Nous avons vu précédemment que les fondations, certainement de grande largeur à la base (5 mètres et plus), reposent sur le « bon sol » des alluvions anciennes dont l'épaisseur est en moyenne moindre (4 mètres). Les contraintes diffusées concernent donc de façon significative la craie altérée sous-jacente, dont les quelques mégapascals de module de rigidité typique donnent à l'ensemble fondation / sol support un comportement suffisamment souple pour rendre compte des rotations à la base des piliers. En effet, un excentrement de charge et le développement d'une pression non uniforme sous la fondation entraînerait aisément quelques centimètres de tassement supplémentaires sur le côté plus chargé, ce qui se traduit bien par une rotation de l'ordre du pourcent.

Soulignons cependant avec insistance que les fondations de cette partie de la cathédrale et le sol sur lequel elles reposent ne sauraient être tenus pour responsable de l'accident de 1573. Elles en ont juste, possiblement, accéléré la survenue.

4 CONCLUSIONS

Nous pouvons donc conclure de cet inventaire d'informations disponibles que les accidents structurels de 1284 et 1573 à la cathédrale de Beauvais n'ont pas une origine géotechnique. Nous avons cependant montré que, au XVIe siècle, l'ensemble fondations / sols porteurs a potentiellement pris une part notable dans le « mécanisme de ruine », contrairement au cas du XIIIe siècle.

Aussi, ces conclusions permettent d'attirer l'attention sur le remarquable travail géotechnique réalisés par les maîtres-maçons des temps considérés, aussi bien dans la prise en compte du terrain, non exempt de risques, que des formidables descentes de charge qu'il allait subir pour de nombreux siècles.

REMERCIEMENTS

Que soit remercié Jean-François Madre, secrétaire de l'Association Beauvais Cathédrale et auteur en 2023 d'un opuscule sur les sculptures figuratives du chœur, qui a joué un rôle au point de départ de cet article. Merci également à Fabrice Reutenauer et François Haaz, du Service Archéologique municipal de Beauvais, pour leur communication de données altimétriques des niveaux archéologique et géologique au droit de l'exèdre à l'est de la cathédrale.

Interpretation of large diameter preliminary pile tests in Ampthill Clay, West Walton and Oxford Clay formations for Thame Valley viaduct

Interprétation des essais préliminaires de pieux de grand diamètre dans les formations Ampthill Clay, West Walton et Oxford Clay pour le Thame Valley viaduct

S. Vitorino*, H. Yeow

**sergiovitorino@gmail.com*

ABSTRACT: Two instrumented preliminary test piles have been installed and tested in Aylesbury, UK, using Osterberg Cell bi-directional load test method, for the purpose of verifying the construction methodology and load performance of the bored piled foundations designed for the 880m long HS2 Thame Valley Viaduct. The local ground conditions comprise stiff clay and mudstone of Ampthill Clay, West Walton and Oxford Clay Formations which constitute part of the Ancholme Group. The significant length of the asset allowed a comprehensive ground investigation package of site and laboratory testing to be undertaken in developing a refined detailed design in accordance with the recommendations of Eurocode 7. The field test results of the two test piles have been interpreted and back-analysed using 3D finite element analyses undertaken to simulate the bi-directional loading of the Osterberg Cell testing method and compared against the ultimate pile capacity estimated during detailed design of the viaduct. Subsequent simulation of the pile loaded from pile head level using the calibrated finite element model provides the required load-settlement characteristic necessary to verify the performance of the pile under serviceability limit state.

RÉSUMÉ: Deux pieux d'essai préliminaires instrumentés ont été installés et testés à Aylesbury, au Royaume-Uni, en utilisant la méthode de test de charge bidirectionnelle Osterberg Cell, dans le but de vérifier la méthodologie de construction et les performances de charge des fondations sur pieux forés conçues pour le Thame Valley Viaduct, HS2, long de 880 mètres. Les conditions locales du sol sont constituées d'argile raide et de mudstone des formations d'argile Ampthill, West Walton et Oxford Clay, qui font partie du groupe Ancholme. La longueur significative de l'ouvrage a permis la réalisation d'un ensemble complet de tests sur site et en laboratoire pour développer une conception détaillée raffinée conforme aux recommandations de l'Eurocode 7. Les résultats des tests sur le terrain des deux pieux d'essai ont été interprétés et rétro-analysés à l'aide d'analyses par éléments finis en 3D réalisées pour simuler la charge bidirectionnelle de la méthode de test Osterberg Cell, et comparés à la capacité ultime des pieux estimée lors de la conception détaillée du viaduc. La simulation ultérieure du pieu chargé depuis le sommet du pieu à l'aide du modèle par éléments finis calibré fournit les caractéristiques de chargement-tassement nécessaires pour vérifier les performances du pieu dans l'état limite de service.

Keywords: Pile; trial; back-analysis; plaxis; Osterberg.

1 INTRODUCTION

Two preliminary test piles (PTP10A to PTP11) were installed and tested using bi-directional Osterberg Load Cell (O-cell) at the 880m long Thame Valley Viaduct, as part of the Aylesbury Area package of the High Speed 2 (HS2) project. The Arcadis, Setec, COWI Design Joint Venture (ASC) has been appointed by Eiffage, Kier, Ferrovial, and BAM Nuttall Joint Venture to provide detailed design services for the civil engineering assets within HS2. Bauer Keller joint venture (BKJV) were responsible for the installation of the piles while Fugro Loadtest was responsible for testing the piles.

Due to access and programme constraints, the test site was located approximately 200m north of the viaduct's proposed north abutment.

This paper presents the interpretation and back-analysis of the test data with the objective of verifying the performance of the pile under serviceability limit state.

2 THE SITE

2.1 Geological setting

Aylesbury Area is situated in the East Midlands Shelf which contains an Ancholme Group succession of clay and mudstone formation which were deposited in the Upper Jurassic period. The ground conditions at the test site are consistent with the ground conditions along the viaduct and comprise less than 1m of Head Deposits (HEAD) overlying Ampthill Clay (AMC), West Walton Formation (WWB) and Oxford Clay (OXC) to depth greater than 60m. AMC and WWB are generally described as stiff to very stiff Clays or calcareous Clays, with small localised pockets of siltstone and limestone, while OXC is generally described as extremely weak Mudstone.

2.2 Site investigation and soil parameters

The ground conditions at the test site have been characterised based on ground investigation works within a 200m radius, which includes 6No. CPTs, 11 No. boreholes 6 No. trial pits and respective in-situ and laboratory tests. The borehole descriptions at the test site and along the viaduct are not always consistent which could imply a very significant variation in the thicknesses of AMC and WWB, even in boreholes located adjacent to each other. This possibly highlights the difficulty in identifying the marker horizons that distinguish AMC, WWB and OXC, therefore resulting in very different stratigraphy being presented in adjacent boreholes. Despite the discrepancies noted above, the analysis of the Atterberg limits suggests a relatively flat stratigraphy throughout the northern section of the viaduct and the pile test site. Other markers such as calcareous siltstone, thinly interbedded limestone and limestone bands present in AMC and WWB formations also support an assumption of horizontal stratigraphy or otherwise a slight dip towards the south, which would be expected following the general trend of the geology in Aylesbury Area.

Figure 1 presents undrained shear strength and Atterberg limits versus elevation while considering the site GI data. Borehole ML065-CR532A has been drilled at the test site.

The undrained shear strength profile has been determined based on in-situ and laboratory tests.

- Where estimated from CPT, $c_u = \frac{q_c - \sigma_v}{N_{kt}}$ with N_{kt} assumed as 17.
- Where estimated from SPTs, $c_u = f_1 N_{60}$ as proposed in CIRIA R143 where $f_1 = 4.5$, based on plasticity index for most of the layers except WWB. For WWB f_1 has been taken as 6 for better fit with the triaxial test data.
- Where estimated from UCS, undrained shear strength was taken as $c_u = UCS/2$.

The design profile of the test pile has been developed based on the characteristic undrained shear strength profile shown as continuous black line in Figure 1.

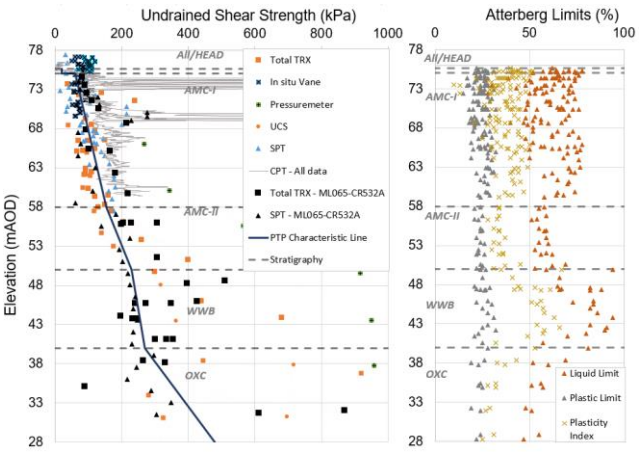

Figure 1. Undrained shear strength and Atterberg limits in the vicinity of the test site.

Table 1 summarises the stratigraphy and the key geotechnical parameters considered at the test site. AMC has been split into AMC I and AMC II to reflect a change in the plasticity index below 58mAOD, with a slight adjustment in the undrained shear strength profile. The equivalent undrained shear strength of the OXC has been determined using the UCS values from laboratory tests of an extremely weak mudstone.

Table 1. Stratigraphy and Geotechnical Parameters assumed at the test site.

Geolog. unit	Top of layer (mAOD)	Thickness (m)	c_u (kPa)	UCS (MPa)
HEAD	75.6	0.6	20	-
AMC I	75	17	60+5.5z	-
AMC II	58	8	154+9.6z	-
WWB	50	10	230+4z	-
OXC	40	Not proven	-	0.54+0.035z

3 VIADUCT AND PILE DESIGN

3.1 Description of the viaduct and the foundations

The viaduct carries HS2 over the Thame Valley flood plain, a relatively flat area of open fields surrounding the Thame River which runs approximately North East to South West across the proposed route.

Thame Valley Viaduct is a 36 span, 880m long continuous structure consisting of 4 No. 20m spans and 32 No. 25m spans. The piers are connected to 12x 2.5x1.8m deep pile caps which are in turn supported on a single row of three 1500mm diameter piles with a fixed pier providing longitudinal restraint. The fixed pier is connected to a 14x14x2m deep pile cap, supported by nine 1800mm diameter piles in a 3x3 layout. The abutments are supported on six 1500mm piles in a 3x2 layout. After completion of the test pile analysis, all the working piles have been constructed as typical cast in-situ bored piles in dry bores.

3.2 Pile Design

The unit shaft resistance in HEAD, AMC and WWB was estimated as $f_s = \alpha c_u$, where α is the empirical coefficient assumed as 0.5 and c_u is the undrained shear strength in Table 1. A limit to $f_s = \alpha c_u$ of 125kPa was applied to shaft resistance in clay. For the length of piles through OXC, the unit shaft resistance has been estimated as $f_s = 0.225\sqrt{UCS}$ (with UCS in MPa). A limit to f_s of 300kPa has been applied to the design.

The unit base resistance in the OXC has been estimated as $f_b = 4.5\,UCS$, where UCS is taken at the pile toe level. Table 2 presents the estimated ultimate resistance of the two test piles.

Table 2. Estimated Ultimate Resistance of the test piles.

Test Pile ID (diam.)	Pile length (m)	Shaft capacity (MN)	Base capacity (MN)	Total capacity (MN)
PTP10A (1.5m)	41.06	17.8	5.7	23.5
PTP11 (1.8m)	39.05	19.2	7.4	26.6

4 TEST PILES

4.1 Description of the tests

As shown in Figure 2, the instrumentation in the two piles included 4 pairs of extensometers and 9 sets of strain gauges. Loadtest provided measurement of the top plate, toe and pile head plus expansion of the o-cell.

The 1500mm test pile, PTP10A, was installed with length of 41.06m, incorporating the O-cell assembly at 36.1m below the pile head. The maximum sustained gross load applied to the pile was 10.75MN in each direction. At the maximum sustained load, the displacements above and below the O-cell assembly were 6.01 mm and 7.97 mm, respectively. At the next load increment with a gross applied load of 11.70 MN in each direction, the upper pile section above the O-cell was unable to sustain the applied load, see Figure 3.

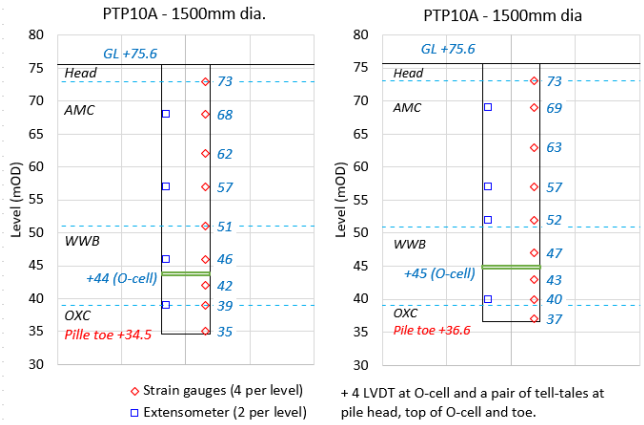

Figure 2. Schematic representation of the instrumentation in the two test piles.

The 1800mm test pile PTP11 was installed with length of 39.05m, incorporating the O-cell assembly at 30.5m below the pile head. The maximum sustained gross load applied to the pile was 13.32 MN in each direction. At this maximum sustained load, the displacements above and below the O-cell assembly were 4.97 mm and 10.13 mm, respectively. Again, the upper pile section was unable to sustain the applied load at the next load increment, see Figure 3.

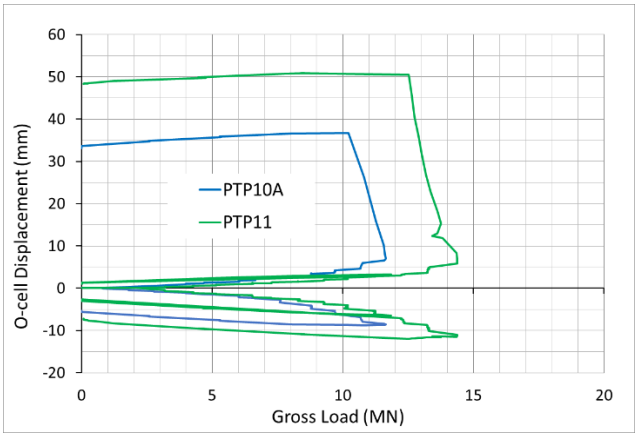

Figure 3. Upper and lower shaft movements.

4.2 Interpretation of the results

The unit shaft friction was estimated based on the interpreted results from strain gauges and this is summarised in Table 3. The strain gauges immediately above and below the O-cell have shown erroneous results and have been omitted from the interpretation on the basis that the close proximity to the O-cell may have led to spurious strain measurement as a result of high stress concentration or lower localised concrete

stiffness caused by anomalies when the concrete was tremied pass the O-cell assembly.

Table 3. Interpreted unit shaft friction.

Levels[(1)] (mAOD)	Strata	Unit shaft friction (kPa)	
		PTP10A	PTP11
75.6 - 73	HEAD	20	13
73 - 68.5	AMC	56	45
68 - 62.5		52	61
62 - 57		89	78
57 - 51.5		83	88
51 - 46	WWB	103	128
45 - 40		145	149
39 - 35	OXC	281	338

Notes: (1) Levels averaged between the two test piles.

The upward and downward movement has been analysed separately using the Cemset Analysis method (Fleming, 1992) to determine the behaviour of the pile above and below the O-cell. Table 4 presents the summary of input parameters for Cemset analysis that produce the best fit load-displacement profile to the measured test pile data. Given that both piles failed upwards, the base capacity has not been fully mobilised, therefore this base capacity has been estimated using the approach presented in Section 3.2 but slightly adjusted to fit the data for the downward movement curves of the two test piles. Figure 4 shows the equivalent top-loading curves for the two test piles determined by adding the upward and downward Cemset curves while corrected for the elastic shortening for a top loaded piles instead of bi-directional loading (according to method proposed by England, n.d.).

Table 4. Summary of input parameters for Cemset analysis above and below the O-cell.

Input Parameter	PTP10A		PTP11	
	Above O-cell	Below O-cell	Above O-cell	Below O-cell
Qs[(1)] (MN)	11.6	9.47	14.38	11.32
Ms (-)	0.0003	0.0004	0.0002	0.0006
Qb[(2)] (MN)	-	5.0	-	6.5
Eb[(3)] (MPa)	-	129	-	188
Lf (m)	31.6	9.46	30.54	9.46
Ke (-)	0.3	0.5	0.3	0.5
Ec (GPa)	40	40	40	40

Notes: (1) Ultimate shaft capacity; (2) Ultimate base capacity; (3) Soil modulus at base.

Table 5 shows the comparison of ultimate capacities between the design approach presented in Section 3.2 and those calculated from the Cemset analysis.

4.3 Comparison with viaduct design

Figure 5 shows a good agreement between the unit shaft friction estimated using the design profile and the values interpreted from the test pile data in most strata except the OXC where there is significant underprediction of the shaft resistance.

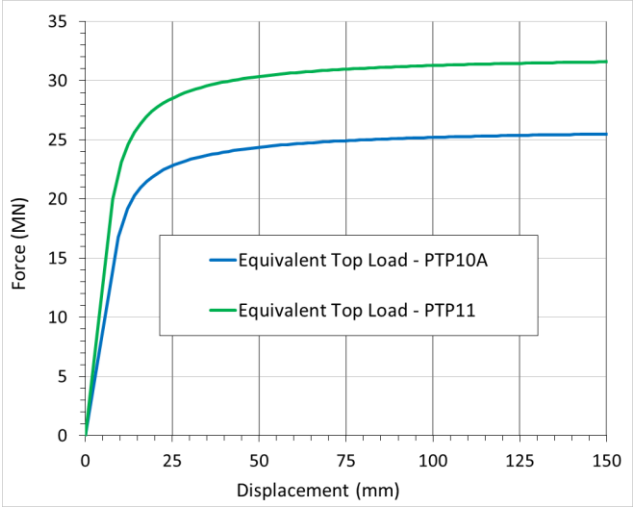

Figure 4. Equivalent top load displacement curves.

Table 5. Summary of estimated pile capacities.

Pile	Ultimate Capacity (MN)	
	Estimated in Section 3.2	Cemset Analysis
PTP10A	23.5 (Qs=17.8; Qb=5.7)	26 (Qs=21.0; Qb=5.0)
PTP11	26.6 (Qs=19.2; Qb=7.4)	32 (Qs= 25.5; Qb=6.5)

Notes: Qs=Ultimate shaft capacity; Qb=Ultimate base capacity;

Particularly throughout AMC-I, the estimation of unit shaft friction based on design profile is slightly lower than interpretation of the test data, as expected given the slightly cautious undrained shear strength profile for the site specific borehole data. There is no such trend for the AMC-II stratum except it is fair to assume the design values are in good agreement with the measured ones. The interpretation of the test data suggests constant unit skin friction between levels 52 and 62mAOD, which is unlikely to be a correct representation since gradual increase in soil strength is expected. In WWB, the estimation based on design profile is slightly lower than interpretation of the test data for the bottom half of this unit, because a limit to $f_s = \alpha c_u$ of 125kPa has been applied to shaft resistance in clay, otherwise a good agreement should be expected. It could be argued that such limit could be higher, for instance a limit to $f_s = \alpha c_u$ of 150kPa could be recommended, however the current limit is only conditioning the unit shaft friction over a short

length and therefore no significant conclusions should be drawn from this small contribution to the overall pile capacity. In OXC it becomes clear that the unit shaft friction based on design profile is being underestimated when compared with interpretation of test data. This is possibly due to the assumption of a conservative characteristic strength in the Mudstone layer that resulted from the wide scatter in the available GI data or a reflection of shaft roughness or overbreak in the OXC. While this is not demonstrated by Figure 5, it is also possible that the base capacity in OXC is being underestimated if the characteristic base parameters are conservative. However, noting that both piles only penetrated a short length into OXC and that more data should be considered to confidently infer any conclusions, it is considered prudent to keep the current approach in the viaduct pile design.

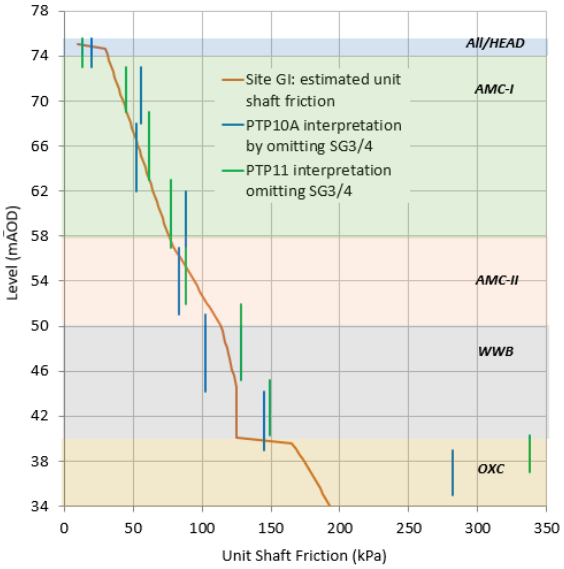

Figure 5. Comparison of unit shaft frictions determined by preliminary test piles and design.

4.4 Analysis using 3D finite element analysis

The preliminary test piles were back analysed using Plaxis 3D finite element (FE) program to mimic the measured performance of the test results under the bi-directional O-cell test before the introduction of load at pile head to derive the equivalent top loaded pile response. Although an axisymmetric 2D model would suffice the decision to adopt a full 3D model allows the assessment of lateral response of the pile be it as a single pile or as a pile group for the design of the viaduct foundations.

4.4.1 Methodology

In the FE model, the test pile was modelled by splitting the shaft into several sections to mimic the positions of the strain gauges installed to measure the load transfers during the test. Each of these shaft sections is then assigned a shear strength parameter to reflect the measured unit skin friction values, see Figure 6. Under the test load, the measure displacements of the O-cell's top and bottom plates, pile head and pile toe were compared and calibrated before the pile is loaded from the top.

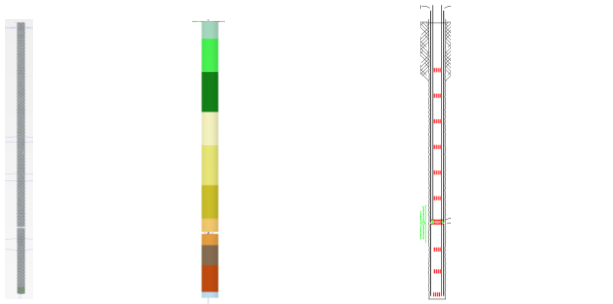

Figure 6. Pile shaft with different shear strength values.

It is worth noting that when assigning individual shear strength using interface element, Plaxis command codes were used to change the input shear strength parameters rapidly for multiple assessments to calibrate the load-displacement of the test pile. The use of automated Python script would speed up this calibration process but this is not used at this stage.

Apart from the shear strength parameters assigned to the test pile, soil properties of the ground and stiffness of the pile concrete are the other two variables which could affect the behaviour of the pile under the applied load. For the calibration undertaken, the following are the soil model and properties used in the FE model:

- concrete stiffness: 40-45 GPa;
- stiffness of the soils: E_u/c_u=500-750

Linear elastic perfectly plastic Mohr-Coulomb soil model has been used to represent the soils since parameters for more complex or advanced soil model are currently not available in this type of soils.

4.4.2 Test pile calibration

The process of calibration started with the first set of parameters based on the pile design approach indicated in Section 3.2 to derive the unit shaft friction of the pile. Due to the low unit shaft friction in the OXC, the lower section of the pile settled excessively beyond a test load of 8MN for PTP10A. Similar observation for PTP11 albeit with slightly higher applied O-cell load.

With the derived unit shaft resistance from the test piles, the load displacement profiles for both the test piles are shown in Figure 7.

When load is applied from pile head, the equivalent load-displacement profiles are shown in Figure 7.

When comparing this to the Cemset back-analysis, the difference in load-settlement performance of the piles at serviceability limit state is negligible although the ultimate capacity of the larger 1.8m diameter test pile is approximately 5% lower. This could be due to more pronounced pile base softening effects on the larger test pile.

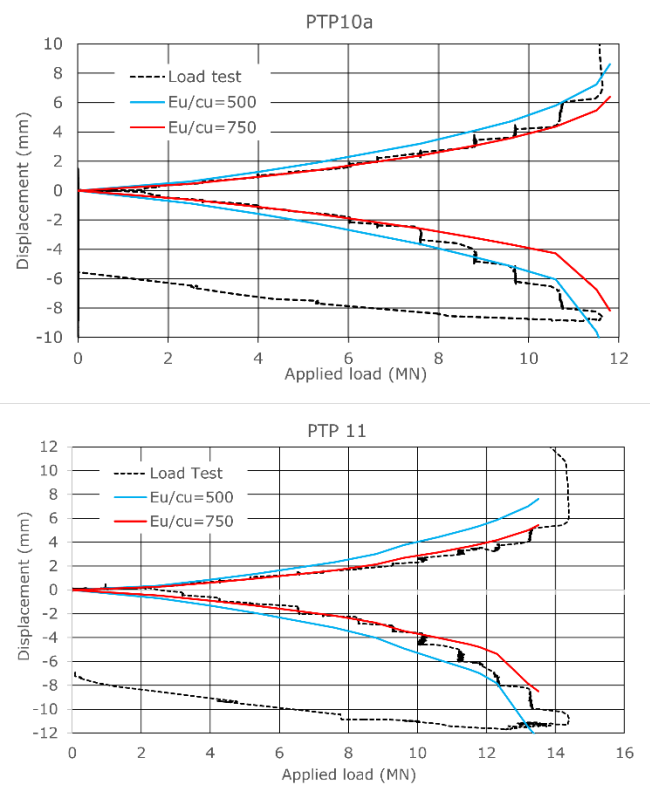

Figure 7. Load-displacement profiles for the two test piles back analysed using Plaxis 3D model.

5 CONCLUSIONS

The ultimate pile capacities estimated using the approach assumed by the designer outlined in Section 3.2 were calculated as 23.5 MN and 26.6 MN for test piles PTP10A and PTP11, respectively. In this approach the unit shaft resistance in HEAD, AMC and WWB was calculated as $f_s = \alpha c_u$, where α is the empirical coefficient assumed as 0.5 and c_u is the characteristic undrained shear strength profile determined based on site specific GI. A limit to $f_s = \alpha c_u$ of 125kPa has been applied to shaft resistance in clay, but this is only exceeded in the design over a short length. For the length of piles through OXC, the unit shaft resistance was assumed to be based on $f_s = 0.225\sqrt{UCS}$. Although a limit of f_s of 300kPa was applied to the design in OXC, this limit is not reached for a pile length of 41m. The unit base resistance has been estimated as $f_b = 4.5\ UCS$, where UCS is taken at the pile toe level.

When this approach is compared with the back-analysed unit shaft frictions from the test pile data, there was a good agreement in the clay layers but it underestimated in the Mudstone layers. It is possible that the assumption in the characteristic strength of the Mudstone layer is conservative. More GI data and pile test in these strata would be required to verify a more optimistic design approach in order to incorporate higher shaft resistance values.

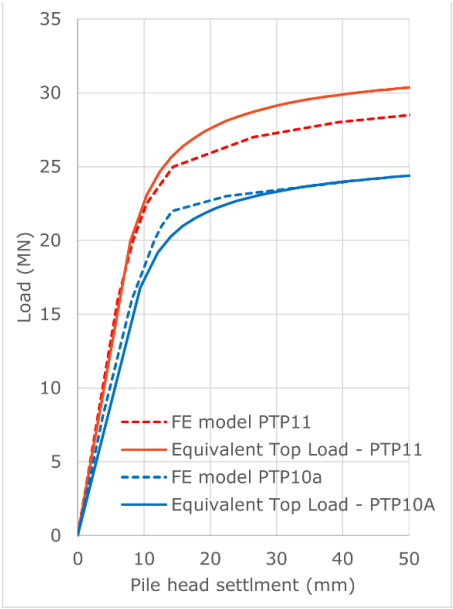

Figure 8. Load-displacement profiles for equivalent top loaded pile.

