations, such as abandoned stream/meanders, point bars, oxbow lakes, dunes and lagoons are detected and traced during this step and a new geomorphological map is compiled. In phase 3 the classification of surficial geological units susceptible to liquefaction is performed. In particular, data provided by the geological maps and the new geomorphological map are used to define the age (<500yr, Holocene, Pleistocene) and the depositional environment of the geological units. Subsequently, the criteria by Youd and Perkins (1978) are applied to classify the geological units according to their susceptibility to liquefaction. In phase 4, a liquefaction susceptibility map is compiled, including four classes (Low, Moderate, High and Very High), where coastal and fluvial deposits are classified as high to very high susceptible units.

2.1 Liquefaction Susceptibility of KVA

KVA is located in the west side of Nestos delta plain in Thrace, Greece. The location of the airport along with the deposition of recent Holocene sediments and the presence of high potential onshore and offshore active faults capable to trigger large earthquakes in the area, were the motivational factors for this application.

By employing the proposed methodology, we noted a deficiency in the geological maps (HSGME) with regard to accurately representing Pleistocene and Holocene deposits. Using historical orthophoto maps dated before 1945 and Declassified Satellite images (KH-4) from 1960 and 1968 we were able to examine the geomorphological evolution of the plain and enrich the original classification of geological formations, mainly with the addition of fluvial and coastal deposits, such as abandoned river channels, oxbow lakes, point bars, dunes and deltaic deposits.

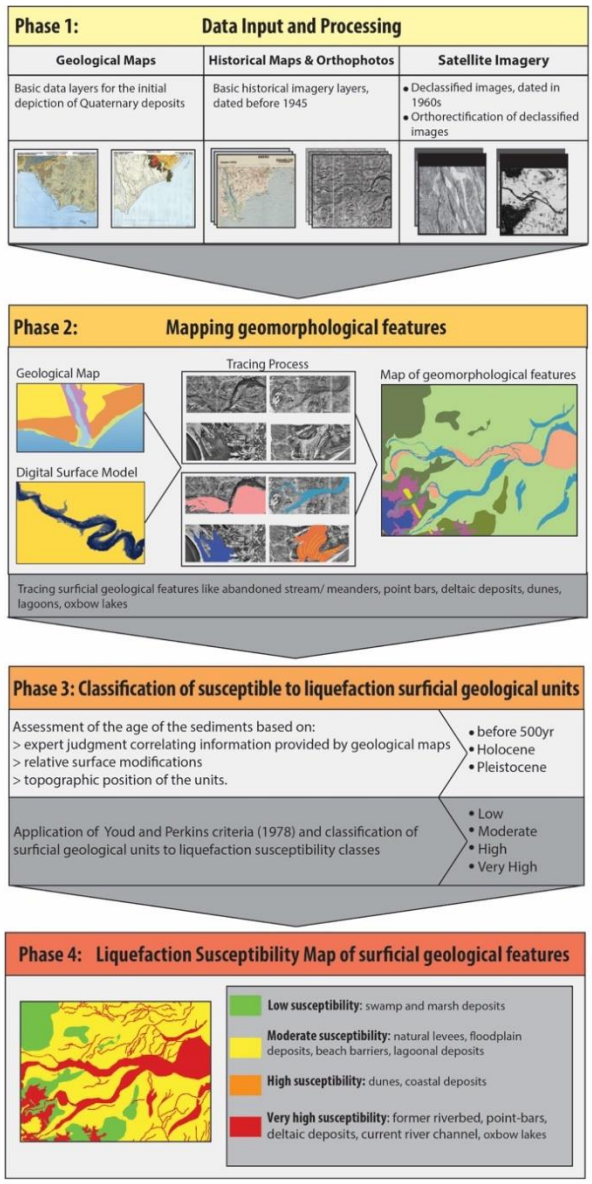

Figure 1. Methodology for assessing liquefaction susceptibility (Taftsoglou et al. 2022).

Another important observation was the extensive river network in the west side of Nestos plain, where old estuaries of Nestos river were formed. The airport was built during 1980s in this area, where land reclamation and modifications had already been occurred. Focusing on this location, the new geomorphological map reveals that a significant part of the airport's facilities and runway were built on an abandoned river branch of old estuaries and deltaic deposits (Figure 2). After the application of Youd and Perkins criteria, it was clear that part of the runway, taxiways and apron are located on a very high susceptible zone.

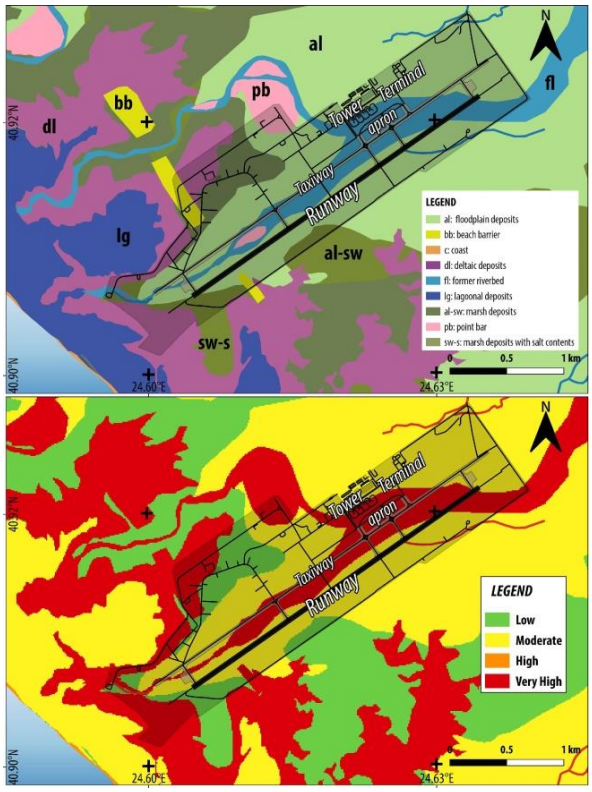

Figure 2. New geomorphological map and liquefaction susceptibility map of KVA.

2.2 Risk Analysis of KVA airport

The HAZUS (FEMA, 2022) methodology was adopted to evaluate the probability of liquefaction and the PGD based on the results described in section 2.1 and a representative seismic scenario based on SHARE and GreDaaS databases of seismogenic sources (Caputo et al, 2012; Giardini et al, 2013). An event of Mw 6.3 in the closest seismogenic source of Kavala-Xanthi-Komotini fault was selected and the ground motion map (PGA) was produced using REDAS software (Papatheodorou et al., 2023). Subsequently, the probability of liquefaction was assessed for each susceptibility category, taking also into account the amplitude of the ground shaking at the airport location (PGA=0.36g) and a groundwater depth of less than 6m. In particular, the probabilities for high and very high susceptibility classes were estimated to be 30 % and 49%, respectively (Figure 3).

The PGD in terms of ground settlements were evaluated following the criteria outlined by Tokimatsu and Seed (1987), while the lack of extended waterways in the vicinity of the infrastructure limited the expectations of lateral spreading phenomena. It is projected that areas classified as highly susceptible will experience ground settlement up to 15.2 cm, while those

categorised as very highly susceptible can reach 30.4 cm of settlement.

The vulnerability of the runway (3,000x45m), taxiways (4,000x35m) and apron (96,000m^2) is assessed based on the fragility functions that are included in HAZUS methodology (Figure 4). The probabilities of exceeding slight/moderate, extensive, and complete damage level were assessed for PGD values of 5.08 cm and 30.4 cm, as the runway, taxiways and apron are located on the moderate and very high susceptibility classes. Based on the probabilities of exceeding each damage state and a repair ratio of 0.1 for slight/moderate, 0.4 for extensive, and 0.8 for complete damage, average loss ratios of 0.125 and 0.590 were calculated for the two PGD values (Argyroudis, 2022). The reconstruction cost was considered equal to 180€/m^2 for the runway and 160€/m^2 for the taxiway and apron (Markovich, 2011). By multiplying the construction cost, average loss ratio and the corresponding area, the direct losses were estimated (Table 1). The total loss for this seismic scenario is assessed equal to €22,2 m. Yet, this is a conservative estimation assuming that liquefaction affects the entire runway, taxiway and apron. In reality, it is expected that ground failure due to liquefaction will likely be more localised, resulting in damage to a portion of these infrastructure.

Table 1. Estimation of direct losses for KVA.

Header	PGD (cm)	Area (m^2)	Loss ratio	Loss (million €)
Runway	5.08	122,247	0.125	2,8
	30.4	12,753	0.590	1,4
Taxiway	5.08	45,513	0.125	0,9
	30.4	99,489	0.590	9,3
Apron	5.08	17,605	0.125	0,4
	30.4	78,468	0.590	7,4

3 VALIDATION DATASETS

The liquefaction susceptibility assessment and risk analysis for the KVA airport are validated in the case studies of Oakland (OAK), Hatay (HTY) and King County (BFI) international airports, where the most extended liquefaction-related damages occurred to the runways areas. The estimated probabilities of liquefaction and PGD according to HAZUS-FEMA methodology, are consistent with the liquefaction occurrences after the earthquakes of Loma Prietta (1989), Turkey-Syria (2023) and Nisqually (2001) in the three airport locations (Table 2).

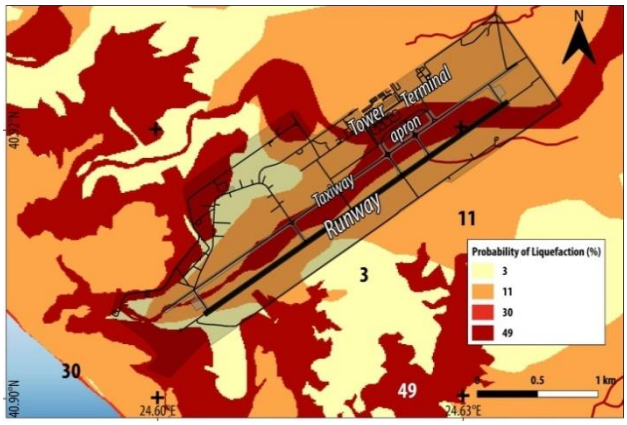

Figure 3. Probability of liquefaction in KVA area.

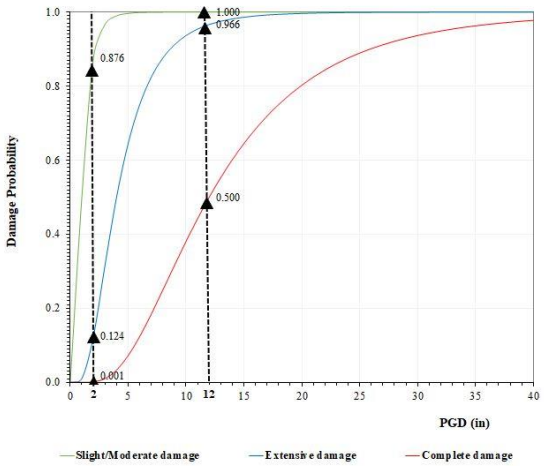

Figure 4. Fragility curves for the runway, taxiways and apron as a function of PGD (FEMA, 2022).

OAK is located on the eastern shore of the San Francisco Bay in western Alameda County. On the northeastern field is located the original part of the airport, built on a tidal marshland with deltaic and stream deposits of San Leandro Creek and fine-grained marsh sediments. The southwestern younger section was constructed on fill over tidal flats and shallow bay areas (Lajoie and Helley, 1975; Witter et al., 2006). During the 1989 Loma Prieta earthquake the extensive liquefaction induced damage resulted in property loss of at least $99 million (Holzer, 1998). According to the FEMA methodology, OAK predominantly falls within the very high susceptibility class, with a probability of 22.3% for liquefaction occurrences, corresponding to PGD of 30.4 cm (Table 2). Validation confirms the consistency between these estimations and the observed damage. Particularly, 900 m of the north-western runway was damaged by sand boils, together with cracking and buckling of the pavement and lateral spreading, while in the adjacent taxiway pavement cracks of 30 cm width and 15 cm vertical displacement were detected. Moreover, the west part of the runway shifted around 0.6 m to the south.

Liquefaction also occurred at the main terminal buildings and taxiways at the south end with pavement settlements up to 8 cm (Holzer, 1998; Seed et al. 1991).

HTY is located in the western part of Amik plain; on the formerly Amik Lake. During the 2023 earthquake doublet of Mw 7.7 and Mw 7.6 on East Anatolian Fault Zone (EAF) extensive liquefaction was observed over the former Amik lake floor, striking also HTY. In particular, the eastern part of the airport was affected by liquefaction shaking deformation phenomena (ground oscillation-lateral spreading) and or possibly triggered shallow slip of pre-existing neotectonic fault traces (Taftsoglou et al., 2023). Ground cracks and soil craters were detected on the runway and its closer area leading to closure of the airport for six days. In contrast to the east side, ground cracks of significant length in the western part of the airport were observed, related to surface fault ruptures of an unknown EAF segment, which cross Amik plain through this area. The results of FEMA's are consistent with the observed damages in this area, with almost all airport infrastructure classified to as highly susceptible to liquefaction, with probability of 98% and PGD of 15.2 cm (Figure 5).

The last case study is the BFI airport. After the 2001 earthquake of Mw6.8 in Nisqually valley, extensive liquefaction was observed at BFI (Nisqually Earthquake Clearinghouse Group, 2001; Bray and others, 2001), which is predominantly situated within an area highly susceptible to liquefaction, with a substantial portion of its runway built upon deposits from abandoned meanders that exhibit an extremely high susceptibility to these phenomena. The extensive liquefaction primarily affected the eastern runway, leading to the formation of ejecta-covered zones extending approximately 90 m in length. Ground surface settlements of up to 20 cm were occurred in this area. While a few isolated sand boils were observed along the western runway, a significant sinkhole measuring 1.2 m in width and 1.8 m in depth was reported at the northern end of the western runway. These phenomena were attributed to apparent ground oscillations, which resulted in the development of cracks in the pavement joints along both runways. Along the west edge of the western runway, a longitudinal crack measuring roughly 3 km in length and ranging from 1.2-2.5 cm in width was noted. Interestingly, the distribution of sand boils and pavement cracking appeared to align with the path of an ancient meander of the Duwamish River. As per HAZUS, the probability values for areas categorized as highly susceptible and very highly susceptible are 7.5% and 16.6% respectively, with estimated PGD of 15.2 cm and 30.4 cm. The observed damaged areas align closely with these estimations, indicating the accuracy in identifying the affected zones.

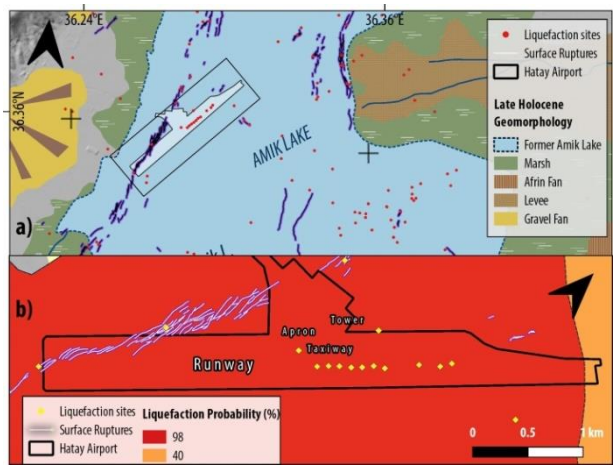

Figure 5. Liquefaction manifestations at HTY, after the 2023 earthquake doublet.

Table 2. Estimation of liquefaction probability (%) and PGD (cm) according to FEMA (2022) for different susceptibility classes (SC).

Airport	KVA	OAK	BFI	HTY	
PGA (g)	0.36	0.20	0.18	0.80	
Mw	6.3	6.9	6.8	7.7	
SC		**Probability (%)**			**PGD (cm)**
VH	49	22.3	16.6	100	30.4
H	29	11	7.5	98	15.2
M	11	3	1.6	41	5.1
L	3	0	0	15.5	2.5

4 CONCLUSIONS

This paper presents an efficient and rapid evaluation tool for assessing the risk of airport infrastructure located in liquefaction-prone areas, using geological and remote sensing data. The methodology is applied to the area where the Kavala International Airport (KVA) in Greece is built to produce a liquefaction susceptibility map. Subsequently, the probability of liquefaction and ground settlements are estimated for a representative seismic event. The direct losses for the runway, taxiways and apron are estimated to €22,2m. However, in reality, the ground failure caused by liquefaction is expected to be more localized, leading to damage in specific sections of this infrastructure and consequently resulting in reduced losses. The methodology is validated using three cases study airports which sustained damage due to liquefaction. The results show a good agreement between the observed and estimated damaged areas confirming the accuracy of the

proposed approach in identifying the susceptibility of areas prone to liquefaction. This research can inform decision making for mitigating risks due to liquefaction hazard in airports, and hence allow for continuous or very quick return to operations following seismic events.

ABSTRACT: Sand boil formation at the toe of river embankments is the typical manifestation of initiation and progression of an internal erosion process known as backward erosion piping, which is recognized to be a major concern in many river systems worldwide. In Italy, more than 130 sand boils have been detected along the Po River, many of them experiencing recurrent reactivations during high-water events. As a consequence of such widespread occurrence and the risk for the safety of the surrounding territory and human activities, the development of a sand boil database has been increasingly seen as an essential tool for identifying triggering conditions and giving priorities for the implementation of mitigation measures. In recent years, as part of the activities of the European Project LIFE SandBoil, a GIS-based web application was developed in order to catalogue the sand boils observed along the Po River. The database allows keeping records of a comprehensive set of information, e.g. geometry of the river embankments, subsoil stratigraphy, data on the sand boils, and characteristics of high-water events. Taking a piping-prone cross-section along the Po River as reference, the paper aims at describing the main features of this versatile and flexible tool, which is meant to help in understanding the conditions causing initiation and the sand boil dynamics, as well as to support flood risk management against backward erosion piping.

RÉSUMÉ: Les phénomènes de boulance à l'aval des digues fluviales sont le signe d'initiation et progression d'un processus d'érosion interne qui se développe au sein des fondations, dans les couches de sables. Ce mécanisme, qui est connu sous le nom d'érosion régressive, est de loin le mécanisme le plus dangereux pour la stabilité des systèmes d'endiguement de plusieurs grands fleuves européens. En Italie, plus de 130 cas de boulance ont été recensés le long du fleuve Pô, lors des crues enregistrées pendant les trente dernières années. En raison des fréquentes manifestations d'érosion discernables en surface et des dégâts très importants, tant matériels qu'humains, qui pourraient être générés par la rupture des digues, le développement d'une base de données est de plus en plus considéré comme un outil fondamental pour identifier les conditions d'initiation du processus et donner des priorités pour la mise en œuvre de mesures de mitigation. Cet article vise à décrire les principales caractéristiques d'une application Web basée sur un SIG, qui a été récemment développée dans le cadre des activités du projet européen LIFE SandBoil afin de cataloguer toutes les amorces d'érosion régressive identifiées le long du Pô. La base de données permet de stocker une grande quantité d'informations, telles que la géométrie de la digue, la stratigraphie du sous-sol, la charge hydraulique, ainsi que les principaux indices alertant sur le mécanisme d'érosion.

Keywords: Backward erosion piping; sand boils; river embankments; Po River; piping database.

1 INTRODUCTION

Backward erosion piping is a major concern for the stability of many river embankment systems worldwide (Van Beek, 2015), during high-water events. The initiation and progression of this phenomenon is typically revealed by the presence of one or multiple sand boils, landward of the river embankment. Indeed, when the hydraulic head difference across the water retaining structure increases so much as to result in excessive underseepage and high local gradients in the underlying aquifer, uplift of the blanket layer may occur and erosion initiates at the exit point. A bubbling spring of fluidized sand is thus observed on the ground surface, most often accompanied by ejection of eroded soil particles to form a sand volcano around the exit zone: sand basically looks like a boiling fluid, hence

the name "sand boil". Once started, the erosion within the aquifer develops progressively in the upstream direction, i.e. towards the river, resulting in shallow pipes beneath the river embankment that cause in turn settlements, with a significant risk for the structure stability. The different phases of the backward erosion piping process, from boiling phase to failure of the water-retaining structure, have been investigated and described by various authors and a detailed description can be found in Van Beek (2015).

In Italy, sand boils are very commonly detected near the toe of the Po River embankments. Indeed, over the last 30 years, more than 130 sand boils have been catalogued: most of them have been mapped in the main course of the river and suffer from recurrent reactivations during high-water events, but those located in the delta area reactivate also at relatively moderate water levels. It is also worth mentioning that sand boils observed along the Po River may be of remarkable size, with some sand volcanoes having an external diameter greater than 3 m. In such cases, abundant and continuous erosion is very likely to occur beneath the river embankment, thus posing a major threat to the structure integrity.

In the last few years, the Interregional Agency for the Po River (AIPo), the Italian authority in charge of flood protection and flood damage reduction in the Po River basin, has been very active in collecting as much data as possible in river segments exhibiting ground manifestation of backward erosion piping. Indeed, the synergic use of a wide variety of data, including geometric features, stratigraphic arrangement, geotechnical and hydraulic characteristics of the foundation subsoil, together with groundwater flow models and records of hydraulic loads in past activations, may undoubtedly help in identifying triggering conditions of piping phenomena, assigning hazard classes to the different river embankment sections, enabling the identification of priorities for mitigation interventions. As a result, a piping database may serve as a useful tool to effectively support flood risk management.

Following early attempts of systematic collection carried out by both the Po River Basin District Authority (AdBPo) and AIPo (Aielli et al., 2019), a GIS-based web application has been recently developed as part of the activities devised in the European project LIFE SandBoil (2020).

This paper describes the main features of this flexible and versatile tool, making reference to a representative cross-section of the Po River, which experienced repeated reactivations of a so-called "historical sand boil".

Figure 1. (a) Satellite view of the Po River basin and location of the selected cross-section; (b) Reactivation of a sand boil in Guarda Ferrarese, during the 2018 high-water event.

2 THE SELECTED RIVER SECTION

In order to provide a meaningful example of the typical stratigraphic features encountered in Po River embankments prone to piping, the cross-section located near Guarda Ferrarese (Figure 1(a)), in the lower catchment of the watercourse, is described herein. This river stretch has indeed a well-known history of internal erosion and sand boil activity, hence over the last years it has been selected to conduct field studies and numerical models for underseepage research (e.g. García Martínez et al., 2020a, 2020b; Marchi et al., 2021; Bertolini et al., 2022). According to the available records, the first evidence of piping was reported in 1994, when it caused severe damage to the road embankment running parallel to the river; more recent sand boil reactivations observed in this segment date back to 2014, 2018 and 2020.

During the 2014 high-water event, in particular, evidence of major underseepage, in the form of a high energy sand boil, was observed, with the throat of the sand boil moving outside the sandbag ring and thus requiring re-ringing alongside, as also shown in Figure 1(b).

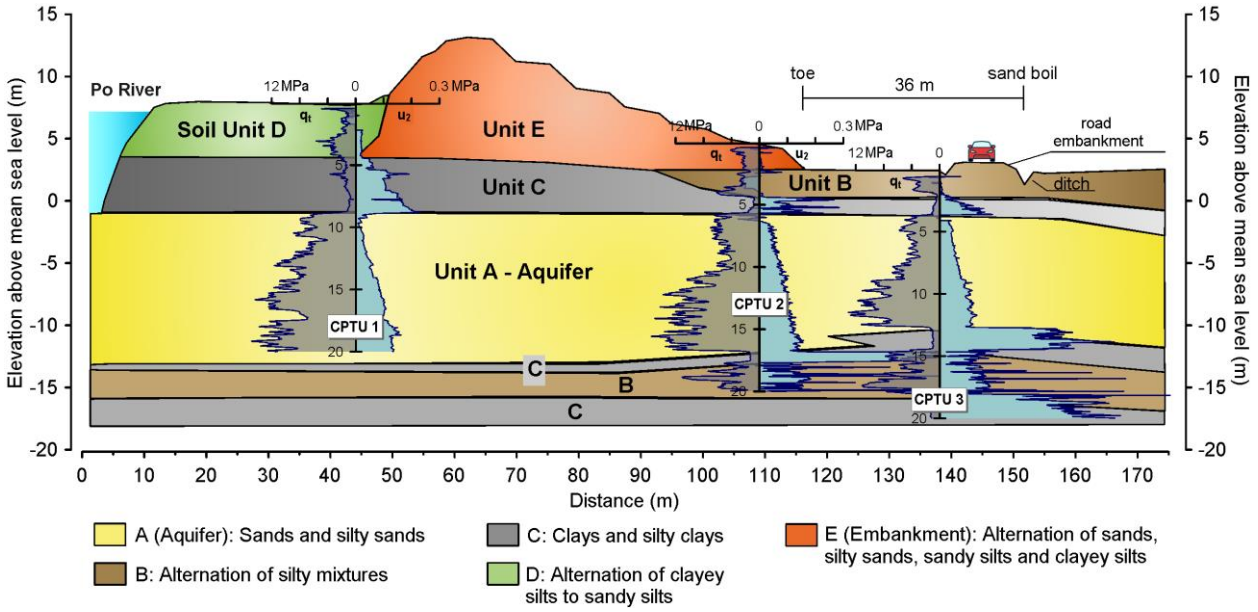

Figure 2. Stratigraphic model of the investigated cross-section in Guarda Ferrarese, with CPTU log profiles (vertical scale magnified). Modified from García Martínez et al., 2020a.

Table 1. Field measurements (net head on the river embankment, ΔH, and length of the vertical pipe, L) and local hydraulic gradients in the fluidized vertical pipe (i_{pipe}) during the monitoring period.

Date (d/m/year)	ΔH (m)	L (m)	i_{pipe} (-)
7/11/2018	4.65	1.46	0.53
9/11/2018	5.12	1.51	0.51
11/11/2018	5,82	1.54	0.50
20/11/2018	2.01	0.73	0.46

In 2018, despite a moderate flood intensity, a sizeable sand boil, having a 1m external diameter volcano, was recorded in a collector ditch as in previous activations. While the flood event was still underway, a comprehensive set of field measurements could be collected, encompassing sand boil geometry, grain size characteristics of the ejected sand, concentration of the sand–water mixture in the sand boil throat, together with a number of relevant hydraulic parameters, such as head loss in the vertical pipe, flow velocity, water discharge, all then interpreted in relation to the water level reached in the river (Marchi et al., 2021). Such field observations turn out to be key pieces of information when predictive models of piping initiation or progression (e.g. Robbins et al., 2020) are used. A selection of the collected hydraulic and geometrical data, namely the head loss ΔH between the river and the landside ditch, the length L of the vertical pipe, and the average gradient in the vertical pipe, i_{pipe}, is shown in Table 1. The vertical pipe was found to have a funnel shape, with a diameter of about 20 cm at the bottom to approximately 35 cm near the exit.

Figure 2 shows the stratigraphic model of the river embankment and the underlying subsoil, as obtained from interpretation of continuous coring boreholes and piezocone tests (CPTU) carried out along a cross-section drawn through the sand boil area. It is worth noting that the stratigraphic arrangement includes a 9–12 m thick sandy aquifer (Unit A), fed upstream by the river and overlain by a clayey soil unit (labelled as *C*) and a predominantly silty layer (Unit B), both forming a fine-grained soil cap typically referred to as *blanket* layer. The thickness of the blanket appears to reduce in proximity of the sand boil location, creating favorable conditions for backward erosion piping initiation. The susceptibility to backward erosion piping was also increased by the excavation of a ditch parallel to the road embankment, as shown in Figure 2.

The grain size analysis of the eroded soil, carried out on samples either collected in the volcano crater or obtained from the fluidized sand in the vertical pipe, provided evidence of a fine, uniform sand, with d_{10} and d_{50} in the ranges of 0.100–0.138 and 0.178–0.228 mm, respectively (Marchi et al., 2021).

Recent geotechnical campaigns carried out in this area have been especially meant to provide a better insight into the hydraulic parameters of the soil units forming the river embankment system, the attention being especially focused on the blanket layer and the aquifer involved in piping effects. Different experimental strategies and methods have been adopted (Lefranc tests, dissipation tests, CPTU-based empirical correlations) in order to obtain an accurate description of the subsoil permeability (k) and its spatial variability through the cross-section. Table 2

summarizes a few representative data for *k*. Details on this subject can be found in Bertolini et al. (2022).

Groundwater level monitoring through a few piezometers located landside (close to the toe, in proximity to the sand boil and approximately 400 m from the river embankment) revealed that the sub-artesian confined aquifer, corresponding to Unit A, is well synchronized with the river, whereas the phreatic surface in Unit B is governed by rainfall and evapotranspiration.

Table 2. Mean values of soil permeability k, as deduced from Lefranc tests and CPTU interpretation.

Soil units	Lefranc test *k* (m/s)	CPTU dissipation *k* (m/s)	CPTU correlation *k* (m/s)
A	8.9E-07	1.9E-06	9.1E-06
B	1.6E-06		1.0E-06
C		4.7E-09	4.6E-09

E			1.2E-05

3 THE SAND BOIL DATABASE

The database described in this paper has been developed within the ongoing European project LIFE SandBoil, whose main objective is the development of an innovative and sustainable technology for the mitigation of backward erosion piping in river embankments. The project is coordinated by the University of Bologna and involves the Interregional Agency for the Po River, Officine Maccaferri Italia, and the North Transdanubian Water Directorate as project beneficiaries.

The database is a web application, built in a geographic information system (GIS). The design of the database was coordinated by AIPo, who is also responsible for data collection and uploading. The application has been designed in such a way that it can easily accommodate data from various river basins, in addition to the Po, and thus become an international database of backward erosion piping phenomena observed worldwide.

3.1 The Database Structure

The database (Hortus, 2021) is basically organized into two main sections, corresponding to the river and the sand boil, respectively. The first section allows specifying the different rivers for which sand boils are defined and the relevant hydrometric stations where river water levels are measured. These measurements are then used as input data by the flood simulation algorithm to obtain the river levels in cross-sections where piping evidences are detected during flood events.

The sand boil section allows uploading a wide variety of information about each river segment affected by piping, with respect to the following items:

- the river embankment, in terms of geometric profile, embankment components, subsoil stratigraphic arrangement;
- the flood event causing the activation/reactivation of a sand boil, described in terms of duration, maximum discharge, data from nearby piezometers;
- the sand boil itself, in terms of geolocation, geometrical features of the sand boil, type of activity, characteristics of the ejected sand, and details on adopted emergency actions.

Figure 3 shows a GIS digital map of the Po River basin, with green dots representing the sand boil locations currently entered into the database.

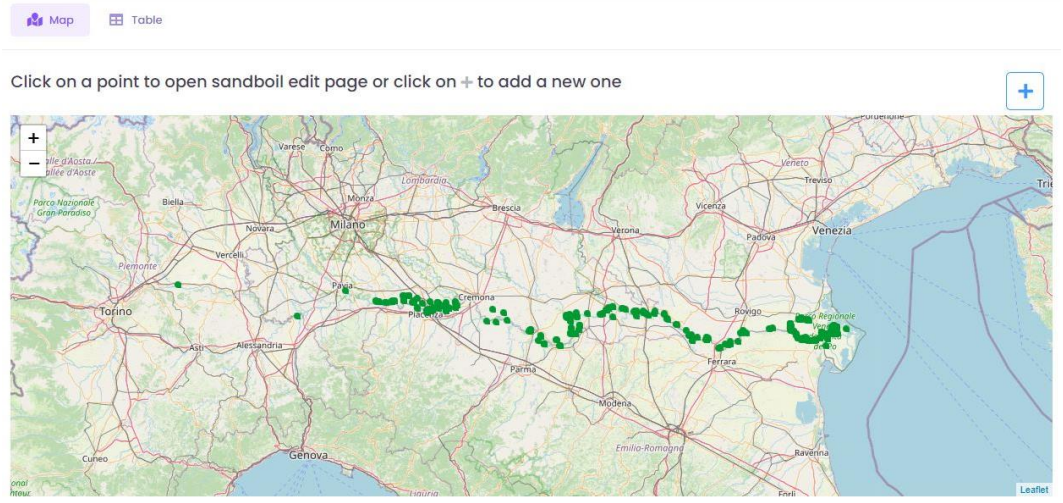

Figure 3. Map showing the location (green symbols) of the sand boils detected along the Po River (downloaded from the database).

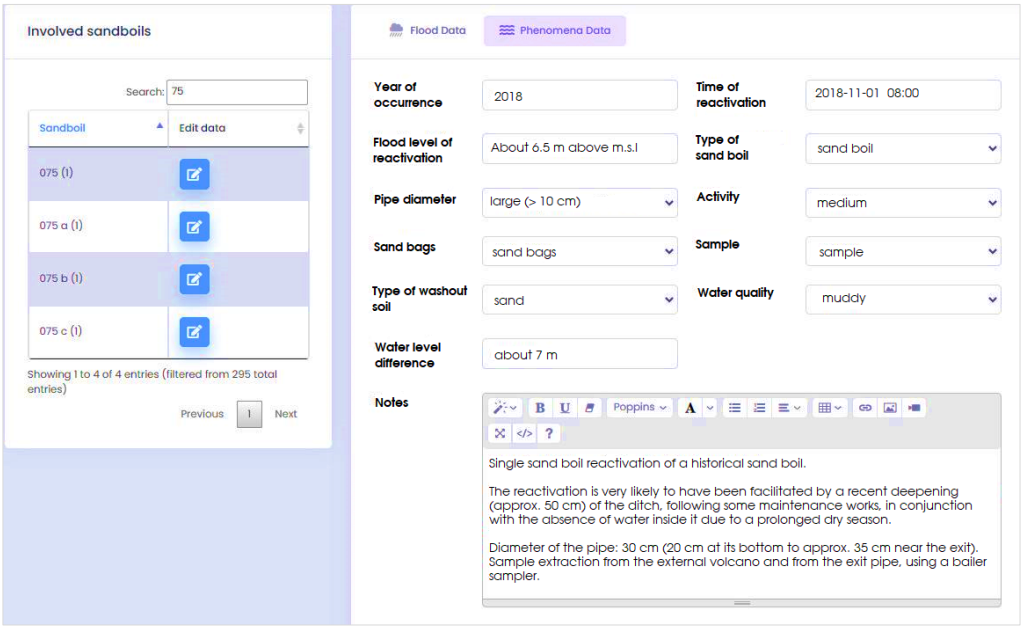

Figure 4. Example of data entry window in the web application, with reference to the sand boil No. 75 located in Guarda Ferrarese, reactivation of November 2018.

An example of the adopted interface for entering data and information is provided in Figure 4, with reference to the window containg data fields on sand boil geometry and piping activity during a high-water event. The entered data refers to the 2018 reactivation of the sand boil in Guarda Ferrarese.

3.2 Database Query

The data stored in the database can be easily exported or interpreted through graphs that allow analysing the effect of different flood events on a selected section along the Po River or comparing the response of different piping-prone river embankments during a specific high-water event. The sand boil management tool allows indeed creating two different types of graphs, referred to as "river graphs" and "historical graphs". The first type consists in a profile of the maximum high-water level reached along the watercourse during a flood event, with the indication of the river embankment sections that experienced some piping activity.

An example of historical graph is given in Figure 5, which provides an overview of the activations/non-reactivations observed at Guarda Ferrarese, for the flood events occurred from 2000 to 2020. The red bars are used to indicate activations or reactivations of the sand boil, the green ones are adopted when no evidence of piping was detected. In Figure 5, the horizontal red line reveals that the minimum water level causing past reactivations is equal to H_{min} = 7.63 m above m.s.l., whereas the maximum hydrometric level (H_{max} = 9.42 m above m.s.l.) for which no activation was observed is shown by the green line.

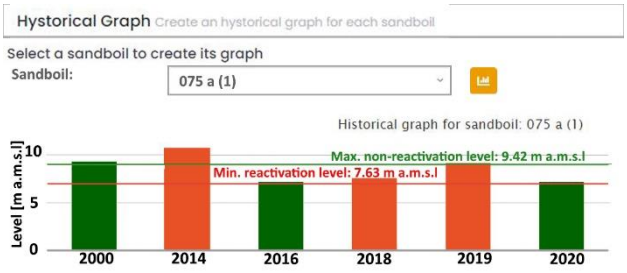

Figure 5. Example of data extraction in the form of "historical graph", with reference to the sand boil No. 75 detected in Guarda Ferrarese.

4 CONCLUSIONS

The paper has described the main features of a database that has been recently developed in order to catalogue the sand boils detected along the main Italian watercourse, i.e. the Po River. The database fields have been presented with respect to a well-documented river embankment section, located in the lower stretch of the Po River, which has experienced recurrent reactivations of a so-called historical sand boil. This flexible and versatile tool appears to be capable of providing an effective assessment of backward erosion piping hazard along the Po River and thus supporting flood risk management against this phenomenon.

ACKNOWLEDGEMENTS

The database presented in this paper was developed as part of the activities of the LIFE SandBoil project

"Natural-based solution to mitigate flood risk due to sand boils reactivations along the Po River" (Grant Agreement no. LIFE19 ENV/IT/000071), funded by the European Commission.

ABSTRACT: Understanding the complex behaviour of cracked ground surface resulting from the desiccation process in swelling soils has received significant attention in recent years. The formation of these cracks is attributed to the complicated interplay between soil comprising of plastic nature and atmospheric conditions; in some cases, the influencing depth of cracking can be extended to several meters below the ground surface. Therefore, the main goal of this research is to investigate the thermo-hydro-mechanical (THM) behaviour of cracked soil strata using CODE-BRIGHT. Results indicated that crack presence led to heterogeneous moisture distribution during the drying process with more significant desiccation in crack edges and walls. In addition, the inclusion of crack into an initially homogeneous soil stratum enhanced the heterogeneous ground deformations, with the most pronounced effects observed near the cracks. Remarkably, the findings indicate that cracks display varying behaviour under diverse climatic conditions. They tend to widen more in warmer climates, and conversely, they exhibit a tendency to close during rainy periods, which can be attributed to soil swelling.

RÉSUMÉ: La compréhension du comportement complexe de la surface du sol fissurée résultant du processus de dessiccation dans les sols gonflants a suscité beaucoup d'attention ces dernières années. La formation de ces fissures est attribuée à l'interaction complexe entre un sol de nature plastique et les conditions atmosphériques ; dans certains cas, la profondeur d'influence des fissures peut s'étendre à plusieurs mètres sous la surface du sol. Par conséquent, l'objectif principal de cette recherche est d'étudier le comportement thermo-hydro-mécanique (THM) des strates de sol fissuré à l'aide de CODE-BRIGHT. Les résultats indiquent que la présence de fissures entraîne une distribution hétérogène de l'humidité pendant le processus de dessiccation, avec une dessiccation plus significative au niveau des bords et des parois des fissures. De plus, l'intégration de fissures dans un substrat de sol initialement homogène a renforcé les déformations hétérogènes du sol, les effets les plus prononcés étant observés près des fissures. Remarquablement, les résultats indiquent que les fissures présentent un comportement variable en fonction des conditions climatiques diverses. Elles ont tendance à s'élargir davantage dans les climats plus chauds, et inversement, elles montrent une tendance à se refermer pendant les périodes de pluie, ce qui peut être attribué au gonflement du sol.

Keywords: THM analysis; soil-atmosphere interaction; desiccation crack; heterogeneous deformation; geohazard.

1 INTRODUCTION

Soil deformation is a complex phenomenon influenced by various factors, including environmental conditions and soil properties. The behaviour of soils in response to changes in moisture content plays a crucial role in numerous engineering applications, from geotechnical engineering to infrastructure design (Yazdani et al., 2024). Cracks that develop within the soil matrix introduce an additional layer of complexity, altering the deformation patterns and redistributing of soil moisture and mechanical stresses (Wang et al., 2022). Understanding the deformation behaviour of soils under wetting and drying conditions is essential for predicting potential subsidence, swelling, and subsequent structural damage (Ghorbani et al., 2023). In this context, the presence of cracks further complicates the deformation mechanism, as cracks provide preferential paths that intensify evaporation and facilitate infiltration (Luo et al., 2023).

In recent years, advanced computational techniques and experimental methods have enabled researchers to delve deeper into soil desiccation cracking (Sanchez et al., 2014; Wei et al., 2016; Guo et al., 2023). Numerical simulations provide insights into the complex interplay between crack geometry, soil

properties, and environmental factors. Moreover, laboratory experiments involving controlled environmental conditions contribute valuable empirical data for the validation and calibration of numerical models. Integrating these approaches facilitates a comprehensive understanding of the soil desiccation cracking mechanisms and their influencing factors. Prior studies have mainly focused on crack initiation and propagation, overlooking the complexities of how these cracks and soil surface deform under actual climate fluctuations. Hence, key aspects such as heterogeneous subsidence and swelling during warm and wet periods, induced by surface layer shrinkage and expansion, were not addressed. Furthermore, most researchs have focused on smaller scales, conducting controlled experiments on soil samples to observe crack behaviour, while larger field-scale cracks are influenced by significant climatic shifts affecting surface topography.

This study seeks to establish a more profound comprehension of the cracked soil deformation and moisture dynamics under the influence of real climate changes with THM analysis using the CODE_BRIGHT finite element program.

2 MATERIALS AND METHODS

2.1 Balance and constitutive equations

The THM model's equations employed in this study are rooted in the theoretical framework introduced initially by Olivella et al. (1994). Therefore, the model contains solid mass, water mass, energy, and momentum balance to consider the changes in soil porosity, liquid pressure, temperature, and displacements, respectively. Moreover, Fourier's and Darcy's laws are used as fundamental thermal and hydraulic constitutive equations of the model. The van Genuchten's model is also utilised to define the soil-water retention curve. In order to incorporate non-advective species fluxes within liquid phases, encompassing phenomena like water vapour diffusion in the gas phase and air diffusion in water, Fick's law is defined.

Regarding the mechanical aspect of the model, the Barcelona Expansive Model (BExM) is employed (Alonso et al., 1999). This advanced model, rooted in the Barcelona Basic Model (BBM) (Alonso et al., 1990), offers an encompassing framework to capture the sequential dynamics of soil shrinkage and swelling in response to wetting and drying cycles (Sadeghi and Ng, 2018; Ghandilou et al., 2023a, 2023b). This model can consider two levels of structure: micro and macrostructure. High suction changes experienced by fine-grained soils during climate variations induce notable alterations in both the micro and macrostructural arrangement of the soil, leading to volumetric changes. These alterations are primarily driven by the soil's response to fluctuations in moisture content (Ng et al., 2017).

At the micro level, fine-grained soils like clays have complex pore networks. As moisture declines, capillary forces dominate, leading to tighter particle packing and shrinkage. On the macrostructural scale, the cumulative microstructural modifications lead to volumetric variations. During hot, dry periods, the soil experiences notable shrinkage and subsidence, causing surface settlement. Conversely, when wet conditions return, the soil swells upon absorbing moisture, leading to surface elevation changes (Sadeghi, 2016; Ng et al., 2017).

2.2 Soil-atmosphere interactions

Soil-atmosphere interactions refer to the exchange of heat and moisture between the soil and the surrounding environment. Transfer of the moisture involves the movement of water vapour due to factors such as moisture content, temperature, and pressure gradients. The exchange of thermal energy occurs through conduction, convection, and radiation (Hemmati et al., 2012).

In analysing soil-atmosphere interactions, the fundamental theoretical framework involves gas, water, and energy fluxes. Evaporation is calculated using an aerodynamic diffusion equation, and the movement of water vapour in soil pores is induced by this evaporation. Hence, the advective flux of vapour by the gas phase is defined. Additionally, thermal energy exchanges are considered by determining sensible and convective heat flux to account for the transfer of thermal energy and internal energy of each phase (Jabbarzadeh et al., 2023; Tourchi et al., 2024).

2.3 THM model

THM analyses are conducted using the finite element program CODE_BRIGHT (Olivella et al., 1996). To cover all input parameters, the Boom clay is considered as geomaterial of the model as its THM parameters were widely reported (Alonso et al., 1998; Delahaye and Alonso, 2002; Sanchez et al., 2005; Gens et al., 2007). In addition, the meteorological data of Qom city from 2015 to 2017, including temperature, wind speed, precipitation, relative humidity, and radiation, are also used to consider climate changes effect on cracked soil deformation. This region was selected because of its vulnerability to significant subsidence caused by its arid and warm climate (Sadeghi et al., 2023).

Recent studies have provided a limited dataset regarding the dimensions of crack geometry observed in the field. While there are other experimental and numerical investigations available, they are not suitable for this study as small cracks are beyond the scope of this research. To make the most of the available data, a dimensionless parameter known as the crack ratio (C_R), which represents the ratio of crack width (C_W) to crack depth (C_D), is introduced. This parameter allows us to utilise crack dimensions from previous experimental and numerical studies as well as field observations. To select modeling scenarios, a crack depth of 1 m is chosen. The deeper desiccation cracks up to 6 m are also reported by Morris et al. (1992). To accurately determine the crack geometry, statistical analyses were conducted using a dataset of crack dimensions reported in previous studies, considering crack ratios ranging from 1% to 42%. The results of these statistical analyses indicate that the distribution of crack ratios follows a lognormal distribution, as depicted in Figure 1(a). This insight has enabled the creation of a probability density function (PDF) for the crack ratios, visualized in Figure 1(b).

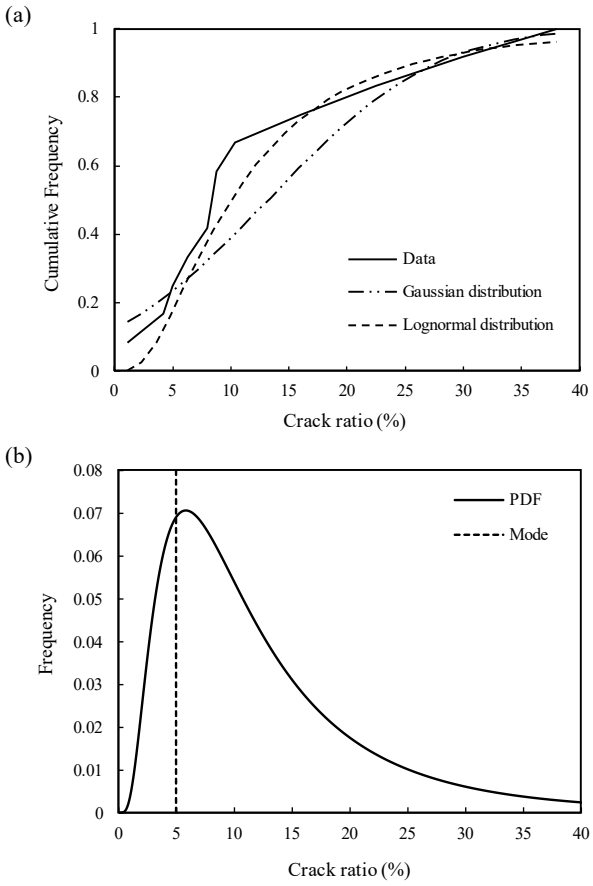

Figure 1. Statistical analysis of the crack ratio data.

Finally, the modeling scenario in terms of crack geometry was developed based on the obtained results. This scenario involves a crack with a depth of 1 m and a crack ratio of 5%, which is the peak of the PDF and shows a mode of data with the highest frequency. Once the crack shape has been established, the identified scenario is integrated into the numerical model to perform the THM analysis. This is accomplished by assigning the appropriate material properties, initial and boundary conditions. In this regard, the initial porosity is assumed to be 0.487, and the initial suction at the soil surface is set at 10 MPa. The suction value decreases linearly to a depth of 50 m, reaching a value of 0.4 MPa. Beyond this point, it declines with a different slope until it reaches the groundwater table at a depth of 90 m. To provide a visual representation, the schematic diagram of the crack geometry is depicted in Figure 2.

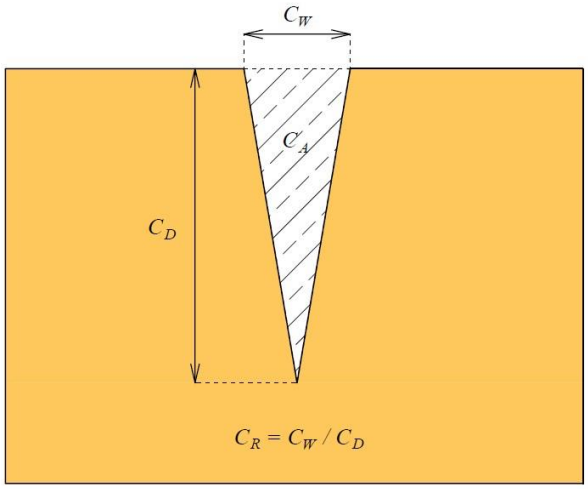

Figure 2. Schematic definition of parameters describing the crack geometry.

3 RESULTS AND DISCUSSION

3.1 Moisture distribution in the cracked soil

The soil maintains ongoing thermo-hydraulic interactions with its surrounding environment, a phenomenon that can be significantly intensified by the presence of cracks within the soil matrix. These cracks can act as conduits, amplifying processes such as water infiltration during rainfall and evaporation on warmer days. Therefore, the distribution of the degree of saturation (S_r) is visually represented in Figure 3 at three distinct time points: 100, 500, and 1000 days. These three selected days correspond to periods during the year when the weather is relatively warm, indicating the drying trend. However, the consecutive wetting-drying cycles before the chosen days have also influenced the moisture variations.

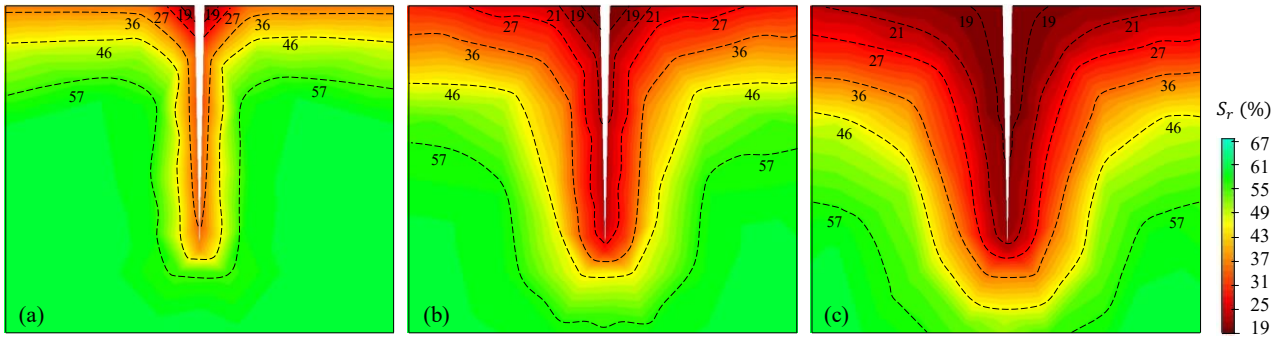

Figure 3. Spatial distribution of degree of saturation in cracked soil after (a) 100 days, (b) 500 days, and (c) 1000 days.

The results indicate that the presence of cracks leads to a heterogeneous S_r distribution, even within a homogeneous and isotropic soil layer. As illustrated in Figure 3(a), during the initial stages of the drying process, the cracked soil exhibits heightened desiccation along the edges of the cracks, while a relatively marginal drying effect is observed along the crack walls. With the progression of the drying period to the 500th day (see Figure 3(b)), the desiccation phenomenon intensifies, particularly within the cracked regions of the soil. This pattern underscores a key insight that within cracked soil, the edges and walls of the cracks are more susceptible to experiencing intensified desiccation under drying conditions. As observed, with the progression of desiccation, the contour lines deviate both horizontally and vertically away from the crack wall. This indicates that the presence of the crack exacerbates the reduction in soil moisture, both at the soil surface and in depth.

3.2 Heterogeneous deformation of the cracked soil under climate changes

The trend of moisture distribution in cracked soils can result in its non-uniform deformation under climatic variations, especially the uneven subsidence triggered by climatic warming. To explore this phenomenon, the deformed geometry of cracked soil is presented in Figure 4 for three distinct time intervals, after 100, 500, and 1000 days, compared to its initial state. As evident, the effect of soil desiccation and the consequent increase in evaporation lead to soil shrinkage and subsidence in the context of drying. This drying-induced subsidence not only affects the soil surface but also induces deformation within the crack geometry.

Notably, the findings demonstrate that the most substantial subsidence occurs along the crack edges, while the subsidence experienced by the soil surface diminishes with increasing distance from the cracks. These observations parallel the results of the moisture distribution within cracked soil, where the edges of cracks exhibited the most pronounced desiccation. Furthermore, as the drying process progresses, cracks widen and experience internal area expansion. This dynamic evolution of cracks' width and internal area alterations is visualised in Figure 5 with 100 days intervals. As evident from the results, the deformation of cracks is influenced by climatic variations in such a way that the crack deformation responds to changes in soil moisture content. With increasing soil moisture, cracks tend to expand, resulting in a reduction in their width and area. Conversely, decreasing soil moisture causes ground shrinkage, leading to their widening and increased area. As depicted in Figure 5, the changes in crack width exhibit a similar trend to those of crack area, although the variation in crack area is also influenced by the deformation of the crack walls. Consequently, this factor has contributed to a broader range of changes in crack area.

A noteworthy observation is that due to the soil's tendency to an equilibrium state, gradually the rate of the deformation diminishes. As evident, the rate of change in crack area exhibits a nonlinear relationship with time, following the trend line plotted in a logarithmic function. This proves that the deformation rate decreases nonlinearly over time. Given that the behaviour of crack width follows a similar trend as crack area, it can be inferred that the change in crack width may also follow this trend. According to Figure 5, crack with an initial width and area of 50 mm and 25000 mm^2 respectively, undergoes deformation. After 900 days, it reaches its maximum values of 114.5 mm and 55230 mm^2, indicating an increase of over twice the initial measurements. This substantial growth highlights the distinct deformation mechanism of cracked soil in comparison to uncracked soil. Coupled with climatic

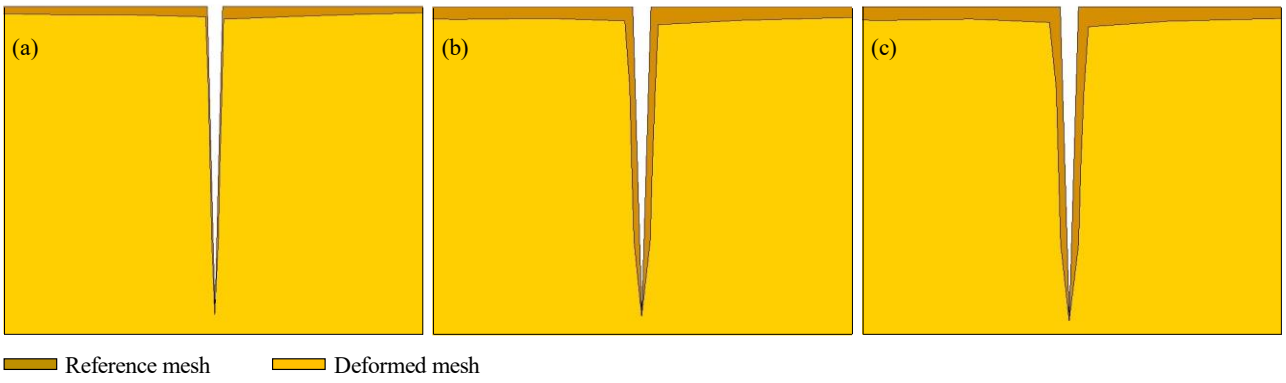

Figure 4. Heterogeneous subsidence of cracked soil under the influence of climate warming after (a) 100 days, (b) 500 days, and (c) 1000 days.

variations and global warming, which induce greater desiccation of surface soil layers, the phenomenon of soil cracking intensifies. This can result in heterogeneous subsidence of the soil surface, potentially leading to structural damages such as tilting, differential settlement, and structural cracks.

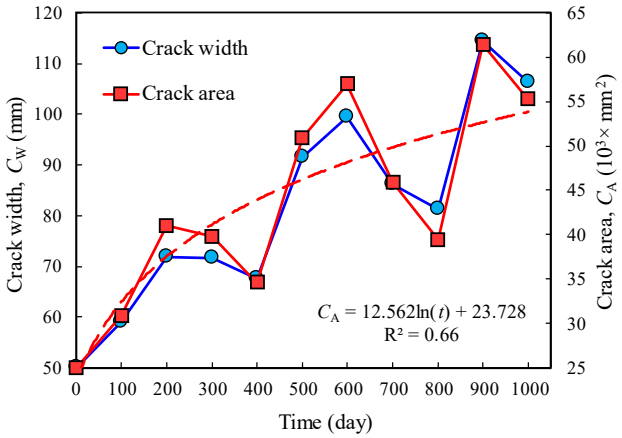

Figure 5. Variations in crack width and area with time under the influence of climate conditions.

4 CONCLUSIONS

This study focused on the THM analysis of desiccation cracked clayey strata, taking into account soil-atmosphere interaction by using real climate data from Qom between 2015 and 2017. The model incorporated various meteorological parameters like temperature, wind speed, precipitation, relative humidity, and radiation to investigate the effect of cyclic wetting-drying cycles on cracked soil behaviour. The characterization of crack geometry was achieved through statistical analysis of existing datasets from prior studies, which revealed a lognormal distribution for crack ratios. The examination of moisture distribution within cracked soil revealed a heterogeneous degree of saturation distribution. Notably, crack edges and walls experienced more pronounced desiccation, with a S_r of 19%. The behaviour of cracks under changing climatic conditions exhibited their sensitivity to moisture levels, impacting both their width and area. The findings highlighted a logarithmic trend in the changes of crack area and width, indicating a tendency toward an equilibrium state in deformation rates. Furthermore, the results underscored that cracked regions were more vulnerable to subsidence compared to uncracked areas, resulting in heterogeneous subsidence patterns in the cracked soils. Significantly, the study revealed substantial increases, exceeding twofold, in both crack width and area due to prolonged climate fluctuations.

ABSTRACT: Changes in water content and suction under climatic actions is one important process in several geotechnical issues, such as earth-structures deformation, foundation heave/settlement or slope failures seated in the vadose zone. In addition, under certain conditions, these changes may act as a forcing condition for the underlying saturated water column and control cyclic pore pressure changes at higher depths. The deterministic modelling of these effects requires considering soil-atmosphere thermo-hydro-mechanical interactions under long time high-frequency series. Associated computational cost appears quickly to be a limitation to this type of simulations, particularly when going to large geometry or regional analyses.This article shows two strategies to estimate the soil hydraulic response in time under climatic series handled by Fourier decomposition. These strategies present similarities with techniques used to analyse soil response under seismic actions and propose to define soil transfer functions relating the input (climatic time series) to the output (water content or suction/pore pressure variation at several depths).

RÉSUMÉ: Les changements dans la teneur en eau et la succion sous les actions climatiques sont un processus important dans plusieurs problèmes géotechniques, tels que la déformation des structures en terre, le soulèvement/affaissement des fondations ou les ruptures de pente situées dans la zone vadose. De plus, dans certaines conditions, ces changements peuvent agir comme une condition de forçage pour la colonne d'eau saturée sous-jacente et contrôler les changements cycliques de pression interstitielle à des profondeurs plus élevées. La modélisation déterministe de ces effets nécessite de considérer les interactions thermo-hydro-mécaniques sol-atmosphère dans des séries longues et hautes fréquences. Le coût de calcul associé apparaît rapidement comme une limitation à ce type de simulations, notamment lorsqu'il s'agit de grandes géométries ou d'analyses régionales. Cet article présente deux stratégies pour estimer la réponse hydraulique du sol dans le temps sous des séries climatiques traitées par décomposition de Fourier. Ces stratégies présentent des similitudes avec les techniques utilisées pour analyser la réponse des sols sous actions sismiques et proposent de définir des fonctions de transfert du sol reliant l'entrée (séries temporelles climatiques) à la sortie (teneur en eau ou variation de succion/pression interstitielle à plusieurs profondeurs).

1 INTRODUCTION

Expected scenarios of climate change point to a modification of the Intensity-Duration-Frequency curves (IDR) of precipitations, in which long periods of dryness will be suddenly interrupted by very intensive rainfalls (Heidari et al. 2020). This extreme phenomenon would rapidly increase the water content within a dry soil mass, leading to major failure probabilities. Modification of IDR may also play a significant role in earthquake-induced soil phenomena such as liquefaction and seismic slope stability (Keefer, 2002; Roback et al., 2018). Accounting for such effects requires estimation of water pressures or water contents within soil masses, under the whole climatic histogram.

Variations of pore pressures or water contents are governed by the mass balance of water, which results mathematically in a convection-diffusion equation. Under climatic actions, it is moreover coupled with the heat equation to model water phase changes and evaporation. These equations describe various diffusion processes of water, vapour and heat in porous

media (Stępniewski et al. 2011), which translate into an attenuation and shift of phase at the depth of surface fluctuations. Under simplifying assumptions, they can be reduced to a system of two diffusion equations that can be solved using classical techniques, avoiding direct-integration schemes (Canuto et al., 2007). For instance, spectral methods by mode decomposition, potentially involving the use of the Fast Fourier Transform (FFT, Cooley and Tukey, 1965). These techniques can be used to reduce the order of the problem by assessing, in the frequency domain, problems unmanageable within the limit of the current computational capacity (long time-periods – predictions under climate change – and large areas – city, hydrological basins). They also present the advantage of handling input defined as a frequency spectrum, avoiding working with time series of climate change scenarios.

Reduction of the computational cost by suppression of the time dimension allows to develop a computational framework to estimate the probability of occurrence of water pressure/water content above thresholds related to soil failure, for a prescribed spectrum of climatic variables. Moreover, computational effort reduction allows considering uncertainties involved, for instance, in the soil mechanical properties, acting loads, climate-related variables, etc.

This article examines two approaches to develop reduced order models capable to predict the evolution of water content in soils, denoted as θ, with time. The first approach is based on the development of transfer functions between climatic variables and θ. These functions are obtained as the ratio between the Fourier amplitude spectra of both θ and the climatic variables. The second approach has been oriented to study the capabilities to predict θ by means of a parametric transfer function. The latter has been developed by considering specific boundary conditions in terms of flux.

2 CLIMATIC VARIABLES AND WATER CONTENT IN THE SOIL

Records of a monitoring campaign carried out in an upper horizontal soil layer during seven years (max. depth 1 m, Calvet et al., 1999) have been analysed. They contain the time-history evolution of the soil water content at several depths. In addition, a series of climatic variables of the area have also been recorded.

2.1 Water content in the soil

Figure 1 shows the time evolution of θ with depth, in the analysed soil profile. Specifically, θ has been recorded at ten depths, the shallowest being at 5 cm from the surface whilst the deepest is at 95 cm.

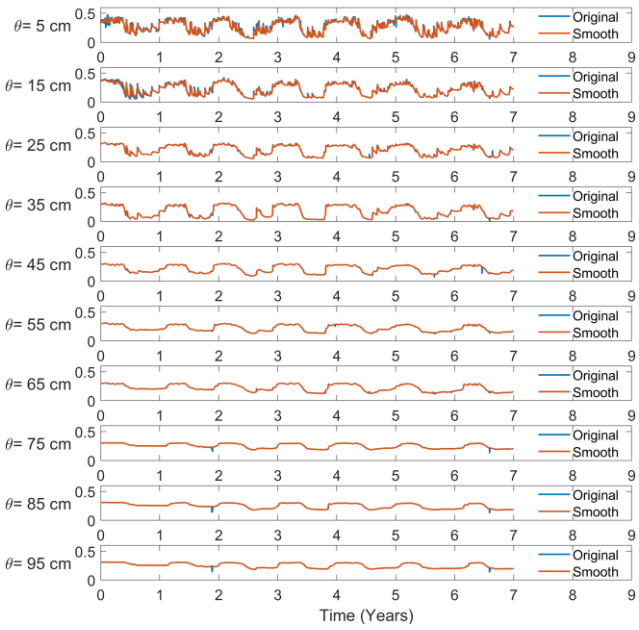

Figure 1. Water content in soils.

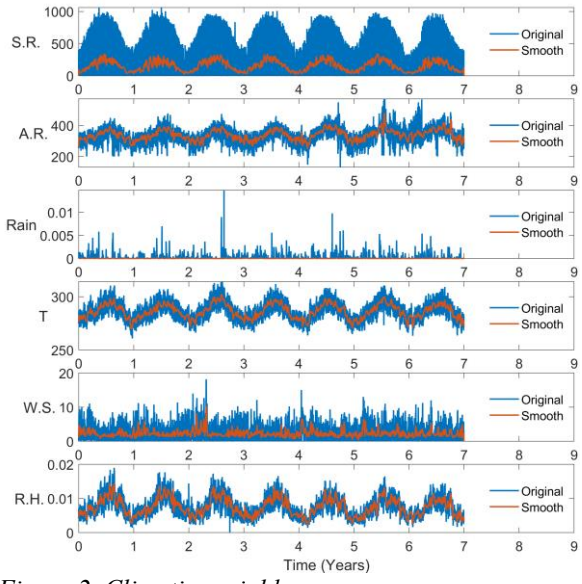

Figure 2. Climatic variables.

Due to some problems with the recording devices, some gaps in the data have been observed. They have been interpolated using a smooth function around a given data gap.

2.2 Climatic variables

Data on solar and atmospheric radiation (S.R. and A.R., respectively), rainfall intensity, temperature (T), wind speed (W.S.) and relative humidity (R.H.) have been collected in the aforementioned campaign (Climate-related variables); Figure 2 shows the time-history evolution of them. This figure also shows data

smoothing to analyse how the mean evolves over time. Data smoothing has not been applied to the time-history climate data.

3 TRANSFER FUNCTION ANALYSIS

The previous records can be seen as input (Climatic variables) and output variables (water contents at depth), namely I/O variables. Based on this perspective, these records have been used to develop TFs capable of making forecasts considering climatic variables as input. These transfer functions have been obtained as ratios between the Fourier's transform of the recorded I/O variables. Specifically, this approach seeks to characterize θ from a transfer function, *TF*. This function is obtained by considering the Fast Fourier transform (FFT) of θ and the Fast Fourier transform of a single climatic variable. The following equation shows the mathematical form that characterizes a *TF*:

$$TF_{i,j}(\omega) = \frac{f_{i,j}(\omega)}{g_j(\omega)} \quad (1)$$

where $f_{i,j}(\omega)$ is the Fourier amplitude spectrum of θ_i; $g_j(\omega)$ is the Fourier amplitude spectrum of the climatic variable g; subscripts i and j stand for a specific depth and a given climatic variable, respectively. The main hypothesis is that, given the time history of θ and a specific climatic variable, g_j, the *TF* obtained through Equation (1) can be used to approximate the Fast Fourier Transform of the Soil Response Parameter (SPR) to another record, g_k:

$$f_{i,k}(\omega) \approx TF_{i,j}(\omega) * g_k(\omega) \quad (2)$$

To validate this approach, the recorded data have been divided into two subsets: $(f_{i,j},g_j)$ and $(f_{i,k},g_k)$. The first one is used to develop the *TFs* whilst the second to evaluate the consistency of the results. It is worth mentioning that both subsets have data for 3 years. The seventh year has not been considered in the analysis to ensure balance between learning and validation time periods while maintaining signal stationarity.

The efficiency of a variable to predict the dynamic response of a system, using a transfer function, depends on the correlation between both (the variable and the response of the system). Therefore, at a first stage, the causality between I/O variables was evaluated. Specifically, a series of correlation analyses were performed to identify the variables that most influence the prediction of θ (Wagener and Pianosi, 2019). First, the bivariate distribution between pairs of I/O variables was studied. The efficiency (predictive capacity) of the input variables was measured in terms of the coefficient of determination, R^2. As a product of this analysis, a ranking based on the efficiency of the input variables was performed. Table 1 presents the R^2 values between I/O variables. The data show that T and R.H. have a strong correlation with θ, which emphasizes the main role of evaporation in water content changes at that site.

Table 1. R^2 between climatic variables and water content.

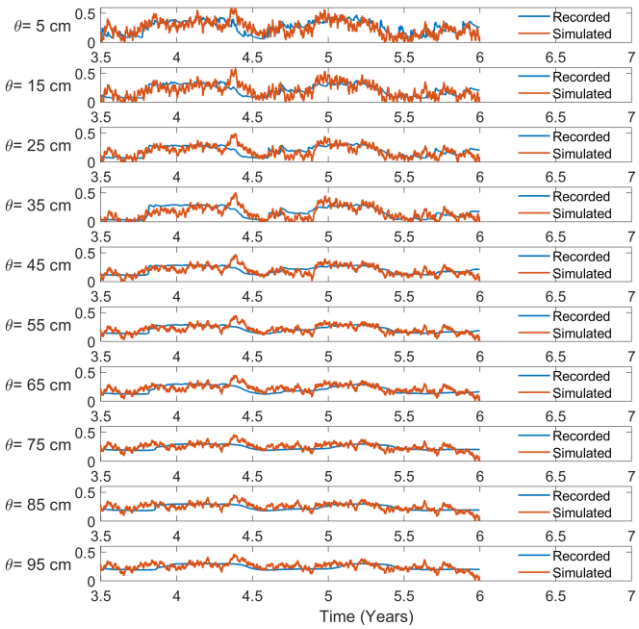

Figure 3. SRP's prediction by using TFs.