Due to the short length of pile in the OXC, where the most discrepancy in the shaft resistance value was found, the design approach presented for pile design in AMC/WWB/OXC is considered appropriate and slightly conservative for pile lengths between 39 and 41m. The two test piles are considered to verify the design approach and provide sufficient confidence to deliver the design of the 880m long Thame Valley Viaduct.

Surface roughness evolution of EPDM and its impact on the long-term sealant performance of gasketed joints of segmental shield tunnels

Évolution de la rugosité de surface de l'EPDM et son impact sur la performance à long terme des joints d'étanchéité des tunnels à bouclier segmentaire

ABSTRACT: EPDM (Ethylene Propylene Diene Monomer) rubber gaskets were widely used as the waterproofing component at the joints of shield tunnels that are expected to serve for decades. However, the alterations in surface roughness of EPDM rubber gaskets due to ageing introduce an aspect that is not yet comprehensively understood in terms of its implications for sealant performance. In this study, a series of AFM (Atomic Force Microscope) tests were conducted on 6 groups of squared EPDM thin slices, each of which had been oxidatively aged to different levels before the tests. The analysis encompassed the determination of both the fractal dimension and the RMS (Root Mean Square)-slope of the surfaces. Supplementary tests utilizing Scanning Electron Microscopy (SEM) and Fourier Transform Infrared Spectroscopy (FTIR) were performed to elucidate the mechanisms governing surface roughening. The results show that the mean value of fractal dimension of EPDM specimens first decreased to 2.16 after 11.2-hour ageing and then increased to 2.42 after 39h-ageing. The evolution of RMS-slope exhibited similar tendencies, escalating from 0.55 to 1.16. Finally, a theoretical model to prognosticate the long-term waterproof capacity based on the percolation theory was proposed, which explicitly incorporated the impact of surface roughness. The outcomes underscore the considerable hydraulic deterioration resulting from surface roughening over a prolonged duration, ultimately leading to the complete loss of waterproof capacity in large opening scenarios.

RÉSUMÉ: Les joints en caoutchouc EPDM ont été largement utilisés comme composants d'étanchéité au niveau des joints des tunnels de protection qui sont censés fonctionner pendant des décennies. Toutefois, les modifications de la rugosité de la surface des joints en caoutchouc EPDM dues au vieillissement constituent un aspect qui n'est pas encore bien compris en termes d'implications pour les performances du mastic d'étanchéité. Dans cette étude, une série de tests AFM a été menée sur 6 groupes de tranches minces d'EPDM carrées, chacune ayant été vieillie par oxydation à différents niveaux avant les tests. L'analyse a porté sur la détermination de la dimension fractale et de la RMS-slope des surfaces. Des tests supplémentaires utilisant la SEM et la FTIR ont été réalisés pour élucider les mécanismes régissant la rugosité de la surface. Les résultats montrent que la valeur moyenne de la dimension fractale des échantillons d'EPDM a d'abord diminué à 2,16 après un vieillissement de 11,2 heures, puis a augmenté à 2,42 après un vieillissement de 39 heures. L'évolution de la pente RMS a montré des tendances similaires, passant de 0,55 à 1,16. Enfin, un modèle théorique a été proposé pour pronostiquer la capacité d'imperméabilisation à long terme sur la base de la théorie de la percolation, qui intègre explicitement l'impact de la rugosité de la surface. Les résultats soulignent la détérioration hydraulique considérable résultant de la rugosité de la surface sur une période prolongée, conduisant finalement à la perte totale de la capacité d'étanchéité dans les scénarios de grande ouverture.

Keywords: Shield tunnel; gasketed joint; sealant performance; EPDM; surface roughness.

1 INTRODUCTION

The hydraulic deterioration of gasketed joints causes leakage defects in shield tunnels in the long term (Xie et al., 2023b). Figure 1 depicts the progressive deterioration of the leakage defects, initially manifesting as wet stains, subsequently evolving into joint leakage indicative of substantial groundwater infiltration, and ultimately culminating in the water and soil gushing, signifying that the gasketed joints have lost all waterproof capacity. Hence, it is of great importance to elucidate the long-term sealant performance of gasketed joints (Shi et al., 2015).

Investigators have highlighted that the sealant performance of gasketed joints is a typical hydro-mechanical behaviour, prominently influenced by the assembly conditions of joints, i.e., the opening, offset, and rotation (Gong et al., 2018). Another main factor is the time-dependent behaviour of EPDM material, with stress relaxation constituting the predominant focus in prior investigations (Arnau et al., 2012; Shi et al., 2015; Zhang et al., 2020).

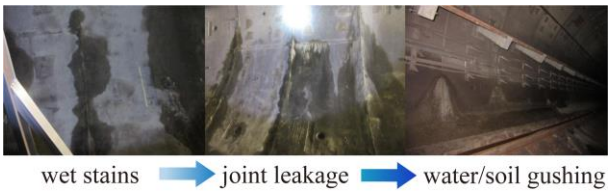

Figure 1. Leakage defects in shield tunnels.

However, the surface roughening of rubber surfaces, constituting another pivotal time-dependent attribute, has often been overlooked in analysing the sealant performance of gasketed joints. Physicians have underscored that the surface roughness has a significant effect on the sealant and seepage behaviours of the rubber seals (Persson, 2022; Persson and Yang, 2008). With an increase in surface roughness, the likelihood of leakage occurring at lower water pressures amplifies. Concurrently, the hydraulic aperture widens, consequently augmenting hydraulic conductivity. Thus, neglecting the phenomenon of surface roughening in gasketed joints may lead to an overestimation of waterproof capacity especially, in the long term.

In this paper, a comprehensive characterisation of the surface roughening phenomenon in EPDM was carried out through the utilisation of AFM tests. Additionally, SEM and FTIR tests were performed to elucidate the underlying mechanisms induced by the ageing process. Then, a refined theoretical model based on percolation theory was proposed to capture the influence of surface roughening on sealant performance. Finally, the model was applied in a specific engineering case, with its long-term waterproof capacity presented.

2 FRACTAL CHARACTERISTICS OF EPDM MATERIAL

2.1 Test methods

In the test, 6 groups of EPDM samples (see Figure 2(a)) were prepared, with dimensions measuring 6 mm × 6 mm × 2 mm. To enhance the generality of our findings, each set underwent three parallel tests. These groups were subsequently subjected to the thermo-oxidative ageing at a temperature of 150 ℃ for varying duration: 0 (unaged), 6.7, 11.2, 16.7, 22.3 and 39 h, as delineated in Figure 2(b) and tabulated in Table 1. Note that the upper side of the EPDM sample was scanned in the AFM test, as depicted in Figure 2(c). This approach ensured that the testing surface was in full contact with oxygen throughout the ageing process.

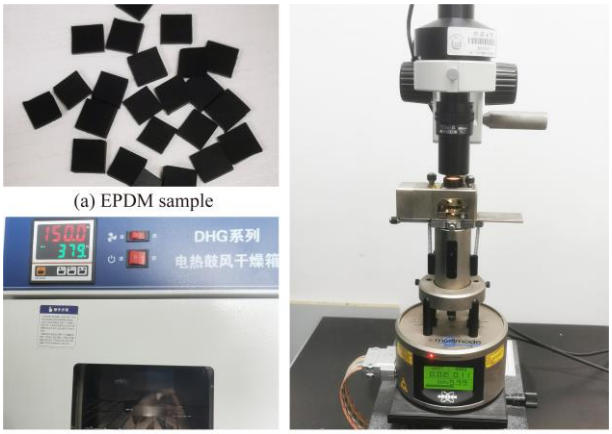

Figure 2. EPDM samples and test devices.

2.2 AFM results

Figure 3 depicts the surface topography of 6 groups, employing an observation scale of 5 μm × 5 μm. The outcomes indicate that the unaged EPDM surface (A1) exhibits a distinct degree of roughness, marked by the dense presence of clustered particles, as illustrated in Figure 3 (a). In the early stage of ageing process as shown in Figure 3 (b) and (c), the EPDM surfaces barely change in surface morphology, and with slightly smoother appearance compared with the unaged scenario in A3.

In the subsequent ageing periods, spanning from A4 to A6, a greater number of particles are observed to detach and accumulate on the EPDM surface over time, leading to the development of pronounced spikes. Importantly, these spikes formed through ageing are

notably sharper in comparison to those on the original surface, signifying a progressive increase in surface roughness. This qualitative evolution, as indicated by the test outcomes, is similar to that from Wang et al. (2020), suggesting that while the waterproof capacity might experience an initial enhancement within a short timeframe, it subsequently diminishes over prolonged duration, in alignment with the progression of roughness.

Table 1. Ageing times for each group.

group	A1	A2	A3	A4	A5	A6
Ageing time (h)	0	6.7	11.2	16.7	22.3	39

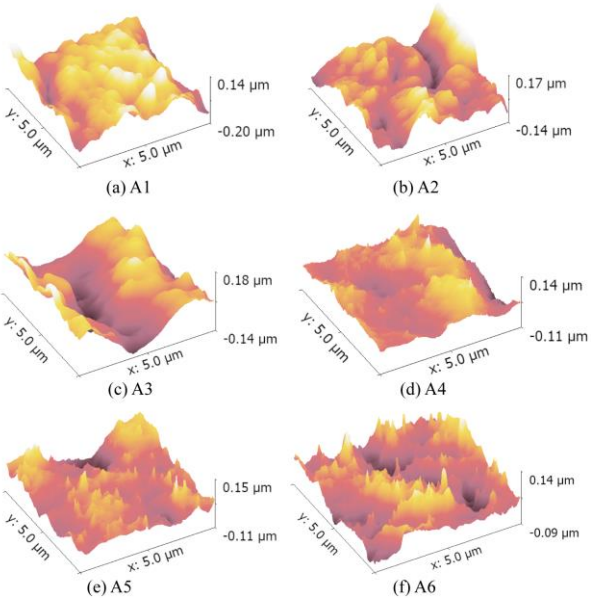

Figure 3. Surface roughness of different groups.

Figure 4 presents the evolution of fractal dimension D_f of the EPDM surface based on the obtained test data using the method of enclosing boxes. The D_f results in the same group exhibit certain disparities, attributed to the inherent discreteness of the surface topography. Nevertheless, the nonlinear variation of D_f with ageing time underscores the shift towards smoother surfaces initially, followed by a transition to increased roughness once the ageing duration surpasses 11.2 hours, corroborating observations in Figure 3. Specifically, the mean value of D_f firstly decreased from 2.27 to 2.16 after 11.2-hour ageing, subsequently ascending to 2.42 following 39-hour ageing.

RMS-slope ξ, another roughness-related parameter, can also be derived from the test data. Figure 5 presents the parallel results of RMS-slope, mirroring a comparable nonlinear ascending pattern as observed in the fractal dimension. Specifically, ξ experiences a slight reduction until the ageing duration reaches 11.2 h, after which it undergoes a significant escalation. When the ageing time approaches 39 h, the average value of ξ culminates at 1.16, notably surpassing that of 0.55 in the unaged scenario.

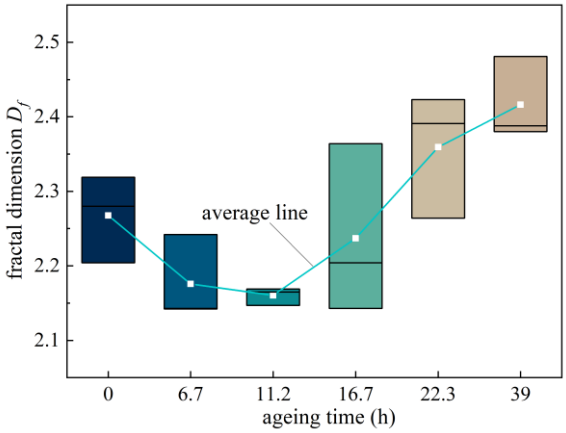

Figure 4. Fractal dimension of EPDM surface.

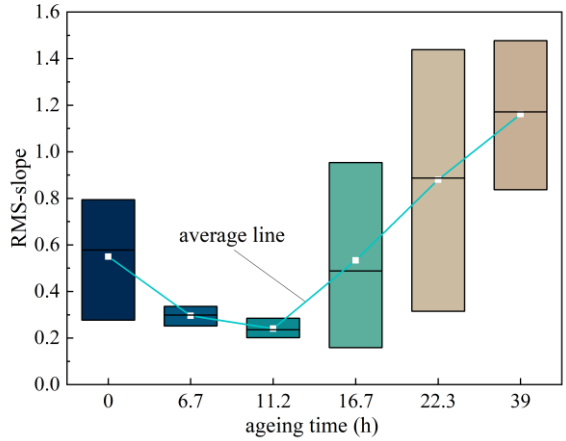

Figure 5. RMS-slope of EPDM surface.

2.3 SEM and FTIR results

To reveal the ageing mechanisms of EPDM surface, a series of SEM and FTIR tests were conducted. Figure 6 gives the surface roughness evolution over time observed through SEM scans, primarily capturing the degradation process prompted by elevated temperature. Evidently, an increased presence of particles becomes apparent, with a dense distribution observed on the EPDM surface. This observation aligns with the findings obtained from the AFM analysis, as illustrated in Figure 3.

Figure 7 graphically illustrates the alterations in chemical composition throughout the degradation process, revealing that ageing predominantly impacts components characterized by wave numbers proximate to 1500 cm^{-1}. This specific wave number range corresponds to the scissoring vibration of C-H bonds, with the intensity of its peak serving as an indicator of material degradation. Notably, the peak intensity of the

unaged sample is lower than that of the subsequent instances, offering insights into the chemical mechanisms driving the initial surface smoothing observed during the early stages of ageing in the AFM results.

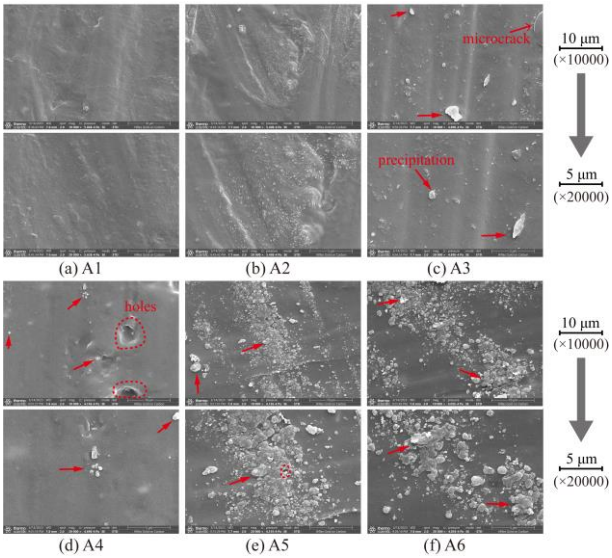

Figure 6. SEM results of EPDM surface of different ageing conditions from A1 to A6.

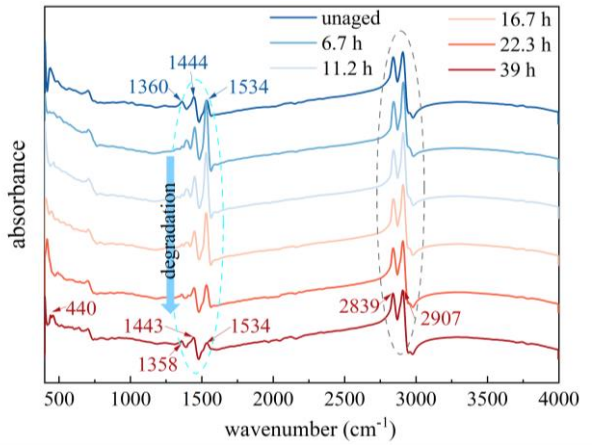

Figure 7. FTIR results of EPDM material of different ageing conditions from A1 to A6.

3 THEORETICAL MODEL OF SEALANT PERFORMANCE

Herein, a refined theoretical model aimed at assessing the sealant performance was introduced (Xie et al., 2023a). In the derivation, the percolation pressure (Persson, 2022) has been employed to elucidate the impact of surface roughness.

3.1 Percolation pressure

According to percolation theory, leakage from the contact area is prevented when the surface percolates at the highest magnification, i.e., the relative contact area $A(\zeta)/A_0$ exceeds 0.4 (Persson, 2022). Accordingly, we define the nominal pressure as percolation pressure P_{perc} when $A(\zeta)/A_0$ reaches 0.4 at a large wavenumber cut-off (Persson, 2022):

$$P_{perc} = \frac{\sqrt{2}}{2}\,\mathrm{erfinv}\left(\frac{A}{A_0}\right)E^*\xi \tag{1}$$

where E^* refers to the effective modulus of the rubber seals, and equals to $E_g/\left(2\times\left(1-v_g^2\right)\right)$ when the seal is composed of two pieces of gaskets in shield tunnel. v_g is the equivalent Poisson ratio of the gaskets, which varies with the compression strain.

3.2 Theoretical model implemented with percolation theory

The sealant performance of the gasketed joints is primarily influenced by the normal confining pressure P_c (Gong et al., 2019). This normal confining pressure undergoes augmentation when subjected to water pressurisation, a phenomenon recognised as the self-sealing effect (Shalabi et al., 2016), characterised by the slope k_0. Notably, the self-sealing effect becomes increasingly prominent, ultimately leading to the establishment of a critical leakage state when the confining pressure P_{c2} attains a value equivalent to the critical leakage water pressure P_{wc}

$$P_{wc} = \frac{1}{1-k_0}P_{c1} \tag{2}$$

where k_0 is the self-sealing coefficient and varies with compression strain ε, and P_{c1} refers to the initial confining pressure

$$P_{c1} = E_g\varepsilon \tag{3}$$

According to the previously mentioned percolation theory, the leakage transpires prior to the onset of the critical leakage state. By incorporating the influence of the percolation process, as symbolised by the percolation pressure P_{perc}, the final equation governing the critical water pressure (Xie et al., 2023a) can be derived as

$$P_{wc} = \frac{E_g\varepsilon - P_{perc}}{1-k_0} \tag{4}$$

Notably, Eq. (4) reflects the effect of surface roughness on waterproof capacity, that is, P_{wc} reduces as the EPDM surface gets rougher.

3.3 Model validation and long-term sealant performance prediction

Based on the proposed theoretical model, the long-term sealant performance of gasketed joints can be prognosticated. The test data from Gong et al. (2018) is used in the model validation. One representative engineering case, labelled as SC1, is subjected to analysis. First, the equivalent modulus of the gaskets E_g is derived based on the data of gasket-in-groove loading test, as given in Eq. (5):

$$E_g = 3 + 1.429 \times 10^{-6} \exp(36.81\varepsilon) \quad (5)$$

Significant nonlinearity of self-sealing effect is observed in these cases. Based on the test data (Gong et al., 2018), a correlation between the slope and compression strain (Xie et al., 2023a) was established. The results indicate that k_0 equal to $4.46\varepsilon^2$. The results of RMS-slope derived from the AFM test are used in calculating the percolation pressure. In the initial unaged condition, RMS-slope registers at 0.55, while following a 39-hour ageing period (full aged), this value increases to 1.16.

Figure 8 present the experimental and theoretical results of critical leakage pressure for case SC1. The results show that the theoretical results in unaged scenario align closely with the test data. When the opening is small, the theoretical estimations slightly exceed the experimental values. This discrepancy suggests an underestimation of the confining pressure within the theoretical model. One main reason for this is that the equivalent modulus is determined through the gasket-in-groove loading test, which does not account for lateral water pressurization. The modulus E_g is further enhanced under enormous water pressure.

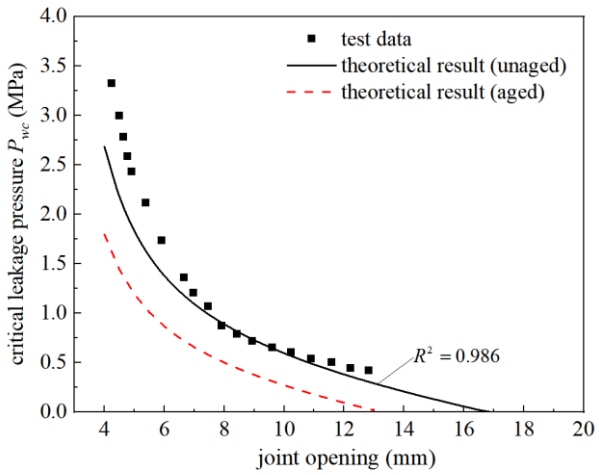

Figure 8. Critical leakage pressure for case SC1

The results of aged scenario represented in dashed lines indicate that the surface roughening has great effect of hydraulic deterioration. The critical leakage pressure experiences substantial decreases across all opening situations, causing the critical leakage pressure P_{wc} approaches 0 much earlier compared to the unaged scenario. The complete loss of waterproofing capacity occurs when the joint opening increases to 13 mm, primarily due to the escalating percolation pressure. In the unaged scenario, this critical opening value is approximately 17 mm.

According to the Arrhenius formula (Zhang et al., 2020), 39-h ageing time at 150°C corresponds to an 80-year service duration at room temperature (20°C). These findings underscore the substantial contribution of ageing-induced surface roughening in EPDM to the long-term hydraulic deterioration of gasketed joints.

4 CONCLUSIONS

The paper mainly focuses on the roughness evolution of EPDM surface induced by ageing, and its long-term implications on the sealant performance of gasketed joints. The results of AFM test reveal a distinctive pattern: the EPDM surface initially experiences a slightly smoothing effect during the early stages of ageing, followed by a progressive increase in roughness after approximately 39-hour ageing. This evolutionary trajectory is further corroborated by the outcomes derived from SEM and FTIR tests.

In response to these findings, a refined theoretical model is introduced to evaluate the long-term sealant performance of gasketed joints. The results underscore the substantial effect of surface roughening on the hydraulic deterioration. Specifically, the gasketed joints lose all waterproof capacity when opening is 17 and 13 mm, in the unaged and aged scenarios, respectively. These findings serve to underscore the critical significance of incorporating the concept of surface roughening in the evaluation of sealant performance of gasketed joints, which also aids in the design of waterproof in segmental tunnels by predicting the waterproof capacity affected by surface roughness and joint deformations.

ABSTRACT: Numerical simulation of mechanized tunnelling in urban areas, both in 2D and 3D conditions, is often carried out by simply applying a displacement pattern at the excavation boundary, especially when the objective of the analysis is the prediction of the displacements away from the tunnel. The principal assumption of this method is that the deformed tunnel shape is similar to the original shape, i.e. circular, while its centre is translated downward. This paper proposes to apply a different, more general, displacement pattern, based on further optimization of previous approaches, considering an elliptical contraction shape. Specifically, the upper and lower parts of the tunnel are allowed to contract assuming two independent elliptical shapes. The method is validated through three-dimensional finite element simulations, with special reference to the deformation pattern of a real case-history of a very shallow and large-diameter tunnel. The results show that: (1) the approach is applicable to shallow-buried and large-diameter tunnels; (2) the deformation pattern of very shallow and large-diameter tunnels is characterized by an elliptical shape in the upper portion of the section and by a circular one in the lower part; (3) the new approach can produce a more accurate prediction of the soil displacement field, if compared with the homothetic contraction of the tunnel section.

RÉSUMÉ: La simulation numérique du creusement mécanisé en milieu urbain, que ce soit dans des conditions en 2D ou 3D, est souvent réalisée en appliquant simplement un champ de déplacement à la limite de l'excavation, particulièrement lorsque l'accent est mis sur la prédiction des déplacements loin du tunnel. L'hypothèse principale de cette méthode est que la forme déformée du tunnel est similaire à la forme d'origine, c'est-à-dire circulaire, avec son centre déplacé vers le bas. Cet article propose un champ de déplacement plus général, fondé sur une optimisation approfondie des approches antérieures, en prenant en considération une forme de contraction elliptique. Notamment, les parties supérieure et inférieure du tunnel sont induites à se contracter selon deux formes elliptiques indépendantes. La méthode est validée par des simulations par éléments finis tridimensionnels, avec une référence particulière à un cas concret de tunnel très peu profond et de grand diamètre. Les résultats démontrent que: (1) l'approche est applicable aux tunnels peu profonds et de grand diamètre; (2) le motif de déformation des tunnels peu profonds et de grand diamètre est caractérisé par une forme elliptique dans la partie supérieure de la section et par une forme circulaire dans la partie inférieure; (3) par rapport à la contraction homothétique de la section du tunnel, la nouvelle approche peut prédire un champ de déplacement du sol plus précis.

1 INTRODUCTION

Tunnel excavation often results in significant ground displacements. Precise prediction of excavation-induced movements is crucial for ensuring tunnel construction safety with respect to pre-existing surface and subsurface structures located nearby (Mair, 2008). Excavation-induced ground movements can be predicted using various methods, including empirical approaches (Peck, 1969), quasi-analytical solutions (Loganathan and Poulos, 1998), or numerical simulations (Nguyen et al., 2021; Yang et al., 2023). When the focus is on ground displacements rather than

on lining design, the displacement-controlled method (DCM) can be employed for simulating tunnel excavation, without considering the presence of the lining (Boldini et al., 2018). Therefore, the setting of a reasonable excavation boundary contraction pattern is of utmost importance (Cheng et al., 2007). Furthermore, when combined with advanced soil constitutive models, such as the Hardening Soil model with small-strain stiffness (HSsmall), very satisfactory results can be obtained also for small values of volume loss (Benz, 2007; Fargnoli et al., 2015).

DCM can assume various displacement patterns. Sagaseta (1987) proposed an isotropic convergence pattern towards the centre of the tunnel boundary. However, especially for shallow tunnels and anisotropic in situ state of stress, the convergence along the tunnel boundary is not uniform, i.e. the displacement at the crown is obviously larger, while that at the invert arch is much smaller (Pinto and Whittle, 2006). Cheng et al. (2007) introduced a widely adopted Circular DCM that accounts for both circular contraction and vertical translation of the tunnel boundary, as shown in Figure 1. While numerous researchers have adopted these approaches and achieved satisfactory predictive results, their applications have been primarily focused on small-diameter or deep-buried tunnels, as for subway tunnels (Amorosi et al., 2014; Boldini et al., 2018). However, for shallow-buried large-diameter tunnels, for which the surrounding soil is characterized by more significant stress and stiffness variations, the accuracy of these displacement-controlled methods could be reduced.

In this study, a novel Bi-Elliptical DCM is introduced for the specific characteristics of shallow and large tunnels. To illustrate its effectiveness, this method is applied to an actual case-history and its performance is compared with the commonly used Circular DCM. Results show limitations of the Circular DCM in analysing the impacts of shallow and large tunnel excavation, while highlighting the advantages and potential applications of the Bi-Elliptical DCM model.

2 BI-ELLIPTICAL DISPLACEMENT-CONTROLLED METHOD

2.1 Limitations of existing DCM

The commonly used DCM currently have the following assumptions: 1) the convergence is not uniform; 2) the deformed tunnel shape is similar to the initial shape; 3) convergence point located between converged tunnel centre and invert (Cheng et al., 2007). Usually, this point is set as the invert, where no displacement occurs (Amorosi et al., 2014; Boldini et al., 2018).

The above displacement pattern is not necessarily realistic because the deformed tunnel shape may not necessarily be similar to the original excavation shape; in addition, due to the effect of unloading, the tunnel bottom may uplift, and its displacement should not be ignored. In practice, the excavation profile tends to be more elliptical in shape due to the non-linearity of the soil properties and the anisotropy of the in-situ state of stress (Loganathan and Poulos, 1998; Marshall et al., 2009).

2.2 Improved Bi-Elliptical DCM

A Bi-Elliptical DCM, which can also degrade to a Circular DCM when necessary, is proposed in the following. Figure 2 shows a schematic plot of the optimized bi-elliptical displacement pattern. There are three assumptions: 1) the deformed tunnel profile is divided into two separate ellipses, the upper and the lower ones, respectively above and below the tunnel axis, 2) the deformed profile is continuous at the two intersections, 3) the deformed tunnel profile is allowed for an overall vertical displacement.

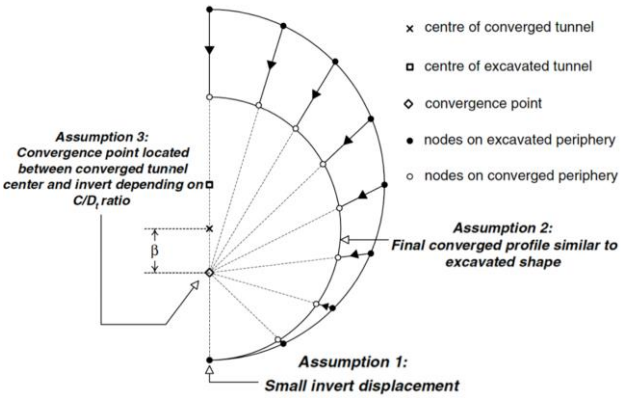

Figure 1. Commonly used Circular DCM (Cheng et al., 2007).

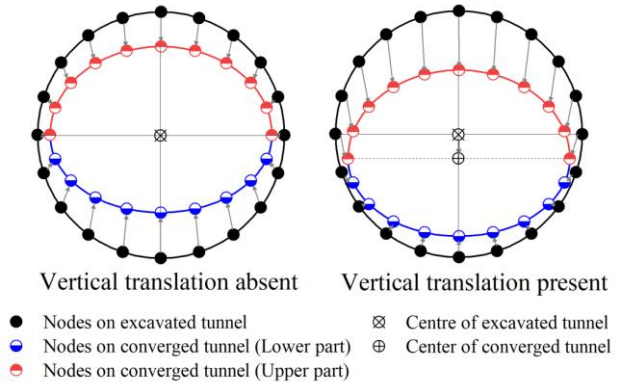

Figure 2. Schematic diagram of the optimized bi-elliptical displacement pattern.

3 NUMERICAL SIMULATION AND VERIFICATION OF BI-ELLIPTICAL DEFORMATION ASSUMPTION

3.1 Description of the reference case

The numerical model is set up on the basis of the very shallow and large Suzhou Tongjing road tunnel, characterized by a tunnel diameter (D) of 13.2 m, a lining thickness of 0.6 m, and an axis depth (H) of 16.7 m (Figure 3). The soil profile at the construction area is also shown in Figure 3. The soil is divided into 10 different layers, namely: 1- fill, 2- clay, 3- silty clay, 4- silt, 5- silty sand, 6- silty clay, 7- clay, 8- silty clay, 9- silty clay, and 10- silty clay. The TBM-EPB tunnel passes through layers 4- silt, 5- silty sand, 6- silty clay and 7- clay. The water table is at 1.5 m below the ground surface and the pore pressure distribution is hydrostatic. During simulation of tunnel excavation, soil layers 1, 4, and 5 are set as drained, while other soil layers are set as undrained.

3.2 Detail of the finite element model

In order to obtain a more accurate representation of the excavation boundary profile, a 3D step-by-step numerical tunnel excavation is implemented in Plaxis. This model incorporates detailed modelling of the TBM-EPB and the tunnel lining (Figure 4). Solid elements are used for the soil and the lining, while plate elements are employed to simulate the machine shield. The finite element discretization consists of over 132249 10-node tetrahedral elements. In the vicinity of the tunnel face, the mesh is refined to provide better approximation to handle significant stress and strain gradients in that region. Interaction surfaces are established between the tunnel lining and the soil, as well as between the shield machine and the soil (Figure 4). The face pressure and the grouting pressure of the shield, which follow a linear interpolation distribution with depth are set equal to the total horizontal stress and total vertical stress at those locations respectively.

The HSsmall constitutive law is adopted to get accurate numerical results. Table 1 shows the parameters of the HSsmall model: all the values are calibrated on laboratory and in-situ tests data (Yang, 2023). The elastic model is used for the lining and the shield (the values of parameters are listed in Table 2).

The construction process is modeled using a sequential excavation scheme (Fargnoli et al., 2015). Plaxis 3D provides a method to simulate tunnel volume loss by assigning a contraction rate (C_{ref}) to the tunnel boring machine shield, without pre-determining the final tunnel contraction pattern. This technique implements a contraction whose actual value depends on the stiffness of the surrounding clusters and objects. The equilibrium state is reached during the iterative calculation process, and the final deformation profile is related to the stiffness of the surrounding soils (Plaxis, 2020).

C_{ref} is set equal to 0.45% based on field surface settlement monitoring results. The corresponding surface volume loss, $V_{l,s}$, results to be 0.48% using a Gaussian distribution curve with a width parameter $K = 0.6$ (Figure 5). It can be observed that the numerical calculation results are in good agreement with the theoretical and monitoring results, indicating the reliability and accuracy of the numerical model used in this study.

Figure 6 illustrates the deformed shape and displacement of tunnel boundary, these latter being amplified by 100 times and normalized based on the tunnel radius. It is evident that for this large-diameter shallow-buried tunnel, the excavation boundary does not exhibit a circular or elliptical contraction. Instead, a distinct bi-elliptical contraction pattern is observed, which the upper part deforms into an ellipse, while the lower shrinks in a circular shape. This observation validates the assumptions of the proposed Bi-Elliptical DCM method.

4 APPLICATION AND COMPARISON OF THE BI-ELLIPTICAL DCM

To further validate the predictive accuracy of the newly proposed DCM for ground surface displacements, a series of numerical simulations are conducted using a single-step excavation method to simulate tunnel excavation without modelling the tunnel lining, as in Boldini et al. (2018). For the Bi-Elliptical DCM, displacements at the excavation boundary from Figure 6 are used as prescribed displacements. Additionally, predictions of ground settlement are made using Cheng's Circular DCM for comparison. β represents the overall tunnel translation magnitude, with $\beta = 0$ indicating no vertical translation, meaning the tunnel is contracting toward its center, and $\beta = 1$ signifying that the tunnel invert is translated to its initial position, i.e. that the tunnel is fixed at the bottom (Figure 1).

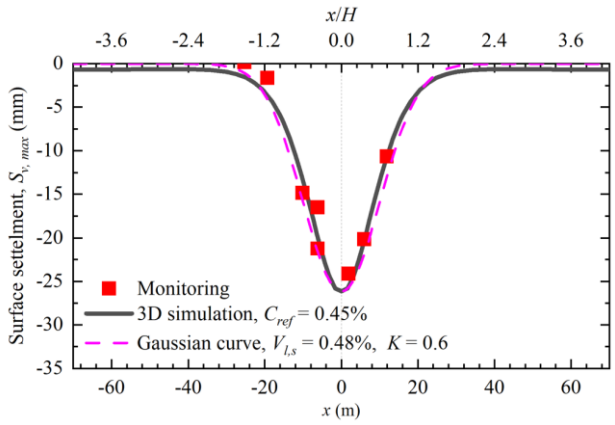

Figure 5. Comparison between numerical simulation results and field monitoring data.

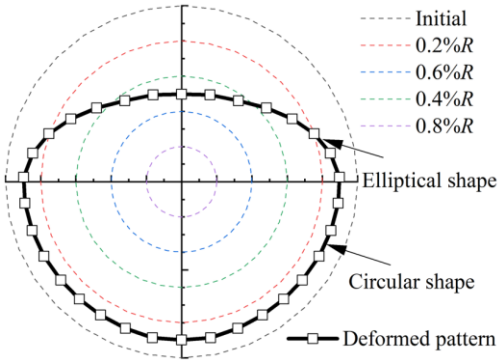

Figure 6. Final deformed tunnel profile for the reference case (Scale: 1:100).

Figure 7 presents the results of the Bi-Elliptical DCM and the Cheng's Circular DCM. For Bi-Elliptical DCM, the tunnel profile is controlled by the elliptical convergence parameters (n_1 and n_2), for the upper and lower parts, and the overall tunnel translation parameter (β). For the reference case, the values of n_1, n_2, and β were set equal to 0.9963, 1.0000, and 0.10, respectively. The Bi-Elliptical DCM, as emphasized before, successfully reproduces the ground settlement profile, showing an excellent agreement with measured data. In contrast, the Circular DCM predicts a wider settlement trough and typically underestimates the maximum ground displacement, especially for low values of β. Furthermore, even when β =1, the predictive profile is shallower than that obtained by the Bi-Elliptical DCM. This demonstrates the advantage of the Bi-Elliptical DCM in predicting ground surface displacements induced by shallow-buried large-diameter tunnel excavation.

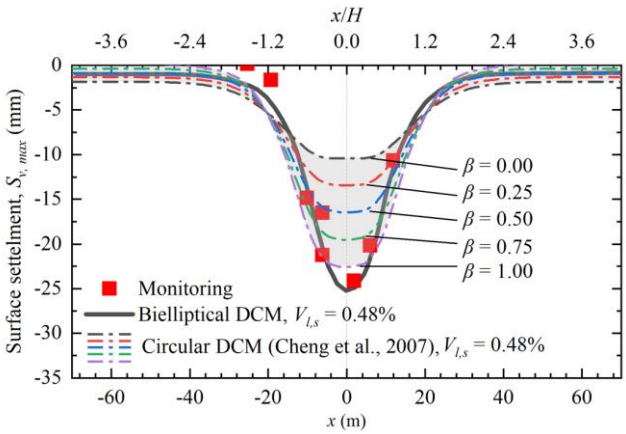

Figure 7. Comparison of the predicted surface settlement of Bi-Elliptical DCM and Circular DCM.

5 CONCLUSIONS

Based on the characteristics of shallow-buried large-diameter tunnels, this paper introduces the Bi-Elliptical deformation model for tunnel boundary. Using numerical simulations and a real case-history, this approach is validated and compared with the Circular DCM. Three key conclusions are obtained from this investigation:

(1) the excavation boundary of shallow-buried large-diameter tunnels exhibit distinct, independent contractions in the upper and lower parts, with the upper part forming an ellipse and the lower part contracting into a circle;

(2) the Circular DCM underestimates the maximum ground settlement and results in a wider settlement trough;

(3) the Bi-Elliptical DCM effectively reproduces the ground surface profile for a specific surface volume loss.

This research demonstrates the validity of the Bi-Elliptical deformation assumptions and its significant potential in accurately predicting ground surface displacements caused by the excavation of large-diameter shallow-buried tunnels.

Evaluation of the induced axial force behaviour for bored tunnel construction adjacent to existing long piles

Évaluation du comportement de la force axiale induite pour la construction d'un tunnel ennuyé adjacent à des pieux longs existants

ABSTRACT: Population growth and increase in urbanisation contribute to an increased use of underground space. Consequently, new tunnel alignments are often situated near existing piled foundations. Thus, evaluating the induced forces and displacement in the piles caused by ground movements due to tunnelling must be considered. This study focused on assessing the maximum induced axial forces (*Max.N*) in long piles. A series of three-dimensional Finite Element Analyses were conducted. The model's validity was established by comparing it with data from a well-known literature. Parametric studies were performed, varying the tunnel depth (Z) and pile length (L_p) (lengths evaluated are 40 m, 50 m, and 59 m). The findings indicate that the behaviour of long piles in response to tunnelling exhibits two dominant characteristics. When tunnelling at a shallow depth ($Z/L_p < 0.5$), the *Max.N* in the piles remains relatively constant regardless of the pile length. However, for deep tunnel constructions ($Z/L_p > 0.5$), shorter piles are less affected compared to longer piles. These findings could benefit engineers when dealing with new pile construction plans or minimising potential impacts on existing piled foundations, as adjusted tunnel alignments could be considered.

RÉSUMÉ: La croissance de la population et l'urbanisation accrue contribuent à la demande d'utilisation de l'espace souterrain. Par conséquent, les nouveaux alignements de tunnels sont souvent inévitablement situés à proximité de fondations en pieux existantes. Selon cette situation, il est nécessaire de prendre en compte l'évaluation des forces induites et du déplacement dans les pieux causés par les mouvements du sol dus au creusement de tunnels. Cette étude s'est principalement concentrée sur l'évaluation des forces axiales maximales induites (Max.N) dans les pieux longs. Une série d'analyses par éléments finis tridimensionnels a été réalisée. La validité du modèle a été établie en le comparant avec la littérature bien connue. Des études paramétriques ont été réalisées, en faisant varier les profondeurs des tunnels (Z) et les longueurs des pieux (Lp) de 40 m, 50 m et 59 m. Les résultats indiquent que le comportement des pieux longs en réponse au creusement de tunnels présente deux caractéristiques dominantes. Lors du creusement à faible profondeur (Z/Lp < 0,5), le Max.N dans les pieux reste relativement constant quelle que soit la longueur du pieu. Cependant, pour un creusement profond (Z/Lp > 0,5), les pieux plus courts sont moins affectés par rapport aux pieux plus longs. Ces résultats pourraient être d'un bénéfice significatif pour les ingénieurs lorsqu'ils traitent de nouveaux plans de construction de pieux ou minimisent les impacts potentiels sur les fondations en pieux existantes, car des alignements de tunnels ajustés pourraient être envisagés.

Keywords: Tunnel; piled foundation; axial force; finite element analysis; parametric studies.

1 INTRODUCTION

The use of underground space has rapidly increased for several applications, such as transportation systems, water supply and drainage systems and cables, particularly in big cities, attributed to population growth and urbanisation and further development of infrastructure. Tunnelling is one of the most popular techniques to meet these demands, especially in congested urban areas. Often, new tunnel construction is aligned closely to existing structures supported by piled foundations, such as high-rise buildings and fly-over bridges. Hence, the potential impacts affecting these piles induced by tunnel construction activities should be considered.

Generally, tunnelling causes ground movements towards the tunnel in both vertical and horizontal directions (Basile, 2014). These ground movements can impact existing piled foundations and, at least two major aspects need to be carefully considered: (i) induced forces in the piles, including axial forces and bending moments; and (ii) tolerable structural movements (Basile, 2014).

To assess the interaction between piles and a new tunnel two configurations need to be considered: short piles and long piles (Loganathan, 1999). Several

research studies were conducted to understand the mechanisms of pile – tunnel interactions using various approaches, including full-scale experiments (Pang, 2006), physical and centrifuge model tests (Jacobsz et al., 2004; Marshall, 2009) as well as analytical and numerical analysis (Loganathan, 1999; Kitiyodom et al., 2005; Jongpradist et al., 2013). However, most of the studies focused on pile settlement and induced bending moments. The mechanism of induced axial force especially when focusing on the case of a long pile subjected to tunnelling is not well understood.

This paper presents the effect of tunnelling on a nearby long pile focusing on the maximum induced axial force (*Max.N*). A three-dimensional finite element analysis (3D-FEM) was adapted using the PLAXIS 3D software package. A parametric study has been conducted varying key parameters: pile lengths (L_p), clearance ($\times D$) and tunnel buried depths (Z). The model is validated using a well-documented historical case study. The effects of the relationship between L_p and Z on *Max.N* are presented and, recommendations on new piled foundation design are presented to minimise the potential impacts.

2 FINITE ELEMENT MODELLING AND VALIDATION

The model was validated using a historical case study reported by Pang (2006). Pier number 20, constructed as part of the Singapore's Mass Rapid Transit (MRT) North-East line project, was used as a prototype model.

The foundation details included a 2×2 square arrangement of four bored piles with a diameter of 1.2 m and a spacing of 3.6 m (centre to centre), with a length of 62 m below the ground surface. Various instrumentation, including inclinometers, settlement points, and strain gauges, were installed in the piled foundation to observe the potential effects of the piles' responses to the tunnel construction activities.

Two tunnels were sequentially constructed in this project at a depth of 21.0 m, named the Southbound (SB) and Northbound (NB) tunnels. The clearance between the outer tunnel lining and the pile group was 1.6 m, and 3.3 m for the SB and NB tunnel, respectively as presented in Figure 1. The volume losses, as reported by Pang (2006), were 1.38% and 1.67% for SB and NB tunnelling, respectively.

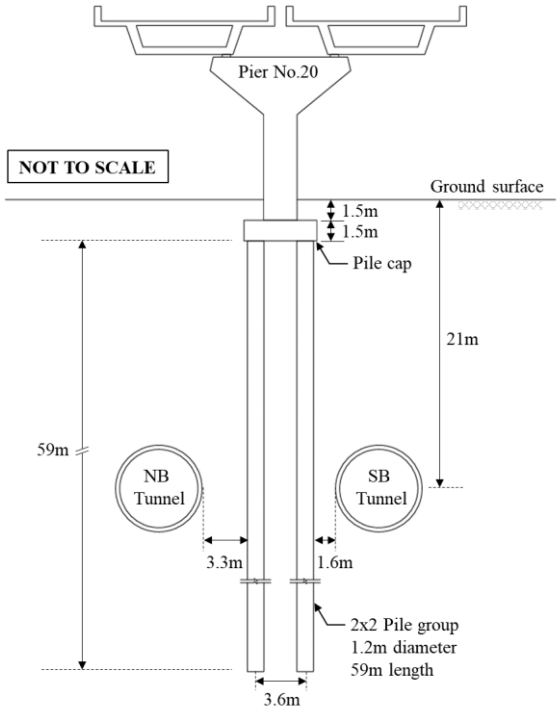

Figure 1. Pile – Tunnel configuration in MRT Singapore project (Modified from Pang, 2006).

2.1 Mesh and Boundary Conditions

Figure 2 presents the mesh and boundary conditions of the prototype model. The boundary of the modelled problem is 140 m long, with a 80 m width and a 75 m depth. The soils were modelled with 10-nodes tetrahedral elements. The tunnel lining and the pile cap were modelled with a plate element along with an interface element to consider the soil-structure interaction, while an embedded beam element was employed to model the bored piles.

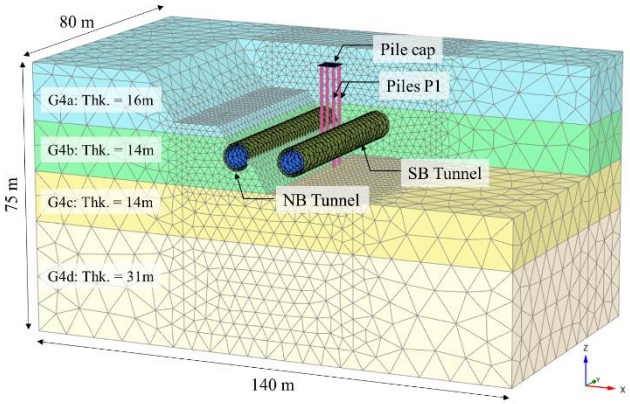

Figure 2. FE model validation mesh and boundary conditions.

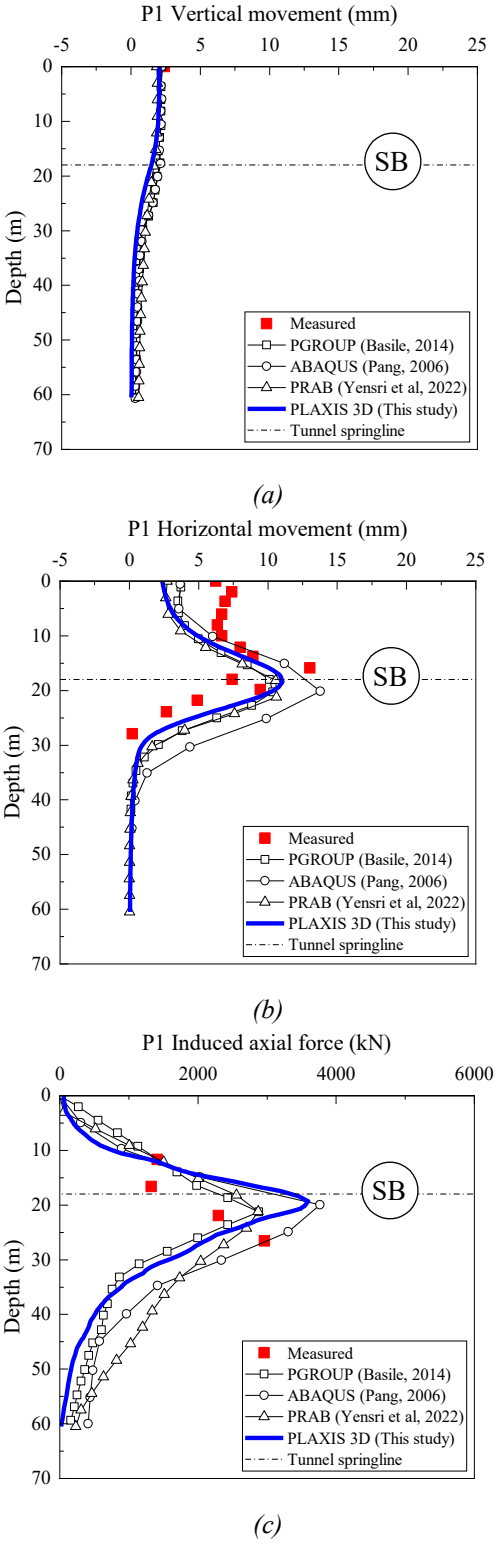
2.2 Validation

Figure 3 illustrates the results of the analysis of pile P1 and the ground surface settlement induced by SB tunnelling, comparing them with the measured data as

well as other prediction methods: analytical method, boundary element and finite element analysis. The maximum difference between computed and the measured data for the pile's movements and the induced forces in the pile caused by SB tunnelling is 20%. This provides confidence that the FE model is suitable to use as a predictive model.



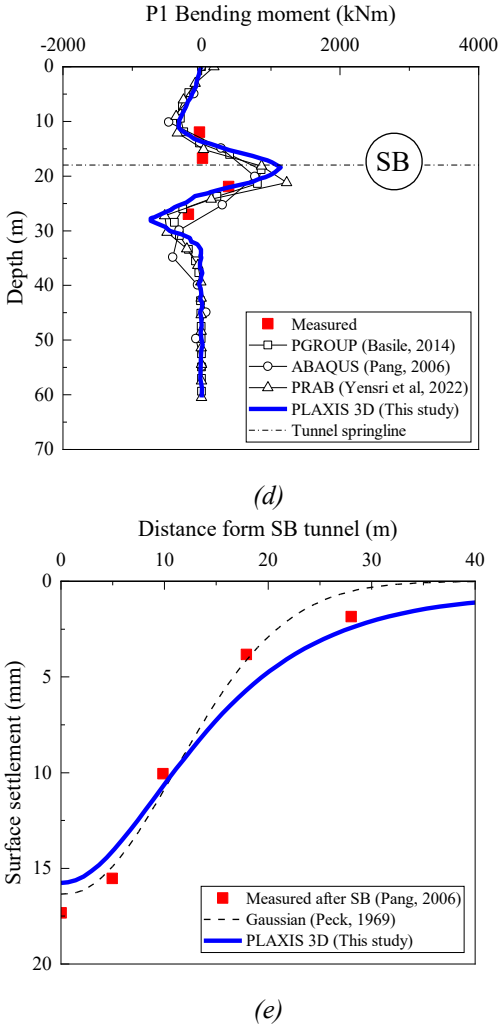


Figure 3. Pile P1 response to the construction of the SB tunnel after passing of the tunnel (a) Settlement (b) Horizontal movement (c) Induced axial force (d) Induced bending after SB (e) surface settlement.

3 PARAMETRIC STUDY

The effect of the pile – tunnel locations are observed through a parametric study using the validated FE model as a prototype model, with various key parameters:

- Pile lengths (L_p) are investigated at 40 m, 50 m and 59 m (same as the prototype)
- Clearance ($\times D_t$) is normalised with the tunnel diameter ($D_t = 6.3m$), and applied at $0.5D_t$, $1D_t$, $2D_t$ and $3D_t$.
- Tunnel buried depths (Z) are modelled at depths of 9.45m ($1.5D_t$), 22.05m ($3.5D_t$), 28.35 m ($4.5D_t$) and 40.95m ($6.5D_t$), representing Z1, Z2, Z3 and Z4, respectively.

Both the tunnel and pile maintain a constant diameter of 6.3 m and 1.2 m, respectively. In the simulation, a tunnel volume loss of 2.0% is used, incorporating face, shield and tail losses without

considering tunnel advancement. The surrounding soils are modelled using the Modified Cam Clay constitutive model, and the critical state parameters and strength properties of the materials are shown in Tables 1 and 2, respectively. The pile cap and tunnel lining are simulated using linear-elastic plate elements with material properties defined by flexural (EI) and axial stiffness (EA). The bored piles are modelled using the embedded beam element, which considers the actual properties and geometry of the pile as well as the geotechnical mechanisms, including skin friction and bearing capacity which can also be added to the model. The interface elements are automatically generated based on the strength of the layered soils. Further details can be found in PLAXIS 3D Scientific Manual (2023). Four different tunnel buried depths are investigated, and the normalisation of the tunnel depth against the pile length is presented in Table 3. The construction sequence begins with the construction of the piled foundation, followed by the tunnel construction.

Table 1. Critical state parameters (Pang, 2006).

Soil layer	κ	λ	e_{int}	M
G4a	0.018	0.113	1.8	1.113
G4b	0.023	0.104	1.9	1.2
G4c	0.007	0.07	2.0	1.2
G4d	0.007	0.07	2.0	1.2

Table 2. Strength parameters (Pang, 2006).

Soil layer	Cohesion (kPa)	Friction angle (°)
G4a	20	28
G4b	30	30
G4c	30	30
G4d	30	30

Table 3. Normalisation of tunnel depth to the pile length.

Tunnel depth	Z/L_p		
	L_p = 40m	L_p = 50m	L_p = 59m
Z1 (9.45m)	0.16	0.13	0.11
Z2 (22.05m)	0.48	0.38	0.32
Z3 (28.35m)	0.63	0.51	0.43
Z4 (40.95m)	0.95	0.76	0.64

4 RESULTS AND DISCUSSIONS

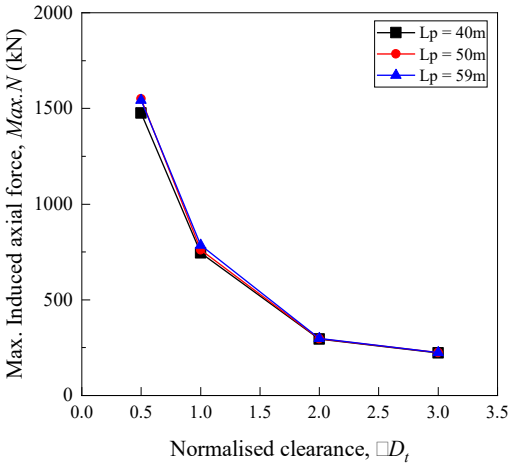
The *Max.N* values of pile P1 obtained from the analysis are discussed in this section. Based on these findings, the depth of the buried tunnels as well as the pile lengths significantly impact on the values of *Max.N* as investigated from each analysis case.

4.1 Maximum Induced Axial Force (*Max.N*)

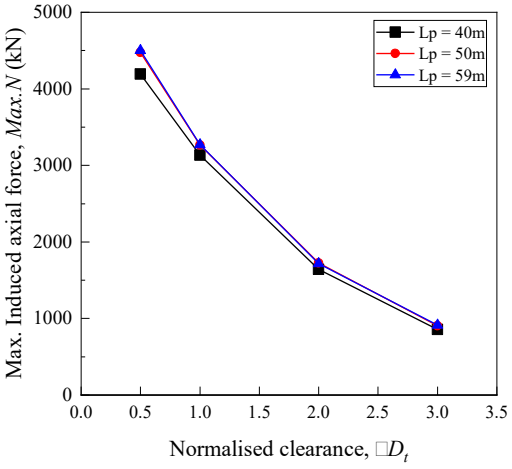
Figure 4 illustrates the correlation between *Max.N* and the clearance of pile P1. The results show that the value of *Max.N* is notably influenced by the tunnel depth as well as the clearance. Regarding tunnel depths Z1 to Z3, the results indicate that the *Max.N* values are not significantly affected by the pile length. However, there is an exception, particularly for the case of L_p = 40 m at the depth Z3. At a clearance of $0.5D_t$, the *Max.N* is 4,306 kN, while for L_p = 50 m and 59 m, the values are 5,625 kN and 5,830 kN, respectively.