Based on the results presented in Table 1 and employing the first approach, a prediction of θ was performed and T was used to develop the transfer functions. Figure 3 shows the obtained results. There is good agreement between predicted and recorded data in terms of maximum values for all the analysed depths. Simulated data of θ show high frequency fluctuations which are not observed in recorded data.

4 PARAMETRIC TRANSFER FUNCTION

Another approach to predict θ by means of spectral methods is to develop a parametric transfer function. To do so, special boundary conditions need to be considered. In this case, the flux ($\frac{d\theta}{dt}$) at a given depth, L'_z, was set at zero and the θ value recorded at a depth of 5 cm was imposed at the surface (See Figure 1, top). In this manner, the analytical solution of the diffusion equation provides the expression of θ at depth z:

$$\theta = \delta_i * A_i \sum_{i=1}^{n} \sin(\omega_i t + \alpha_i * (z - L'_z) + \varphi_i + \frac{\pi}{2}) \quad (3)$$

where $\delta_i = \frac{e^{\alpha_i z} - e^{-\alpha_i z}}{e^{\alpha_i L'_z} - e^{-\alpha_i L'_z}}$; $\alpha_i = \sqrt{\frac{\omega_i}{2\kappa}}$; k is the diffusion coefficient, in a mathematical sense; A_i and φ_i are the amplitude and the phase of the harmonic with frequency ω_i, extracted from the Fourier's amplitude spectrum, respectively; $\bar{\theta}$ is the mean of the water content during the period taken into account.

Equation (3) has allowed estimating, at all the depths, the pair (κ, L'_z) that minimizes the mean square error (MSE) with respect to the recorded data. This was achieved by means of the Monte Carlo method. It is worth mentioning that the estimation provided by Equation 3 depends on the number of harmonics. Thus, the Monte Carlo minimization was performed using 100 harmonics. Figure 4 shows the evolution of the MSE as a function of κ and L'_z.

-3-3

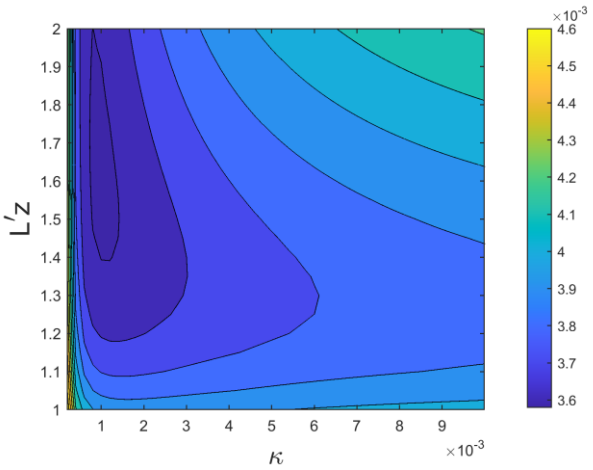

Figure 4. MSE as a function of κ and L'_z.

From Figure 4, it can be inferred that the optimal pair (κ, L'_z) is κ= 0.001 and L'_z= 1.6 m. By using these values, θ has been estimated for all depths; Figure 5 shows a comparison of both simulated and recorded data, using 100 harmonics in Equation 3. Simulated and recorded data are in good agreement for all depths. Simulated results do reproduce well both the attenuation with depth of the water change amplitudes and the disappearance of the higher frequency modes. This is consistent with the characteristics of the diffusion equation underlying the infiltration/ evaporation process and indicates that the sensitivity of water content changes to atmospheric fluctuations decays with depth.

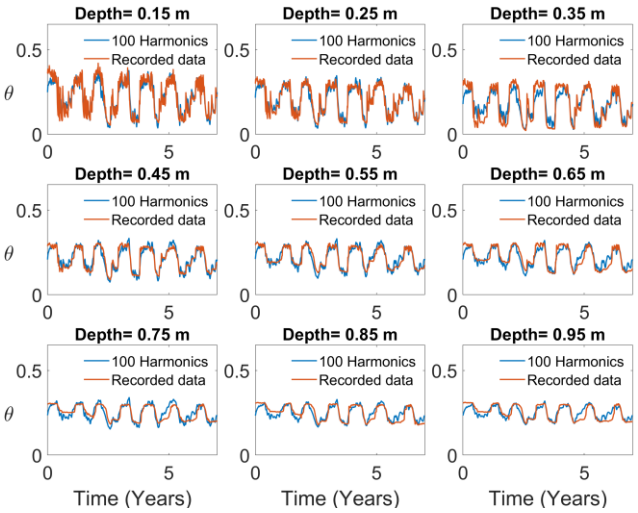

Figure 5. θ prediction considering 100 harmonics.

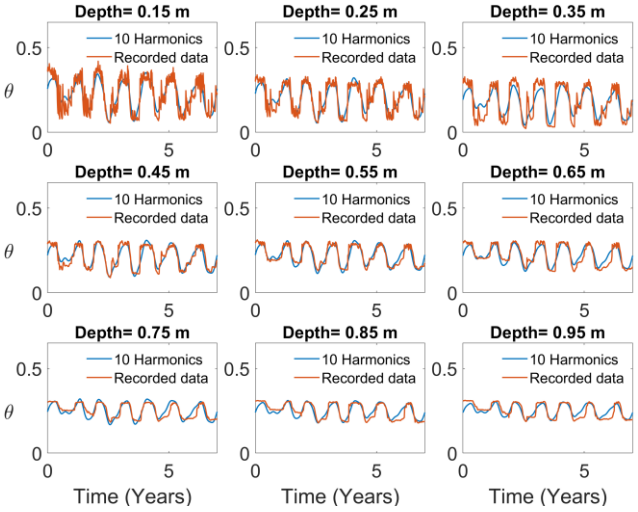

Figure 6. θ prediction considering 10 harmonics.

To study possible reduction of the computational cost, another analysis was conducted using the same pair (κ, L'_z) that minimizes the MSE and considering only the 10 harmonics (Figure 6) provided with the higher amplitudes. The agreement between simulated and recorded data is similar to the one observed for the analysis with 100 harmonics. This provides information about the most relevant modes to be used in future predictions of water content under climatic actions, at this site. The number of harmonics to be used decreases with depth as the result of the

attenuation of the fluctuations of higher frequencies with the distance to atmospheric boundary conditions.

5 CONCLUSIONS

This article presents two approaches based on spectral methods, for estimating soil water contents at different depths. The attractiveness of both methods relies mostly on the reduction of computational times. Data from a monitoring campaign carried out in an upper horizontal soil layer (max. depth 1 m, Calvet et al., 1999) were considered. These records implicitly contain information on the interaction of complex physical processes that trigger highly random variability. They provide an opportunity to conduct causality studies aimed at analysing which climate variables (input) have the highest explanatory capacity to predict soil water content, θ (output variable).

In the first approach, transfer functions connecting variables that influence climate (Solar and atmospheric radiation, rainfall intensity, temperature, wind speed, atmospheric pressure and relative humidity) and θ at several depths were operated. Data show that temperature and relative humidity are the atmospheric variables with the highest predictive capacity of θ. The correlation between these climatic variables and θ can increase if a multi-regression model composed of sub-groups of climatic variables is employed (See Vargas-Alzate et al., 2022). One of the main shortcomings of the first approach is that simulated data tend to fluctuate more than recorded series, over short time periods. However, these fluctuations can be mitigated if filters that act on the resulting signals are considered. Future research should be conducted to this end.

With regard to the second approach, a deterministic transfer function was employed, based on specific boundary conditions. Predictions based on this method are better than those based on the first approach, provided that parameters are previously estimated by back-analysis on sub-sets of data series. As depth increases, it is possible to consider fewer harmonics than close to the soil surface. Estimating the optimal number of harmonics as a function of depth would help improving the model efficiency. The use of a specific parameter that varies with depth would help addressing the intrinsic non-linearity of the diffusion coefficient.

Managing uncertainties in the geotechnical design of climate change resilient infrastructures

Gérer les incertitudes dans la conception géotechnique d'ouvrages résilientes au changement climatique

P. Vitale*, Z.Q. Liu

ABSTRACT: The design of geotechnical infrastructures is the outcome of a qualitative interpolation of a series of factors, from the feasibility study to the final design phase. It is good practice to start the geotechnical assessment from the geo-morphological data available at the studied area. This is combined afterwards with available information from surrounding projects, additional geotechnical investigations and professional experience. The overall outline of the design is provided by technical standards, other than by the needs of customers and society. One of the challenges that the geotechnical engineer encounters during the design is to find the correct balance between those decision factors, especially in areas where the risk for geohazards may be relevant both for the project itself and for the socio-economic development of the area. Furthermore, it is more and more acknowledged that uncertainties in geotechnical design also need to be addressed in relation to the impact of climate change on structures. This paper presents an overview of the current climate change adaptation strategies for geo-structures in Europe, highlighting the need for scientific research for the implementation of methodologies centred on geotechnical engineering practice and design. Hence, it invites to discuss at a more practical level about the future needs for conceiving geotechnical infrastructures resilient to the effects of climate change.

RÉSUMÉ: La conception des infrastructures géotechniques est le résultat d'une interpolation qualitative d'une série de facteurs, depuis l'étude de faisabilité jusqu'à la phase de conception finale. Il est de bonne pratique de démarrer l'évaluation géotechnique à partir des données géomorphologiques disponibles dans la zone étudiée. Ceci est ensuite combiné avec les informations disponibles sur les projets environnants, des enquêtes géotechniques supplémentaires et l'expérience professionnelle. Le cadre de la conception est défini par des normes techniques, autres que par les besoins des clients et de la société. L'un des défis de l'ingénieur géotechnique est de trouver le bon équilibre entre ces facteurs de décision, en particulier dans les zones où les géorisques peuvent être pertinents à la fois pour le projet lui-même et pour le développement socio-économique de la zone. Ensuite, il est de plus en plus évident que les incertitudes dans la conception géotechnique doivent également être prises en compte en ce qui concerne l'impact du changement climatique sur les structures. Cet article présente un aperçu sur les actuelles stratégies d'adaptation au changement climatique pour les géostructures en Europe, en soulignant le besoin de faire de la recherche pour la mise en œuvre de méthodologies centrées sur la pratique et la conception géotechnique. Ainsi, il invite à discuter des besoins futurs pour concevoir des infrastructures géotechniques résilientes aux effets du changement climatique.

Keywords: Climate change adaptation; reliability; sustainability; uncertainties; geotechnical design.

1 INTRODUCTION

Climate change is the greatest global health threat facing humanity in the 21st century, as stated by the World Health Organization in Health and Climate Change (2018). The European Commission has committed to be climate-neutral by 2050, by establishing a set of measures through the European Green Deal (2019) and in line with the long-term strategies in the Paris Agreement (2015). The European Commission adopted its new strategy to become climate resilient by 2050 in the EU Climate Adaptation Strategy (2021).

Despite the international commitment to cut net global emissions to zero by 2050, average global temperature will increase because of a raising concentration of greenhouse gas emissions in the atmosphere and governments are challenged to limiting the global temperature rise to 1.5°C (International Energy Agency, 2021). In this context, the outlined decarbonization roadmap needs to be addressed faster and with more efficient solutions.

Climate change signals (i.e., a general increase in temperature and a changing precipitation pattern) have been observed in Europe, with a different degree of

impact on geo-structures throughout the region (Insana et al., 2021; IPCC, 2023). To deal with the changing frequencies and intensities of environmental hazards induced by climate change, geotechnical engineers need to rationally consider climate change when designing a new structure. However, it remains a challenge to assess and quantify the impact of climate change on geo-structures. In this view, reliability and risk-based approaches that account for uncertainties in climatic loads and soil strengths are useful tools for engineering recommendations and final decisions.

This paper provides a panoramic of the alternative strategies and methodologies to tackle climate change effects on geo-structures. Relying on a "factor of safety" design approach and conservative assumptions (especially when in lack of geotechnical and environmental data) is not considered a viable way in the actual environmental situation. Thus, this short review aims at enhancing the discussion on the future needs of the industry to design climate change resilient geotechnical infrastructures.

2 CLIMATE CHANGE ADAPTATION OF GEO-STRUCTURES

2.1 Causal chain mapping of climate change impacts on geotechnical infrastructures

Concern for environmental issues in Europe arose in the second half of the 19th century, when people became more and more aware of environmental pollution and damages to nature following the Industrial Revolution. This is also the background of the first United Nations Conference on the Human Environment, held in Stockholm in 1972 (UN Chronicle, 2007). Protecting ecological integrity became the core of the discussion and, hence, economic and social development happened to be constrained by environmental limits. This led to the concept of sustainable development and, hence, to environmental sustainability (Our Common Future, 1987, From One Earth to One World §I-3 and Part I §2-I). The latter was, then, defined as the ability to maintain an ecological balance in our planet's natural environment and conserve natural resources to support the wellbeing of current and future generations (Our Common Future, 1987; Paris Agreement, 2015).

Insana et al. (2021) presented an overview of research and literature review studies conducted in the last three decades on climate change impact on geo-structures. Their research shows that, in Europe and in most parts of the world, the concern is mostly focused on natural and engineered slopes, and far outnumbers those dealing with geo-structures. However, the concern over the impact of climate change on onshore geotechnical infrastructures has been rising in the last decade, especially in Europe. This is shown in the analysis carried out by Gariano et al. (2016) and updated by Insana et al. (2021). Geoscientists and engineers are analysing and mapping the causal chain of climate change impacts on geo-structures.

An in-depth study was conducted by Insana et. al. (2021) with regards to European regions. The research shows how climate change signals can have multiple effects on geotechnical and geological properties. Hence, the instability of slopes is just the visible output of a series of processes in the ground, groundwater, and vegetation, which leads to soil properties degradation. The survey conducted in this research shows that the most relevant impacts of climate change for geo-structures in Europe are the following: instability of natural and engineered slopes, damage/failure of engineered structures from flooding, and overtopping/breaching of dikes and levees.

There are many climate change features that have been identified in the context of climate change scenarios. Vardon (2015) and Vahedifard et al. (2016) provide an overview of climate change impacts on geotechnical infrastructures.

2.2 Climate change adaptation strategies related to geo-structures

Strategic documents on climate change adaptation (CCA), such as national adaptation plans (NAPs) and related action plans, have been initiated and drafted by most of the countries all over the world, as recommended in COP 16 (Conference of the Parties to the United Nations Framework Convention on Climate Change at its 16th Session, 2021). NAPs and related actions drafted by European countries are aligned one to another, and they refer to CCA of geo-structures with regards to damages of infrastructures (roads and rails) as a cause of instability of slopes, soil erosion, soil subsidence, and flooding. However, as highlighted by Insana et. al. (2021), specific strategies for geotechnical CCA are lacking. Put differently, strategies developed for adaptation of geo-structures are not centred on geotechnical engineering practice and design, but more on the consequences of climate change on natural hazards.

In the actual context of climate change, risk assessment and monitoring have become the most common adaptation strategies. In this regard, early warning systems, hazard and vulnerability mapping, and improved drainage are common management tools for climate change associated risks (Insana et al., 2021; IPCC, 2023). The implementation of these strategies is

mainly in relation to slope stability (Insana et al., 2021).

In the future, it is crucial to give attention also to other geo-structures, while enhancing slope stability. In this context, other measures such as reliability theory and probabilistic approach, adaptation of technical standards for the design of geotechnical infrastructures, the observational method and pre-mortem analyses, need to be assessed and implemented further in daily engineering practice.

3 THE EFFECT OF UNCERTAINTIES ON THE PERCEIVED FACTOR OF SAFETY

3.1 Uncertainties in design from climate change

The question that the geotechnical engineer needs to address during the design is how safe the structure is under the applied loads and given the assessed geotechnical conditions. Furthermore, the geotechnical assessment needs to include the impact of climate change on all loads and geotechnical factors.

As a response to a changing climate, it is necessary to adapt the geotechnical design to the mutation of uncertainties associated with a geotechnical problem. The uncertainties identified in the prediction of the response of geo-structures (i.e., spatial variation, limited site exploration and observation, soil parameters, various testing methods, loads, calculation model) need to be re-assessed in terms of altered environmental load and remodeled soil parameters due to climate change (i.e., soil drying, soil suction, soil dessication, soil erosion and flooding, soil saturation).

The upcoming second generation of Eurocodes may respond to some extension to such imminent demand.

3.2 Safety factor and reliability-based design

The factor of safety is a deterministic approach to a safety assessment, and it embodies a quantification of the margin of safety (M). As elaborated by Lacasse et al. (2019), the uncertainty in the safety margin can be addressed as a spectrum of failure probabilities (P_f). The risk analysed in a safety assessment will never be zero, because there will always be a certain level of uncertainty (i.e., a finite probability that a failure may occur). Silva et al. (2008) summarised in a diagram the correlation between safety factor and failure probability, based on experience, engineering judgement and historical statistics. One of the take-aways of the diagram is that for a certain factor of safety there is a wide range of perceived failure probability, depending on the uncertainties in the analysis. Lacasse et al. (2019) shows well this concept for slope stability issues in *Figure 1*.

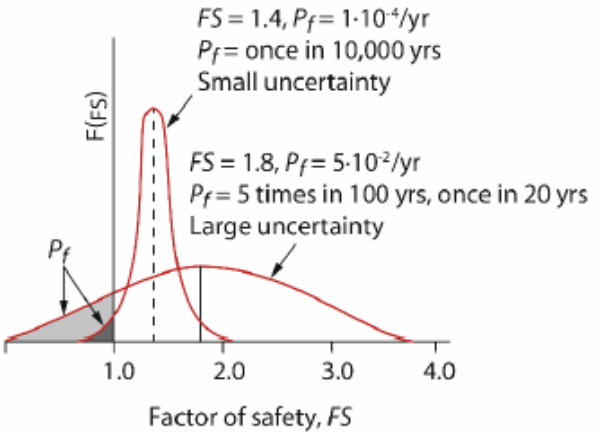

Figure 1. Variation of the safety factor of a slope with regards to failure probability (Lacasse et al., 2019).

A reliability-based approach accounts for the uncertainties in the analysis and their correlation, hence leading to a more rational assessment of safety of geotechnical structures. Such approach should, therefore, be used as a complement to the deterministic analysis, to provide a more robust design (Lacasse et al., 1998, 2019).

A simplification of the full reliability-based design is given through the LRFD (load and resistance factor design) approach. The partial safety factors in the LRFD approach reflect the uncertainty encountered in the design. The partial safety factors can also be calibrated such that a targeted safety level is ensured for determined levels of uncertainty in the geotechnical problem. However, uncertainties may be different from those assumed in the calibration phase, especially in the current environmental context. So, it is fundamental to couple such approach with a full reliability analysis using a target reliability index, to improve resilience to climate change effects in geotechnical design. Several examples of application of the reliability approach to actual case studies on- and off- shore are described by Farrokh (2017).

4 CONCLUSIONS

This short review shows that there is an increasing need for adapting the geotechnical design of geo-structures to the effects of climate change.

Our planet is undergoing an environmental adaptation to climate change. This process is happening fast, and it is affecting geotechnical infrastructures. It is difficult for geotechnical engineers to quantify such uncertainties and to take them into account in the design phase.

The interest for implementing efficient strategies to tackle climate change effects on geo-structures is increasing in Europe.

There are many different strategies which are assessed and developed in the European region (i.e., adaptation of technical standards, implementation of monitoring systems and of the observational method, implementation of reliability-based methodologies). The main challenge that geotechnical engineers face nowadays is how to combine those strategies and tools into practical solutions for a sustainable and climate change resilient design. Furthermore, such difficult task needs to be contextualized in interdisciplinary projects and with a holistic approach to design. In the future, there is the need to increase the connection between research and practice in geotechnical engineering for a climate change resilient design.

ACKNOWLEDGEMENTS

The authors would like to express their sincere gratitude to main contributors and mentors S. Lacasse, S. Feizi and J. Langford. We also acknowledge the support from NGI for making this work possible.

ABSTRACT: Small-scale slope modelling is being conducted at the Faculty of Civil Engineering, University of Rijeka, to investigate various aspects of landslides triggered by rainfall, such as effects of initial soil moisture and soil hydraulic properties, the characteristics and patterns of rainfall on the hydro-mechanical response of slopes, and the physical processes and mechanisms driving the initiation and propagation of rainfall-induced landslides, as well as the effectiveness of various remediation measures. Understanding the test results of the physical slope model requires, among others, knowledge of the shear strength properties of the soil(s) forming the model. This study comprises a series of laboratory tests to investigate the shear strength of clean sand used as a base soil material for the construction of slope models. A series of laboratory shear tests were performed using conventional direct shear, triaxial and ring shear devices under a wide range of confining stresses, including low confining stresses typically present in 1g model tests. The strain-controlled tests were performed on sand samples installed at the same density conditions representative to the sand material used in the small-scale slope physical models and under stress conditions representative in small-scale and real slopes.

RÉSUMÉ: Une modélisation des pentes à petite échelle est actuellement menée à la Faculté de génie civil de l'Université de Rijeka pour étudier divers aspects des glissements de terrain déclenchés par les précipitations, tels que l'effet de l'humidité initiale du sol et de ses propriétés hydrauliques, les caractéristiques et les régimes des précipitations sur le sol, la réponse hydromécanique des pentes et, les processus, les mécanismes physiques à l'origine de l'initiation et de la propagation des glissements de terrain induits par les précipitations, ainsi que l'efficacité des diverses mesures d'assainissement. Comprendre les résultats des tests du modèle physique de pente nécessite, entre autres, la connaissance des propriétés de résistance au cisaillement du ou des sols formant le modèle. Cette étude comprend une série d'essais en laboratoire visant à étudier la résistance au cisaillement du sable propre utilisé comme matériau de base pour la construction de modèles de pente. Une série d'essais de cisaillement en laboratoire ont été réalisés à l'aide de dispositifs conventionnels de cisaillement direct, triaxial et annulaire sous une large gamme de contraintes de confinement, y compris les faibles contraintes de confinement généralement présentes dans les essais sur modèle 1g. Les tests de déformation contrôlée ont été effectués sur des échantillons de sable installés dans les mêmes conditions de densité représentatives du matériau sableux utilisé dans les modèles physiques de pente à petite échelle et dans des conditions de contrainte représentatives des pentes à petite échelle et réelles.

Keywords: Landslides; laboratory testing; shear strength; low effective confining stresses.

1 INTRODUCTION

Landslides are among the greatest geohazards and are being studied in a variety of fields worldwide, including landslide modelling and landslide remediation.

A research project funded by the Croatian Science Foundation entitled "Physical modelling of landslide remediation constructions behaviour under static and seismic actions" was a part of extensive research on small-scale slopes. The main task of the project was to compare the responses of scaled slope models from different soil types and geometric conditions with and without remediation measures subjected to different loading conditions - static (rainfall-triggered landslide) and seismic (earthquake-triggered landslide) instrumented with geodetic and geotechnical monitoring equipment. More on the tests performed on the physical model can be found in Jagodnik & Arbanas (2022); Pajalić et al. (2021); Peranić et al. (2022); Vivoda Prodan et al. (2023).

The shear strength of sand at low confining stresses present in small-scale slope physical model needs to be investigated. One of the pioneering researches on the shear strength of sands at low confining stresses

was done by Ponce & Bell (1971). The authors have registered the dilatative behaviour of loose sands at low confining stresses, similar to dense sands' behaviour at moderate confining stresses. General shear strength and dilatative characteristics of saturated sands at low confining stress were further investigated and presented by Fukushima & Tatsuoka (1984). Shaoli et al. (2003) studied the undrained behaviour of sand under low confining stresses, and found that static liquefaction in such conditions is dominantly governed by the sand's relative density. Laurent et al. (2006) showed in their research that at low confining stresses, the sands' friction and dilatancy angle are stress-dependent. Finally, Chakraborty & Salgado (2010) used a series of triaxial compression and plane-strain compression data results to analyze the dependence of dilatancy and friction angle on sand specimens' relative density and confining stress. Winters et al. (2016) found that a better representation of the relationship between shear stress and normal stress can be found by curving the failure envelope at low confining pressures.

Based on an extensive literature showing the differences between the results that can be obtained with different devices (Castellanos & Brandon, 2013; Cuomo et al., 2016; Vivoda Prodan et al., 2016), different test devices were used in this study.

The ring shear tests were conducted using the ICL-1 ring shear device, (Marui & Co., Ltd., Osaka, Japan) developed in 2010 (Figure 1a), which can simulate the formation of the landslide sliding surface with the following post-failure motion, observe the consequence of mobilized shear resistance and the post-failure shear displacement as well as the generated pore water pressure. The ICL-1 can perform stress (monotonic, dynamic, seismic), strain and pore water pressure controlled tests in drained or undrained conditions. It can maintain a pore water pressure of up to 1 MPa and apply a normal stress of up to 1 MPa, making it suitable for investigation of large-scale and deep-seated landslides. The cylindrical sample has an inner and outer diameter of 10 and 14 cm, respectively and a maximum height of 5.2 cm. The maximum and minimum shear rate is 5.4 and 0.01 cm/s, respectively and cyclic torque control tests can be performed at a maximum frequency of 1.0 Hz (Oštrić et al., 2014). Vivoda Prodan et al. (2016); Vivoda Prodan & Arbanas (2020) investigated the influence of the weathering process on the shear strength of siltstones from a flysch rock mass on the northern Adriatic coast of Croatia using the ICL-1.

Direct shear tests were performed using the Back Pressured Shear Box (GDS Instruments Ltd., London, United Kingdom), (Figure 1b). The device enables the testing of square soil samples in a saturated or partially saturated state with the dimensions 100x100x30 mm at a maximum normal force of 10 kN and a maximum shear force of 5 kN. The maximum shear displacement is ±12.5 mm, while the maximum working back pressure that can be applied is 1 MPa. The device was used by Peranić et al. (2020) to perform standard, strain-controlled tests on undisturbed samples of residual soil from flysch rock mass in unsaturated (i.e. suction-controlled) and saturated conditions. Peranić & Arbanas (2020) used the same device to investigate the behaviour of the soil when undergoing the wetting process.

Static triaxial tests were performed using the Wykeham Farrance static triaxial system (Figure 1c). Tests were performed on a sample with a height to diameter ratio of 100/50 mm. The maximum pressure capacity of the static triaxial system is 1 MPa, the load cell used had a maximum force of 25 kN. The maximum axial displacement is 50 mm (Jagodnik et al., 2020).

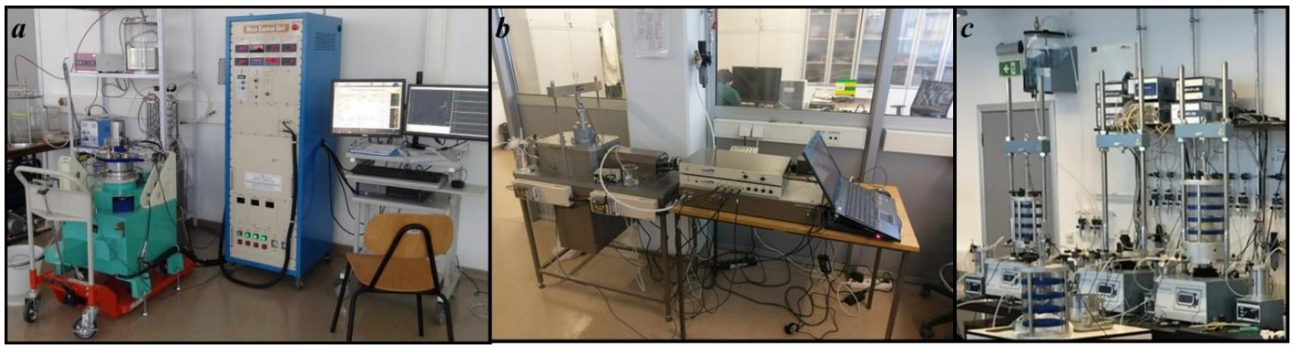

Figure 1. Devices at the Geotechnical laboratory at the Faculty of Civil Engineering University of Rijeka to determine shear strength of sand: a) ring shear (RS) device, b) back pressurized direct shear (DS) device for soil testing in saturated and unsaturated conditions, c) triaxial (TX) device.

The focus of this study is to investigate the shear strength properties of a uniformly graded fine sand used in physical slope modelling. So far, a series of laboratory tests were carried out using direct shear,

triaxial and ring shear devices under a wide range of confining stresses, including relatively low values of stresses representative for the 1g modelling tests.

2 LABORATORY TESTING

Barotropy, i.e. the dependence of the mechanical behaviour of the soil on the stress level, is known to be one of the greatest limitations in a use of small-scale physical models under 1g conditions. The main objective of conducted laboratory tests is to establish relationships between soil material behaviour in a small-scale model and a prototype, i.e., a real slope in a field.

2.1 Sand properties

The fine-grained (0–1 mm) Drava River sand was selected as the base material to represent cohesionless slopes. Figure 2 shows the physical model after the installation of the material and monitoring equipment. The basic physical properties of the described material are given in Table 1.

Figure 2. View of the small-scale physical model.

Table 1. Basic physical properties of the sand material built in the small-scale model.

Parameters	Values
Specific gravity, G_s	2.70
Dry density, ρ_d (g/cm^3)	1.52
Effective particle size	
D_{10} (mm)	0.19
D_{60} (mm)	0.37
Uniformity coefficient, c_u	1.947
Coefficient of curvature, c_c	1.092
Minimum void ratio, e_{min}	0.641
Maximum void ratio, e_{max}	0.911

2.2 Testing devices and methodology

Laboratory tests included direct shear (DS) tests, ring shear (RS) tests, and triaxial (TX) tests on the sandy material performed at the Geotechnical laboratory in the Faculty of Civil Engineering University of Rijeka, Croatia (Figure 1).

The samples were prepared under the same initial conditions as in the physical model, i.e. initial relative density of 50%, initial porosity equal to 0.44, and initial water content equal to 2%. Based on the known conditions related to the desired porosity, and an initial moisture of the tested samples, the mass of mixed sand and water installed in the devices was determined. After installation, samples were consolidated under a range of effective vertical stresses from 4 up to 200 kPa. The strain-controlled tests were performed under drained conditions with different strain rates, as presented in Table 2.

The ring shear box was filled with wet sand samples and then circulated with CO_2 and deaired distilled water. After consolidation at the effective vertical stresses in the range of 30 to 200 kPa with a back pressure of 15 to 50 kPa, shearing was performed at a shear rate of 0.01 cm/s.

Sand material was compacted in the shear box to achieve the sample height of 3 cm and the targeted porosity. Once the sample was installed, the chamber was filled with the deaired water and the sample was left to saturate in the following 24 hours period. After the saturation, the samples were consolidated under a range of confining stresses between 4 and 120 kPa. Finally, the samples were sheared at a low shear rate of 0.0087 mm/min to ensure drained response of the soil.

The samples for testing in the triaxial device were prepared using the undercompaction method, developed by Ladd (1978). The degree of undercompaction was 5%. To achieve faster saturation, the sample was percolated with CO_2 before water percolation. This assures that the Skemptons' *B* coefficient reaches value of 0.97, in average, after back pressurising. The rate of axial strain was 0.6 mm/min.

Table 2. List of the performed strain-controlled laboratory tests.

Device	Effective vertical stress (kPa)	Shear rate (cm/s)
RS	30, 60, 120, 200	0.01

2.3 Test results

This section presents the results of performed drained tests with ring shear (RS), direct shear (DS) and triaxial (TX) devices on the uniform sand material. Figure 6 presents the peak and shear strength envelopes for steady-state conditions obtained in all

devices. The results are fitted using the Mohr-Coulomb strength criteria in σ'-τ plane.

Samples tested in the ring shear device show a tendency for compaction and then dilatation. The material experiences a sudden pronounced peak shear resistance followed by strain softening to the steady state (Figure 3). The residual shear strength envelope (Figure 6a) was obtained for the shear stress values corresponding to the maximum shear displacement reached during the tests, which could be infinite.

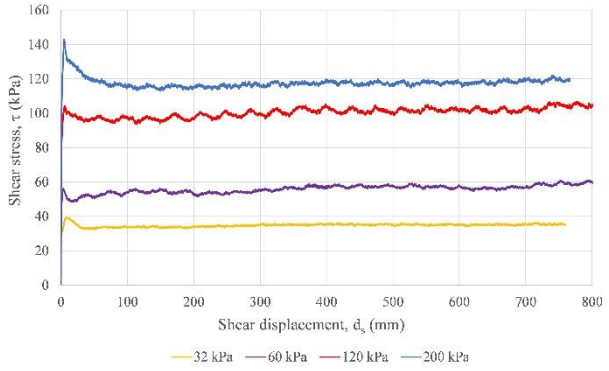

Figure 3. Shear stress-shear displacement of the RS tests.

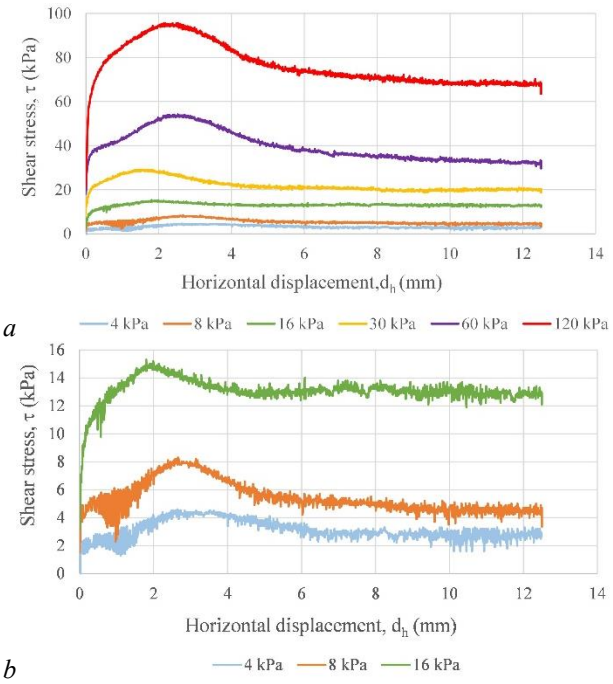

Figure 4. Shear stress- shear displacement results of the DS tests at a) all range of vertical effective stresses, b) low vertical effective stresses.

All direct tests show a clearly pronounced shear resistance peak and subsequent strain softening (Figure 4). The higher the effective vertical consolidation stress, the higher the peak and residual shear resistance. Figure 4b shows shear strength at low effective normal stresses from 4 to 16 kPa. The values of the test results for peak and residual conditions show a non-linear relationship, over the entire stress range of effective normal stresses (Figure 6b).

The test results obtained using triaxial tests are presented in Figure 5. Mean effective stress and deviatoric stress are calculated according to MIT principle (Lambe, 1967). For better comparison with the results obtained with DS and RSA, peak and residual values of shear strength obtained through triaxial tests (Figure 6c) were converted to the equivalent vertical and shear stress that would correspond to shear state obtained using the equipment with predefined shear surface.

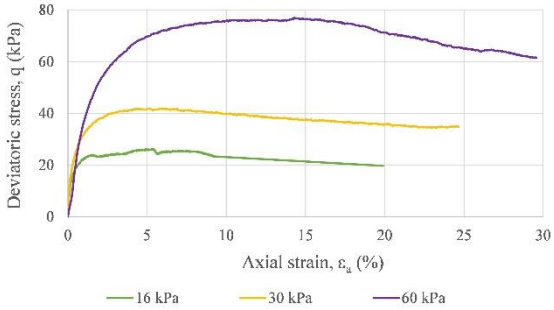

Figure 5. Deviatoric stress- axial strain results of the TX tests.

Figure 7 shows the peak and residual shear strength values for different vertical effective stresses according to the test results for all testing devices. The peak shear strength values obtained with the TX and RSA devices are close to each other, while the highest values were obtained with the DS device. The highest value of residual shear strength was obtained with the RSA device, while the values for the TX and DS devices were close to each other. Regardless of the testing device, the tests have the mean square error (R^2) greater than 0.87 (Figure 6).

The calculated effective friction angle for the peak and critical state obtained with different devices is analysed. The peak and residual friction angles obtained with the DS were 44° and 35° respectively for low effective normal stresses and reduced to 40° and 28° for higher stresses. The peak friction angle obtained with the DS is the highest, while the residual friction angle is the lowest among the used devices.

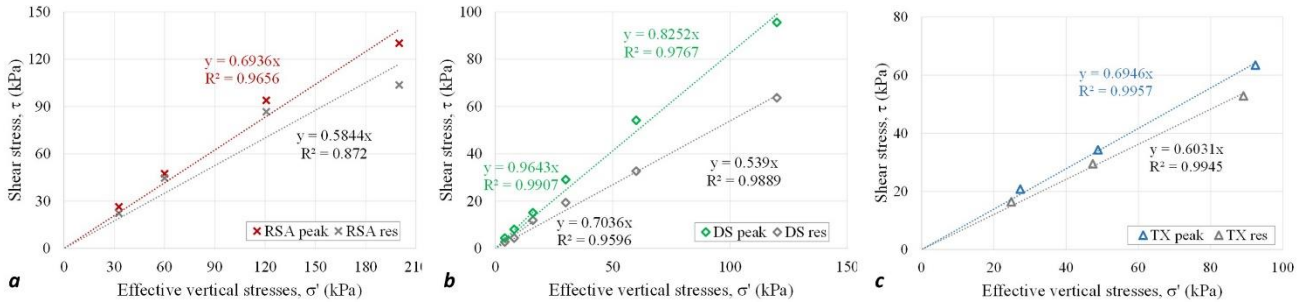

Figure 6. Mohr-Coulomb saturated shear strength envelope of sand obtained in the: a) ring shear tests, b) direct shear tests, c) triaxial tests.

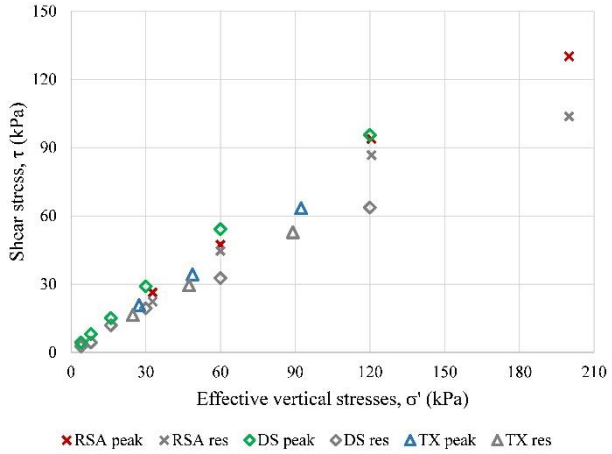

Figure 7. Peak and critical shear strength values of sand for different vertical effective stresses according to test results on all testing devices.

The peak value of the effective friction angle is between 40° and 35°, while the residual value is between 31° and 28° for higher stresses for the different devices.

It should be noted that the soil critical state is reached at different displacements depending on the type of the testing device (Figures 3, 4, and 5). For the DS and RSA tests, the critical state is reached in the range of 3 to 9 mm depending on the effective vertical stress value.

3 CONCLUSIONS

The paper dealt with the characterization of the sandy soil shear strength used in the small-scale physical models. Ring shear, direct shear, and triaxial tests were performed to investigate the differences in terms of friction angle under a range of stresses corresponding to the overburden stresses in the small-scale model and the real slope.

The paper showed that the experimental tests are fully reproducible as it concerns both the specimen preparation procedure and the testing technique.

The comparison between the results obtained with the different devices was made based on the residual and peak shear strength obtained and by calculating the effective friction angle. The test results indicate that the higher the effective vertical consolidation stress, the higher the peak and residual shear strength. The preliminary results of the tests indicate that the shear strength depends on the magnitude of the effective stresses and that as the stress level increase, the friction angle decreases. The ring shear device and triaxial devices show similar peak stress envelope while residual envelope is closer for direct shear and triaxial devices. A difference was found between the friction angle of sand at small normal stresses and at large normal stresses, indicating the need to use different values for the friction angle in the numerical modelling of the small-scale model and the real slope.

The results obtained in this study will be implemented in the future numerical modelling activities: while the shear strength characteristics obtained at relatively low confining pressures will be useful for a better understanding of small-scale slope models, the results obtained under higher stresses will be useful for numerical studies of real-size slopes.

ACKNOWLEDGEMENTS

The research presented in this paper was supported by Croatian Science Foundation under the Project IP-2018-01-1503. This work has been supported in part by the Ministry of Science, Education and Sports of the Republic of Croatia under the project Research Infrastructure for Campus-based laboratories at the University of Rijeka, number RC.2.2.060001. ABSTRACT: Liquefaction induced by earthquakes causes instability of buildings such as large settlements resulting in damage to the building structures. Usually, when an earthquake occurs, the saturated loose sandy ground is most susceptible to liquefaction. Even for the saturated silty ground with small SPT *N*-values, the possibility of liquefaction needs to be considered in the design process. Tender Net Foundation (TNF) is a kind of shallow foundation with a combination of grid-shaped soil improvement to depths of 2 to 3 meters, concrete slab, and concrete single footings. In this paper, the dynamic analysis of an actual TNF on the silty ground subjected to three consecutive earthquakes is conducted. Measurements of the settlements of the TNF were made after the second earthquake. The silty ground is modeled by the UBC3D-PLM model. Ground accelerations recorded about 10 km away from the site area are used as the input accelerations in dynamic analyses. The responses of the TNF as well as the ground during and after the earthquakes are analyzed. The numerical analyses simulated well the measured settlements.

RÉSUMÉ: La liquéfaction induite par les tremblements de terre provoque une instabilité des bâtiments tels que de grandes agglomérations, entraînant des dommages aux structures des bâtiments. Habituellement, lorsqu'un tremblement de terre se produit, le sol sablonneux meuble et saturé est le plus susceptible de se liquéfier. Même pour les sols limoneux saturés avec de faibles valeurs SPT *N*, la possibilité de liquéfaction doit être prise en compte dans le processus de conception. Tender Net Foundation (TNF) est une sorte de fondation peu profonde combinant une amélioration du sol en forme de grille jusqu'à des profondeurs de 2 à 3 mètres, une dalle de béton et des semelles simples en béton. Dans cet article, l'analyse dynamique d'un TNF réel sur un sol limoneux soumis à trois tremblements de terre consécutifs est réalisée. Des mesures des tassements du TNF ont été réalisées après le deuxième séisme. Le sol limoneux est modélisé par le modèle UBC3D-PLM. Les accélérations du sol enregistrées à environ 10 km de la zone du site sont utilisées comme accélération d'entrée dans l'analyse dynamique. Les réponses du TNF ainsi que du sol pendant et après les séismes sont analysées. L'analyse numérique a bien simulé les tassements mesurés.

Keywords: TNF system; liquefaction; settlement; silty ground; FEM.

1 INTRODUCTION

Tender Net Foundation (TNF) is a kind of shallow foundation with a combination of grid-shaped soil improvement, concrete slab and concrete single footings (see Figures 1 and 2). The original soil is improved by blending with cement as a solidification material using a backhoe. Cement powder with lower elution of hexad chrome is mixed with the original soil at the site for environmental friendliness. The mass of cement per unit soil volume is varied so that the improved soil has an unconfined compression strength q_u of 300 to 450 kPa in common. Cong et al. (2022) analyzed the TNF system subjected to vertical loading and demonstrated that the TNF system is an efficient foundation for reducing settlement and volume of soil improvement compared to the conventional shallow soil improvement method.

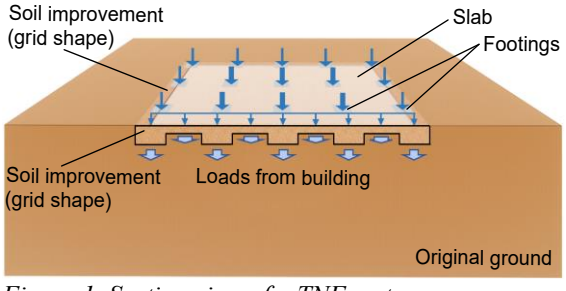

Figure 1. Section view of a TNF system.

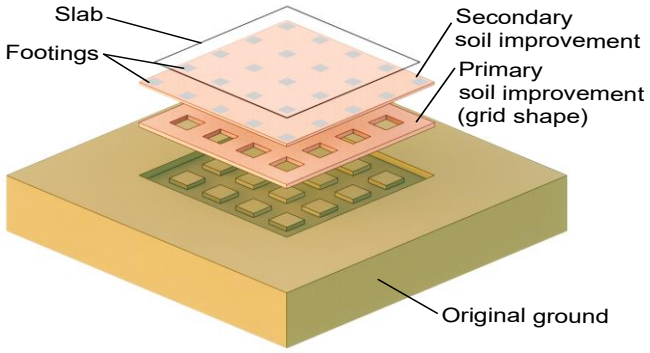

Figure 2. Composition of a TNF system.

By improving the surface layer to depths of 2 to 3 meters in a grid shape, the TNF may be an efficient foundation for suppressing the damage to buildings when liquefaction occurs.

In this paper, the dynamic analysis of an actual TNF on silty ground subjected to three consecutive earthquakes is conducted. Measurements of the settlements of the TNF were made after the second earthquake.

PLAXIS 3D FEM software (Bentley, 2022) is used for simulation analysis. The silty ground is modeled by the UBC3D-PLM model. The time histories of ground accelerations during three earthquakes recorded about 10 km away from the site area are used as the input accelerations in the dynamic analyses of the TNF. The responses of the TNF as well as the ground during and after the earthquakes are calculated. The analysis shows that liquefaction occurs in the silty ground. The calculation simulated well the measured settlements. To demonstrate the efficiency of the TNF for suppressing the settlements induced by liquefaction, a similar analysis of a conventional shallow foundation is also carried out for comparison purposes.

2 OUTLINE OF BUILDING

Figure 3 shows the plan view of the construction site and two boreholes (BHs). The target of this analysis is a TNF for the foundation of a factory constructed in Japan. The factory is a 1-story building with a floor area of 30 × 19.5 m and a height of 5.7 m.

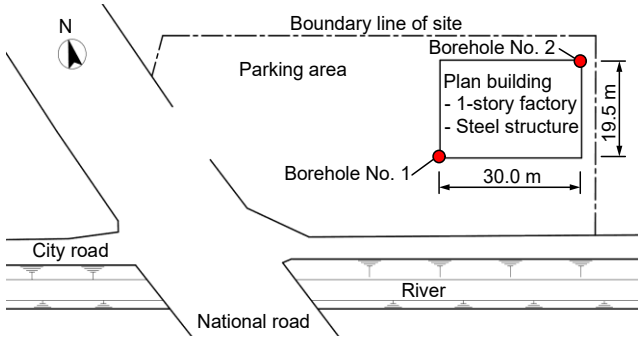

Figure 3. Plan view of the construction site and boreholes.

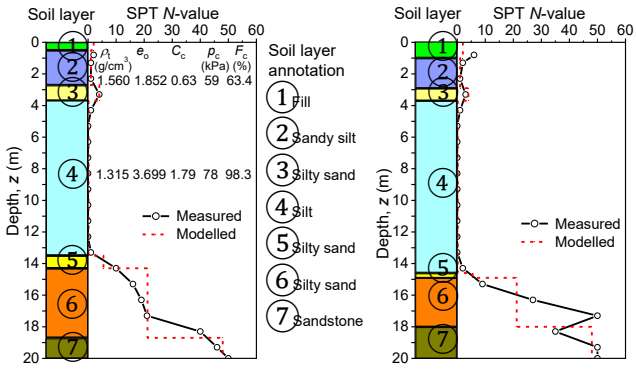
Figure 4 shows the profiles of soil layers and SPT *N*-values. The ground at each borehole consists of 7 soil layers. The sandy silt layer ② (N = 1) exists at depths 0.5 to 2.7 m (2.2 m thick) at BH No. 1, and at depths 1.0 to 2.9 m (1.9 m thick) at BH No. 2. The silt layer ④ (N = 0) exists at depths 3.7 to 13.5 m (9.8 m thick) at BH No. 1, and at 3.7 to 14.6 m (10.9 m thick) at BH No. 2. The groundwater level is 0.9 m at BH No. 1 and 0.65 m at BH No. 2 below the ground surface.



(a) Borehole No.1. *(b) Borehole No.2.*

Figure 4. Profiles of soil layers and SPT N-values.

Figure 5 shows the plan view of the TNF system considered in the design process. The size of the TNF system is 33.7 m × 25.6 m having a primary soil improvement layer with a thickness of 1.5 m, and a secondary soil improvement layer with a thickness of 0.75m. The thickness of the concrete footings is 0.4 m, and the thickness of the concrete slab is 0.2 m.

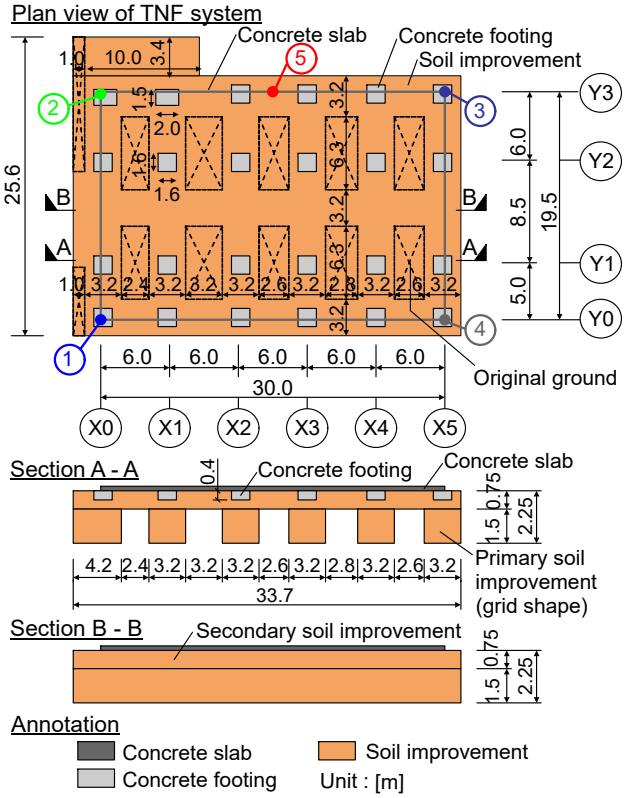


Figure 5. Plan view of the TNF system.

Figure 6 shows the construction progress, earthquakes history, and measured settlements at the five points of the TNF (see Figure 5). The settlement measurements were started just after the earthquake with Japan Meteorological Agency (JMA, 2023) Seismic Intensity scale (*SI* scale) of 5- on 2017-02-28. For example, an earthquake with *SI* scale of 5- is one in which many people are frightened and feel the need to hold onto something stable. Hanging objects such as lamps swing violently. Dishes in cupboards and items on bookshelves may fall. Small cracks may form and liquefaction may occur in the ground. Refer to JMA (2023) for more details on *SI* scales.

It is seen that the differential settlement Δw occurred. Interestingly, large ground settlements were measured after the occurrence of earthquakes having *SI* scale of 5- or higher.

Hence, the influence of earthquakes is strongly suspected as the cause of the differential settlement.

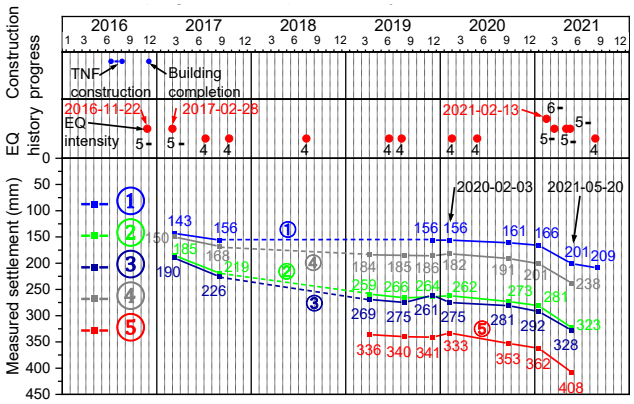

Figure 6. Construction progress, earthquakes history, and measured settlements.

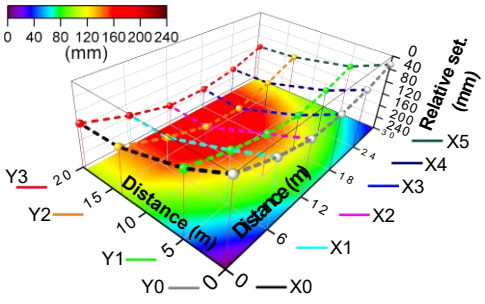
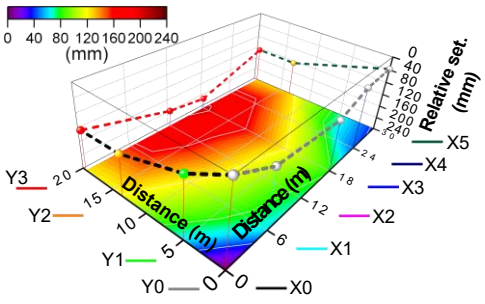


(a) on 2020-02-03.



(b) on 2021-05-20 (after the EQ on 2021-02-13).

Figure 7. Measured relative settlements of the TNF.

Figure 7 shows the distributions of relative settlements of the TNF measured on 2020-02-03 and on 2021-05-20, respectively. The measured relative settlements were defined as the difference between the settlement at given points and the settlement at point ① (X0, Y0). It is seen that the maximum Δw and the average settlement w_{ave} on 2021-05-20 increased compared with those on 2020-02-03. That is, the maximum Δw was 186 mm and settlement at the reference point ① was 156 mm in Figure 7(a). Those were 207 mm and 201 mm in Figure 7(b).

To investigate the cause of settlements of the TNF, the dynamic FEM analysis is conducted.

3 DYNAMIC ANALYSIS CONDITIONS

Figure 8 shows the PLAXIS 3D FEM analysis model. The ground was modeled by 7 soil layers. The thickness of fill layer ① is 0.65 m at BH No.1 and 1.19 m at BH No.2. The vertical loads of the building were applied as the point loads on the footings and as the uniform surface load on the slab. The earthquake loads were applied to the bottom of the ground.

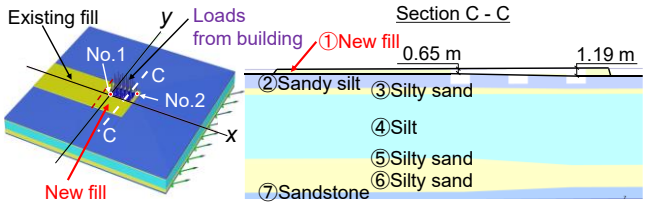


Figure 8. PLAXIS 3D FEM analysis model.

Figure 9 shows the analysis phases. The analysis phases were set following the construction progress and earthquake history.

In this research, earthquakes with seismic intensity scale *SI* of 5- or higher on 2016-11-22 (1st EQ, *SI* = 5-), on 2017-02-28 (2nd EQ, *SI* = 5-), and on 2021-02-13 (3rd EQ, *SI* = 6-) were considered. The seven earthquakes with *SI* of 4 between 2017-02-28 and 2021-02-13 were omitted in this particular analysis because the settlements caused by these earthquakes were considered negligible.

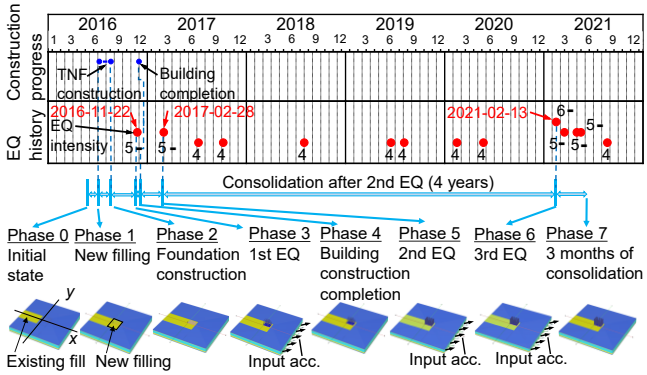

Figure 9. Analysis phases.

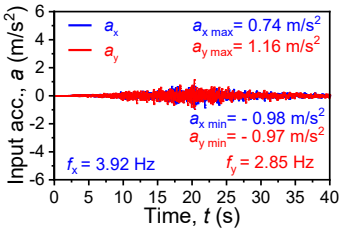
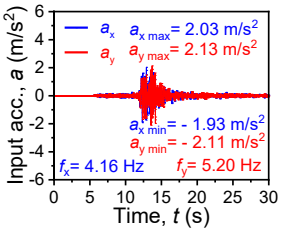
The ground accelerations of the earthquakes recorded about 10 km away from the site area were used as input accelerations of the three earthquakes in the dynamic analyses at Phases 3, 5 and 6. The other phases were set by consolidation analysis.

Undrained conditions were set for the ground below the groundwater level, while drained conditions were set for the ground above the groundwater level.

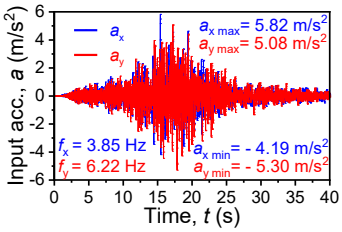
Figure 10 shows the input acceleration data used in the dynamic analyses. The acceleration data were obtained from K-NET strong-motion seismograph network (2022) and were converted to acceleration data into *x*- and *y*-directions.



(a) 1st EQ on 2016-11-22.



(b) 2nd EQ on 2017-02-28.



(c) 3rd EQ on 2021-02-13.

Figure 10. Input acceleration data.

Table 1 shows the physical and mechanical properties of each soil layer.

The averaged *N*-value in each layer was used for estimating V_s using Eq. (1) specified in Japan Road Association (2012):

$$V_s\ (\mathrm{m/s}) = \begin{cases} 100N^{1/3} & \text{for clay} \\ 80N^{1/3} & \text{for sand} \end{cases} \quad (1)$$

Shear modulus G was calculated using Eq. (2):

$$G = \frac{\gamma_t}{g} V_s^2 \quad (2)$$

Young's modulus E was calculated using Eq. (3):

$$E = 2(1+\nu)G \quad (3)$$

Poisson's ratio ν and coefficient of permeability k of each soil layer were assumed as shown in Table 1.

Table 2 shows the parameters of the UBC3D-PLM model for each soil layer. The relative density D_r was estimated according to Tokimatsu and Yoshimi (1983). The fine grain content ratio F_c is needed for estimating D_r. F_c of sandy silt layer ② and silt layer ④ was obtained from soil test results (see Figure 4), while F_c of other soil layers was assumed to be 10 %.

The cohesion c of the silt layer (layer ④, $N = 0$) was estimated to be 0 using $c = 6.25N$ kPa (BCJ, 2019). The c of sandy silt and silty sand layers was set to 0.

The other parameters of the UBC3D-PLM model in Table 2 were obtained using D_r following PLAXIS 3D Manuals (Bentley, 2022).

Table 1. Physical and mechanical properties of each soil layer.

No.	Soil layer type	Soil model	t_1 (m)	t_2 (m)	SPT N	γ_t (kN/m³)	V_s (m/s)	G (kPa)	E (kPa)	ν	k (m/day)

n_p = Rate of stress dependency of plastic shear modulus, φ_{cv} = Constant volume friction angle,
φ_p = Peak friction angle, c = Cohesion, f_{dense} = Densification factor, f_{Epost} = Post-liquefaction factor, R_f = Failure ratio

Table 3. Material parameters of concrete and soil improvement used for the TNF system.

Material	Soil model	Total unit weight, γ (kN/m^3)	Shear wave velocity, V_s (m/s)	Shear modulus, G (kPa)	Young's modulus, E (kPa)	Poisson's ratio, ν
Concrete (Slab, Footing)	Linear elastic	24	2001	9.79×10^6	23.50×10^6	0.2
Soil improvement	Linear elastic	17	271	1.28×10^5	3.20×10^5	0.25

The parameters of soil improvement of the TNF in Table 3 were estimated using Eqs. (1), (2) and (3) with *N*-value assumed as 20.

4 ANALYSIS RESULTS

Figure 11 shows the calculated settlement curves of the TNF at Points A, B, C, D. Large settlements occurred during each earthquake. Settlements were largest in the 3rd EQ with *SI* = 6-. It is seen that the earthquakes also caused differential settlements of the TNF.

The analysis of no earthquake was also conducted to evaluate the influence of the earthquakes. The calculated settlement curve at Point C of no earthquake is added in Figure 11. It is seen that the earthquakes were the main cause of large settlements of the TNF.

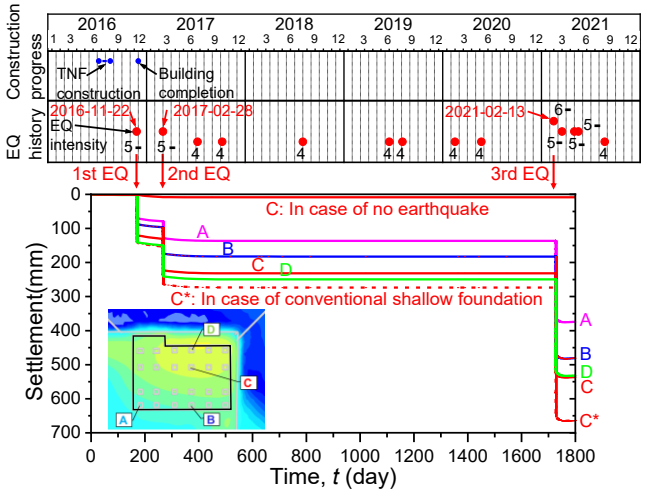

Figure 11. Calculated settlement curves of TNF.

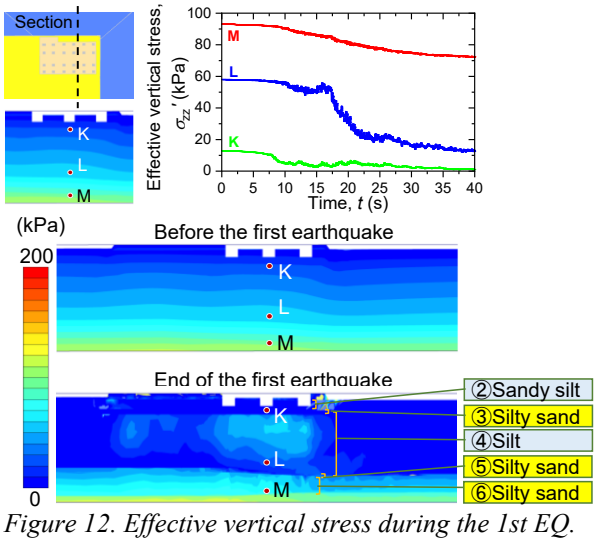

Figure 12. Effective vertical stress during the 1st EQ.

Figure 12 shows the effective vertical stress σ_{zz}' during the 1st EQ. The σ_{zz}' of all soil layers of the ground decreased during the EQ. At the end of the 1st EQ, the σ_{zz}' of silty layers (layers ② and ④) and sandy ground (layer ③) decreased nearly to 0 kPa. It is seen that liquefaction occurs even in the silty ground.

Figure 13 shows the excess pore water pressure p_{excess} during the 1st EQ. The p_{excess} of the whole ground increased during the EQ, and p_{excess} at the end of the 1st EQ was much larger than those before the earthquake. p_{excess} at the end of the 1st EQ caused consolidation settlements of the TNF and the surrounding ground after the earthquake as shown in Figure 11.

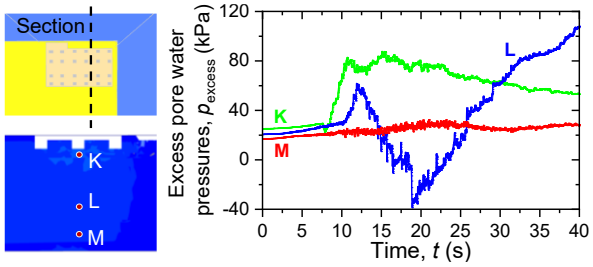

Figure 13. Excess pore water pressure during the 1st EQ.

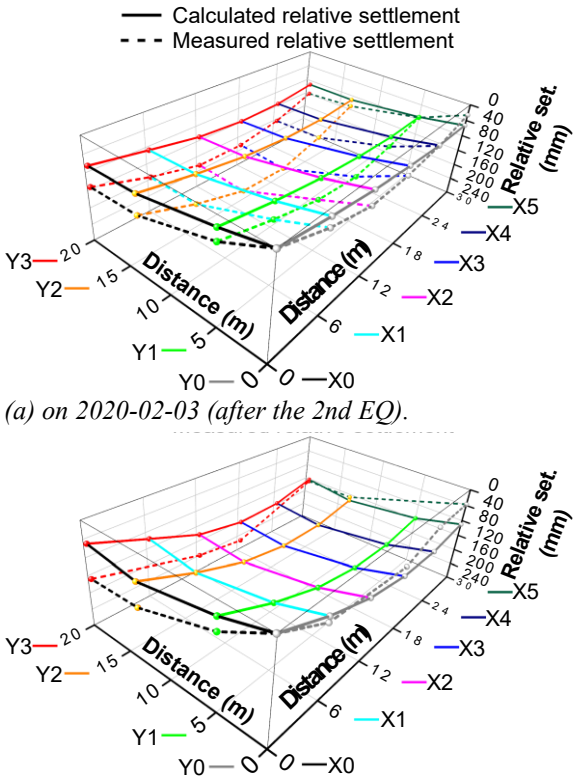


(a) on 2020-02-03 (after the 2nd EQ).

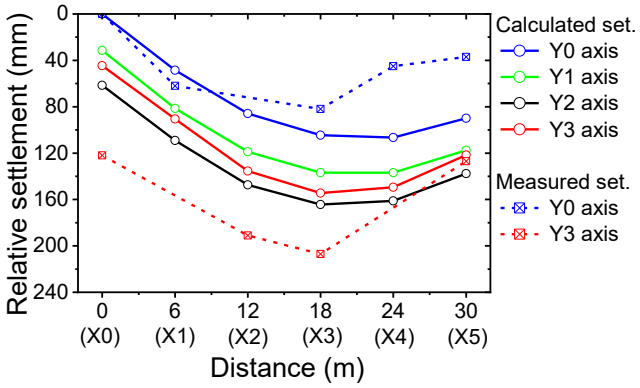
(b) on 2021-05-20 (after the 3rd EQ).

Figure 14. Comparison of calculated relative settlement and measured relative settlement of the TNF.

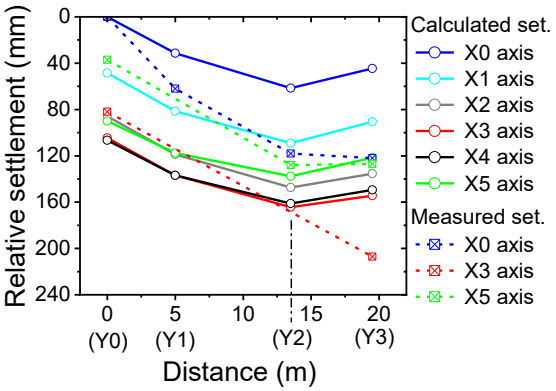
Figure 14 compares the calculated relative settlement and measured relative settlement of the TNF on 2020-02-03 and 2021-05-20, respectively.

As shown in Figure 14(a), the distributions of relative settlement in the measurement and the calculation are almost the same although the calculated settlement is a little bit smaller than the measured settlement. In Figure 14(b), although the number of measurement points is less, the calculated results are close to the measured results again.

Figure 15 shows the comparison of the calculated and measured settlements on 2021-05-20 (after the 3rd EQ). It is seen that the calculation simulated well the measured settlements. Along the Y-axis direction (Figure 15a), maximum settlement occurred at the center points (X3 axis) in both the measurement and the calculation, and the settlement gradually decreased toward the edges. Along the X-axis direction (Figure 15b), the measured and calculated maximum settlements occurred at the Y2 axis. Although there were only two measurement points along the X3 axis, it is inferred that a similar trend occurred.



(a) along the Y-axis direction.



(b) along the X-axis direction.

Figure 15. Comparison of calculated settlements and measured settlements on 2021-05-20 (after the 3rd EQ).

To demonstrate the efficient performance of the TNF for suppressing the settlements induced by liquefaction, a similar analysis of a conventional shallow foundation shown in Figure 16 was conducted.

Figure 16. Section view of conventional shallow foundation.

The settlement curve of the conventional shallow foundation at Point C has been indicated in Figure 11 to compare with the TNF. It is seen that the settlement of the TNF is much suppressed compared to the settlement of the conventional shallow foundation, especially in the 3rd EQ (*SI* = 6-).