In the context of Z4, a notable difference appears in the behaviour of *Max.N* compared to the depths of Z1 to Z3. It can be observed that the increase in pile length contributed to an increase in the value of *Max.N*. For instance, at a clearance of $0.5D_t$, the *Max.N* values are 2,478 kN, 5,444 kN and 7,736 kN for L_p = 40 m, 50 m and 59 m, respectively.

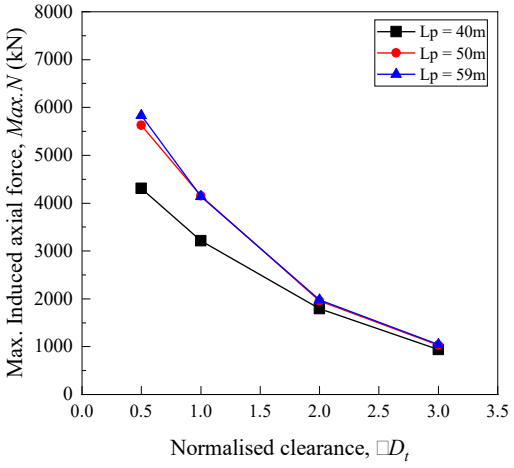
Based on these findings, it can be concluded that for shallow tunnelling ($Z/L_p < 0.5$), the increase in pile length does not significantly impact the drag force subjected to the vertical ground movement along the pile shaft. In contrast, for deep tunnelling ($Z/L_p > 0.5$), changes in the toe level of the pile influence the developed drag force considerably.



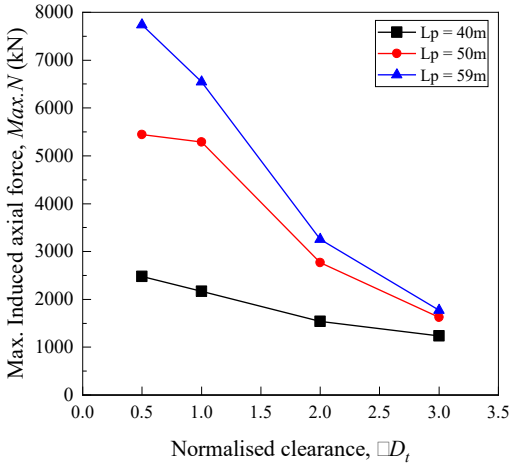
(a)



(b)



(c)



(d)

Figure 4. The maximum induced axial force in the pile against the normalised clearance at depths of (a) Z1, (b) Z2, (c) Z3 and (d) Z4.

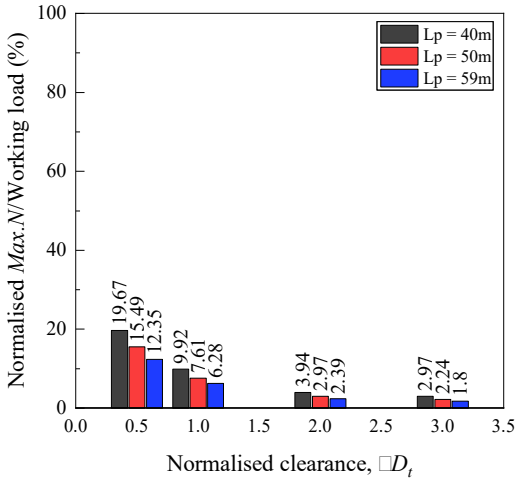
4.2 Normalisation of *Max.N*

The normalisation of *Max.N* with respect to the applied working load for each pile length is discussed in this section. In order to assess the pile's structural and geotechnical capacity affected by tunnelling, this value can be utilised for evaluation purposes together with the load distribution along the pile length. The applied working loads adopted in this study are 7,500 kN, 11,000 kN and 12,500 kN for L_p = 40 m, 50 m and 59m, respectively. Figure 5 illustrates the analysed results, focusing on the *Max.N* for each tunnel buried depth.

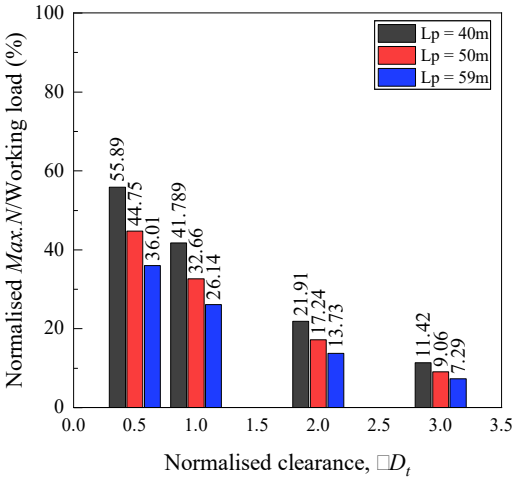
Based on the results, it is indicated that, at depths of Z1 to Z3 where the value of Z/L_p ranges from 0 to 0.5, the shorter pile, in contrast to the longer pile, experiences a significantly higher induced axial force compared to their working load. For instance, at a depth of Z2 with a clearance of 0.5D_t, the normalised *Max.N* to working load ratios are 55.89%, 44.75% and 36.01% for Z/L_p = 0.47, 0.38 and 0.32, respectively, with L_p values of 40 m, 50 m and 59 m, respectively.

In the case of deep tunnelling, with values of Z/L_p approximately greater than 0.5, Max.N is reduced for the shorter pile compared to the longer pile, especially at small clearances (0.5D_t to 1D_t). For example, at a depth of Z4 with a clearance of 0.5D_t, the normalised *Max.N* values are 33.04%, 54.44% and 61.89% for the value of Z/L_p = 0.93, 0.75 and 0.64.

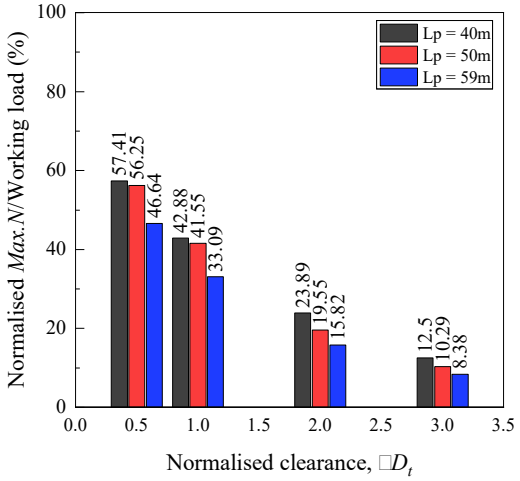
According to the results, it was demonstrated that the longest pile is advantageous in terms of minimising the impact from *Max.N* compared with the shorter pile, which could potentially affect a pile's structural capacity and stability during shallow tunnelling at depths ranging from Z/L_p = 0 to approximately 0.5. In contrast, for deep tunnelling configuration, i.e. Z/L_p > approximately 0.5, it suggests that the shortest pile play an important role in effectively decreasing *Max.N* compared to the longer piles.



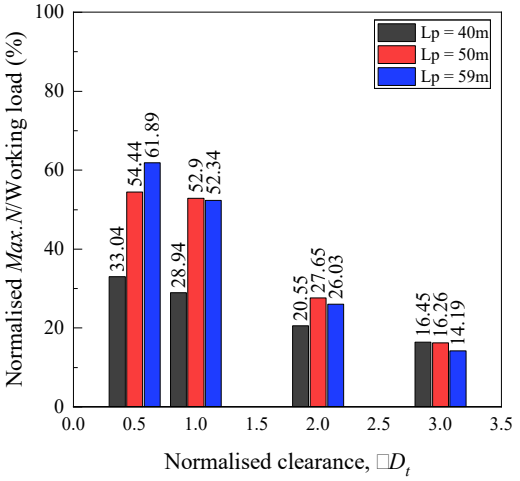
(a)



(b)



(c)



(d)

Figure 5. The comparison of normalised Max.N at depths of (a) Z1, (b) Z2, (c) Z3 and (d) Z4.

5 CONCLUSIONS

Based on the results obtained from the FE analysis, it is observed that the behaviour of the *Max.N* is significantly influenced by the tunnel buried depth relative to the pile length. Meanwhile, it can be deduced that the vertical change in tunnel alignment also contributes to the potential impact on the pile, particularly in terms of increasing axial force along the pile. The mechanisms are as follows:

- For shallow tunnelling ($Z/L_p < 0.5$), a longer pile is advantageous in terms of minimising the impact from the induced axial force, which could impact the stability of the pile (reduction of the factor of safety).
- In contrast, in the case of deep tunnelling ($Z/L_p > 0.5$), the longer pile appears disadvantageous compared to the shorter pile.

Recommendations can be made regarding minimising the *Max.N* in the new pile due to deep tunnel construction ($Z/L_p>0.5$) by adjusting the pile arrangement and decreasing the pile length. However, compromising on structural settlement, as well as pile stability must be taken into account in this case.

ABSTRACT: The Next Generation (NG) of Eurocodes are currently being drafted and scheduled to be rolled out in later part of 2027. The existing code does not cover the use of numerical modelling in geotechnical design although its use for serviceability limit state assessment and even for ultimate limit state (ULS) design has gone on for many years. The draft document will provide some guidance on the use of numerical modelling for ULS design of geotechnical structures. Clause 8.2 in Part 1 of this new draft code covers the recommended procedure for the application of numerical modelling in ULS design of geotechnical structures. This paper describes the evolution of the use of numerical modelling in geotechnical design and the recommended procedure included in this new code. A comparison is also made on the consequences of this procedure on the existing design approaches currently implemented in the existing code.

RÉSUMÉ: La prochaine génération d'Eurocodes est en cours d'élaboration et devrait être déployée durant l'année 2027. Le code actuel ne couvre pas l'utilisation de la modélisation numérique dans la conception géotechnique, bien que son utilisation pour l'évaluation de l'état limite de service et même pour la conception de l'état limite ultime (ELU) se poursuivent depuis de nombreuses années. Le document en cours d'élaboration fournira des indications sur l'utilisation de la modélisation numérique pour la conception ULS des structures géotechniques. L'article 8.2 de la partie 1 de cette nouvelle version du code couvre la procédure recommandée pour l'application de la modélisation numérique dans la conception des structures géotechniques ULS. Cet article décrit l'évolution de l'utilisation de la modélisation numérique dans la conception géotechnique et la procédure recommandée pour être incluse dans ce nouveau code. Une comparaison est également faite sur les conséquences de cette procédure sur les approches de conception existantes actuellement mises en œuvre dans le courant code.

Keywords: Eurocode; numerical modelling; ultimate limit state.

1 INTRODUCTION

The Structural Eurocodes are the current European design standards for buildings and construction works covering a wide range of structural materials and fields of civil engineering. Eurocode 7 (EC7), which is the standard for geotechnical engineering design in Europe, introduces the concepts of limit state design and partial safety factors distinguishing between Serviceability Limit State (SLS) and Ultimate Limit State (ULS).

The development of advanced geotechnical software, together with the introduction of cutting edge and less expensive hardware has resulted in 2D and 3D advanced numerical methods such as Finite Element Method (FEM) being routinely used in the Geotechnical Engineering field. Moreover, the introduction of advanced constitutive models that allows for better simulation of the soil behaviour has resulted in the increasing use of advanced numerical methods in geotechnical engineering to predict deformations and verify against SLS.

Eurocode 7 allows the use of numerical methods for verification against ULS but gives no guidance to the designer in a number of important and practical issues regarding the implementation of the guidance. These issues have triggered an important debate in the geotechnical engineering community over the feasibility of routine use of FEM for ULS checks.

Various concerns were raised in the application of numerical methods in ULS geotechnical design in accordance with EC7 in late 1990s early 2000s, more specifically with the use of finite element modelling.

These include effects of initial stresses, effects of stress history, choice of soil model, when the partial factors are applied and significance of the failure of structural member (Bauduin *et al*. (2000, 2003), Katsigiannis (2017), Simpson and Yazdchi (2003), Yeow (2014, 2022)).

Despite these early concerns, application of numerical methods has been adopted widely by practitioners even with a lack of guidance in its use for ULS design under the existing EC7. The most commonly adopted approach is to undertake the analysis with characteristic ground parameters and subsequently apply partial factor to the structural forces or the *effects of actions*. As the UK adopt Design Approach 1 with the need to undertake two combinations of design assessments, Simpson and Yazdchi (2003), Katsigiannis et al. (2014, 2015) and Yeow (2014, 2015, 2018, 2019 and 2022) used the approach by taking modelling excursion to allow for ULS design with design material properties which allowed the stress state in the ground to be maintained at its characteristic value prior to the introduction of factored or design soil properties.

This paper outlines the approach currently drafted into the next generation (NG) of EC7 for the application of numerical methods in geotechnical design.

2 NUMERICAL MODELLING IN THE NECT GENERATION OF EC 7

The next generation of the Structural Eurocodes are currently being drafted and EC7 is near the stage of final votes in 2024 before finalisation of the documents likely during first half of 2025 for the preparation of nation annexes by individual countries by end of 2025. This paper focuses only on the numerical modelling aspects of the updated EC7 guidance and does not provide any details on other changes introduced to the revised standard.

In the revised standard, numerical models are defined as *calculation models involving numerical approximation to obtain solutions.* These include, but not limited to, finite element, finite difference boundary element, discrete-element and subgrade reaction methods. These models could be used for the verification of limit states including the failure modes and ground movements.

It is worth noting that when using numerical method, verification of specific mode of failure, e.g., sliding, overturning, bearing capacity etc, may not be possible as such approach would produce the most critical deformation and failure mode depending on the geotechnical structure being considered and the ground strength and stiffness of the model.

3 PROCEDURE OF NUMERICAL MODELLING IN THE NEXT GENERATION OF EC7

3.1 Procedure for numerical modelling

The guidance on the procedure for numerical modelling is given in Clause 8.2 of Part 1 of the revised standard. At the time of writing this paper, this clause stipulates that ULS verification of geotechnical structures should be based on the less favourable outcomes given by the:

- input factoring (of material properties):
  - factors on actions γ_F from Verification Case 3 (VC3) and;
  - factors on material γ_M from Set M2;
- output factoring (of the effects of actions):
  - factors on effects-of-actions γ_E from Verification Case 4 (VC4) and;
  - factors on material γ_M from Set M1.

The input factoring is also known as the Material Factor Approach (MFA) in the current code which is still in use in the revised code while the output factoring is the Effects Factor Approach (EFA) in the current code but is no longer used as a term in the next generation of EC7. Clause 8.2 also refers to Table 8.1 which details the above ULS verification procedure. The VC3 and VC4 can be found in Table A1.8 of the revised EN 1990 Eurocode and depending on the type of geotechnical structure, one or both of these verification cases will be recommended in the new code. These two tables are reproduced in Appendix A of this paper for information. It is worth noting that the details in these two tables are defined as National Determined Parameters (NDPs) under the new standard, hence each individual country should be able to make appropriate selection or changes in their National Annex accordingly.

3.2 Ultimate limit state modelling procedure

As discussed above, the next generation of EC7 requires that both input and output factoring combinations are checked when undertake ULS verifications using numerical methods in order to determine the least favourable outcomes to be used for design.

The most straight forward combination is the output factoring approach under VC4 whereby representative values of soil properties (M1) are used to analyse the geotechnical problem and the partial

factors are then applied to the output of the model or in this case the effects of actions.

The input factoring procedure under VC3 has two possible methods of applying the material factor M2. These two methods are discussed and compared in depth by Katsigiannis (2017).

In the first method, characteristic values of the parameters are used in the calculations, and at critical discreet stages, the user applies the material factor M2 for the ULS verifications. Such method is also known as the "modelling excursion" approach whereby partial factor M2 on soil properties is applied as and when necessary to invoke the design under VC3.

In the second (i.e. alternative) method, users apply the partial safety factors to the material parameters right from the start of the analysis and the calculations are carried out using the design values of the parameters.

Despite the apparent simplicity of the second method, the recommended method based on the updated standard is to only apply the material factor M2 to the soil properties at critical stages during the construction sequence. The main reason that this method is recommended, is mainly because users can verify against both SLS and ULS by carrying out their design using one numerical analysis model.

Figure 1 shows an example of the ULS design procedures for a retaining wall with multi-stage construction sequence.

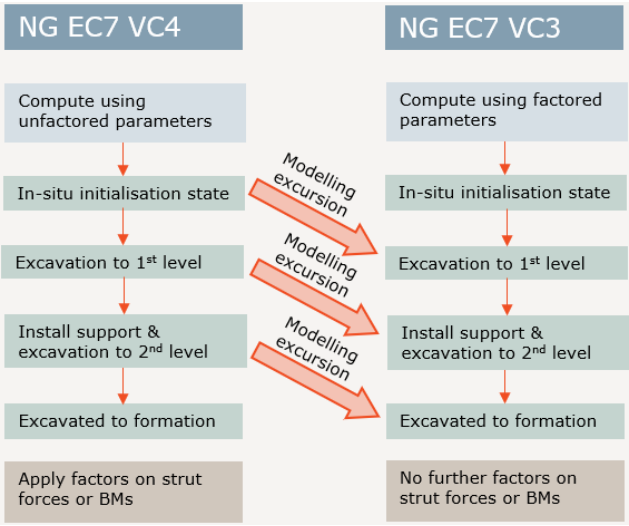

Figure 1. Procedures to undertake ULS verification as per next generation of EC7.

4 COMPARISON WITH CURRENT EC7 APPROACH

For the comparison with the design approaches under the existing EC7 when undertaking design verification using numerical methods, the partial factors published in Section A.3 of Annex A of BS EN1997-1 (2014) are used. No consideration is given of any variations implemented under the National Annex of individual countries.

4.1 Design Approach 1 (DA1)

In accordance with the DA1, ULS design verification of the design under the less favourable of the two combinations of partial factors in the following forms:

- Combination 1 (C1): A1 "+" M1 "+" R1
- Combination 2 (C2): A2 "+" M2 "+" R1

Under DA1 C1, the partial factors are applied to actions or the effects of actions with material factor set to unity, i.e., M1. This is the same with the output factoring (VC4 "+" M1) approach of the revised standard. For DA1 C2, the partial factors are applied to the material properties, i.e., M2, and this is the same with the input factoring (VC3 "+" M2) approach of the revised standard.

Except for pile design in the current standard, the resistance factor R1 is equal to 1.0 for the design of most geotechnical structures. Therefore, the geotechnical design undertaken using DA1 is consistent with the proposed procedures outlined in the revised next generation of EC7 and designers in countries which have adopted DA1 such as the UK, will see little impact on their current established practice when using numerical methods.

4.2 Design Approach 2 (DA2)

DA2 only requires one check based on the following combination:

- Combination: A1 "+" M1 "+" R2

This is similar to the output factoring (VC4 "+" M1) approach of the revised standard with the exception of the application of resistance factor R2 of greater than 1.0. The value of R2 ranges from 1.1 for sliding resistance and earth resistance for slope stability assessment to 1.4 for bearing capacity and earth resistance for retaining structure. However, when undertaking design assessment using numerical analysis, the introduction of a resistance factor to the model is not straight forward as these parameters are not input in the numerical calculations. Therefore, those who used numerical modelling resolve to applying a partial factor on the effects of actions similar to DA1 C1.

Under DA2 there is no verification by applying partial factor to the material properties, i.e., M2. Under conditions whereby input factoring (VC3 "+" M2) approach governs the design, such approach would be unsafe.

Some authors suggest the DA2* approach as an alternative to DA2 for numerical methods (Frank et al.,

2004). For retaining wall design, for example, DA2*, requires that the characteristic active earth pressures is used in the analysis while any variable surcharge is factored by $\gamma_G/\gamma_Q = 1.5/1.35 = 1.1$. The passive earth resistances need to be factored by the resistance factor γ_R and the load factor γ_G. The design values of the structural forces are obtained at the end of the analysis, after factoring the outputs by the load factor, γ_G. While the use of DA2* seems to be straightforward for simple methods of analysis such as Limit Equilibrium, factoring the passive earth resistance is not possible in advanced numerical analysis.

Based on the updated EC7 guidance, designers in countries which have adopted DA2 will have to carry out both input and output factoring approaches when using numerical methods, with the combination that gives the most adverse results being critical and governing the design.

4.3 Design Approach 3 (DA3)

DA3 only requires one check based on following combination:

- Combination: (A1* "or" A2†) "+" M2 "+" R3

* on structural actions

† on geotechnical actions

For DA3, the R3 resistance factor is equal to 1.0 hence for geotechnical actions the procedure is similar to input factoring (VC3 "+" M2) approach of the revised standard. For structural actions, however, applying both partial factors on both the actions (A1) and material properties (M2) would be more conservative than input factoring (VC3 "+" M2) approach. While currently under DA3 there is no need for verification with output factoring approach, according to the updated EC7 guidance, designers in countries which have adopted DA3 will have to carry out both input and output factoring approaches when using numerical methods.

5 CONCLUSIONS

The next generation of Eurocodes are currently being drafted to improve the guidance for designers both in the management of safety and risks in design and subsequent execution of construction works. The incorporation of more detailed and consistent guidance on numerical modelling in the revised EC7 will result in numerical methods to be more routinely used for ULS verifications while providing designers who have access to advanced design tools the ability to produce more economical and safer design. However, the use of such tools requires experience, fundamental understanding of the principles of soil mechanics and sound engineering judgement.

The revised EC7 is addressing one of the biggest challenges of the current standard by enabling further harmonization and ease-of-use. This is being achieved with the elimination of the different Design Approaches for numerical methods, effectively recommending all countries to follow the most critical case of the dual factoring approach. This approach seems to provide sufficient levels of safety, rigor and economy and reasonably consistent levels of reliability can be achieved for a wide range of construction problems This harmonization of practice among all countries adopting the Eurocodes definitely represents a major advance over the current version of the standard.

ACKNOWLEDGEMENTS

ABSTRACT: Pore characteristics have considerable effects on the physical properties and mechanical behavior of structured marine clay. However, the distribution characteristics and morphology of pores cannot be quantified by a single method, and a combination of methods with different measuring ranges is required. This paper focuses on a typical structured marine clay retrieved from Zhanjiang in China (referred to as ZJ clay). The methods of scanning electron microscopy (SEM) and mercury intrusion porosimetry (MIP) were used in combination to (i) analyze the microscopic characteristics of the pores in natural soil and (ii) establish the relationships between the microstructural characteristics and macro-mechanical behavior of the soil. The test results show that ZJ clay is characterized by a randomly oriented open-flocculated structure with cementation bonding, and the particles within ZJ clay are interconnected by edge-to-face or edge-to-edge contacts with high structural strength and stability. The results also show that the combination of SEM and MIP facilitates both qualitative and quantitative analysis of the complete pore size distribution characteristics of marine clay. The present study improves the understanding of the pore characteristics of marine clay from a microscopic perspective.

RÉSUMÉ: Les caractéristiques des pores ont des effets considérables sur les propriétés physiques et le comportement mécanique des argiles marines structurées. Cependant, les caractéristiques de distribution et la morphologie des pores ne peuvent pas être quantifiées par une seule méthode, et une combinaison de méthodes avec des gammes de mesure différentes est nécessaire. Cet article se concentre sur une argile marine structurée typique prélevée à Zhanjiang en Chine (appelée argile ZJ). Les méthodes de microscopie électronique à balayage (SEM) et de porosimétrie à intrusion de mercure (MIP) ont été utilisées en combinaison pour (i) analyser les caractéristiques microscopiques des pores dans le sol naturel et (ii) établir les relations entre les caractéristiques microstructurales et le comportement macro-mécanique du sol. Les résultats des essais montrent que l'argile ZJ se caractérise par une structure ouverte-floconneuse orientée aléatoirement avec une liaison de cimentation, et que les particules au sein de l'argile ZJ sont interconnectées par des contacts bord-à-face ou bord-à-bord avec une résistance et une stabilité structurelles élevées. Les résultats montrent également que la combinaison de la SEM et de la MIP facilite l'analyse qualitative et quantitative des caractéristiques complètes de distribution de la taille des pores de l'argile marine. La présente étude améliore la compréhension des caractéristiques des pores de l'argile marine d'un point de vue microscopique.

Keywords: Pore; clay; mercury intrusion porosimetry; scanning electron microscope; microstructure.

1 INTRODUCTION

Defined as the combination of soil fabric and interparticle bonding (Mitchell and Soga 2005), soil structure is acknowledged to be responsible for the mechanical responses of natural soil being distinct from those of remolded soil (Burland 1990). Among the most important indicators for the structure of soil are its pore characteristics, which were found to influence soil's geotechnical behavior, including its hydraulic conductivity, soil–water characteristics, and shear strength (Zhang et al. 2017). Specifically, natural soil derived from sedimentation or post-sedimentation is highly structured and has a different pore structure from that of remolded soil (Cotecchia and Chandler 2000), which lead to their distinct mechanical behaviors. Therefore, the different mechanical behavior of structured natural soil from that of the

remolded one is attributed mainly to their initial pore characteristics as well as the rearrangement and compression of pores during soil deformation. However, a valid method for characterizing and quantifying the pore structure (in particular, the intra- and inter-aggregate pores) of quaternary marine clay remains to be explored. In general, intra- and inter-aggregate pores are related to only the porosity of soil and have negligible influence on its mechanical behavior. However, although single intra-aggregate pores are relatively small, their total volume is relatively large; once the interparticle cementation bonding is destroyed, these pores released from the aggregation inevitably have significant influences on the soil's geotechnical behaviors, and so further studies are vitally important.

Various microscopy techniques have been adopted to investigate the pore characteristics of natural clay from a microscopic perspective including (i) Imaging techniques, e.g., scanning electron microscopy (SEM); (ii) Fluid-injection techniques, e.g., mercury intrusion porosimetry (MIP) (Zhang et al. 2017; Zhang et al. 2020). These techniques are applicable for different pore-size measurement ranges from microscopic to macroscopic, therefore combining them is an ideal way to fully realize their advantages for multiscale pore analysis, to sufficiently investigate the intra-aggregate pores within marine clay.

In this study, we combined SEM and MIP to investigate the pore evolution and the corresponding influencing factors of a typical marine structured clay, with the advantages and disadvantages of each method being quantified. This paper is organized as follows. First, the sampling details and testing methods are introduced concisely, then the basic soil characterizations of the studied clay are detailed. Next, the results of the different methods for testing the pore characteristics of the clay are presented; the pore characterization is evaluated quantitatively considering the measuring range of each method. Peculiar pores within the studied soil are also discussed, with the applicability of the combined analysis for characterizing the pores in marine clay being verified. The study improves our understanding of the structural characteristics of natural sedimentary soil and its corresponding geotechnical behavior.

2 MATERIALS AND METHODS

2.1 Soil materials

The undisturbed ZJ clay samples were retrieved at a foundation pit in Zhanjiang, China, by using thin-walled tube samplers from two depths at h_1 = 14.0–16.0 m and h_2 = 28.0–32.0 m, respectively. Some important index properties of the ZJ clay were summarized in Table 1. From this table, it can be found that ZJ clay comprises mainly clay components (over 70%), consistent with the high void ratio, high Atterberg limits, and low permeability of the soil. Besides, the specific surface area is also relatively high. Also, the studied clays from different depths have almost identical mineral compositions, including high content of illite, kaolinite, and quartz. Note that a content of 6% of iron-bearing minerals (pyrite and hematite) was also detected, which was proved to enhance the soil strength and stiffness by forming cementation in the soil structure (Zhang et al. 2017).

Both the natural and remolded samples were prepared (Zhang et al., 2020), with all samples being controlled with identical moisture content and dry density. Samples for strength tests were prepared as 50 mm in diameter and 100 mm in height, while those prepared for compression tests were prepared as 61.8 mm in diameter and 20 mm in height. Samples for SEM and MIP tests were dehydrated using vacuum freeze-drying to preserve the initial soil structure effectively (Mitchell and Soga 2005).

Table 1. Index properties of ZJ clay.

Index	Value	
	ZJ clay (h_1)	**ZJ clay (h_2)**
Void ratio e	1.43	1.30
Specific surface area (m^2/g)	138	125
Permeability coefficient K (10^{-8} cm/s)	7.33	2.65
Liquid limit w_L (%)	64.26	66.83
Plastic limit w_p (%)	32.25	29.57
Plasticity index I_p (%)	32.01	37.26
Clay fraction (%)	70.9	73.1

2.2 Test details

The compressibility and strength properties of the soil samples were measured through a standard oedometric compression test using incremental loading and unconfined compression strength (UCS) test following procedures from ASTM standards. Formal tests are performed on both natural and remolded samples after the saturation, which is realized by flooding the samples with distilled water under vacuum for 12 h.

Microstructural observations were performed on natural and remolded ZJ clay through SEM and MIP tests. An FEI-Quanta-250 SEM under multilevel magnifications (from × 800 to × 20000) was used to systematically investigate microstructural features from the primary morphologies to the contact modes among the soil particles. MIP tests were performed using a Quantachrome Pore Master 33 mercury

intrusion porosimeter. The results of MIP tests are presented as the cumulative pore volumes ($CV = \sum_i \Delta V_i$) and log-incremental pore volumes ($IV = -\Delta V_i/\Delta \log d_i$), where V_i is the measured total intruded pore volume corresponding to the diameter d_i. For convenience, the soil pores are classified based on the diameter d as macropores (d > 10 μm), mesopores (1 μm < d < 10 μm), micropores (0.1 μm < d < 1 μm), or nanopores (d < 0.1 μm) according to Brewer (1964).

3 COMPRESSION AND STRENGTH PROPERTIES

Fig. 1(a) shows the I_v–log σ'_v curve of ZJ clay (Burland 1990), with the intrinsic compression line (ICL) and the sedimentation compression line (SCL) proposed by Burland (1990) also being included. The yielding points of the compression curves of natural soils are located at the right side of the SCL, while the compression curves of the remolded clay are shifted to the left (approaching ICL) with no observable turning point, indicating the significant structural characteristics of natural clay. The gradual process of destruction of cementation bonding was reflected by that (i) after yielding, the I_v–log σ'_v curve approaches the ICL and (ii) when σ'_v = 3200 kPa, the compression curves tend to converge to the ICL.

The shear behaviors of ZJ clay obtained from the UC tests are shown in Fig. 1(b), from which the strain softening of the natural soil is evident with well-defined peaks, due to degraded cementation (Zhang et al. 2017). Natural ZJ clay has poor physical properties (w > 50% and e > 1.4) but relatively satisfactory mechanical properties (q_u = 175–190 kPa). However, the high strength of ZJ clay is decreased significantly by cementation degradation and fabric rearrangement, therefore it can be classified as a structured clay with high sensitivity.

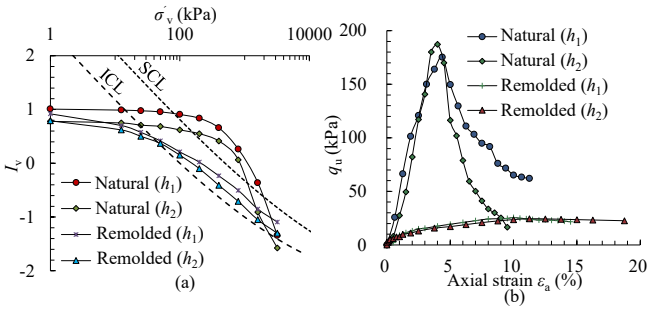

Figure 1. Results of (a) Compression tests and (b) strength tests of natural and remolded ZJ clay.

4 PORE CHARACTERISTICS OBTAINED USING SEM

Natural soil had an open-flocculated structure with interconnected soil aggregates [Figs. 2(a) and 2(b)]. Nonuniformly distributed pores in natural clay were not obviously connected, consistent with its low permeability, despite the high pore volume. The positively charged free iron oxides within natural clays distributed at the contacts between soil particles bind to the negatively charged soil particles to form larger soil aggregates with enhanced stability (Zhang et al., 2017), responsible for the high porosity and sensitivity of natural clay. The remolded soils [Figs. 2(e) and 2(f)] were mainly aggregates comprising irregular flaky clay plates with a more-dispersed and finer pattern. Macropores could be frequently observed in remolded soils due to remolding, which seldom appeared in the natural clay. Although the remolded soils had similar physical indices to the natural soil, their mechanical properties differed significantly from those of the natural soil because of the cementation degradation and particle rearrangement.

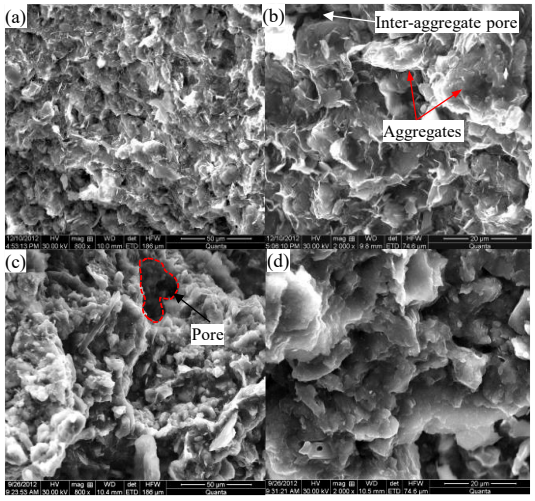

Figure 2. SEM images of soil samples. (a)−(b): natural soils; (c)−(d): remolded soils.

5 PORE CHARACTERISTICS OBTAINED USING MIP

For all natural and remolded samples, the intrusion–extrusion cycles show obvious hysteresis between the branches, indicating some intruded mercury remained in the pore system (Fig. 3). This hysteresis is attributed to the widely distributed ink-bottle type pores in ZJ clay. The nonuniformly distributed pores in the flocculated structures of the clay (Fig. 2) constitute the narrower throats and wider inner spaces of ink-bottle pores. Intrusion into the entire inner body occurs when the mercury is forced into the narrower pore neck;

during the extrusion, mercury withdraws in the opposite sequence, resulting in isolated mercury droplets in the inner pores. For remolded clay, less mercury was entrapped in the ink-bottle pores than that in natural clay, which reflects that (i) the ink-bottle effect is attenuated gradually by remolding and (ii) the occurrence of hysteresis is closely associated with the structural characteristics of the pores.

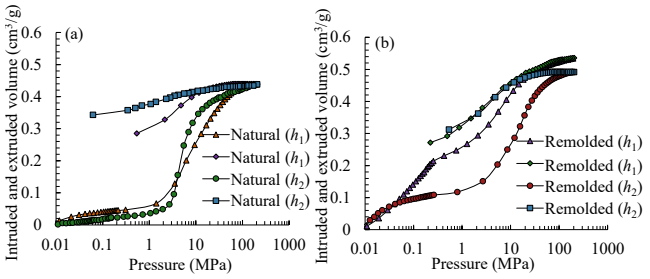

Figure 3. Mercury intrusion–extrusion curves of MIP tests on (a) natural clay and (b) remolded clay.

Fig. 4(a) shows that the cumulative pore volume (*CV*) distributions of the shallower and deeper ZJ clay were essentially identical. As shown in Fig. 4(b), the micropores within the ZJ clay dominated the total pore volume, followed by the nanopores, which is strongly associated with the single dominant peak of the pore size distribution (PSD) curve for the natural clay. Unlike the natural clay, a bimodal distribution of pore sizes occurred after remolding, with one peak at 0.1–1 μm and another at 1–10 μm. In particular, the total volume of micropores and nanopores decreased significantly, while the total volume of macropores and mesopores increased. The difference between the *CV* curves for the natural and remolded samples perhaps reflects the existence of tinier ($d < 0.01$ μm) intra-aggregate pores within the natural ZJ clay, which is consistent with the results from SEM analysis.

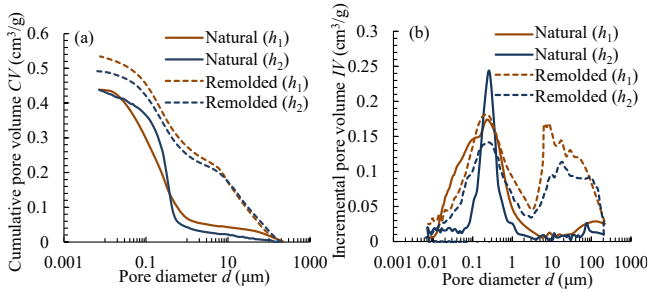

Figure 4. MIP test results of the studied soil: (a) cumulative pore volume; (b) pore size distribution.

Actually, these two adopted methods are characterized by different advantages and applicability for pore characteristics investigation. SEM is a direct observation of geometrical morphologies and sizes of soil pores and allowed qualitative analysis of the pore characteristics. On the contrary, MIP is for the quantitative evaluation of pore volume and the pore distribution. Therefore, combining SEM and MIP with distinct measuring ranges for obtaining the full-scale pore characteristics of marine clays with complete pore sizes ranging from nanopores to macropores.

6 CONCLUSIONS

The main conclusions are as follows:

(1) ZJ clay is a strongly cemented structured clay, and the strength of which is reduced significantly by cementation degradation and fabric rearrangement.

(2) By combining SEM and MIP techniques, the complete pore-size distribution of ZJ clay ranging from micropores to macropores was described well.

(3) ZJ clay is characterized by an open flocculated structure with interconnected domains; free iron oxides related to the cementation bonding bind to soil particles to form larger soil aggregates. These structural characteristics result in the high strength and sensitivity of ZJ clay.

(4) MIP test results verified the existence of ink-bottle pores in ZJ clay. After the degradation of interparticle cementation bonding, such pores released from the aggregations have significant influences on the mechanical properties of the soil.

ABSTRACT: Based on cone penetration tests (CPT) data, a number of soil's physical and mechanical parameters can be interpretated, like soil unit weight, etc. Even though various studies have been conducted and methods are proposed, uncertainties still exist and the applicability of each method needs be further clarified. A case study on the interpretation of CPT results is performed which based on the measured data from an offshore site close to Shandong Province, China. This paper focus on sandy soil layers and presents an assessment of CPT data interpretation methods for the derivation of sandy soil's unit weight, effective friction angle and relative density. It shows that Mayne's method proposed in 2016 provides better predictions of soil unit weight; Kulhawy's 1990 method performs well in predicting sandy soil's effective friction angle under low-stress conditions, while Robertson's 1983 method is more suitable for high-stress conditions; Schmertmann's model with Baldi's recommendation is better in predicting soil relative density.

RÉSUMÉ: Sur la base des données des essais de pénétration au cône (CPT), plusieurs paramètres physiques et mécaniques du sol peuvent être interprétés, tels que la masse volumique du sol, etc. Bien que diverses études aient été menées et des méthodes proposées, des incertitudes persistent et l'applicabilité de chaque méthode doit être clarifiée davantage. Une étude de cas sur l'interprétation des résultats du CPT est réalisée sur la base des données mesurées sur un site en mer près de la province du Shandong, en Chine. Cet article se concentre sur les couches de sol sableux et présente une évaluation des méthodes d'interprétation des données du CPT pour la détermination de la masse volumique du sol sableux, de l'angle de frottement effectif et de la densité relative. Les conclusions indiquent que la méthode R3 permet de mieux prédire la masse volumique du sol; FA2 performe bien dans la prédiction de l'angle de frottement effectif du sol dans des conditions de faible contrainte, tandis que FA1 est plus adaptée aux conditions de forte contrainte; DR2 montre une bonne capacité à prédire la densité relative du sol.

Keywords: Cone penetration test (CPT); unit weight; effective friction angle; relative density, sandy soil.

1 INTRODUCTION

Cone penetration tests (CPT) are widely used to characterize site conditions for its handiness, multifunctionality and automatization (Lunne *et al.* 1997), especially for offshore sites. During these tests, cone resistance, sleeve friction and pore water pressure (ASTM D5778) are commonly recorded during the probe's penetration (Mayne 2007). Based on these recorded data, a number of soil's physical and mechanical parameters can be interpretated, like soil behaviour type, soil unit weight, etc. Even though various studies have been conducted and methods are proposed (Robertson 2009), uncertainties still exist and the applicability of each method needs be further clarified. A case study on the interpretation of CPT results is performed which based on the measured data from an offshore site close to Shandong Province, China. In this site, series of in-situ cone penetration tests were conducted and soil samples were retrieved at various depth. From which, physical and mechanical

parameters were obtained from laboratory tests on these retrieved soil samples, as well as from the interpretation of CPT results. This paper focus on sandy soil layers and presents an assessment of CPT data interpretation methods for the derivation of sandy soil's unit weight, effective friction angle and relative density. Based on the comparison between values obtained by laboratory tests and those derived from CPT data according to various methods, the reliability and applicability of each method are clarified and the most suitable method for each soil parameter is recommended.

2 CURRENT METHODS

Based series of test data, several studies developed methods to derive soil's unit weight(γ), effective friction angle(ϕ'), as well as the relative density(D_r), which are commonly used. These methods are sumarized in Table 1.

Table 1. Summary of current models.

Parameter	Model	Tests	Model equation	Reference
Unit weight γ	R1	-	$\gamma/\gamma_w=0.27\log(R_f)+0.36\log\left(q_c/\sigma_{atm}\right)+1.236$ Where: R_f= friction ratio = $(f_s/q_t)100\%$, γ_w = unit weight of water in same units as γ, σ_{atm}= atmospheric pressure in same units as q_t.	(Robertson and Cabal 2010)
	R2	215	$\gamma=11.46+0.33\log(z)+3.1\log(f_s)+0.7\log(q_c)$ Where: z (m) = depth, f_s (kPa) = sleeve friction, q_c (kPa) = measured tip resistance.	(Mayne *et al.* 2010)
	R3	-	$\gamma/\gamma_w=\left[1.22+0.15\ln\left(100f_s/\sigma_{atm}\right)+0.01\right]$	(Mayne 2016)
Effective friction angle ϕ'	FA1	5	$\tan\phi'=\frac{1}{2.68}\left[0.29+\log\left(\frac{q_c}{\sigma_{v0}'}\right)\right]$	(Robertson and Campanella 1983)
	FA2	24	$\phi'=17.6+11\log(q_{t1})$ Where: q_{t1} = stress normalized tip resistance: $q_{t1}=(q_t/\sigma_{atm})\cdot(\sigma_{atm}/\sigma_{v0}')^{0.5}$	(Kulhawy and Mayne 1990)
Relative density D_r	DR	-	$D_r=\frac{100}{C_2}\cdot\ln\left(\frac{q_c}{C_0\cdot(\sigma_{v0}')^{C_1}}\right)$ Where: C_0 C_1 and C_2 are empirical coefficients parameters.	(Schmertmann 1978)

Model DR was used to interpret sandy soil's relative density from the CPT experimental data, and a total of 4 sets of model parameters (C_0, C_1 and C_2) were selected. These parameters were derived by analysing on sandy soils retrieved from different sites, and reproduced in Table 2.

Table 2. DR Model parameters.

Model	C_0	C_1	C_2	Reference
DR1	0.157	0.550	2.41	(Baldi and O'Neill 1995)
DR2	0.086	0.530	3.29	
DR3	0.140	0.550	2.90	(Jamiolkowski *et al.* 2003)
DR4	0.175	0.500	3.10	

3 CASE STUDY

3.1 General description

This offshore site is close to Shandong Province, belongs to the Yellow Sea of China. Water depth is about 32 m. Series of in-situ piezocone penetration tests were conducted and soil samples were retrieved at various depth. From which, physical and mechanical parameters were obtained from laboratory tests on these retrieved soil samples (GB/T 50123-2019、GB 50021-2001), as well as from the interpretation of CPT results. Figure 1 presents geotechnical stratigraphic log with USCS classification, the values of fines content and measured cone tip resistance, sleeve friction and porewater pressure on shoulder (u_2).

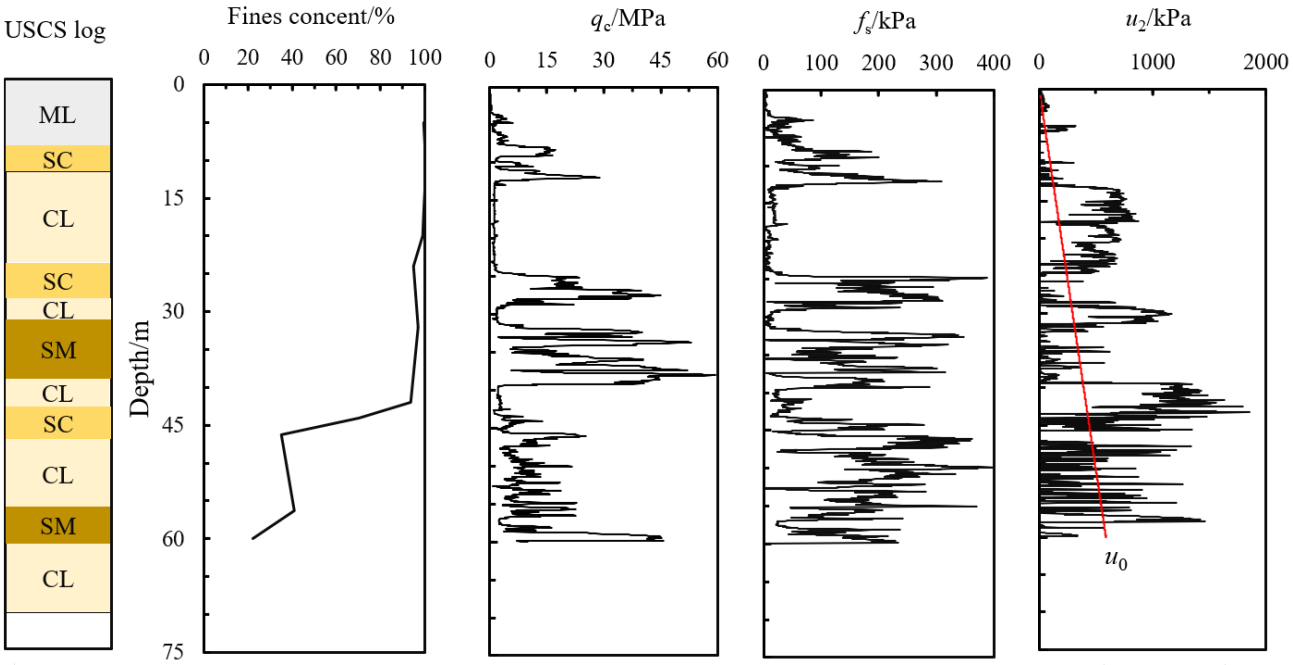

Figure 1. Geotechnical stratigraphic log with USCS classification, fines contents and the recorded CPT data.

3.2 Analysis and discussion

3.2.1 Soil unit weight

Figure 2 (a), (b) and (c) presents a comparison of soil unit weight between measured in lab and derived from CPT data with three methods (R1, R2 and R3) in Table 1. It can be seen that, in general, the relative errors of the three methods are within the range of ±15%, see Figure 2 (d), and they all overestimate the magnitude of soil unit weight, even though there is some underestimation at shallow depth. This overestimation may be caused by the soil disturbance, say stress release when being retrieved at depth below sea bed, which leads to an expansion of soil samples used in laboratory tests. Among these three methods, R3 agrees well with those values from laboratory tests, and R2 shows a poor estimation. Therefore, R3 is recommended to predict the unit weight.

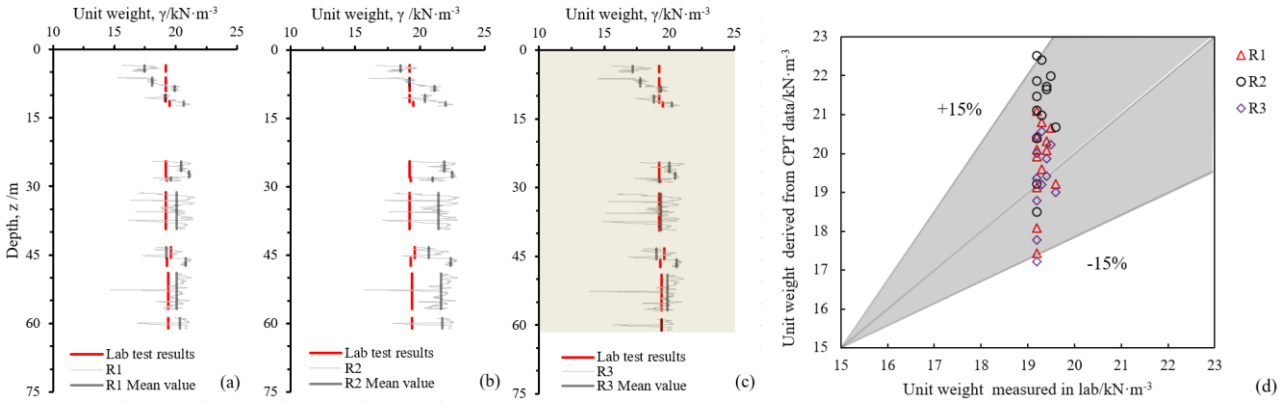

Figure 2. Comparison of soil unit weight between measured in lab and derived from CPT data.

3.2.2 Effective friction angle

Figure 3 (a) and (b) illustrates a comparison of effective friction angle between measured in lab and derived from CPT data with method FA1 and FA2 in Table 1, which shows that FA1 produces an overestimation and FA2 gives an underestimation. So mean values between those calculated with FA1 and FA2 for each layer are plotted in Figure 3 (c). It can be seen that the relative errors of the three methods are generally within the range of ±30%, see Figure 3 (d). In the shallow depth (less than 30m, and corresponding to a lower stress condition), FA2 provides a better prediction, while FA1 gives a very good prediction for the deep depth. The average of the two approaches brings the overall prediction closer to the laboratory test results but fails to produce a better prediction. So, FA2 can be employed at a lower stress condition, while FA1 should be better for higher stress condition.

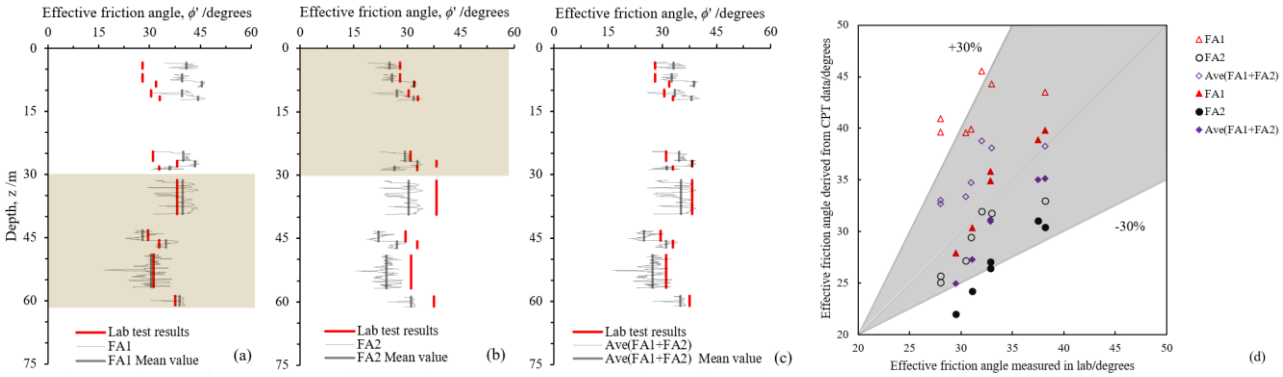

Figure 3. Comparison of soil effective friction angle between measured in lab and derived from CPT data.

3.2.3 Relative density

Figure 4 (a), (b), (c) and (d) shows a comparison of soil relative density between measured in lab and derived from CPT data with four methods (DR1, DR2, DR3 and DR4) in Table 2. It can be seen that, in general, the relative errors of the four methods are within the range of ±40%, see Figure 4 (d), and all these methods underestimate the magnitude of soil relative density, even though there is kind of extremely overestimation at shallow depth. Among these methods, DR2 clearly shows a better estimation, and is recommended to predict sandy soil's relative density.

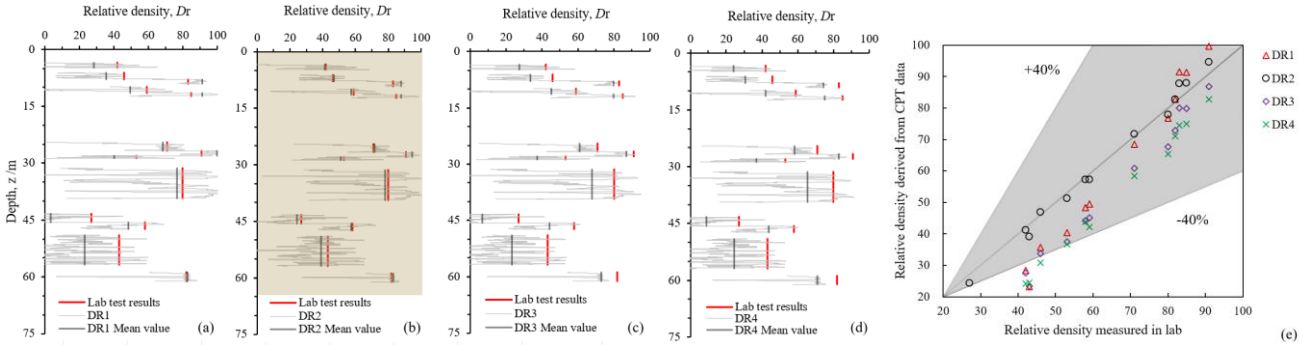

Figure 4. Comparison of soil relative density between measured in lab and derived from CPT data.

4 CONCLUSIONS

Based on a case study focusing on the offshore site in Yellow Sea of China, this paper presents an evaluation on current interpretation methods for CPT data recorded at sandy soil layers. By comparison of soil parameter values between tested in laboratory and interpretated from CPT data, main findings and recommendations are made for sandy soil layers:

Even though a lower estimation is shown in shallow depth, method R3 generally produces a relatively well estimation of soil unit weight. With regards to sandy soil's effective internal friction angle, FA2 produces a better prediction at shallow depth (i.e. lower stress condition) and FA1 suits for deep depth (i.e. higher stress condition). Compared with DR2, the other three methods show relatively poor estimations of sandy soils relative density, therefore DR2 is recommended. This study enables a further design optimization of monopiles used by offshore wind turbine constructed in this site.

Small- and full-scale test programme on uplift induced slope failure

Programme d'essais à petite et à grande échelle sur l'instabilité des pentes induite par le soulèvement de la couche imperméable

ABSTRACT: Sub soil stratum in deltaic regions typically include a succession of permeable and non-permeable layers. Consequently, dikes built to protect delta areas, should be able to resist not only extreme surface water levels, but also an increase in hydraulic head in permeable layers. The rise in hydraulic head might result in uplift of the cover layer, inducing either backwards erosion piping or slope stability. A large research programme, including the combination of numerical analysis, centrifuge testing and field trials, is started to study the uplift phenomenon. Preliminary results show that uplift has a clear influence on dike stability. Horizontal compression of the cover, during uplift, might trigger slope failure. Large cracks in uplifted cover layer were not found in the field trials, although some local failure, resulting in sand boils, was observed. The test results provide valuable experimental data to further validate numerical tools and stability assessment procedures.