5 CONCLUSIONS

The dynamic analysis of the actual TNF on the silty ground subjected to three consecutive earthquakes was conducted. The responses of the TNF as well as the ground during and after the earthquakes were calculated to investigate the occurrence of liquefaction in the silty ground. Furthermore, a similar analysis of a conventional shallow foundation was carried out. From comparisons between the measured and calculation results, the main conclusions are drawn as follows:

1) The calculation simulated well the measured settlements.
2) Earthquakes were the main cause of settlements and differential settlements of the TNF in this project.
3) Liquefaction occurs even in the silty ground.
4) The TNF is an efficient foundation for suppressing the settlements induced by liquefaction compared to the conventional shallow foundation.

ABSTRACT: The application of aerial imagery for landslide anomaly detection encapsulates a promising avenue for early geohazard identification. This study utilizes GANomaly, a model built upon Generative Adversarial Networks (GAN), to identify anomalies by learning to reconstruct normal data and measuring reconstruction errors to discern anomalies. Initially, a pre-processing process was developed to enhance the clarity and quality of images, thereby facilitating more effective training and testing by GANomaly. This pre-processing process encompasses several steps: image RGB channels adjustments, image slicing into tiles, tile classifications, and tile rotations. The GANomaly model is then employed, trained on a substantial dataset derived from the pre-processing stage, and tested to evaluate its efficacy in detecting landslide anomalies within the aerial imagery. The entire process involved the selection and analysis of over 120,000 tiles, each acting as a data point to feed the robust anomaly detection framework. The results highlight the potential of integrating advanced pre-processing techniques with GAN-based anomaly detection models, forging a framework for real-time geohazard monitoring and early-warning systems. The results were verified from the confusion matrix parameters to ensure the potential of integrating advanced pre-processing techniques with GAN-based anomaly detection models.

RÉSUMÉ: L'utilisation de l'imagerie aérienne pour repérer les anomalies de glissements de terrain offre une méthode prometteuse d'identification précoce des risques géologiques. GANomaly, un modèle sur les réseaux GAN, apprend à identifier les anomalies en reconstruisant et analysant les erreurs des données normales. Un prétraitement améliore la qualité des images pour un entraînement et test efficaces de GANomaly, incluant l'ajustement RGB, le découpage en tuiles, leur classification, et rotation. Testé sur un grand ensemble de données prétraitées, GANomaly évalue son aptitude à détecter les anomalies de glissements. L'analyse de plus de 120 000 tuiles démontre l'intégration réussie de prétraitement avancé et de détection d'anomalies par GAN, établissant une méthode pour le suivi des géorisques et l'alerte précoce. Les résultats, validés via la matrice de confusion, confirment l'efficacité de cette approche.

Keywords: landslide; aerial imagery; artifical intelligence; anomaly detection.

1 INTRODUCTION

Generative Adversarial Networks (GANs) represent a groundbreaking advancement in the field of artificial intelligence, particularly within the domain of deep learning. Developed by Goodfellow et al. (2014), GANs have improved the way machines understand and generate data. At their core, GANs consist of two neural networks, the generator and the discriminator, engaged in a continuous competition. The generator creates data that is indistinguishable from real data, while the discriminator evaluates this data, differentiating between the authentic and the artificial. This dynamic results in the generator becoming increasingly proficient at producing realistic data, making GANs highly effective for tasks in image generation(Salimans et al., 2016; Zhao et al., 2020), industry(Yan, 2021), and medical purposes(Skandarani et al., 2023; Struski et al., 2023).

GANomaly (Akcay et al., 2018), a variant of GAN, is specifically tailored for anomaly detection. It extends the conventional GAN architecture by introducing an additional encoder network. This setup allows the model not only to generate new data but also to reconstruct input data. In the context of anomaly detection, GANomaly works by training on a dataset of 'normal' instances. The model learns to recreate these instances, and when presented with an anomalous instance, it struggles to reproduce it accurately. This discrepancy in reconstruction is then used as a signal for anomaly detection.

Utilizing aerial imagery for detecting landslide anomalies introduces a transformative method in geohazard analysis. Traditional techniques often emphasized on the diverse appearances of landslides(Bui et al., 2020; Prakash et al., 2021; Syifa et al., 2019). Here, GANomaly's application marks a significant advancement. Unlike conventional methods that depend on labeled datasets, GANomaly excels in unsupervised learning environments. It learns from unlabeled data, detecting anomalies by their deviation from 'normal' patterns. This is especially beneficial in contexts where anomalies are infrequent or ambiguous(Ferrari et al., 2023; Han & Chang, 2023; Li et al., 2020; Madzia-Madzou & Kuijf, 2022). GANomaly's sophisticated pattern recognition abilities are adept at identifying early indicators of land shifts or unusual terrain features, enabling proactive risk mitigation and timely response in landslide management.

This study aims to apply GANomaly, an advanced variant of Generative Adversarial Networks (GANs), in the analysis of aerial imagery for detecting landslide anomalies. The approach is structured into two key phases: an extensive training phase and a subsequent testing phase. The training phase emphasized on preparing the GANomaly model to accurately identify and distinguish normal terrain from potential landslide anomalies. It began with the RGB Adjustment of the aerial images, where the color channels were tuned to enhance the consistancy on overall RGB characteristics. Following this, the images were segmented into smaller tiles. Further, these tiles were classified where they were categorized based on distinct terrain features. This step aids in training the model the various characteristics of normal terrain. To augment the dataset and enhance the model's ability to recognize patterns from different perspectives, these tiles were then subjected to rotations. This rotational variation ensures that the model is robust and can accurately identify anomalies irrespective of the orientation of the features in the imagery. The testing phase was designed to rigorously evaluate the model's effectiveness. This phase employs a smaller batch of normal tiles to ensure the model's accuracy in recognizing normal terrain patterns without raising false positives. Additionally, the model is tested with known abnormal tiles, which contain features characteristic of landslide anomalies. This step is pivotal in verifying the model's capability to detect deviations from normal terrain patterns.

2 METHODOLOGY AND RESULTS

2.1 Description of aerial images

The aerial images utilized in this study were specifically sourced from the mountainous regions within the Fuxing District of Taoyuan City, Taiwan. This area, known for its complex terrain and susceptibility to landslides, presents an ideal location for analysing the capabilities of GANomaly in detecting terrain anomalies.

The aerial images for this study were captured using aerial remote sensing aircraft, operated by the Aerial Survey and Remote Sensing Branch of the Forestry and Nature Conservation Agency, under the Ministry of Agriculture. These aircraft were flown at an altitude of 35,000 feet. The orthophoto images obtained were corrected by ground control points, and adjusted by digital orthoimage mosaicking and toning, ensuring a consistent scale and an accurate representation of the earth's surface. Each image possesses a resolution of 25 cm, which is an essential benefit for the detailed and precise identification of potential landslide anomalies in the complex terrain of the study area.

2.2 Procedure for image pre-processing

In this study, an image pre-processing procedure was employed to prepare aerial images for the training and testing of the GANomaly model, focusing on landslide anomaly detection. The procedure commenced with an step of RGB profile adjustment. The aerial images, containing three channels, were standardized against a base image chosen for its optimal RGB balance. This involved a comparison of the RGB histograms of all images against the base image. The mean values of these histograms were then adjusted to align with those of the base image, ensuring a consistence on RGB profile representation across the dataset. This step aims to establish a consistent coloration for the accurate identification and analysis of terrain features. Figure 1 presents the base image (Image 1) along with its corresponding RGB histograms and mean values. Figure 2 and Figure 3 illustrate the images before (Image 2) and after (Image 3) RGB adjustment, respectively.

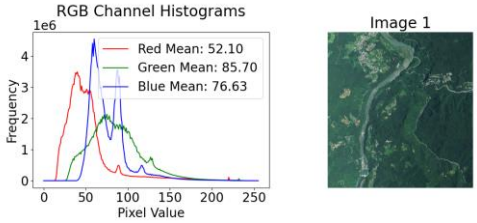

Figure 1. Plot of RGB histograms of the base image.

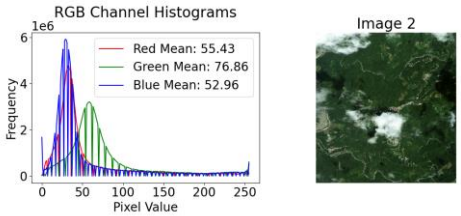

Figure 2. Plot of RGB histograms of the image required adjustment.

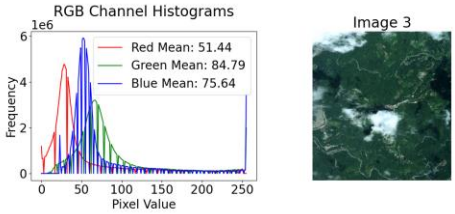

Figure 3. Plot of RGB histograms of the image after RGB adjustment.

Following the RGB profile adjustment, the images were sliced into tiles, each measuring 128×128 pixels. This slicing step allowed for a more granular examination of the terrain, enabling the GANomaly model to focus on specific areas and detect subtle anomalies that might be indicative of potential landslide risks. The smaller size of the tiles ensures that even minor variations in the terrain are captured and analysed.

To further refine the dataset, a classification of tiles was implemented. Tiles were categorized based on prominent terrain features visible in images, such as trees, agricultural land, buildings, roadways, rivers, and riverbanks. This classification allowed for a detailed characterization of normal terrain, establishing a baseline for the model to identify deviations that signify anomalies.

Figure 4. Examples of tiles classified as trees.

Figure 5. Examples of tiles classified as agricultural land.

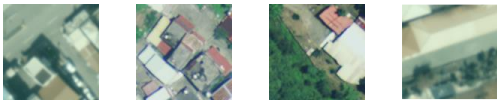

Figure 6. Examples of tiles classified as buildings.

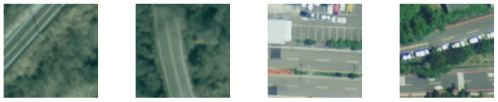

Figure 7. Examples of tiles classified as roadways.

Figure 8. Examples of tiles classified as rivers.

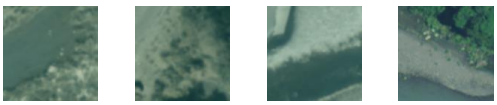

Figure 9. Examples of tiles classified as riverbanks.

The final step in the preparation process was the rotation of tiles. Each tile underwent rotations at angles of 90, 180, and 270 degrees, as shown in Figure 10. This step was particularly important for addressing the disparity in the number of tiles available for certain categories. Notably, the categories of agricultural land, buildings, roadways, rivers, and riverbanks were underrepresented compared to the number of tiles depicting trees. By rotating the tiles, the study effectively augmented the dataset for these less represented categories, ensuring a more balanced and comprehensive training set for the GANomaly model.

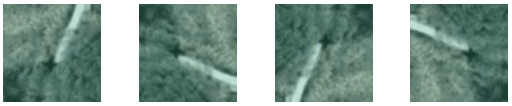

Figure 10. Examples of tiles after rotation.

2.3 Training

The training stage of the GANomaly model is designed to equip the model with the ability to accurately identify potential landslide anomalies in aerial imagery. The primary purpose of this training was to enable GANomaly to learn and differentiate between various terrain features, particularly focusing on patterns that deviate from what is typically observed in normal landscapes. For the training process, a substantial dataset comprising approximately 120,000 tiles was used in the training stage. This large number of tiles ensured that the model was exposed to a wide range of terrain features and conditions, thereby improving its learning and accuracy.

A significant portion of this dataset, about 100,000 tiles, represented areas covered with trees. Trees often dominate aerial imagery in mountainous regions, making them an component of the dataset for the model to understand and recognize as part of normal terrain. The remaining 20,000 tiles were evenly distributed among other crucial categories, namely agricultural land, buildings, roadways, rivers, and riverbanks. This equal division of the remaining tiles among these categories was strategically implemented to provide a balanced representation of various terrain types.

Among the mountainous regions, given the lower availability of tiles in these categories compared to those depicting trees, the approach of rotation tiles ensured that the model was not overly biased towards tree-covered areas and could effectively recognize and analyze a diverse range of terrain features. This balanced training approach was pivotal in preparing GANomaly for the task of landslide anomaly testing and detection, ensuring it could operate effectively across the varied landscapes present in the mountainous aerial imagery.

2.4 Testing and results

For the testing stage of the GANomaly model, a database comprising both normal and abnormal tiles was used. The normal tiles, amounting to 5,800 in total, were selected from the same aerial imagery of the mountainous areas in the Fuxing District. However, these tiles were distinct from those used in the training dataset, ensuring a rigorous testing process. In the distribution of these normal tiles, about half, or approximately 2,900 tiles, represented tree-covered areas. The remaining half was evenly divided among other categories: agricultural land, buildings, roadways, rivers, and riverbanks. This distribution was designed to mirror the diverse landscape features of the region and provide a comprehensive basis for testing the model's accuracy in differentiating normal terrain features. The number of 100 abnormal tiles were collected through visual inspections of landslide-affected areas. These tiles were used in evaluating the model's efficacy in detecting anomalies that are characteristic of landslide occurrences. Some example tiles in abnormal class are shown in Figure 11.

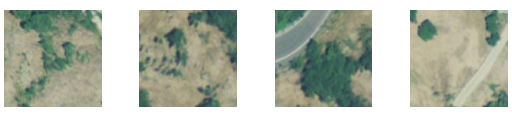

Figure 11. Examples of abnormal tiles in testing stage.

During the testing procedure, a receiver operating characteristic (ROC) curve was generated to determine the effectiveness of the model in distinguishing between normal and abnormal tiles, as shown in Figure 12. Two threshold determination approaches were employed: Youden's J statistic(Youden, 1950) and the closest to top-left threshold method. These approaches yielded the best threshold values of 0.0047 and 0.0048, respectively.

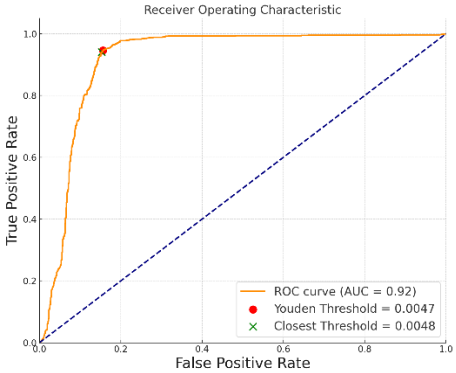

Figure 12. ROC curve in testing stage.

Adopting a threshold value of 0.00475 for the final analysis, the results were quantified using a confusion matrix. The metrics derived from this analysis were: an area under the curve (AUC) of 0.917, an accuracy rate of 0.895, an F1 score of 0.900, a precision of 0.857, and a recall of 0.947. These results indicated a high level of efficacy of the GANomaly model in detecting landslide anomalies, demonstrating its potential as a powerful tool in geohazard monitoring and risk assessment. The combination of high accuracy, precision, and recall underscores the model's reliability in identifying both the presence and absence of landslide-related anomalies in the aerial imagery.

3 CONCLUSIONS

In this study, we demonstrated the potential of employing GANomaly, an advanced Generative Adversarial Network model, for detecting landslide anomalies in aerial imagery of Fuxing District's mountainous terrain. Our methodology involved an training database of around 120,000 tiles, predominantly featuring tree-covered areas, balanced with a variety of other terrain types. This diverse dataset ensured a comprehensive and effective learning process for the GANomaly model. The testing phase, using 5,800 normal and 100 visually-inspected abnormal tiles, validated the model's precision in anomaly detection. The application of ROC curve analysis and optimal threshold determination through Youden's J statistic and closest to top-left threshold methods resulted in performance metrics: an AUC of 0.917, an accuracy of 0.895, and an F1 score of 0.900.

These results feature the potential of artifical intelligence in enhancing geohazard monitoring and risk assessment. The integration of GANomaly in high-resolution aerial imagery analysis marks a significant advancement in environmental monitoring, paving the way for more sophisticated, real-time monitoring systems.

ABSTRACT: Slope failures pose a significant threat to infrastructure and human safety, primarily influenced by factors such as rainfall, surface runoff, changing soil water content, and slope movement. However, most of the existing technologies rely on separate devices with limited integration capabilities. This study addresses these limitations by developing the Smart Pole, a multifunctional slope monitoring device. Equipped with sensors including a rain gauge, humidity and temperature sensor, surface water runoff sensor, camera, soil moisture content sensor, and an Inertial Measurement Unit (IMU), the Smart Pole offers versatility in assembling and disassembling sensors to meet specific monitoring needs. The device incorporates a power supply system and a Microcontroller Unit (MCU) for data collection, processing, and transmission using LoRa technology. This article introduces the purpose, functional requirements, and components of the Smart Pole. Additionally, laboratory calibration and field testing were conducted to validate the Smart Pole's performance. The testing process presents the calibration process of the device's soil water content measurements. The final performance presents the integration of the Smart Pole.

RÉSUMÉ: Les glissements de terrain représentent une menace significative pour l'infrastructure et la sécurité humaine, influencés principalement par des facteurs tels que les précipitations, le ruissellement de surface, la variation de la teneur en eau du sol, et les mouvements de pente. Cependant, la plupart des technologies existantes reposent sur des dispositifs séparés avec des capacités d'intégration limitées. Cette étude aborde ces limitations en développant le Mât Intelligent, un dispositif de surveillance de pente multifonctionnel. Équipé de capteurs tels qu'un pluviomètre, un capteur d'humidité et de température, un capteur de ruissellement d'eau de surface, une caméra, un capteur de teneur en humidité du sol, et une Unité de Mesure Inertielle (IMU), le Mât Intelligent offre une polyvalence dans l'assemblage et le désassemblage des capteurs pour répondre aux besoins spécifiques de surveillance. Le dispositif intègre un système d'alimentation et une Unité de Microcontrôleur (MCU) pour la collecte, le traitement et la transmission des données via la technologie LoRa. Cet article présente l'objectif, les exigences fonctionnelles et les composants du Mât Intelligent. De plus, une calibration en laboratoire et des tests sur le terrain ont été réalisés pour valider les performances du Mât Intelligent. Le processus de test illustre la calibration de l'appareil pour les mesures de la teneur en eau du sol. La performance finale met en avant l'intégration du Mât Intelligent.

Keywords: Slope stability; monitoring device; laboratory calibration.

1 INTRODUCTION

In landscapes susceptible to the repercussions of vigorous meteorological events, understanding and analysing rainfall-induced slope failures become crucial. The failure of slopes due to excessive rainfall has a sequence of occurring in stages, initiating with the saturation of the slope surface and followed by infiltration into the interior of the slope. This process can induce several potential slope failure conditions, such as deformations, cracks, sliding, and in dire situations, complete slope collapse. It's noteworthy that the acceleration in the severity of deformation is often directly related to increasing rainfall amount, thus necessitating a deeper examining monitoring and mitigation strategies in the context of these phenomena. To effectively manage and potentially

curtail the progression of failure phenomena, a diligent monitoring framework is indispensable.

To accomplish the objective of gathering field data for subsequent data analysis, Karunarathne et al. (2020) illustrated the use of an Internet of Things (IoT) device equipped with wireless communication capabilities for monitoring landslides. This research highlighted the evolution of IoT technology for data collection, curation, and presentation, with the potential for future machine learning applications. Accompany with the landslide susceptibility assessment, Jeong et al. (2020) utilized wireless sensor network technology to connect multiple individual sensors to monitor a potential slope failure threatened by rainfall events. With the assistance of diverse monitoring sensors, Bai et al. (2020) constructed a microservices architecture incorporating a web service to enhance the provision of early warning services for landslide hazards. Li et al. (2021) developed a risk assessment methodology that leveraged 5G and IoT technology to measure potential landslide indicators, including surface displacement, rainfall, and ground cracks. This early warning system was implemented and validated using an actual project as an example. To explore the failure mechanism of shallow landslides, research by Bovolenta et al. (2020) has revealed that the water content of the slope surface serves as a important indicator for reliably illustrating the slope failure process. Chen et al. (2020) presented the calibration and filed performance of the tilting measurements on a underground structure in a landslide area.

Monitoring is important for tracking slope failures, collecting data for future models, and enhancing safety and sustainability. This study presents the Smart Pole device, equipped with sensors for soil water content, runoff, humidity, temperature, tilt, camera, and rain gauge, plus a MCU, storage, and power. This article presents calibrating the soil water content sensor and the camera's trigger mechanism, activating at excessive tilt.

2 DESIGN AND METHODOLOGY

An effective monitoring system comprehensively incorporates multiple factors that contribute to potential failure, with rainfall amount being at the forefront. However, merely observing rainfall quantities is not sufficient. Analysing the soil water content of the slope surface offers insight into the amount of infiltration, which is a key element influencing slope stability. Once surface runoff is initiated, the velocity of water runoff and the volume of water accumulating on the slope during flow can affect the stability and erosion of the slope.

When slopes begin revealing signs of failure, observing and recording of the slope inclination can provide important indications regarding possible initiation and progression of failure. Employing on-site cameras, which can be triggered when certain failure criteria are met, can offer visual documentation of the failure process. Additionally, considering environmental factors like humidity and temperature is also crucial, as these can influence the micro-environmental conditions of the slope.

As illustrated in Figure 1, the distinct levels of the Smart Pole were each equipped with sensors meticulously tailored to gauge different parameters and facets of slope stability. Among the various sensors, there are two functional blocks. Each block has its own memory storage and MCU. A key distinction lies in the triggering logic for the camera. As illustrated in Figure 1, when IMU records a tilting angle surpassing a specific threshold—such as exceeding 15°—the camera is triggered to capture a picture.

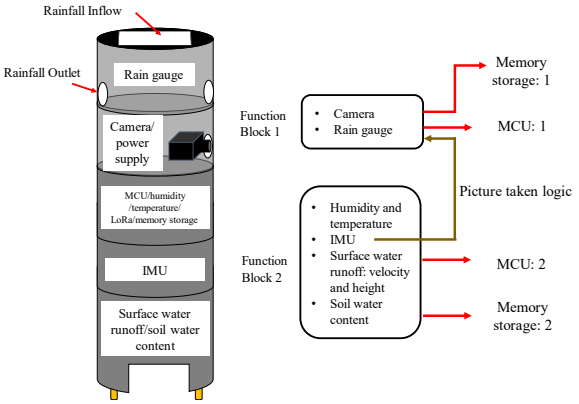

Figure 1. Scheme of Smart Pole device.

3 CALIBRATION AND PROTOTYPE ASSEMBLY DEMONSTRATION

3.1 Calibration of soil moisture measurement

The function of measuring soil moisture was utilized by the YL-69 hydrometer sensor. Three distinct soil types were meticulously prepared for calibration purposes: reddish laterite clay (typical to the local soil), Ottawa sand, and a 1:1 weight mixture of reddish laterite and Ottawa sand. Utilizing the Harvard Miniature Compaction approach, soil samples were produced with a height of 71mm and a diameter of 33mm. Soil samples were compacted using a combination of diverse of dry soils and water. Water content within the soil samples was determined by calculating the weight of the water added to the dry

soils. As indicated in Figure 2, The YL-69 sensor was inserted into each soil sample, and analogue readings were recorded. Note that, to prevent loss of water content during measurement, the sample with the YL-69 was sealed inside a plastic bag, which is not shown in Figure 2.

Figure 2. Calibration process of soil water content sensor.

In the scope of this study, both the volumetric water content (VWC) and gravimetric water content (GWC) were calibrated with sensor, providing a holistic view of the moisture within the soil samples. The calibration results are depicted in Figures 3 and Figure 4, which also display the calibration equations for the reddish laterite. These equations will subsequently be utilized in the following demonstration step.

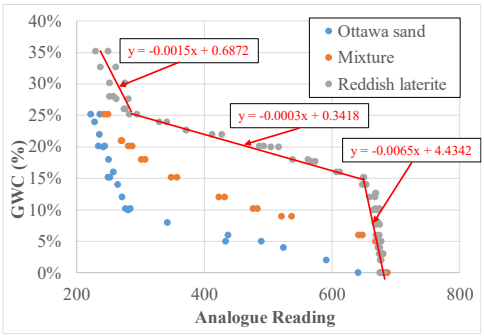

Figure 3. Calibration results of gravimetric water content (GWC) versus YL-69 analogue readings for 3 types of soils.

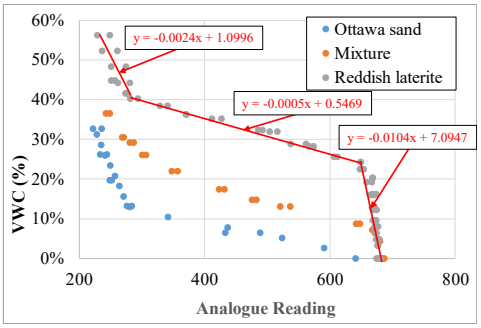

Figure 4. Calibration results of volumetric water content (VWC) versus YL-69 analogue readings for 3 types of soils.

3.2 Prototype assembly demonstration

Figure 5 displays the prototype of the Smart Pole device, with the left side illustrating the inner levels with various sensors, and the right side depicting the finished exterior. Figure 6 illustrates the field setup for measuring soil water content. On the left side of Figure 6, picture shows that the YL-69 sensor was inserted on the surface of the local soil (reddish laterite), while the right side demonstrates a laptop computer used for data collection via LoRa. The initial soil condition was dry; by pouring water from a bottle, as indicated in Figure 7, the measured analogue reading indicates increasing GWC. Figure 7 demonstrates a good agreement when compared to the calibrated data presented in Figure 3.

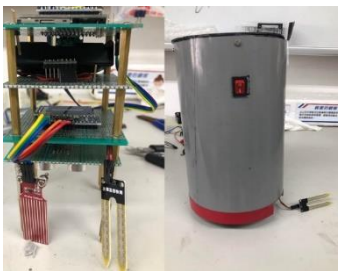

Figure 5. Smart Pole device.

Figure 6. Field testing on measuring water content.

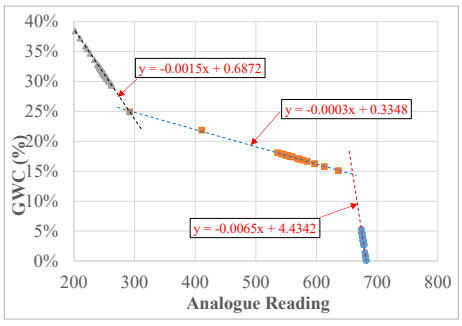

Figure 7. Field testing on gravimetric water content (GWC) versus YL-69 analogue readings.

Figure 8 displays the setup for triggering the camera action based on the tilting angles measured by the IMU (model: MPU6050). As shown in Figures 9 and 10, when the measured tilting angles exceed 15° in the X direction, a picture was taken to show the surroundings, as picture shown on the right side of Figure 8. The angle of 15 degrees was chosen arbitrarily for a functional test with taking only a single image. In future developments, the tilting angle can be set more purposefully according to specific requirements, with multiple pictures captured as

needed. For further exploration, since central MCU processes all the signals within devise, additional data could serve as criteria for triggering picture capture, such as the amount of rainfall accumulation, rainfall intensity, a combination of tilting on different directions measured by the IMU, surface water runoff conditions, and soil water content.

4 CONCLUSIONS

This study introduces the Smart Pole device, aiming to address the challenges associated with slope failures, particularly those prone to occur during rainfall events. The primary objective of this device is to meticulously monitor and gather physical data related to the various factors affecting slope stability. The Smart Pole incorporates an array of sensors, encompassing measurements such as soil water content (e.g., GWC and VWC), surface runoff velocity and depth, slope tilting angle, humidity, temperature, camera, and a rain gauge. Each of these sensors was tailored to capture distinct micro-environmental parameters crucial for assessing slope stability.

Empowered by its self-contained power source and data transmission capability via LoRa, the Smart Pole was proficient in providing real-time data for in-depth analysis of rainfall-induced slope failures. Additionally, it served the purpose of an early warning system. To showcase the capabilities of this device, the study conducted laboratory calibrations for GWC and VWC using three different soil types: Ottawa sand, reddish laterite clay, and a 1:1 mixture of Ottawa sand and reddish laterite clay. Furthermore, a field test demonstrated the measurement of GWC in the field, with data collected and transmitted through LoRa. The Smart Pole's triggering mechanism, which activated a built-in camera based on measured tilting angles from an IMU sensor, was also showcased. This feature allowed the device to potentially record immediate environmental changes during critical slope movements.

In summary, the Smart Pole, along with its comprehensive design, calibration methods, and validated functionalities, not only enriches existing academic and practical knowledge but also lays the foundation for future research and field applications in this domain.

ABSTRACT: The A83 Loch Shira landslide has been active since the early-1990s, and this paper will present a brief history of this mass movement. Significant movements are evident in the bund immediately adjacent to the road, narrowing the verge from around 2m in 1995 to effectively zero in places. Movement is also apparent in the cut slope above the bund and evidenced clearly by the significant distortion of a catch pit, the date of installation of which, while post-1995, is unknown. The movement of the landslide is driven by groundwater, specifically water from rockhead at the interface with the superficial deposits. This drives movement downslope to the stiffer complex formed by a retaining wall, the road and the rockfill bund adjacent to the road. In 1995 it was postulated that this stiffer complex could store energy and potentially lead to a catastrophic failure. The movement of the bund and the cut slope above seems likely to be a manifestation of a limited pressure (or energy) release and the current state of the landslide is of concern. The potential adverse influences of climate change on the landslide include increased water in the system from both direct rainfall and recharged groundwater, storm effects on the retaining wall and erosion of the slope above the retaining wall from increased road runoff.

RÉSUMÉ: Le glissement de terrain A83 du Loch Shira est actif depuis le début des années 1990, et cet article présentera un bref historique de ce mouvement de masse. Des mouvements importants sont évidents dans la digue immédiatement adjacente à la route, rétrécissant l'accotement d'environ 2 m en 1995 à effectivement zéro par endroits. Le mouvement est également apparent dans la pente coupée au-dessus de la digue et mis en évidence par la déformation importante d'un puisard dont la date d'installation, bien que postérieure à 1995, est inconnue. Le mouvement du glissement de terrain est entraîné par les eaux souterraines, en particulier l'eau de la tête rocheuse à l'interface avec les dépôts superficiels. Cela entraîne un mouvement vers le bas de la pente vers le complexe plus rigide formé par un mur de soutènement, la route et la digue en enrochement adjacente à la route. En 1995, il a été postulé que ce complexe plus rigide pourrait stocker de l'énergie et potentiellement conduire à une défaillance catastrophique. Le mouvement de la digue et de la pente de coupe au-dessus semble être la manifestation d'une libération de pression (ou d'énergie) limitée et l'état actuel du glissement de terrain est préoccupant. Les influences négatives potentielles du changement climatique sur le glissement de terrain comprennent l'augmentation de l'eau dans le système à partir des précipitations directes et des eaux souterraines rechargées, les effets des tempêtes sur le mur de soutènement et l'érosion de la pente au-dessus du mur de soutènement due à l'augmentation du ruissellement routier.

Keywords: Landslide; instability; drainage road; infrastructure.

1 INTRODUCTION

Loch Shira is located approximately 65 km to the northwest of Glasgow (Figure 1) and the A83 trunk (strategic) road to mid-Argyll follows its shoreline on the approach to Inverary.

Since the earliest history of the landslide in the 1970s, only relatively minor works have been undertaken to reduce instability. The site was highlighted as high risk in the Scottish Road Network Landslides Study (Winter et al., 2005, 2008, 2013).

In this paper we examine the history of the landslide and indicate the likely approach to remediation.

2 HISTORY

In the mid-1970s a 1 m high masonry retaining wall that showed signs of distress was removed and the toe of the slope cut back. Soon after, what was described as a major slip occurred and, following emergency works to clear the road, a 2m high gabion basket wall was installed with rockfill behind.

In 1992 the stability of the gabion basket wall was questioned. The wall showed signs of bulging, the baskets were rounded in shape and the fill seemed to be loose. There was no evidence of any compromise to the overall stability of the wall.

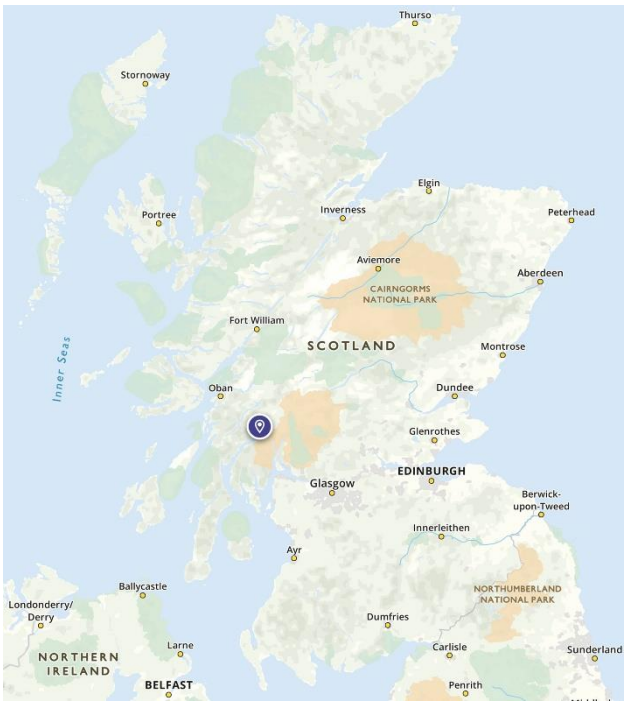

Figure . Map of Scotland (excluding Orkney and Shetland) showing the location of the Loch Shira landslide.

At this time the slope was inspected and multiple shallow slip circles and scarps up to 300 mm in height identified. Trees with vertical trunks of 3 m to 5 m height were [erroneously] cited as evidence of a lack of movement. Monitoring pins were established on the road, the top of the wall and on the slope; no movement of the pins was recorded between December 1992 and March 1994.

In April 1994, 15 mm to 20 mm of rotational movement was recorded [it remains unclear how this was determined to be rotational movement]. An emergency contract was let to remove the gabion wall and trim the cut slope to 1:2. During the contract there was a slope failure at the southern end of the works and remedial works were extended 20 m in this direction. Movement began at the northern end of the works and a 0.5 m rockfill blanket was installed at the toe of the cut slope. The contract was completed in June 1994 and the surface of the cut slope left exposed to allow visual detection of water flow. In September 1994 slope filter drains were installed and a minor slope failure repaired.

In December 1994, exceptionally heavy rainfall caused two minor slips above the surface water cut-off drain at the top of the cut slope. Further emergency works were carried out to repair the drainage system and to install a 6 m high rockfill bund extending 80 m along the toe of the slope. During these works extensive cracking was observed in the area above the cut slope. Extensive monitoring using wooden surface pegs was established and this minor downslope movement over the next six to 12 months.

Contemporaneous, local rainfall data is not available. The nearest current gauge is at Loch Restil which gives an average annual rainfall for 2013 to 2022 of 3,341 mm with a range of 2,613 to 4,110 mm. However, the distance (approximately 12 km) from and relative elevation (around 250 m higher) of this gauge to Loch Shira does perhaps question whether this is entirely representative. In addition, Inverary is anecdotally known for having something of a microclimate with unverified sources suggesting annual average rainfall closer to 1,600 mm.

In April 1995, the first author and a colleague undertook an assessment of the slope (Figure 2). The primary conclusion of that work was that the failure was most likely controlled by water pressure at rockhead. Both old and new scarps were identified, recent slips in the regraded cut slope were observed and the entire area of the landslide was wet with some areas being identified as particularly boggy. Streams, both active and ephemeral were encountered, some of which fed into tension cracks and/or scarps. Other slips were identified in the area outside the landslide as might be expected.

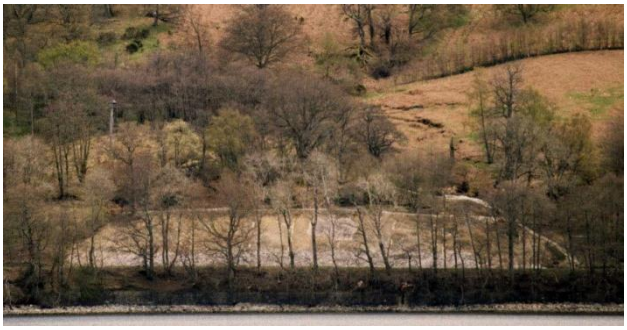

Figure 2. The Loch Shira landslide in 1995.

The depth to the Phyllite rockhead (Anon., 1897; Hill et al., 1905) at road level was, to some degree, uncertain (see Figure 3) and fundamental to the likely behaviour of the landslide. While only minor movements had been observed since the December 1994 rainfall, it was considered that further such rainfall could initiate further significant movement. The prevalence of an extensive network of drainage ditches talking water from a former forestry plantation to the head of the landslide and the removal of the trees were considered to be contributory factors. A full ground investigation was recommended and designed and supervised in summer 1995 by the first author.

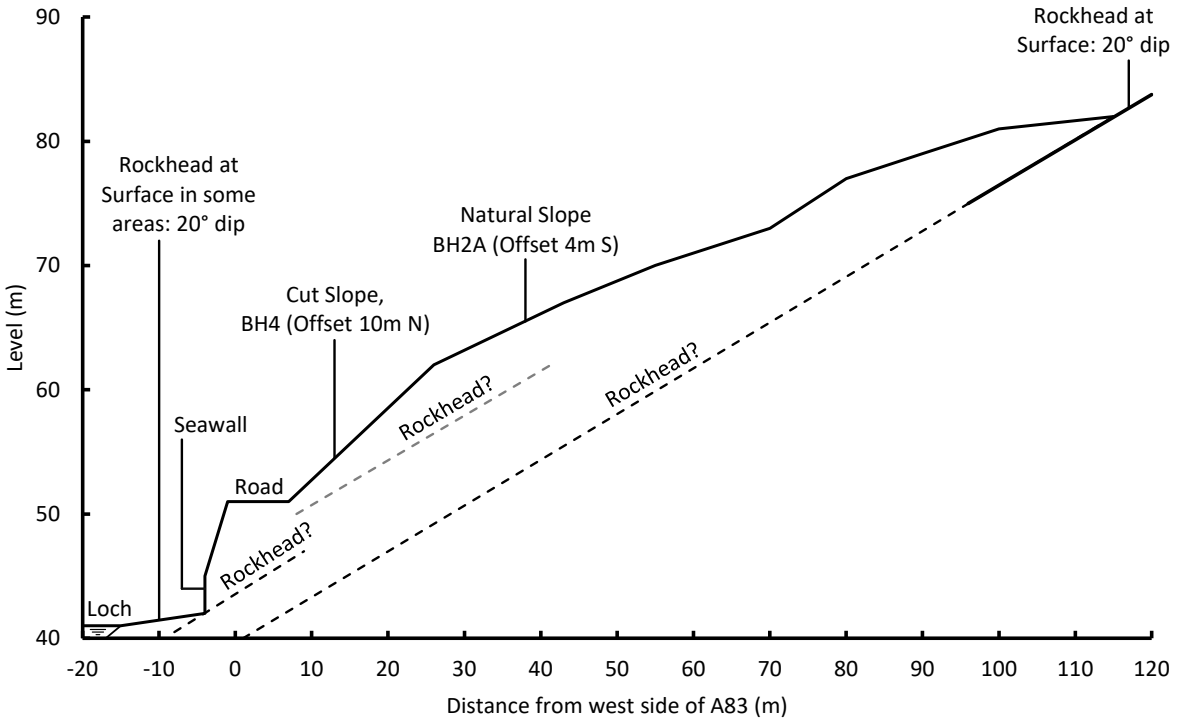

Figure 3. East-west section through the Loch Shira slope: the landslide is approximately 100m at road level.

The investigation comprised 10 boreholes sunk primarily by cable percussion, although four were sunk into bedrock by rotary drilling, and eight trial pits were sunk to depths of between 2.8 and 5.2 m with the extensive use of benching and trench support. Fifteen standpipe piezometers were installed (11 single installations and two twin installations) in the boreholes and trial pits to enable the long-term monitoring of groundwater; inclinometer tubes were installed in boreholes at the outer edge of the road to allow the long-term monitoring of subsurface lateral displacements.

The piezometer in the centre of the landslide regularly exhibited hydrostatic pressures in excess of 2.5 m above ground level. This broadly confirmed the hypothesis that high water pressures at the soil-rock interface were a major cause of instability.

Rockhead was originally conjectured in three locations but the ground invcestigation conformed the deeper location with daylighting at the loch shore.

3 RECENT CONDITION

Following the ground investigation, a remedial design was developed to stabilise the landslide. This involved the removal of ground water and the effective capture of surface water in order to reduce the water content of the soils and increase their strength and therefore the stability of the landslide mass. The design comprised:

- A pattern of downslope drainage on the natural slope consisting of well points to access water entering the landslide linked by a series of deep, lined rockfill trench drains linked to an external drainage system alternating with less deep, lined rockfill trench drains (without well points) on the body of the landslide with adjacent trench drains linked by herringbone drains.
- On the cut slope a system of counterfort drains linked by herringbone drains was proposed.

This preliminary design was not taken forward and there followed a period of almost two decades of irregular inspections which revealed relatively little movement at road level other than a significant degree of distortion to the rockfill bund immediately above the road. This occurred post-1998 when the first author's observations indicate that the rockfill bund remained planar, while by mid-1999 a sinusoidal shape could be observed along its length.

In the early-2010s the inspections recognised that the existing post-1995 drainage provision was in poor condition, effectively failed, and key elements of the drainage system were replaced, and additional drains installed to supplement the existing design in early-2016.

In 2022 (14 April, 18 and 26 October) the site was inspected by the authors as part of Transport Scotland's Vulnerable Locations Operations Group activities, which inter alia include identifying assets that need adaptation to provide adequate resilience to the effects of climate change. It was immediately apparent that there had been significant outward movement of the rockfill bund (Figure 4); as late as 1999 the distance from the toe to the edge of the

running surface was 2m whereas by 2022 the bund was, in places, touching the edge of the running surface.

Inspection of the 2016 drainage scheme revealed measured strains of up to 15% in the downslope direction and up to 10% orthogonally (Figure 5).

Figure 4. The original distance of the toe of the bund from the edge line of the carriageway was approximately 2m, by April 2022 the distance had reduced to zero in places.

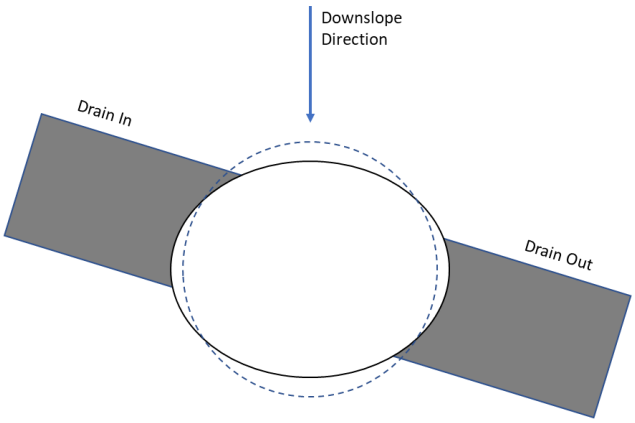

Figure 5. Catch pit plan view showing the original circular shape (600mm diameter, dashed blue line) the current shape of the ellipse (minor axis 510mm, major axis 660mm as a solid black line), the inflow and outflow pipes, and the downslope direction.

4 WAY FORWARD AND CONCLUSIONS

The A83 Loch Shira landslide has been of concern for around three decades.

Recent observations suggest that significant downslope movement is occurring within the landslide mass and that this is manifesting at road level in downslope movement and distortion of the rockfill bund. The major concern is that if the movements are occurring at rockhead then energy is being stored behind the mass formed by the seawall, the road and the slope between, leading to the potential for a brittle failure of those components.

The existing design is heavily predicated towards the use of deep and surface drains to capture groundwater and surface water, as would be expected for a landslide such as that at Loch Shira that is driven by water. These in turn rely on filter drains, including counterfort, herringbone and deep well points and trench drains. Recent work on the longevity of such drains (Nettleton et al., 2022) strongly suggest that significant maintenance of such drains, amounting to renewal of the filtration and drainage media, would be required approximately every 15 to 25 years. This is supported by the fact that the drains installed in the early-1990s had failed and were replaced and supplement in 2016, slightly more than 20 years after installation.

A review of potential remedial solutions is currently underway, but it is difficult to envisage a solution that does not involve large scale drainage features.

Back analysis of flexible barrier response following an open hillslope landslide impact at Pa Mei, Hong Kong

Analyse rétrospective de la réponse d'une barrière flexible suite à un impact de glissement de terrain sur une pente ouverte à Pa Mei, Hong Kong

ABSTRACT: An open hillslope landslide occurred above Ma Wan New Village at Pa Mei on Lantau Island, Hong Kong in October 2021, involving a total debris volume of approximately 240 m^3. About half of the debris was deposited on the hillside while the rest travelled further downslope to hit the edge panels of two flexible rockfall barriers, which had a rated energy capacity of 3,000 kJ. The debris was stopped and retained by the barriers with limited observable damage to the barriers. This paper documents the back analysis of the response of the flexible barriers using the finite element program LS-DYNA. A numerical simulation was first conducted to replicate a full-scale rockfall test to calibrate the flexible rockfall barrier model. The landslide impact process was then reconstructed numerically and calibrated against field observations. The impact velocity and energy were estimated from free-field debris mobility analysis and coupled debris-barrier interaction. Using the calibrated numerical model, a hypothetical landslide debris impact event close to the energy rating of the barrier system is also investigated. Future work on the design of flexible rockfall barrier systems subjected to landslide debris impact is discussed.

RÉSUMÉ: Un glissement de terrain à pente ouverte s'est produit au-dessus du Nouveau Village de Ma Wan à Pa Mei sur l'île de Lantau, à Hong Kong, en octobre 2021, impliquant un volume total de débris d'environ 240 m^3. Environ la moitié des débris ont été déposés sur le flanc de la colline, tandis que le reste s'est déplacé plus loin vers le bas de la pente pour heurter les panneaux de bord de deux barrières pare-pierres flexibles, d'une capacité énergétique nominale de 3,000 kJ. Les débris ont été arrêtés et retenus par les barrières, avec des dommages visibles limités sur les barrières. Cet article documente l'analyse rétrospective de la réponse des barrières flexibles à l'aide du programme d'éléments finis LS-DYNA. Une simulation numérique a d'abord été réalisée pour reproduire un test de chute de pierres à grande échelle afin de calibrer le modèle de barrière anti-chute flexible. Le processus d'impact du glissement de terrain a ensuite été reconstruit numériquement et calibré par rapport aux observations sur le terrain. La vitesse et l'énergie d'impact ont été estimées à partir d'une analyse de la mobilité des débris en champ libre et de l'interaction couplée débris-barrière. À l'aide du modèle numérique calibré, un événement hypothétique d'impact de débris de glissement de terrain proche de la cote énergétique du système de barrière est également étudié. Les travaux futurs sur la conception de systèmes de barrières anti-pierres flexibles soumis à l'impact des débris de glissements de terrain sont discutés.

Keywords: Flexible barrier; landslide; debris impact; back analysis; LS-DYNA.

1 BACKGROUND

An open hillslope landslide occurred above Ma Wan New Village at Pa Mei, Lantau Island in October 2021. Approximately 110 m^3 of landslide debris impacted on two flexible rockfall barriers (3000 kJ model). The debris was successfully stopped and retained by the flexible barriers with limited observable damage to the barriers. This incident provided a good opportunity for studying the behaviour of rockfall barriers subjected to impact from debris consisting primarily of granular soil.

It was estimated that the landslide occurred in the evening of 9 October 2021 (Fugro, 2022). The shallow landslide was probably rain-induced and was attributed to the development of transient elevated pore water pressures within the colluvium and completely decomposed tuff layers above the shallow bedrock. The landslide source measured approximately 20 m long by 13.5 m wide by 1.5 m deep. The failure volume at the source area was

estimated at 220 m^3. The length of the landslide trail between the crown of the landslide scar and the barriers was approximately 40 m. A debris volume of 20 m^3 was estimated to have been entrained along the landslide path. About a third (80 m^3) of the total landslide debris was observed to have deposited upslope of flexible barrier FW-1A, of which approximately 20 m^3 was retained by the south-eastern edge panel of barrier FW-1A. After impact, the maximum net elongation (outward deflection) of FW-1A was found to be about 2.3 m measured from the barrier axis (i.e. line connecting base of barrier posts) from hand-held LiDAR scanning. The residual height of the barrier net was 84% of the original minimum net height of 4.9 m. The rest of the debris (160 m^3) deposited upslope of lower barrier FW-1B, of which approximately 90 m^3 was retained behind the barrier net in its north-western edge panel. The maximum net elongation of FW-1B after impact measured 2.8 m from the barrier axis. The residual height of the barrier net was 78% of the original minimum net height.

2 FLEXIBLE BARRIER SYSTEM

Six separate flexible barriers totalling approximately 388 m in length, were constructed in 2012 to protect the downslope area against boulder fall and open hillslope landslide hazards originating from the natural hillside.

A general view of the flexible barriers is shown in Figure 1. The barriers hit by landslide debris, FW-1A and FW-1B, were located in a largely planar natural hillside sloping at about 30°. FW-1A comprised five net panels while FW-1B comprised four net panels. All panels were approximately 12 m wide. The steel posts in the barriers consisted of 5.5 m high HEB 200 beams. Two top longitudinal "suspension cables" suspended the principal nets in alternate spans (Figure 2). Brake elements were provided to each suspension cable in alternate spans. A third longitudinal cable, the "brake cable", ran parallel to the two suspension cables. The brake cable was provided with brake elements at the centre of each span. The arrangement of the bottom longitudinal "ground cables" followed a similar arrangement, i.e. two ground cables and one brake cable. The principal net consisted of a diagonal net made up of 10 mm diameter wire ropes arranged in a 140 mm × 140 mm square pattern. The wire ropes were 6×7 IWRC stranded ropes with breaking force of 72 kN. The energy-dissipating devices (brake elements) are mobilised through friction developed as cable loads cause the wire ropes to slip through the openings in each brake plate, tightening and taking up the available length in the wire rope loop (Figure 2). After mobilisation, the force in each brake element stays relatively constant before the maximum elongation is reached. No major signs of movement were noted in the brake elements after the incident, although signs of abrasion in the stranded ropes to the extent of 1-2 cm were observed. A more detailed description of the components and the working mechanism of the barrier system is given in Wong and Lau (2022).

Figure 1. General view of barriers FW-1A (left) and FW-1B (right) after installation in 2012.

Figure 2. Longitudinal cables and brake elements.

3 NUMERICAL MODEL

3.1 Material models and properties

The material models used in the numerical model of the 3000 kJ flexible barrier and the main input parameters are summarised in Table 1. The steel posts were modelled as elastic-perfectly plastic beam elements. Wire ropes, including those making up the diagonal net, were modelled as elastic cables which develop no internal forces in compression or bending. A typical value of the elastic modulus for stranded wire ropes was used. For stranded wire ropes, the range of the modulus of elasticity has been given as between approximately 100 and 130 GPa (e.g. DIN, 1984; Feyrer, 2000; Boroška et al., 2014). The nominal

metallic cross sectional area was used with typical values from EN 12385-2 (BSI, 2008).

Brake elements were modelled as inelastic springs with fully specified force-elongation relationships as shown in Figure 3.

Table 1. Material models and input parameters used in numerical model.

Component and element type	LS-DYNA material model	Key input parameters
Boulder (solid)	RIGID	ρ = 2478 kg/m^3
Landslide debris (solid)	SOIL_AND_FOAM	ρ = 2000 kg/m^3 G = 6 MPa B = 12 MPa (bulk modulus) ν = 0.3 c' = 1 kPa ϕ_1' = 30°
Posts (beam)	PLASTIC_KINEMATIC	ρ = 7850 kg/m^3 E = 205 GPa ν = 0.3 p_y = 235 MPa
Wire ropes (beam)	CABLE_DISCRETE_BEAM	ρ = 7900 kg/m^3 E = 120 GPa
Net (beam)		
Brake elements (beam)	SPRING_INELASTIC	See Figure 3

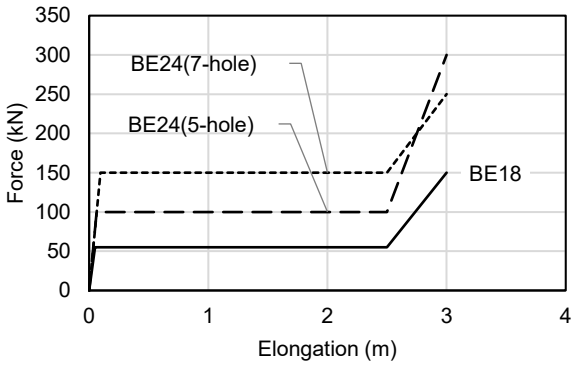

Figure 3. Force-elongation relationship of brake elements.

3.2 Replication of full-scale rockfall test

The diagonal net was tied to the suspension cables through seam ropes. It is expected that the friction between the diagonal net and suspension cables could be greater than that in ring-net type barrier nets, in which the principal net consists of ring-nets suspended from longitudinal cables directly or through shackles. Koo and Kwan (2016) carried out numerical simulation of a punching rockfall test using a coefficient of friction of $\mu = 0.1$ for the sliding contact between shackles and steel cables, with good agreement with physical test results. To model the sliding contact between the diagonal net and suspension cables through seam ropes under the present study, different values of the coefficient of friction was attempted.

The deformed shape of the barrier is shown in Figure 4. The deceleration and location of the block was consistent between measurement and simulation results. The difference in maximum elongation of the barrier net was within 5%. The overall mode and magnitude of deformation were well reproduced in the simulation. Overall, a value of $\mu = 0.9$ returned simulation results most consistent with the physical test. The average anchorage forces for the top longitudinal cables were within about ±10% of the measured values in the physical test while the anchorage forces in the bottom longitudinal cables were smaller than measured values by 13%. The simulated net elongation and residual height were also within 1 to 3% of physical test results.

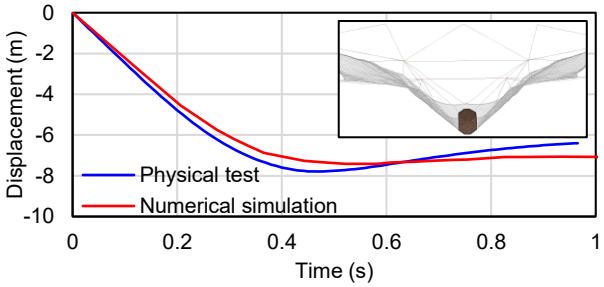

Figure 4. Displcaement of test block after impact.

3.3 Model setup for coupled analysis

The setup of the numerical model is shown in Figure 5. As-built coordinates of the barrier posts and anchorages were used to construct the numerical model. Shell elements were used to construct the three-dimensional topography from airborne LiDAR data obtained in 2020 at 0.5 m resolution. Following the landslide event, hand-held LiDAR scanning of the source area was carried out. The 2020 topography was locally modified to take into account the depression at the source area resulting from the landslide. A "landslide source container" was constructed following the outline of the landslide source area delineated from field investigations. The container was topped by a "lid", which was identical to the pre-landslide topography shell elements but offset vertically by a prescribed distance to make up the target landslide source volume. The landslide source was generated in the space enclosed by the container, the topography and the lid. The debris was released by lifting the landslide source container. A regular array comprising of regular tetrahedral solid elements ("the ALE mesh") was set up to define the largest possible extent of the debris.

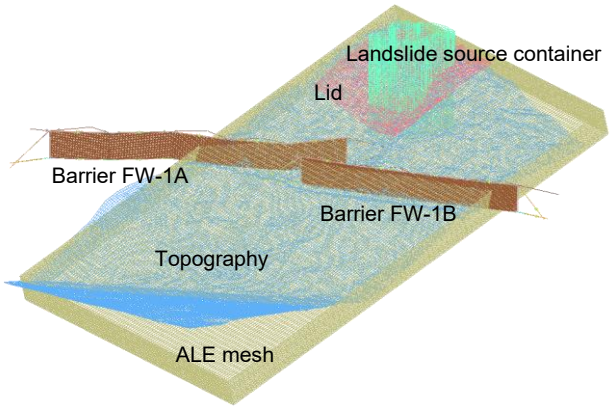

Figure 5. Numerical model setup.

Koo (2017) carried out back analysis of notable open hillslope landslides and channelised debris flows in Hong Kong using LS-DYNA. The back-calculated internal friction angle ϕ_i of landslide debris was found to be in the range of 25° to 30° for open hillslope landslides. The back-calculated apparent basal friction angle ϕ_a was found to be 20° for the Sham Wan Road landslide (GEO and Knill, 1995), which had occurred in a similar open hillslope setting. GEO (2012) recommends that ϕ_a = 25° and 20° should be used in mobility assessments for open hillslope landslides with source volume small than or equal to 500 m^3 and larger than 500 m^3, respectively.

The Drucker-Prager yield criterion was used for modelling the landslide debris (Table 1). An internal friction angle of 30° was adopted as a first estimate, while values between 27° to 32° were also attempted. The derivation of input parameters for the Drucker-Prager criterion from ϕ_i followed the procedure in Koo (2017). It is known that modelling results are not sensitive to the values of shear modulus, bulk modulus and Poisson's ratio and that sufficiently low stiffness values may be used for computational efficiency (Koo, 2017). A basal friction angle ϕ_a of 25° to 28° were attempted.

4 RESULTS OF COUPLED ANALYSIS

4.1 Barrier deformation

The frontal impact velocity, barrier deformation and debris geometry are presented in Table 2 for the case of internal friction angle of 30° and basal friction angles of 27°. The impact process is shown in Figures 6(a) and (b). The debris largely came to a stop at the end of the simulation as evidenced by the velocity contour shown in Figure 6(c). The total kinetic energy of the entire debris also reached a residual level (Figure 6(d)).

The deformation of the barriers was in general consistent with field observations (Figures 6(e) and (f)). For the upper barrier, the net elongation and the residual height were consistent with field measurements. In the simulation, a gap of about 1.5 m developed between the edge post and the net, as a result of the net elongation and sliding of the net along the longitudinal cables under the force of the oblique impact. Measurements using hand-held LiDAR scanning indicated that the opening was about 2 m wide.

4.2 Retained volume

There were uncertainties as to the relative proportions of debris depositing along the debris trail and of the debris directly retained by the barriers, given that the debris body was a continuum in the simulation. Nevertheless, the volume of debris at the upper barrier was largely consistent with field observations. Although the net elongation and the residual height of the lower barrier were also replicated reasonably well in the simulation, the debris volume was smaller than field observations. This is evidence of the challenging nature of modelling the behaviour of multiple-barrier systems, especially one involving edge impacts.

Table 2. Results of debris-barrier interaction.

	Upper barrier		**Lower barrier**	
	Numerical simulation	**Field observation**	**Numerical simulation**	**Field observation**
Debris frontal velocity at impact (m/s)	5.5	-	5.8	-
Maximum elongation of principal net (m)	2.3	2.3	2.1	2.8
Normalised residual height	82%	84%	81%	78%
Width of retained debris (m)	12	8	12	12
Volume of retained debris (m^3)	21	20	62	90

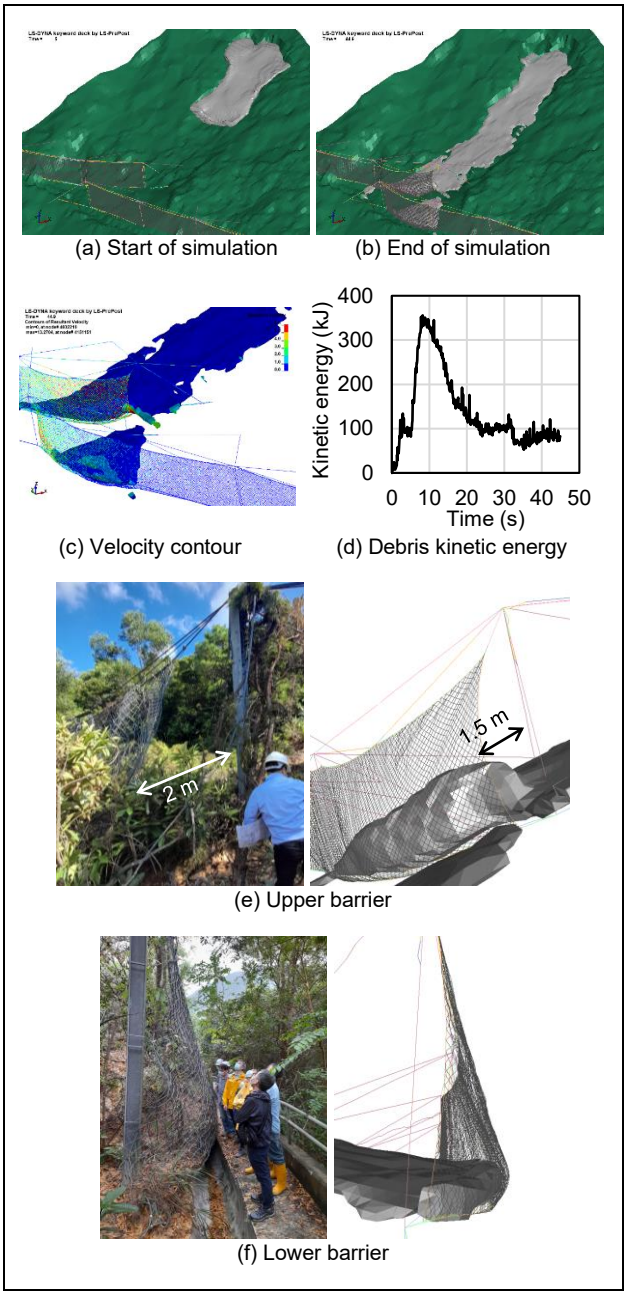

Figure 6. Results of coupled analysis.

4.3 Mobilisation of brake elements

The elongation of brake elements in the simulation was up to about 20% of the available length of the brake loops. As will be discussed later, the characteristics of the friction type brake elements make it difficult to achieve a close match between numerical and field results in terms of brake mobilisation under low energy impacts. Nevertheless, the overall deformation of the barriers was reasonably replicated in the numerical simulation. There was no overloading of wire ropes or brake elements.

4.4 Hypothetical impact scenario

Following the validation of the debris-barrier numerical model against field observations, an alternative impact scenario was studied by removing the upper barrier to investigate the condition if the lower barrier alone was subjected to a hypothetical 500 m^3 event, which gives rise to an impact energy close to the energy rating of the barrier.

Without the upper barrier, the lower barrier was able to resist the 500 m^3 debris impact, with greater net elongation (2.8 m) and lower residual height (77%) than either of the two barriers in the original twin-barrier layout. The brake element at the ground cable anchorage would also be mobilised to a far greater extent (30% as opposed to 17%). Nevertheless, a substantial reserve capacity was evident in terms of the utilisation of structural capacity of components and displacement limits of brake elements.

5 DISCUSSION

5.1 Impact energy

Three-dimensional debris mobility modelling using the numerical program 3d-DMM (Law et al., 2022), based on the SPH technique, was used to estimate the cumulative kinetic energy passing through the barrier locations under free-field conditions. In Hong Kong, this free-field cumulative kinetic energy is used for estimating the debris impact energy sustained by an energy-rated rockfall barrier. Although LS-DYNA could be used to perform debris mobility modelling (e.g. Koo, 2017), the computational demand is high. In this study, the frontal velocity from LS-DYNA was found to be close to 3d-DMM results, considering that the same 3D ground profile derived from LiDAR data was used in both programs. This confirms that it is reasonable to estimate the flow kinematics and impact energy using 3d-DMM.

It could therefore be estimated from 3d-DMM that the impact energy of the debris at barriers FW-1A and FW-1B was approximately 568 kJ and 421 kJ, respectively, accounting for approximately 15% to 20% of the energy capacity of the barrier. The relatively low impact energy resulted in relatively small deformations (i.e. high residual height).

Results of the present study indicate that a single barrier installed at Pa Mei would be able to resist an open hillslope landslide with a source volume of 500 m^3. Results from 3d-DMM give an impact energy of about 3100 kJ, i.e. close to the energy rating of the barrier. The barrier was able to sustain the impact without overloading of structural components or excessive deformation of brake elements.

5.2 Dynamic characteristics of brake elements

For brake elements which dissipate energy by plastic deformation, studies have shown that the forces developed and hence the amount of energy dissipated are marginally greater under dynamic condition than under static condition (Lam and Sze, 2021).

The behaviour for friction type brake elements used at the Pa Mei flexible barriers appears to be different. The mobilised forces in the brake elements are consistently lower under dynamic loading. This is consistent with the general rule that static friction is greater than dynamic friction. The use of force-elongation relationships obtained from static load tests may therefore overestimate the energy dissipation capacity of a friction type brake element. Nevertheless, landslide debris generally travels at a much lower velocity than a rockfall impact with the same kinetic energy. The use of static relationships is generally considered acceptable.

6 CONCLUSION AND FUTURE WORK

The response of the flexible barriers affected by the open hillslope landslide at Pa Pei has been back analysed using LS-DYNA. The numerical model was able to reproduce the barrier deformation and debris distribution to a reasonable extent.

This back analysis has enabled the development and validation of a coupled numerical model to investigate debris-barrier interaction. It has been demonstrated that the barrier system would be able to sustain a hypothetical impact event at or above its rated energy capacity.

The validated numerical model of flexible barriers and terrain under this study would enable a supplementary study on the assessment of the energy capacity of flexible rockfall barriers subjected to landslide debris impacts. This would also allow further optimisation of the design of flexible debris-resisting barriers by fully utilising the rated energy capacity of flexible rockfall barriers and by providing guidance on the appropriate residual height to be adopted for the assessment of retention capacity.

ABSTRACT: This study seeks to elucidate technical facets of the Tskneti landslide occurred in June 2015, Tbilisi, Georgia. Unfolding during an extraordinary intense storm on 13-14 June 2015, the landslide originated 10 km west-southwest of Tbilisi. The event resulted in the catastrophic destruction of a significant segment of the Tskneti-Betania highway and a portion of the Akhaldaba road. Subsequently, massive debris flow temporarily obstructed Vere river, leading to the formation of an artificial berm along the riverbed. Due to the substantial hydrostatic pressure resulting from the accumulated water mass, this berm collapsed. Debris flow transportation along the riverbed towards to Tbilisi city centre lead to flash flood and 22 fatalities ensued. The technical underpinnings of the landslide and landslide-induced flood will be evaluated by geological, topographical and hydrological aspects. The remediation approach for the damaged roads will be assessed in geotechnical engineering perspective.

RÉSUMÉ: Cette étude vise à élucider les aspects techniques du glissement de terrain de Tskneti survenu en juin 2015 à Tbilissi, en Géorgie. Survenant lors d'une tempête extraordinairement intense les 13 et 14 juin 2015, le glissement de terrain a pris naissance à 10 km à l'ouest-sud-ouest de Tbilissi. L'événement a entraîné la destruction catastrophique d'un segment significatif de l'autoroute Tskneti-Betania et d'une partie de la route d'Akhaldaba. Par la suite, un écoulement de débris massif a temporairement obstrué la rivière Vere, conduisant à la formation d'une digue artificielle le long du lit de la rivière. En raison de la pression hydrostatique substantielle résultant de la masse d'eau accumulée, cette digue s'est effondrée. Le transport des écoulements de débris le long du lit de la rivière vers le centre-ville de Tbilissi a conduit à des inondations soudaines et à 22 décès. Les fondements techniques du glissement de terrain et des inondations induites par le glissement de terrain seront évalués en tenant compte des aspects géologiques, topographiques et hydrologiques. L'approche de remédiation pour les routes endommagées sera évaluée dans une perspective de génie géotechnique.

Keywords: Landslide; remediation; MSE wall.

1 INTRODUCTION

This paper aims to define the technical aspects of the Tskneti landslide which was occurred on June 2015 in Tbilisi. On 13-14 June 2015, during an intense storm, the landslide developed at 10 km west-southwest of Tbilisi (Kuparadze and Pataridze, 2019). Located on the south side of the Vere River watershed in the Lesser Caucasus Mountains, the landslide catastrophically destroyed a big portion of the Tskneti - Betania Highway and a portion of the Akhaldaba Road. Due to the heavy rainfall and storm, approximately 65 landslides are detected around the region with small to minor scale. The major Landslide caused a massive debris with 1.2 cubic millions of soil and rock fragments while the 60000 cubic meters of plant roots and trees are dislocated from the upper edges of the Tskneti-Betania Road. This massive debris flow has temporarily blocked the Vere River and caused to an artificial berm along the riverbed. By the effect of the enormous hydrostatic pressure caused by the water mass, berm failure was occurred, and debris flow went through to the Tbilisi City Center. As a result of flood, 22 people dead in the disaster.

The technical background of the disaster will be summarized in the sections by evaluating geological, topographical, hydrological facts. The remediation plan for the damaged roads will be expressed by geotechnical perspective.

The general layout for area of interest is given in Figure 1.