RÉSUMÉ: La stratification du sous-sol dans les régions deltaïques comprend généralement une succession de couches perméables et non perméables. Par conséquent, les digues construites pour protéger les zones deltaïques doivent pouvoir résister non seulement à des niveaux d'eau extrêmes, mais aussi à une augmentation des charges hydrauliques dans les couches perméables. L'augmentation de la charge hydraulique peut entraîner un soulèvement de la couche imperméable, induisant soit une érosion régressive, soit une instabilité des pentes par glissement rotationnel. Un programme de recherche, combinant des analyse numériques, expérimentations dans une centrifugeuse et expériences de terrain, a été lancé pour étudier le phénomène de soulèvement. Les résultats préliminaires montrent que le soulèvement exerce une influence évidente sur le glissement rotationnel des digues. La compression horizontale de la couche imperméable, pendant le soulèvement, semblerait déclencher le glissement rotationnel. Les expériences de terrain n'ont pas révélé de grandes fissures dans la couche imperméable une fois soulevée, bien que certaines ruptures locales, comme des bouillonnements, aient été observées. Les résultats expérimentaux fournissent des données précieuses pour valider davantage les outils numériques et les procédures d'évaluation du glissement rotationnel.

Keywords: Stability; experimental soil mechanics; uplift.

1 INTRODUCTION

Typically, hydraulic loads on water retaining constructions during design conditions not only include the free water acting on the dike body, but also changes in pore water pressures in sub soil layers. Figure 1 shows a classical case in which, due to a hydraulic connection between a sand layer and the free water, the hydraulic head increases until uplift of the non-permeable cover layer occurs, which reduces the slope stability. Moreover, due to uplift the cover layer might break, starting erosion of the sand layer: backward erosion piping.

In deltaic regions, subsoil stratification often contains a succession of permeable and non-permeable layers. As such, depending on design load conditions and dimensions of the dike, the typical deltaic subsoil is in principle susceptible to uplift.

Several studies have been conducted to show how the uplift phenomenon should be accounted for in stability assessment of dikes, Marsland & Cooling (1953), Marsland (1988), Van et al. (2005).

These studies assume that for uplift conditions the cover layer remains intact. Some guidelines on dike stability assessment (TAW, 2001) hypothesize that thin cover layers, < 4 m, will break and lose their

integrity during uplift. Consequently, in these guidelines, the cover layer is assumed to have no strength under uplift conditions.

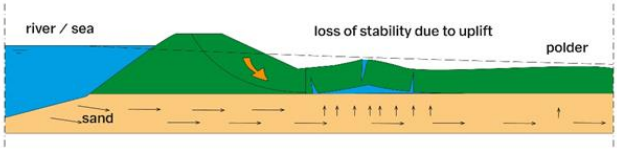

Figure 1. Sketch of slope instability due to breaking of the cover layer due to uplift.

Although local failure of the cover layer by cracks that result in sand boils and facilitate backward erosion piping, are regularly found (a.o. Bezuijen, 2017), field cases in which the cover layer completely loses its integrity, inducing slope failure, are not known to the authors.

Climate change and the corresponding sea level rise will result in a more frequent occurrence of the uplift mechanism. At the same time, the increase in urbanisation of deltaic areas will reduce the available space for dike reinforcement. Consequently, the uplift phenomenon needs to be properly understood to face future challenges in flood protection.

The study aims for generating experimental data and validate existing numerical tools for stability assessment of dikes. To maximise impact, the study includes numerical simulation, centrifuge testing and field trials. The centrifuge testing allows to study the impact of varying relevant parameters, like the thickness of the cover layer or cover layer properties under controlled and simplified conditions. A field trial includes all relevant uncertainties but is only related to the specific geometry and soil conditions at the test site. The combination of scale modelling and field trials allows for checking on possible scale or schematisation effects which might be incorporated in centrifuge modelling. Vice versa, scale modelling helps in generalising the results from the field trials.

2 NUMERICAL ANALYSIS

A numerical study employing advanced finite element analyses, Visschedijk (2020), showed 4 different potential failure mechanisms under uplift conditions, see Figure 2. In mechanism *a* uplift does not influence failure, resulting in a circular sliding plane. Mechanism *b* includes the uplifted zone and a passive failure plane. Mechanism *c* describes buckling of the cover layer, resulting in loss of integrity. Mechanism *d* shows horizontal compression of the cover layer followed by slope instability.

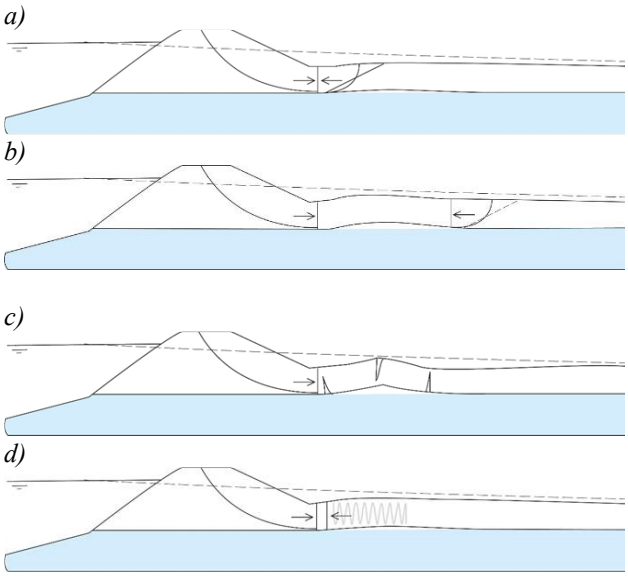

Figure 2. Sketch of the 4 different failure mechanisms observed in the numerical analysis, after Visschedijk (2020).

Mechanism *a* and *b* allow for stability assessment by Limit Equilibrium Methods, as shown by Van et al., (2005). For the few cases in which slope failure due to uplift was found in the field, no passive failure plane could be observed. This makes it difficult to distinguish between mechanisms *b* and *d* for field conditions.

The numerical analysis predicts mechanism *c* only for specific conditions, i.e. a thin cover layer < 2 m with large stiffness, Young's modulus > 3 MPa and high permeability in the sand layer to maintain the uplift pressure during deformation of the cover layer.

Mechanism *d* is dominated by the interaction between slope stability and horizontal compression of the cover layer. An unstable slope induces a horizontal compression on the cover layer, which increases when the cover layer is lifted. Further compression of the cover layer will induce displacements along the active part of the sliding plane. Depending on the material of which the dike is constructed, these deformations might start progressive failure, when locally the peak strength is exceeded.

The numerical analysis showed that mechanism *d* was the decisive mechanism for cover layer thicknesses up to 4 m. A numerical analysis, using PLAXIS 2D v22, was performed to get more understanding of this mechanism.

Figure 3 shows the horizontal displacements found at uplift of the cover layer. The geometry contains a dike with height 6 m, and slope 1(V): 2.5 (H). The cover layer thickness is 3 m and is followed by a 12 m thick sand layer. The Mohr-Coulomb model is used to model soil behaviour. Table 1 gives the relevant parameters. An interface, with the same strength

characteristics as the surrounding soil, was applied between the cover layer and sand layer to obtain a discrete shear plane. For this geometry, the maximum horizontal displacement is in the order of 0.17 m.

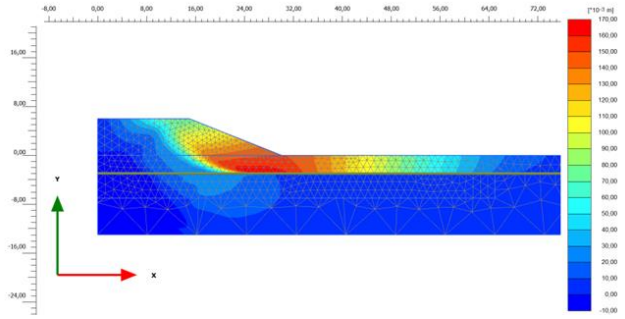

Figure 3. Horizontal displacements under uplift conditions.

3 CENTRIFUGE TESTS

A series of 13 centrifuge tests has been conducted. Details of the tests are presented by Cengiz et al. (2024). The tested model contains a sand layer, a clay cover layer and dike body build from sand. Uplift was activated at 80g after which the g-level was increased further to reach failure.

Figure 4 shows the horizontal displacements in the cover layer for a typical failure found in the test series. The horizontal displacements are assessed from the test results by Particle Image Velocimetry, PIV analysis. The observed mechanism complies well with the numerical results shown in Figure 3.

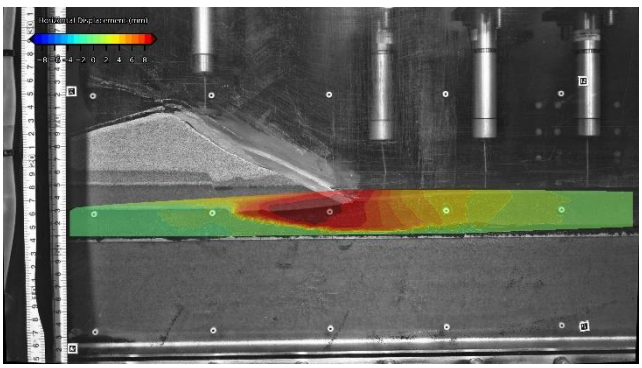

Figure 4. Horizontal displacements in cover layer at slope failure, green = 0 mm, red = 8 mm.

4 FIELD TRIAL

The field trial was conducted on a dike section along the River IJssel, near Kampen, the Netherlands. New flood protection works made this dike section redundant and as such available for testing.

The subsoil is divided into a cover layer containing a clay and peat layer followed by a sand deposit. To enhance instability additional measures were taken:

- The dike height was increased by 2.6m.
- At the toe, the soil was excavated by 1.25 m. total slope height was 7.75 m.
- 8 infiltration wells were placed to increase the hydraulic head in the sand layer.
- A drain was placed in the sand core to increase the phreatic level in the dike.
- Clay was added to the dike to prevent local slope instability.
- The slope was changed into 1(V): 2(H)
- A row of 10 containers, which could be filled remotely, was placed on top of the dike.

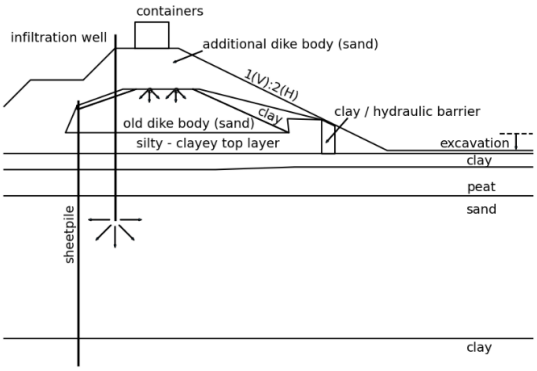

Figure 5. Test set-up, sketch of cross section.

Figure 5 shows the tested cross section. Prior to the main field trial, the uplift of the cover layer was tested in a separate but nearby field. This test showed that 1) the planned infiltration system could lift the cover layer, 2) that the uplift could be maintained for at least 3 days, after which the test was terminated and 3) hardly any leakage occurred despite the instrumentation that was placed in the cover layer or sand layer below.

The instrumentation of the main field trial was placed in three rows, containing 12 pore pressure transducers in the sand layer, 30 in the cover layer, 3 in top layer directly below the dike body, 7 open standpipes to measure the hydraulic head in the dike body, 15 inclinometers to measure horizontal displacements, 9 extensometer measuring vertical deformations at three different depths. Additionally, surface deformation was measured at 96 positions using a total station. Figure 6 presents an impression of the test set-up at the start of the main field trial.

Figure 6. Impression of the main field trial.

5 RESULTS

The test started on Monday 14 August 2023 at 9:00 by stepwise increasing the hydraulic head in the sand layer. Already in the first step the horizontal displacements directly responded to the hydraulic head increase.

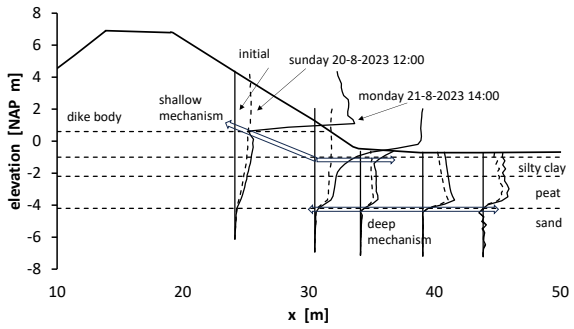

Figure 7. Horizontal displacements during the test.

Figure 7 shows the horizontal displacements measured during the test at the centre cross section. The horizontal displacement measurements at all but the left-most location clearly show a horizontal displacement at the interface of peat and sand. During the test the horizontal displacements developed uniformly over the cover layer thickness. This corresponds to mechanism *d* in Figure 2 and numerical analysis given by Figure 3. At these positions, the horizontal displacements are ranging between 0.05 to 0.10 m.

In the last stages of the test, starting on Sunday 20 August 2023, the last part of the sand core was filled, which caused a shallow failure plane to develop. The three instruments on the left side clearly indicate the position of the shallow sliding plane.

6 CONCLUSIONS

Uplift of a cover layer near the toe of a dike has impact on slope stability. This impact was studied by a combination of numerical analyses, centrifuge testing and a field trial. Analysis of the results is still ongoing. The experimental results clearly show the horizontal displacements which are induced at uplift of the cover layer. The observed displacement field corresponds to the numerical and experimental results, which clearly show that uplift results in horizontal compression of the cover layer.

In contrast to the centrifuge tests, the horizontal compression of the cover layer did not result in a deep failure in the field trial. Instead, the last stage in filling the sand core resulted in shallow failure.

Further analysis of the test results will lead to recommendations on stability assessment for dikes under uplift conditions.

ABSTRACT: Soil compaction is a critical consideration in earthworks in arid areas because of a lack of water sources, low precipitation, and high evaporation rates. Water transportation is expensive and has a negative impact on the project's cost. The soil compaction with its natural moisture content is the alternative solution to achieve the earthworks projects in these areas. The present paper studies the feasibility of soil compaction at low water content using dune sand located in the Oued-Souf region of Algeria. A series of laboratory tests were conducted, including grain size distribution, standard and modified Proctor compaction tests, and California bearing ratio (CBR) tests. The used soil compacted at its natural moisture content, which is about 2%, with a progressive energy level in the first phases. The results show that increasing the energy level does not enhance the density or the California Bearing Ratio values. In the second phase of this paper, the grain size was corrected by the progressive addition of marble powder to the dune sand. The results of California bearing ratio (CBR) tests and density are significantly improved.

RÉSUMÉ: Le compactage des sols est un facteur critique dans les travaux de terrassement dans les zones arides en raison du manque de sources d'eau, des faibles précipitations et des taux d'évaporation élevés. Le transport d'eau est coûteux et a un impact négatif sur le coût du projet. Le compactage du sol avec sa teneur en eau naturelle est la solution alternative pour réaliser les projets de terrassement dans ces zones. Le présent article étudie la faisabilité du compactage des sols à faible teneur en eau d'un sable de dune localisé à la région d'Oued-Souf en Algérie. Une série d'essais en laboratoire ont été effectués, comportant l'analyse granulométrique, les essais de compactage Proctor normal et modifié et les essais de portance (CBR). Le sol utilisé est compacté à sa teneur en eau naturel, qui est d'environ 2%, avec un niveau d'énergie progressif dans la première phase. Les résultats montrent que la densité et portance du sol sont faible et l'augmentation de l'énergie de compactage est sans effet. Dans la deuxième phase, une correction de la granulométrie est effectuée par ajout progressive de poudre de marbre au sable de dune. Les résultats de la portance et de la compacité sont considérablement améliorés.

Keywords: Compaction energy; low water content; dune sand; marble powder.

1 INTRODUCTION

The development of Saharan regions requires the design of communication roadways, especially roads, to connect urban areas. The scarcity of materials and the arid climate have promoted engineers and researchers to look at various possible solutions to this challenge. One of these solutions is to reuse local materials, including dune sand, as a subgrade material in the engineering of Saharan pavements. The construction of pavements in deserted areas is challenged by the unavailability of water necessary for the compaction of materials. The scarcity of water makes compaction in these regions costly and difficult.

According to estimations, constructing 1 km of road in these areas could require up to 2,800 m3 of water, which could represent up to 20% of all construction costs. (Newill and O'Connell 2020). The Sahara covers about a third of the surface of Africa. Moreover, the dune sand covers about 30% of the Algerian Sahara, which represents around 80% of the surface of Algeria (Daheur, Goual et al. 2019). The use of dune sand for the construction of Saharan roads has great interest. Dry compaction is one of the most economical solutions for pavement structures For example, the experimental road embankment of a black silty clay of Sudan compacted at low moisture content has performed satisfactorily for one and a half years (Ellis 1980), and the road projects in Kenya constructed at low moisture content have performed equally well for two years (O'Connell 1987).Recently, many researchers have developed a lot of techniques and solutions to improve these materials at a reasonable cost, such as the effect of adding finer particles to the dune sand. The CBR value increased

with the increase in wastemarble powdercontent (Yorulmaz, Sivrikayaet al., 2021). 25% of marble dust has been considered to improve the CBR value of sandy soil. (Jain, Jha et al. 2020). The optimum moisture content (OMC) decreases as the percentage of marble powder increases; however, the values of the maximum dry density (MDD) increase as the percentage of marble powder increases to 6% (Rouaiguia, El Aal et al. 2020). The maximum dry density (MDD) increases with increasing ceramic waste and marble dust added to the soil. Moreover, the CBR values increase with the addition of ceramic waste and marble dust (Deboucha, Aissa Mamoune et al. 2020).

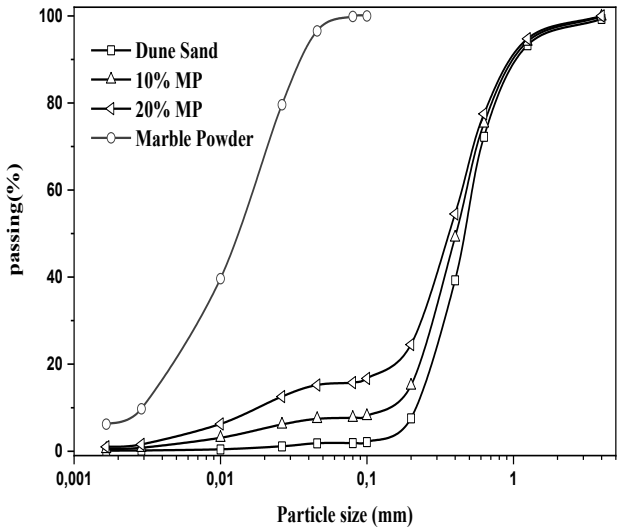

Figure 1. Particle size distribution of dune sand and Marble powder and mixture of dune sand with different adding of marble powder.

Table 1. Studied material formulations.

Designation	Dune sand (%)	Marble Powder (%)
DS100	100	0
DS90+MP10	90	10
DS80+MP20	80	20

2 MATERIALS AND METHODS

2.1 Dune sand of oued-souf

The dune sand (DS) is extracted from Oued-Souf city, located 640 km in the south-east of Algieria and characterized by a hot desert climate. This dune sand has a very high amount of sand (94%) and a low content of fine particles (2.5% silt and 0.5% clay). This dune sand is classified as fine sand (A-3) according to the American Association of State Highway and Transportation Organizations classification system (AASHTO) and poorly graded sand (SP) according to the Unified Soil Classification System (USCS).

2.2 Marble powder

The marble powder was obtained from the cutting and polishing of marble stones, and it was extracted from the FIL-FILA Quarry, which is about 25 km east of Skikda city, north-east of Algeria. The particle size distribution of the materials is presented in Figure 1.

2.3 Methods

The materials investigation is conducted by experimental tests, such as the sieve analyses and laser diffraction analysis (ASTM E3340-22), specific gravity (Gs), test by Gas Pycnometer (ASTM D5550-14)), sand equivalent test (ASTM D2419) and Methylene Blue Index (MVB)(ASTM C837) The particle size distribution of the materials is presented in Figure 1. Table 2 presents the principal properties of the materials. Standard and modified Proctor compaction testsis conducted according to the ASTM standard (ASTM D1557) in the aim to obtain the MDD and OMC. The same mould is used with a volume of 944 cm3 on each material. The California Bearing Ratio (CBR) tests are done in the CBR mould according to ASTM standard (ASTM D1893) to measuring the bearing capacity of the used soil at OMC.The dune sand is mixing with different proportions of marble powder which varying from 0, to 20% by weight. As seen in Table 1.

Table 2. Basic properties of dune sand.

Coefficient of gradation (Cc)	0.9
MBV	0.07
Liquid Limit LL (%)	NP
IP	NP
ES	77

3 RESULTS AND DISCUSSION

3.1 Compaction caracteristique at the optimum

The result of compaction caracteristics as shown in figure 2, the Dune sand of Oued-souf under modified compaction effort, has a MDD value of 17.2 kN/m³, while under the normal compaction effort, is 16.9 kN/m³. For the modified compaction effort, the OMC is 7.6%, while for the normal compaction effort, it's 9%. The high sand content (94%) and lack of fines (3%) makes Oued-Souf soil less susceptible to compaction energy. This behaviour can be explained by the non reduce of voids between sand's particles because of its uniformed size, while compacting, as indicated by Cu and Cc coefficient, The CBR value under modified compaction test is 13%,wich is low value for the sub-grade construction.similar work has been seen in (Virgil Ping, Yang et al. 2002).

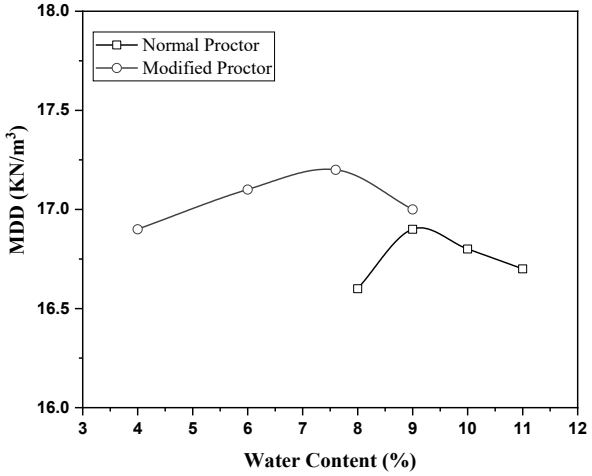

Figure 2. Normal and modified Proctor test curves.

3.2 Dune sand improvement by adding marble powder at low water content

3.2.1 Effect on grain size distributions

As shown in the figure 1, the progressive incorporation of marble powder (MP) modified the curve's shape; an upward movement was noticed of the grain size distribution curve for the treated soil. this shift is consequently due to the content of marble powder's role in displacing and reducing sand particles that leads to an increase of fine particles content in the mixture. the oued-souf material with no addition of marble powder has a poorly graded particle size distribution (cu = 2.25 and cc=1.05). the addition of 20% of marble powder changes the particle size distribution to to well graded, cu and cc rise respectively to 22.78 and 7.8, indicating that the particle size distribution has become less steep with a wide range of particle sizes.

3.2.2 Effect on compaction characteristics

The dune sand of Oued Souf under modified compaction effort at low water content (W=2%) reaching a maximum value of MDD, 20 KN/m^3 with the addition of 20% of marble powder (80DS + 20 MP) with an increase of 16%,as shown in Figure 3, this increase in MDD is related to the effect of finer particles that's helps the reduction fo voids in this dune sand, the peak of MDD at 20% of marble powder that's mean the powder occupied all the voids and reach the maximux density, similar behavior has been seen in (Omar, Zentar et al. 2022).

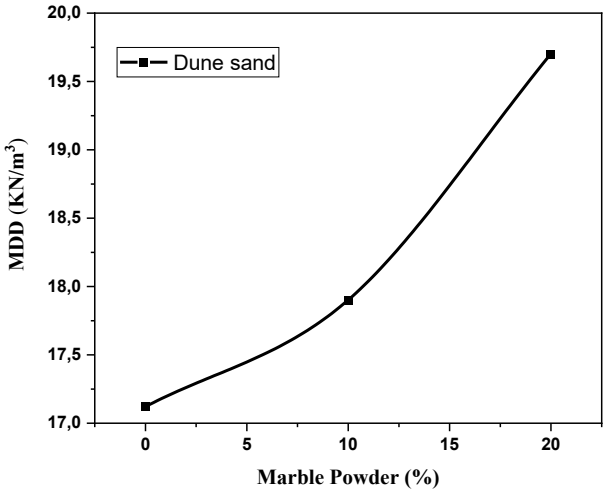

Figure 3. Effect of Marble Powder on the MDD of Dune sand.

3.2.3 Effect on the California Bearing Ratio (CBR) tests

The CBR values results for dune sand, with various content of marble powder is given by Figure.4. The CBR values increase from 10% to 37% Which is almost 4 times increase at the addition of 20% of marble powder, indicating that the material has reached its maximum compactness at this water content (W=2%).

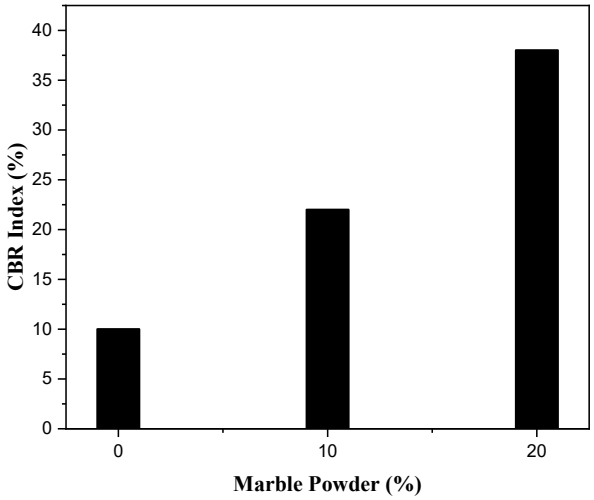

Figure 4. Effect of Marble Powder on on the CBR value of Dune sand.

4 CONCLUSION

The present experimental work on soil compaction at low water content involves mixing marble powder. The main results obtained are as follows. Increasing compaction energy has almost no effect on sand with uniform grain size as dune sand. The improvement of the density and bearing capacity of uniform grain size sand can be well achieved with the addition of insensitive water finer particles and mixing together. This solution helps to reduce the void ratio and increase the MDD. The compaction parameters as MDD and the CBR values have shown a considerable improvement with the addition of 20% of marble powder at low water content.

Design, construction and monitoring phases of a diaphragm wall shoring application near the Golden Horn

Phases de conception, de construction et de surveillance d'une application de soutènement en paroi moulée près de la Corne d'Or

ABSTRACT: One of the landmark buildings of Istanbul on the shores of the Golden Horn was damaged due to the large settlements occurred in the years after its construction. A comprehensive soil investigation study was held to determine the problem. The investigations revealed loose soil layers prone to settlement and also have liquefaction risk under earthquake loads. Remediation options were evaluated in the beginning of the construction. Demolishing of the existing structure and reconstruction of the new one with basement floors were recommended by the Consultant. A 9.5m excavation was planned for basement construction. It was decided to apply diaphragm wall supported with one row of strut and jet grouting on the toe. Due to the large excavation sizes and required long steel struts, king post barrettes were decided to be applied. Jet grout columns were applied with high efficiency monitor systems to obtain an improved layer and a thick bottom plug. Groundwater seepage was successfully minimized. Monitored displacements due to excavation were below the calculated ones. The project which was located in a very congested area with challenging soil conditions and construction difficulties was completed in a safe and timely manner.