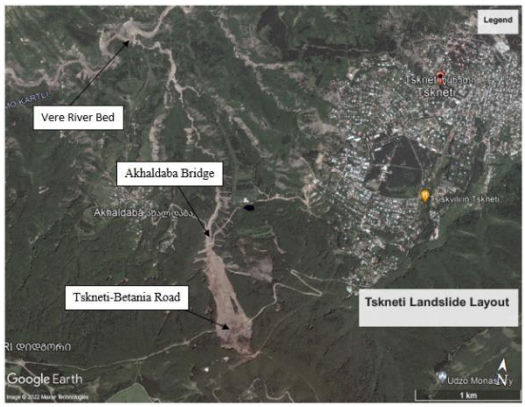

Figure 1. General layout of the area.

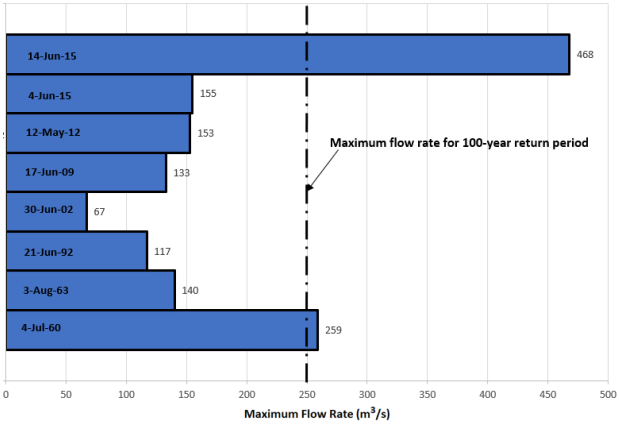

Figure 2. Maximum flow rates of Vere river.

2 TECHNICAL BACKGROUND

Geological, hydrological and meteorological conditions of the site are presented in this chapter.

2.1 Geological conditions

The territory of Georgia, as a part of the Caucasus, is located within the collision zone of the Eurasian and Afro-Arabian plates, in the Mediterranean (Alpine-Himalayan) belt, at the interface of European and Asian segments. (UNDP 2015).

The landslide zone is located to the South-East from Tskneti village at an altitude of 1180-1300 meters composing of Oligocene and lower Miocene clays, sandstones, conglomerates (Maikop series), marine molasse. The landslide zone is located in the central part of the Adjara-Trialeti fold system – on the northern flank of the Telety anticline (Gamkrelidze et. al.,2021). The western slopes are steeper, and the eastern slopes are flatter showing the monoclinic form of the Telety anticline (Kuparadze and Pataridze, 2019).

2.2 Hydrological conditions

Based on the local database for Vere River, the annual rate flow of river ranges between 0.26 m^3/s to 1.22 m^3/s. The maximum flow rate with 100 year return period is assumed as 240 m^3/s. The peak flow rates are reported as 259 m^3/s and 153 m^3/s in 1960 and 1972, respectively (UNDP, 2015).

The study of Gorum and Fidan (2021) claims that majority of the fatal rainfall-induced landslides occurred by following the extreme peak summer rainfalls, not during the rainiest periods. The hydrological portrait of the disaster fits with this approach while the landslide occured after the maximum flow rate measured in summer season. The maximum flow rate is measured as 468 m^3/s, almost double the maximum design flow (i.e. 240 m^3/s) for 100-year return period (Figure 2).

3 SITE INVESTIGATIONS

As a part of rehabilitation works, geophysical investigations including vertical electrical sounding (VES) and magnetometer surveys were performed to identify the landslide characteristics (Kuparadze and Pataridze, 2019). The scope of investigation covers 2 individual sections of the damaged road called as Site W-1 and T-1 including the drilling of 9 boreholes and 10 sets of VES alignment.

Magnetometer survey results show that, sandstone layers composed of large blocks with intercalations of argillite has high values of magnetic fields (>49530 nanoTesla) while thin-grained sandstones have relatively low magnetic field values (i.e. <49500 nanoTesla).

VES results identify two individual layers along the survey depth as follows:

Geoelectric layer with specific electrical resistance 100-170 Ohm · m – intensively weathered fractured sandstones with interlayer's of argillite and conglomerates.

Geoelectric layer with specific electrical resistance of 175-330 Ohm · m – slightly weathered fractured sandstones with interlayer's of argillite and conglomerates.

As a summary of geophysical survey results, western part of the investigation zone is estimated as the zone of crushing (fracture), contact zone between coarse and thin-layered sandstone. It has been stated that, potential landslide may have been occurred in the past by the movement of individual blocks at this section.

Groundwater was encountered in all boreholes. Drill holes indicate temporary presence of groundwater. Groundwater levels were measured between 1285 m to 1325 m located nearby the bedrock elevation.

Site investigation layout and potential fracture alignments are given in Figure 3.

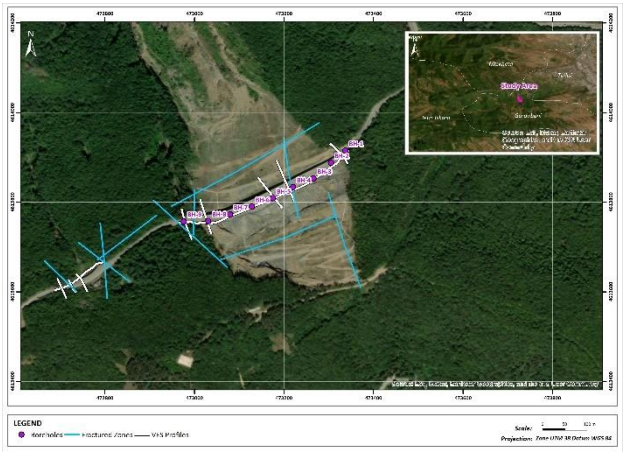

Figure 3. Site investigation layout & fracture zones.

4 REMEDIATION WORKS

Within the scope of remediation studies of damaged roads, different solutions have been evaluated. Remediation sections called T1, G1 and W1 are to support the Tskneti-Samadlo road platform while the A1 places at the Akhaldaba road which was completely destroyed (See Figure 4).

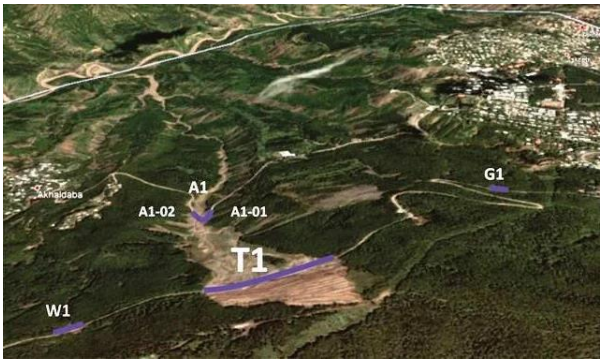

Figure 4. Remediation sections.

The remediation classification for sections referring Holtz and Schuster (1996) approach is listed in Figure 5.

Section	Category	Procedure
G1	1 - Avoid Problem	Remove unstable materials
	4- Increase Internal Strength	Use reinforced backfill (MSE Wall)
A1	1 - Avoid Problem	Install bridge / remove unstable materials
	4- Increase Internal Strength	Reinforced backfill (MSE Wall)
W1/T1	1 - Avoid Problem	Remove unstable materials
	3 - Use structural systems / anchor installation	Reinforced concrete walls with injection piles / Anchor installation for back-face stabilization of trimmed slope
	4- Increase Internal Strength	Reinforced backfill (MSE Wall) above RC wall

Figure 5. Method of rehabilitation per section (Adapted from Holtz and Schuster (1996)).

T1 area is placed at the center of landslide-zone where the inclination angle of sliding slope is measured as 40° with the maximum elevation difference between the natural ground and new road level is ≈ 15.0 m.

4.1 Hybrid Solution for W1 and T1 Sections

W1 and T1 sections are very close to the main landslide zone leading complexity in remediation system. The remediation method has been identified as a combination of anchors, reinforced concrete retaining wall and Mechanically Stabilized Earth (MSE) wall.

Even if the MSE walls are not common in landslide stabilization (Holts and Schuster, 1996). Turner (2005) provided as a good reference of using a hybrid retaining structure system a combination of soil nailing and MSE walls in landslide remediation.

T1 and W1 is a kind of modified version of the section advised by Turner (2005). First component of the system; Reinforced concrete wall with soil nails are used to stabilize the fill slope. This component also provides an adequate spacing for construction of second component: MSE wall (Figure 7).

The key notations for composite retaining system are given as follows:

Prior mission of reinforced concrete base wall is to stabilize the toe section.

Reinforced concrete base wall is helpful to reduce the strip lengths of the MSE wall.

Minimizing the MSE wall height helps to reduce the amount of earthwork and prevent new landslides during construction, triggered by earthwork operations.

The MSE wall is founded on the compacted coarse-grained structural fill behind the reinforced concrete wall. Foundation soil with good mechanical characteristics is sufficient to use shorter strips at the bottom of MSE wall. (FHWA).

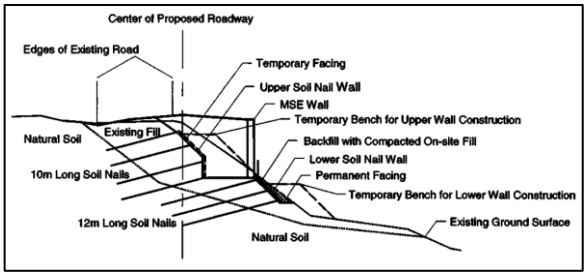

Figure 6. Hybrid wall section advised by Turner (2005).

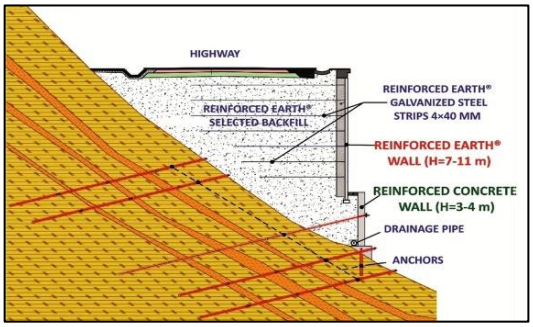

Figure 7. Typical section for W1 and T1.

The pictures showing the site conditions before and after construction presented in Figure 8 and Figure 9 for W1 and T1.

Figure 8. Rehabilitation works for W1 section.

Figure 9. Rehabilitation works for T1 section.

5 CONCLUSIONS

In this study, the technical background of Tskneti landslide occurred in 13-14 June 2015 is examined for significant engineering aspects. The geological and hydrological facts of the disaster are evaluated. Scope of site investigation ana remediation studies of the damaged roads are ezplained in detail.

The landslide zone is located to the South-East from Tskneti village at an altitude of 1180-1300 meters composing of Oligocene and lower Miocene clays, sandstones, conglomerates (Maikop series), marine molasse.

Per hydrological perspective, the maximum flow rate with 100 year return period is assumed as 240 m^3/s for Vere River. In 13-14 June 2015, the maximum flow rate reaches to 468 m^3/s, almost 2 times higher than the maximum design flow for 100 year return period.

The geophysical methods including vertical electrical sounding and magnetometer survey was used to describe the possible fractured zones of the area. As a summary of geophysical survey results, western part of the investigation zone can be defined as the zone of crushing (fracture), contact zone between coarse and thin-layered sandstone. It has been indicated that, potential landslide may have been occurred in the past by the movement of individual blocks at this section.

The technical details of the remediation method for damaged roads are presented in Section 4. A hybrid solution for critical W1 and T1 sections, combining soil nails, reinforced concrete toe wall and mechanically stabilized earth (MSE) was explained in detail with technical advantages.

In brief, landslide stabilization projects shall be classified as a multidisciplinary study including geology, hydrology, meteorology, geotechnical perspective. A remediation project shall not be limited to construct the damaged structures in a very short time. The simple reconstruction procedure without any action plan ignoring the possible reasons of the disasters will not be the proper solution. A comprehensive study of related engineering fields is mandatory: Both for the detecting the possible reasons and proper engineering solutions.

ABSTRACT: Site response analysis is a key aspect in the quantification of seismic risk. Parameters defining the main dynamic properties that characterize a specific site mainly depend on the ground motion at the bedrock level and the soil features close to the ground surface. Integrating both, ground motion and soil features, within a probabilistic framework that considers the randomness of the mechanical properties of existing civil infrastructures is challenging, especially because of the computational effort involved. In addition, the dynamic properties of the soil tend to be affected at very low shear strains. These limits mainly depend on the duration and intensity of the ground motion. This study aims to apply a recently developed computational framework that allows for probabilistic considerations of the dynamic interaction between the ground and the surrounding structures during seismic events. Specifically, a set of ground motion records has been selected to propagate through random soil profiles. The resulting signals at the ground surface are transmitted to building models of varying heights, and their dynamic behaviour is evaluated. Then, using the cloud analysis approach, intensity measures, vibration periods of the degraded soil profile and structures have been used to search for the best-fit model that minimizes errors in predicting the influence of the site. The results of this study are expected to have significant practical applications in earthquake engineering and risk prevention.

RÉSUMÉ: L'analyse de la réponse du site est un aspect essentiel de la quantification du risque sismique. Les paramètres définissant les principales propriétés dynamiques qui caractérisent un site spécifique dépendent principalement du mouvement du sol au niveau du socle rocheux et des caractéristiques du sol à proximité de la surface du sol. L'intégration du mouvement du sol et des caractéristiques du sol dans un cadre probabiliste qui prend en compte le caractère aléatoire des propriétés mécaniques des infrastructures civiles existantes est un défi, notamment en raison de l'effort de calcul nécessaire. En outre, les propriétés dynamiques du sol ont tendance à être affectées par de très faibles contraintes de cisaillement. Ces déformations dépendent principalement de la durée et de l'intensité du mouvement du sol. Cette étude vise à appliquer un cadre de calcul récemment développé qui permet des considérations probabilistes de l'interaction dynamique entre le sol et les structures environnantes pendant les événements sismiques. Plus précisément, un ensemble d'enregistrements de mouvements du sol a été sélectionné pour se propager à travers des profils de sol aléatoires. Les signaux résultants à la surface du sol sont transmis à des modèles de bâtiments de différentes hauteurs, et leur comportement dynamique est évalué. En utilisant une approche d'analyse de nuage, les mesures d'intensité, les périodes de vibration du profil de sol dégradé et des structures ont été utilisées pour rechercher le meilleur modèle d'ajustement qui minimise les erreurs dans la prédiction des effets du site. Les résultats de cette étude devraient avoir des applications pratiques significatives dans le domaine du génie sismique et de la prévention des risques.

Keywords: Seismic risk, probabilistic model, dynamic interaction, cloud analyses approach.

1 INTRODUCTION

Soil-structure interaction is a fundamental factor in seismic risk estimation, where soil acts as a filter amplifying or damping harmonics based on its dynamic properties (Cruz and Miranda, 2021). Structures may resonate with the soil, leading to a rethinking of seismic risk paradigms, as observed during the 1985 earthquake in Mexico City (Beck and Hall, 1986). Therefore, understanding the dynamic response of the soil beneath a civil structure is crucial

for seismic risk studies. Advanced nonlinear models, such as 3D finite element method representations, offer insights into this complexity. However, for computational efficiency, simplified 1D models like Kelvin-Voigt solids, which effectively approximate soil dynamics, are often used (Hardin and Scott, 1967).

This article employs a computational framework (Zapata-Franco et al., 2023) to analyse steadfastness in intensity measures (IMs) for predicting nonlinear building responses. This statistical property allows grouping results stemming from different building models without losing efficiency. This is of particular interest since new tendencies for seismic hazard characterization are evolving from 'Uniform Hazard Spectrum' to 'Uniform Risk Spectrum'. This enhanced approach is influenced by collapse fragility functions that should represent a large variety of buildings for consistent collapse probabilities across regions.

The framework has been originally developed for Reinforced Concrete structures, RC, which were modelled by considering Multi-Degree-of-Freedom systems. However, it has proven to be adaptable to a variety of structures, providing insights on seismic risk predictions (Vargas-Alzate et al., 2022). Particularly, in this article, simplified proxies built from Single-Degree-of-Freedom systems, SDoFs, have been employed to model RC buildings.

Bogotá has been chosen as a study site due to soft soil deposits and a comprehensive soil profile database, providing valuable data for seismic risk assessment (Pagliaroli et al., 2014). Regression analyses, comparing Scalar-based and Vector-valued IMs with building responses, indicate efficiency gains when grouping buildings by similar height ranges. This research provides insights into improving seismic risk predictions, particularly for cities with diverse building heights like Bogota.

2 PROBABILISTIC SOIL MODEL

A probabilistic soil model is generally used in geotechnical applications to consider the spatial and temporal variability of soil properties, and their effects on civil structures. These models rely on statistics and probability theory to simulate soil features such as strength and stiffness, which can vary with location and time. In this article, the probabilistic soil model presented in Zapata-Franco et al. (2023) has been employed. Figure 1 is a sketch of this computational framework. The variables represented within the soil profile scheme (shear modulus, density, damping parameter and layer thickness, G_i, ρ_i, ξ_i and h_i, respectively) determine the dynamic features of the modelled soil.

In summary, the probabilistic framework presented in Zapata-Franco et al. (2023) allows for:

i. Introducing a ground motion record at the bedrock level of a soil profile.
ii. Estimating the stiffness degradation and increase of damping in each soil layer based on the equivalent linear method.
iii. Calculating the resulting ground motion at the surface after propagation through the soil profile, taking into account the degradation of soil properties.
iv. Considering the resulting ground motion estimated in the previous step, by applying it at the base of one of the probabilistic building models.

These steps have been implemented after generating random samples of both soil profiles and structures, which are affected by ground motion records selected from a seismic database. These records have been acquired in seismic stations located on hard-soils.

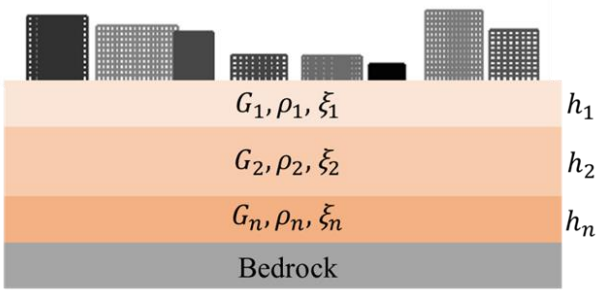

Figure 1. Schematic representation of the complete model.

2.1 Case of study: Bogotá Microzonation

This study focuses on Lacustrine soils that compose a critical deposit in Bogotá city, which is characterized by soft clays with high compressibility, interspersed with lenses of loose sand, volcanic ash, and peat up to 1m in thickness. The sediment width for this deposit varies from 50m to 500m.

2.2 Probabilistic generation of soil profiles

The probabilistic framework used in this research employs the Toro's model to generate soil profiles. (Silva et al., 1996). In brief, this probabilistic model consists of three main elements: i) a model describing the random stratigraphy at the site; ii) the median wave velocity profile; iii) a model considering both the deviation of the velocity from the median and its correlation with respect to the layer above. In the following, the elements of the Toro's model, applied to the lacustrine data for Bogotá city, are described.

2.2.1 Random stratigraphy at the site

For soil parameterization, 10 lacustrine profiles of the city have been employed (FOPAE, 2011). The random stratigraphy is characterized by using the "Layering Model" (Silva et al., 1996). This allows to consider that, often, as the soil layer deepens, it becomes thicker. Accordingly, the following power law is adopted:

$$\lambda(h) = C_3[h + C_1]^{-C_2} \quad (1)$$

where λ is the layer boundary rate (1/m) and h is the depth in meters. The estimation of the values C_1, C_2 and C_3 is carried out by using the capabilities of the Monte Carlo method to minimize multi-dimensional functions (Kucherenko et al., 2015).

2.2.2 The median wave velocity profile at the site

Due to the cumulative process associated to the creation of sedimentary deposits, it has been observed that a log-normal distribution adequately parametrizes the aleatory character of shear wave velocities (Toro, 2022). This parametric distribution has been adopted in the sampling process of the shear wave velocity. Note that, according to the Toro's model, the velocity is estimated at the layer midpoints.

2.2.3 Deviations of the velocity in each layer

Another important aspect observed in soil profiles is related to the spatial correlation between closer layers. The closer the layers the higher the correlation (Angelini and Heuvelink, 2018). This implies that widely separated layers tend to be less correlated. It has been assumed that the correlation between adjacent soil layers decreases with distance by means of the following model:

$$\rho_{i,j} = \begin{cases} i = j & \rho_{i,j} = 1 \\ i = j \pm k & \rho_{i,j} = 1 - \frac{k}{r} \geq 0 \end{cases} \quad (2)$$

where k is a number related to the position of a layer belonging to the same profile; r is a coefficient associated to the rate of correlation between adjacent layers. In this research, r has been fixed to 100/3.

2.3 Probabilistic simulation of soil profiles

Based on the description of the probabilistic features that soil profiles must meet, statistic models have been obtained via Monte Carlo simulations. The resulting soil profiles can be seen in Zapata-Franco et al. (2023). They all correspond to low shear strains.

3 SEISMIC HAZARD

3.1 Colombian seismic database

A compilation of ground motions recorded in Colombia between 1993 and 2017 has been considered, with a magnitude greater than 4.0 Mw. Accordingly, a total of 1992 records have been extracted from the SGC (SGC, 2020). From this set, 1236 ground motion recorded at hard soils have been used in this research.

3.2 Ground motion identification and scaling

In order to obtain a more precise representation of the seismogenic environment of Bogotá, the proximity algorithm developed in Zapata-Franco et al. (2023) has been employed. Bogotá has been regarded as a reference point, considering a radius of 400 km around the city. A set of 1023 ground motions recorded on hard-soils have been identified. 1000 of them have been employed to perform the calculations in this research.

There are several methods for scaling ground motions from a database (Haselton C.B., 2012). Typically, the aim is to have enough records leading the buildings to different performance levels. However, in current databases, there are often no strong ground motion records with high intensity values. This leads to excessive scaling, which may introduce bias in the structural response (Haselton C.B., 2012). To address this issue when using cloud analysis (Jalayer et al., 2015), the method proposed by Vargas-Alzate et al. (2022b) to select and scale ground motion records has been used. Figure 2 shows the total set of scaled ground motions acting at the bed rock level.

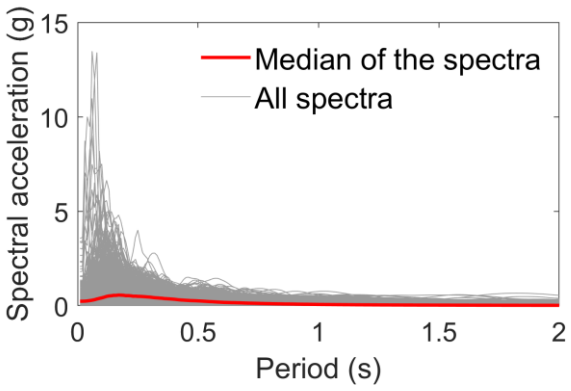

Figure 2. Spectra of ground motion records acting at bedrock level.

4 SEISMIC WAVE PROPAGATION

Seismic wave propagation leads to the degradation of soil stiffness and an increase in material damping in each layer. These alterations are dependent on the maximum shear strain experienced by the soil during seismic events. Several methods address this effect, one of the most widely used being the linear equivalent method (Kumar and Mondal, 2017).

This method iteratively estimates physical properties of a compatible soil profile using linear approximations, emulating the dynamic response obtained through computationally expensive non-linear analyses. The equivalent linear method considers stiffness degradation and increased material damping, utilizing normalized shear modulus and hysteretic damping curves. Reference curves from a geotechnical report (FOPAE, 2011) have been considered in this research to estimate the nonlinear response of probabilistic soil profiles. To do so, the ground motions have been scaled following the description presented in section 3.2. The resulting spectra of the ground motion at the surface, once applied the equivalent linear approximation, are shown in Figure 3.

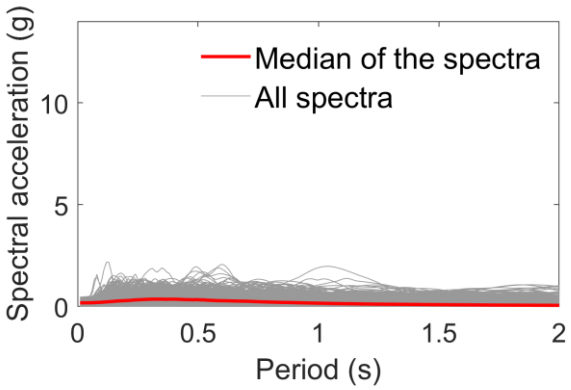

Figure 3. Spectra of ground motion records at the surface.

5 STRUCTURAL MODELLING

Simplifying structural models is crucial for efficient computations, allowing faster analyses of multiple buildings. The Single Degree of Freedom (SDoF) system is commonly used for dynamic calculations, offering easy time-history responses based on the fundamental period and damping. However, SDoF responses overlook stiffness loss due to plastic damage and the effect of higher modes. To address both issues, a proposed approach involves approximating the dynamic behaviour of Reinforced Concrete (RC) structures by averaging the time-history response of a set of SDoF systems within the interval ($0.1T$, $1.8T$), where T is the fundamental period of the analysed building in the main direction.

The dynamic response associated with each oscillator has been estimated by means of the dynamic equilibrium equation for SDoF systems:

$$m\ddot{u}(t) + c\dot{u}(t) + ku(t) = -m\ddot{u}_g(t) \quad (3)$$

where $\ddot{u}(t)$, $\dot{u}(t)$ and $u(t)$ are the spectral acceleration, velocity and displacement time history responses of the SDoF, respectively; $\ddot{u}_g(t)$ is the acceleration ground motion; m, c, and k represent the mass, damping, and stiffness of the system, respectively. Thus, the spectral time history response of a building in terms of displacements, $\bar{u}(t)$, is estimated as follows:

$$\bar{u}(t) = \frac{1}{p}\sum_{i=1}^{p} u_{(i)}(t, T_i) \quad (4)$$

where $u_{(i)}(t, T_i)$ is the response of the SDoFs with period T_i within the interval ($0.1T$, $1.8T$).

Several engineering demand parameters (EDPs) can be extracted from the averaged time-history responses described above. For example, the maximum global drift ratio of a structure, MGDR, which is an EDP widely used in seismic risk estimations employing the capacity spectrum method (Freeman, 1998), can be estimated according to the following equation:

$$MGDR = PF_1 \frac{max\ (u_{(x,y)})}{\mathrm{H}} \quad (5)$$

where PF_1 is the load participation factor (Applied Technology Council, 1996); H is the height of the building. Regarding PF_1, it has been assumed that this variable is a function of the number of stories. In this research, $PF_1 = (\frac{7}{460}N_{st} + \frac{123}{115})$, where N_{st} represents the number of stories. In this manner, the higher the structure the larger PF_1.

Due to the probabilistic approach followed in this article, a set of fundamental periods has been generated to represent the analysed typology. Classical relationships between the evolution of this period and the height of the structure can be used (Goel and Chopra, 1997). For the case of study, it has been employed the following formula to relate the fundamental period vs the height of the structure (AIS, 2010):

$$T_1 = C_h * H^{0.9} \quad (6)$$

where C_h is a random regression coefficient which depends on the type of structure. This allows to

consider possible uncertainties in the characterization of T_1. In the case of RC typologies, the average C_h is 0.047; it has been assumed a coefficient of variation equal to 0.12.

Three different structural typologies have been simulated. The difference between them is the number of stories. Thus, Low-, Medium- and High-Rise RC structures are composed of buildings whose number of stories varies from 2-6, 7-15 and 16-25, respectively.

6 CLOUD ANALYSIS

Cloud analysis requires to calculate the best fit curve between a set of IM-EDP simulations in the log-log space. In the following, the efficiency in terms of the coefficient of determination, R^2, has been calculated considering two approaches: i) using the ground motion records acting at bedrock levels to estimate IMs; ii) develop a multi-regression model that allows combining information provided by the soil profile and the IMs calculated in the previous approach. The IMs described in Zapata-Franco et al. (2023) have been employed to find the best correlated arrangements to predict the MGDR in both approaches. In addition to IMs, the following set of soil variables have been employed in the multi-regression model (Approach 2):

Table 1. Soil information variables.

Variables	Equation	Description
T_{S_L}	$\sum_{i=1}^{nlayer} T_{S_{L,i}}$	Fundamental period of the soil profile
$\bar{\xi}_L$	$\frac{\sum_{i=1}^{nlayer} \xi_{L,i}}{nlayer}$	Average linear damping of the soil profile
$\bar{\xi}_{NL}$	$\frac{\sum_{i=1}^{nlayer} \xi_{NL,i}}{nlayer}$	Average nonlinear damping of the soil profile
$\overline{Vs}_L$	$\frac{\sum_{i=1}^{nlayer} Vs_{L,i}}{nlayer}$	Average shear wave velocity of the soil profile
ΔT_L	$\lvert T_{S_L} - T_B \rvert$	Absolute difference between the fundamental period of the soil profile and fundamental period of the building (T_B)

6.1 Approach 1

After assessing the bivariate distribution between IMs and the MGDR, Zapata-Franco et al. (2023) show that AvSd is the best correlated IM to predict the MGDR. Accordingly, in approach 1 the authors focus on this IM for the statistical analysis. Results are summarized in Figure 4 for Low, Medium, and High-rise structures; results for a combination of the three typologies (All) have also been included.

6.2 Approach 2

The multi-regression model described in (Vargas-Alzate et al., 2022) has been used to identify the optimal combinations between IMs and soil parameters to predict the MGDR. Arrangements of three information variables have been assessed. Results are summarized in Figure 4 for Low, Medium, and High-rise structures; results for a combination of the three typologies (All) have also been included.

As Figure 4 indicates, for all types of structures, approach 2 shows higher regression coefficients than approach 1.

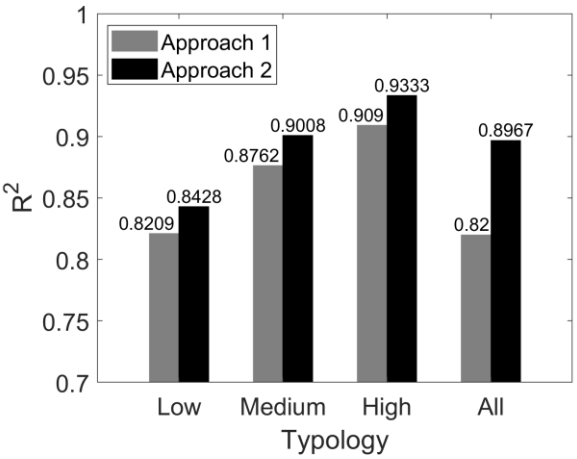

Figure 4. Regression coefficient Approach 1 and 2.

7 CONCLUSIONS

This article delves into the efficiency to predict the seismic response of simplified building models by considering inelastic responses of soils. These models are based on the average response of SDoFs around the fundamental period of each building. By employing the equivalent linear method to address the non-linear behaviour of soils, this study has integrated probabilistic soil profiles, structural models, and ground motion records into a Monte Carlo-based framework. Specifically, random samples of soil profiles have been generated and subjected to a set of accelerograms extracted from a Colombian database. The resulting motions at the ground surface have been employed to perform calculations on structural SDoF-based models.

At a first stage, it has been investigated the causal relationship between scalar-based IMs at the base of soil profiles and the resulting MGDR of structural models (Approach 1). The main conclusion is that AvSd is the most robust scalar-based IM for predicting the buildings response, when considering the interferences produced by the propagation of seismic

waves through soil media. This conclusion holds when structural models are grouped by their number of stories or not. Note also that grouping buildings results in a significant increase in R^2, compared to a regression performed with the total amount of data. In general, the correlation increases when the number of storeys making up a subgroup also increases. This may be related to the fact that as the height of the buildings increases, the periods of both the structure and the ground profiles become more similar.

The objective of the second approach has been to analyse the increase in efficiency when considering vector-valued IMs. These IMs consider information of both the ground motion acting at the bedrock level and soil profiles. Again, AvSd has placed a central role in the regression analysis. This IM appears in all statistical regressions performed. In terms of the soil profile parameters, variables related to damping, velocity and period are the ones producing the highest increase in efficiency. These results highlight the importance of considering both structural and geotechnical factors to improve design and assessment of structures.

Future research should investigate the IM behaviour considering different soil types, seismogenic environments and structural typologies. Also, it would be usefully to extend the computational framework to 3D soil models.

FEM parametric analyses of the seismic behaviour of tunnel-soil-overstructure systems

Analyses paramétriques FEM du comportement sismique des systèmes tunnel-sol-surstructure

ABSTRACT: Nowadays, the urgent need to achieve high levels of environmental sustainability motivates researchers to look at solutions to solve the environmental pollution generated by road traffic, and so to improve the quality of life. Surely, tunnels represent one solution for urban areas and so they are in continuous development. In their design it is extremely important to assess the possible damage that can occur during an earthquake to the tunnel and to the aboveground structures, to provide adequate mitigation measures. Very care must be devoted to this evaluation because the presence of tunnels close to aboveground structures may modify the response of these structures, and, at the same time, the presence of aboveground structures may modify the dynamic response of tunnels. Furthermore, the dynamic properties of the soil "involved" by the aboveground and underground structures play an important role. The present paper deals with a tunnel-soil-aboveground building system, whose studies are still very few. The focus is the evaluation of the effects of the tunnel on the seismic response of the aboveground building and vice versa; this study was performed by different parametric FEM analyses. Starting from a cross-section of the recently built underground network in Catania (Italy), involving heterogenous soils and including an aboveground building, the tunnel's depth, the aboveground building's position, and the seismic inputs were changed, analysing their effects in terms of lining forces on the tunnel and seismic horizontal forces on the aboveground structures.

RÉSUMÉ: Aujourd'hui, le besoin d'atteindre des niveaux élevés de durabilité environnementale motive les chercheurs scientifiques à chercher des solutions pour résoudre la pollution environnementale générée par le trafic routier et donc améliorer la qualité de vie. Les tunnels représentent sûrement une solution pour les zones urbaines et en fait ils sont en développement continu. Lors de leur conception, il est extrêmement important d'évaluer les dommages possibles aux tunnels et aux structures surélevées qui peuvent survenir lors d'un tremblement de terre et donc fournir des mesures d'atténuation adéquates. Une grande attention doit être apportée à cette évaluation car la présence de tunnels à proximité de structures peut modifier la réponse de ces structures et, en même temps, la présence de structures peut modifier la réponse dynamique des tunnels. De plus, les propriétés dynamiques du sol jouent un rôle important. Le présent article traite d'un système tunnel-sol-structure, sur lesquels il existe encore peu d'études. L'accent est mis sur l'évaluation des effets des tunnel sur la réponse sismique du bâtiment surélevé et vice versa. Cette étude a été réalisée par différentes analyses paramétriques FEM. A partir de la section transversale d'un réseau souterrain récemment construit à Catania (Italie), impliquant des sols hétérogènes et un bâtiment surélevé, la profondeur du tunnel, la position du bâtiment surélevé et les inputs sismiques ont été modifiés, analysant leurs effets en termes de forces sur les tunnels, de forces sismiques horizontales sur les structures surélevées.

Keywords: Tunnel depth; building location; seismic tunnel lining forces; acceleration response spectra.

1 INTRODUCTION

Today, underground structures play a crucial role in transportation and utility networks in urban areas. Their static design has achieved a high level of accuracy. Instead, tunnels' efficient seismic design is not yet completely gotten.

The present paper deals with a tunnel-soil-aboveground building system, whose studies are still very few (Vassilis et al., 2014; Abate & Massimino, 2017). The effects of a tunnel crossing heterogeneous soils on the response of the aboveground building and vice versa are analysed by means of 2D FEM parametric analyses. Starting from a cross-section of the recently built underground network in Catania (Italy), the tunnel's depth, the aboveground building's position, and the seismic inputs were changed, analysing their effects in terms of lining forces on the tunnel and seismic horizontal forces on the aboveground building.

2 THE REFERENCE CASE-STUDY

The cross-section of the underground network in Catania (Italy) is shown in Figure 1.a. The tunnel is a reinforced concrete structure, with a diameter equal to 10 m and a tunnel cover equal to 17 m. The building is a typical reinforced concrete structure, with foundation beams; its symmetry axis is shifted of a distance equal to 20 m in respect of the vertical symmetry axis of the tunnel. As for the soil, Figure 1.b shows the V_s profiles: achieved by HVSR tests, hypothesized to find the conventional bedrock (found at 80 m where V_s = 800 m/s, neglecting the rock layer present at z = 5-20 m). For more details see Abate et al. (2023).

3 THE FEM MODELLING

For developing the parametric analyses, the tunnel's depth, the aboveground building's position, and the seismic inputs were changed. Three different accelerograms were used: one recorded during the 1990 earthquake at the Sortino station (Eastern Sicily); two synthetic accelerograms reproducing the 1693 and 1818 scenario earthquakes for the city of Catania (Azzaro & Barbano, 2000). The three inputs were scaled to PHA = 0.383g (the average expected value at the bedrock for the reference case study; NTC2018). They differ in the frequency content: f_{input} = 2 Hz for the 1990 seismic input, $f_{1,input}$ = 0.7 Hz and $f_{2,input}$ = 5 Hz for the 1693 seismic input, f_{input} = 0.6 Hz for the 1818 seismic input. Indicating with ΔZ the tunnel cover and with ΔY the distance between the building symmetry axis and the tunnel symmetry axis, the values ΔZ = 17 m, 12 m, 7 m, and ΔY = 20 m, 5 m, 0 m were chosen (ΔZ = 17 m and ΔY = 20 m were the values of the reference case-study). Combining them, nine different 2D FEM models were performed by the ADINA FEM code (ADINA, 2008). They consisted of a soil 80 m deep (see Figure 1.b), and 300 m wide, to reduce the boundary effects (Figure 2.a). The soil was divided into 8 horizontal layers (see Figure 1.b). The nodes of the soil vertical boundaries were linked by "constraint equations" that imposed the same displacements at the same depths. The nodes at the base were constrained only in the vertical direction; moreover, in the horizontal direction, dashpots were implemented to simulate the elastic bedrock according to Kuhlemeyer & Lysmer (1973). The seismic inputs were applied through these dashpots. Contact surfaces were defined at the soil-structure interface to model probable uplifting and/or sliding phenomena, assuming the Coulomb friction coefficient $\mu = 2/3\ \phi$. As for the soil-tunnel interface, the condition for which soil and tunnel cannot slide relative to each other was assumed (μ = 1). The tunnel and the building were modelled by linear visco-elastic constitutive models, assuming: E_l = 36283 MPa and ν_l= 0.2 for the tunnel; E_b = 30000 MPa and ν_b = 0.2 for the building; γ = 25 kN/m^3 and D = 5% for both the structures. The soil was modelled by a linear-equivalent-visco-elastic constitutive model, for considering its soil nonlinearity. So, according to the achieved shear strains for each soil layer and for each seismic input, evaluated by iterative procedures using the $G(\gamma)$ and $D(\gamma)$ curves shown in Figure 2.b (concerning the Catania volcanic soil; Cavallaro et al., 2006), the operative values of G_s and D_s were estimated. The Rayleigh coefficients α e β were adopted for simulating the material viscosity according to (1), where D are the damping ratios and ω the natural angular frequencies of the involved systems:

$$\alpha = 2 \cdot \frac{D \cdot \omega_i \cdot \omega_j}{\omega_i + \omega_j};\ \beta = 2 \cdot \frac{D}{\omega_i + \omega_j} \qquad (1)$$

The soil's natural angular frequencies were evaluated as $\omega_i = \omega_1 = (V_{s,av}/4H)\cdot 2\pi$ and $\omega_j = 3\cdot\omega_1$ (Kwok et al., 2007), with H heigh of the soil deposit and $V_{s,av}$ weighted average of the shear wave velocities of the soil deposit. The tunnel's frequencies were assumed equal to those of the soil, because tunnel and soil respond approximately in agreement to the movement induced by the earthquake. The structure's frequencies were computed by means of modal analyses.

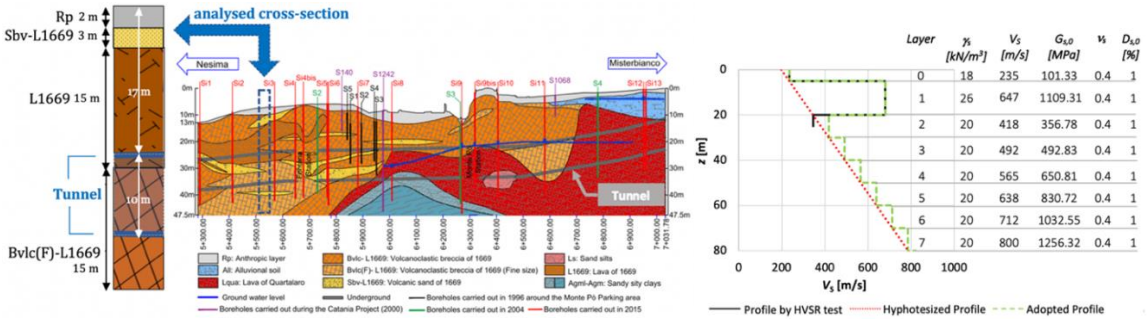

Figure 1.a Soil profile along the Nesima-Misterbianco segment of the underground network in Catania and zoom on the analysed cross-section next to borehole Si3 (after Abate et al. 2023); 1.b $V_s(z)$ profile (after Abate et al. 2023).

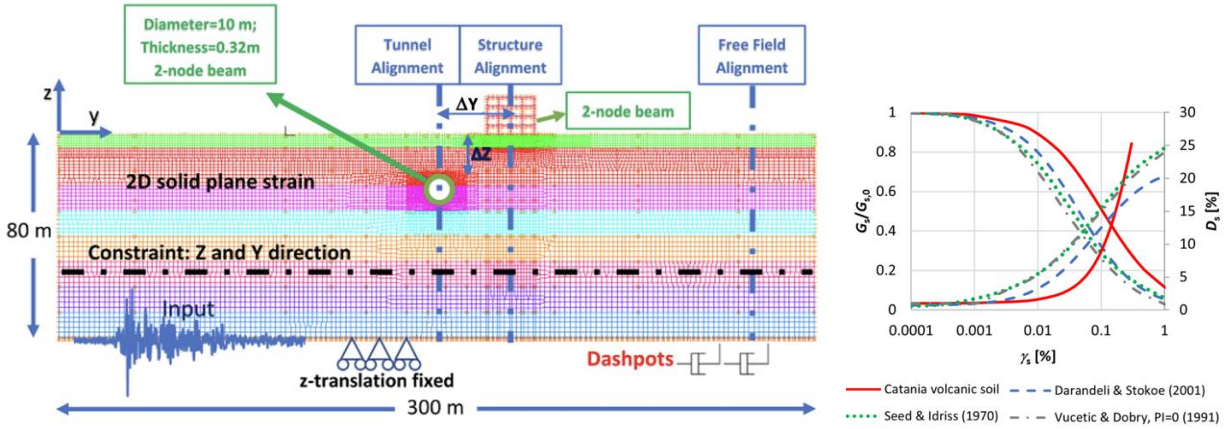

Figure 2.a FEM Model of the configuration for the reference case-study: ΔZ = 17 m and ΔY = 20 m. (after Abate et al. 2023). 2.b Adopted $G_s/G_{s0}(\gamma)$ and $D_s(\gamma)$ curves (after Abate et al. 2023).

4 THE MAIN RESULTS

The seismic response of the tunnel was investigated in terms of lining internal forces, evaluated both numerically and analytically (Wang, 1993; Penzien, 2000). Nevertheless, these analytical solutions refer to a circular tunnel inside a homogeneous soil. So, for using them, the authors fit them for the analysed heterogeneous soil (for details see Abate et al. 2023).

Figure 3 shows the comparison between the numerical and analytical maxima ΔM and ΔN.

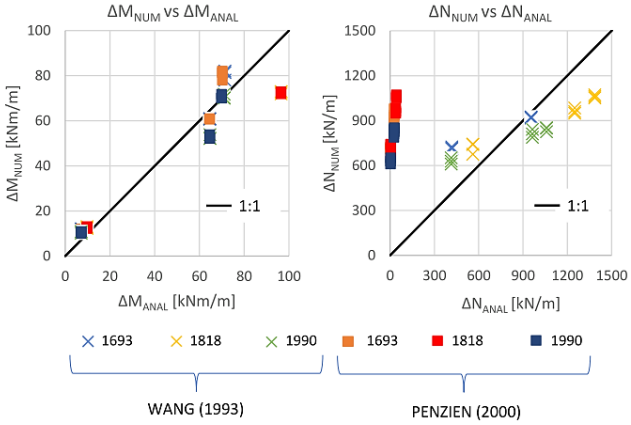

Figure 3. Comparison between numerical and analytical dynamic bending moments and dynamic axial forces.

Wang (1993) reproduced quite well the numerical results; Penzien (2000) drastically underestimates ΔN. The best agreement was achieved for ΔZ = 7 m, for which the tunnel crossed a homogeneous soil; furthermore, the lowest ΔM were obtained, because of the lack of strong impedance ratio, that led to small strains which in turn produced low ΔM. For ΔZ = 17 m, the highest ΔM were obtained, because the tunnel crossed a major thickness of more deformable soil layer. Similar results concerned the ΔN, even if the tunnel cover had a minor influence. The position of the aboveground structure had a low influence on the lining internal forces; in fact, similar values were achieved for all the three hypothesized ΔY. Finally, the highest values of lining forces were generally obtained for the 1818 seismic input. This was due to probable resonance. The closer the input predominant frequency f_{input} was to the soil natural frequency f_{soil}, the higher the strains were and so the higher the forces were, too.

The seismic response of the structure was investigated in terms of horizontal forces. The numerical ones were compared with the values achieved by the expression furnished by NTC2018:

$$F_{hi} = F_h \cdot z_i \cdot \frac{w_i}{\sum_j z_j w_j} \qquad (2)$$

where $F_h = S_e(T_1) \cdot W \cdot \lambda / g$; w_i and w_j are the weights of the ith and j^{th} floors, respectively; z_i and z_j are the heights of the masses from the foundation level; $S_e(T_1)$ is the spectral acceleration value at the first natural period of the structure; W is the weight of the whole aboveground structure; λ is a coefficient equal to 0.85 because $T_1 < 2T_C$ and the aboveground structure has more than three floors; g is the gravity acceleration (9.81m/s^2).

Figures 4 shows that NTC2018 furnished values three times higher than the numerical ones. So, numerical analyses should be always recommended for avoiding too expensive designs. The seismic forces varied slightly with ΔY and ΔZ, recording a minimal improvement for ΔY = 0 and ΔZ = 7 m. Different responses were found to the different seismic inputs, due to probable resonance: the higher F_h achieved for the 1693 input motion can be due to the ratio f_{input}/f_{stru} very close to the unit value, where f_{stru} = 3.7 Hz is the first natural frequency of the structure resting on the soil including the tunnel, evaluated as ratio between the Fourier spectra computed at the top and at the bottom of the structure.

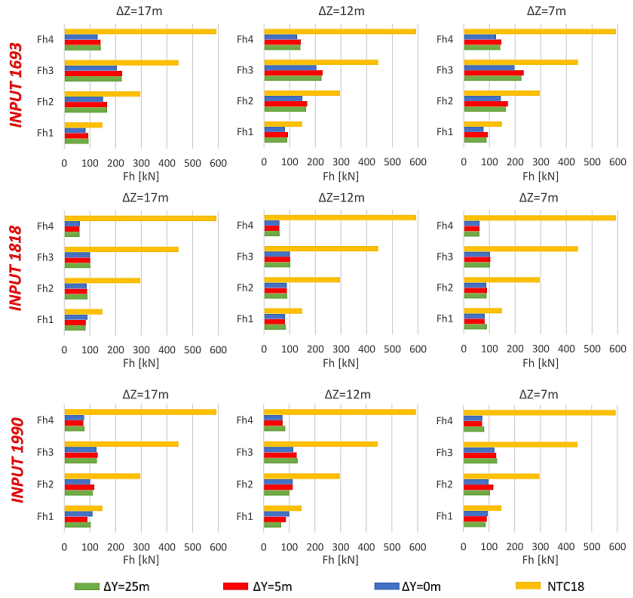

Figure 4. Horizontal seismic forces on the structure.

5 CONCLUSIONS

Starting from a typical cross-section of the underground network in Catania (Italy), the paper deals with FEM parametric analyses of the seismic response of a full-coupled tunnel-soil-aboveground building system. Tunnel cover, aboveground building's position, and seismic inputs were varied. The main results can be summarised as follows.

The lowest values of dynamic lining forces were obtained for the tunnel completely inside a homogeneous soil layer, as well as the highest ones were obtained when the tunnel crosses a greater portion of the more deformable soil layer. These results highlight the importance of evaluating the exact soil profile and eventual heterogeneities.

The seismic forces on the building recorded a minimal improvement for aligned tunnel-structure and the shallow tunnel. Strong differences were achieved between the numerical values and the values suggested by NTC2018. This because the numerical modelling considered uplifting and sliding phenomena at the soil-structure interface, that led to a decrease in seismic forces on the aboveground structure.

ABSTRACT: A proper evaluation of the seismic performance of geotechnical systems is a fundamental step for assessing the functionality of a transportation network after the occurrence of an earthquake. This paper illustrates the preliminary results of a novel methodology aimed at identifying geotechnical systems characterized by an unsatisfactory seismic performance, resulting in a compromised functionality of the overall road network. The proposed framework is applied to an ideal case study using gravity retaining walls as an illustrative example of more complex geotechnical systems. The potential damage to each retaining wall is quantified through *ad-hoc* generated fragility curves, starting from a scenario ground motion map. A new scale of functionality loss is proposed by exploiting existing damage scales. Information on partial or complete road closures is incorporated as part of a standard transportation engineering framework. Such framework is used to estimate variations in the performance of the road network by means of specific indicators, e.g. active accessibilities and path generalized costs. The analysis of these indexes is used to quantify the effects of loss of functionality of the retaining walls and the resulting actions on the overall performance of the transportation network. The versatility of the proposed framework allows it to be applied to any transportation network and geotechnical system.

RÉSUMÉ: Une évaluation rigoureuse de la performance sismique des systèmes géotechniques est une étape fondamentale pour évaluer la fonctionnalité d'un réseau de transport après un tremblement de terre. Cet article illustre les résultats préliminaires d'une nouvelle méthodologie visant à identifier les systèmes géotechniques caractérisés par une performance sismique insatisfaisante, ce qui compromet la fonctionnalité de l'ensemble du réseau routier global. Le cadre proposé est appliqué à une étude de cas idéale, utilisant des murs de soutènement gravitaires comme exemple illustratif de systèmes géotechniques plus complexes. Les dommages potentiels à chaque mur de soutènement sont quantifiés à l'aide de courbes de fragilité ad-hoc, à partir d'une carte de mouvement du sol scénarisée. De nouvelles échelles de perte de fonctionnalité sont proposées en exploitant les échelles de dommages existantes. Les informations sur les fermetures partielles ou complètes de routes sont incorporées dans un cadre standard d'ingénierie des transports. Ce cadre est utilisé pour estimer les variations de la performance du réseau routier au moyen d'indicateurs spécifiques (e.g., accessibilités actives et les coûts généralisés des chemins). L'analyse de ces indices permet de quantifier les effets de la perte de fonctionnalité de chaque système individuel, et des actions qui en découlent, sur la performance globale du réseau de transport. La polyvalence du cadre proposé permet son application à tout réseau de transport et système géotechnique.

Keywords: geotechnical systems, fragility curve, seismic resilience, road infrastructure, transportation networks.

1 INTRODUCTION

Transportation networks represent a crucial civil infrastructure in developed nations, playing a vital role in the advancement of interconnected communities, and aiding in the recovery process during and/or after natural disasters such as earthquakes. Transportation networks comprise several critical components, such as viaducts, tunnels, embankments, and retaining structures (key components). While the seismic performance is studied through fragility curves for systems like viaducts and tunnels, there is a lack for embankments and retaining walls. Retaining walls are among the most frequent key components in transportation networks providing critical support to slopes, embankments, and various infrastructural elements. Damage or failure of these structures can impact the entire network's functionality.

Existing literature on this topic (Argyroudis et al., 2013, Zamiran et al., 2018, Cosentini et al., 2019) highlighted the dependence of the performance on the amplitude and frequency content of the input motion, but they often deal with specific case studies and consequently lack generality.

Starting from the initial outcomes of ongoing research on the topic (Amendola et al. 2023, 2024) this paper employs fragility curves derived using a novel approach for a comprehensive quantification of seismic fragility, applicable to all types of retaining walls founded on whatever soil type.

These fragility curves are then utilized to assess the resilience of road networks by looking at the decrease in functionality (such as reduced speed, partial or full closure) caused by the failure of key components. Additionally, it evaluates the network's resilience by comparing its performance before and after an earthquake.

The methodology is fully described by Amendola et al. (2023). In the following, its application to a case study is presented.

2 CASE STUDY

The proposed framework has been applied herein for demonstration purposes to the case of a simple road network with a distribution of 27 retaining wall (Figure 1).

This network layout is inspired by the existing road infrastructure in Basilicata, Italy, and comprises three distinct road categories (namely Road class A, B, and C) adhering to the specifications stipulated by the Italian National Regulation (MIT, 2001) with specific geometric characteristics and speed limits. The distinctions in these attributes are incorporated into the analysis through the utilization of the Bureau of Public Roads (BPR) link performance function (Cascetta, 2013).

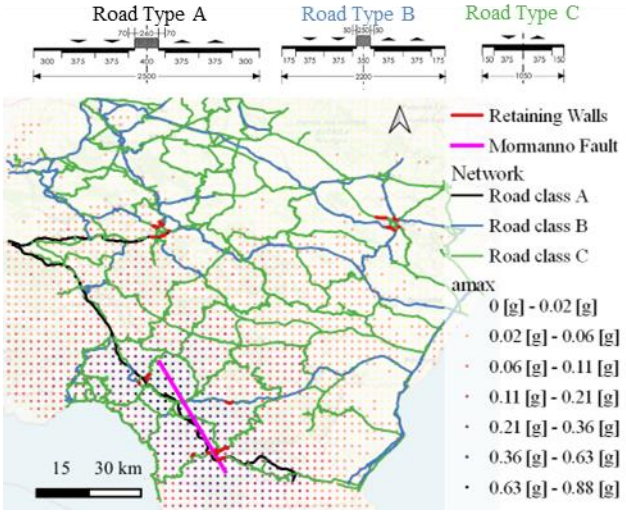

Figure 1. Analysed road network on the map of peak ground acceleration (a_{max}) at bedrock for the simulated earthquake scenario and cross sections of the road classes.

Within the proposed framework, the pre- and post-event performance of the transportation system is assessed incorporating an estimation of travel demand levels within the region. The analysis is conducted considering the typical morning peak hour of a working day at the regional scale considering data from the Italian National Institute of Statistics (ISTAT). Link flows for each simulated scenario are computed using the software PTV Visum, which assigns the estimated demand levels to the transportation network (Cascetta, 2013).

The post-earthquake network analysis was executed considering the occurrence of a seismic event with a moment magnitude of M=6.6 originating from the Rimendiello-Mormanno normal fault (Figure 1).

The distribution of retaining walls along the network was chosen to be on the main important links (i.e., close to main cities and to the epicentre). One typology is selected corresponding to a critical acceleration of the wall, a_c=0.15g, associated with a sliding failure mechanism. This prototype is inferred from recurrent retaining walls along Italian roads and it is designed according to the Italian Building Code (NTC, 2018). More details are provided in Amendola et al. (2023).

3 FRAGILITY CURVES AND FUNCTIONALITY LOSS

Starting from the peak ground acceleration (a_{max} in Figure 1) on the location of each retaining wall, its

probability of failure was estimated through fragility curves by Amendola et al. (2024).

These curves were derived by employing a nonlinear single degree of freedom (SDoF) oscillator (Conti and Caputo, 2019) based on the capacity model proposed by Callisto (2019). The nonlinear response of the system was modelled through a hyperbolic capacity curve, as depicted in Figure 2. This curve correlates the horizontal seismic coefficient (k_H) with the normalized horizontal displacement at the top of the wall (u/H), where H is the height of the wall. The maximum of this curve denotes the critical acceleration coefficient, $k_c=a_c/g$, with a_c denoting the critical acceleration, achieved at a normalized displacement (s_F) associated with the initiation of a plastic mechanism within the soil-wall system. Table 1 presents the parameters of the capacity curve employed in this study, including ξ_{ur}, which stands for the damping ratio during unloading-reloading cycles, and k, representing the ratio between k_c and the actual asymptote of the hyperbolic function (Caputo et al., 2023).

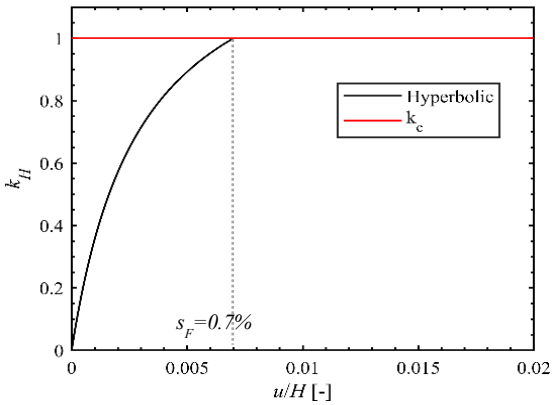

Figure 2. Hyperbolic approximation of the wall capacity curve obtained with the model parameters reported in Table 1(modified after Callisto, 2019).

Table 1. Parameters defining the capacity curve (Callisto, 2019) and the considered prototypes of retaining walls.

Type	ξ_{ur}	k	s_F	H [m]	a_c	Soil Class
Gravity	5%	0.7	0.7%	2,4,6	0.1, 0.2,0.3	A,B,C,D

To provide a comprehensive fragility model, systems with different height and capacity (i.e. different critical acceleration coefficient, $k_c=a_c/g$) were considered for the analyses. Finally, this simplified SDoF model was excited by free-field motions of natural earthquakes (Pitilakis et al., 2013), recorded on different soil classes (i.e. Soil Class A, B, C and D as defined in the EC8, CEN, 2005) following the so-called Cloud method (Jalayer et al. 2017). The results of nonlinear dynamic analyses provided the seismic-induced horizontal permanent displacement at the top of the wall, u. The results are displayed in Figure 3 as a function of a_{max}/a_c for the considered input motions.

As expected, displacements increase with increasing the ratio a_{max}/a_c. To compute fragility curves, the results are fitted using a unique linear regression on the whole set of analyses, thus disregarding the soil class and the wall type. The regression line is superimposed to Figure 3 along with the defining parameters, i.e. slope, b, intercept, a and the value of the standard deviation, σ.

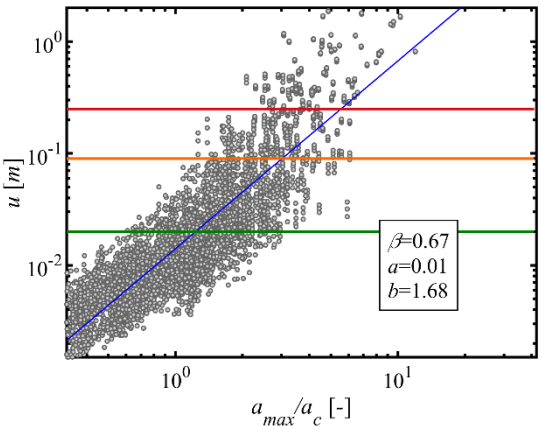

Figure 3. Regression law calculated on the horizontal wall displacements derived from the analyses as a function of a_{max}/a_c.

The so-calculated fragility models are reported in Figure 4 and they are expressed in terms of an intensity measure IM=a_{max}/a_c. They refer to three different damage states (DS): minor, moderate, and extensive/complete. The latter are associated with horizontal displacement thresholds (see Figure 3) obtained from the typical vertical displacements directly impacting the accessibility of the road lane (Argyroudis et al., 2013) . In detail, when the retaining wall is employed for supporting road, embankments or bridge abutments, the horizontal permanent displacement at the top of the wall results in simultaneous cracks and vertical displacements, denoted as 'v', across the lanes of the road. Following the criteria outlined by Argyroudis et al. (2013), low damage is categorized for displacements falling within the range of 2 cm < v < 8 cm, moderate damage for 8 cm < v < 22 cm, and substantial damage for 22 cm < v < 58 cm. This study adopts a conservative approach by considering the displacement thresholds equal to 2 cm, 9 cm and 25 cm respectively.

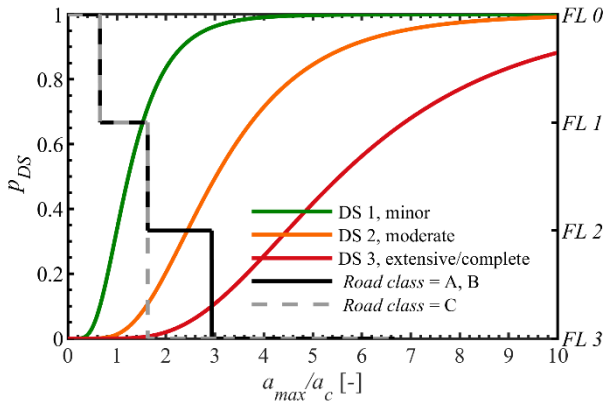

Figure 4. Fragility curves and functionality loss function adopted in this study.

The attainment of the different DS produces a functionality loss (FL) of the road above the wall (right axis in Figure 4), that is a speed reduction (FL 1); a speed reduction and a partial closure (FL 2); and the full closure (FL 3). In this study, FL 2 is not considered for the road class C. The link is assumed to suffer the FL(i) if the DS(i) overcomes a probability of failure equal to 10%. The functionality loss step function is overlapped with the fragility curves in Figure 4. showing that full closure (FL 3) is estimated starting from moderate a_{max}/a_c values.

4 RESILIENCE ASSESSMENT

An examination of the functional analysis of the 27 retaining walls within the network revealed that the seismic event impacted only 12 of them. To gauge the resilience of the road network, a concurrent assessment was conducted utilizing two indices: Traffic Flow Betweenness (TFB) of a link "*l*" (Li et al., 2020), and Accessibility Loss (AL) of the road network resulting from the failure of a subset of links (Maltinti et al., 2012).

Traffic Flow Betweenness serves as a link-based metric for evaluating the significance of a link, irrespective of specific events. This metric can be seen as a measure of the link importance in the network, and proves advantageous when formulating strategies to bolster the network's resilience. AL, on the other side, is related to a specific event, and represents the loss of accessibility by evaluating the increase in travel costs associated with the consequences of the seismic event (e.g. with road closures). The findings of the resilience evaluation show that: (i) the seismic event and ensuing road closures induce a redistribution of traffic flows across the network, potentially without causing increased congestion; (ii) the reshuffling of traffic flows and deterioration in traffic conditions, if any, may extend beyond the immediate vicinity of the affected link; (iii) the traffic load on links subjected to actions, such as speed or capacity reduction, may not necessarily decrease.

The phenomena described in (i) and (ii) arise because variations in the link cost impact the costs associated with all routes using that link. Specifically, such changes may affect routes connecting origins and destinations situated far from the link itself. Variations in route cost can heighten the probability of travellers opting for alternative routes, thereby influencing other segments of the network.

Conversely, in certain scenarios (e.g., links characterised by the highest value of TFB among those computed), elevating route costs may prove insufficient to prompt a switch to alternative routes. In such cases, described in (iii), the flow on the link could potentially increase as a consequence of the same mechanisms triggered by actions, such as road closures, applied to other links. This circumstance is particularly pronounced in a network resembling the one exemplified in this case study, characterized by relatively low road density.

As a consequence of the event, it is estimated a reduction of accessibility conditions of 11.4% with reference to the value of the initial accessibility index *A(0)* and to the accessibility index excluding closed links *A(e)* are $7.9 \cdot 10^7$ and $8.8 \cdot 10^7$, respectively. It is worth noting that this severe reduction results from actions taken on the only 12 links actually affected by the event, which represent a tiny percentage of the link of the network.

5 CONCLUSIONS

The aim of the present study is to introduce and apply a framework for assessing the network impacts of disruptive events, focusing specifically on geotechnical systems exposed to seismic actions. The modelled network is derived from the actual infrastructure in the Basilicata region, Southern Italy, featuring a realistic estimation of traffic flows and subjected to a hypothetical seismic event. In this investigation, only one type of retaining wall is examined as a geotechnical key component. However, it is essential to note that such simplified assumptions can be relaxed, and this constitutes an ongoing research focus for the authors.

The case study analysis reveals that an effective prediction of the consequences of a disruptive earthquake requires a combined application of approaches from diverse engineering disciplines.

Detailed knowledge of the geotechnical system's characteristics is crucial for estimating specific event

effects and the subsequent necessary actions. Simultaneously, a profound understanding of traffic patterns across the broader area, along with the network's structure, is essential for forecasting the overall post-event network functionality.

ACKNOWLEDGEMENTS

The research activities discussed in the paper were funded by the European Union - Next Generation EU, M4C2 mission of the Italian National Recovery and Resilience Plan, investment 1.1-, through the research project of relevant national interest Framework to Assess the Infrastructure Resilience and Management Operations In Roads After Earthquake, FAIR MOIRAE (Project Code: P202224T7S).

ABSTRACT: An experimental landfill was built at Serra do Sapo Mine using filtered iron ore flotation tailings. The main purpose was to evaluate the constructive methodology regarding the equipment, layers thickness and geotechnical evaluation of the material behaviour in order to support the development of a filtered tailings pile design. The landfill consists of eleven layers: eight of them with 0.50m and three with 0.70m thickness. After each layer completion, sand replacement method tests were carried out to determine the in-situ density and verify the material compaction. In addition, samples were also collected in all layers to obtain the water content and compaction using oven-drying method and Standard Proctor tests. According to tests results, the material was compacted with a water content below the optimum moisture content and a greater in-situ density due to higher compaction energy. In the 2nd, 5th, 9th and 11th layers, geotechnical characterization, drained and undrained triaxial tests were conducted. Regarding geotechnical characterization, the material is a fine silty sand and does not present variations on the particle size distribution. In order to monitor the pore pressures during the landfill implementation, three piezometers were installed and there is no significant variation in data results and low values of increase in pore water pressure during the layers construction.

RÉSUMÉ: Une digue expérimentale a été construite en la mine de Serra do Sapo en utilisant des résidus de flottation de minerai de fer filtrés. L'objectif principal était d'évaluer la méthodologie constructive en ce qui concerne l'équipement, l'épaisseur des couches et l'évaluation géotechnique du comportement des matériaux afin de soutenir le développement de la conception d'un tas de résidus filtrés. La décharge est composée de onze strates: huit d'entre elles d'une épaisseur de 0,50 m et trois d'une épaisseur de 0,70 m. Après l'achèvement de chaque couche, des essais de remplacement de sable ont été effectués pour déterminer la densité in situ et vérifier le compactage du matériau. En outre, des échantillons ont également été collectés dans toutes les couches pour obtenir la teneur en eau et le compactage par séchage au four et par essais Proctor standard. Selon les résultats des essais, le matériau a été compacté avec une teneur en eau inférieure à la teneur en eau optimale et une densité in situ plus élevée en raison d'une énergie de compactage plus élevée. Dans les 2e, 5e, 9e et 11e couches, des essais de caractérisation géotechnique, triaxiaux drainés et non drainés ont été réalisés. En ce qui concerne la caractérisation géotechnique, le matériau est un sable limoneux fin et ne présente pas de variations dans la distribution granulométrique. Afin de surveiller les pressions interstitielles pendant la mise en place de la décharge, trois piézomètres ont été installés. Il n'y a pas de variation significative dans les résultats des données et les valeurs d'augmentation de la pression interstitielle sont faibles pendant la construction des couches.

Keywords: Filtered flotation tailings; experimental landfill; tailings characterization.

1 INTRODUCTION

Filtered tailings disposal in piles has become popular in recent years, however, without many experiences and acquired knowledge, applicable legal regulations and studies focused on this method. Piles can reach hundreds of millions of cubic meters and considerable heights, which requires a specific monitoring plan and a consistent design.

The evaluation of the geotechnical behaviour of tailings piles considering geotechnical parameters, construction process, quality control and operating mode is substantial to ensure a safe and sustainable

operation of these structures (Ulrich and Coffin, 2013). In this scenario, the construction of experimental landfills is required for assessing the performance of the filtered tailings during and after layers compaction. Performance must be verified both in terms of geotechnical properties and material workability. For the pile design, the geotechnical properties identified in the experimental landfill will be used in the geotechnical model.

This paper covers the construction of an experimental landfill of filtered iron ore flotation tailings. This landfill represents an important first step in the development of tailings filtration process in Minas-Rio Iron Ore Operation, at Anglo American mine site, located in Conceição do Mato Dentro, Minas Gerais, Brazil.

The purpose of the experimental landfill was to provide a preliminary assessment of filtered tailings pile in terms of equipment, compaction degree and eventual lamination issues, cracks, or those related to excess pore pressure generation. During construction, geotechnical investigation was performed, including field tests and disturbed and undisturbed samples collection for laboratory tests. Furthermore, electrical piezometers were installed to monitor the excess pore pressure generation.

2 METHODOLOGY

The experimental landfill was built from January to August 2022 and it is 20m wide, 85m long and 5.9m high. The landfill was prepared in eleven layers: eight of them with 0.5m and three with 0.7m thickness. To reproduce the operating conditions, equipment commonly used for this type of construction was used: trucks, backhoe loader, bulldozer, compactor roller, moto grader, loader and water tank truck were used. The layers were constructed in order to present a minimum value of 98% compaction. The general arrangement of the area is presented in Figure 1.

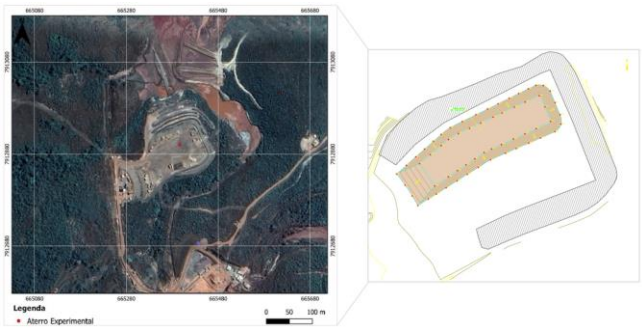

Figure 1. Experimental landfill location.

2.1 Compaction control

After each layer completion, tests were carried out to obtain the situ density using the sand replacement method to verify the material compaction. Additionally, samples were collected to obtain the moisture content using the oven method and to conduct Standard Proctor test.

Field tests were carried out by Fugro company from January to August 2022 and, in total, 96 sand replacement method test were performed in the 11 layers of the experimental landfill. In addition to sand replacement method test, 11 samples were collected for Standard Proctor test, 30 samples for over-drying method and 4 disturbed and undisturbed samples for laboratory tests.

2.2 Tailings characterization

Laboratory tests were performed using samples collected in the 2nd, 5th, 9th and 11th layers of the experimental landfill. The particle-size distribution was defined by sieve and hydrometer analysis in accordance with ABNT NBR 7181 standard.

Over-drying method was used to obtain the natural moisture content of the soil (w) in accordance with ABNT NBR 645 standard. The specific gravity of soil solids was obtained by pycnometer method in accordance with ABNT NBR 6458 standard. Atterberg limits tests were also carried out as recommended by the ABNT NBR 6459 standard and ABNT NBR 7180 standard.

The maximum void ratio was obtained by Method B (ABNT NBR 16840:2020 Corrected Version:2021) and the minimum void ratio by Method B.1 (vibrating table for sieving and dry material; ABNT NBR 16843:2020). Standard Proctor tests were conducted according to ABNT NBR 7182. Each of the points of the compaction curves was obtained without material reuse.

2.3 Monitoring system

The experimental landfill geotechnical instrumentation consisted of three electrical piezometers installed at the base of the landfill. Monitoring data was obtained from February to June 2022 during construction. The automated instruments recorded readings over a 24-hour period.

3 RESULTS AND DISCUSSION

The disturbed samples used for compaction tests are represented as S21012, S21020, S21064 e S21079. Undisturbed samples were also collected for triaxial tests and they are identified in Table 1.

Table 1. Samples identification.

Samples	Layer	Samples
S21010	2ª	Undisturbed
S21012		Disturbed
S21018	5ª	Undisturbed
S21020		Disturbed
S21062	9ª	Undisturbed
S21064		Disturbed
S21077	11ª	Undisturbed
S21079		Disturbed

The Standard Proctor tests results are presented in Figure 2. An average value of maximum dry density of 1.87 g/cm³ (1.79 g/cm³ < dry density < 1.96 g/cm³) and optimum moisture content, with an average value of 13% (11.50% < moisture content < 14.20%).

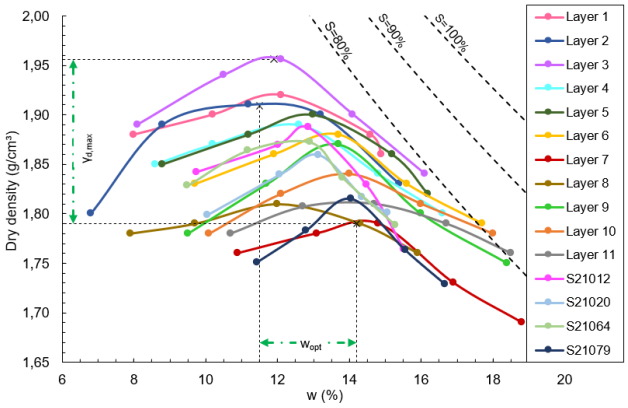

Figure 2. Compaction tests results.

According to tests results (Figure 3), the material was compacted with a water content below the optimum moisture content and a greater in-situ density due to higher compaction energy.

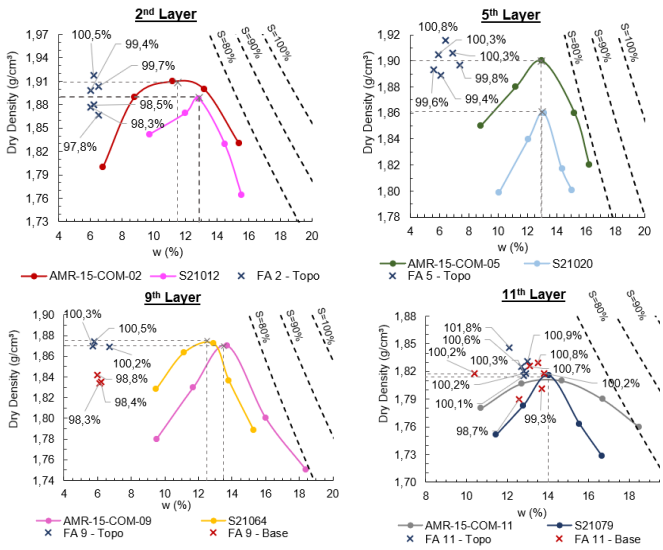

Figure 3. Comparison between sand replacement method and compaction curves.

Technical specification has considered 98% of the Proctor density. Besides that, moisture content correction was not carried out in the initial layers. There is also a discrepancy between the optimum moisture content carried out on samples collected in different layers. This behaviour could be explained due to the higher compaction energy close to 100%.

Laboratory tests results including specific gravity, moisture content, void ratio and Atterberg Limits are presented on Table 2 and 3.

Table 2. Specific gravity and moisture content.

Samples	Gs (g/cm³)	Moist. Content (%)
S21010	-	4,76
S21012	2,97	-

Particle-size distribution curves are indicated in Figure 4. The results indicated that filtered flotation tailings does not present significant grain size variability and are defined as fine silty sand.

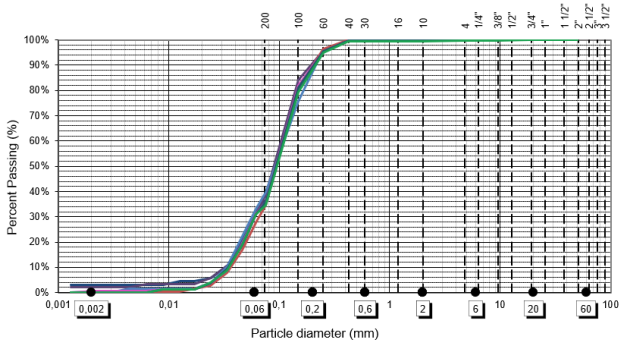

Figure 4. Grain size distribution.

Consolidated-drained test (CID) and consolidated-undrained test (CIU) were performed and the results indicate a high shear stress and friction angle ranging from 32° to 40° and null cohesion intercept (Figure 5 and Figure 6).

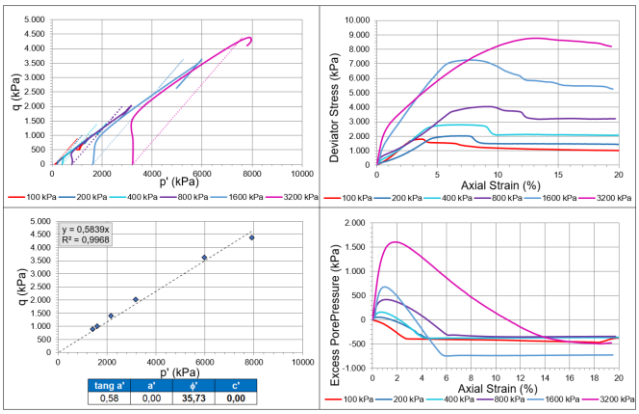

Figure 5. CIU results – 9th layer.

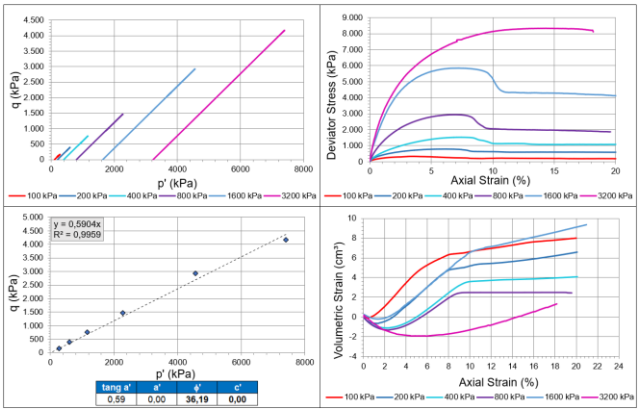

Figure 6. CID results – 9th layer.

Regarding geotechnical monitoring system, piezometers monitoring data was obtained from February to June 2022 during construction. The results (Figure 7) confirms that there was no significant variation in readings during this period, therefore, the development of excess pore pressures was very low. This behaviour may be due to the fact that the experimental landfill layers were compacted with moisture content significantly below the optimum content.

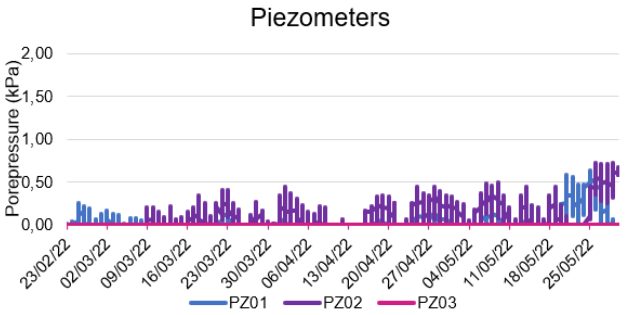

Figure 7. Monitoring data.

4 CONCLUSIONS

The experimental landfill construction was a remarkable step in order to provide data regarding geotechnical parameters and also material workability. According to field tests results, the material achieved the required degree of compaction (98%) and the average maximum dry density was 1.87g/cm³ with optimum moisture content with an average value of 13%. The filtered flotation tailings were compacted with a water content below the optimum moisture content and a greater in-situ density due to a higher compaction energy during construction.

The material does not present variability in particle size distribution and is defined as a fine silty sand. Triaxial tests indicates high shear stress and friction angle ranging from 32° to 40° and null cohesion. It was not identified excess pore pressure generation during construction according to electrical piezometers data.

Monitoring and analyzing vibrations from tunnel boring machine in urban areas

Suivi et analyse des vibrations générées par les tunneliers en zones urbaines

ABSTRACT: To enhance safety during the excavation phase of the urban tunnel construction using a Tunnel Boring Machine (TBM), we conducted an experimental study focused on the vibratory impact of excavating Line 18 of the Grand Paris Express in France, particularly at the Orly site. Our experimental setup involved strategically placing geophones and accelerometers along the tunnel route: on the surface, in the ground near the TBM, and inside the TBM itself. This article presents and analyzes the outcomes of the experiments, encompassing measurements of characteristic velocities and the identification of frequency ranges with elevated energy levels. The results not only illustrate the distribution of vibration energy linked to the excavation process but also offer insights into how the ground responds to these vibrations.

RÉSUMÉ: Afin d'améliorer la sécurité lors de la phase d'excavation au tunnelier (TBM) de la construction de tunnels urbains, nous avons réalisé une campagne expérimentale visant à étudier l'impact vibratoire du creusement de la Ligne 18 du Grand Paris Express (France) sur le site d'Orly. Le dispositif expérimental incluait des géophones et des accéléromètres positionnés sur le tracé du tunnel à la fois en surface, dans le sol proche du tunnelier et à l'intérieur du tunnelier. Cet article présente et analyse les résultats expérimentaux, qui englobent des mesures de vitesses caractéristiques et l'identification de plages de fréquences présentant des niveaux d'énergie élevés. Les résultats mettent en évidence non seulement la distribution de l'énergie vibratoire liée au processus de creusement, mais fournissent également des informations sur la réponse du sol à ces vibrations.

Keywords: Ground-borne vibrations; tunnel boring machine; in-situ measurements; dynamic characterization; frequency domain decomposition.

1 INTRODUCTION

Urban tunneling operations employing tunnel boring machines (TBMs) have become increasingly common. The analysis of vibrations generated by these excavations is deemed essential, given their impact on public safety and nearby structures. The selection of TBMs, whether earth pressure balanced shield (EPBS), slurry shield (SS), or open/hard rock TBMs, is contingent on geological conditions and project requirements. To advance our comprehension of these vibrations' behavior, their characterization can be achieved through the application of analytical methods and numerical models. Nevertheless, it is imperative to have these models validated using experimental data collected from various locations. Vibrations resulting from TBM excavations have been researched, with some studies conducted within the TBM itself and others concentrating on surface measurements, such as (non-exhautive list, a deeper review can be found in (Rallu et al., 2023)): Flanagan (1993) for the Buffalo metro (USA) and Hiller and Crabb (2000) for the London JLE metro (UK). A time-domain and frequency-domain analysis of vibrations measured simultaneously inside the TBM and on the surface had been performed on four tunnel projects in different geological contexts in Rallu et al. (2023). Moreover, Lu et al. (2022) conducted vibration measurements at different depths in a tunnel cover during the excavation phase in order to characterise the influence of geometric and geological parameters.

This study aims to compile data from various positions, including inside the TBM, within the ground, and on the surface, at the Orly, France, Metro Line 18 tunnel project. Various sensor types and

analyses are employed to enhance our understanding of the vibrations' behavior.

2 CASE STUDY OVERVIEW: METRO LINE 18

2.1 Study area description

The investigation was carried out at the metro Line 18 project, affiliated with the Grand Paris Express initiative and situated in the vicinity of Paris' Orly Airport. Covering a total distance of 35 kilometers, Line 18 comprises both an elevated and an underground segment, with a specific focus on the latter for this study. This metro line employs an earth pressure balance shield boring machine with a diameter of 9.15 m and features 10 stations along its route.

To understand the soil composition at the site, cross-hole in situ tests were conducted, and soil core samples were collected, providing insights into its characteristics. It is important to note that the site is saturated with water. In the studied site, overburden is around 28 m, see Figure 1.

A diverse range of sensors, including the Tromino from the Moho brand and 3D geophones with high precision (10^{-7}mm/s) capable of measuring ambient noise, were implemented on the construction site. The sensor has the option of being affixed to the soil using its three small pointed legs or simply placed on the surface. The coordination of these sensors involved the utilization of the global positioning system (GPS), with its limitations in underground areas recognized. To address this, all sensors were synchronized at a central surface location to collect GPS time data before being deployed to their respective positions.

The Soil Spy Rosina sensor, comprising vertical 1D geophones that can be positioned in the ground or on the surface, was also used. These geophones are connected to a central computer for data acquisition, and each Soil Spy Rosina sensor is characterized by an accuracy level of about 4×10^{-8} mm/s.

In this scenario, cylindrical 3D accelerometers from Syscom, featuring an impressive measurement range of up to $\pm$4g, were employed. These sensors are intricately connected to their dedicated central acquisition unit via a lengthy 50-meter cable. Despite their primary role in measuring acceleration, it is noteworthy that the transformation of this data into velocity is achievable through the integration of the acceleration data. This transformation process includes additional steps, such as filtering the data, to enhance accuracy.

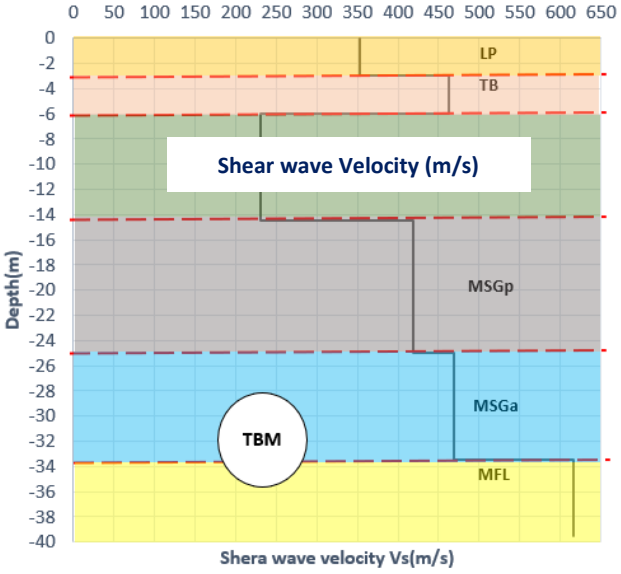

Figure 1. Site geological profile (scale not represented).

Figure 2. Types of sensors: Tromino, Rosina, and Syscom (from left to right).

At the construction site, two boreholes, namely T1 and T2, were employed, spaced 10 meters apart and possessing diameters of 80 mm. The lengths of these boreholes were 26 m and 38.8 m for T1 and T2, respectively. These boreholes played a pivotal role in the precise positioning of our sensors, adhering to the experimental setup illustrated in Figure 3:

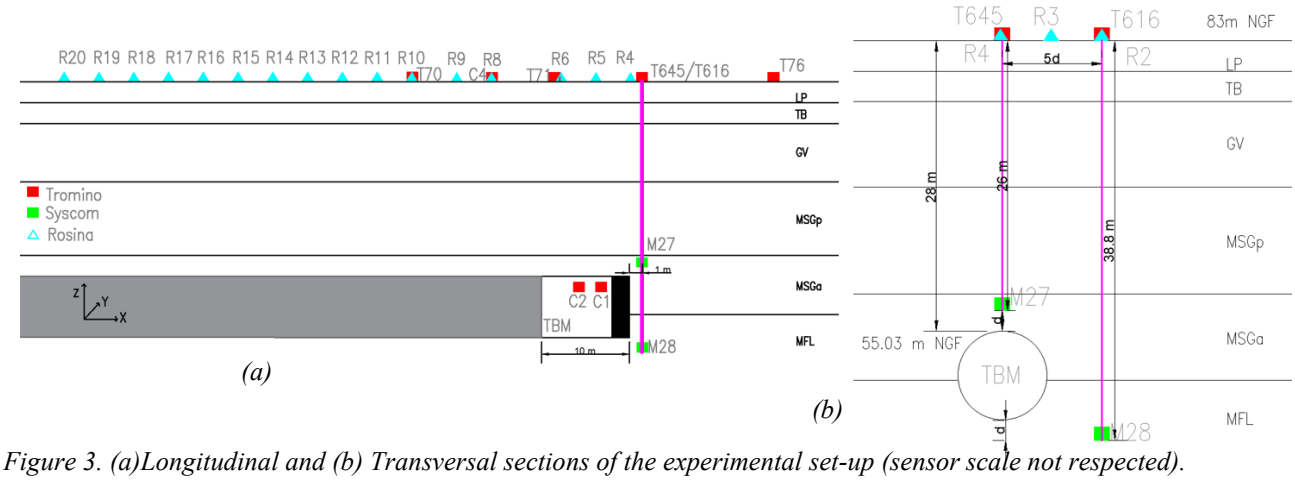

Figure 3. (a)Longitudinal and (b) Transversal sections of the experimental set-up (sensor scale not respected).

- On the surface, seven Trominos were strategically placed with a 10m separation between each (C4/T70/T71/T75/T76/T616/T645);
- Within the TBM's manlock, two Trominos (C1/C2) were positioned, with distances of 2.5 m and 4.5 m from the cutter wheel, respectively;
- On the surface, an L-shaped array consisting of 18 Rosina sensors (R2-R20) was organized, with a 5 m gap between each sensor;
- At the bottom of each borehole, two Syscom sensors were positioned: M27 and M28. M27 was installed d = 2 m above the tunnel crown, while M28 was installed d = 2 m below the tunnel raft. Both sensors were situated at the same longitudinal distance of 1 m from the face of the TBM, as illustrated in Figure 3.

3 DATA PROCESSING METHODOLOGY

Two distinct field campaigns were undertaken in this research. The first, conducted in January 2023, aimed to collect data in the presence of normal mechanical noise conditions. The second campaign, executed in April 2023 upon the arrival of the TBM at our site, centered on synchronized data collection from all designated sensors. This phase was dedicated to capturing data during the TBM's specific operational conditions to assess the vibrations emitted by the tunnel.

3.1 Data pre-processing

The primary aim at this stage is to ensure the reliability and quality of collected sensor data. To achieve this, a series of procedures were implemented to clean, improve, and prepare the data for further analysis. These procedures involve:

- restricting time traces to a relevant interval showing stationary behaviour;
- iltering signals within the frequency range 0-160 Hz, aligning with typical frequencies in building engineering;
- ensuring a zero-mean value for the time-histories.

By applying these steps, the data is refined enabling more dependable analysis in subsequent stages.

3.2 Data post-processing

Two primary methods were employed for data analysis in our research: Time Domain Analysis (TDA) and Frequency Domain Analysis (FDA). In the TDA, the characteristic vibratory level was measured using characteristic velocity per channel. This value corresponds to the absolute velocity within a 0.5% probability of being exceeded and captures the majority of signal energy, effectively eliminating non-representative peaks. On the other hand, FDA involved signal transformation to reveal its spectral content, allowing the understanding of how energy is distributed across different frequency components. These two approaches were employed in synergy, contributing to the overall improvement of signal characterization.

4 RESULTS AND DISCUSSION

4.1 Temporal analysis

Conducting a TDA with data from sensors strategically placed within the TBM, within the ground, and on the surface, the evaluation aimed to precisely measure the vibrations generated by the TBM during excavation and their subsequent propagation into the surrounding environment.

Figure 4 provides a detailed depiction:

- The time history for sensor C2 (blue color) in the Z direction reveals a characteristic velocity, as indicated by the envelope of the data, measuring around 1 mm/s;
- The time history for sensor M27 (orange color) in the Z direction exhibits a characteristic velocity of approximately 0.1 mm/s, noticeably lower compared to those observed inside the TBM.

As a result, it is relevant to consider that the signals acquired within the ground and inside the TBM are quasi-stationary. Additionally, the velocity magnitude inside the TBM is approximately 10 times larger than that within the ground (as measured by the Syscom sensor): $v_{k,TBM} \approx 10\, v_{k,soil}$. This indicates that not all the energy generated by the TBM is transferred to the surrounding area.

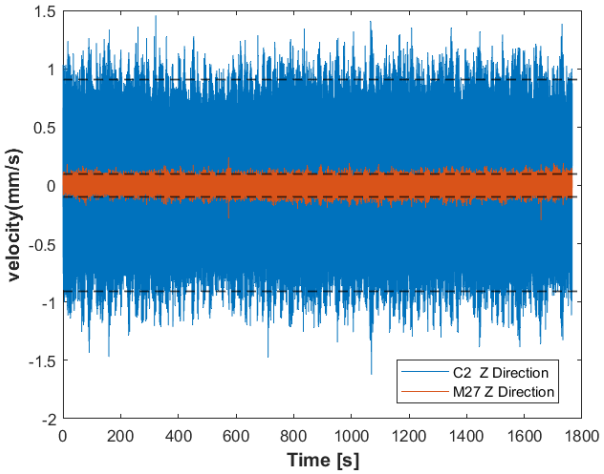

Figure 4. Time histories of sensors C2 (inside the TBM) and M27 (inside the ground) in the direction Z. Horizontal dashed lines represent the characteristic velocities.

The characteristic velocities of the sensors in the Tunnel Boring Machine (TBM), within the ground, and on the surface are depicted in Figure 5 for each acquisition direction. These velocities are presented as a function of their distance from the center of the cutting wheel, calculated based on the Pythagorean norm $\sqrt{x^2 + y^2 + z^2}$. The plot in Figure 6 illustrates the change in characteristic velocity (mm/s) for the Z direction across all sensor locations. Notably, Figure 5 reveals the similarity in amplitudes for all three directions at each sensor position. Furthermore, the vibration levels exhibit high comparability among the TBM (1 mm/s), within the soil (0.1 mm/s), and at the surface (0.01 mm/s). As a result, it can be inferred that the total energy is not entirely transferred to the surroundings. Instead, there is dissipation within the TBM itself and through the geological layers.

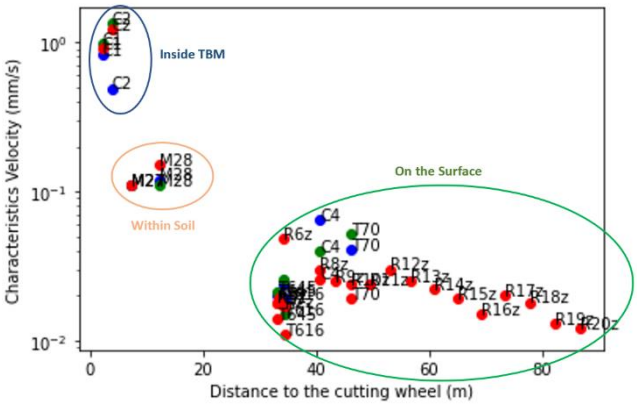

Figure 5. Characteristic velocities in function of the distance of the sensor to the cutting wheel, in the three directions of acquisition (X, Y, Z) for sensors located inside the TBM, on the surface and within the ground.

4.2 Frequency analysis

The distinct contributions of the signal at specific frequencies are revealed by the frequency analysis, often characterized using Fourier analysis. The vibration source's frequency characteristics are clarified, and the relationship between this frequency representation and its impact on the surface is established as primary objectives.

A method to estimate a signal's frequency spectrum involves the calculation of its power spectral density (PSD) through the Welch method, which combines the concept of Fourier transform and averaging to provide a more robust and reliable estimate of the PSD. In this method, the input signal is divided into overlapping segments, and a periodogram (an estimate of the signal's spectrum) is computed for each segment. These periodograms are then averaged to obtain a smoother and more accurate estimate of the PSD.

Detecting the relevant frequency ranges representing both the excitation level of the source and the ground's response is challenging when employing individual spectrum analysis from each sensor. To address this challenge, an approach inspired by the Frequency Domain Decomposition (FDD) technique was employed. Dominant frequency content in groups of synchronized sensors is identified by this technique, enhancing the representation of correlated frequencies across all signals and eliminating isolated peaks.

It is important to note that the traditional FDD plot often involves multiple Singular Value Decompositions (SVDs). In this case, the focus is on visualizing the first singular value (σ). This approach, introduced in the research conducted by Rallu et al. (2023), aims to evaluate the energy levels of signals concerning their frequencies in various underground

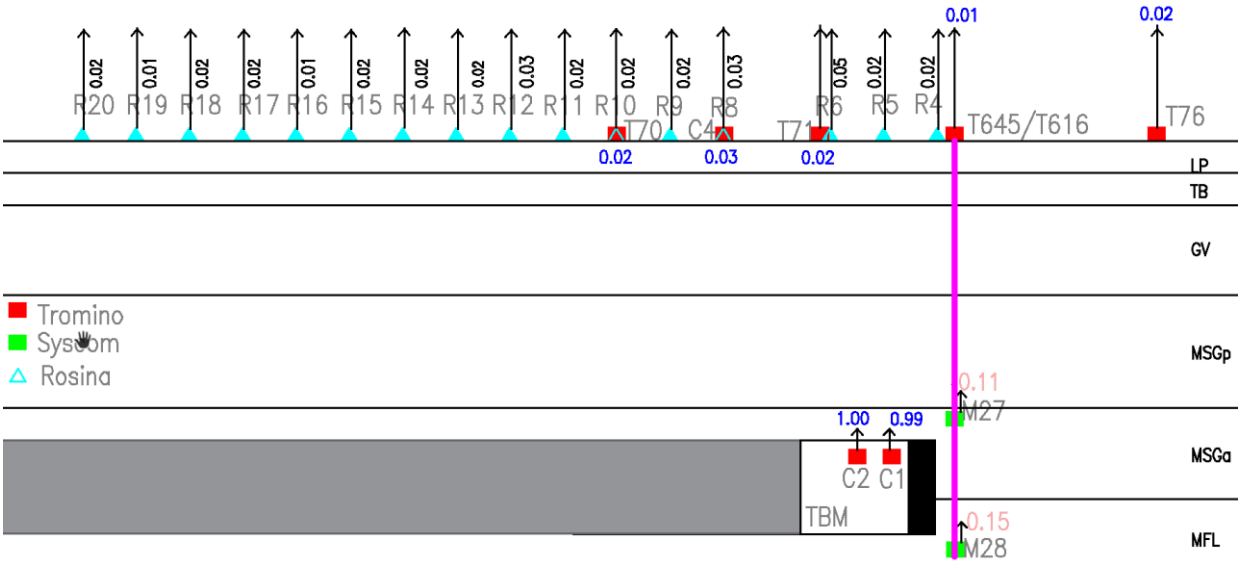

Figure 6. Depiction of vertical (Z) characteristic velocities in mm/s across all sensors throughout the excavation phase in a longitudinal section.

projects. Notably, it reveals the frequency coherence between signals recorded within the Tunnel Boring Machine (TBM) and those captured on the surface during excavation.

Two scenarios were employed in the study, encompassing the measurement of ambient noise before excavation and measurements during excavation, which included on-surface, within the soil (utilizing Syscoms), and inside the Tunnel Boring Machine (TBM). Examining the scenario of surface sensors capturing mechanical ambient noise, energetic peaks in the site spectra corresponded to frequency bands around the soil's eigenfrequencies. The initial singular value (σ) derived from the Power Spectral Density (PSD) matrix serves as an indicator of signal energy across diverse situations and orientations. This visual representation facilitates a comprehensive exploration of connections and correlations between these signals. The lack of strong intercorrelation between two signals may result from weak values in one or both signals or a feeble correlation between them. Conversely, if two signals contribute energetically in the same frequency band, a robust intercorrelation in that band occurs. Referring to Figure 7, irrespective of the sensor's position during the excavation phase, the overall trend of the first singular value across frequencies remains consistent, displaying identical local peaks with varying amplitudes.

Figure 7 illustrates a significant difference in energy levels at three positions during excavation: approximately $10^{-2}(mm/s)^2$ inside the TBM, $10^{-5}(mm/s)^2$ within the soil, and $10^{-6}(mm/s)^2$ on the surface. This disparity supports the conclusion that energy transfer is not uniform towards the surface.

Additionally, it shows the consistent evolution of the three directions for the three sensor positions is observed during the excavation phase. In contrast, under ambient noise, differences emerge, with a peak at a higher frequency in the Z direction, attributed to the terrain's anisotropy.

Upon comparing the spectra in Figure 7, it becomes evident that peaks around 85 Hz and 175 Hz, present inside the tunnel boring machine, are also observed in the ground and on the surface during excavation. Consequently, the excavation phenomenon is characterized by the presence of two peaks: 85 Hz and 175 Hz.

In the frequency range below 70 Hz, the soil, exposed to ambient noise, displays an energetic frequency band typical of classical soil eigenfrequencies. This results in a robust response significantly influenced by the TBM, generating energetic reactions on the surface that extend beyond the vicinity of the tunnel axis. However, beyond 100 Hz, the site-spectrum under ambient noise functions as a transfer function. Therefore, the response on the surface and within the soil under TBM influence corresponds to the convolution between the TBM and ambient noise. Identical local peaks observed on both the surface and near the tunnel axis represent the frequencies of the source.

5 CONCLUSION

Extensive vibration measurements were undertaken as an integral component of the Metro Line 18 Grand Paris project. These measurements encompassed

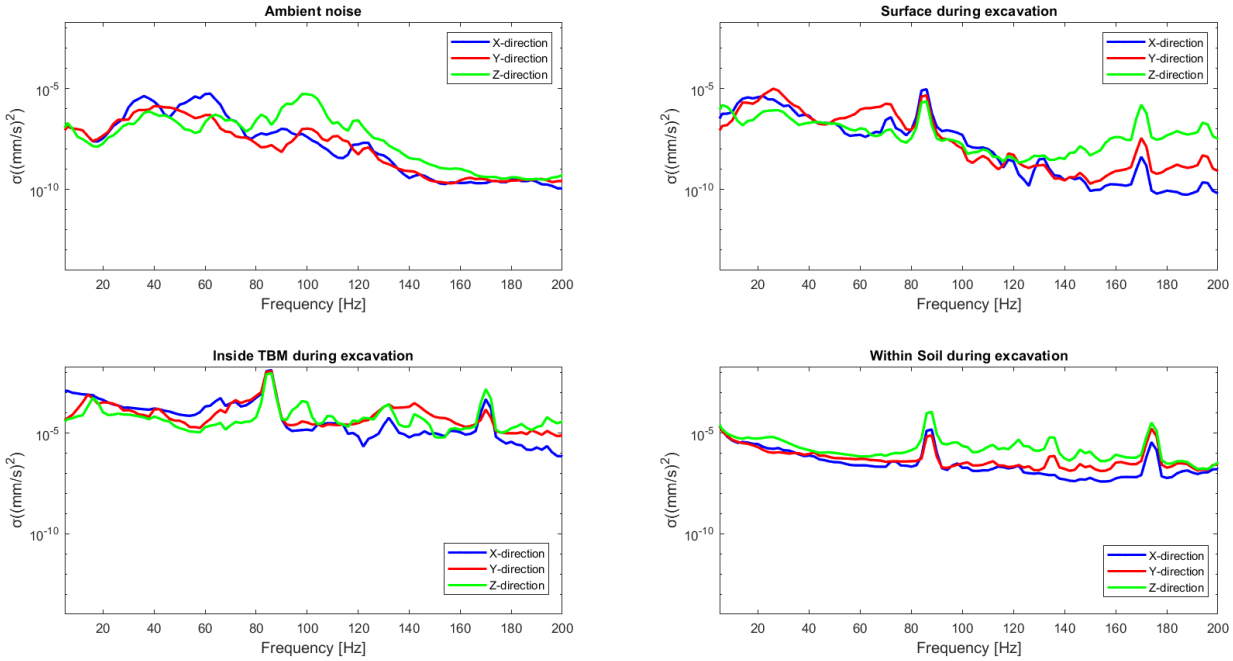

Figure 7: Representation of the intercorrelation between 3 sensor positions: (at the surface, within the soil and inside the TBM) for the 2 cases: (ambient noise and during excavation).

sensors strategically positioned on the surface, within the ground, and inside the Tunnel Boring Machine (TBM), both during excavation and ambient noise conditions. The analyses focused on assessing characteristic velocity amplitudes and frequency characteristics of the recorded signals, leading to several key findings:

- Surface velocity vibrations (10^{-2} mm/s) were significantly lower than those inside the TBM (100 times);
- Velocity amplitudes within the TBM were ten times higher than those within the ground via Syscom sensors which is 1 m apart from the TBM face, indicating energy dissipation within the TBM ;
- Energy dissipation was confirmed by analysing the highest singular values of spectral density matrices from all sensors, with three levels of energy recorded: approximately $10^{-2}(mm/s)^2$ inside the TBM, $10^{-5}(mm/s)^2$ within the soil, and $10^{-6}(mm/s)^2$on the surface.
- During the excavation phase, two frequencies, namely 85Hz and 175Hz, were observed within the Tunnel Boring Machine (TBM), within the ground, and on the surface. Notably, these frequencies were absent under ambient noise conditions, indicating their association with the excavation phenomenon.

ACKNOWLEDGEMENTS

The authors are grateful for the assistance provided by CETU and Me2i for establishing the geological profile as well as for the support provided by the Société du Grand Paris. Results presented in this paper have been obtained within the framework of the French research Project E-PILOT (Evaluation of the impact on Piles response during Tunnelling).

ABSTRACT: Pile driving adjacent to or in slopes can trigger landslides, specifically in marginally stable slopes and in the presence of sensitive soil deposits. Slope failure incidents due to pile driving have been reported in countries such as Norway, Sweden and Canada where soft sensitive clay deposits are prevalent. However, the failure mechanisms involved in such incidents are not well studied nor understood. Furthermore, the methods currently used to estimate the reduction in the slope's factor of safety during pile driving lack scientific consensus. This paper describes how pile driving can reduce slope stability by means of empirical relations and analytical solutions from soil mechanics as well as numerical analysis.

RÉSUMÉ: Le battage de pieux à proximité ou dans des pentes argileuses peut déclencher des glissements de terrain, particulièrement dans des pentes peu stables et en présence de sols mout et sensible. Des glissements de terrain dus au battage de pieux ont été répertoriés dans différents pays comme la Norvège, la Suède et le Canada, pays dans lesquels les argiles sensibles. Cependant, les mécanismes de rupture qui explique ces incidents ne sont pas clairement identifiés ni compris. De plus, les méthodes actuellement disponibles pour quantifier les coefficients de sécurité des pentes durant le battage de pieux manque de précision scientifique. Cet article décrit comment le battage de pieux peut affecter la stabilité de la pente.

Keywords: Pile driving; slope stability; excess pore pressure; strain softening; numerical modelling.

1 INTRODUCTION

Pile driving generates stresses, strains, excess pore pressures and vibrations in the soil (Seed and Reese, 1957). Pile driving in clay is an undrained type of loading where multiple hammer-blows generate excess pore pressure in the adjacent soil which may lead to cyclic degradation of the soil (Randolph and Gourvenec, 2011). These effects are visually depicted in Figure 1. As a result, characteristics of the soil (such as plasticity index and strength among others) in the vicinity of the pile change during and for a period after the pile driving. These changes are usually temporary, and the soil regains its initial strength to some extent (Karlsrud and Nadim 1990). But this process can take many months depending on the properties of the soil, mainly permeability and stiffness of the soil material.

In some cases, these temporary changes in the soil can lead to a reduction in the factor of safety of a slope and lead to excessive movements or initiate a landslide. Understanding the mechanisms involved and methods to account for this reduction in the safety factor can help reduce risks related to pile driving conducted in slopes.

There are not many reported and documented cases of landslides due to pile driving in the literature (Attari et al., 2023). Reviewing the few numbers of reported cases shows that this type of slope failure is more common in Norway, Sweden and Canada where sensitive and brittle clay materials are present in the soil (Attari et al., 2023). For instance, a large landslide occurred in 1950 in the Gota river valley area, located nearby Gothenburg city in Sweden. The landslide affected 240,000 m^2 of the area and swept away 31 family houses and resulted in a loss of life (Bernander, 2011). At the time of the landslide, pile driving was being conducted at the top of the slope. A landslide took place in 1966 a few hours after completion of driving 50 wooden piles into soft sensitive clay (Broms and Bennemark, 1967). Another landslide occurred in Quebec, Canada in 1978 while pile driving was in operation for an electrical tower (Carson, 2011). The results of grain size analysis and drilling

reports indicated lenses of sand and silt in the deposit and the investigating committee report concluded that the vibrations induced by pile driving have resulted in the liquefaction of these sand lenses, causing the surrounding clay to lose part of its shear strength, resulting in continuation of the movements even after pile driving had stopped (Carson, 2011).

A list of slope failure incidents due to pile driving is provided in Attari et al. (2023). In some of these cases, noticeable rise in pore pressure was observed prior or after the landslide and a lot of the soil investigation reports indicate lenses of silt and sand between the clay layers. Despite the significance of this problem, there is still not a standard method developed to accurately account for the reduced stability of a slope due to pile driving (Langford et al., 2021).

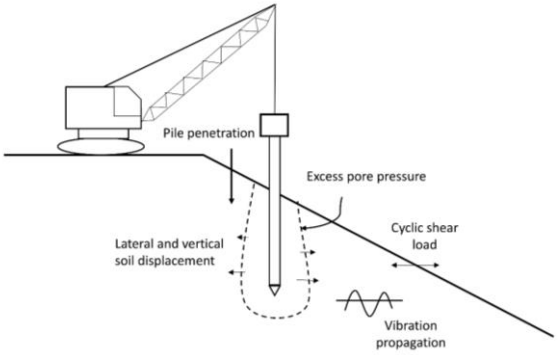

Figure 1. Effects of pile installation in a slope (Attari et al., 2023).

Common practice in Norway to account for reduced stability of a slope during pile driving, is to monitor pore pressures during construction. Limits are set on maximum allowable pore pressure levels to avoid slope failure. Piling operations are stopped when these limits are exceeded and are continued where pore pressures return to allowable rates (Tefera et al., 2013). However, the basis for obtaining these limiting values is not accurate. Moreover, the costs for waiting time or for moving pile-driving machines to different locations to allow for pore pressure dissipation can be large and there are a lot of uncertainties in the installation/construction phase, which usually infers extra costs. Therefore, there is a strong need for further research to develop an approach to account for pile installation effects on slope stability in a more reliable manner.

2 REVIEW OF THE BASIS OF THE TRADITIONAL METHODS

The basis for the currently used methods in practice together with measuring of pore pressures is that soil strength is dependent on effective stresses (Ladd & Foott, 1974). The SHANSEP technique which assesses the effect of stress history on the shear strength of soil was developed by Ladd & Foott (1974). This concept is based on a series of laboratory tests which establish undrained shear strength as a function of Overconsolidation Ratio (OCR) and accordingly, calculates the undrained shear strength based on the in-situ vertical effective stress, using Equation (1).

$$S_u = S.OCR^m.P' \quad (1)$$

$$P' = P - \Delta u \quad (2)$$

where S_u is the undrained shear strength, P is the *in-situ* vertical stress, P' is the *in-situ* vertical effective stress, Δu is pore pressure, S is undrained shear strength ratio in normally consolidated state (OCR=1) and m is a constant dependent on the type and Plasticity Index of clay. Using the SHANSEP principle in a pile driving scenario will provide reduced shear strength values (Kirkebø et al., 2008) due to the reduction in P' given by Equation (2). The methods assume that the excess pore pressure results in reduced effective stresses in the soil adjacent to the pile, and as given by the SHANSEP formula, the undrained shear strength reduces. Accordingly, the reduced Su results in a lower safety factor of the slope.

However, these assumptions do not consider that pile driving is an undrained loading mechanism in clay (considering the low permeability of clays) which increases the total stresses. Thus, according to equation (2), which is the basis of the effective stress concept by Terzaghi (1943), the change in effective stresses is dependent on both total stress and excess pore pressure which are both increasing. A more in-depth evaluation of these methods can be found in Attari et al. (2023).

3 NUMERICAL ANALYSIS

It is a complex task to simulate pile driving using Finite Element Analysis (FEA). For the purpose of this study, it was deemed suitable to only take into account the effect of the lateral push that is generated due to driving a pile in the slope, assuming the row of piles are installed simultaneously to full depth. For this reason, pile driving was simulated using the prescribed

volumetric strain feature in the finite element code Plaxis, where in a 2D setting, lateral strains are applied to a wished-in-place pile modelled as a soil cluster. This volumetric strain feature expands or contracts a soil cluster equal to the applied strain (Brinkgreve et al., 2021). This change in strains will then affect the surrounding soil until equilibrium is reached between all clusters. Application of prescribed volumetric strains on the pile cluster, generates lateral displacements in the soil similar to the expansion of a cylindrical cavity in a soil medium, which is widely used in combination with a constitutive soil model to simulate the effects of pile driving in soil (Hunt, 2000). Although this method disregards the changes in vertical stresses during pile driving, it still provides good estimates of stresses, displacements and excess pore pressures in the soil due to pile penetration (Hunt, 2000). The accuracy of the results in these analyses are highly dependent on the choice of the constitutive soil model. For instance, a simple soil model such as Mohr-Coulomb cannot simulate several important effects of pile driving (stress dependent stiffness, strain softening) and are therefore not able to capture the reduction of the safety factor of the slope. More advanced constitutive models such as Soft Soil can provide better estimates of, for example, the excess pore pressure and, accordingly, provide a better understanding of the extent of undrained shear strength mobilization in the soil after pile driving.

More advanced constitutive models that can take into account strain-softening of the clay are further employed in FEA. Sensitive clays show a reduction in their undrained shear strength after the peak strength is reached in undrained conditions. This characteristic is referred to as strain-softening. A gradual progression of strain-softening behavior throughout the slope could ultimately lead to a global failure (Urciuoli et al., 2007). This type of failure is defined as progressive failure in sensitive deposits where a local disturbance may trigger a landslide Bernander (2011). The NGI-ADPSoft model is an elastoplastic constitutive soil model that can be used in total stress analysis of soils and can simulate the strain softening behaviour of sensitive clays and hence, can capture the reduction of the undrained shear strength in the soils as a function of strain level in undrained conditions. This could be used to calculate a representative factor of safety in the sensitive clay slope (see Figure 2). This representative factor of safety is obtained by increasing the unit weight of the soil int the analysis (instead of reducing the soil strength) until failure is reached. More information about this soil model can be found in Jostad et al. (2014) as well as Grimstad & Jostad (2012).

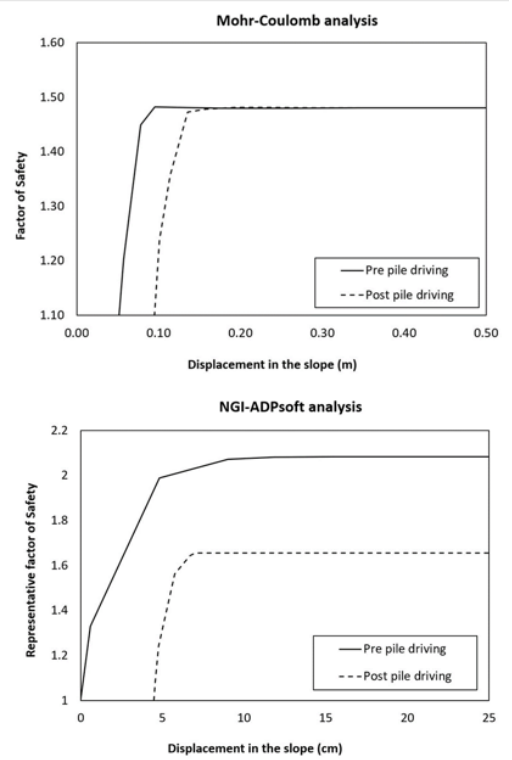

Figure 2. Comparison of factor of safety using different constitutive soil models in Plaxis (Attari et al., 2023).

4 CYCLIC SOIL DEGRADATION DUE TO PILE DRIVING

Soil response to cyclic loading is substantially different from the soil response under monotonic loading and depends on the mode, amplitude and frequency of the cyclic loading. To investigate if the cyclic loading generated due to pile driving can influence the stability of slopes due to cyclic degradation of the soil strength the following methodology is being investigated. A pile driving analysis is conducted to provide pile displacements in time by means of 1D stress wave analysis using the GRLWEAP software. The displacement versus time output can be used in a dynamic finite element analysis to estimate the extent and magnitude of the changes in stresses, strains and excess pore pressures due to the cyclic loading. These results can be used in combination with cyclic degradation contour diagrams developed by Andersen (2009) to determine the reduction in shear strength. These diagrams are developed for a great range of soils and are based on large numbers of laboratory tests on block samples (Andersen, 2009). The result of this study is planned to be included in future articles by the authors.

5 CONCLUSIONS

Throughout this study, changes occurring in clay due to pile driving have been briefly explained and their possible effect on the reduction of soil strength was pointed out. Subsequently, methods currently used by geotechnical engineers to take into account the reduction in the stability of a slope during pile driving were presented. It was pointed out that these methods lack theoretical consensus. Furthermore, examples of how numerical analysis can contribute to better understanding of this problem were outlined.

Effect of increased vertical stress on the state of grains in tailings

Effet de l'augmentation du stress vertical sur l'état des grains dans les résidus miniers

ABSTRACT: The mining industry has experienced rapid growth, leading to the accumulation of substantial mine waste, commonly referred to as tailings. Tailings are typically stored in tailings storage facilities, conventionally consisting of an impoundment surrounded by tailings dams. The construction of tailings dams can involve various methods, with the upstream method being commonly used in the industry. It is crucial to comprehend the long-term mechanical and geochemical behavior of deposited tailings to ensure the safety of upstream constructed tailings dams. The mineral composition, particle size distribution, and particle shape all affect the susceptibility to particle breakage or physical alteration. Therefore, there is an interest in understanding how grain size and grain shape relate to mineral composition and potential particle breakage to ensure the understanding of the long-term mechanical behavior. This study focuses on characterizing deposited tailings from various depths and investigates the impact of increased vertical stress on tailings, particularly examining the potential for crushing effects. The findings highlight the importance of considering these factors for a comprehensive understanding of tailings behavior and their implications for the long-term safety of tailings dams.

RÉSUMÉ: L'industrie minière a connu une croissance rapide, entraînant une accumulation substantielle de rejets de concentrateur, communément appelés résidus miniers. Les résidus sont généralement stockés dans des parcs à résidus, traditionnellement constituées d'un bassin entouré de digues construites de résidus. La construction de digues avec des résidus se fait avec différentes méthodes, la méthode amont étant couramment utilisée dans l'industrie minière. Il est crucial de comprendre le comportement mécanique et géochimique à long terme des résidus déposés pour garantir la sécurité des digues de résidus. La composition minéralogique, la distribution granulométrique et la forme des particules ont toutes une influence sur la susceptibilité des particules à se briser. Par conséquent, il est essentiel de comprendre comment la variation de taille et de forme des grains est liée à la composition minéralogique et à la possibilité de rupture des particules afin de garantir le comportement mécanique des digues à long terme. Cette étude se concentre sur la caractérisation des résidus déposés à différentes profondeurs dans la digue et examine l'impact de l'augmentation de la contrainte verticale sur les résidus, en particulier en ce qui concerne le potentiel d'effets de broyage. Les résultats mettent en évidence l'importance de prendre en compte ces facteurs pour une compréhension complète du comportement des résidus et de leurs implications pour la sécurité des digues de résidus à long terme.

Keywords: Tailings; mineralogy; particle size distribution; particle shape.

1 INTRODUCTION

The mining industry, vital for modern life, has seen rapid growth and thereby increasing notably the mine waste (Lyu et al., 2019). One type of mine waste is tailings and this leftover material is typically stored within impoundments surrounded by tailings dams, which are often built and raised up using tailings itself (Villavicencio et al., 2014).

Tailings dam construction can be classified into three main methodologies: upstream, centreline and downstream construction methods. Traditionally many tailings dams have been built by the upstream method and in this approach, embankments are placed on top of previous deposited tailings, implying that the tailings impoundment will eventually become part of the dam body and foundation for future embankments. Many upstream facilities have demonstrated satisfactory performance; however, this construction method is generally considered the least reliable (e.g., Fourie et al., 2022).

Intuitively, it is essential to understand both the mechanical and geochemical behavior of tailings to be able to perform safety assessments of upstream tailings dams over time (e.g., Vick, 1990).

According to Vick (1990), there could be a potential change among some of the intrinsic

properties of the tailings related to the long-term behavior, which thereby likely modifies the mechanical behavior. Some changes could be related to particle size distribution (PSD) and particle shape, as they adapt to new state properties (stress state and void ratio). Potentially crushing, particle breakage or degradation can occur implying a change in the PSD and particle shape. Zhang et al. (2020) emphasize that the magnitude of change in PSD and particle shape is strongly dependent of the mineralogic composition.

Bhanbhro (2017) looked at the crushing for uniform sized tailings (i.e. tailings sorted out in different group gradations) and exposed them to stepwise increased vertical stress from oedometer test making a comparison of the strength parameters, particle shape and breakage analysis.

The aim of this paper is to investigate the potential for particle breakage or physical alternations in form of change in the PSD on a whole tailing gradation, exposed to increased vertical stress (i.e., from slow and stepwise increased overload due to continued deposition). By conducting a comparative analysis, the study provides inputs that may enhance the understanding of tailings behavior under increased vertical load, although from the results presented herein it is understood and highlighted how mineralogical analysis must be merged into the analyses of PSD and particle shape analyses for better understanding.

2 METHODOLOGY

This study involved the analysis of disturbed samples extracted from a borehole within a tailings impoundment in northern Sweden, reaching a depth of approximately 40 m. Laboratory work was conducted on 4 samples collected from the borehole at varying depths, separated by approximately 10 meters each. These samples were designated as A (4.2 – 4.5 m), B (15.0 – 15.4 m), C (24.5 – 25.0 m), and D (33.5 – 34.0 m) as shown in Figure 1.

The samples underwent initial characterization, including PSD, particle shape and mineralogy. Subsequently, they were subjected to vertical stepwise loading through oedometer testing up to 640 kPa. Finally, another PSD characterization was performed on the oedometer tested samples.

The samples exhibited a PSD of sand and silt grains, with a fines content (<0.063 mm) ranging between 10 and 30%. The maximum grain size identified within the samples was 2.00 mm.

Samples were reconstituted using tamping methodology and the non-linear undercompaction method by Jiang et al. (2003). Additionally, one sample (D) was also prepared as a slurry to investigate possible effects of soil fabric and particle arrangement in the oedometer results.

For particle shape and mineralogical analyses, a qualitative assessment was done for particles greater than 0.063 mm through imaging using reflected light and scanning electron microscopy (SEM), respectively. SEM analysis was performed only in 2 out of 4 samples (A and B) since it was not possible to complete the test in all samples as expected due to some technical equipment problems.

Initial PSD samples were determined through wet sieving and sedimentation methods, while a dynamic image analysis was executed after oedometer testing using a Camsizer XT equipment. This equipment uses LED light sources and high-resolution cameras to scan particle collective injecting compressed air. This approach emerged as an alternative due to the limited amount of sample obtained after oedometer testing and potential uncertainties in the results when employing traditional sieving.

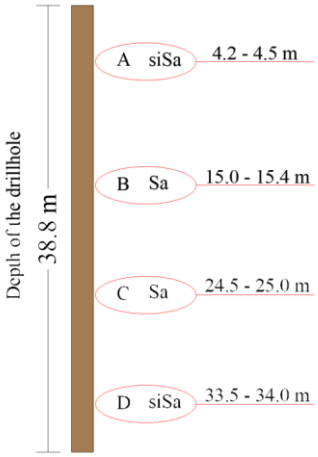

Figure 1. Drillhole and sampling schema.

3 RESULTS

3.1 Particle size distribution

The study presented herein focus on the changes in particle size distribution comparing before and after oedometer testing. The findings showed that the incremental stepwise loading produced minor and, in some cases, negligible variations in PSD. These variations were primarily observed in the coarser particles, leading to an increase in fines content. The most noticeable deviations occurred between sieves with apertures of 1.00 mm and 0.063 mm. Figure 3 and Figure 2 displays the PSD for sample A and D, correspondingly. Samples B and D showed the most prominent changes at the 0.125 mm sieve size with an

increase of 2.93% and 3.83% compared to their original PSD, and belonging to decrement at the 0.5 mm sieve size about 0.48% - 1.71%. Sample A displayed the lowest variation in fines after testing, with a maximum deviation of 0.46% at the 0.125 mm sieve.

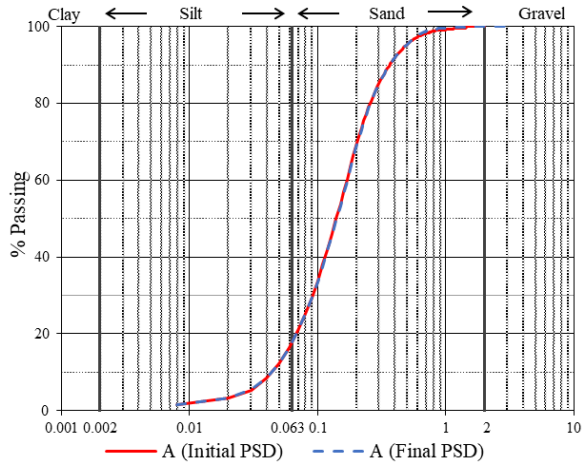

Figure 2. PSD sample A before and after testing.

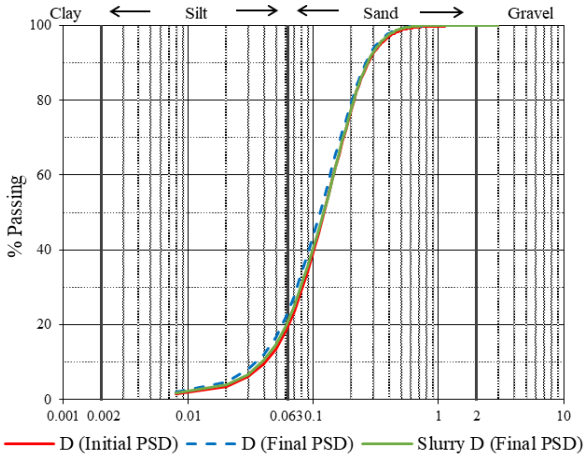

Figure 3. PSD sample D before and after testing.

In this study the change of PSD before and after oedometer testing are relatively small. However, the results are consistent in that all samples exhibited an increment of finer particles after oedometer testing. These results agree with the findings of Bhanbhro (2017), who for the tailings with the same origin showed that in uniform gradings coarser particles are more prone to breakage than finer particles. The uniform gradings of large particles (1-0.5 mm) in Bhanbhro (2017) exhibited a decrement around 14% at the 0.5 mm sieve. Thereby, it is clear that the uniform particles showed a more distinct physical alteration than the whole gradation tested samples in this study. If magnitude of alteration in PSD is disregarded all samples (from both studies) indicate that larger particles are more prone to physical alterations under vertical loading. This may be attributed to the presence of internal fractures and stress concentration at particle edges, that are more present at larger particles. The reason to only a small change in PSD for the whole grading samples in this study are likely attributed to finer particles filling out the voids between the coarser particles.

Slurry sample D (green in Figure 2) exhibits reduced susceptibility to potential physical alteration of particles, with a maximum deviating increment of 1.31%, compared to its initial PSD at sieve 0.063 mm. Corresponding deviating increment for tamped sample D was 3.58% (blue in Figure 2). This result suggests that slurry samples display another interlocking behavior between particles, where finer particles protect the larger ones more effectively than tamped samples.

3.2 Mineralogy

The mineralogical composition of particles is generally similar among the analyzed samples, but variations in element concentrations are evident as shown in Figure 4 and Figure 5. Assessing the elements concentration on particles, the most common minerals identified in both samples include mica, feldspar, plagioclase, and quartz. However, other residual minerals are also found. Sample A exhibited gangue minerals such as sorosilicate, K-feldspar, and apatite, while sample B contained iron, hematite, pyrite, illite, and biotite.

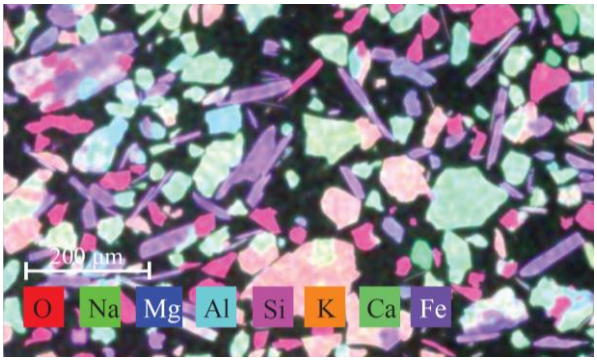

Figure 4. SEM analysis of sample A, depth 4.2 – 4.5 m.

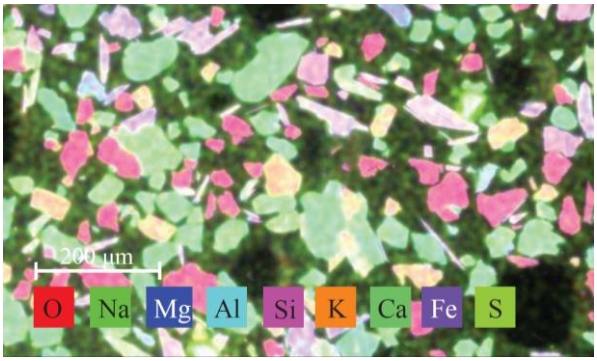

Figure 5. SEM analysis of sample B, depth 15.0 – 15.4 m.

3.3 Particle shape

Qualitative analysis of the results obtained from reflective light imaging and SEM analysis was performed using the roundness qualitative scale developed by Powers (1953). The tailings in this study have particles with a low sphericity shape where larger tailings particles are mostly subangular. Meanwhile the smaller the particles become, the shape turns into a combination of subangular and very angular. The black holes observed in Figure 4 and Figure 5 are voids that became trapped during sample preparation; however, they did not affect the interpretation.

4 CONCLUSIONS

This study shows that change in PSD of silty-sandy tailings tested in oedometer are evident, although the changes are small to neglectable. Tamped samples were found to be more susceptible to changes in PSD after oedometer testing compared to slurry samples. Furthermore, the magnitude of the change in PSD are smaller in this study than the similar, but uniform graded, tailings tested by Bhanbhro (2017).

Consequently, this implies that the characteristics of the soil fabric is important when consider the potential for physical alterations of particles due to increased vertical stress. The presence of fine particles and the manner they fill the voids and confine the larger particles clearly influence the vulnerability for particle breakage or physical alterations of particles. To some extent this is intuitive, if one considers that the particle-to-particle contact, stress distribution as well as the possibility of particle rearrangements directly are affected by how and to what extent the fine particles connect to the larger particles.

It is essential to assess the entire particle size distribution when evaluating susceptibility to breakage in a particular tailings sample. In addition, this study has shown that soil fabric can affect susceptibility to particle breakage or other physical alterations due to increased vertical stress. Neither tamped nor slurry prepared soil fabric in the laboratory might be the accurate replicate of field conditions. It is a complex topic and among several factors the in-situ soil fabric varies due to deposition methods, sedimentation, consolidation, saturation conditions, geochemical processes, etc.

Depending on tailings mineralogy and particle shape composition, there might or might not exist risk of change in PSD due to particle breakage or physical alterations which in the end likely will influence the mechanical behavior. Quantification and detailed analysis of the potential for particle breakage is complex. A step forward is believed to link the particle shape and particle size to the mineralogic composition as differences in hardness will affect the change in PSD. This, then can increase the understanding for the potential to physical alterations of particles and thereby the susceptibility of tailings to suffer from change in mechanical behavior over time.

Spatial vulnerability of levees to cascading hazards

Vulnérabilité spatiale des digues aux aléas en cascade

M. Bačić, N. Rossi*, L. Librić, M.S. Kovačević
University of Zagreb, Faculty of Civil Engineering, Zagreb, Croatia
*nicola.rossi@grad.unizg.hr

ABSTRACT: Levees are vulnerable to a multitude of hazards which may cause their partial or complete failure, thus leading to loss of their main purpose of protection against floods. As earthen structures, levees are also highly susceptible to earthquakes. A major concern arises in the unlikely case that these two events occur at the same time with extreme magnitudes. A similar situation occurs when an earthquake damages upstream components of the same flood protection network, such as dams, causing water waves to propagate downstream. The loads are not simultaneous, but within the short delay the damage to the levees would not have yet been identified/repaired to prevent flooding of the surrounding area. This paper analyses cascading scenarios of strong earthquakes followed by water waves resulting from damaged dams, acting upon the downstream levees. The levees in the cross-border area of Croatia and Slovenia, sharing the seismic and flooding hazards, are selected for validation of the vulnerability assessment methodology. The vulnerability of levees was modelled considering the influence of earthquakes on both the levee network and the upstream hydropower plant. Probabilities of failure are derived, enabling the categorization of the levee network, and giving valuable information to infrastructure managers and first responders on the criticality of the network whose overall efficiency is controlled by the weakest link.

RÉSUMÉ: Les digues sont vulnérables à une multitude d'aléas qui peuvent provoquer leur rupture partielle ou totale, entraînant ainsi la perte de leur fonction principale de protection contre les inondations. En tant que struct. en terre, les digues sont également très sensibles aux tremblements de terre. Une préoccupation majeure surgit dans le cas peu probable où ces deux événements se produiraient en même temps avec des ampleurs extrêmes. Une situation similaire se produit lorsqu'un tremblement de terre endommage les composants en amont du même réseau de protection contre les inondations, tels que les barrages, provoquant la propagation des vagues d'eau en aval. Les charges ne sont pas simultanées, mais dans un court laps de temps, les dommages causés aux digues n'auraient pas encore été identifiés/réparés pour éviter l'inondation des zones environnantes. Cet article analyse des scénarios en cascade de forts tremblements de terre suivis de vagues d'eau résultant de barrages endommagés, agissant sur les digues en aval. Les digues de la zone transfrontalière de la Croatie et de la Slovénie, partageant les risques sismiques et d'inondation, sont sélectionnées pour la validation de la méthodologie d'évaluation de la vulnérabilité. La vulnérabilité des digues a été modélisée en tenant compte de l'influence des tremblements de terre à la fois sur le réseau de digues et sur la centrale hydroélectrique en amont. Les probabilités de défaillance sont dérivées, permettant la catégorisation du réseau de digues et fournissant des informations précieuses aux gestionnaires d'infrastructure et aux premiers intervenants sur la criticité du réseau dont l'efficacité globale est contrôlée par le maillon le plus faible.

Keywords: Probability of failure; cascading effect; levees; point estimate; categorization.

1 INTRODUCTION

Throughout history, humans have been continuously trying to establish control over rivers, both for resources and for containing and regulating damaging floods. This is done by altering the watercourse by constructing hydraulic structures such as dams, levees, weirs, culverts, etc., at which point the river loses its natural flow regime. The more regulating structures are constructed, the more potential failure points there are, which are subject to many uncontrollable conditions which may deteriorate their stability, resulting with a lot of variability and uncertainty in risk management. Such uncertainty is usually addressed by conducting probabilistic analyses where probabilities of failure or unwanted behaviour are calculated, which serve as a basis for conducting maintenance works. The considered loads can be diverse, mostly high river discharges, rainfall, and earthquakes, or a combination of loads such as the one analysed in this study.

2 PROBLEM DESCRIPTION

This paper presents a case study pertaining to the categorization of a stretch of levees along the river Sava, between the hydropower plant (HPP) in Brežice (Slovenia) and the Jankomir bridge in Zagreb (Croatia), an area of mutual interest for flood protection (Figure 1). At the same time, this cross-

border area is extremely prone to earthquakes due to its position in a seismically active area.

The categorization also includes levees along the 6 tributary rivers, for a total length of 51 km. It consists of determining the probability of failure of the levees, induced by the cascading effect of high river discharges due to partial failure of the HPP Brežice dam caused by an earthquake. Two earthquakes are considered, one occurring near Brežice, and the other near Zagreb, both with 2475-year return periods. As a starting assumption, we take it that both earthquakes will surely lead to a partial failure of the dam, which is defined through 5 scenarios that generate different hydrographs (Rak et al., 2023). Due to the relatively large area of interest, a simplified methodology is used to efficiently assess the stability of the levees.

3 METHODOLOGY

3.1 Cross-section selection

To categorize a large stretch of levees with limited resources, optimizing the number of considered cross-sections is necessary. To discretize the levees, they are divided into reaches, which ideally would not only be defined by similar geometrical, physical, and mechanical properties, but also by equal consequences (flooded area) in the case of failure of any of the sections along the reach. However, to simplify the selection of relevant sections in accordance with the available data, both sides of each tributary river's levees are deemed one reach (6 reaches), and the river Sava's levees are divided into reaches where breaks in their continuity occur on each side of the river, such as bridges, tributaries, etc., resulting in 7 reaches. One of the seven Sava reaches was further divided due to geometrical differences, which finally resulted in 14 reaches total. Each reach is defined by one section, whose positions are shown in Figure 1. For a division into reaches, however detailed it is, the safety of the whole reach is defined by its most critical section (the weakest link). The sections' geometries are assessed through LiDAR data shown in Figure 1, provided by courtesy of the International Sava River Basin Commission (ISRBC), as well as from the respective projects of the levees not covered by the LiDAR.

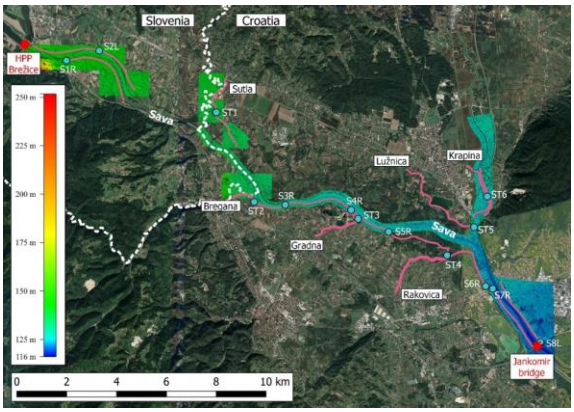

Figure 1. Situational view of the study area, with LiDAR.

3.2 Site characterization

The soil profiles and the geotechnical parameters are determined from existing borehole logs with SPTs, used to check the validity of the division into reaches, and supplementary CPTu data on the exact section locations. The necessary parameters for the analyses $(c, \varphi, \gamma, k, n)$ are thus determined separately for each selected cross-section. The foundation soil throughout the whole area is relatively similar, due to all the levees being constructed on the Sava river-terraces and floodplain, which consist predominantly of gravels and sands, with some clay content. Local differences are found mostly in thin, fine-grained, surface layers.