RÉSUMÉ: Un des bâtiments emblématiques d'Istanbul, sur les rives de la Corne d'Or, a été endommagé en raison des vastes tassements survenus dans les années qui ont suivi sa construction. Une étude exhaustive du sol a été menée pour déterminer le problème. Les investigations ont révélé des couches de sol lâches susceptibles aux tassements et présentant également un risque de liquéfaction sous des charges sismiques. Des options de remédiation ont été évaluées dès le début de la construction. La démolition de la structure existante et la reconstruction d'une nouvelle avec des étages en sous-sol ont été recommandées par le consultant. Une excavation de 9,5 mètres a été prévue pour la construction du sous-sol. Il a été décidé d'installer un soutènement en paroi moulée supporté par un niveau de butons et du jet grouting en pied. En raison de la taille importante de l'excavation et des longs butons nécessaires, il a été décidé d'installer des supports intermédiaires via des barrettes avec des poteaux métalliques pré-fondés. Des colonnes jet grouting ont été appliquées avec des systèmes de surveillance à haute efficacité pour obtenir une couche améliorée et un bouchon épais au fond. Les infiltrations d'eau souterraine ont été efficacement minimisées. Les déplacements surveillés dus à l'excavation étaient inférieurs à ceux calculés. Le projet, situé dans une zone très congestionnée avec des conditions de sol difficiles et des difficultés de construction, a été achevé de manière sûre et opportune.

Keywords: Diaphragm wall; king-post barrettes; jet grout; monitoring.

1 INTRODUCTION

One of the remarkable buildings located alongside the Golden Horn was damaged due to large settlements. It was demolished and reconstructed with additional basement floors and this case study summarises the design, construction and monitoring phases of the diaphragm wall shoring applied to retain the basement excavation of this project.

Damaged building was constructed in the beginning of 70's and it was close to the Eminönü square which is a very congested side of Istanbul. There were some historical shops served for olive oil trade on this location before the building and large settlements were also detected under these ones (Toğrol et al., 1986). Therefore, some sand piles were implemented down to 25m before the construction of this building and shoreline was supported with fill (Peynircioğlu, 1976).

Large settlements were detected during its service life which threaten the structural stability of the building so it was decided to demolish and reconstruct it in the same place. To eliminate the settlement problem and increase the lateral stability it was decided to construct the building with two basement

floors standing on a block type thick soil improvement layer.

Within the soil investigation studies a total of 14 boreholes were applied with a maximum depth of 60 m. 10 of the boreholes were applied before the building demolition and 4 of them were after. SPT, PMT and MASW tests were conducted in the site. Site was close to the shoreline and groundwater table was encountered between 0.0m and 0.4m elevations. Soil profile and average SPT test results are given in Table 1 (Zemin Etüd ve Tasarım A.Ş., 2021).

Table 1. Soil Profile.

Average Depth	Layer
0 m / -38 m	Uncontrolled Fill Sand with Gavel and Clay. $(N_1)_{60ave}$=10
-38 m / -50 m	Clay $(N_1)_{60ave}$=15
under -50 m	Shale/Claystone

Distribution of the SPT $(N_1)_{60}$ values with the depth is given in the Figure 1.

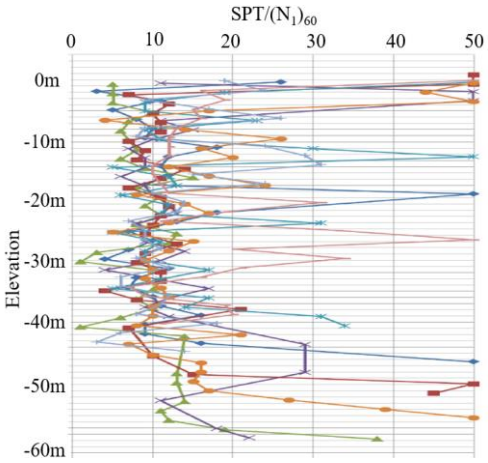

Figure 1. SPT $(N_1)_{60}$ distribution.

43 numbers of pressuremeter tests were conducted inside 4 numbers of the boreholes within the first 30 m depth. Menard Modulus E_M values were observed between approximately 1.5 and 47 MPa and net limit pressure P^*_{LM} values were between 0.1 and 1.9 MPa. Distributions of the E_M and P^*_{LM} values with the depth are given in the Figure 2.

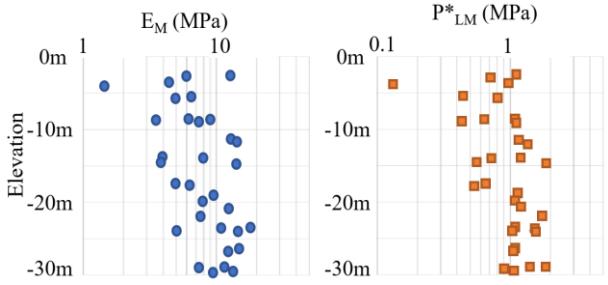

Figure 2. E_M and P^*_{LM} distributions.

MASW and PS logging tests were conducted within the geophysical survey. Besides, a ground penetration test was applied in the site to investigate the locations of the sand piles. Corrected Vs30 values were calculated between 190 and 330 m/s.

Plasticity index PI of the clay layer was calculated between 18 and 25, undrained cohesion value was 76 kPa. Unconfined compression values of the shale samples were observed between 14 and 40 MPa (Zemin Etüd ve Tasarım A.Ş., 2021).

Design parameters for shoring calculations were considered as in Table 2 based on the given soil investigation results. Fill layer was decided to split into 2 parts as above and below 20.0m. Elasticity modulus of the top uncontrolled fill layer was calculated as 20 MPa however it was considered as 6 MPa to be on the safe side due to high risks of debris and wood particles inside this layer.

Table 2. Considered Soil Properties.

Layer	Depth	γ kN/m³	Es MPa	c', kPa	φ',°
Fill	0-20m	18	6	1	30
Fill	20-38m	18	30	1	32
Clay	38-50m	18	8	7	25

2 DESIGN PHASE

After completion of the first phase of the boreholes, retrofitting and re-construction alternatives were discussed by the parties in the project. In overall stability analyses, structure had sufficient safety under static condition, but safety factor was calculated below the limits under the earthquake loads. Also, high liquefaction risk was pointed in the studies (Zemin Etüd ve Tasarım A.Ş., 2021).

After evaluating the gathered data re-constructing the structure after demolishing was determined as the best solution by the Employer and the Consultant.

Structure was planned to be constructed with 2 basements to remove some effective soil pressure under foundation. It was planned to be standing on a thick improved layer which will provide an efficient solution for settlements and lateral stability. A basement excavation with 9.5 m depth was required for construction as illustrated in the Figure 3.

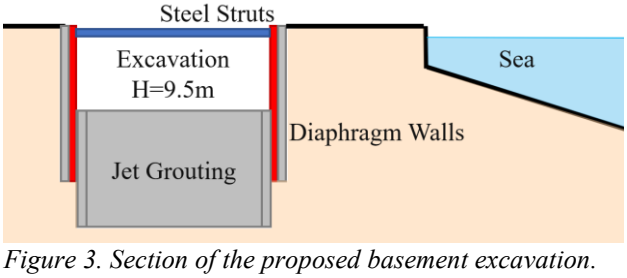

Figure 3. Section of the proposed basement excavation.

Site was at a very crowded and congested district of the city and close to many important infrastructure and historical places. Besides ground water table was close to surface. Due to these reasons shoring design became important in terms of waterproofness and displacements. Sheet pile, secant pile and diaphragm wall options were discussed in the design phase. The sheet pile option was eliminated because of the vibration risk under the existing historical structures. The diaphragm wall option was preferred instead of secant piles to provide better water tightness with reducing the number of joints between the vertical elements. Proposed thickness of the diaphragm wall was 800 mm with a depth of 17 m. Strutting was preferred instead of anchors due to the limited capacities which could be attained in the existing uncontrolled fill layer.

Jet grouting was selected as a ground improvement method which was the most suitable technique for the soil conditions. Jet grout columns were planned to be constructed with 1000 mm diameter in tangent pattern. In design UCS value of the jet grout columns was considered as 1.0 MPa due to the uncertain conditions of the fill layer. Elasticity modulus was considered as 300 times of the UCS value. Area replacement ratio between soil and jet grout columns was calculated as 0.79. Properties of the improved soil layer was calculated as the weighted average of the soil and jet grout columns.

Critical sections were modelled in Plaxis software as given in the Figure 4, displacements and section forces were calculated accordingly.

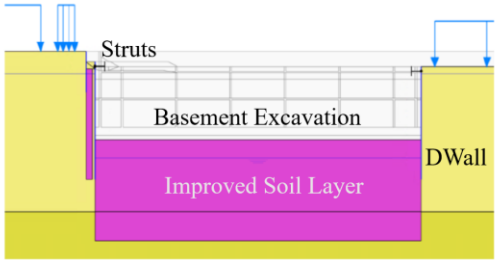

Figure 4. Plaxis Model of the Calculation Section.

Since the uncontrolled fill layer contains debris such as wood, plastic and bricks there were high risks in temporary stability of the excavated diaphragm wall shafts. Therefore, jet grout columns with 800 mm diameter were proposed under the guide walls adjacent to the diaphragm wall panel excavation. Diaphragm wall panel excavation could be done without any collapse.

Micropiles were implemented to support one part of the site which was 2.4 m higher than the rest. The shape of the basement was square with a side of 46 m as presented in the Figure 5.

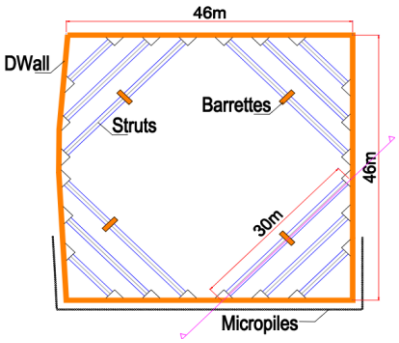

Figure 5. Layout of the Shoring System.

Four numbers of king-post barrettes were planned to be constructed to split the buckling length of struts for safety. Proposed shoring section was given in the Figure 6.

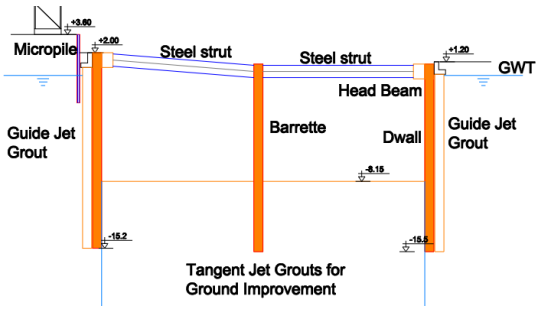

Figure 6. Section of the Shoring System.

Elevations were not equal everywhere in the site therefore different strut loads were calculated on the adjacent sides of the shoring. Due to these different strut loads, king-post barrettes needed to be checked in terms of lateral stability and cage design was prepared accordingly.

3 CONSTRUCTION PHASE

Application was started with jet grouting works. Trial jet grout columns were implemented to determine the application parameters. During these trials, with the permission of the Employer, large diameter jet grout columns were applied. Jet grout columns could be achieved up to 3.0 m in diameter with using high-efficient monitor and injection pump systems (Figure 7). A double fluid monitor was used with 6 mm diameter single nozzle, 400 bar pressure and 15 cm withdrawal rate.

Figure 7. Large Diameter (up to 3m) Jet Grouting Trial.

During the diaphragm wall excavation wood particles were encountered. To eliminate clogging in the plant these pieces were collected with a special sieve basket lowered inside the shaft during the operation (Figure 8).

Figure 8. Diaphragm Wall Construction.

Head beam was constructed with triangular parts to connect the struts perpendicular to reinforced concrete surface (Figure 9). Barrettes and these triangular parts cut and removed by the Employer parallel to the construction as planned in the early phases of the project.

Figure 9. Head Beam and Strut Installation.

This choice eased the precautions required for sliding safety of struts and provided a robust solution.

Diaphragm walls provided a watertight barrier and jet grout columns minimized groundwater seepage below the toe. Soil could be excaveted easily and transported under dry conditions. UCS values of the samples collected from jet grout columns were between 1.5 and 3.0 MPa. Additional excavations like lift pits could be done perpendicular and without any support with the help of high modulus and strength of the jet grout layer (Figure 10).

Figure 10. Excavation Phase.

4 MONITORING PHASE

Diaphragm walls were monitored with inclinometers during the excavation and lateral displacements were recorded approximately 10 mm which was calculated 25 mm during the design phase (Figure 11).

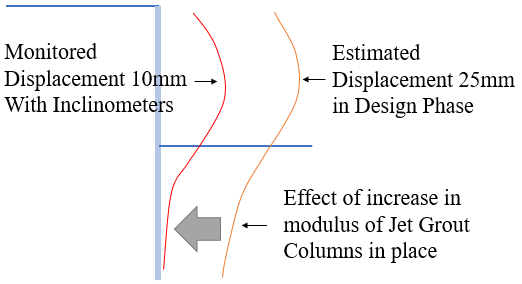

Figure 11. Calculated and Monitored Displacements.

UCS value of the jet grout columns was considered as 1 MPa with 400 kg/m^3 cement dosage and E/UCS ratio was considered as 300 to be on the safe side since there were debris and wood particles in the fill layer. Elasticity modulus of the jet grout layer was re-estimated by back calculation method with considering the encountered displacement 10 mm. Measured average UCS value was approximately 2 MPa and back calculation study pointed that 1200 MN/m^2 elasticity modulus could be considered for jet grout layer. E/UCS ratio is calculated approximately as 600 in this project for the fill layer.

5 CONCLUSION

Diaphragm wall shoring, steel strut and soil improvement with jet grouting techniques were successfully applied to support the basement excavation on the shores of the Golden Horn. Despite the challenging soil conditions and construction difficulties project completed in a safe and timely manner.

Physical, geometrical and chemical characterisation of incinerator bottom ash towards its use as recycled aggregate

Caractérisation physique, géométrique et chimique des mâchefers d'incinération en vue de leur utilisation comme granulet recyclé

F. Almeida, J.R. Carneiro*, M.L. Lopes
CONSTRUCT, Faculty of Engineering of University of Porto, Porto, Portugal
**rcarneir@fe.up.pt*

ABSTRACT: This work performs an extensive characterisation of incinerator bottom ash (IBA), analysing its physical, geometrical and chemical properties. Experiments included the determination of particle size distribution, flakiness and shape indexes, particle density and water absorption, the chemical analysis of the residue and also its leaching behaviour. The latter comprised, among others, the quantitative determination of different chemical species. The results obtained in the chemical analyses were compared with the limit values established in the European legislation for inert and non-hazardous waste classification. The outcomes of the investigation revealed that some properties of IBA were unsuitable for its use as recycled aggregate. To be a viable alternative to natural aggregates, IBA would need at least some preliminary treatment.

RÉSUMÉ: Ce travail réalise une caractérisation extensive des mâchefers d'incinération (IBA), en analysant leurs propriétés physiques, géométriques et chimiques. Les expériences ont inclus la détermination de la distribution granulométrique des particules, des coefficients d'aplatissement et de forme, de la masse volumique réelle et du coefficient d'absorption d'eau, de l'analyse chimique des résidus et également de leur comportement de lixiviation. Ce dernier comprenait, entre autres, la détermination quantitative de différentes espèces chimiques. Les résultats obtenus lors des analyses chimiques ont été comparés avec les valeurs limites établies dans la législation Européenne pour la classification des déchets inertes et non dangereux. Les résultats de l'enquête ont révélé que certaines propriétés des IBA n'étaient pas adaptées à son utilisation comme granulat recyclé. Pour constituer une alternative viable aux granulats naturels, les IBA nécessiterait au moins un traitement préliminaire.

Keywords: Incinerator bottom ash; chemical analysis; leaching behaviour; waste valorisation.

1 INTRODUCTION

The incineration process of municipal solid waste leads to the generation of large amounts of a residue known as incinerator bottom ash (IBA), which commonly ends up landfilled. The accomplishment of the targets included in the United Nations 2030 Agenda for Sustainable Development (UN, 2015) forces the development of solutions involving the valorisation of waste among the different industrial activities.

The use of IBA in the building and construction sector involves the implementation of an effective circular construction paradigm that depends on the will and joint work carried out by the government and construction professionals, including designers, entrepreneurs, manufacturers, contractors, engineers, architects and researchers (Almeida et al., 2022).

One core priority to assist designers in the decision-making process regarding the use of IBA as raw material is the understanding of its short and long term behaviour by assessing its mechanical, physical, geometrical and chemical properties.

IBA may be used in cementitious materials and as recycled aggregate in concrete or in road construction (Xuan et al., 2018). The latter application opens opportunities for IBA's valorisation in geotechnical engineering. Indeed, there is a wide range of potential geotechnical applications where IBA can be used as recycled aggregate, e.g., in backfill of trenches, in unbound layers of road pavements (base and subbase), in embankments of different transport infrastructures, or even in the subgrade of pedestrian and cycle paths. As can be understood, IBA might represent a significant source of raw materials, avoiding the excessive use of natural aggregates.

The aim of this work was to provide insights into several physical, geometrical and chemical properties of IBA considering its use as recycled aggregate in geotechnical engineering applications. To achieve such aim, an extensive experimental campaign was conducted.

2 EXPERIMENTAL DESCRIPTION

IBA was provided by a Portuguese incineration plant of municipal solid waste (Figure 1). Laboratory tests were conducted to obtain insights into its physical, geometrical and chemical properties. IBA was tested as received.

Figure 1. IBA.

The geometrical properties determined included particle size distribution, and flakiness and shape indexes. These properties were obtained according to EN 933-1 (CEN, 2012a), EN 933-3 (CEN, 2012b) and EN 933-4 (CEN, 2008), respectively. In addition, the coarse particles of IBA were classified based on the procedures defined in EN 933-11 (CEN, 2009). In this last test, a 20 kg sample of IBA with particles below 31.5 mm was passed through a 4 mm sieve. Then, around 4 kg of the particles larger than 4 mm (reduced sample) were classified as: R_u – unbound aggregate and natural stone; R_b – ceramics; R_g – glass; R_m – metals; or R_i – unidentifiable by-products of the incineration process. The results will be presented as the mass percentage of the constituents in the reduced sample.

Regarding physical properties, it was determined the particle density and water absorption (EN 1097-6 (CEN, 2022)) for two different particle size fractions: 0.063/4 mm and 4.0/31.5 mm.

The chemical characterisation of IBA included the determination of the parameters listed in the Council Decision 2003/33/EC (EU, 2003) both for the residue and its eluate. The eluate was obtained according to EN 12457-4 (CEN, 2002) at a liquid to solid ratio of 10 L/kg for the particle size fraction of IBA below 10 mm. The results obtained in the chemical analyses were compared with the limit values defined in the Council Decision 2003/33/EC (EU, 2003) for inert and non-hazardous waste.

3 RESULTS AND DISCUSSION

3.1 Physical and geometrical properties

The particle size distribution of IBA can be found in Figure 2. The maximum particle size (D_{max}) of IBA was 22.4 mm and the fines content (f) was 2.9 %. The values of C_U – coefficient of uniformity (20.57) and C_C – coefficient of curvature (1.88) indicate that IBA was a well graded aggregate having roughly 60% of its particles below 10 mm.

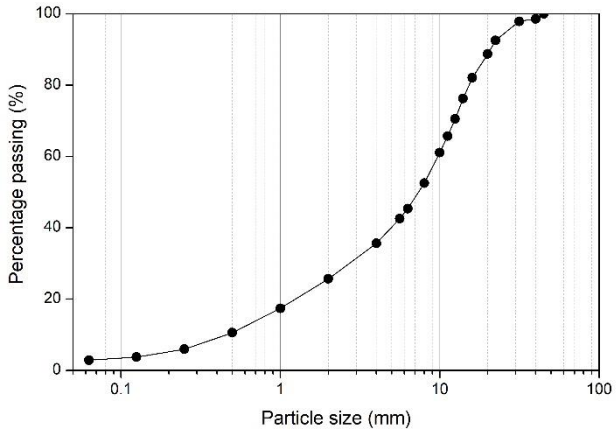

Figure 2. Particle size distribution of IBA.

The values obtained for the shape and flakiness indexes (Table 1) revealed that the coarse particles of IBA tended to be elongated and flaky. This is not a positive outcome considering, for instance, the use of IBA as filling material in road construction since that type of particles are more prone to fracturing when subjected to cyclic loads imposed by vehicle traffic.

Table 1. Shape and flakiness indexes of IBA.

Property	Result (%)
Shape index	40
Flakiness index	36

The main constituent of IBA was R_i, followed by R_g (Table 2). These two constituents accounted for 86.0% of the sample. The large amount of glass can be considered a drawback due to its brittle behaviour. This aspect can be associated with inadequate waste segregation conducted by households.

Table 2. Constituents of IBA.

Constituent	Percentage by mass (%)
R_u	2.1
R_b	9.4

R_m	2.5
R_i	48.5

The apparent (ρ_a), oven-dried (ρ_{rd}) and saturated (ρ_{ssd}) particle densities of the size fractions 0.063/4.0 mm and 4.0/31.5 mm, as well as the water absorption of IBA are shown in Table 3. The results showed that the size fraction 0.063/4.0 mm had lower densities (ρ_a, ρ_{rd} and ρ_{ssd}) and greater water absorption than the size fraction 4.0/31.5 mm. In addition, the densities of the size fraction 0.063/4.0 mm were below those normally found in natural aggregates. This feature, as well as the high water absorption, may configure a problem for using the lower size fraction of IBA as recycled aggregate in geotechnical engineering.

Table 3. Particle densities and water absorption of IBA.

Property	Size fraction	
	0.063/4.0	4.0/31.5
ρ_a (Mg/m^3)	2.28	2.40
ρ_{rd} (Mg/m^3)	1.69	2.12
ρ_{ssd} (Mg/m^3)	1.95	2.24
Water absorption (%)	15.2	5.5

3.2 Chemical analysis

The results obtained in the chemical analysis of IBA and its eluate are displayed in Tables 4 and 5. These tables also include the limit values defined in the Council Decision 2003/33/EC (EU, 2003) for inert (Criteria A) and non-hazardous (Criteria B) wastes, when applicable.

Table 4. Organic parameters of IBA (mg/kg).

Parameter	IBA	Criteria A
TOC	26000	30000
BTEX	5.5	6
PCBs	<0.021	1
Mineral oil	<20	500
PAHs	<0.16	100

Regarding the total content of organic parameters, IBA complied with all limit values to be classified as inert waste (Table 4), namely: TOC (total organic carbon), BTEX (benzene, toluene, ethylbenzene and xylenes), PCBs (polychlorinated biphenyls), mineral oil (C10 to C40), and PAHs (polycyclic aromatic hydrocarbons). The limit value of PAHs is set by each Member State and therefore the value indicated in Table 4 refers to the Portuguese legislation.

The results of the chemical analyses of the eluate (Table 5) showed that IBA complied with most of the requirements to be classified as inert waste. In total, five non-conformities were found: copper, chloride, sulphate, DOC (dissolved organic content) and TDS (total dissolved solids). When comparing with the criteria for non-hazardous waste, IBA complied with all limit values.

Table 5. Chemical analysis of the eluate (mg/kg).

Component	IBA	Criteria A	Criteria B
Arsenic	0.03	0.5	2
Barium	1.38	20	100
Cadmium	<0.04	0.04	1
Total chromium	<0.5	0.5	10
Copper	9.1	2	50
Mercury	<0.01	0.01	0.2
Molybdenum	0.28	0.5	10
Nickel	<0.3	0.4	10
Lead	<0.3	0.5	10
Antimony	<0.01	0.06	0.7
Selenium	0.01	0.1	0.5
Zinc	3.2	4	50
Chloride	4000	800	15000
Fluoride	<10	10	150
Sulphate	2200	1000	20000
Phenol index	0.3	1	—
DOC	580	500	800
TDS	15000	4000	60000

The copper and chloride contents were around 5 times higher than the limit values for classifying IBA as inert waste. Referring to the same classification, the excess in the sulphate content was smaller, being approximately twice the limit value. However, in this case, the Council Decision 2003/33/EC (EU, 2003) mentions that if the content of sulphate does not meet the 1000 mg/kg limit at a liquid to solid ratio of 10 L/kg, the residue can still be considered as complying if the value does not exceed 6000 mg/kg. Therefore, the excessive sulphate content in IBA ends up not being very relevant.

The excess in DOC was small, exceeding the limit value for classification as inert waste by 16.0%. The Council Decision 2003/33/EC (EU, 2003) also has a note for DOC, stating that if the waste does not meet the limit value for DOC at its own pH value (which was the case with IBA), it may be alternatively tested at a pH between 7.5 and 8.0. The test at this pH range was not carried out.

Finally, the TDS content exceeded by 3.75 times the limit value for classifying IBA as inert waste. The Council Decision 2003/33/EC (EU, 2003) does not provide any tolerance for TDS but mentions in a note that the value obtained for this parameter can be used alternatively to the values for sulphate and chloride. Therefore, considering that the sulphate and chloride contents were above the maximum allowable values, it is understandable that the TDS content exceeded its limit value. The previously mentioned note may also indicate that the analysis of TDS is not mandatory.

It should be noted that IBA is often pre-treated by natural weathering, which helps reducing its leaching potential (Bandarra et al., 2023). In the present work,

IBA was not submitted to any pre-treatment. Thus, the non-conformities with the acceptance criteria as inert waste could have been benefited if IBA had been subjected to weathering.

4 CONCLUSIONS

The results obtained in the physical, geometrical and chemical tests showed that most properties of IBA allow considering its use as recycled aggregate in geotechnical engineering applications. However, there were some non-conforming properties, which need to be improved. IBA pre-treatment operations are necessary.

The size fraction of IBA below 4 mm should be discarded due to its low densities and high water absorption. In addition, IBA will be benefited from the decrease of the glass content. Still, it should be noted that the high amount of glass may be a particularity of the sample studied in this work. IBA from other batches or generated in other incineration facilities may contain less glass.

IBA complied with the acceptance criteria defined in the European legislation for non-hazardous waste but failed some parameters declared for inert waste. Natural weathering of IBA, a common pre-treatment that was not adopted in this work, could be useful to improve the leaching behaviour, making this material more environmentally sustainable.

Finally, it will be important to carry out a more detailed analysis of the unidentifiable by-products of the incineration process (the main component of the coarse particles of IBA). Additional tests may include the determination of the elemental composition, the identification of mineral phases, the study of morphology, or the assessment of porosity.

ABSTRACT: This article presents a solution for the design and construction of reinforced jet-grouting structures. In particular, it discusses the application of reinforced jet-grouting for retaining walls in excavations for basement construction. The use of jet-grouting as a structural element with flexural work is not common, as this product is typically used almost exclusively under pure compression. Flexural forces require the reinforcement of this material with steel bars, and the use of a finite element model is presented as a possible design tool for this purpose. The work described was successfully completed using the concept of reinforced jet-grouting with corrugated steel bars. Additionally, the article outlines the specific procedure for performing jet-grouting in a complex colluvial geology with large, embedded rock blocks in a heterogeneous granular matrix, making it challenging to create ideal intersecting cylindrical jet-grouting columns.

RÉSUMÉ: Cet article présente une solution pour la conception et la réalisation de structures renforcées de jet-grouting. En particulier, l'étude de la solution de jet-grouting renforcé appliquée aux murs de soutènement des excavations pour la construction des sous-sols est commentée. La technique du jet-grouting en tant qu'élément de structure avec travail de flexion n'est pas courante puisque ce produit est généralement utilisé presque exclusivement en compression pure. Les efforts de flexion rendent nécessaire de renforcer ce matériau avec une armature en acier et l'utilisation d'un modèle d'éléments finis est présentée comme un outil de conception possible à cet effet. Les travaux commentés, menés à bien, ont été calculés et exécutés avec ce concept de jet-grouting renforcé de barres d'acier ondulées. De même, l'article présente la procédure particulière pour effectuer le jet-grouting dans une géologie colluviale complexe avec de grands blocs de roche encastrés dans une matrice granulaire hétérogène qui rendent difficile la réalisation de colonnes cylindriques idéales de jet-grouting se croisant.

Keywords: Jet-grouting; retaining walls.

1 GUIDELINES

This article introduces a specific procedure for the design and construction of retaining walls using the reinforced jet-grouting technique in areas with complex colluvial geology. To provide a practical example, the application of this method is illustrated through a project carried out in Andorra la Vella (Andorra). The project was designed by the architect Jordi Batlle Jordana, and the original calculations were performed by Beal AEC, S.L. using their own methods.