3.3 Conducted analyses

The analyses need to consider the previously described cascading effect. However, when an earthquake occurs, it will not only damage the dam but also the levees. To consider this effect, we would first need to quantify the earthquake-damage on the levees, before moving on to the stability during the water waves from the five scenarios. This type of damage includes soil liquefaction, subsidence, slope failures, longitudinal and perpendicular cracks, as seen in (Sasaki et al., 2012), and is unfeasible to quantify as an effect on the mechanical properties of soil. Thus, we need to introduce some assumptions and disregard all earthquake effects except slope failure. That way, we can compare the damage caused by earthquakes with the damage expected from high-water events. This is done in two stages. The first is analysing the slope stability during the earthquake, and if the levee fails at this stage, then further analyses are irrelevant, i.e., stability is determined by the earthquake alone. This means that the earthquake would give us a lower bound for the stability measure. If the levee holds (i.e., has satisfactory stability during the earthquake), then the oncoming water wave might bring it to failure. As we did not consider the effect of the damage on mechanical properties, the next stage consists of a simultaneous occurrence of the earthquake and the high-water, which is not realistic is this situation due to the source of the water wave but can give us a higher bound to the stability measure. Thus, the true stability measure should be found in between the two analysed cases. GeoStudio is used, with finite-element and limit equilibrium (Morgenstern-Price) methods for transient seepage and stability analyses, respectively.

An example of a model is shown in Figure 2, for the ST2 cross-section. The initial water table in each model is set to the corresponding hydrograph's starting elevation and is modelled as dependent of the water wave. After creating the models for each section, and assigning the five corresponding hydrographs, it is found that many hydrographs do not raise the water levels enough to even reach the levees' toes. In cases where the water does rise over the toe, the relatively short durations of the water waves (about 12 hours) are not enough to generate any meaningful seepage through the bodies. For this reason, only the water side stability is considered (during drawdown).

The analysed levees vary in sizes, and thus not all are vulnerable to slope failures of the same magnitude (depth, volume). To account for that, the slip surfaces are limited to a minimal depth which varies depending on the geometry of each section. For very small levees the limit is 0.5 m, for most sections the limit is 1 m, and for one section (S6R) the limit is set to 3 m.

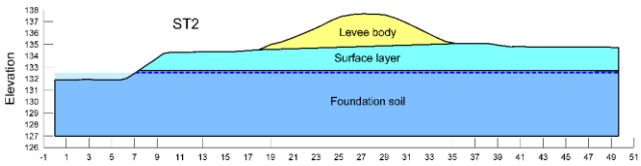

Figure 2. Example of a calculation model.

3.3.1 Probability of failure

The results of the described analyses are deterministic factors of safety (FS). To calculate the stability measure as the probability of failure (p_f), multiple LE analyses are required, and to optimize the required number of calculations on each section Rosenblueth's Point Estimate Method (PEM) (Christian and Baecher, 1999) is employed. It is assumed that the factors of safety are functions of only one random variable, the PGA, while all the others are deterministically known. In such case, this method requires only three analyses to estimate the distribution of the FS, assumed to be normal. The PGA follow a lognormal distribution, meaning that in the logarithmic space it is symmetric and approximately Gaussian. By evaluating the FS at the mean PGA and at two more values symmetrically spaced around the mean ($\mu_x \pm \sqrt{3}\sigma_x$), we can estimate the mean and standard deviation of the FS from its expected value raised to the power of m (Eq. 1).

$$E[Y^m] \approx P_-(y_-)^m + P\left(y_\mu\right)^m + P_+(y_+)^m \quad (1)$$

where y are the FS estimates, and P are weights at the corresponding points ($2/3$ for the mean, and $1/6$ for the rest). From this we estimate the mean and standard deviation as in Equations 2 and 3.

$$\mu \equiv E[Y] \quad (2)$$

$$\sigma \equiv \sqrt{E[Y^2] - (E[Y])^2} \quad (3)$$

Considering failures occur at FS equal to unity, the reliability index (β) can be calculated, and from it the p_f. This procedure is performed twice, first for the Zagreb earthquake, then for the Brežice earthquake.

4 RESULTS

The results are shown in Table 1. Along the scenarios 1-5 defined by 5 hydrographs resulting from different partial failure modes of the dam, an additional scenario designated 0 is introduced to indicate the earthquake acting on the levee alone. The blank cells show the scenarios where the water level did not rise over the levee toe. The scenarios which yield the highest increase in p_f are highlighted in red for each section. The increase might be interpreted as the maxium effect that the high water corresponding to the specific scenario has on increasing the probability of failure, after the slope being damaged by an earthquake, where the slope failure caused by the earthquake is further propagated by the water wave.

According to USACE (1997), the probability of slope failure deemed hazardous corresponds to 16%, which is far exceeded by many sections. However, two aspects are to note. First, the calculated probabilities relate to slope failure, and do not equal the probability of breaching, i.e., failure of the whole section. Thus, these calculated probabilities may be interpreted as total damage instead of failure. Global failure may be eventually achieved by propagation of the developed failure surface during future hazards, if not mended in the meantime. Second, in most cases the p_f values stem from the earthquake, with only a small percentage added due to the water wave, while only in a handful of cases the water wave has a major effect on increasing the p_f. This is because the analysed scenarios luckily generate such hydrographs that raise the water level not much over the toe, so even if complete failure would occur, the consequences are not expected to be great, other than the damaged levees. More so for the fact that failure is calculated during the receeding period of the water wave (RDD). Finally, a categorization is conducted based on the probabilities, shown in Figure 3. The reaches are divided into 5 categories, where the first two correspond to the values reported by USACE (1997) for „high" to „above average" behaviour ($p_f \leq 0.1\%$) and „above average" to „hazardous" behaviour ($p_f \leq 16\%$), while the rest all fall into the „hazardous"

category, but are still arbitrarily divided into three groups. Even if whole reaches are categorized by one section, this does not mean that whole levees will fail, due to the variations in local conditions.

Table 1. Probability of failure (%) for all analysed sections.

Z – Zagreb, B – Brežice

5 CONCLUSIONS

The categorization of levees in the cross-border area of Croatia and Slovenia, resulting from the presented methodology, shows very high probabilities of slope failure (or damage), which are mostly attributed to the effect of the earthquake, and not so much to the water discharge scenarios, with the exception for a handul of scenarios. This means that even if slope failures do occur at certain sections, they may not propagate much further to cause a breach, and if they do, the water level is mostly too low to cause substantial consequences. For the damaged levees to breach and cause consequential floods, future hazards should occur. Finallly, it is more likely that the Brežice earthquake, closer to the HPP, will cause the partial failure of the dam, in which case the reported probabilities are much more acceptable. If the Croatian earthquake does indeed not fail the dam, then the high p_f still remains, but with no fear of flooding.

ABSTRACT: LevelAMS is a cutting-edge asset management software designed for extensive geotechnical assets networks. This cloud-based platform integrates a comprehensive suite of services and features aimed at optimizing daily operations and resources for concessionaires. Its primary objectives include enhancing safety measures and minimizing geotechnical hazard risks. In addition to maintaining an inventory of assets, LevelAMS offers a user-friendly experience by enabling visual inspections, work scheduling, and comprehensive data storage for registered occurrences and accidents. The platform goes beyond basic functionalities by providing users with access to risk maps and a condition index.This study provides initial insights into the utilization of LevelAMS within the Brisa geotechnical network, encompassing 11,837 slopes (embankments and cuts) and 570 retaining walls of diverse types. The vast and heterogeneous nature of this network, spanning over 1,100 km, underscores the imperative for advanced asset management software and risk mitigation tools. Noteworthy advantages of LevelAMS include the ability to categorize asset conditions, identify urgent intervention needs, and closely monitor assets on a daily basis.

RÉSUMÉ: LevelAMS est un logiciel de gestion d'actifs de pointe conçu pour les vastes réseaux d'actifs géotechniques. Cette plateforme basée sur le cloud intègre une suite complète de services et de fonctionnalités visant à optimiser les opérations quotidiennes et les ressources des concessionnaires. Ses principaux objectifs consistent à améliorer les mesures de sécurité et à minimiser les risques géotechniques. En plus de maintenir un inventaire des actifs, LevelAMS offre une expérience conviviale en permettant des inspections visuelles, la planification des travaux et le stockage complet des données pour les occurrences et les accidents enregistrés. La plateforme va au-delà des fonctionnalités de base en offrant aux utilisateurs l'accès à des cartes de risques et à un indice de condition. Cette étude fournit des premières impressions sur l'utilisation de LevelAMS au sein du réseau géotechnique de Brisa, comprenant 11 837 pentes (remblais et coupes) et 570 murs de soutènement de différents types. La nature vaste et hétérogène de ce réseau, s'étendant sur plus de 1 100 km, souligne l'impératif d'un logiciel de gestion d'actifs avancé et d'outils de mitigation des risques. Les avantages notables de LevelAMS comprennent la possibilité de catégoriser les conditions des actifs, d'identifier les besoins d'interventions urgentes et de surveiller de près les actifs au quotidien.

Keywords: Geotechnical asset management; risk mitigation tools; asset's condition; Brisa's network.

1 INTRODUCTION

LevelAMS is a sophisticated geotechnical asset management software designed for daily use, providing decision-makers with optimized tools to effectively manage their assets. The management of linear assets, which often constitutes a substantial number, requires a standardized and streamlined process to mitigate geotechnical accidents resulting from asset degradation. In response to this need, levelAMS offers a comprehensive and integrated solution for the monitoring and management of such assets.

This work aims to provide a detailed overview of the asset management software, outlining its features, advantages, and its practical application within a real motorway network.

Brisa, a private motorway concession company based in Portugal, boasts an extensive network of over

1100 km of motorways. Despite the meticulous management of various assets, geotechnical assets are frequently lacking a fully assessed management process. Recognizing this gap, there is an imperative to digitize and integrate the management of these assets for enhanced efficiency and comprehensive oversight.

2 BRISA'S NETWORK

Brisa's Motorway Concession (BCR) is a private Portuguese company within the Brisa Group, tasked with overseeing the management of an extensive motorway network spanning over 1100 km. The network comprises 12 highways that traverse from the north to the south of Portugal, encompassing critical road axes in major cities such as Lisbon and Porto (Figure 1).

Within the scope of Brisa's geotechnical assets, there exists a total of 12,406 assets, categorized into slopes and retaining walls with 11,836 and 570 assets, respectively. Approximately 60% of the slopes consist of cuts, while the remaining 40% are embankments, varying in length from 6 m to 2200 m and reaching a maximum height of 50 m. Notably, around 10% of the slopes are protected with shotcrete.

In terms of retaining walls, they exhibit diverse characteristics, with a maximum length of 1400 m and a height of 24 m. The various types of retaining walls include gabion, cantilever, gravity walls, and a few reinforced soil or concrete walls, with or without anchors.

The lithology of the network is notably heterogeneous. In the northern region, slopes are predominantly composed of granite and schist, while the central region features mainly sandstones and limestones. In the southern region, the prevalent geological composition consists mostly of sands and limestones.

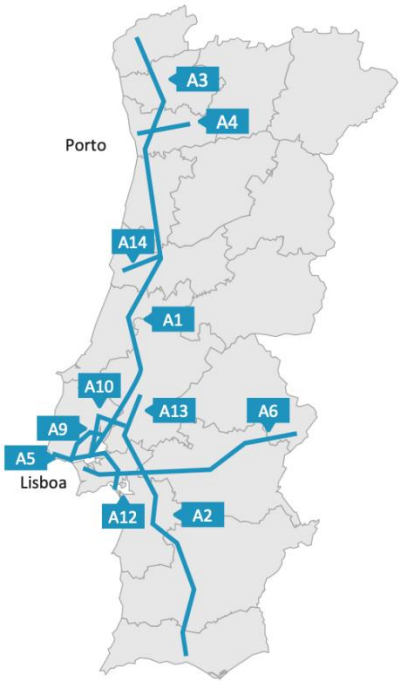

Figure 1. Brisa's motorway network.

3 GEOTECHNICAL ASSET MANAGEMENT

3.1 LevelAMS description

LevelAMS is a comprehensive software solution designed for the management and risk assessment of geotechnical assets, specifically focusing on retaining walls and slopes. This innovative solution encompasses a range of features, including a database with an inventory of geotechnical assets, mobile platforms for on-site inspections and incident recording, interactive risk maps utilizing a 5-level scale, and a customizable dashboard presenting network analytics for retaining walls and slopes.

This geotechnical asset management software effectively addresses the primary requirements of asset management, including inventory management, risk assessment, documentation of visual inspections, recording of occurrences, and the planning of conservation and maintenance efforts. The efficiency of this management is facilitated through a georeferenced database that houses both inventory information and data collected during visual inspections and incident recording. The standardization and centralization of these processes contribute to enhanced asset management effectiveness and improved cost control.

LevelAMS employs a qualitative and quantitative classification system for assets, utilizing a condition index developed as part of an academic research project (Pinheiro et al., 2015). This condition index,

informed by various factors directly and indirectly linked to asset stability and condition, enables the establishment of risk levels and identifies geotechnical assets requiring closer monitoring or conservation actions. The outcome is a more streamlined and economically efficient management approach for geotechnical assets.

It is worth noting that the system and its associated processes are flexible and can be tailored to the specific needs and realities of road management companies, accommodating diverse characteristics and complexities within their road networks.

3.2 LevelAMS main features

In addition to the previously highlighted features, the key functionalities of levelAMS are summarized in Table 1. These core functionalities comprehend a customizable dashboard, an extensive assets database, a module for warnings and inspections lists, risk maps with filter options based on risk levels, and a financial analysis module. The financial analysis module serves to compare the annual budget with the actual execution, providing valuable insights into budgetary performance. This comprehensive set of features ensures that levelAMS offers a versatile and robust solution for the efficient management and assessment of geotechnical assets.

Table 1. levelAMS main features description.

	Modulus	General Description
1	Dashboard	Analytical representation of the most relevant data of the assets network: number of assets by condition index, number and type of inspections, work and incidents carried out or registered, and the severest inspections results
2	Assets	Georeferenced inventory database, which contains all the information for each of the geotechnical assets (retaining walls and slopes)
3	Warnings	Alert system for all assets network that is triggered whenever: an incident is registered; a given instrument registers a value higher than the predefined threshold; and the condition index exceeds a predefined value
4	Risk maps	Depending on the condition index, assets are classified according to their level of risk on a qualitative scale (very low; low; moderate; high; very high) and quantitative ranging from 1 to 5. Risk maps are georeferenced using a colour scale to identify the associated asset risk
5	Continuous Monitoring	Optional functionality. Allows you to visualize through a map the assets that include continuous monitoring
6	Financial analysis	It allows an annual economic control of the network of assets, through the direct comparison of the budget value versus the real cost per road and concession for the different actions available
7	Reporting	Contains all the reports that summarizes all data and changes made about the asset or the assets network during a period of time to be selected
8	Inspections	Stores and show all inspections forms and details performed on the network

3.3 Asset condition index (CI)

The qualitative and quantitative classification of assets through a condition index was developed by Pinheiro et al. (2015) as part of a comprehensive scientific investigation conducted over several years in collaboration with the University of Minho. This condition index serves as a fundamental tool for characterizing and diagnosing the condition of retaining walls and slopes within the asset network.

During the operational phase, the utilization of this condition index proves invaluable in providing insights into the overall health of the assets network. The Condition Index (CI) allows users to classify slopes on a scale ranging from 1 to 5, where 1 indicates very good condition and 5 reflects a very poor condition. The index is based on various factors and parameters directly or indirectly linked to the stability of retaining walls and slopes. Each group of parameters is assigned different weights based on its relevance to slope and wall stability.

Importantly, these weights are adaptable to the specific characteristics and geographical nuances of road networks managed by concessionaires. Users have the flexibility to adjust the weights assigned to each factor and the parameters of the CI for each type of asset. Such customization enables a tailored approach, allowing for the incorporation of diverse network characteristics. Any adjustments made by the user will subsequently impact the calculation of the CI. For a detailed understanding of the CI calculation methodology, please refer to the publication by Pinheiro et al. (2015).

3.4 Risk Map

Based on the outcomes of the condition index, assets undergo classification according to their risk level on both a qualitative (very low, low, moderate, high, very high) and a quantitative scale ranging from 1 to 5. This dual-scale approach enables the identification of assets at the highest risk, pinpointing those requiring urgent interventions and specifying the type of necessary action.

Moreover, it facilitates the examination of the proposed monitoring plan, as outlined in Table 2, to be

implemented strategically in response to the assessed risk levels.

Table 2. Recommendation and indications to be adopted according to the risk level of the geotechnical asset.

Risk Levels	Inspections	Recommended actions	Temporal Space
Low	Routine inspections up to every 2 years Principal Inspections up to every 8 years	Only needs preventive or current maintenance actions	No relevant actions except for current maintenance
Moderate	Routine inspections up to every 2 years Principal Inspections up to every 4 years	Requires current maintenance actions and, possibly, conservation actions with the need for a design project	Medium Term Intervention
High	Routine inspections up to every 1 year Principal Inspections up to every 2 years	Dedicates a need for rehabilitation or replacement actions. However, complementary diagnostic actions (e.g., monitoring) may be necessary to mitigate associated risks	Short to Medium Term Intervention
Very high	Principal Inspections up to every 1 year	Requires immediate implementation of additional monitoring/diagnostic measures and conditioning for continued use	Short Term Intervention Immediate Mitigating Measures and Conditioning to Circulation

3.5 Degradation models

Utilizing the evolution of the Condition Index (CI) over time enables the visualization of the degradation curve for each asset, as can be seen in the example shown in Figure 2-a)). With real-time updates for every new entry in the software, users can observe the dynamic changes in the CI, providing insights into the asset's condition evolution.

Given that the CI is categorized into groups, users gain the ability to analyze the performance of each group and its contribution to the overall condition of the asset. This categorization facilitates a detailed examination of which specific aspects may be underperforming, offering valuable information to guide interventions and improve the overall CI of the asset. In the example shown in Figure 2-b), environmental conditions, visual inspections results and geological characteristics are the ones contributing to a poorer CI.

In essence, this feature empowers users with actionable insights, guiding them on where interventions are most needed to enhance the condition of the asset.

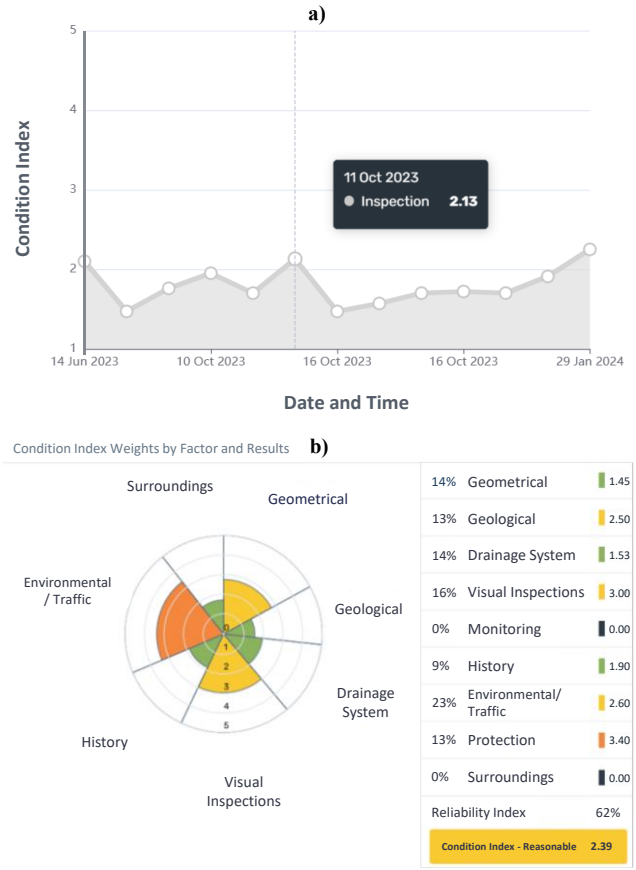

Figure 2. Degradation model graphic (a)) and details of group classification (b)).

4 RESULTS

The entire network of geotechnical assets has been successfully integrated into levelAMS, resulting in the classification of their condition into two classes: reasonable (8,396) and good (4,010), as illustrated in Figure 3. Despite the software 5 classes classification, most of the uploaded information are geometrical and traffic related. Moreover, environmental information remains the same for each asset. Therefore, the 5 classes are not fully represented by this initial set of assets. Regarding the parameters group that presents a relevant weight for the CI, namely geological and visual inspections there are no information uploaded. Although, it is important to mention that as more visual inspection are done, incidents and monitoring are registered, the assets group should obtain a more unfavourable class, mainly 4 or even 5.

The liability index, based on the amount of field information available, ranges from 48% to 66%. Notably, the reliability of the Condition Index (CI) increases with more comprehensive information.

Consequently, certain factors such as details about the surroundings, structural specifics, or geological data remain empty due to insufficient information. It is important to highlight that due to the lack of information, the amount of data imported for each asset is almost the same, therefore, the liability index remain quite stable. As more actions are done on levelAMS, meaning works or inspections added, this index should present a higher variation. According to maintenance actions, levelAMS provides a summary of the visual inspection helping decision makers to correct any pathologies observed. Since CI evaluates several parameters additional to visual inspections, the classes variation is reduced and controlled.

Following the initial campaign of inspections, some of the assets introduced in levelAMS have undergone assessment and monitoring. Critical assets that are instrumented can benefit from continuous monitoring using levelAMS, as depicted in Figure 4. Using the icon and colour scale it is possible to quickly identify the status of the monitoring system and understand if an alert or alarm threshold is reached (yellow and red, respectively). The software provides users with a user-friendly interface, offering real-time status updates of the assets and serving as a graphical display for the installed sensors. Additionally, warnings can be triggered and displayed if an asset surpasses a specified CI threshold.

Figure 3. 5-classes distribution of Brisa's network of geotechnical assets.

Figure 4. Critical asset network of sensors using icons (TM-tiltmeters, I-Inclinometers, P-Piezometers, O-Other) and colours (Green-sensors are OK, Red-alarm threshold and Gray-no connection).

5 CONCLUSIONS

This study provides initial insights into the newly developed geotechnical asset management software, levelAMS, implemented within Brisa's network. In addition to facilitating inventory management, the software enables the classification of assets based on their condition, utilizing the Condition Index developed by Pinheiro et al. (2015).

Centralizing all asset information within a single platform and enabling seamless processes for inspections, work registrations, and incident recording stand out as primary advantages of the software. To further comprehend the full spectrum of benefits, additional inspection campaigns are warranted. The platform's potential for risk assessment emerges as a significant advantage, particularly for the management of extensive asset networks.

This comprehensive mapping capability holds the promise of fostering a more strategic approach to short and long-term intervention planning. It also offers the ability to analyse the individual or macro-level condition evolution of slopes, thereby contributing to more informed and rational decision-making processes in geotechnical asset management.

ACKNOWLEDGEMENTS

The authors thank the Brisa Concessão Rodoviária for the provided information. The levelAMS results used on this work were obtained from levelAMS software, a cloud-based platform from level company.

ABSTRACT: Distributed fibre optic sensing (DFOS) is more and more applicable in civil and geotechnical engineering to monitor the structural performance during construction and operation. The main advantage of this approach is the ability to measure selected physical quantities continuously over the entire length of the sensor – from few millimetres to hundreds of kilometres. This makes DFOS particularly useful for monitoring linear structures such as tunnels, roads, highways, bridges, pipelines, dams or embankments. The article describes the principles of this technique, including its main advantages and limitations, and then focuses on practical applications in several road embankments, including one of the highest in Poland. Depending on the project requirements, the type of the DFOS sensor and the configuration of the whole system, distributed strains, displacements (settlements) and temperatures can be extracted from measurements and analysed in detail. The article summarises a number of good practices and lessons learned on practical issues like selection of the sensor and optical device, installation method, thermal compensation, post-processing algorithms and data visualisation to facilitate its engineering interpretation.

RÉSUMÉ: La détection distribuée par fibre optique (DFOS) est de plus en plus utilisée en génie civil et géotechnique pour surveiller les performances structurelles pendant la construction et l'exploitation. Le principal avantage de cette approche est la possibilité de mesurer des quantités physiques sélectionnées en continu sur toute la longueur du capteur - de quelques millimètres à des centaines de kilomètres. La DFOS est donc particulièrement utile pour la surveillance des structures linéaires telles que les tunnels, les routes, les autoroutes, les ponts, les pipelines, les barrages ou les remblais. L'article décrit les principes de cette technique, y compris ses principaux avantages et limites, puis se concentre sur des applications pratiques dans plusieurs remblais routiers, dont l'un des plus hauts de Pologne. En fonction des exigences du projet, du type de capteur DFOS et de la configuration de l'ensemble du système, les déformations réparties, les déplacements (tassements) et les températures peuvent être extraits des mesures et analysés en détail. L'article résume un certain nombre de bonnes pratiques et d'enseignements tirés sur des questions pratiques telles que la sélection du capteur et du dispositif optique, la méthode d'installation, la compensation thermique, les algorithmes de post-traitement et la visualisation des données afin de faciliter leur interprétation technique.

Keywords: Distributed fibre optic sensing; earth embankment; strain; temperature; settlement.

1 INTRODUCTION

Distributed fibre optic sensing (DFOS) is finding increasing applications in civil (Bado and Casas, 2021) and geotechnical (Shi et al., 2021) engineering. The characteristic feature of that measurement technology and, at the same time, its main advantage, the ability to measure different physical quantities continuously over the entire length of the sensor. These quantities include strain, stress, crack, temperature displacement (Piątek et al., 2023) or vibration (Zhu et al., 2022). Distributed sensing capabilities can directly address one of the main goals and challenges of structural health monitoring (SHM), namely direct local event (or damage) detection. Local events along the measurement path can include, among other things, cracks in concrete, (Howiacki, 2022), leakages in pipelines (Bednarz et al., 2021), sinkholes and settlements in geotechnical structures (Bednarski et

al., 2021) or different types of third-party intrusions (Tanimola and Hill, 2009). The distance range can be from a few millimetres to hundreds of kilometres, making DFOS particularly useful for monitoring linear structures (Popielski et al., 2021) such as tunnels, roads, highways, bridges, pipelines, dams or embankments. However, it must be stressed that this is not a plug-and-play solution. The configuration of the system and the measurement parameters should always be tailored to the expectations and requirements of a particular project. The remainder of the article briefly describes the general assumptions and discusses three practical examples of geotechnical embankment applications. Each of the selected case studies concerns the DFOS-based measurement of different physical quantities: strains, temperatures and settlements.

2 SYSTEM CONFIGURATION

In general terms, the DFOS-based system consists of the sensor and the interrogator unit (optical data logger) – Figure 1. Usually, interrogators utilise three main physical phenomena, which are Rayleigh (Palmieri et al., 2022), Brillouin (Bastianini et al., 2019) and Raman (Li and Zhang, 2022) scattering. The first two enable measuring strains (which are the sum of mechanical and thermal effects), while Raman approach is sensitive only to thermal changes. It can be used to compensate the strain results or as an independent diagnostics solution to detect events related to temperature change (e.g. fires or leakages).

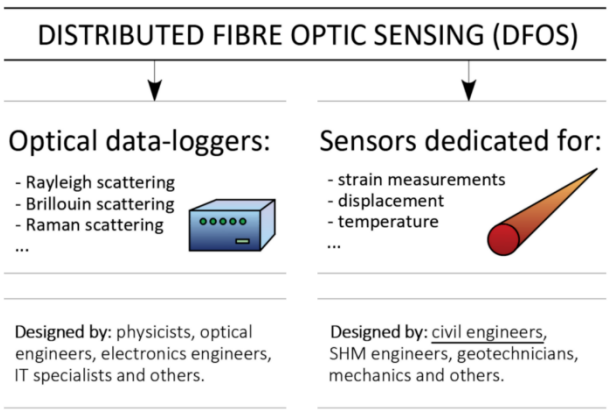

Figure 1. Design of DFOS-based measurement system.

When designing the system, interrogator parameters such as distance range, special resolution, accuracy, sampling frequency or acquisition time should be considered. Although they have a significant impact on the quality of the measurements, the sensors remain the key component of the overall system. Firstly, their long-term interaction with the structure must allow correct interpretation of the results. Secondly, if a data logger fails, it is technically easy to replace. However, this is not possible with long sensors that are permanently integrated into the structure (e.g. embedded in an earth embankment).

The design of the sensor should provide the best possible strain transfer from the structure to the internal optical fibre, which is always the main sensing element. Despite the fact that many commercial solutions are sold for the same purpose (strain measurement), the results obtained may be significantly different (Howiacki et al., 2023). The research shows, that the best performance in Rayleigh-based detection of local events is shown by the monolithic DFOS sensors, in which optical fibre is integrated into composite core without intermediate layers – Figure 2.

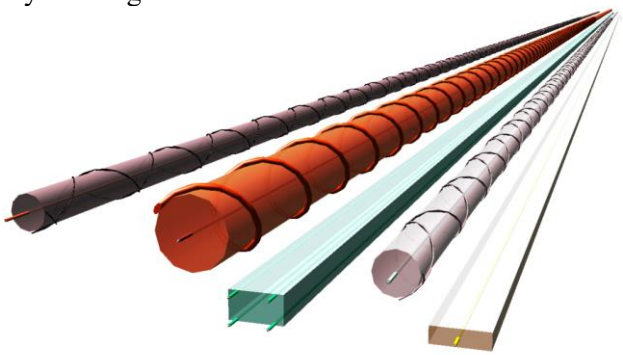

Figure 2. Visualisation of different monolithic sensors.

Although the general idea of monolithic sensors remains the same, some of their parameters can be adapted to the application (Bednarski et al., 2022). These include the shape and size of the cross-section, the stiffness, the number of fibres or the presence of an external braid. For example, in geotechnical applications, high stiffness and robustness are of great importance, whereas for laboratory research, softer and more flexible sensors are desired.

In addition to the interrogators and sensors, other aspects should be considered when designing and creating an efficient DFOS-based measurement system. The most important of these are the installation methods, the thermal compensation approach, the acquisition system, the post-processing algorithms, the data visualisation methods, the interpretation and, finally, the procedures to be followed if an anomaly is detected in the operation of a structure.

In the practical examples of installations and experiences described below, distributed monolithic sensors were used for strain (Nerve-Sensors - EpsilonRebar, 2023) and displacement (Nerve-Sensors - 3DSensor, 2023) measurements.

3 CASE 1 – STRAIN SENSING

The first example concerns an innovative earth embankment that was reinforced at its base with composite rebars. Some of these have been replaced by rigid monolithic sensors, which in this particular case have a dual function in the structure: both sensing and reinforcing.

Figure 3. Monolithic sensor delivered on site in coil.

The sensors were delivered to site in coils (Figure 3) and then stabilised in their intended positions. It should be noted that the installation conditions within the geotechnical structure are very often more challenging for the sensors to survive than those during normal operation - Figure 4. The sensor must therefore be sufficiently robust.

Figure 4. Challenging field conditions during embankment construction.

Figure 5 shows the arrangement of all the DFOS sensors installed within the mesh of the composite reinforcement. There are 6 longitudinal sections (along the embankment axis) of 20 m each and 8 transverse sections (in the lower and upper aggregate layers) of 62 m each. Their exact positions were documented with a geodetic survey immediately after installation.

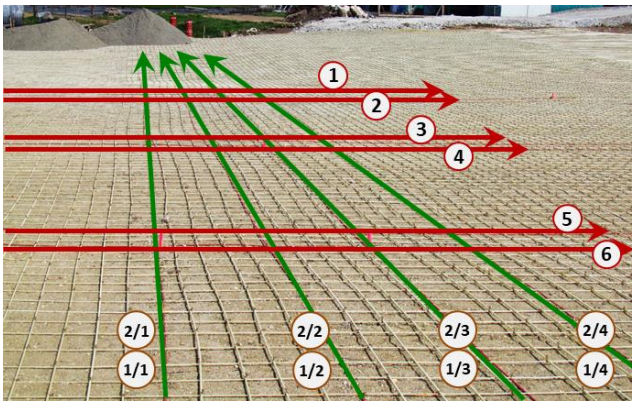

Figure 5. View of the DFOS strain sensors arrangement.

The distributed measurements were carried out as planned during the construction of the subsequent soil layers and after the road embankment had been commissioned. One of the objectives was to estimate strain-based stresses in the reinforcement to assess its effectiveness and compare it with theoretical predictions. Figure 6 shows selected strain profiles measured by one of the longitudinal sensors at subsequent construction stages. The profiles are not uniform along the length and local extremes (stress concentrations) can be clearly observed. These are caused by the uneven substrate and the random stiffness of the heterogeneous aggregate layer.

The strain results were compensated for the thermal changes, which were measured by both a Raman-based device and spot thermistors.

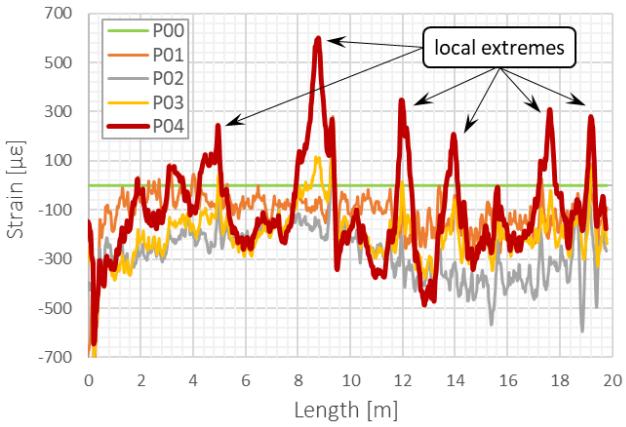

Figure 6. Example DFOS strain results from longitudinal section in subsequent sessions.

It should be noted that the costs of DFOS-based monolithic sensors are negligible compared to the cost of the structure. However, the sensors become an integral part of the earth embankment and can be read at any time. The comprehensive strain results can be valuable during the warranty period and also for long-term assessment of structural condition and health. The durability of the composite sensors is comparable to the lifetime of the structure itself.

4 CASE 2 – TEMPERATURE SENSING

The second case refers to one of the highest road embankments in Poland, exceeding 30 m in some locations – Figure 7.

Figure 7. The view of the road embankment in question during construction.

It was therefore essential to control its deformation during construction in order to ensure efficient work and the earliest possible commissioning. In order to achieve this goal, it was decided to install vertical inclinometers as well as horizontal measurement lines at the base of the embankment, equipped with the following techniques: horizontal inclinometers, hydraulic profilers to measure vertical displacements and, finally, monolithic DFOS-based sensors for temperature distribution control. A typical cross section of the embankment equipped with selected measurement solutions is shown in Figure 8.

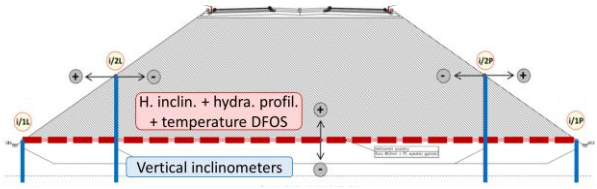

Figure 8. Typical cross-section of the embankment equipped with selected measurement solutions.

The temperature data was used, among other things, to compensate for the readings from two other settlement measurement techniques. All solutions were installed within the HDPE pipe filled with cement-bentonite injection, as shown in the spatial visualisation in Figure 9. The reason for this was that the installation was carried out when some of the soil layers had already been built and compacted. Special cross boreholes were made to allow the installation of the measurement system.

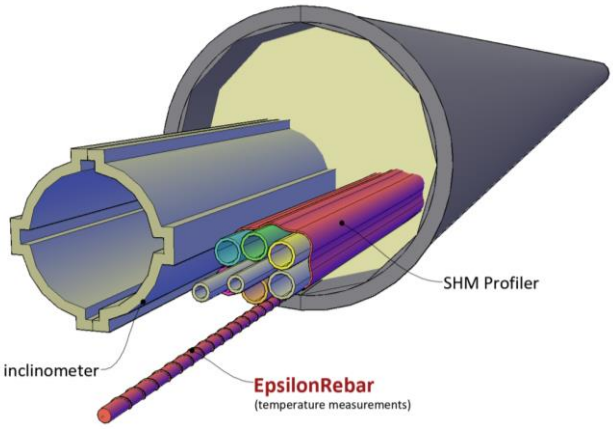

Figure 9. Spatial visualisation of horizontal inclinometer casing, hydraulic profiler and DFOS temperature sensor.

Figure 10 shows example temperature profiles recorded in 20 subsequent readings during one of the measurement sessions. The temperature gradients over length are strictly related to the embankment geometry and they reach more than 10°C along the first 15 m on both sides (influence of slopes). Such large differences can affect the results of settlement measurement techniques and require compensation for correct physical interpretation.

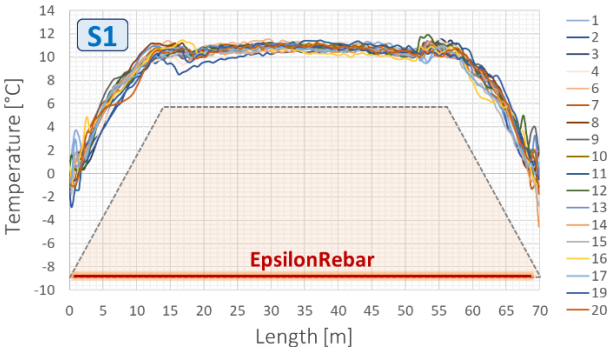

Figure 10. Example temperature distributions in subsequent measurements in reference to the embankment geometry.

Besides the geometry itself, the temperature distribution is also influenced by the current weather conditions, the solar exposure of the slopes and the location of the measurement sections – Figure 11.

Figure 11. Selected locations of measurement cross-sections (S1 – S5) within the embankment - top view.

5 CASE 3 – SETTLEMENT SENSING

The last example focuses on the road earth embankment built over the substrate strenghtened with Controlled Modulus Columns (CMC), as shown in spatial visualisation in Figure 12.

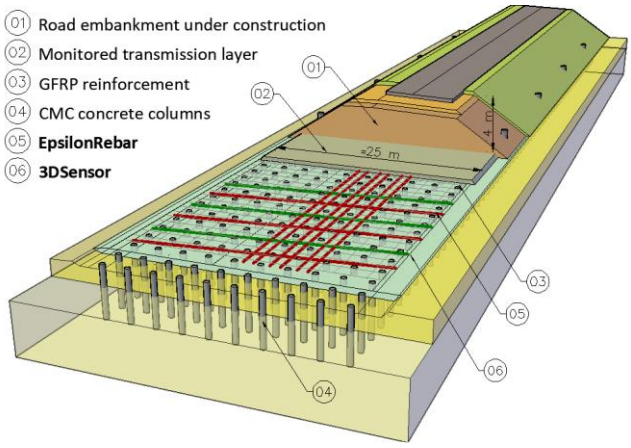

Figure 12. Spatial visualization of the embankment over the substrate strengthened with concrete columns.

Distributed strain and displacement sensors were installed within the transmission layer, both in longitudinal and transverse direction (Figure 13), as a part of GFRP reinforcement mesh. It is worth noting that the transverse sections are not perfectly perpendicular and run through areas directly above the column range as well as between the column ranges.

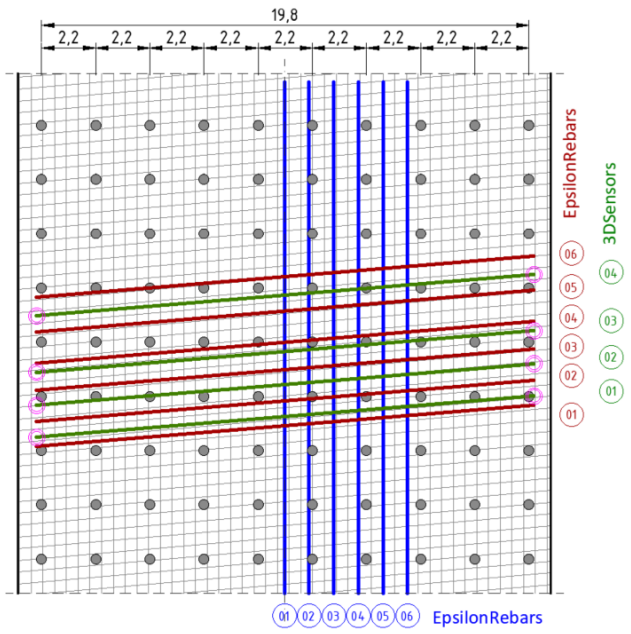

Figure 13. The arrangement of GFRP reinforcement and optical sensors within transmission layer.

The sensors were placed on the ground during construction and then backfilled with successive layers of soil. The installation stage is shown in Figure 14.

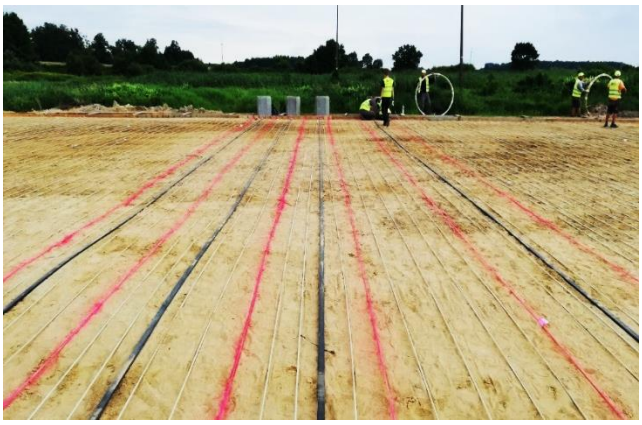

Figure 14. Installation of EpsilonRebars and 3DSensors at the base of the embankment.

The readings were taken during the construction of the embankment according to the planned schedule. An example of the vertical displacements (settlements) of 3DSensor no. 2 is shown in Figure 15. The area between the columns, where the graphs are smooth, and the area immediately above the columns with their local influences on the displacement profiles, can be clearly observed. The boundary conditions (start and end displacement values) were measured by geodetic survey. The 3DSensor internal design allows self-compensation due to the temperature changes in time and length (Bednarski et al., 2021).

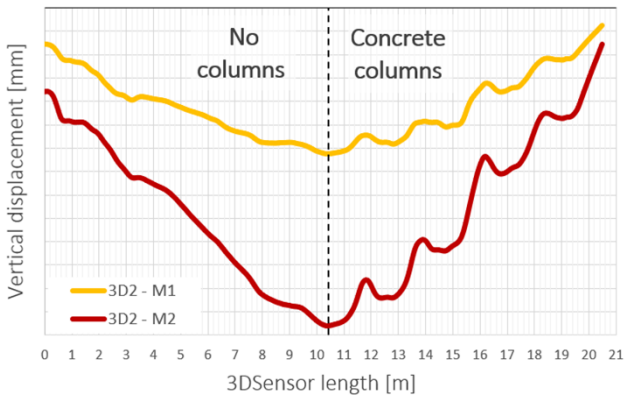

Figure 15. DFOS settlement results from 3DSensor no. 2 in two subsequent measurement sessions M1 and M2.

6 CONCLUSION

The case studies briefly described in the article confirm the versatility of the DFOS technique in monitoring various physical quantities such as strain, temperature or displacement. The ability to acquire distributed profiles makes it suitable and increasingly used for monitoring civil engineering and geotechnical structures. Key challenges include automation and the development of data processing and analysis software.

FUNDING

Selected works presented in this paper were supported by the projects "*Innovative fibre optic sensor for measuring strain and temperature*" (POIR.01.01.01-00-1154/19) and "*Development of the new fibre optic sensor allowing for the determination of the vertical and horizontal displacements of the studied objects at the distances of up to 120 km*" (POIR. 01.01.01-00-0550/15) funded by the National Centre for Research and Development within the Intelligent Development Operational Program 2014-2020. Both projects were realised by SHM System, Krakow, Poland (SHM System, n.d.).

ABSTRACT: Tailing storage facilities are complex geotechnical structures to safely store the waste products resulting from mining processes. Proper knowledge of the hydro-mechanical behaviour of tailing wastes under unsaturated conditions allows for assessing reliable stability analysis of tailing dams. This research provides the preliminary results of an experimental campaign carried out on silty tailings to analyze their pre-shearing state of stress. The experiment was performed on statically compacted and remoulded samples through oedometric tests under saturated and unsaturated conditions. The dependency of the 1d-Normal Compression Line (1d-NCL) on suction and sample preparation technique is investigated, with the suction level evaluated based on the water retention tests performed on the same soil. The compressibility and the occurrence of a transitional behaviour depending on the suction level and preparation method were finally analyzed based on the Basic Barcelona Model.

RÉSUMÉ: Les installations de stockage des terrains résidus sont des structures géotechniques complexes destinées à stocker en toute sécurité les déchets résultant des processus d'exploitation minière. Une bonne connaissance du comportement hydromécanique des résidus dans des conditions non saturées permet d'évaluer une analyse fiable de la stabilité des digues à résidus. Cette recherche fournit les résultats préliminaires d'une campagne expérimentale menée sur des résidus limoneux afin d'analyser leur état de contrainte avant cisaillement. Les essais œdométriques ont été réalisés sur des échantillons statiquement compactés et reconstitués dans des conditions saturées et non saturées. La dépendance de la 1d-NCL par rapport à la succion et à la technique de préparation de l'échantillon est étudiée, le niveau de succion étant évalué sur la base des tests de rétention d'eau effectués sur le même sol. La compressibilité et l'apparition d'un comportement transitoire en fonction du niveau de succion et de la méthode de préparation ont été analysées sur la base du Basic Barcelona Model.

Keywords: Unsaturated soil; oedometric test; 1d-NCL; compressibility; water retention curve.

1 INTRODUCTION

Tailing storage facilities ('TSF') are complex disposal systems mainly consisting of an embankment and a basin. They contain the waste products of the mining industry ('tailings') composed of a slurry mixture made of soil, rock and water that remain after the mineral values have been extracted from the ore. Owing to the complexity and high rate of failure of TSF, a deep knowledge of tailings response under unsaturated conditions represents an essential tool for reliably assessing the stability of tailing storage facilities (Bella and Musso 2024; Bella *et al*., 2023; Girardi and Bella, 2023; Deng *et al.,* 2020; Tarantino and Mountassir 2013; Zanardin *et al*., 2009). This research provides the preliminary results of an experimental campaign aimed at investigating the mechanical behaviour of the Stava silty tailings collected from the lower portion of the upper embankment which remained in place after the collapse occurred in 1985 in Stava, Italy. The pre-shearing state of stress under nearly saturated and unsaturated conditions is investigated by performing oedometric and water retention tests. The effects of the sample preparation method and suction level on the compressibility and 1d-NCL of Stava tailings are investigated. The outcomes are then compared to those obtained by the same soil tested under fully saturated conditions.

2 MATERIAL CHARACTERIZATION

The experimental campaign was carried out at the soil testing laboratory of the University of Applied Sciences and Arts of Southern Switzerland (SUPSI)

and Politecnico di Torino. Silty samples passing through a 0.074 mm sieve were tested since they represent the finer tailings fraction deposited into Stava basins (Bella *et al.,* 2024). According to Carrera (2008), liquid limit, plastic limit, and plasticity index, are w_L=27.4%, w_P=18.0%, PI=9.4%, while the specific gravity and hydraulic conductivity are G_S=2.83 and k=10^{-7} m/s. X-ray diffraction analysis showed that Stava tailings were predominantly made of quartz, with a relevant amount of calcite and fluorite (Bella, 2017; Bella and Musso 2023).

3 EXPERIMENTAL TECHNIQUES AND TESTING APPARATUS

3.1 Oedometric tests

Oedometric tests were performed to investigate the dependency of the compressibility on the degree of saturation (and in turn the matric suction level) of the Stava tailings. Specimens 50mm diameter, 20 mm in height are prepared by imposing different void ratio, degrees of saturation, or preparation methods:

- the static compaction outside the oedometer cell (SC) is the procedure adopted to create unsaturated samples (Sr≤90%) and nearly saturated samples in the current research (90%<Sr<100%). The same technique was adopted by previous studies performed by Carrera (2008) on Stava silty samples under fully saturated conditions (Sr=100%). All samples were prepared by hand-mixing a certain amount of dry soil with the required amount of demineralized, de-aired water to obtain the desired initial water content. The mixture was then put into a hermetic cylindrical mold and statically compacted by gradually applying an axial force until the desired volume was reached.
- The remoulded specimen (RS) edo_0.76-100 was prepared inside the oedometer cell by mixing a known quantity of dry soil with a certain amount of demineralized, de-aired water to obtain a slurry sample (water content equal to the liquid limit). Back analysis then allowed to evaluate the initial degree of saturation and void ratio of the sample.

All tests were carried out by using a conventional oedometer cell (Figure 1). Constant water content conditions were imposed for testing the unsaturated samples, indeed a mass-based analysis performed at the end of each test showed no water content variations during the entire test. An axial loading sequence was imposed, followed by an unloading path. The axial displacements experienced by the samples were measured by using an external linear variable differential transducer (LVDT). Table 1 lists the RS sample and the SC tested in the current research together with the initial state of the SC-saturated samples tested by Carrera (2008).

Table 1. Initial state: initial void ratio, degree of saturation, saturation state, sample preparation method.

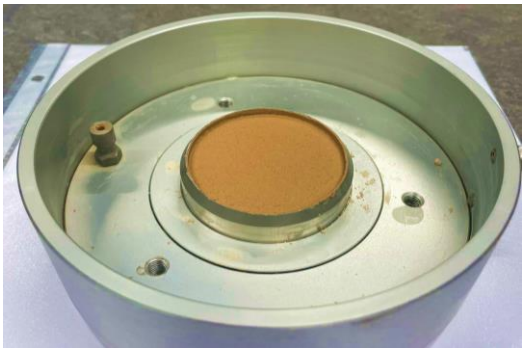
a)



b)

Figure 1. a) Conventional oedometer apparatus; b) detail of the sample inside the oedometer cell.

3.2 Water retention tests

The suction level reached by the samples during the loading phase was estimated by carrying out water retention tests based both on techniques where the suction was imposed and the water content was

measured ('axis translation technique' ATT, 'vapor equilibrium technique' VET), and on tests where the water content was imposed and the suction was measured ('dew point technique' DPT). The axis translation technique was applied into a suction-controlled oedometer cell on samples 50mm diameter and 20mm height (Figure 2). The vapor equilibrium and dew point measurements were performed, respectively, into a relative humidity-controlled sealed box and by using a chilled-mirror psychrometer on samples 20mm diameter, 10mm height. More details are provided in Bella, 2021.

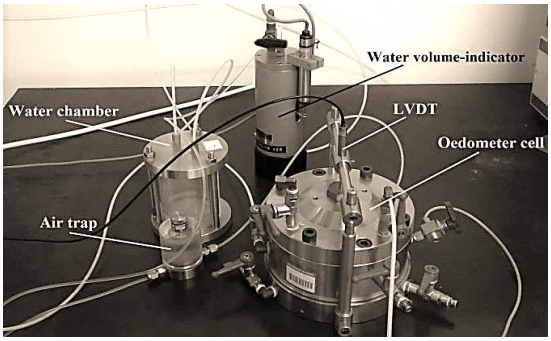


Figure 2. Suction-controlled oedometric cell (Bella, 2021).

4 EXPERIMENTAL RESULTS AND INTERPRETATION

4.1 Estimation of the matric suction levels

The experimental results obtained by the water retention tests on a silty sample (e_0=0.60) are provided on the (e_w–s) plane in Figure 3, where the water ratio is evaluated as e_w=Sr·e. The green squares represent the outcomes given by applying the axis translation technique; blue circles are the results obtained from the vapor equilibrium technique, while red triangles stand for the experimental points obtained by the dew-point technique. To account for the variation of the void ratio experienced during the oedometric loading phase, the experimental points were fitted by applying the model proposed by Gallipoli *et al.* (2003):

$$Sr = \frac{1}{\left(1+\left[\Phi(v-1)\psi s\right]^{n}\right)^{m}} \qquad (1)$$

where v is the specific volume, and dimensionless parameters n, m, ψ, and Φ (kPa^{-1}) are soil constants to be calibrated (Tab.2).

Table 2. List of the Gallipoli retention parameters.

Main drying branch				Main wetting branch			
n (-)	**m (-)**	**Φ (1/kPa)**	**Ψ (-)**	**n (-)**	**m (-)**	**Φ (1/kPa)**	**Ψ (-)**
1.67	0.40	0.28	5.32	1.50	0.33	5.40	7.81

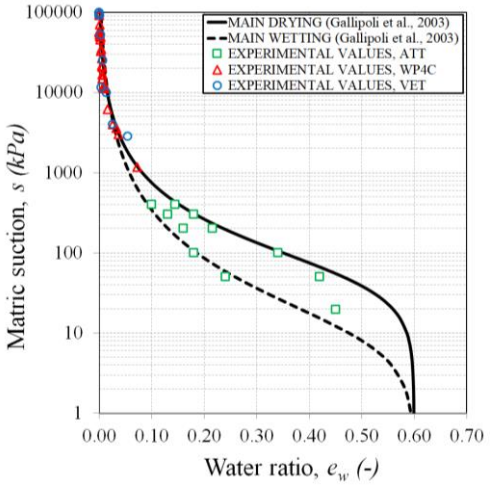

Figure 3. Experimental points and fitting curve for the three applied techniques.

Then, knowledge of the water ratio allowed to define a vertical hydraulic path (Figure 4, red arrow) because of the constant water content conditions. The hydraulic path crosses the main wetting branches of the WRC evaluated at void ratio e_i and e_f reached by the compression curve (1d-NCL), so the suction level can be obtained as the average value. A suction level equal to 13kPa was estimated for unsaturated sample edo_0.650-066 as shown in the figure below.

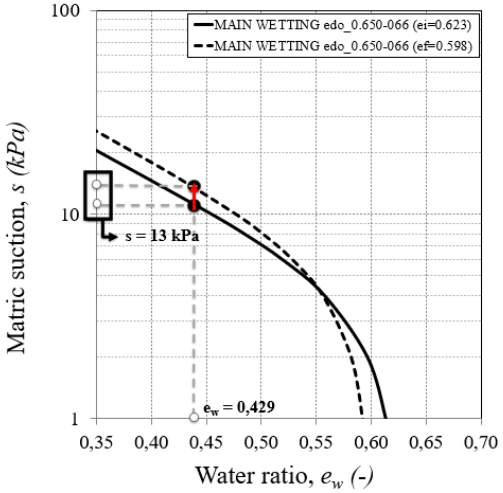

Figure 4. Evaluation of the matric suction level for sample edo_0.650-066.

The same procedure allowed the estimation of the matric suction level reached by all unsaturated samples (Tab.3). It is worth noting that the Stava silt is an inorganic soil with low plasticity, so the osmotic suction represents a small amount of the total suction. Therefore, the total suction can be assumed equal to the matric suction.

4.2 Pre-shearing state of stress of Stava tailings

The oedometric tests performed by Carrera on SC saturated samples (black lines) and the test carried out on the RS saturated sample (red line) are given in Figure 5a. All the curves converge toward a unique 1d-NCL regardless of the preparation method (compressibility index λ approx. 0.104). According to Carrera (2008), the uniqueness of the 1d-NCL of Stava silty tailings under fully saturated conditions seems to confirm the absence of a "transitional behaviour". On the other hand, the saturation state of the sample seems to influence the behaviour of Stava tailings. Indeed, oedometric tests performed on fully saturated samples (grey lines) and tests carried out on SC nearly saturated samples (blue lines) are given in Figure 5b. A little transitional behaviour is observed for the latter ones with the 1d-NCL moving up with initial void ratio and maintaining the same slope because of similar suction levels reached during the loading phase.

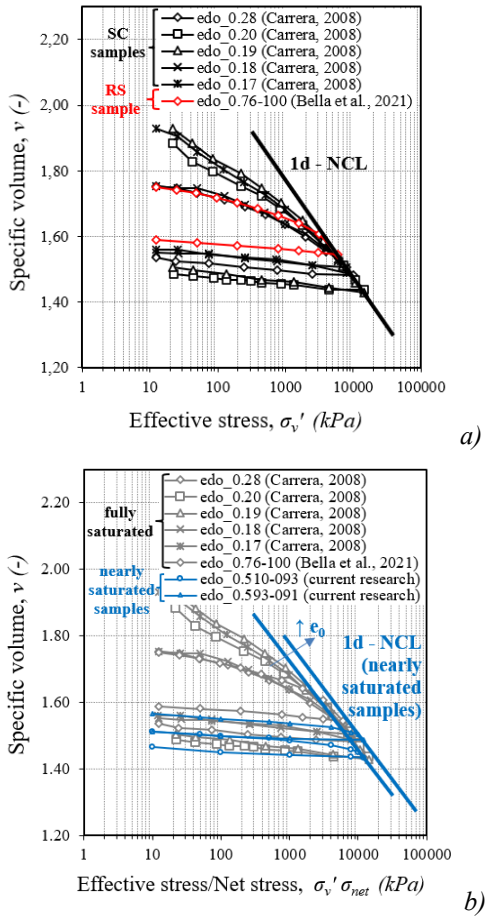

Figure 5. Compression curves and 1d-NCL: a) RS fully saturated sample and SC fully saturated samples; b) fully saturated samples and nearly saturated samples.

Some research has shown that transitional behaviour can be expected also for tailings (Al-Tarhouni *et al.*, 2011; Coop, 2015), but there is still some debate about whether the initial fabric has a relevant effect on the behaviour of soils (Li *et al.*, 2019). The normal compression lines for different suction levels are given in Figure 6. It is worth noting that the suction levels, estimated by the WRCs, are derived from the combined effect of the water content and the void ratio of the samples during the oedometric compression. Indeed, the retention properties of Stava tailings were found to largely depend on the void ratio (Bella and Musso 2024; Bella, 2021). For this reason, the denser sample edo_0.528-078 shows a suction level higher than those of looser samples edo_0.568-074 and edo_0.650-066. According to Alonso *et al.* (1990), a reduction of the compressibility index can be observed as the matric suction increased and this is due to the increase of the soil stiffness with the degree of saturation reduction. Indeed, the higher λ=0.059 was obtained for the SC sample edo_0.650-066 (green line) associated with the lower suction values s=13kPa. On the other hand, the lower compressibility index λ=0.052 was obtained for the SC sample edo_0.528-078 (red line) associated with the higher suction values s=35kPa. A summary of the suction level reached by Stava samples is provided in Table 3.

Table 3. List of matric suction level and compressibility index of Stava silty tailings.

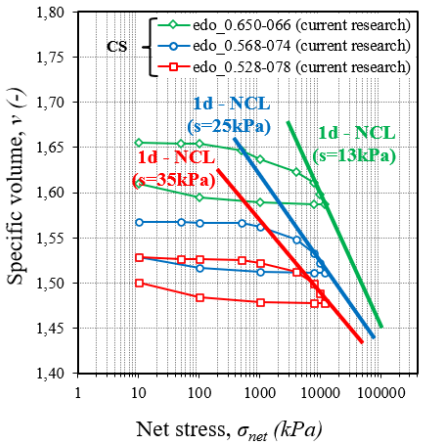

Figure 6. Influence of the suction level on the 1d-NCL.

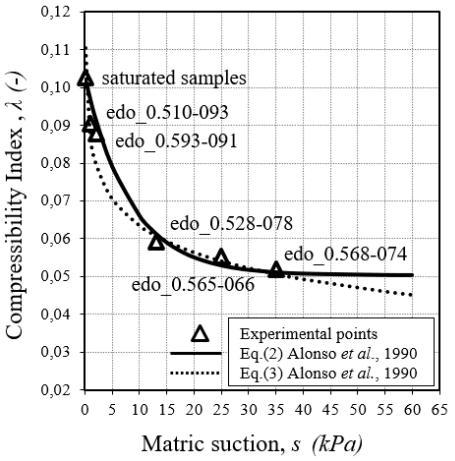
The Basic Barcelona Model (BBM) is then adopted to interpret the experimental data, so the compression index with suction is estimated:

$$\lambda(s) = \lambda(0)\cdot\left[(1-r)e^{-\beta s} + r\right] \qquad (2)$$

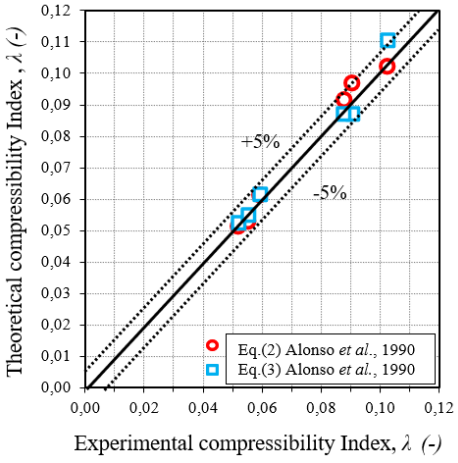
where $\lambda(0)$ is the compressibility index under fully saturated conditions, s is the matric suction, while r and β are model parameters calibrated based on the experimental data (r = 0.49, β = 0.12). As shown by the solid line in Figure 7a, an increase in stiffness (decrease of the compressibility index) is observed with a suction increase, suggesting that the minimum value could be achieved at suction greater than 40-50 kPa. An additional formulation was proposed by Alonso *et al.* (1990) to evaluate the compression index with suction (dotted line, Figure 7a):

$$\lambda(s) = b + d\cdot ln(s) \qquad (3)$$

where b and d are dimensionless parameters to be calibrated (b = 0.087, d = -0.0102).



a)



b)

Figure 7. a) Dependence of the compression index from suction level according to Eq.(2) and Eq.(3). b) Experimental compressibility index and theoretical compressibility index as predicted by Eq.(2) and Eq.(3).

Both Eq.(2) and Eq.(3) well predict the compressibility index with suction but it is worth noting that, according to Alonso *et al.* (1990), results provided by Eq.(3) are less realistic than those given by Eq.(2). Indeed, also for Stava silty tailings, Eq.(3) predicts an unlimited increase in soil stiffness ($\lambda \rightarrow 0$) for increasing s and this may be a limitation for wide ranges of suction variations. As shown in Figure 7b, the two formulations are finally compared with the experimental results providing reliable prediction (max error approx. 5%) within the suction range under investigation.

5 CONCLUSIONS

The effect of the matric suction on the hydro-mechanical response of Stava silty tailings is investigated. Based on the experimental test results, the following considerations can be drawn:

- The sample preparation method seems not to affect the occurrence of the transitional behaviour, while the saturation state little affects the uniqueness of the 1d-NCL;
- The compression index decreased with suction because the soil stiffness increases with matric suction;
- Water retention tests were performed on Stava silt by applying different techniques and not-conventional apparatus, such as a suction-controlled oedometer cell, vapor equilibrium technique, and chilled-mirror psychrometer;
- Water retention tests allowed to estimate the WRC of the soil under investigation, thus providing the suction level reached by the samples during the oedometric tests;
- The formulations proposed by the Basic Barcelona Model were adopted to estimate the compression index with suction. An increase of the soil stiffness with matric suction was observed within the suction range investigated.

Following the above outcome, additional investigations may be performed to better reproduce the real environment of tailing dams. At this scope, the aging effects (i.e. rearrangements, macro-interlocking or the cementation of the particles), together with the effect of the temperature could be considered for further investigations.

ACKNOWLEDGEMENTS

The authors are grateful to Prof. Guido Musso (Politecnico di Torino) for his valuable inputs, suggestions and support while analyzing the experimental data.

ABSTRACT: The expansion of Lisbon's Underground network through the Yellow and Green lines extension project is taking place in a densely urbanized area of Santos and Cais do Sodré. The area, close to the Tagus River, combines challenging ground conditions and a large diversity of vulnerable assets, including heritage listed buildings, residential buildings and major utilities companies' assets. The project comprises the construction of the new Santos station and adjacent tunnels using the Conventional Method. The construction works will employ a sequential excavation method through poor ground conditions and low ground cover, including sections with less than one diameter of ground cover between the tunnels and the surface. In order to reduce the risk of damage to the buildings located in the zone of influence of the excavation works, a comprehensive damage assessment study was carried out in the initial stage of the project to assist the design of the tunnel primary lining and cut & cover retaining walls. This article will present the key challenges faced by the design team and the adopted solutions to reduce the risk of damaging the existing assets.

RÉSUMÉ: L'expansion du Métro de Lisbonne comprend d'extension de la lignes Jaune et Vert se développe dans une zone densément urbanisée de Santos et Cais do Sodré. La zone, proche du Tage, combine des conditions de sol difficiles et une grande diversité d'actifs vulnérables, particulièrement, édifices historiques, des édifices résidentiels et des actifs de services publics. Le projet comprend la construction de la nouvelle gare de Santos et des tunnels adjacents selon le méthode conventionnelle NATM (New Austrian Tunneling Method). Les travaux de construction utiliseront une méthode d'excavation séquentielle dans un massif avec faible résistance, y sections avec moins d'un diamètre de couverture entre les tunnels et la surface. Afin de réduire le risque de dommages aux édifices situés dans la zone d'influence des travaux souterrains, une étude complète d'évaluation des dommages a été réalisée dès la phase initiale du projet pour aider à la conception du tunnel, à la séquence d'excavation et au soutènement primaire. et calcul des structures de soutènement. Cet article présentera les principaux défis rencontrés par l'équipe de projet et les solutions adoptées pour réduire le risque de dommage des édifices.

Keywords: Building damage assessment; ground movements; damage assessment model and mitigation measures.

1 INTRODUCTION

The extension of the Yellow and Green lines is the most significant upgrade to Lisbon's subway network in the last decade. By creating a new connection between two existing lines (Green and Yellow), this project will form a circle line which will enhance the usability of public transportation services in the city centre (Figure 1). Construction works started in 2021 and passenger services are planned to start in 2025.

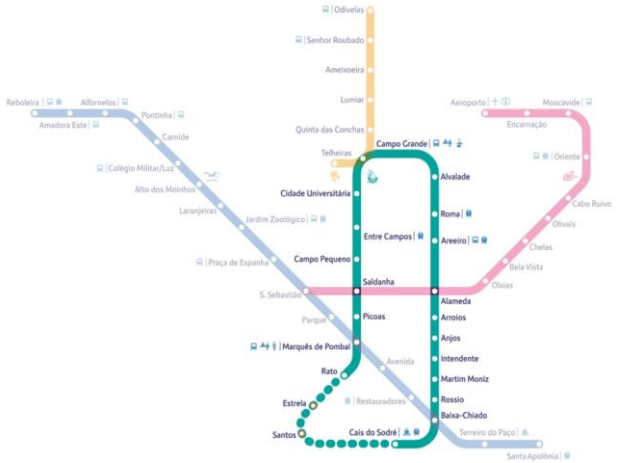

Figure 1. Lisbon's subway network (Metropolitano de Lisboa).

The project comprises a total of 1984 metres of running tunnels, two new underground stations, station upgrades at Rato and Cais do Sodré stations and a new flyover at Campo Grande. Works are divided into four lots, with Lots 1 and 2 splitting the civil works, Lot 3 includes the Campo Grande Flyover and Lot 4 includes all Mechanical, Electrical, Public Health and Architectural works.

This paper provides an overview of the building damage assessment analysis carried-out for Lot 2. This lot comprises 664 metres of new railway tunnels, running from the new underground station at Santos to the existing Cais do Sodré station (Figure 2).

The ground conditions change significantly along the route of the project, with Miocénic and Lisbon's Vulcanic formations at Santos' station, gradually changing to Tagus' River Alluvium Deposits at Cais do Sodré station.

The excavation works comprise deep shaft excavation, NATM/SCL tunnelling for the station platform tunnels, running tunnels and Cut and Cover excavations.

The zone of influence of the excavation works is a medium density urbanised area of Lisbon's downtown area. As part of the damage assessment analysis, 104 assets were analysed, comprising residential buildings, commercial buildings, listed buildings, railway lines and utilities. This paper will only cover the building damage assessments.

Figure 2. Plan view of Lot 2 (Yellow and Green lines extension project).

The damage assessment analysis provided essential information regarding the expected response of structures to ground movements induced by the excavation works. This allowed the design team to effectively adjust the construction methodology and, where required, to design ground movement mitigation measures. The requirement for ground movement mitigation measures to be implemented was identified by the damage assessment analysis. The efficiency of these measures was also confirmed by the damage assessment analysis. The ground movement mitigation measures included modifications to the construction methodology, underpinning of buildings, ground movement reduction barriers and structural bracing of buildings.

In areas where vulnerable buildings were located, the construction methodology for tunnels was adjusted to reduce the ground movements to the required magnitude to avoid damage.

The monitoring plan also was developed considering the output from the damage assessment analysis.

This paper provides an overview of the methodology adopted by the design team to develop the building damage assessment and how its output was used to assist on decisions regarding the construction methodology, the application of ground movement mitigation measures and the monitoring plan. An example of the implementation of this methodology to one of the buildings is presented in this paper.

2 METHODOLOGY

2.1 Building damage assessment model

The damage assessment analysis was part of the detailed design for the civil works. The analysis started

with the development of a damage assessment model using specific software (Oasys Xdisp Pro). This software automates building damage assessments based on Burland's (1995) assessment method. The model covered the full length of the project, including all the assets and excavation works (Figure 4).

In parallel, condition surveys were conducted to assess the condition of each building in the zone of influence of the excavation works. The condition surveys provided the design team with valuable information reg to understand the structure type (i.e. concrete framed or masonry), the type of foundation (i.e. shallow or deep foundations) and preexisting damages.

Each asset was defined in the model considering its generic dimensions (layout, foundation level, height, and structure type).

The building damage assessment analysis followed the staged risk assessment approach (Burland, 1995), which includes a preliminary assessment, a second stage assessment and detailed evaluation.

A total of sixty-eight buildings were damage assessed and ten required a combination of ground movement mitigation measures and more precise instrumentation and monitoring equipment (Figure 3).

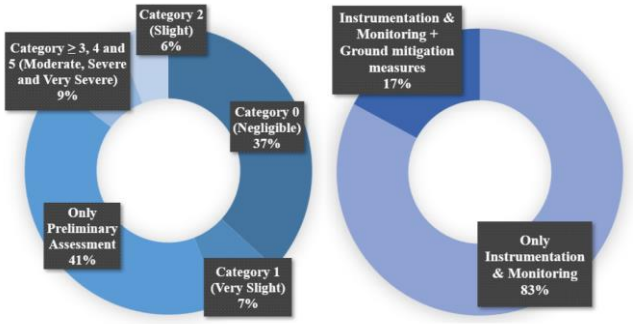

Figure 3. Assessed building damage categories (Burland, 1995) and ground movement mitigation measures.

2.2 Ground movement curves

The ground movements were calculated for each building and along each of its walls. The curves were obtained from bi-dimensional and tri-dimensional finite elements models (FE) (Figure 5). The curves were obtained for surface and sub-surface ground movements (vertical and horizontal).

The FE models were used to design the shaft support, retaining walls and the tunnel primary lining. These included the geotechnical model of the ground, the excavation support, surcharges of adjacent structures and the construction stages. The ground movement curves obtained from the FE models were compared with empirical curves from Peck (1969) and CIRIA 760 for reference.

Figure 4. 3D view of the damage assessment model.

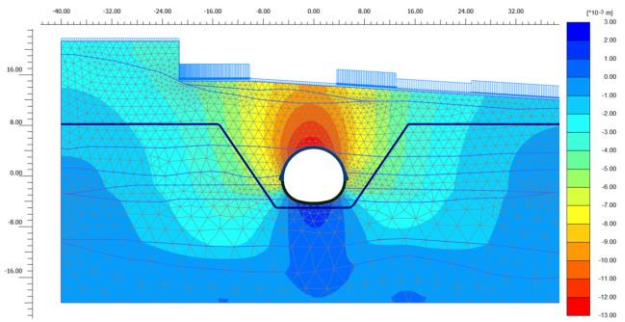

Figure 5. Example of a bi-dimensional finite element model.

2.3 Buildings

To assess damage categories in accordance with Burland's (1995) assessment method, a set of properties were required to be assigned to each building wall. These properties are representative of the building's geometry and the type of structure so that the maximum resulting tensile strains can be calculated and compared to the damage category limits.

In order to consider the vulnerability of listed buildings, the obtained damage category was increased by up to two levels, depending on preexisting damage and architectural features.

3 RESULTS

For the purpose of presenting an example of the building damage assessment work carried-out for this project, the following points describe the results to assess damage on a vulnerable listed building near Santos' station excavation works. Ground movement mitigation measures were implemented in this building to ensure that the resulting damage category was kept within the project's requirement (equal or below Damage Category 2).

3.1 Description of the building

This building was dated to the sixteenth century and it was part of a larger monastery where it was used as a lower choir. Over the centuries this building experienced several modifications to its architecture and to its use. However, the original columns, arches and ceiling paintings are still preserved (Figure 6 and Figure 7).

Figure 6. Low Choir (building's exterior view).

Figure 7. Low Choir (building's interior view) (Left) and Ceiling paintings (right).

3.2 Building damage assessment results

Due to its proximity to Santos' station excavation works, the ground movements estimated at the location of this building were in exceedance of 40 mm (Figure 8).

It was estimated that if no ground mitigation measures were implemented at this building, it could reach damage category 3 (Moderate), and considering the vulnerability of its architectural features, it would reach damage category 5 (Very Severe).

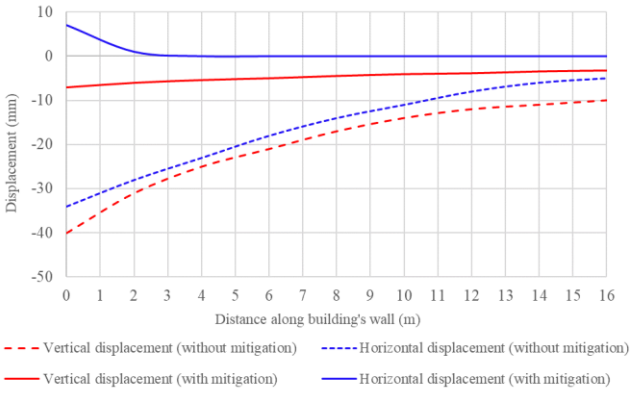

Figure 8. Ground movement profile along the most critical wall (with and without ground movement mitigation measures).

3.3 Ground movement mitigation measures

A desk study was carried-out to determine the most viable, safe and efficient ground movement mitigation measures. It was determined that the measures would be the installation of a ground movement reduction barrier, consisting of a bored piled wall (0,8 metre diameter piles, spaced at 1,0 centres) (Figure 9). and internal bracing of the building's structure (Figure 10).

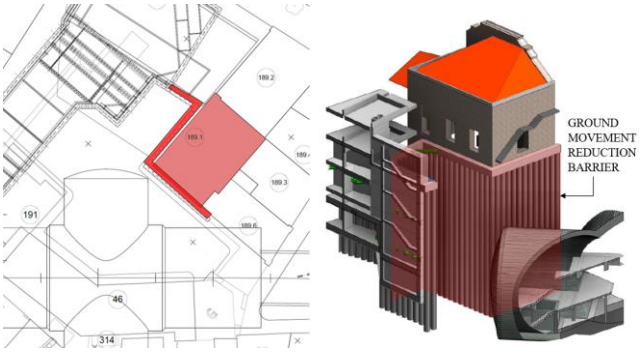

Figure 9. Location of the ground movement barrier.

Figure 10. Internal bracing of the building's structure.

3.4 Assessment of the effectiveness of ground movement mitigation measures

A detailed analysis based on 3D finite element modelling (3D FEM) was carried-out to assess the effectiveness of the ground movement reduction barrier (Figure 11).

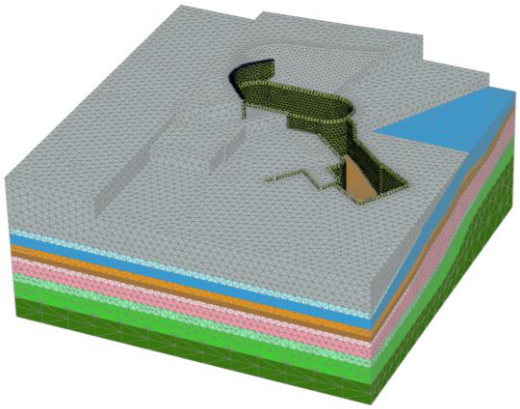

Figure 11. 3D FE model for Santos station (southern side).

The 3D FE model was developed to perform safety check calculations for all identified failure mode mechanisms. In order to reduce the calculation time, Santos station was analysed using two 3D FE models, one 3D FE model for the northern part and another 3D FE model for the southern part of the station. To assess the effectiveness of the ground movement reduction barrier, the southern 3D FE model was used. This model considered the heterogeneity of geological and geotechnical ground conditions, the groundwater conditions, the soil-structure interaction conditions, the construction sequence and the reinforcement elements, such as the primary lining and retaining walls (Figure 12).

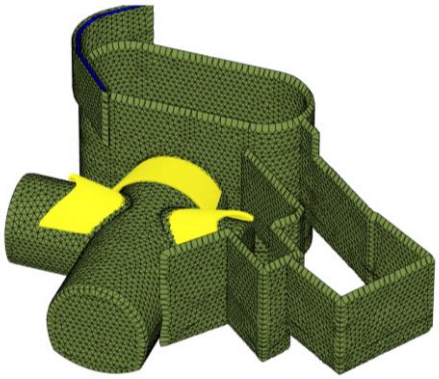

Figure 12. 3D FE model for Santos station (southern side) including primary lining and retaining walls elements.

The ground movement reduction barrier was modelled as a plate element and its stiffness and soil-structure interaction parameters, were assigned accordingly. The presence of the Low Choir building was modelled as a distributed load at ground level. The ground displacements were obtained from the 3D FE model (Figure 13).

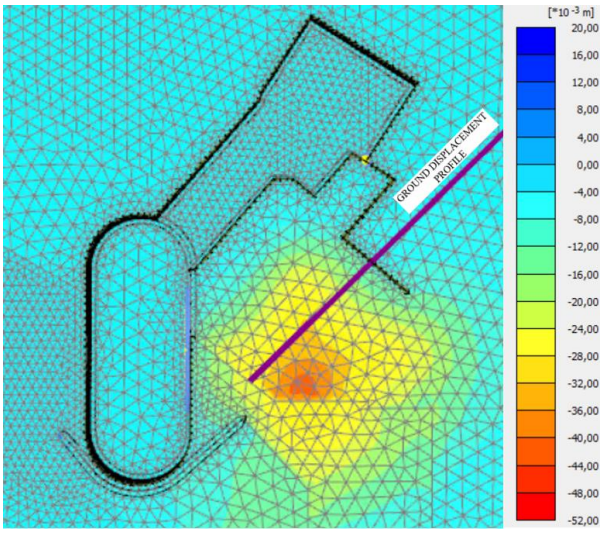

Figure 13. Estimated total displacements with ground movement mitigation measures (3D FEM).

The ground displacements were processed (Figure 14) and its analysis indicated that the inclusion of ground movement mitigations reduced the damage category to category 0 (Negligible), and considering the vulnerability of its architectural features, the damage category was estimated at damage category 2 (Slight).

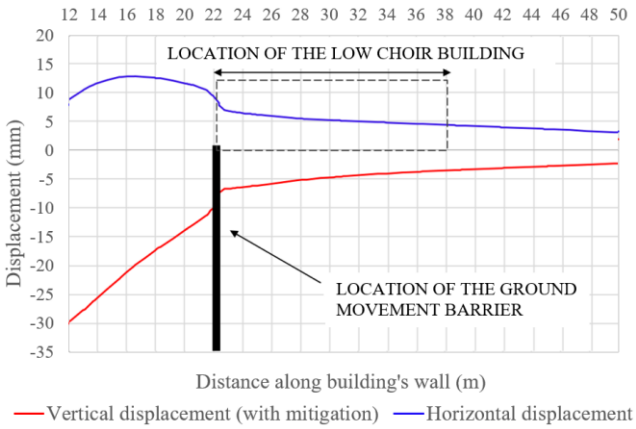

Figure 14. Ground displacement profile with ground movement mitigation measures (ground settlement profile).

4 CONCLUSIONS

This paper provides an overview of the building damage assessment work carried-out to assist the design team on the design of the excavation works for Lot 2 of the extension of the Yellow and Green lines.

The building damage assessment is an essential part of a large infrastructure project including excavation works in an urban environment.

The ability to combine in a damage assessment model multiple sources of ground movement, provides the opportunity to analyse the combined effects of various works. The opportunity to automate this analysis is critical to provide timely input to the design development so that efficient mitigation measures can be introduced, and adjustments can be made to the excavation methodology.

Eurocode 7 – Second Generation: Retaining structures – Looking beyond the partial factors for safety in design

Eurocode 7 – Deuxième génération – Ouvrages de soutènement – Au-delà des facteurs partiels de sécurité dans la conception

W. Bogusz*
Jacobs, Warsaw, Poland
**witold.bogusz@jacobs.com*

ABSTRACT: The second generation of Eurocode 7 brings many changes to various aspects of geotechnical design. The new Clause 7 "Retaining structures" of EN 1997-3 is one of the updated elements of this standard. As code-compliance in design is often associated with ultimate limit state verification and application of partial factors, there are less obvious improvements, which ensure the reliability of design involving ground-structure interaction and improved harmonisation of design rules between different Eurocode parts. In geotechnical design, it is vital to identify the relevant design situations, to formulate design assumptions, and to understand their underlying uncertainties. Application of the safety factors and verification of limit states is only one of the last steps in ensuring that the design is safe and fit-for-purpose. The paper presents the major elements related to design of retaining structures in the new Eurocode 7.

RÉSUMÉ: La deuxième génération de l'Eurocode 7 apporte de nombreux changements à divers aspects de la conception géotechnique. Le nouvel article 7 « Structures de soutènement » de l'EN 1997-3 est l'un des éléments mis à jour de cette norme. Comme la conformité aux codes dans la conception est souvent associée à la vérification de l'état limite ultime et à l'application de facteurs partiels, il existe des améliorations moins évidentes, qui garantissent la fiabilité de la conception impliquant une interaction sol-structure et une meilleure harmonisation des règles de conception entre les différentes parties de l'Eurocode. En conception géotechnique, il est essentiel d'identifier les situations de conception pertinentes, de formuler des hypothèses de conception et de comprendre leurs incertitudes sous-jacentes. L'application des facteurs de sécurité et la vérification des états limites ne constituent que l'une des dernières étapes permettant de garantir que la conception est sûre et adaptée à son objectif. L'article présente les principaux éléments liés à la conception des structures de soutènement dans le nouvel Eurocode 7.

Keywords: Eurocode 7; standardisation; retaining structures; partial factors, safety.

1 INTRODUCTION

Retaining structures, included in Part 1 of the first generation of Eurocode 7 (CEN, 2004), were moved to Clause 7 of the second generation EN 1997-3 (CEN, 2024b). As no revolutionary changes were introduced in regard to their design, the main improvements are the results of general changes to the entire set of the Eurocodes. This evolution resulted in overall increase of harmonisation of general rules for structural and geotechnical design (CEN, 2023a) as well as across all the new Eurocodes. More importantly, within the Eurocode 7 itself (CEN, 2024a, 2024b), design rules for all geotechnical structures are aligned to a greater extent. In the case of retaining structures (Clause 7), the design is strongly interrelated with other structures, most significantly, with slopes and cuttings (Clause 4), as well as anchors (Clause 8). Figure 1 presents, as an example, a schematic view of a retaining structure, where different Eurocode parts are involved. The main guidance of Clause 7 on retaining structures covers basis of design, geotechnical analysis, limit state verification, and quality assurance of:

- Gravity walls;
- Embedded walls;
- Composite retaining structures - composed of elements of gravity and embedded walls.

The normative content of Clause 7 is further supplemented by the informative Annex D, containing additional guidance on aspects such as estimation of earth pressures. The use of this annex and its content is subject to the choice of each CEN member country in their National Annex.

The main advantage of the new version of the code is the improvement in more holistic view on the design process. The verification of limit states is only one of the aspects of Eurocode 7 design.

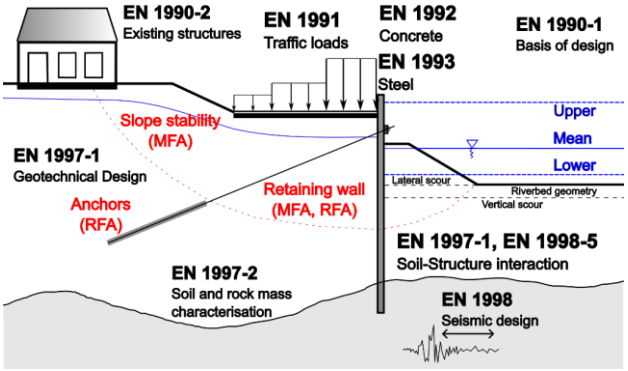

Figure 1. Interrelation of various design aspects covered by different Eurocodes.

The partial factors prescribed by the code are only part of the way of providing sufficient margin of safety. Their importance is often overestimated, as the real challenge is to identify relevant design situations, adopting realistic but cautious design assumptions, selecting representative values of actions and parameters, as well as prescribing quality assurance requirements for execution and maintenance. The updated version of the code addresses all of those aspects, but some still cannot be fully covered by standardisation.

The paper presents some of the major aspects and design requirements relevant for retaining structures that are introduced by the second generation of the Eurocode 7 Part 1 and 3 (CEN, 2024a, 2024b).

2 BASIS OF DESIGN

The basic elements affecting the design of retaining structures that have to be considered are:

- Zone of influence – including impact on existing structures;
- Consequences of failure, Geotechnical Complexity Class, Geotechnical Category;
- Robustness, durability and sustainability requirements for the given service life;
- Ground model, with representative stratigraphy and groundwater conditions;
- Design situations and geometrical properties;
- Actions and environmental influences;
- Groundwater conditions;
- Identification and verification of relevant limit states with reliable calculation models;
- Representative ground properties for each limit state considered;
- Quality management requirements.

Due to the limited scope of this paper, only some of those aspects are discussed, but all of them are covered in sufficient detail in the new Eurocode 7 (CEN 2024a, 2024b). Although the standard now offers the guidance for all the elements of design process, it is not intended to replace sound engineering judgement, but to supplement it.

The second generation of Eurocode 7 (CEN, 2024a) improves the concept of the "zone of influence". To ensure that the assumed Ground Model accounts for all the relevant strata that might affect the behaviour of the structure, the extent of site investigation is directly related to it. Next, a Geotechnical Design Model has to be developed, based on the Ground Model, for each geotechnical design situation, with corresponding combinations of actions and associated relevant limit states. Loads within the zone of influence may be considered as concentrated or uniform, depending on their nature and proximity to the retaining structure. In that regard, significant improvement is provided in EN 1991-2 Eurocode 1 (CEN, 2023b), where traffic load models specific for geotechnical applications are introduced. However, it is still the role of the designer to identify the relevant design situations and load combinations taken under consideration.

After the publication of the first generation of Eurocode 7, Simpson et al. (2011) highlighted the need for careful evaluation of a full range of credible scenarios based on engineering expertise, which cannot be simply substituted by requirements of a standard. In practice, the limit state analysis should cover situations considered as the worst credible conditions. For example, the design has to account for future anticipated excavations, and possible scour or erosion in front of the retaining structure, even if it might occur post-construction.

This also requires understanding of construction sequence and its effects on distribution of ground and water pressures. However, it is important to understand the difference between prediction of behaviour, serviceability limit state (SLS) analysis, and ultimate limit state (ULS) verification. Their level of conservatism in assumptions of representative parameters (material, geometrical, pressures, etc.) might differ.

3 GROUNDWATER

Significant consideration has been given to groundwater and water pressures in the process of the second generation of Eurocode 7 development. It is commonly recognised that effects of water pressures are very important in geotechnical design, especially for retaining structures. Usually, appropriate selection of the representative water levels (pressures) for each relevant design situation is considered as more important than application of partial factors in

providing safety in design. Consideration has to be given to a number of different factors in the selection process. Among them, climate change influence should be considered, as well as variation with time.

If there is sufficient data to derive the representative value of groundwater pressure on the basis of the annual probability of exceedance, it can be assumed in two ways, as:

- Upper ($G_{wk,sup}$) or lower ($G_{wk,inf}$) single characteristic permanent value (Figure 1) – the more adverse for the given limit state;
- Permanent mean value with variable amplitude.

Moreover, design situations can be divided into persistent, transient, and accidental situations, which can further influence the selection of the representative values.

However, if there is insufficient data to derive the values based on statistics, which often is the case in practice, upper and lower values should be selected as cautious estimates of the most adverse values likely to occur. The main point is to determine the most critical design scenarios and the water pressures associated with them. In practice, the analysis might consider various design situations, with different possible combinations of upper and lower estimate values, in front and behind the retaining wall.

The design value of groundwater level (pressure) for ULS can be obtained by:

- Direct assessment,
- A deviation to the representative value,
- Applying a partial factor to the representative groundwater pressures or their action effects.

In many cases, the most appropriate and most robust way of providing prescribed margin of safety will be to apply an offset of water pressures from their representative values, i.e. raising or lowering of the water levels. However, engineering judgement has to be used in that process.

Groundwater pressures arising from a common source of groundwater or surface water should be considered as a single action. However, upper- and lower-estimates should be considered if the water pressures can have both favourable and unfavourable effects. Furthermore, potential obstruction of natural groundwater flow caused by embedded retaining walls has to be considered. This applies to the possible increase of water level (dam effect) as well as the possibility of considering the pressures as coming from a single source. In some cases, detailed consideration has to be given to water levels on both sides of the retaining wall, especially in case of waterfront and flood protection structures.

Additional guidance on groundwater control measures has been also presented in Clause 13 of part 3 (CEN, 2024b). Its content is particularly important for cases where temporary or permanent drainage might be provided, or where an embedded wall acts as a cut-off barrier.

4 GEOTECHNICAL ANALYSIS

The geotechnical analysis of retaining structures is mostly related to the determination of earth pressure distribution and its impact on effects of actions. It has to take account of the expected failure mechanisms and deformations at the limit state under consideration. In general, three kinds of models can be used in the analysis:

- Analytical models - including limit equilibrium models and limit analysis.
- Semi-empirical models - including earth pressure envelopes.
- Numerical models - including beam-on-spring or continuum models.

Eurocode 7 Part 3 (CEN, 2024b) gives detailed description how to determine limiting values of earth pressure analytically for active, passive, and at-rest values of earth pressures. Intermediate values of earth pressure have to be determined considering the wall movement and its direction relative to the ground. Moreover, earth pressures due to backfill compaction have to be considered.

For embedded retaining structures, aside from the simplest of design cases, ground-structure interaction with numerical methods might be advisable. In such cases, all the relevant components (ground, retaining wall, support elements, etc.) have to be modelled in a realistic manner for the range of expected behaviour; an appropriate ground model and properties are key to obtaining reasonable estimates of performance (Haberfield, 2017).

The most critical geotechnical failure mechanism or combination of failure mechanisms may be determined by numerical continuum models using shear strength reduction approach. Although all the relevant failure modes not always can be checked in a single numerical analysis, a continuum numerical model can be used concurrently for overall stability calculations as well as to verify rotational resistance, stability of excavations, and structural failure.

5 ULTIMATE LIMIT STATES

Ultimate limit states specific to all retaining structures, in addition to those given in EN 1997-1 (CEN, 2024a) for all geotechnical structures, include but are not limited to:

- Failure of structural elements, their connections or their interfaces;

- Combined failure in the ground and structural element;
- Excessive movement of the retaining structure (potential collapse of the structure, nearby structures or services that rely on it).

For gravity retaining walls, additional ULS are to be considered:

- Bearing failure;
- Failure by sliding along the base;
- Failure by overturning or by toppling.

On the other hand, for embedded walls, verification includes:

- Failure by rotation or translation of the wall;
- Failure by lack of vertical equilibrium.

In addition, in the presence of hydraulic gradients, it shall be verified that limit states due to uplift, hydraulic heave, and internal erosion or piping, or bottom failure mechanisms, i.e. basal heave due to ground unloading, are not exceeded.

The verification of ultimate limit state by partial factor method can take two forms (CEN, 2023a). It can typically be considered in terms of effects of actions as forces and stresses (eq. 1), or in some cases in terms of deformations or strains (eq. 2):

$$E_d \leq R_d \quad (1)$$

$$E_d \leq C_{d,ULS} \quad (2)$$

where: E_d is the design value of effects of actions; R_d is the design value of the corresponding resistance; $C_{d,ULS}$ is the limiting design value for ULS of the excessive deformation that is considered to cause an ULS.

As alternative to verification by partial factor method, retaining structures may be verified using the Observational Method.

For structural resistance analysis, Eurocodes relevant for a given material should be used. Resistance shall be verified considering all geotechnical failure mechanisms that can interfere with the retaining structure. For advanced analysis, when elasto-plastic behaviour of structural elements is considered and load redistribution is allowed for non-linear problems, the input values of structural resistances may already be factored.

5.1 Overall stability

The problem of overall stability of retaining structures is often connected to the slope stability covered by Clause 4 of EN 1997-3 (CEN, 2024b). For retaining structures in sloped ground, where additional thrust on the wall would be induced by the slope deformation, one of the three possible approaches should be used:

- a continuum numerical model to check effects of actions on the retaining structure;
- a limit equilibrium method to check failure surfaces intercepting the retaining structure;
- a limit equilibrium method with an additional model factor to check failure surfaces not intercepting the retaining structure;

In such case, using continuum numerical methods offers an advantage of checking both the wall and the overall stability using a single model. However, the structural elements should have the properties defined as either:

- Elastic - forces in these structural elements have to be checked based on the Eurocode relevant for a given material.
- Elasto-plastic - verification is conducted based on Eurocode 7 Part 1 (CEN, 2024a), with structural ultimate resistance based on other relevant Eurocode.

5.2 Partial factors

In general, partial safety factors should be applied to where the major uncertainty exists, and when applied, to drive the solution towards reaching the ULS. When ULS verification by partial factor method is considered, two approaches for retaining structures are possible (Table 1), with corresponding sets of factors:

- Material Factor Approach (MFA) – where actions and material properties are factored;
- Resistance Factor Approach (RFA) – where actions and resistances are factored.

The sets of partial factors for actions or effects of actions are based on Verification Cases (VC) given in EN 1990 (CEN, 2023a) - Annex A. The partial factors for material properties (set M) are given in EN 1997-1 (CEN, 2024a).

In the case of RFA, the possibility of using partial factors for actions (VC1) or effects of actions (VC4) exists. Factoring the effects of actions (VC4), in a similar manner to DA2* approach from the first generation Eurocode 7, may be especially useful when applying continuum numerical methods, and for problems where water pressures have dominant impact on design.

For structural design of the wall, effects of actions in terms of structural forces should be factored to obtain their design values for verification of the relevant limit states.

Table 1. Partial factors for retaining structures for fundamental design situations.

Verification of	Partial factor on	Symbol	Material Factor Approach both (a) and (b) or only (c)			Resistance Factor Approach	
			(a)	(b)	(c)	(d)	(e)
Overall stability	Based on Clause 4 (Slopes, cuttings, and embankments)						
Gravity walls	Actions, Effects of actions	γ_F, γ_E	VC4	VC3	VC1	VC1	VC4
	Ground properties	γ_M	M1	M2	M2	Not factored	
	Bearing resistance	γ_{RN}	Not factored			1,4	
	Sliding resistance	γ_{RT}				1,1	
Embedded walls	Actions, Effects of actions	γ_F, γ_E	VC4	VC3	Not used	VC1	VC4
	Ground properties	γ_M	M1	M2		Not factored	
	Vertical resistance, basal heave	γ_R	Not factored			1,4	
	Passive earth resistance	γ_{Re}				1,4	

As retaining structures are often designed as part of slope stabilising measures (Figure 1), it is worth highlighting that for slope stability problems (Clause 4) only MFA (sets VC3 and M2) is allowed. On the other hand, for anchors, often used as support elements, only RFA approach is possible.

The new Eurocodes (CEN, 2023a, 2024a, 2024b) allow for consistent ULS verification of multiple problems with the same sets of partial factors, even for solutions combining more than one retaining wall or geotechnical structure. This is especially important when continuum numerical methods are used. Those methods are gaining popularity as designers generally prefer to conduct design limit state verifications, both ULS and SLS, with as few models as possible. The verification of ULS with the use of continuum numerical methods in the context of Eurocode 7 has been a subject of interest for a long time, e.g. by Bauduin et al. (2005) or Simpson et al. (2011). However, a lack of formal guidance on the code-compliant procedure of partial factors implementation has been often considered as a problem. The new code (CEN, 2024a) finally provides that guidance, explicitly offering following possibilities:

- Approach 1 (preferred) with two verifications:
  1. Output factoring - factoring effects of actions (VC4), e.g. bending moments.
  2. Input factoring - factoring primarily material properties (sets VC3 and M2).
- Approach 2 (alternative) – factoring effects of actions (VC4) and resistances, without the reduction of ground properties (set M1).

5.3 Supporting elements

Supporting elements for retaining structures include, but are not limited to: walls, piles, anchors, props, soil nails, and rock bolts. They have to resist the design values of the effects of actions E_d from the structure given for VC1 and VC3 (eq. 3), or VC4 (eq. 4), as:

$$E_d = \gamma_{Sd} max\{F_{ULS,d}; \gamma_F F_{SLS,rep}\} \quad (3)$$

$$E_d = \gamma_{Sd} max\{\gamma_E F_{ULS,rep}; \gamma_E F_{SLS,rep}\} \quad (4)$$

where: $F_{ULS,d}$ and $F_{ULS,rep}$ are respectively the design and representative values of action that supporting element shall provide to prevent ULS; $F_{SLS,rep}$ is the representative value of action that supporting element shall provide to prevent SLS; γ_{Sd} is a model factor; γ_F and γ_E are partial factors converting forces to their design values.

To maintain consistency of design, Clause 8 on anchors does not include partial factors on actions or effects of actions, as those will be transferred from the supported structure. Furthermore, the equations in Clause 4 for supporting elements of slopes, cuttings, and embankments, have a similar form. However, in their case, the wall itself can be a supporting element.

6 SERVICEABILITY LIMIT STATES

Serviceability limit states specific to retaining structures, in addition to those given in EN 1997-1 (CEN, 2024a) for all geotechnical structures, include but are not limited to:

- Movements of the retaining structure that cause damage or affect the appearance or the use of the structure, or nearby structures or services.
- Unacceptable leakage through or beneath the structure.
- Unacceptable change in the groundwater conditions induced by the retaining structure.

The impact on adjacent structures and services is now explicitly included and emphasised. It is often one of the factors governing the design of retaining walls

in an urban environment. The tolerance to displacements of supported structures and utilities within the zone of influence should be considered in selection of limiting values of ground movements around the retaining wall. The serviceability criteria may be defined as proportion of the limiting values of the deformations of the affected structures.

When assessing the serviceability limit states, which should be based on reasonably anticipated worst case situations, the SLS verifications should not be confused with prognosis of behaviour, which will depend on the most probable baseline scenario (calculations with best-estimate values).

7 IMPLEMENTATION OF DESIGN

Significantly more attention is now given to implementation of design in execution, which covers: inspection, monitoring, maintenance, testing, and reporting requirements. The need for specific plans, as part of the design, is now dependent on the Geotechnical Category of the structure. Furthermore, the importance and levels of validation of adopted calculation models with their assumptions are also emphasised. They might often involve checking the calculations against alternative methods and comparable experience.

The monitoring of a retaining structure should be planned based on identified mode of deformation. It should be specified, which aspects of the behaviour of the geotechnical structure shall be monitored to confirm compliance with the serviceability criteria. Moreover, limiting as well as threshold values should be established in design.

When the safety and the serviceability of the retaining structure depend on the successful performance of a drainage system, a Maintenance Plan has to be prepared.

To increase transparency of design process and to allow for third-party verification of design and the construction process, detailed reporting requirements are provided in the Eurocode 7. They cover not only the design documentation, but also Geotechnical Construction Record and Geotechnical Test Reports, prepared during execution, when implementing the design.

8 CONCLUSIONS

The new Eurocode 7 in terms of requirements for retaining structures offers an evolution rather than a revolution compared to the first generation. The main improvements are due to greater harmonisation between different Eurocode parts and across different geotechnical structures. In many aspects, the requirements are just aligned with the current state-of-the-art industry's practices and guidelines. However, the standard still maintains sufficient flexibility for modification and supplementation at the national level through National Annexes. Therefore, the designers should not find it overly challenging to implement the second generation of Eurocode 7 for the design of retaining structures.

ACKNOWLEDGMENTS

I would like to acknowledge the contribution of the members of the Task Group CEN TC250/SC7 TG-D1 on "Slopes, Retaining Structures, and Anchors", which I had the privilege of leading from 2020 to 2023. The group provided a significant contribution to the development and improvement of the Clauses 4, 7, and 8 of EN 1997-3 on geotechnical structures.

Excavation and tunnelling impact on existing structures in the context of the second generation Eurocodes

Impact des travaux d'excavation et des tunnels sur les constructions existants dans le contexte des Eurocodes de deuxième génération

W. Bogusz*
Jacobs, Warsaw, Poland
**witold.bogusz@jacobs.com*

ABSTRACT: Ground deformations due to construction of deep excavations and tunnels, often affecting serviceability and causing damage to existing buildings, are important considerations in the design of underground structures. While the first generation of Eurocode 7 has not covered those aspects in much detail, the updated standard indirectly offers a design framework where this issue can be addressed in a code-compliant way. The paper presents some of the requirements implemented in second generation of the Eurocodes, relevant in the context of excavation-related impact assessment, as well as supplement them with information extending this guidance to tunnelling-induced deformations. Although tunnel design is still not officially covered even under the updated Eurocode framework, European standards are often used also for those applications. With ongoing efforts to officially bring underground structures under the scope of these standards, a general proposal is provided on how existing code can cover assessment in the case of tunnelling.

RÉSUMÉ: Les déformations du sol dues à la construction d'excavations et de tunnels profonds, affectant souvent la fonctionnalité et causant des dommages aux bâtiments existants, sont des considérations importantes dans la conception des structures souterraines. Bien que la première génération de l'Eurocode 7 n'ait pas couvert ces aspects de manière très détaillée, la norme mise à jour offre indirectement un cadre de conception dans lequel ce problème peut être résolu de manière conforme au code. Le document présente certaines des exigences mises en œuvre dans la deuxième génération des Eurocodes, pertinentes dans le contexte de l'évaluation des impacts liés aux excavations, et les complète par des informations étendant ces lignes directrices aux déformations induites par les tunnels. Bien que la conception des tunnels ne soit toujours pas officiellement couverte, même dans le cadre des Eurocodes mis à jour, les normes européennes sont souvent également utilisées pour ces applications. Dans le cadre des efforts continus visant à soumettre officiellement les structures souterraines au champ d'application de ces normes, une proposition générale est fournie sur la manière dont le code existant peut couvrir l'évaluation dans le cas des tunnels.

Keywords: Eurocode 7; impact assessment; deep excavations; tunnels, serviceability.

1 INTRODUCTION

Impact of underground construction works on existing structures is one of major problems associated with execution of deep excavations and tunnels. The second generation of the Eurocodes offers now a sufficiently detailed framework to address this problem in a code-compliant way. Basis of design aspects for new structures (CEN, 2023a) has been supplemented with requirements for assessment of existing structures (CEN, 2023b). Moreover, Eurocode 7 (CEN, 2024a) explicitly highlights the concept of the zone of influence of geotechnical structures and the need of assessing the impact on existing structures and utilities within that zone. The detailed guidence, relavant for underground construction activities, is mostly provided in Clause 7 on retaining structures of the new Part 3 (CEN, 2024b). However, together with the general provisions of the Eurocodes, it can easily be applied also for tunnelling-induced ground deformations and their impact on buildings, other structures, and utilities. Even though the development of tunnelling specific guidance is underway (Athanasopoulou et al., 2022), the Eurocodes are already commonly applied to different aspects of tunnel design (Figure 1). In this light, the existing Eurocode framework, based on its second generation, already provides a good basis for code-compliant impact assessment to be used.

2 ZONE OF INFLUENCE

A zone of influence is defined as a zone where construction works or the geotechnical structure can adversely affect the safety and serviceability of the

geotechnical structure, other structures, utilities, ground, or groundwater (CEN, 2024a).

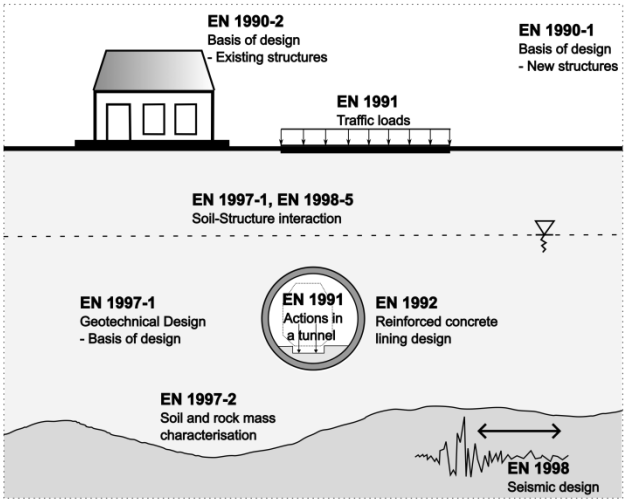

Figure 1. Applicability of Eurocodes to underground structures (adopted after Bogusz et al., 2023).

This zone is also related to the extent of potential failure surfaces and occurrence of significant ground displacements that have to be determined in design. The impact on ground, existing structures, and utilities within this zone should be investigated.

3 EXISTING STRUCTURES

All the existing structures within the zone of influence should be identified and assessed. The assessment of an existing structure should be carried out following a stepwise process with increasing levels of detail and accuracy (CEN, 2023b). It should include:

- Condition survey;
- Preliminary stage of assessment;
- Detailed stage of assessment.

Based on the assessment, the serviceability criteria for the existing structures, utilities, and ground within the zone of influence should be defined.

Furthermore, as the importance of existing structures and potential consequence of their failure cannot be ignored, their presence should be taken into account when deciding on the selection of Geotechnical Category in design.

4 EXCAVATION-INDUCED GROUND MOVEMENTS

Prediction of displacement due to deep excavations or tunnelling is needed to assess their influence on adjacent structures. Viable methods of prediction, in the case of impact assessment, include:

- Prescriptive rules;
- Empirical methods;
- Numerical methods;
- The Observational Method.

The current state-of-the-art approach in most cases of impact assessment is to implement empirical methods and 2D numerical models. When considering the use of empirical models, it is necessary to consider the conditions under which they were established and for which they are applicable. Despite that limitation, there is no restriction to use those models in the context of limit state design or probabilistic analysis that fulfils the requirements of the standard. However, Eurocode 7 does not provide a specific calculation model for prediction of ground movements in vicinity of structures; such models would have to be supplemented by additional guidelines. In the case of numerical models, their level of complexity for the impact analysis can vary, ranging from relatively low for 2D analysis to highly complex 3D modelling as summarised in Table 1.

Table 1. Model complexity levels for tunnelling impact assessment.

Model complexity level[1)]		Extent of required information[2)]	Geometry	Tunnel construction modelling	Adjacent structures
1	Low	Medium[3)]	2D	Volume loss method or Convergence-confinement method	Greenfield conditions
2	Normal				Equivalent load
3					Equivalent load and stiffness[4)]
4					
5	High	High	3D		Structural elements explicitly modelled
6		Very high		Detailed sequence	

[1)] Complexity levels 1 to 3 are typical for normal assessment, while levels 4 to 6 for detailed assessment.
[2)] For simplifies (prescriptive) and semi-empirical methods, the extent of required input information can be considered as very low and low, respectively.
[3)] Constitutive modelling of the ground will often need to account for non-linear stiffness for realistic prediction.
[4)] For plane-strain analysis (2D), stiffness of adjacent structures may be represented by consideration of simplified structural elements (e.g. foundation slabs, floors, walls, columns, piles, etc.) or structure with equivalent stiffness.

Loads within the zone of influence may be considered as concentrated or uniform depending on their nature and proximity to the retaining structure or a tunnel. However, it is often impractical to perform a detailed evaluation of loads for each adjacent building, unless benefits of such detailed assessment justify the effort. For practical applications, simplified representation is often sufficient. For example, in Polish practice, depending on the type and the use of a building, an assumption of uniformly distributed load of 10÷15 kN/m² per floor or 2.5÷3.0 kN/m² per one meter of height of the building is considered as a sufficient approximation, assuming sufficient distance from the new structure.

Ground movement around retaining structures, as well as tunnels, and their effects on supported structures and services, always have to be checked against comparable experience.

5 IMPACT ON EXISTING STRUCTURES

When the deformations imposed on surrounding ground by the excavation are predicted, their impact on the existing structure can be verified. This can be done based on limit state design framework of the Eurocodes, with distinction between serviceability (SLS) and ultimate (ULS) limit states.

States prior to structural collapse may be treated as ULS related to excessive movement that may cause collapse of the nearby structure or services. Movements that cause damage that can affect the appearance or inhibit the use of the nearby structure or services are considered as SLS. Limiting values of ground movements, as the serviceability criteria, have to consider the tolerance to displacements of supported structures and utilities within the zone of influence. Those criteria should be established for serviceability limit states (SLS) concerning:

- the functioning of the structure or structural members under normal use;
- the comfort of people;
- the appearance.

In general, serviceability requirements for each project should be specified individually. For protecting the historical, cultural or societal value of the structure, more restrictive serviceability criteria should be considered.

To limit the adverse impacts on existing structures, serviceability criteria may be defined as a proportion of the limiting value of the deformation of the affected existing structures. Although it is not explicitly stated, the limiting values of deformations may be established for performance-based design, where different values of deformations are assigned to specific performance levels or categories of damage.

The new version of the Eurocode (CEN, 2023a) already allows for verifications of both SLS and ULS in terms of deformations or strains using inequalities:

$$E_d \leq C_{d,SLS} \quad (1)$$

$$E_d \leq C_{d,ULS} \quad (2)$$

where: E_d is the design value of effects of actions; $C_{d,SLS}$ is limiting design value of the relevant serviceability criterion – it may be different for different serviceability considerations or level of damage (Figure 2); $C_{d,ULS}$ is limiting design value for ULS of excessive deformation.

Depending on which limit state is considered, not only the limiting design values should be differentiated, but also the considered actions resulting in ground displacements. The analysis has to be based on the representative values of actions and properties, appropriate for the considered limit state, usually considered as cautious (SLS) or worst credible (ULS) estimates. However, for prognosis of behaviour during execution, calculation with best-estimate values may be used.

In the case of tunnelling, usually volume loss associated with specific tunnelling method and ground conditions will be the major design assumption. Ideally, the choice of a representative value of volume loss should be based on the statistical analysis of prior tunnelling experiences in the considered area. Values for different probabilities of exceedence may be assumed in design for different limit states, based on risk tolerance level adopted. In case of lack of sufficient well documented experience to establish a statistical basis, a nominal value based on expert judgement can be selected.

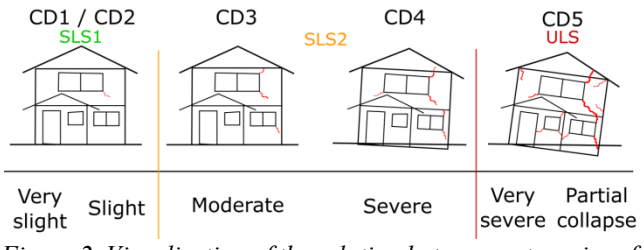

Figure 2. Visualisation of the relation between categories of damage (CD) and limit states (Bogusz, 2021).

6 EXAMPLE

As a short example, Figure 3 shows possible approach to selection of representative values of a tunnelling-related volume loss for Earth Pressure Balance Tunnel

Boring Machine (EPB-TBM) construction method, based on prior experience from M2 metro line construction in Warsaw (Bogusz, 2021). On the basis of that experience, representative values were adopted for impact assessment of new tunnels designed in similar ground conditions (Figure 4). The assessment has been conducted with both the empirical (preliminary assessment; Figure 5) and numerical (detailed assessment; Figure 6) methods. Due to the limitations of this paper, the full version of the design example is not presented here; however, it can be found in the annex to the JRC Report (Athanasopoulou et al., 2022) published online in open access.

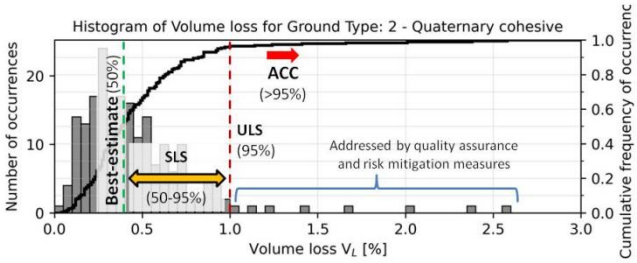

Figure 3. Selection of representative values of tunnelling volume loss based on statistical data.

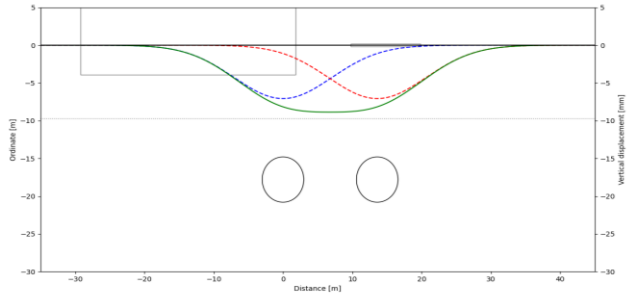

Figure 5. Ground displacement distribution from semi-empirical model (Athanasopoulou et al., 2022).

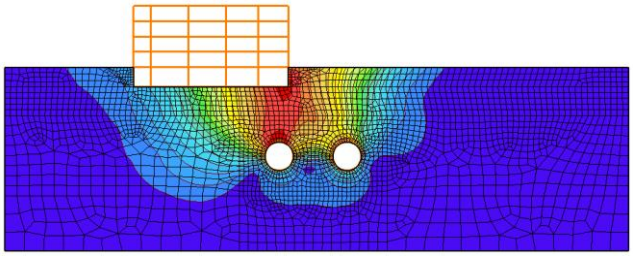

Figure 6. Ground displacement distribution from numerical model (Athanasopoulou et al., 2022).

7 CONCLUSIONS

The second generation of the Eurocodes does not solve all the issues associated with the impact of underground works on adjacent structures. However, it provides a good framework for impact assessment to be conducted in a code-compliant way. Additional supplementation with relevant calculation models and specific guidance would be useful; however, this can be easily provided by national or industrial guidelines and in the future by an additional Eurocode part, which is intended to be developed.

Pile response to the effect of basement construction in soft clay

Réponse des pieux à l'effet de la construction de sous-sols dans de l'argile molle

T. Boonyarak*, A.Y. Aung
Department of Civil Engineering, King Mongkut Institute of Technology Ladkrabang, Bangkok, Thailand
Z.Z. Aye
Seafco Public Company Limited, Bangkok, Thailand
**thayanan.bo@kmitl.ac.th*

ABSTRACT: Basement construction and deep excavation in very soft clay could induce excessive ground movements and cause adverse effects on piles located inside the excavation area. The research was conducted using data from field monitoring on the instrumented pile inside the basement and three-dimensional numerical back-analysis to evaluate the pile-soil interaction under various basement construction techniques. The key factors investigated in this study include the influence of the basement construction method, system stiffness, pile-soil stiffness, and duration of construction period. Moreover, the influence of soil consolidation, pore pressure dissipation, and time-dependent soil behaviour on pile response is thoroughly investigated. Field measurements are conducted at selected construction sites in Bangkok, where retaining structures include jet-grouted retaining walls and cut-slope excavation. The diameter bored pile ranges from 0.6 m to 1.5 m and the depth of the pile tip is 50 m. The fully coupled three-dimensional finite element method using a hardening soil model with small strain stiffness is utilized to simulate the complex soil-structure interaction, considering the time-dependent behavior of soft clay to provide insights into observed behavior. A series of numerical parametric studies are carried out to identify the impact of each investigated factor affecting pile movement. The key results highlight the importance of system stiffness of the retaining structure that strongly impacts pile movement inside the basement. The time-dependent behaviour can cause larger pile movement in retaining systems with smaller stiffness, such as cut-slope excavation, than those with rigid retaining walls.

RÉSUMÉ: La construction de sous-sols et les excavations profondes dans des argiles très molles pourraient entraîner des mouvements excessifs du sol et avoir des effets néfastes sur les pieux situés à l'intérieur de la zone d'excavation. Cette étude a utilisé des données de surveillance sur le terrain sur le pieu instrumenté à l'intérieur du sous-sol et une analyse numérique tridimensionnelle pour évaluer l'interaction sol-pieu sous diverses techniques de construction de sous-sols. Les principaux facteurs étudiés incluent l'influence de la méthode de construction du sous-sol, la rigidité du système de structure de retenue, la rigidité sol-pieu, et la durée de la période non contreventée. De plus, l'impact de la consolidation du sol, de la dissipation de la pression interstitielle, et du comportement du sol dépendant du temps sur la réponse des pieux est examiné en détail. Les mesures sur le terrain sont réalisées à Bangkok, où les structures de retenue comprennent des murs de soutènement injectés au jet et des excavations en pente. La méthode des éléments finis tridimensionnels est utilisée pour simuler l'interaction sol-structure, en tenant compte du comportement dépendant du temps de l'argile molle.

Keywords: Pile-soil interaction; basement construction; soft clay; case history; three-dimensional numerical analysis.

1 INTRODUCTION

The construction of basements in soft clay environments significantly influences the behavior and response of bored piles inside the excavation area, rendering it a topic of substantial interest and study within geotechnical engineering. Soft clay presents unique challenges for constructing basements, primarily due to its low stiffness, high compressibility, and susceptibility to significant deformation under load.

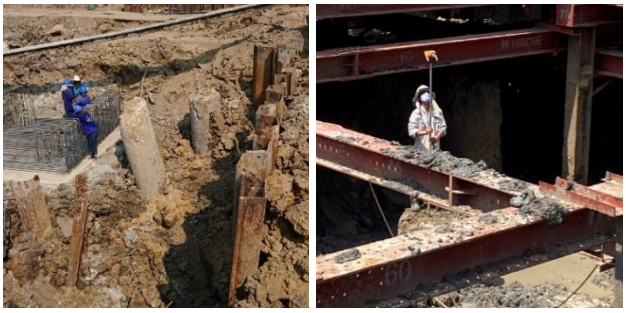
In many cases, the excavation contractors inadvertently damage piles within the excavation area, the integrity of the pile, safety considerations, and project timeline may all be affected. Thus, it is crucial to understand the causes, and implementing appropriate necessary measures are essential steps in preventing such incidents.

Pile lateral movement due to excavation has been investigated and reported by Poulos & Chen (1997), Leung et al. (2003), Elkady (2013), and Aye et al. (2016). However, the in-depth response of the pile caused by excavation in soft clay is still not fully understood.

For many practical engineers, pile movement caused by basement construction is not fully aware. Figure 1a shows inclined bored piles caused by excavation works using cut-slope excavation and unbraced sheet pile walls. This pile movement causes pile integrity problem that requires remedial work.

To avoid disputes between the piling contractor and the excavation works contractor, survey markers are installed on the pile head to collect the initial location of the pile after piling works as shown in Figure 1b. When the excavation of the basement started, the pile location was measured to compare the movement of the pile caused by basement construction.

The objective of this paper is to provide a better understanding of pile behavior subjected to lateral movement caused by excavation works for basement construction. Parameters affecting the lateral movement of the pile, induced bending moment, and time-dependent movement are investigated.



(a) (b)

Figure 1. (a) Deviated pile induced by excavation; (b) Pile location measurements using survey method.

2 GEOTECHNICAL INFORMATION

To understand the ground response due to excavation, typical geotechnical data of Bangkok is described below.

2.1 Typical soil profile

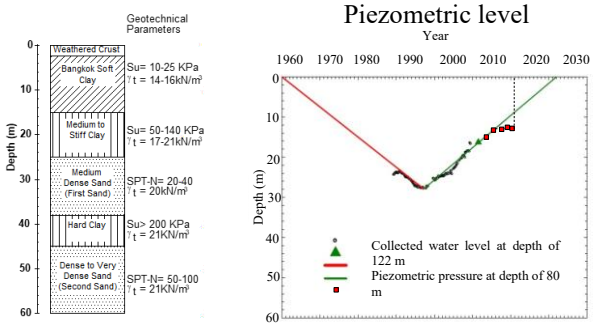
Bangkok's typical soil profile is shown in Figure 2a. A thick Bangkok soft marine clay layer (about 12-18 m thick) is located at the top followed by a thin layer of medium clay underlying alternating layers of stiff clay and dense sand. The undrained shear strength of soft clay ranges between 10 and 25 kPa. In stiff and hard clay, undrained shear strengths are about 150 and 200 kPa, respectively. The angles of internal friction (ϕ') of dense sands are estimated to be from 31˚ to 33˚.

2.2 Piezometric level

Apart from the geotechnical parameters, the distribution of measured pore water pressure and estimated trend line is given in Figure 2b. For Bangkok aquifers, there was a decrease in pore water pressure from 1988 to 1997 due to excessive underground water pumping. This effect of pore pressure decrease caused land subsidence. Thus, underground water pumping has been prohibited since 1997. This policy resulted in a recovery in the pore water pressure until 2011. Since 2011, the depth of the groundwater table has been stable at 13 m.

3 OBSERVED PILE MOVEMENT DUE TO EXCAVATION WORKS

Data from two case studies of pile movement due to basement construction is interpreted and presented in this paper.



(a) (b)

Figure 2. (a) Typical Bangkok soil profiles; (b) Piezometric level of Bangkok.

3.1 Case Study 1: Excavation with jet-grout column retaining wall

The basement excavation of Case Study 1 is shown in Figure 3. Excavation depth to the pile head is varying from 3.35 m to 7.75 m. The deep foundation to support the building is bored piles diameter 1.0 with a depth of 50 m. The retaining system comprises three rows of 0.6 m with a depth of 15 m jet-grout column and an I-section driven pile with a dimension of 400 by 400 mm with a depth of 15 m. One and two layers of bracing are used for excavation depths of 3.35 m and 7.75 m, respectively.

According to the measured data, pile movement with the range from 25 to 35 mm was recorded for a pile head level of -3.35m. These movements were

induced by jet-grout installations, pile-driving activities, and basement excavations.

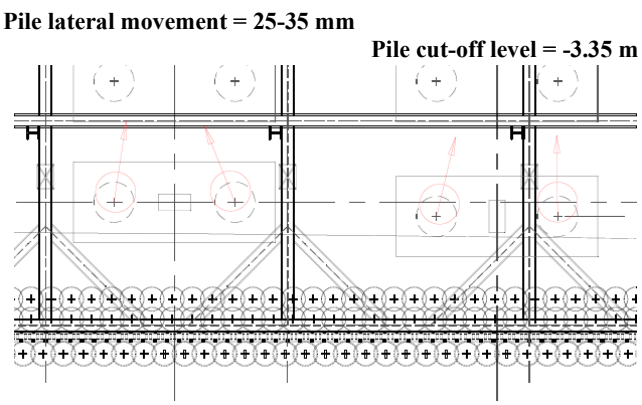


Figure 3. Case study 1: Pile movement due to excavation works using jet-grout column wall.

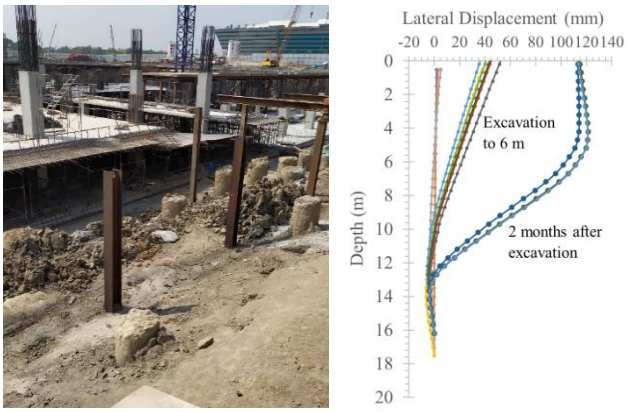
3.2 Case Study 2: Excavation with jet-grout column wall

Construction of the Case Study 2 is shown in Figure 4a. The pile cut-off level of this project is -7.5 m. The excavation method of this project was the cut slope with a horizontal to-vertical distance ratio of 2:1. Inclinometer tubes installed at the crest of the slope are used to monitor the soil movement as shown in Figure 4b. The soil movement induced by excavation works when reaching the maximum excavation depth is 110 mm. After leaving the slope unbraced for 2 months, the maximum soil lateral movement became 122 mm.



(a) *(b)*

Figure 4. Case study 2: (a) Excavation works using slope; (b) Inclinometer measurement in the soil in the slope crest.

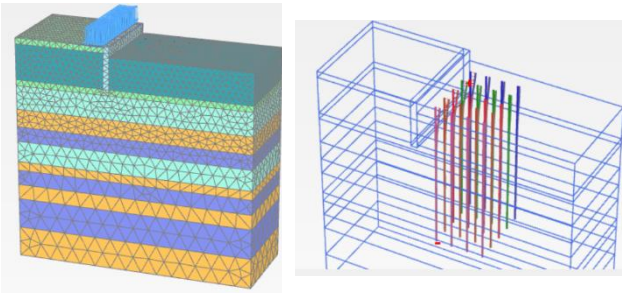
Measured data on the pile markers show that slope excavation caused pile movement from 120 to 140 mm toward the toe of the slope.

4 NUMERICAL ANALYSIS

To assess the effects of excavation on the bored pile inside the excavation area, a three-dimensional numerical back-analysis and parametric study were carried out using the finite element program PLAXIS 3D 2023.

4.1 Mesh and boundary conditions

The finite element mesh used for back-analysis of the monitored results of Case Study 1 is shown in Figure 5a. For brevity of the paper, the mesh of Case Study 2 is not shown. The dimension of the mesh is set to the location near the retaining wall only to minimize the calculation time for three-dimensional analysis. Note that the distance from the wall to the boundary is larger than 3.5 times the excavation depth as reported as influence distance by Wang et al. (2010).



(a) *(b)*

Figure 5. (a) Mesh of three-dimensional numerical analysis; (b) Model piles of the Case study 1.

The boundary conditions of the four vertical sides were roller support while hinge support was applied to the bottom boundary as it is expected no lateral movement at the base. The boundary conditions for water flow are open for all sides and closed for the bottom of the model.

The jet-grout column wall was simulated as soil elements. Bored piles (as shown in Figure 5b) were simulated using embedded beams where friction and end bearing of each pile were taken into account. Fixed-end anchor was used for the temporary bracing. The surcharge simulated in the analysis is 15 kPa.

4.2 Model parameter and sequence of analysis

To back-analyze the result and carry out the parametric study, the Hardening Soil model with Small strain stiffness (HSS) considered (Schanz et al., 1999; Benz et al. 2009) was adopted. Unlike the conventional elastic-perfectly plastic soil model, the HSS model can simulate soil stiffness dependency on stress, strain, and path. Input parameters for Bangkok soil were adopted and modified by Surasak et al. (2012), Likitlersuang et

al. (2013), and Aye et al. (2016). All parameters are summarized in Table 1.

The sequence of numerical analysis is as follows. First, generate the initial conditions of stress in soil and pore water pressure. Construct retaining wall and bored pile. Apply surcharge and excavate soils in undrained conditions. For time-dependent behavior, perform consolidation analysis, which is a fully hydro-mechanically coupled analysis, for 60 days to simulate the actual time of construction on site.

4.3 Numerical parametric study

To extend a better understanding of pile behavior due to excavation activity, a series of three-dimensional numerical parametric studies were carried out.

Factors affecting the pile movement including pile diameter, distance of the pile to the retaining wall, and depth of excavation are investigated.

Table 1. Summary of input parameters.

Part 1

Soil Type	From (m)	To (m)	c' (kPa)	ϕ' (°)	Ψ' (°)	E_{50}^{ref} (kPa)	E_{oed}^{ref} (kPa)
Medium stiff clay	0	2	5.0	27	0	5,150	6,425
Soft clay	2	14	1.0	27	0	800	850
Medium stiff clay	14	16	5.0	27	0	5,150	6,425
Stiff to very stiff clay	16	24	11.5	28	0	5,150	6,425
Dense sand	24	30	0.1	31	5	27,000	27,000
Hard clay	30	42	11.5	28	0	9,500	12,000

5 INTERPRETATION OF RESULTS

According to the measured results and three-dimensional numerical analysis, the findings are interpreted as described below.

5.1 Effect of pile diameter and pile distance from the retaining wall

Pile head lateral displacements due to excavation using jet-grout retaining wall is shown in Figure 6. The measured pile movement is taken from Case Study 1 (refer to Subheading 3.1 and Figure 3). The measured movement of 1.0 m diameter bored piles ranges from 25 to 35 mm (2.5 – 3.5% Pile diameter, D).

The computed movement of pile diameter 1.0 at the same distance from the retaining wall (X) as in Case Study 1 (X/excavation depth, H of 1.0) is 3.1%D, which is similar to the measured results. It suggests that the 3D numerical model and its parameters can be used to investigate pile response due to basement construction.

For the effects of pile diameter on the induced movement, as expected, the smaller piles are subjected to higher movement than the larger piles. Although the pile head displacements are normalized by their diameter, the normalized movement is still not identical. This is because of pile-soil stiffness interaction. The smaller piles are subjected to larger shear strain, thus the soil stiffness becomes smaller. Also, the flexural rigidity of the smaller pile is much smaller than that of the larger pile.

The pile movement reduces with increasing distance from the retaining wall. At X/H of about 4, the pile lateral movement reduces to about half of that at X/H of 1. It suggests that the major influence of excavation effects on pile movement is about four times the excavation depth.

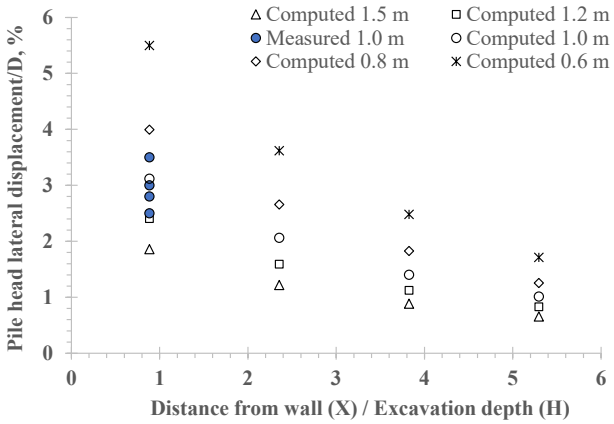

Figure 6. Pile movement for soil-cement column wall.

5.2 Effect of system stiffness on pile lateral movement

For excavation in soft clay, the system stiffness of a retaining system plays a critical role in maintaining the stability of the excavation. The stiffness of the system is important for controlling wall deflection, minimizing ground movements, and ensuring the safety of adjacent structures. Figure 7 shows system stiffness and normalized pile lateral movement with the excavation depth (H). Clough et al. (1989) defined a parameter for system stiffness as $EI/\gamma_w s^4$, where E, I, γ_w, and s are Young's modulus of retaining wall, a second moment of inertia, unit weight of water, and average vertical spacing of strut, respectively.

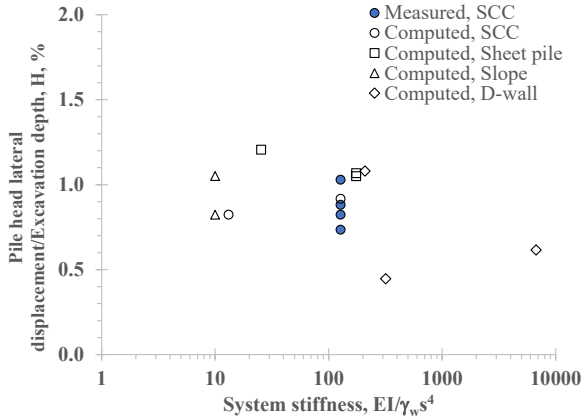

Figure 7. Effect of system stiffness on pile lateral movement.

The results in this figure include that from measured (from Figure 3) and numerical parametric study that varies excavation depth (3.35 m and 6.0 m) and type of retaining system (jet-grouted wall, sheet pile wall, slope excavation, and diaphragm wall).

The general trend suggests that normalized pile lateral displacement decreases with increasing system stiffness. The lateral movement of the pile significantly reduces if the system stiffness is larger than 300. The flexible wall induced significantly larger pile lateral movement than the rigid wall (diaphragm wall). However, when the diaphragm wall is in cantilever condition, the pile movement is still large (1.1%H). This is because no lateral bracing is provided to control the pile movement.

It appears that the excavation depth can be used as the normalizing factor as there is no significant difference in normalized pile movement between the excavation depth of 3.35 m and 6 m.

5.3 Time-dependent pile behavior

The measured data of time-dependent behavior of the pile response due to basement construction and numerical analysis is from Case Study 2 (refer to Figure 4). Figure 8a shows the measured and computed lateral displacement of 0.8 m diameter piles after the excavation depth reached 7.5 m and two months before the casting of the base slab. The location of the piles is on the crest of the slope, where the soil movement measured by the inclinometer was about 122 mm (refer to Figure 4b).

The displacements of the piles are between 85-92 mm and 120 to 140 mm, for the former and the latter, respectively. The computed back-analysis results mainly capture the pile response due to the excavation works.

The extent of depth of pile movement is about 15 m from the existing ground, which is the base of a soft to medium stiff clay layer (refer to Table 1). The lower soil layers (stiff clay, hard clay, and dense sand) provide much larger soil stiffness than the former.

Due to the excavation of the slope, a bending moment was induced in the bored pile as shown in Figure 8b. The maximum bending moment was 230 kN.m on the crest side of the slope. The depth of the maximum bending moment when the excavation reached the maximum depth was 15 m. This depth is the boundary between the soft soil and the stiffer soil. After two months, the depth of the maximum bending moment shifted to 9 m. This is because of the excess pore water pressure dissipation.

To further investigate the time-dependent behavior, excess pore water pressure (Δu) computed from soil elements along the 0.8 m pile at the slope crest is shown in Figure 8c. At depths from 0 to 3 m, the positive Δu up to 120 kPa was induced. This is because of shearing behavior due to soil movement at the slope crest. From a depth of 3 to 8 m, negative Δu occurs. This is due to unloading from excavation works. Two months after the final excavation, the Δu was fully dissipated. This caused the shift in the depth of the maximum bending moment of Figure 8b.

6 CONCLUSIONS

Based on field monitoring, numerical back-analysis, and numerical parametric study results, the following conclusions may be drawn.

(a) The smaller piles are subjected to higher movement than the larger piles, as expected. Although the pile head displacements are normalized by their diameter, the normalized movement is still not identical. This is because the smaller piles are subjected to larger shear strain, thus the soil stiffness becomes smaller. Also, the flexural rigidity of the smaller pile is much smaller than that of the larger pile.

(b) The induced pile movement reduces with increasing distance from the retaining wall. At the distance from the retaining wall to excavation depth ratio (X/H) of 4, the pile lateral movement reduces to about half of that at X/H of 1. It suggests that the major influence of excavation effects on pile movement is about four times the excavation depth.

(c) In general, normalized pile lateral displacement decreases with increasing system stiffness. The lateral movement of the pile significantly reduces if the system stiffness is larger than 300. The flexible wall induced significantly larger pile lateral movement than the rigid wall (diaphragm wall). However, when the diaphragm wall is in cantilever condition, the pile movement is still large (1.1%H). This is because no lateral bracing is provided to restrain the pile head movement.

(d) Pile lateral movement increases by 35% after two months of reaching the maximum depth of excavation. The extent of the pile movement depth is at the boundary between soft soils (soft to medium stiff clays) and stiffer soils (stiff to hard clays).

(e) The soil at the top part (from 0 to 3 m) of the pile registered positive excess pore water pressure. This is because of shearing behavior due to soil movement at the slope crest. From a depth of 3 to 8 m, negative excess pore water pressure occurs. This is due to unloading from excavation works. Two months after the final excavation, the excess pore water pressure was fully dissipated. It caused the shift in the depth of maximum bending moment in the pile from 15 m to 9 m.

ABSTRACT: Reservatório Cerro da Mina is an industrial water reservoir, consisting of rockfill lined by an impervious HDPE membrane. Monitoring showed that the rockfill experienced a few moments of sudden deformation in the first years of operation. The assessment of the environmental conditions in the periods of interest revealed that these more abrupt displacements coincided with periods of intense rainfall, rise in the water level in the reservoir and low evaporation. Both vertical and horizontal deformations of the rockfill showed a tendency of sudden increase when a new maximum in the precipitation record occurred and the precipitation values exceeded the potential evaporation, indicating that the increase in humidity in the rockfill voids led to a significant decrease in the rock pore suction, causing wet-induced collapses in the rockfill. Additionally, except potentially for the first load due to filling, the influence of the oscillation of the water level in the reservoir was not considerable for the vertical displacements, but significant in the horizontal direction.

RÉSUMÉ: Le Reservatório Cerro da Mina est un réservoir d'eau industrielle, constitué d'un remblai en enrochements recouverts d'une membrane imperméable en PEHD. L'auscultation a montré que l'enrochement a connu quelques instants de déformation brusque au cours des premières années d'exploitation. L'évaluation des conditions environnementales au cours des périodes d'intérêt a révélé que ces déplacements plus brusques coïncidaient avec des périodes de précipitations intenses, d'élévation du niveau de l'eau dans le réservoir et de faible évaporation. Les déformations verticales et horizontales de l'enrochement ont montré une tendance à une augmentation soudaine lorsqu'un nouveau maximum dans l'enregistrement des précipitations se produisait et que les valeurs des précipitations dépassaient l'évaporation potentielle, ce qui indique que l'augmentation de l'humidité dans les vides de l'enrochement a conduit à une diminution significative de la succion des pores des blocs rocheux, provoquant des effondrements due au mouillage de l'enrochement. De plus, hormis potentiellement la première charge due au remplissage, l'influence de l'oscillation du niveau d'eau dans le réservoir n'était pas considérable pour les déplacements verticaux, mais significative dans les horizontales.

Keywords: Wet-induced collapse; impervious rockfill dam; rockfill deformations.

1 INTRODUCTION

Reservatório Cerro da Mina (RCM) experienced a few moments of relatively small, yet sudden settlements on the rockfill embankment during the first years of operation. Under constant load, the largest post-constructive settlements are normally anticipated at the beginning of the operation of the dam, and the rates in which strains occur are expected to reduce over time (Oldecop and Alonso, 2007, Kermani et al., 2017). In this case, however, superficial settlement markers, vertical extensometers and inclinometers installed in the rockfill recorded peaks of movements some years after the end of construction and first load due to filling. The moments of increase in the settlement rates coincided with periods of large pluviosity, when the water level in the reservoir and the moisture in the rockfill tend to rise.

The relation between shift in environmental conditions and change in deformation rates are quite known in geotechnical monitoring, and assessing the mechanisms involved can enhance the understanding of the structure's behaviour and provide a better prediction of future movements. This study aims to present monitoring data of the rockfill, correlate with the conditions existent in the moments of sudden deformation and, based on that assessment, explain the mechanisms involved.

2 ROCKFILL CHARACTERISTICS

RCM is a 1,45 hm^3 industrial water reservoir located in Castro Verde, Portugal. The embankment consists, on the west side, of a main embankment with a maximum height of approximately 30 m, and on the north side, of a saddle embankment of 11 m on its highest section. Due to chemical activity of the industrial water stored, the reservoir is operated considering zero discharge to the environment. A double lining system was installed, consisting of a 2,5 mm HDPE membrane, lying on a geocomposite clay liner. The embankment was constructed with sound or moderately weathered greywackes excavated from the pond area, according to the zoning in Figure 1:

- Type A: support material for the lining system. Only sound greywacke rock used. Less than 5% of fines, 40 mm ≤ D100 ≤ 60 mm; 3,3 mm ≤ D50 ≤ 12 mm.
- Type B: filter for materials type A and C. Only sound greywacke rock used.
- Type C: good quality material, well compacted rockfill with high deformability modulus. Only sound greywacke rock used. Less than 5% of fines, 300 mm ≤ D100 ≤ 600 mm; 20 mm ≤ D50 ≤ 150 mm.
- Type D: random finer rockfill. Use of moderate weathered greywacke rock allowed. Less than 5% of fines, 60 mm ≤ D100 ≤ 280 mm; 7 mm ≤ D50 ≤ 55 mm.
- Type E: protection layer. Blocks between 50 mm and 800 mm.

The geomechanical characterization of the rockfill was executed in two phases. For the design, samples from not so fresh greywacke were tested. In the beginning of construction, fresh greywacke from the experimental fills was tested to validate the design assumptions. The main results are shown in Table 1.

3 DISPLACEMENT MONITORING

The monitoring plan of RCM was conceived according to the Portuguese dam safety regulation and specificities of the reservoir. Regarding the assessment of displacements on the rockfill, there are 25 superficial survey beacons installed on the crest, 17 of which located on the main embankment and 8 on the saddle embankment. There are 3 inclinometer casing tubes, each one associated to vertical extensometers (consisting of magnetic rings) in different elevations of the rockfill. Additionally, the water level on the reservoir is recorded daily and a meteorological station measures precipitation and evaporation potential.

Table 1. Index-properties of greywacke rockfill (mean ± standard deviation [number of samples]).

Parameter	Design phase	Construction
Apparent density (kgm^{-3})	2581 ± 17 [10 samples]	2588 ± 33 [6 samples]
Porosity	4.81 ± 0.83 [10 samples]	4.25 ± 0.71 [6 samples]

Crushing – Pa_{50} air dried (kgf)	1219 ± 378 [4 samples]	1033 [1 sample]
Crushing – Pa_{50} saturated (kgf)	690 ± 218 [4 samples]	506 [1 sample]
Los Angeles abrasion test	39.0 ± 5.7 [2 samples]	27 [1 sample]
Slake durability – 7th cycle, dry	2.5 ± 0.3 [4 samples]	-
Slake durability – 7th cycle, wet	7.2 ± 2.7 [4 samples]	-
Maximum water content (%)	1.86 ± 0.35 [10 samples]	1.65 ± 0.27 [6 samples]

This study will present the analysis of the inclinometer and extensometers installed in the centre of tallest section of the rockfill, IB3. Table 2 presents the initial elevation of the extensometers.

Table 2. Initial elevation of extensometers in section IB3.

Extensometer	Initial elevation (m)
IB 3 – Ring 9	238.215
IB 3 – Ring 8	235.079
IB 3 – Ring 7	232.088
IB 3 – Ring 6	228.959
IB 3 – Ring 5	225.859
IB 3 – Ring 4	222.731
IB 3 – Ring 3	219.654
IB 3 – Ring 2	216.541
IB 3 – Ring 1	213.465
Datum	211.920

Figure 2 presents the total vertical displacements measured and Figure 3 the post-construction vertical displacements measured in the extensometers IB3. As expected, the readings suggest that the largest deformations occurred during the construction and initial months after its completion. The form of the vertical displacement curves in the first year (between the end of 2013 and November of 2014) was similar to the expectations, with the general shape resembling a logarithmic relation in time, steeper in the beginning,

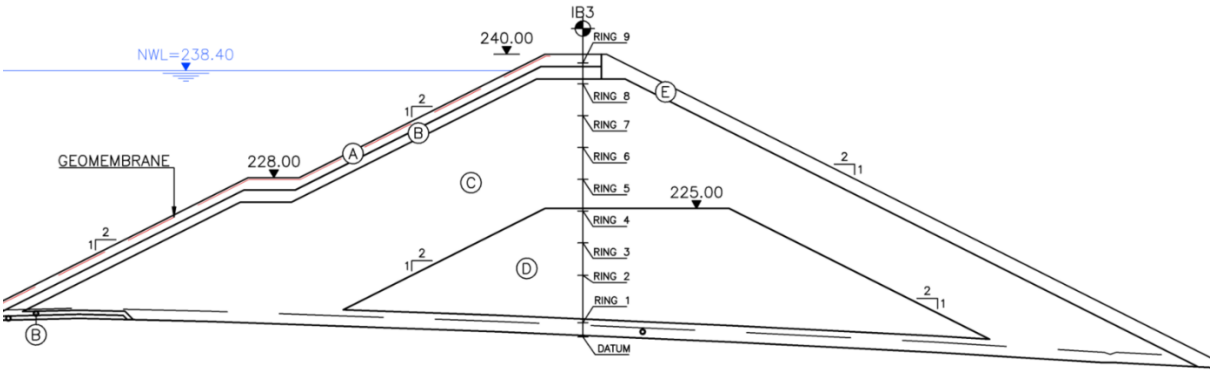

Figure 1. Typical cross section of RCM (adapted from Cenor, 2010).

reducing inclination after the first few months and showing a tendency to future stabilization. In addition to these predictable significant movements recorded in 2014, it is possible to notice though three moments of abrupt settlement: in the last months of 2014 and the first months of 2017 and 2018.

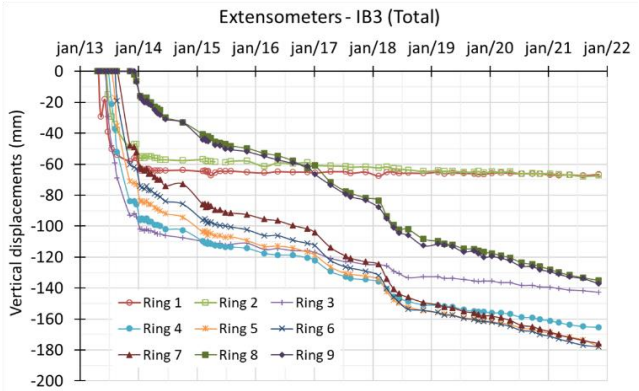

Figure 2. Total vertical displacements at IB3.

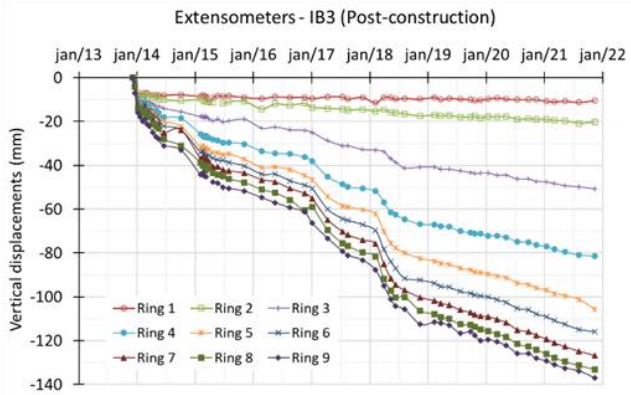

Figure 3. Post-construction vertical displacements at IB3.

Figure 4 presents the horizontal displacements in the main axis of inclinometer IB3. To associate the displacements in the vertical and horizontal directions of the rockfill, Figure 5 depicts the evolution of horizontal movements in the points of the inclinometer at the closest elevations of the magnetic rings. These readings suggest a significant increase in the horizontal displacement at the three moments previously identified in the vertical direction. Additionally, these instruments also show the tendency of a periodic horizontal movement of the embankment, superposed with those discussed moments of abrupt displacement and with long-term deformations. These fluctuating movements are significant smaller than the recorded in the moments of abrupt vertical deformation, but still evident.

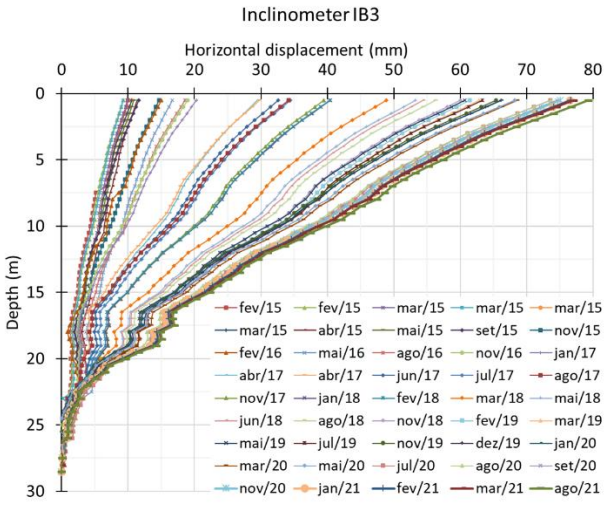

Figure 4. Horizontal displacements at inclinometer IB3.

Figure 6 presents the relations between post-constructive vertical and horizontal displacements for the extensometers on IB3. In terms of this relation, an interesting aspect is that the ratio in which the displacement of the rings occurred did not show any tendency of shift caused by the collapses. Except for the extensometers located at the lowest elevation (Rings 1 and 2), which did not exhibit clear tendencies in any direction, the trends of the ratio of vertical and horizontal displacements remained virtually unchanged after the collapses, suggesting that these events affected the movements in both directions in a similar manner. It is also noticeable that the ratio between vertical and horizontal displacement tends to increase with depth.

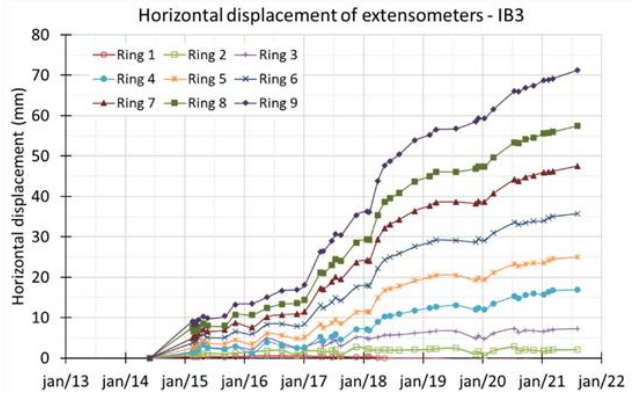

Figure 5. Horizontal displacements elevations equivalents to the vertical extensometers at IB3.

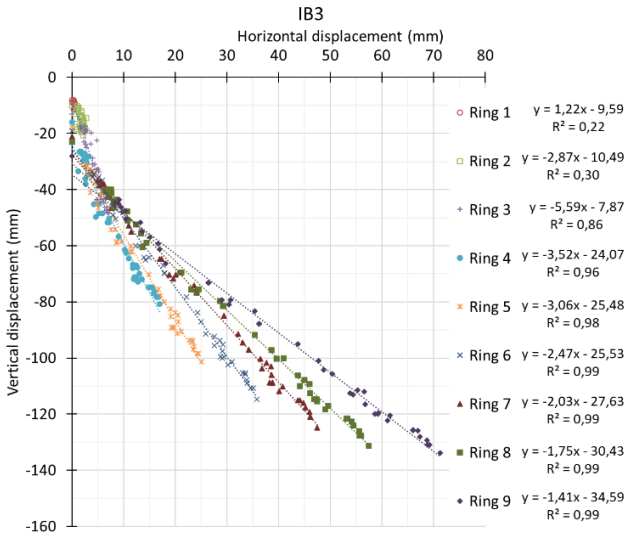

Figure 6. Relation between vertical and horizontal post-constructive displacements on IB3 section.

4 ENVIRONMENTAL CONDITIONS AND DEFORMATION MECHANISMS

Figure 7 presents the monthly measurements of precipitation and potential evaporation. The moments of abrupt movements recorded in the displacements monitoring devices coincide with intense pluviosity and low potential evaporation. The sudden deformation due to intense wetting of a rockfill mass can be often linked to the well-known phenomenon of wet-induced collapse, which is associated to the increase of humidity in the rockfill voids, causing a reduction of suction in the pores of the rock particles (Alonso and Cardoso, 2010, Alonso and Tapias, 2019). This loss of suction permits the fractures of the rock elements to suddenly propagate at a much higher velocity, causing rapid particle breakage, leading to rearrangement of these fractured elements and consequent reduction of the rockfill voids. This phenomenon is expected to occur every time a new lowest value of suction is reached in the rock pores, until zero suction is reached for the first time (Alonso et al., 2005).

All 3 moments of abrupt increase in displacement rates correspond to the highest record of accumulated precipitation until that moment. In addition, no historical maximum occurred without an abrupt settlement, causing this interesting one-to-one relation. Furthermore, in every moment of abrupt settlement, the amount of precipitation surpassed the potential evaporation, which occurred only a few times (17 of 108 months) in the period of monitoring. It should be acknowledged, though, that the excess precipitation for the second collapse does not correspond to a new maximum. It is consistent, however, to the largest period recorded in which the balance of rainfall is positive: 3 consecutive months. These observations indicate that wet-induced collapse is probably the mechanism responsible for the abrupt settlements recorded in the rockfill.

Figure 8 presents the variation of water level in the reservoir. Despite acknowledging pluviosity as the main cause for the deformations, it is possible that the variations of the water level in the reservoir have also affected the deformations of the rockfill, and therefore their influence should be assessed as well. Since RCM has an impervious HPDE membrane internally, the influence of the water level is restricted to the load on the embankments, without any percolation on the rockfill or foundation directly associated to the pond. Table 3 presents the variation in the cartesian stresses calculated by a stress-strain model of the section of inclinometer IB3, estimated in points halfway between the rings, comparing before and after the filing of the reservoir. The results show that the variation in the vertical stress due to filling is practically negligible in the vertical direction, but significant on the horizontal direction.

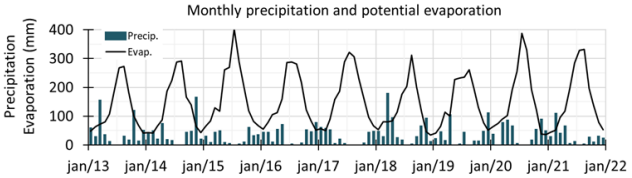

Figure 7. Monthly precipitation and potential evaporation.

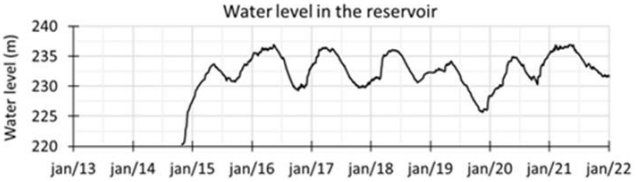

Figure 8. Water level in the reservoir.

Table 3. Variation of vertical and horizontal stresses with filing of the reservoir.

Elevation	Variation on effective stress	
	Vertical	Horizontal
Datum - Ring 1	+2,7%	+1,9%
Ring 1 - Ring 2	+2,5%	+5,2%
Ring 2 - Ring 3	+2,2%	+10,0%
Ring 3 - Ring 4	+2,0%	+17,4%
Ring 4 - Ring 5	+1,7%	+25,4%
Ring 5 - Ring 6	+1,1%	+31,7%
Ring 6 - Ring 7	+0,8%	+36,1%
Ring 7 - Ring 8	+0,4%	+28,0%
Ring 8 - Ring 9	+0,3%	+9,2%

Another relevant aspect regarding the variation of the reservoir level is that none of the 3 moments of collapse corresponded the maximum level recorded in the reservoir. In that matter, in the first semesters of 2016 and 2021 water levels were higher than in any of the moments of abrupt deformation, and on these occasions the movement rates did not show significant increase.

Besides the small effect on the vertical stress underneath the centre of the crest and the fact that the moments with the highest water level do not correspond to the highest settlement rates, two other relevant aspects support the conclusion that variation of water load does not play a key role in the abrupt vertical displacements. First, the extensometers and superficial settlement beacons did not exhibit any clear tendency of swell associated to the partial drawdowns of the reservoir. If those increases in vertical stress were the main cause for additional compression of the rockfill, decreases should produce some level of extension – or at least significant reduction in the settlement rate –, which did not happen. The second point relates to the fact that after the maximum load was reached for the first time, the rockfill would be subject to unload-reload cycles, in which the stiffness of the material would be substantially higher. Therefore, the deformations associated to the fluctuation in the reservoir level following that moment should be much smaller than the associated to the first filling, differently from what really occurred.

Concluding that collapse due to wetting is the main mechanism responsible for the abrupt settlements recorded in RCM suggests that Rings 1 and 2 of all extensometers, which did not show clear pattern shift for their deformation trends through time, probably have reached very low values of suction (perhaps even zero) at least once, probably during construction were seepage may have happened before the lining installation. There are no measurements to confirm that proposition, but these are the rings located at the lowest elevation in the rockfill, placing them closer to the bedrock seepage and further from the atmosphere, thus less subject to evaporation in dry periods than the more superficial rings.

Regarding the association with environmental conditions and measurements of the inclinometers, substantial increases in the horizontal displacements were recorded concomitantly to the abrupt settlements. In the moments of wet-induced collapse, the horizontal movements essentially follow the same behaviour registered for the vertical displacements. Therefore, all considerations made regarding the association of settlements and pluviosity is valid for the horizontal movements as well. The moments of the 2nd and 3rd collapses are quite evident, and although before the 1st collapse there was only the initial measurement 8 months earlier, the horizontal displacements registered next are substantial, suggesting that a collapse could have happened.

On the other hand, the important influence of the water level in the reservoir on the horizontal stress acting on the rockfill is fairly noticeable on the displacements recorded in the inclinometers, contrasting with the reduced impact seen in the vertical direction. Occurring simultaneously with long-term deformations, the oscillation of horizontal movements related to the fluctuation on the water level is very clear. The superposition of these two phenomena produces a curve that resembles a periodic relation (due to the variation in the water level) around an inclined axis (due to the time dependent deformations). Rises on the reservoir levels tend to produce larger horizontal movements, while partial drawdowns generates slowing or even recuperation of those displacements. Nevertheless, the influence of wet-induced collapses still is much more prominent in terms of total displacements, with a substantial portion of all horizontal measurements being caused by them.

5 CONCLUSIONS

The analysis of the instruments monitoring movements of the embankment in association with the environmental conditions allowed to conclude that the mechanism responsible for the unexpected abrupt settlement registered in the embankment was wet-induced collapse, a very well-known post-construction deformation mechanism for rockfill. The main arguments to support this proposition are based on the fact that all collapses recorded were associated to a new maximum in the precipitation historical series, and every time a new maximum was registered, a collapse occurred. Also, every collapse occurred in months in which precipitation exceeded potential evaporation, suggesting that an increase in humidity in the rockfill was probable. The analysis of the

fluctuations of the water level in the reservoir permitted to conclude that these oscillations represented a small change in the vertical stress underneath the centre of the crest, making improbable the association of these events to the rapid settlements. Moreover, no abrupt deformation was recorded when the water level reached its maximum, and the extensometers and superficial beacons never registered swell associated to the reduction of load due to partial drawdowns of the reservoir.

All these evidences support the conclusion that the influence of the variations of the water level in the reservoir is probably very reduced and, if existent, restricted to the first filling. In addition to that, the general behaviour registered by the extensometers and superficial settlement beacons in RCM were very similar to typical deformation curves of rockfill upon wetting (Justo, 1990, Alonso et al., 2005, Alonso and Cardoso, 2010, Oldecop and Alonso, 2007).

The inclinometers demonstrated substantial increases in the horizontal movements in the same moments that abrupt settlements were recorded in the extensometers, suggesting that wet-induced collapse causes deformation in both directions. However, differently from what happened with vertical displacements, measurements in the inclinometers showed that fluctuations in the water level have impact in the horizontal movements of the rockfill. Rises in the reservoir are coincident with increases in the horizontal displacements rates, as well partial drawdowns are followed by reduction in the movements rates, eventually even indicating some recuperation in the displacements. Nevertheless, this influence is only perceptible in the periods when no collapses occur, since when the mechanisms overlap the displacements due to plastic strains are considerably larger.

ABSTRACT: The reinforced fill structures are well-known and established worldwide as an economic and ecological valuable construction method. In many countries, standards and recommendations exist for reinforcing steep slopes, walls, and other applications. On the European level until now, there was only a standard for the execution of such construction available, but no standard for the design. With the second generation of Eurocode 7 (EN 1997), this gap is filled. Specific requirements for reinforcing materials (geosynthetics, steel, polymeric coated steel woven wire meshes) and specific requirements for the reinforcing elements due to the environment and their interaction with the fill material are provided with basic design approaches and appropriate partial factors.

RÉSUMÉ: La technique des remblais renforcés est reconnue dans le monde entier comme une méthode de construction économique et écologique. Dans de nombreux pays, il existe des normes et des recommandations pour le renforcement des pentes raides, des parois, et d'autres applications. Au niveau européen, il n'existait jusqu'à présent qu'une norme pour l'exécution de ce type de construction, mais aucune norme pour leur dimensionnement. La seconde génération de l'Eurocode 7 (EN 1997) comble cette lacune. L'Eurocode 7 fournit des règles spécifiques pour les matériaux de renforcement (géosynthétiques, acier, treillis métalliques enduits de polymères) ainsi que des exigences spécifiques pour les éléments de renforcement tenant compte de leur durabilité et de leur interaction avec le matériau de remplissage avec des approches de dimensionnement et des facteurs partiels appropriés.

Keywords: Reinforced fill structures; soil reinforcement; geosynthetics; steel; polymeric coated steel woven wire meshes.

1 BACKGROUND

Reinforced fill structure is a well-known technique and established worldwide. In many countries, standards and recommendations exist for reinforcing steep slopes, walls, and other applications. On the European level, there is only a standard for the execution of such construction: EN 14475, but no standard for the design. With the new generation of Eurocode 7 (EN 1997) a clause is introduced, developed from the various national design standards, to fill this gap.

Reinforcement materials such as geosynthetics and steel are used for decades and the material properties and their testing are regulated in different European standards. Combined products such as polymeric coated steel woven wire meshes are currently difficult to use in practice or cannot be used with an equivalent level of safety and robustness because they cannot be clearly assigned to known material groups and because they do not have appropriate standards. This situation is solved with the new EN 1997 by specific rules for these products.

The clause "Reinforced Fill Structures" (EN 1997-3, Clause 9) is part of EN 1997 and the design principles are defined elsewhere in the code (EN 1990, EN 1997-1 and -2). Also is the calculation of overall stability of slopes and embankments (EN 1997-3, Clause 4), of the bearing and sliding resistance (EN 1997-3, Clause 5) and of the static equilibrium (EN 1997-3, Clause 7) defined in the aforementioned clauses. EN 1997-3, Clause 9 therefore concentrates on the effect of the reinforcement used and the special features of the interaction between fill material and reinforcement and their consideration in the design.

This publication does not intend to go into details of EN 1997-3, Clause 9, but tries to highlight the important topics.

2 FIELD OF APPLICATION

EN 1997-3, Clause 9 deals with all kinds of applications where engineered fill (not asphalt) is reinforced. Reinforcing of ground (not engineered

fill) is dealt in other clauses (e.g. Clause 8 Anchors, 10 Soil nailed structures, 11 Rock bolts and rock surface support, 12 Ground improvement).

Especially mentioned are reinforced walls and abutments, reinforced slopes, basal reinforcement for embankments (including load transfer platforms over inclusions and areas prone to development of voids) and reinforcement along slope surface (veneer reinforcement) (see Figure 1).

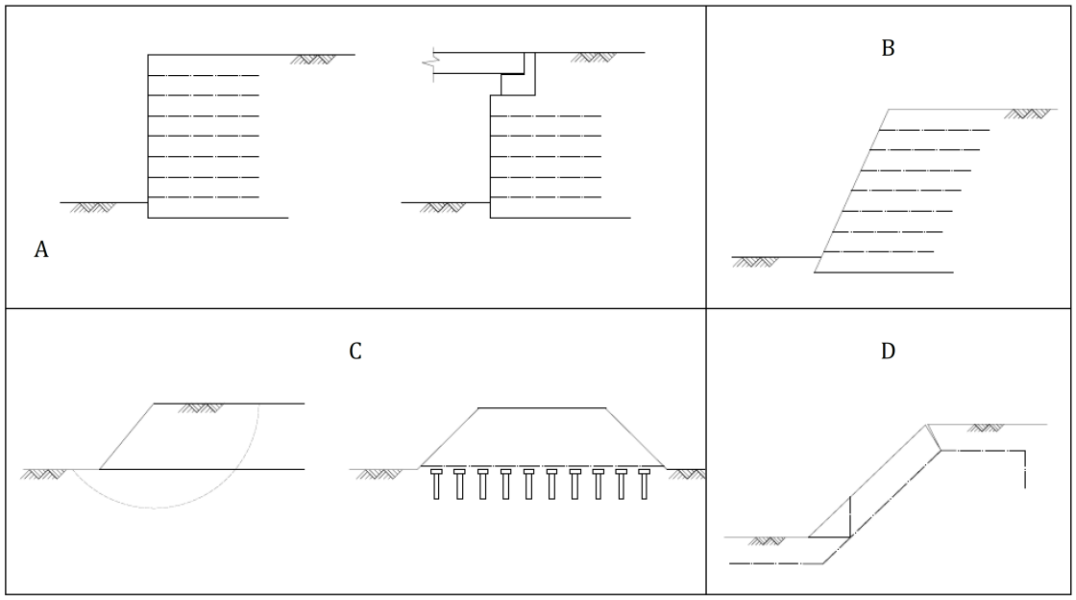

Figure 1. Reinforced fill structures: A - reinforced wall and abutments, B - reinforced slope, C - basal reinforcement for embankments (including load transfer platforms over inclusions and areas prone to development of voids), D - Veneer reinforcement (EN 1997-3, Clause 9).

Geotextile encased columns are covered in EN 1997-3, Clause 12 “Ground Improvement”.

3 BASIS OF DESIGN

General design principles (e.g. design situation, geometrical properties, zone of influence, actions), given in EN 1997-1, are also valid for reinforced fill structures.

3.1 Environmental influences

An exception are the environmental influences as they may affect the reinforcing material directly. Chemical components of ground (soil outside the reinforced construction) or groundwater may influence the durability of all reinforcement as well as ultra violet exposure and high temperature especially for polymeric based reinforcement. Therefore their properties have to be tested in the appropriate extent.

3.2 Ultimate limit states

The ultimate limit states are described and defined by EN 1997-3, Clause 9 in detail. On the one hand, they refer to other clauses when the reinforcement has no influence (e.g. failure entirely outside of the reinforced fill structure):

- calculation of overall stability of slopes and embankments (EN 1997-3, Clause 4);
- calculation of the bearing and sliding resistance (EN 1997-3, Clause 5);
- calculation of the static equilibrium (EN 1997-3, Clause 7).

On the other hand, they are specific whenever the reinforcement is involved in the failure mechanism, mainly:

- rupture of the reinforcing element;
- rupture of any connection between a reinforcing element and a facing element of the structure (reinforcement at the connection, facing element at the connection, connector);
- rupture of any seam or joint between the reinforcements themselves;
- failure along slip surfaces that pass wholly or partially through the reinforced block, either through the fill or along a reinforcement (sliding);
- failure at the interface between the fill and the reinforcing element (pullout).

Besides other aspects also the topic “excessive deformation” of the reinforced fill structure is mentioned as an ultimate limit state (and not as a serviceability limit state), because this might cause failure of nearby structures. Many published

measurements however show that the deformations of well-designed reinforced structure are at no risk and that the structures are ductile due to the reinforcement used.

A particular concern in the drafting of this clause was the clear separation of failure mechanisms that affect the reinforced fill body and those that exclusively affect the facing and the connection of the reinforcement there. Therefore, possible ultimate limit states for the facing system are mentioned, mainly:

- structural and equilibrium failure of the facing element;
- connection failure between reinforcement and facing units;
- shear failure between face elements i.e. bulging;
- shear failure between face elements and reinforcements.

It is obvious that the most critical failure mechanism (whichvere ULS it originates from) has to be found wherever it occurs in the reinforced fill structure.

3.3 Serviceability limit states

The serviceability limit states deal with the different deformations that might occur. The consideration of the following main topics are listed:

- deformations of the reinforced fill structure itself;
- differential settlement along the facing due to subsoil deformation;
- differential movement between facing and reinforcing elements;
- deformation of the reinforced fill structure, which can cause serviceability limit states of nearby structures or services that rely on it;
- deformations of the facing system.

Although the items are obvious, the calculation with analytical methods is often not possible. The calculation of the settlement of a structure is standard, but horizontal deformations depend on the interaction of reinforcement and fill material and soil. The behaviour can, if at all, generally only be determined using numerical methods or estimated using measurements on existing monitored structures.

4 MATERIALS

The chapter “Materials“ deals with all materials involved, whereas for “engineered fill“ material within the reinforced zone and the “ground“ (soil outside the reinforced zone) only references are also given. Specific requirements are given for the materials used as reinforcement or for the facing system.

4.1 Geosynthetics

For geosynthetics, a lot of European standards are available. The most relevant standard is EN 13251 which deals with the characteristics of geotextile-related products required for use in earthworks, foundations and retaining structures and the marking of these products. Relevant tests needed for reinforcements are referred, mainly for the determination of their characteristic tensile strength (T_k) based on EN ISO 10319. In order to use this value T_k for the design service life, reduction factors (well known in most national standards) must be taken into account for the:

- tensile creep rupture or excessive deformation due to sustained static load at the design temperature;
- mechanical damage during transportation, installation and execution;
- weathering;
- chemical and biological degradation at the design temperature;
- intense and repeated loading (fatigue);
- joints and seams between geosynthetic reinforcing elements.

Reference is especially made to ISO/TS 20432 for the determination of these reduction factors, which may mean adjustments to the partial safety factors discussed later when implemented in national standards (e.g. National Annex to EN 1997).

4.2 Steel

For reinforcement made of steel (strips, bars or rods, wire meshes, etc.) the appropriate material standards are referred as well as the standards for galvanization. The main issue with steel is corrosion which is introduced by using the net reduced cross-sectional area of the reinforcing element, allowing for the effects of potential corrosion. For determining this value, requirements are given based on electro-chemical properties (cf. EN 14475:2006) by corrosion parameters for galvanized and non-galvanized steel with or without water and corrosion concentration factors taking into account the geometry and dimensions of the steel reinforcement.

Long-term effects of sustained load in reinforcement (creep), long-term changes in fill properties, and potential damage of the reinforcement during transport, storage and installation shall be considered anyhow.

4.3 Polymeric coated steel woven wire meshes

Polymeric coated steel woven wire meshes as reinforcement material are a mixture of the above-

mentioned steel and polymeric components. This leads to confusion in the practice, because often not appropriate rules for steel or geosynthetics are used leading to an economical benefit of the polymeric coated steel woven wire meshes. Here EN 1997-3, Clause 9 is attempting for the first time to specify a clear procedure for this specific material. As for the other materials, reduction factors are defined for the effects of mechanical damage to the steel during transportation, installation, and execution and for the adverse effects of degradation of the element by corrosion over the design service life of the structure. The latter factor is to be determined due to the local loss of protection caused by mechanical and chemical damage to the polymeric coatings in the long term. The loss of strength of the material for the service life of the structure has to be determined due to the long-term effects of sustained load in reinforcement (creep) and long-term changes in fill properties.

4.4 Material for facings

There is a great variety of materials for the facings. The main materials (concrete, steel, masonry, timber) are mentioned with their appropriate Eurocode or material standards.

4.5 Other materials

For all reinforcement and facing materials, an opening phrase is given to allow the use of not-mentioned materials and to allow the development of new materials. They have to follow appropriate material standards, that might be defined in national standards (e.g. National annex to EN 1997).

5 GEOTECHNICAL ANALYSIS AND ULTIMATE LIMIT STATES

For the calculation of external and compound failure mechanisms in a reinforced fill structure, the references are given to other clauses whereas the benefits of the reinforcing elements are described in Clause 9.

For internal failure mechanisms and for design procedures specific to the application, different approaches exist in Europe. They are mentioned with references to the national standards and recommendations, mainly (in alphabetic order):

- ASIRI, Recommandations pour le dimensionnement, l'exécution et le contrôle de l'amélioration des sols de fondation par inclusions rigides;
- BS 8006-1, Code of practice for strengthened / reinforced soils and other fills;
- CUR 226 Design guideline basal reinforced piled embankments;
- EBGEO, Recommendations for design and analysis of earth structures using geosynthetic reinforcements;
- NF P 94 270 Calcul géotechnique - Ouvrages de soutènement - Remblais renforcés et massifs en sol cloué.

Reinforced slopes, walls, and bridge abutments should be verified using one or more of the following:

- coherent gravity method;
- tie-back wedge method;
- multiple wedge method or;
- slope stability methods.

Basal reinforcement for embankments, load transfer platforms over discrete ground improvement, overbridging systems and veneer stability are also listed in EN 1997-3, Clause 9 with their essential requirements. Detailed design approaches still have to be defined or developed by national bodies.

The effect of a reinforcing element for the calulation is based on the tensile resistance (determined specific for each type of reinforcing material), the pull-out resistance and the resistance in direct shear. The latter two resistance values are determined in EN 1997-3, Clause 9 for sheet and discrete reinforcement elements. Each value gets assigned a partial factor of safety that are presented in Table 1. The table shows in the first three lines the references to the design procedures in the basic clauses for the aforementioned failure mechanisms. For the internal failure mechanisms, the references to EN 1990:2023 and the Verification Cases (VCs) are given.

The following lines of the table present the partitial factors to be adopted for the reinforcing and the facing elements whenever such an element is impacted by a failure mechanism. The presented values are the result of a european compromise leading to higher and lower values compared to the actual national standards. They are selected in such a way that a design with them enables a safe construction taking into account that the reduction factors are derived based on the procedure described in the “Material“ section (e.g. for geosynthetics especially according to ISO/TS 20432).

As the table is NDP (national determined parameter), each country has the possibility to define other values in national standards. They can be defined e.g. by comparative calculations ensuring the continuity of their current level of safety.

Table 1. Partial factors (NDP) for the verification of resistance of reinforced fill structures for fundamental (persistent and transient) design situations from EN 1997-3, Clause 9.

Verification of	**Partial factor on**		**Symbol**	**Material Factor Approach**	**Resistance Factor Approach**
Overall and compound failure mechanisms	See Clause 4				
Bearing resistance and sliding	See Clause 5				
Overturning	See Clause 7				
Internal failure mechanisms	Actions, Effect of actions		γ_F, γ_E	VC3[a]	VC1 [a]
	Ground properties		γ_M	M2[b]	Not factored
Pull-out and direct shear	Pull-out resistance of reinforcement		$\gamma_{R,po}$	Not factored	1,25
	Resistance to direct shear along interface		$\gamma_{R,ds}$	Not factored	1,25
Rupture of reinforcing element	Tensile resistance of	geosynthetic reinforcement	$\gamma_{M,gs}$	1,25	
		structural steel per EN 10025-2 or EN 10025-4	γ_{M0}	specified in EN 1993-1-1	
			γ_{M2}	specified in EN 1993-1-1	
		reinforcing steel per EN 10080	γ_S	specified in EN 1992-1-1	
			γ_t	1,25	
		polymeric coated steel wire mesh reinforcement	$\gamma_{M,pwm}$	1,25	
Rupture of connections to facing	Tensile resistance at connection	Reinforcement	$\gamma_{R,con,el}$	As specified above for rupture of reinforcement	
		Connector	$\gamma_{R,con,c}$	As specified in the relevant material Eurocode	
		Facing element	$\gamma_{R,con,f}$	As specified in the relevant material Eurocode	

a Values of the partial factors for Verification Cases (VCs) 3 and 4 are given in EN 1990:2023, Annex A.

b Values of the partial factors for sets M1 and M2 are given in FprEN 1997-1:2024, Table 4.8.

6 GEOTECHNICAL ANALYSIS AND SERVICABILITY LIMIT STATES

The clause about serviceability limit states simply refers to previous clauses 4, 5 and 7. As the modelling of the system “fill material/reinforcement“ is still not finally solved, it is rarely possible to use analytical methods. With numerical methods the behaviour could be modelled in some cases, but have to be verified with site experience. As this is often not possible or cost- and time-consuming, EN 1990:2023 allows the omission of the verification of serviceability limit states of reinforced fill structures provided that ultimate limit states are verified.

7 FINAL CHAPTERS AND ANNEX

The last chapters in EN 1997-3, Clause 9 are following the general structure of EN 1997-3 and give general hints and references for the implementation of design (inspection, monitoring and maintenance), testing and reporting.

The (informative) annex to this Clause 9 has a long history from a short version via a version as a handbook back again now to a very short version. The final consideration of the involved countries was that each country will prepare its own annex. Countries that want to adopt the annex directly should be warned that a design of reinforced structures with this standard and its default annex version will still require additional contribution from other guidelines regarding the details of design. The standard aims to provide only a general framework for design.

8 CONCLUSIONS

With the 2nd generation of EN 1997-3 a widely recognized, often already nationally standardised, economic and sustainable construction method is harmonised at the European level and makes it available to a wider range of users. This is a major step, but one that has also involved many years of work. The base for the design is now given in the 2nd generation of EN 1997, although details and checks of the safety levels to be achieved are still pending at the beginning of 2024. Also updates of related standards have to follow (e.g. EN 14475).

ACKNOWLEDGEMENTS

The present clause "Reinforced Fill Structures" of EN 1997-3 2nd Generation is based on preliminary work in various working groups since 2011 under the leadership of my predecessors Martin Vanicek (Czech Republic) and Nicolas Freitag (France). The active members of all working groups until now have been consistently active over many years with great commitment, great tenacity and a strong desire for agreement and harmonization. I want to take this opportunity to express my sincere thanks to all of them!

The text of this paper contains many phrases derived from EN 1997-3, Clause 9 which is the nature of things. Many thanks to CEN/TC 250/SC 7 for their understanding and support.

The implications of poor leadership on geotechnical risk

Les implications d'un mauvais leadership sur le risque géotechnique

C.A. Bridges*
Queensland University of Technology, Brisbane, Australia
**chris.bridges@hdr.qut.edu.au*

ABSTRACT: Major infrastructure projects require that a wide range of design and construction specialists be fully integrated in order to achieve the project goals. Of critical importance to these projects are the geotechnical engineers who work on the project from investigation through design and onto construction. The failure of geotechnical teams and engineers to adequately integrate into a wider team can result in greater risks being taken by the project. Through a case study of a major infrastructure project, this paper discusses how issues can arise and the consequences that can result. It then presents thoughts on how they can be overcome with appropriate leadership and management.

RÉSUMÉ: Les grands projets d'infrastructure nécessitent qu'un large éventail de spécialistes de la conception et de la construction soient pleinement intégrés afin d'atteindre les objectifs du projet. Les ingénieurs géotechniques qui travaillent sur le projet depuis l'enquête en passant par la conception et jusqu'à la construction sont d'une importance cruciale pour ces projets. L'incapacité des équipes géotechniques et des ingénieurs à s'intégrer adéquatement dans une équipe plus large peut entraîner une prise de risques plus importante pour le projet. À travers une étude de cas d'un projet d'infrastructure majeur, cet article explique comment les problèmes peuvent survenir et les conséquences qui peuvent en résulter. Il présente ensuite des réflexions sur la manière de les surmonter grâce à un leadership et une gestion appropriée.

Keywords: Leadership; risk.

1 INTRODUCTION

Geotechnical risks can result in failures on projects when they are not effectively communicated by geotechnical engineers or understood by non-geotechnical engineers. For risks to be appreciated by non-geotechnical engineers, they have to have confidence in the geotechnical engineers communicating those risks.

On a major infrastructure project in Eastern Australia, the geotechnical design team was identified as having issues of poor performance. This resulted in a lack of confidence in the ability of that team. Once these issues were addressed, the geotechnical site team was identified as having similar concerns. This paper presents an analysis of the team, what caused the poor performance issues, and how these were resolved. The paper concludes with some recommendations for team leaders on similar projects.

2 THE PROJECT

The project consisted of the widening 11 km of an existing motorway from four-lanes to six-lanes. This involved major earthworks, new bridges, ground treatment and new pavements. The project cost over AUD 1.1 bn.

The works were undertaken under a Design and Construct contract for the State Road Authority with a major contractor (the Contractor) undertaking the construction supported by two design consultancies who formed a Design Joint Venture (DJV).

3 THE GEOTECHNICAL TEAM

The Geotechnical Team (GT) was made up from the two DJV companies and a specialist sub-consultant (SSC).

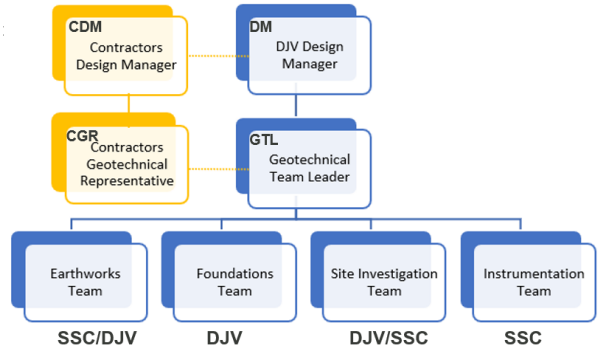

Figure 1. Geotechnical Team structure.

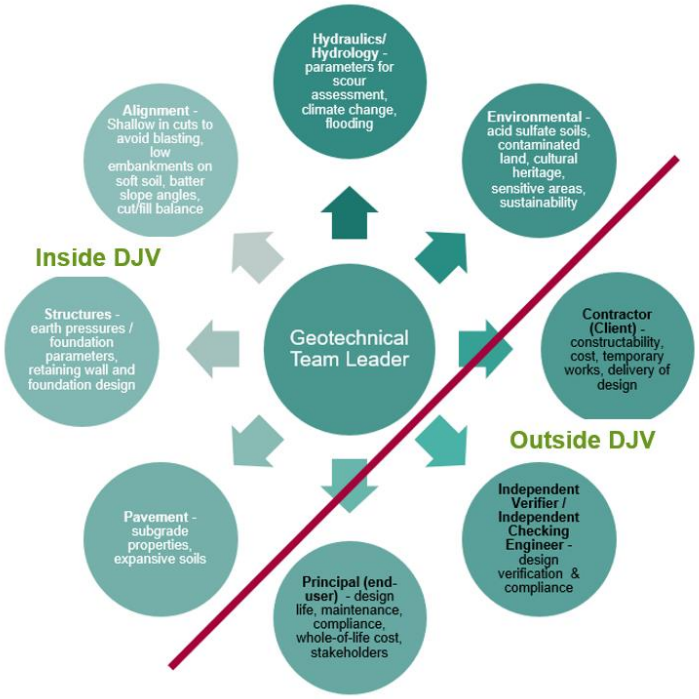

Figure 2. Geotechnical Team Leader interactions (after Bridges (2019)).

Table 1. Assessment of Geotechnical Team performance.

Input	Process	Output
Individuals: • engineers / geologists from different companies • variable levels of motivation • different levels of competencies • some diversity in the team • some pre-existing social connections • different team members working on flexible work arrangements (i.e. 4 days per week, 9-day fortnight) **Team:** • functional based • low team spirit • task focused • independent team • team chosen based on availability not ability • some tasks based on company **Environment / Context:** • large scope of work (multiple deliverables) • complicated technical task • high pressure environment • difficult client representative • tight deadlines and budget • interface with other teams	**Leadership Process:** • weak leader • developed a culture of "us vs. them" with respect to Client Representative • task-focused • poor delivery • no coaching **Team process:** • poor coordination of tasks • lack of empowerment • uneven work load and budget responsibility • diverse levels of commitment • lack of team spirit • bunker attitude • uncommunicative • lack of cohesion • no team learning or mentoring • no team building opportunities • keeping certain tasks within individual companies	**Individual:** • mental and physical fatigue • feeling of unfairness / resentment • loss of motivation **Team:** • failure to deliver on budget (4 x over budget) • low performance team • damaged reputation • siloed team **Project:** • delays due to late deliverables • design over budget • constant complaints from contractor • poor solutions

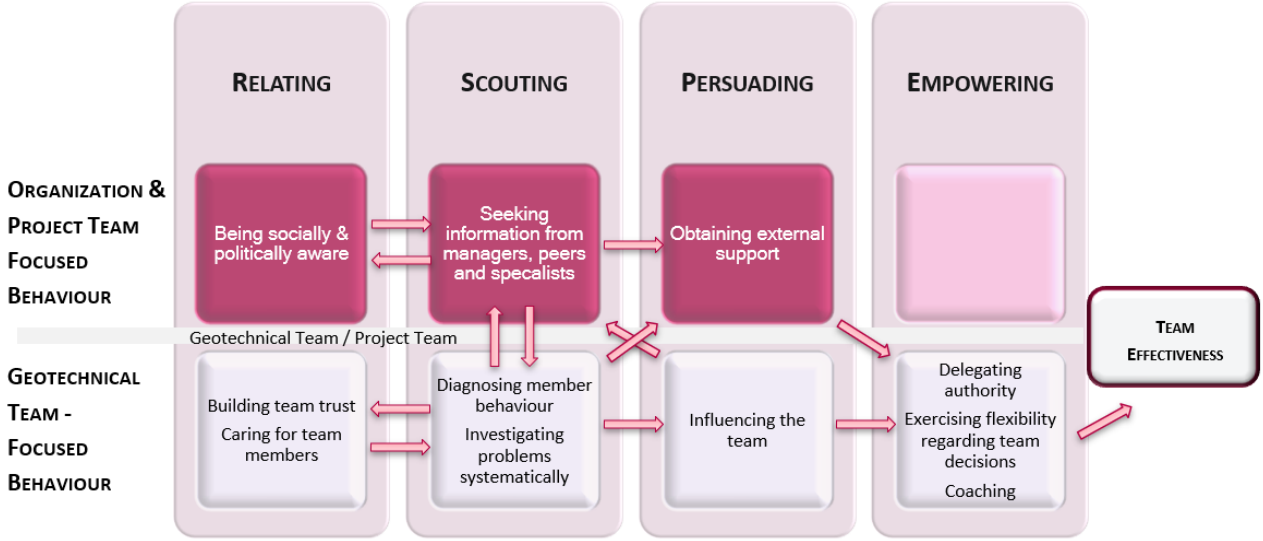

Figure 3. Team Leaders should be focused internally and externally (after Druskat and Wheeler, 2004).

During the tender phase the geotechnical support had been provided solely by the SSC, however, unable to agree terms with the Contractor after project award, the DJV took over the geotechnical design and the SSC was retained as a sub-consultant.

Starting the detailed design phase of the project, therefore, the GT had some underlying complexity around structure (Figure 1) and incorporating an unhappy SSC. Unfortunately, some of the tasks were separated by company – for example, the use of certain proprietary software - which meant that even if someone wasn't busy, they were restricted to limited tasks.

Like most major projects the GT Leader reported to a Design Manager - in this case of the DJV – who liaised with the Contractors Design Manager (CDM). The GT Leader also liaised with multiple stakeholders within the design team and externally of the DJV, including the Independent Verifier and the Principal (the State Road Authority) (Figure 2).

Both internally, within the DJV, and externally by the CDM, concern was raised about the poor performance of the GT, particularly with respect to delivery of reports and designs. This led to the CDM appointing an external Geotechnical Representative (CGR) to oversee the GT.

4 ANALYSIS

An analysis of the GT was undertaken using an Input-Process-Output assessment (Mathieu et al., 2009) and this is presented in Table 1. Outward signs of problems included poor delivery, and observations that there was no communication between the geotechnical team members – everyone quietly working at their desks all day and not speaking to each other. The GT Leader was noted especially for not delivering any of her design reports and having an incredibly fractious relationship with the CGR.

Druskat and Wheeler (2004) identify that team effectiveness increases if the team leader undertakes *boundary spanning* activities (going outside the team to get support, influence and information) and *empowers* the team through delegating, coaching and mentoring (Figure 3).

4.1 Boundary spanning

It is important to understand the political environment within a project. It is not uncommon for the geotechnical team to be accused of poor delivery or of conservatism in design – ultimately without any justification.

Building relationships within the wider design team and externally with a client or contractor and understanding the drivers of critically important individuals will, therefore, enable the GT Leader to ensure that these can be addressed – for example, programme or procurement constraints, or poor experiences on previous projects. The advantage of having trusted relationships will enable feedback early to avoid or address problems early. Unfortunately, this was not undertaken by the GT Leader on this project, and this led to GT being devoid of external support when problems arose.

As with this project, the team may not have the experience that is needed. Even if they do, it is always important that the geotechnical team is supported by others such as: reviewers, verifiers and experienced individuals from who advice can be sought. Again, the GT Leader needs to build these relationships to ensure

the right resources are available at the right time to enable delivery targets to be met.

4.2 Team focused behaviour

Working on projects has become more complex over time. Instead of one company, geotechnical teams are typically made up from engineers and geologists from different companies, including subconsultants and subcontractors. In the post-Covid19 environment, many individuals may work from home, from another state or from multiple local offices.

The GT Leader on this project did not really engage with her team which caused the dysfunction that resulted. Especially given the fact they came from different companies and were under a lot of pressure to perform. Although difficult, the GT Leader needs to be open, supportive and communicative with a sense of humour. The positivity of the GT Leader is important and likely to improve team performance (Avey et al., 2011; Balkundi et al., 2011). Each person will have different needs and expectations that will have to be met in some way (Jiang et al., 2015; Kerns, 2019) and creating a unified team culture is ultimately critical in maintaining an effective team (Ammeter and Dukerich, 2002; Druskat and Wheeler, 2004; Jiang et al., 2015; Jordan et al., 2015; Kerns, 2019; Sharma and Bhatnagar, 2017). Having the right behaviour and creating the right environment can create an engaged team.

5 CONCLUSIONS AND RECOMMENDATIONS

The performance of the GT Leader severely impacted the team and impacted the project through increased risk by late communication of project risks due to deliverable delays, which undermined the value of the geotechnical advice, and caused project delays.

In order to improve the GT Leader's performance and maintain an effective project team, the following are recommended:

- Network within your team and within the wider project team – build trusted relationships
- Minimise your own deliverables – do not get distracted from the bigger picture
- Delegate, but support (coaching)
- Provide a focus for the team – be empathetic to the client's needs
- Have a team that is adequately experienced for the task
- Obtain senior resources for review and advice on an "*as needed basis*".

Designing a pre-load embankment for the construction of a stage over a sanitary landfill founded in soft soils

Conception d'un remblai de précharge pour la construction d'une scène au-dessus d'une décharge sanitaire fondée sur des sols meubles

ABSTRACT: For World Youth Day event in 2023 (JMJ), the organizing committee selected an area in *Parque das Nações* that met the imposed requirements, notably in terms of area (for 1 million spectators) and proximity to the Lisbon center. This area, on the other hand, has the distinction of being a sanitary landfill, which was sealed in 1997 as part of the EXPO98 interventions, and which previously, in 1995, experienced a large-scale landslide in the direction of the river, with a front of 300 m of extension, enveloping the foundation up to significant depths. The fundamental cause of the landslide, according to studies undertaken at the time, was the low undrained strength of the foundation's soft soils that were still in the sub-consolidation phase, particularly at the deepest levels. Considering this scenario, LNEC performed limit equilibrium stability analyses as well as three-dimensional stress and strain finite-element analyses to estimate the magnitude and evolution of the settlements of the JMJ stage to be built in the southern area. The analyses carried out, the results of which are presented in the article, revealed the need of a pre-load embankment and were used to define criteria for the constructive phasing of the work, which was inherently dynamic and based on the outcomes of the monitoring system installed on site. Finally, values obtained from the monitoring system installed during the construction phase are compared to the values estimated during the design phase.

RÉSUMÉ: Pour les Journées Mondiales de la Jeunesse 2023 (JMJ), le comité d'organisation a sélectionné une zone du *Parque das Nações* qui répondait aux exigences imposées, notamment en termes de superficie (pour 1 million de spectateurs) et de proximité avec le centre de Lisbonne. Cette zone, en revanche, a la particularité d'être une décharge contrôlée, qui a été scellée en 1997 dans le cadre des interventions EXPO98, et qui auparavant, en 1995, avait connu un glissement de terrain à grande échelle en direction de la rivière, avec un front de 300 m d'extension, enveloppant la fondation jusqu'à des profondeurs importantes. La cause fondamentale du glissement de terrain, selon les études réalisées à l'époque, était la faible résistance non drainée des sols meubles des fondations, encore en phase de sous-consolidation, en particulier aux niveaux les plus profonds. À la lumière de ce scénario, le LNEC a réalisé des analyses de stabilité statique ainsi que des analyses par éléments finis de contraintes et de déformations tridimensionnelles pour estimer l'ampleur et l'évolution des tassements de l'étage JMJ à construire dans la zone sud. Les analyses réalisées, dont les résultats sont présentés dans l'article, ont révélé la nécessité d'un remblai de précharge et ont permis de définir des critères pour le phasage constructif des travaux, par nature dynamique et basé sur les résultats du système de surveillance installé sur place. Une comparaison est effectuée entre les valeurs obtenues dans le système de surveillance et l'estimation réalisée lors de la phase de conception.

Keywords: Sanitary landfill; pre-load embankment; soft soils; slope stability; consolidation.

1 INTRODUCTION

The use of an old sanitary landfill in the Lisbon area for the Catholic Youth World Event in August 2023 required some adjustments of the landfill. The first involved modelling the landfill in the northeast, expanding it north, and flattening the slopes. The second intervention was the construction of a stage in the southeast part of the area.

Given the history of instability of the landfill and the geological-geotechnical characteristics of its foundation, as described in the second chapter of this document, numerical analyses were performed using the limit equilibrium method to verify the global static stability of the landfill after the construction of the South stage. Given the short duration of the event, no seismic stability check was carried out.

Based on numerical analysis utilising three-dimensional finite element models and resorting to the PLAXIS 3D software, Chapter 3 presents an estimate of the magnitude and evolution of settlements and their impacts on the foundation caused by the stage load. These settlements are compared to the actual settlements measured during construction, as covered

in Chapter 4, which also covers a number of other aspects of construction.

Some final considerations are made in Chapter 5.

2 GEOLOGICAL-GEOTECHNICAL FRAMEWORK

Extensive field testing was carried out in the Beirolas sanitary landfill site, since 1984 to 2020, including boreholes, field vane tests and cone penetration tests (Figure 1). According to this geotechnical investi-gation (Figure 2), beneath the deposit of contami-nated soil and municipal waste that reaches a maximum height of 20 m is a layer of heterogeneous landfill containing silt-clay materials mixed with sand and rubble, dumped on site in the 1980s. The average thickness of this "artificial" landfill is 4 to 5 metres but decreases closer to the river until it disappears in the area covered by the tide. In some localized areas the thickness of the landfill was discovered to be higher, probably as a result of prior instability.

An alluvial deposit made of compressible silt soils with very variable thickness occurs beneath the "artificial" landfill layer. The depth of the muddy soils in the south stage area increases towards the river from 2 m to 25 m but remains constant from north to south. After the large-scale landslide in 1995, studies revealed that these soft soils had a low undrained strength and were still in the sub-consolidation phase, particularly at the deepest levels. At the base of the alluvial deposit a layer of sand and pebbles ranging in thickness from a few centimetres to 2 m have been discovered. Immediately underneath, the Miocene formation includes sandstones, calcarenites, and limestones, that are more or less marly.

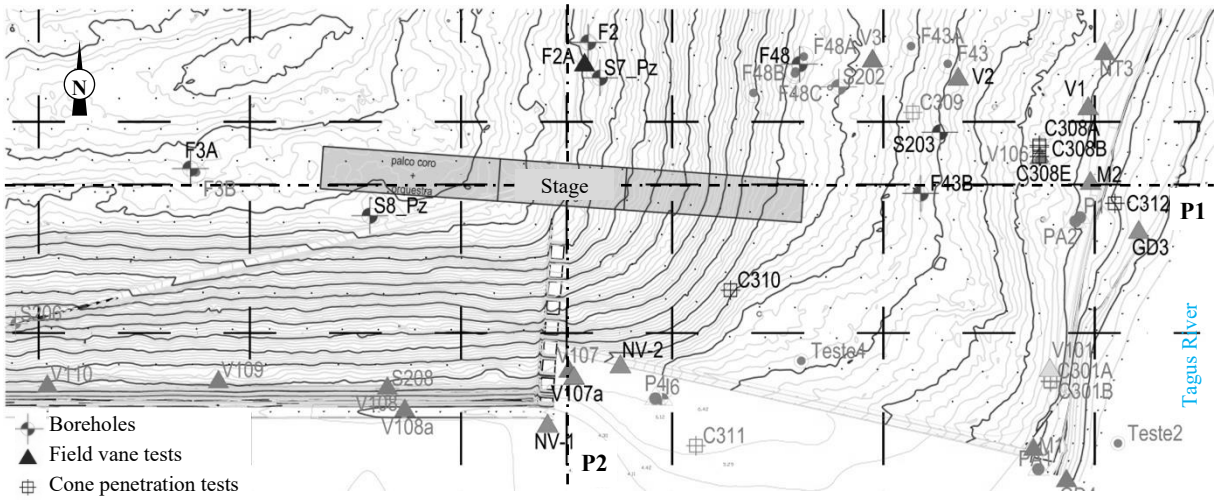

Figure 1. Ground investigations conducted around the southern stage's site.

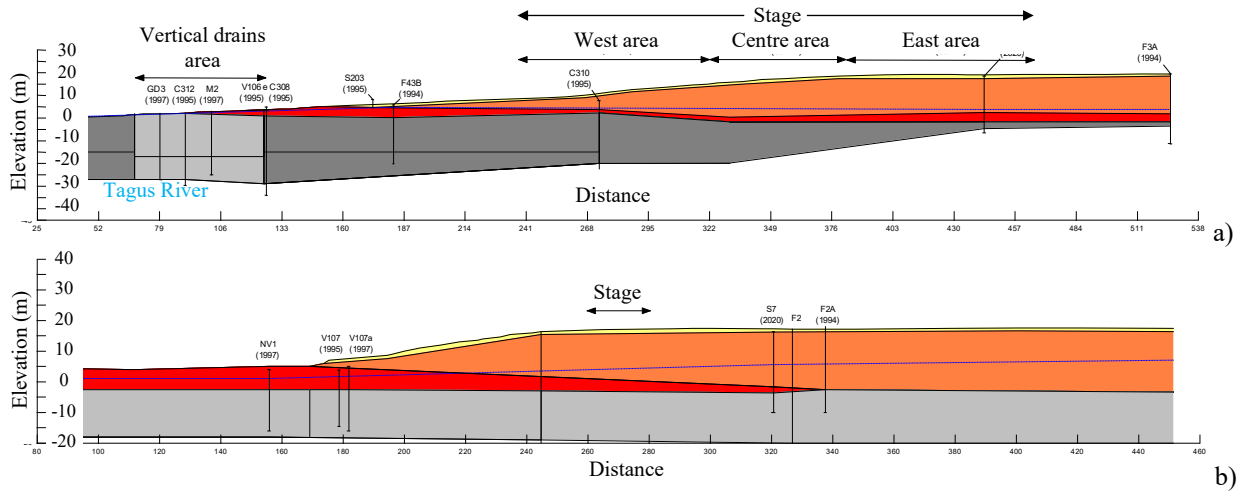

Figure 2. Geological-geotechnical cross-sections at the south stage site: a) P1; b) P2.

The sanitary landfill itself includes urban waste deposited in 1991 and layers of compost and contaminated soil deposited in cells and other areas from 1995 to 1997. Its thickness varies from about from 16 m to the west to about 4 m at the east end of the stage layout. It turned out to be a very heterogeneous landfill made up of layers of different materials with varying compressibility.

3 SETTLEMENTS ASSESSMENT IN THE SOUTH STAGE AREA

3.1 Calculation model description

The width of the calculation model illustrated in Figure 3 is equal to the width of the stage + 30 m on each side (1.5 times the width of the stage), to reduce the influence of the borders on the results. The base of the model is in the top of the Miocene formation, at -24 m. Due to calculating software constraints, the topography of the terrain was simplified by neglecting the slope in the south-north direction.

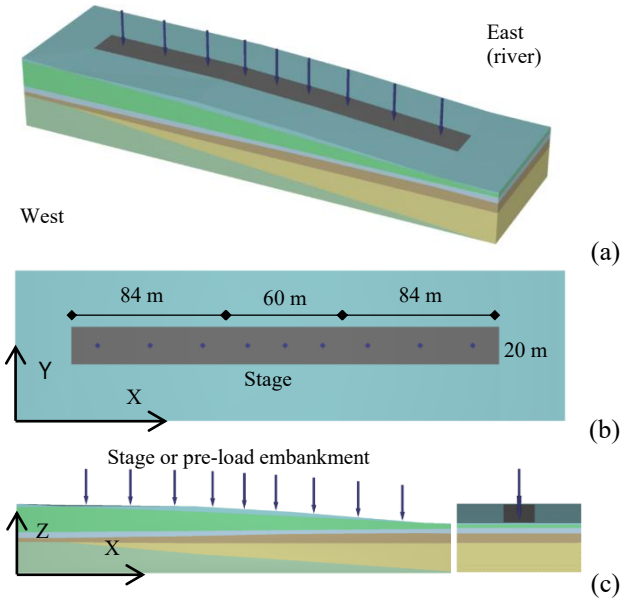

Figure 3. Calculation model geometry: (a) perspective; (b) plant; (c) elevations.

The preload embankment and stage were simulated by applying distributed loads on the area designated for the South stage. In the central and western areas, a value of 60 kPa was considered, whereas in the eastern area, a lower value, of 50 kPa, was used to ensure the overall stability of the landfill and its foundation. Calculations were carried out in two phases. Settlements caused by the construction of the stage were evaluated in the first phase. According to the JMJ organizing committee, the load imposed to the foundation due to the construction of this stage, would be 50 kN/m^2. In a second phase, a pre-load embankment was built prior to the stage, with a height of 3 m in the central and western areas. Due to stability issues, the height of this pre-load embankment was limited to 2.5 m on the east side.

Two options were considered in this second calculation. In the first option, the pre-load embankment would be removed one year after it was constructed, and the stage would be built immediately afterwards. The second option calls for the embankment to be removed six months after it is constructed and the stage to be built six months after the pre-load embankment is removed.

3.2 Materials characterization

The "soft soil" constitutive model (Bentley, 2020) was used to integrate the effect of consolidation process on the behaviour of muddy materials (superficial and deep clayey mud) as well as on the behaviour of the materials that form the sanitary landfill and the "artificial" landfill.

The elasto-plastic constitutive model with the Mohr-Coulomb failure criterion was used for the cover landfill, and the elasto-linear model was used for the Miocene formation.

Table 1 provides the values for the physical and mechanical parameters of the soft soil constitutive model materials, whereas Table 2 shows the values for the cover embankment and the Miocene formation. These parameters were based on laboratory tests conducted to date and prior LNEC studies (LNEC, 1996a, 1996b, 1997, 1999).

3.3 Calculation model results

Table 3 presents the settlement values of the stage for the most critical phases, assuming no pre-load embankment is built beforehand. The points in the table are fictious points at the top of the embankment, in the centre of each of the three regions of the stage, as shown in Figure 4. The time required to attain a consolidation degree of 95 % and 98 % is also provided in the same table. Table 4 presents the total settlement of the foundation considering the pre-load embankment construction.

According to Table 3, stage settlements can achieve significant values of the order of 0.29 m, but with reduced relevance in terms of differential settlements, although with the potential to affect its serviceability if built one year before the JMJ event.

Table 1. Parameters adopted for materials with soft soil constitutive model.

Description	γ (kN/m³)	e_0	Cc	Ce	ϕ'(º)	c' (kPa)	k (m/day)
Sanitary landfill	15,4	0,5	0,2	0,02	25º	10	0,086
"Artificial" landfill	18,0	0,3	0,1	0,04	25º	0,3[1]	1,64 x 10^{-4}
Superficial clayey mud (up to -5 m)	18,8	1,2	0,2	0,09	28º	0,3	2,25 x 10^{-5}
Deep clayey silt	16,5	1,8	0,2	0,04	28º	0,3[1]	1,11 x 10^{-5}

γ – unit weight; e_0 – initial void ratio; C_C – compression index; Ce – swelling index; ϕ` – effective friction angle; c` – effective cohesion intercept; k – permeability coefficient.

Table 2. Parameters adopted for materials with elasto-plastic and linear-elastic constitutive models.

Description	γ (kN/m³)	E (MPa)	ν	ϕ' (º)	c'(kPa)	k (m/day)
Cover landfill	20	25	0,35	30	0,3	3,456
Miocene Formation	21	100	0,33	-	-	0,864 x 10^{-3}

γ – unit weight; E – deformation modulus; ν – Poisson ratio; ϕ` – effective friction angle; c` – effective cohesion intercept; k – permeability coefficient.

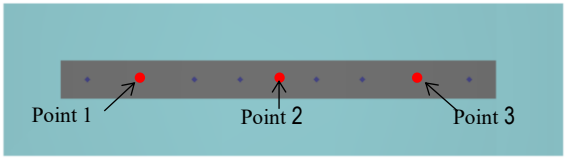

Figure 4. Location of calculation points.

Table 3. Stage settlements and time to attain a consolidation degree (without a pre-load embankment).

Point	δ_i (m)	δ_{1y} (m)	δ_{max} (m)	T_{95} (years)	T_{98} (years)
1	0.113	0.211	0.219	1,5	2
2	0.112	0.175	0.203	11	92
3	0.164	0.233	0.316	30	92
Max	0.213	0.290	0.407	-	-

δ_i – initial settlement; δ_{1y} – settlement 1 year after construction; δ_{max} – maximum settlement; T_{95} – time required to attain a consolidation degree (CD) of 95 %; T_{98} – time required to attain a CD of 98 %.

Table 4. Accumulated settlement of the foundation considering pre-load embankment construction.

Point	δ_{1y} (m)	δ_{3m} (m)	δ_{6m} (m)
1	0.256	0.245	0.246
2	0.213	0.205	0.206
3	0.227	0.235	0.239
Max	0.298	0.297	0.302

δ_{1y} – foundation settlement after 1 year of pre-load; δ_{3m} – accumulated settlement of the foundation 3 months after stage construction; δ_{6m} – accumulated settlement of the foundation 6 months after stage construction.

Because equal compressibility was assumed for both materials, stage settlement increases as the sum of the thickness of the sanitary landfill and the muddy soils increases. This explains why point 1 has a higher settlement than point 2 and point 3 has a higher settlement than point 1. However, results show that the closer the river, the slower the evolution of the settlements, i.e., the time necessary to achieve the same consolidation degree (CD). Therefore, even though the maximum settlement (considering a CD equal to 98 %) of point 3 is 40 % greater than that of point 1, this relationship is only 1.1 times at the end of one year.