Jet-grouting technology enables the creation of cement-treated soil volumes with significantly improved strength and deformation properties compared to the original soil, while also achieving a substantial reduction in permeability. However, it is uncommon to use this technique for creating structural inclusions in the ground capable of withstanding flexural forces, such as retaining walls.

In the specific case we present, the choice of the structural type of retaining wall is influenced by two main factors:

- The ground consists of colluvial soil with large rock boulders (>1m) within a heterogeneous granular matrix.
- The water table is high, located above the excavation floor.

1.1 Containment geometry

The case that serves as our example involves an excavation for constructing multiple basement levels on a site with a sloping topographic surface, featuring an elevation difference of about 10 meters, ranging from 1028 to 1018. The site covers an area of approximately 8000 square meters, and the required excavation depth entails the construction of retaining walls, spanning heights from 7.50 to 16.50 meters. (See Figure 1 and Figure 2).

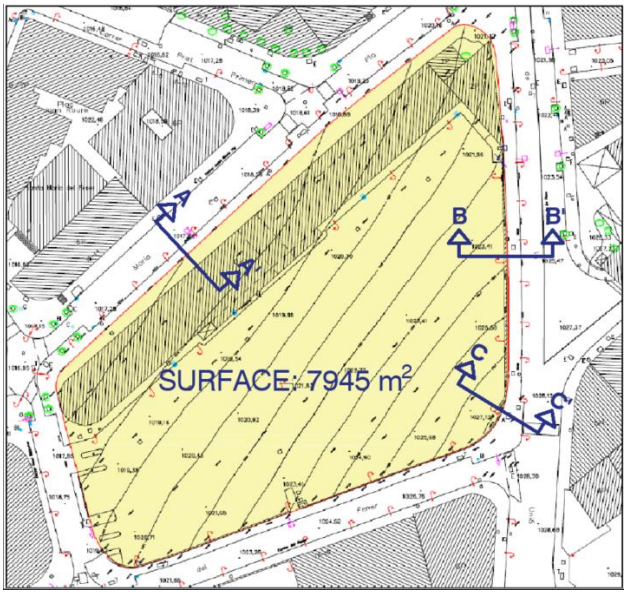

Figure 1. Perimeter of the excavation and location of the typical cross-sections.

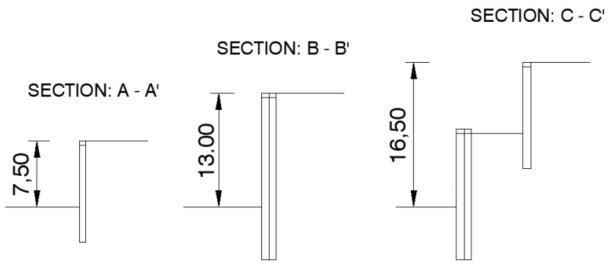

Figure 2. Typical cross-section, showing the highs of the contention in meters.

1.2 Ground characteristics

The ground to be excavated and retained consists of a thin anthropic layer followed by a thick, coarse fluvio-torrential alluvial layer with granite boulders of up to 1 meter in size, within a heterogeneous granular matrix of sand and gravel.

Distinct layers can be identified:

Geotechnical Layer 1: Surface Granular Material

- Density: 18 kN/m3
- Cohesion: 0,0 kN/m^2
- Friction Angle: 28º
- Deformation Modulus: 11 MPa

Geotechnical Layer 2: Fluvial-Torrential Granular Material (Figure 3)

- Density: 19,8 kN/m^3
- Cohesion: 5,0 kN/m^2
- Friction Angle: 30º
- Deformation Modulus: 44 MPa

Figure 3. Soil samples taken from Geotechnical Layer 2. Granite boulders wrapped in sandy clay matrix.

2 EXECUTION OF STRUCTURAL WALLS USING REINFORCED JET-GROUTING

The walls were constructed using secant soil columns treated with jet-grouting. Jet-grouting columns are created by mixing the soil with a slurry through drilling to the maximum depth of the column and blending it with cement slurry during the ascent, with rotation of the drilling rods. (See Figure 4).

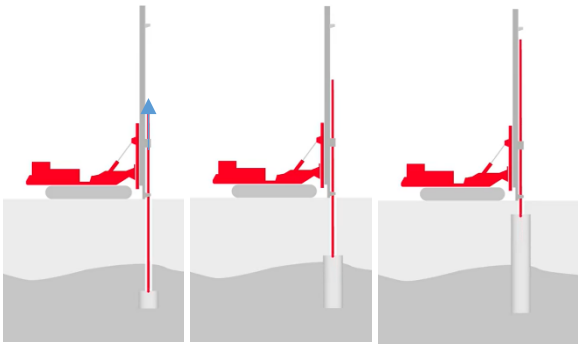

Figure 4. Execution of a jet-grouting column. From bottom to top, withdrawal with rotation while de cement slurry is injected.

Among the different variants of jet-grouting, the one commonly known as Type 1 jet-grouting was used, which employs a cement slurry as the cutting and mixing fluid (For further information on jet-grouting, you can refer to P. Croce 2014 book.).

However, executing a jet-grouting column in soil with large rock boulders, as is the case here, presents a

series of challenges that, until recently, seemed insurmountable:

2.1 Challenges in executing Jet-grouting columns in alluvial boulder deposits

- The initial drilling is generally performed with rotary drilling equipment, which is incapable of penetrating the rocky boulders that require rotary-percussive drilling. Rotary drilling is traditionally used for jet-grouting as it allows the injection of slurry through the drilling rods.
- Large boulders hinder the formation of a jet-grouting column with a cylindrical geometry since the "shadow effect" caused by any intercepted rock boulder screens the ideal axial symmetry of the jet. (See Figure 5)

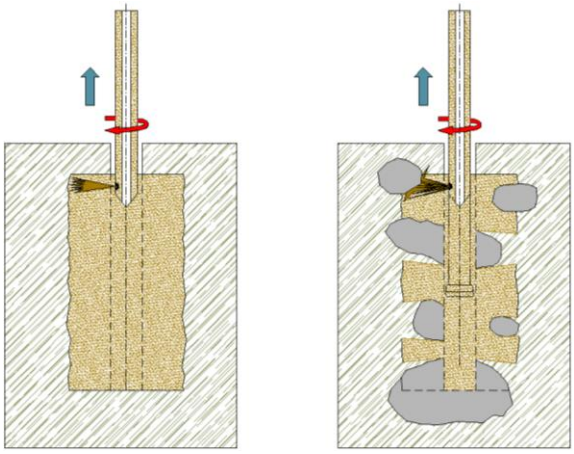

Figure 5. Comparison of Column Formation in Fine Granular Soil and Soil with Large Boulders.

2.2 Solution to the execution challenges of jet-grouting in rocky boulders

To address the previously mentioned problems, the following measures were taken:

a) A DHH pointed hammer was used at the bottom of the drilling to enable rotary-percussive drilling of the rocky boulders. In order to conduct the compressed air to the bottom hammer and, simultaneously, to conduct the cement slurry to the monitor at the bottom of the drilling rod, a Type 2 jet drilling rod with double concentric pipes was used. (See Figure 6).

Note: Commonly, the Type 2 jet drilling rod is a dual rod that allows the conduction of compressed air to a dual nozzle through which cement slurry is injected, enveloped in a concentric jet of air, reducing the dispersion of the jet and concentrating its energy in a smaller impact area.

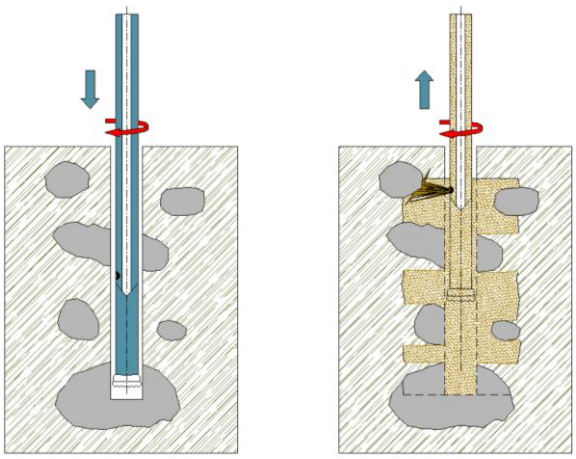

Figure 6. Drilling and injection phase. During drilling, the compressed air actions the hammer. During withdrwal, the cement grout jet erodes the soil and mixes with it.

b) The wall geometry is designed with two or three overlapping rows of jet-grouting columns, ensuring the continuity and impermeability of the wall despite the irregularities that may be caused by intercepted boulders. (See Figure 7).

Plan layout of jet-grouting columns: double or triple row of columns: (See Figure 7).

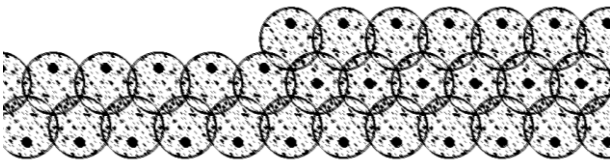

Figure 7. Layout of the jet-grouting columns in plan. The thickness of the wall is created by a double or triple row of intersecting columns.

3 ALTERNATIVE DESIGN METHODS FOR REINFORCED JET-GROUTING WALLS

The common approach for calculating or designing a jet-grouting wall is to model it as a plate element (or the cross section as a 1D beam) that interacts with the ground in terms of stress and deformation. It's also common to model the interaction between the wall and the ground using an elasto-plastic spring model.

When the jet-grouting wall is thick and unanchored, it can be considered as a gravity wall where the self-weight of the jet-grouted volume plays a crucial role in supporting the excavation. In cases where the jet-grouting wall is heavily reinforced, for example, with HEB-type beams and anchors, the stiffness of the wall is typically only considered with the metallic beams, disregarding the structural collaboration of the jet-grouting.

However, when the jet-grouting wall is designed as a two-dimensional, flexible, and anchored element, and its reinforcement is light, for example, with corrugated steel bars (rebars or threaded bars), various considerations arise when modeling this "composite retaining wall", particularly in terms of modeling the behavior of the jet-grouting material.

Since the thickness of the wall consists of a treated and resistant soil volume and steel reinforcement, similar to reinforced concrete, one could model the section as a two-dimensional element with the characteristics of a reinforced concrete plate. However, the configuration of jet-grouting walls consists of overlapping columns in one, two, or even three rows (see Figure 7). This makes the wall thickness significant in relation to the other two dimensions, and a 2D plate model raises certain doubts regarding its suitability.

For these cases of thick, lightly reinforced, anchored jet-grouting walls, we propose the possibility of using a finite element model with a specific representation of the jet-grouting wall thickness.

In the case study, we have created a model for different sections of the retaining wall with the grids shown in Figure 8.

This model offers the advantage of evaluating the influence of the jet-grouting wall thickness and its interactions with anchors and parallel walls.

World experience on the problem of reinforced jet-grouting working as a wall is presented as case studies for many authors, but references do not mention design method or simply reference to conventional D-Wall calculation or Soldier-pile calculation. For Finite Element design of this type of jet-grouting walls the authors could find the Thesis of David Tran Yohanes Armediaz: *On the Modelling of Jet Grouting for Deep Excavation Analysis*, Chalmers University of Technology, Gothenburg, Sweden 2021.

Regarding the modeling of jet-grouting material, there are also references that discuss how to parameterize a low-strength mass concrete using the parameters of a Mohr-Coulomb model (for reference, see: Plaxis Bulletin, Spring issue 2009, www.plaxis.nl).

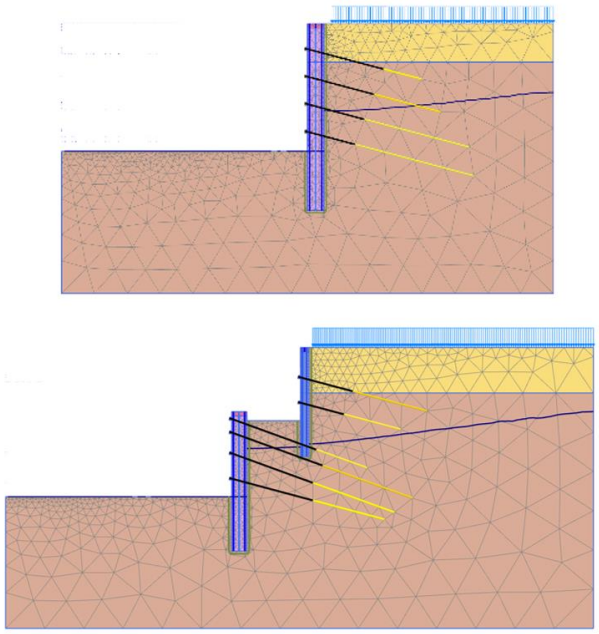

Figure 8. Finite element meshes used to model the jet-grouting walls in the case study.

Additionally, to account for the cracking of jet-grouting under tension, a conservative approach was taken by assuming zero tensile strength in the jet-grouting, instead of the usual approximate value of $f_{ctk}=10\%\cdot f_{ck}$, a value of $f_{ctk}=0$ was used. This consideration particularly affects the deformation of the wall since there is no tensile collaboration of the jet-grouting in the elastic phase before reaching plasticity.

Working in this manner and modeling the embedded steel bars in the jet-grouting as equivalent stiffness steel plate elements, it is possible to obtain the stresses generated in the jet-grouting and perform the corresponding design check (see Figure 9). The stresses in the reinforcing steel bars can also be obtained from this model based on the efforts in the plate elements that represent them.

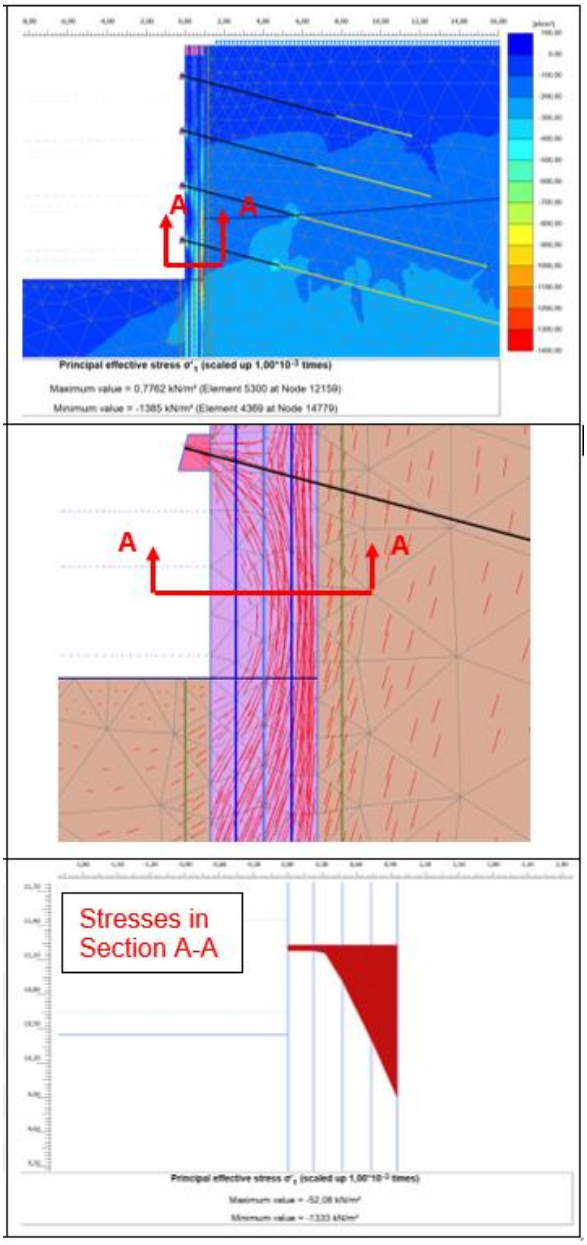

Figure 9. Estimation of the stresses generated in the body of the jet-grouting.

4 CONCLUSIONS

In the "El Fener" project in Andorra la Vella, a retaining wall has been successfully constructed using jet-grouting columns. The geotechnical complexity of the terrain required the development of jet-grouting execution systems that are compatible with the ability to drill throuh large granite boulders. To achieve this, the team has implemented rotary-percussive hammers at the tip of the drilling rods, under the jet-grouting nozzle holder.

The design of the wall, composed of 2 and 3 overlapping rows of overlapping jet-grouting columns, has ensured excellent structural performance as well as impermeability to the high-water table behind the wall.

Figure 10. Some photographs of the retaining wall after the excavation of the site.

The final result after excavation can be seen in the photographs in Figure 10.

The utilization of finite element models has made it easier to evaluate the stresses within the jet-grouting body and the embedded reinforcing steel. The finite element modeling has considered the behavior of the jet-grouting material according to an elasto-plastic Mohr-Coulomb type model, without tensile strength capacity.

ABSTRACT: In this study, driving records of 18 open-ended steel tubular piles installed in dense sandy soil conditions at five sites in the Netherlands were utilized to evaluate models that are currently used in practice for predicting the static soil resistance during driving (SRD), as well as a recently developed method, known as the Unified Method. Since the Unified Method is a static axial capacity-CPT-based design method, slight modifications to the originally proposed formulas were examined to allow estimation of the SRD. This paper presents a modified format of the Unified Method and its performance is assessed by comparing predicted with measured hammer blow count profiles. It is eventually shown that the modified Unified Method leads to overall improved blow count predictions compared to current approaches.

RÉSUMÉ: Dans cette étude, les enregistrements de battage de 18 pieux tubulaires en acier à extrémité ouverte installés dans des conditions de sol sableux denses sur cinq sites aux Pays-Bas ont été utilisés pour évaluer les modèles actuellement utilisés dans la pratique pour prédire la résistance statique du sol pendant le battage (SRD), ainsi qu'une méthode récemment développée, connue sous le nom de méthode unifiée. Étant donné que la méthode unifiée est une méthode de conception basée sur la capacité axiale statique CPT, de légères modifications des formules initialement proposées ont été examinées pour permettre l'estimation du SRD. Cet article présente un format modifié de la méthode unifiée et ses performances sont testées en comparant les profils de nombre de coups de marteau prédits et mesurés. Il est finalement démontré que la méthode unifiée modifiée conduit à des prévisions globalement améliorées du nombre de coups par rapport aux approches actuelles.

Keywords: Pile driveability; SRD; Unified Method.

1 INTRODUCTION

The driving process is commonly assessed by utilizing commercially available pile driveability software that are based on 1-D wave equation analysis. These enable the modelling of the hammer – pile – soil system as a series of masses and springs and simulate the stress wave phenomena during the installation process.

The total soil resistance consists of both a static and a dynamic component and is usually represented by elasto-plastic springs with dashpots at the toe and around the pile shaft area. The static component, also referred to as SRD (static resistance during driving), represents the cumulative increase of shaft resistance with further pile penetration, and the toe resistance associated with each driving increment (Prendergast et al (2020)). The dynamic component is typically quantified by damping factors (Schneider et al (2010)) that depend on soil type and is expressed as function of the SRD.

This paper examines the applicability of the Unified Method (Lehane et al (2020)) in driveability predictions. The Unified Method is a CPT-based static axial capacity design method for driven piles in silica sand. This design approach is included in the 2022 edition of ISO-19901-4 replacing the four CPT methods (ICP-05, Fugro-05, NGI-05 and UWA-05).

Since SRD differs from pile axial capacity in terms of consolidation, stress equalization, and time effects (Schneider et al (2010), Byrne et al (2018), Prendergast et al (2020)) modifications are required to allow estimation of SRD. The modifications applied to the Unified Method are inspired by the ones proposed by Byrne et al (2018) and Prendergast et al (2020) that were successfully applied at very similar axial capacity design methods (ICP-05, UWA-05) for estimation of the SRD, leading to improved driveability predictions.

A common and practical way to assess the pile driving resistance using specific hammering equipment, is through the number of required hammer blows per 25 cm increment of penetration. Utilizing as input to the driveability model the impact hammer energy record of 18 open-ended tubular piles driven in mainly dense sand conditions at 5 sites in the Netherlands, an assessment of the modified Unified Method is made as well as a comparison with frequently used in practice SRD models in terms of predicted against measured hammer blows per 25cm.

2 MODIFIED UNIFIED METHOD

Analytical explanation of the Unified Method and of the formulas used to calculate the shaft and toe capacity can be found in Lehane et al (2020). The following sections provide the modifications that were applied to this method, which can also be found in detail in the Master Thesis by Argyroulis (2022). Section 2.3 provides the formulas of the modified Unified Method.

2.1 Modified shaft resistance

The Unified CPT-based Method was calibrated using the 'Unified database' (Lehane et al (2017)) comprising 71 static pile load tests in siliceous sand deposits with diameters between 300 and 800 mm. As explained in Lehane et al (2020), the shaft capacity of driven piles in sand increases with time over a period of about one year and the Unified Method was calibrated to estimate the shaft capacity at around 14 days after driving. Therefore, the shaft resistance during driving will be lower than the shaft capacity currently estimated by this approach.

Jardine et al (2006) interpretation of Intact Ageing Curves of piles installed in the Dunkirk (France) dense sand revealed that the shaft capacity 1 day after driving was approximately 70% of the shaft resistance estimated with the ICP-05 method (10-30 days after installation). Lehane et al (2017), included records from piles installed in dense sand at Blessington (Ireland) and Lavrik (Norway) and derived the following time factor (best fit line – (1)) that can be applied when using the pile capacity methods: API-00, ICP-05, UWA-05, Fugro-05 and NGI-05:

$$F_{time} = \frac{1}{exp(-0.1*t^{0.68})+0.45} + d_{offset} \qquad (1)$$

where t (days) after installation and d_{offset} (-) an offset value depending on the method used.

Setting the offset and time to zero a factor of about 0.7 is obtained. By using a time factor of 0.7, Byrne et al (2018) and Prendergast et al (2020) showed improved driveability predictions when using the ICP-05 and UWA-05 methods. Due to great similarity of the aforementioned CPT based design methods (API-00, ICP-05, UWA-05, Fugro-05 and NGI-05) with the Unified Method, 70% of the shaft capacity predicted with this method is considered to be a reasonable estimation of the shaft resistance mobilized during driving.

2.2 Modified toe resistance

The original toe resistance formulation cannot be directly used for pile driveability predictions since the base resistance estimated, is the one mobilized at pile tip displacements equal to 10% the pile diameter. In normal driving conditions though, the pile will only displace a few mm per hammer blow. Thus, for driveability analysis, it is required to define the maximum toe resistance that corresponds to the assumed quake value (displacement at yield). Signal matching analyses of dynamic driving data indicate quake values of about 2.5 mm for both the shaft and toe resistances.

Due to its simplicity the recommended by API (2000) tip load-displacement model (Table 1) was used in this case to derive an appropriate toe resistance mobilized during driving.

*Table 1. Pile tip-load-displacement (Q-z) curve (*API (2000)*).*

$\frac{w_b}{D}$	$\frac{q_b}{q_{b0.1}}$
0.002	0.25
0.013	0.5
0.042	0.75
0.073	0.9
0.1	1

where w_b represents the base displacement (mm), D is the pile diameter (mm), $qb_{0.1}$ is the mobilized toe resistance at 10% the pile tip displacement (kPa), and q_b (kPa) the mobilized toe resistance at w_b tip displacement. Utilizing the original formula of toe resistance of the Unified Method and a quake value of

2.5 mm, the mobilized q_b driving toe resistance can be determined.

Based on Table 1, equation (10) was developed to match the tabulated API base displacement response with the addition of an extra term used to account for residual loads (q_{res}) after a hammer blow. While Paik et al (2003) measured that residual stresses were in the range of 11-14% of the CPT qc value for 356 mm (diameter) open and closed-ended piles in dense sand, Byrne et al (2018) suggested values 1-10% of the qc in medium dense sands for large offshore steel open-ended monopiles. Clearly, there is an uncertainty on the residual loads, and thus a 10% of the $qb_{0.1}$ was used in the following case studies presented.

2.3 Formulas of modified Unified Method

Below the modified formulas of the Unified Method that can be used to estimate the SRD are presented.

Shaft resistance

$$Q_{shaft} = \pi * D * \int_0^L \tau f_{SRD} dz \quad (2)$$

$$\tau f_{SRD} = F_{time} * (\sigma'_{rc} + \Delta\sigma'_{rd}) * tan\delta_f \quad (3)$$

$$\sigma'_{rc} = \frac{q_c}{44} * A_{re}^{0.3} * \beta \quad (4)$$

$$\beta = \left[\max\left(1, \frac{h}{D}\right)\right]^{-0.4} \quad (5)$$

$$A_{re} = 1 - PLR * \left(\frac{D_i}{D}\right)^2 \quad (6)$$

$$PLR = \tanh\left[0.3 * \left(\frac{D_i}{D_{CPT}}\right)^{0.5}\right] \quad (7)$$

$$\Delta\sigma'_{rd} = \left(\frac{q_c}{10}\right) * \left(\frac{q_c}{\sigma'_v}\right)^{-0.33} * \left(\frac{D_{CPT}}{D}\right) \quad (8)$$

where:

τf_{SRD}	unit shaft resistance (kPa)
D	outer pile diameter (m)
D_i	inner pile diameter (m)
D_{CPT}	CPT cone diameter, 0.0357 m
F_{time}	time factor, 0.7 (-)
σ'_{rc}	radial effective stress (kPa)
β	fatigue factor (-)
h	distance of soil horizon from pile tip (m)
$\Delta\sigma'_{rd}$	increase in radial effective stress (kPa)
δ_f	constant volume friction angle, 29°
A_{re}	effective area ratio (-)
PLR	plug length ratio (-)

Toe resistance

$$Q_b = q_{b_{SRD}} * \pi * \frac{D^2}{4} \quad (9)$$

$$qb_{SRD} = 2.23 * \left(\frac{w_b}{D}\right)^{0.347} * q_{b0.1} + q_{res} \quad (10)$$

$$q_{b0.1} = (0.12 + 0.38 * A_{re}) * qc \quad (11)$$

$$q_{res} = 0.1 * q_{b0.1} \quad (12)$$

3 REMARKS ON MODIFIED UNIFIED METHOD

Some important notes regarding the modified and original Unified Method are summarized below.

With respect to the shaft resistance, the one calculated by equation (3) represents the shaft resistance developed at the external shaft area of the pile. Other SRD models, like the Alm & Hamre (2001) which is used for comparison in the case studies below, incorporate the internal shaft resistance to the external shaft formulation of open-ended piles, while the toe resistance is acting on the pile tip annular area. Contrary to these models, the Unified Method accounts for the internal shaft resistance (plug resistance) to the toe resistance formulation (equation (9)). In that sense it can be expected that for large offshore piles the (modified) Unified Method will predict lower (external) shaft resistance compared to the (external and internal) shaft resistance of Alm & Hamre (2001) model, while the opposite occurs for toe resistance since the modified Unified Method is applied at the gross pile base area, taking into account as well the (inner shaft resistance) plug resistance. This will eventually result in a similar estimation of SRD.

Furthermore, it should be noted that the shaft resistance of the (original) Unified Method considers variation of τf with the degree of soil displacement imparted during driving. This is quantified, as explained in Lehane et al (2020), with the effective area ratio A_{re} that represents the ratio of the soil volume displaced during installation to the pile total volume and the plug length ratio, PLR. Therefore, the original formulas are not only applicable to fully coring cases, but also to partially plugged piles ($PLR < 1$) or even to close ended piles ($A_{re} = 1$). Although the modified version is basically 70% (time factor) of the original shaft resistance, this paper evaluates only fully coring cases, while it would be interesting in the future to assess the performance of the modified Unified Method for closed-ended or partially plygged piles.

Finally, it is mentioned for the modified toe resistance that formula (10) allows the calculation of the maximum driving toe resistance for any quake value chosen (e.g., w_b based on specific project data), while the residual load used requires further research.

4 CASE STUDIES

The detailed analysis of the 18 open-ended piles can be found in (Argyroulis (2022)). In this section, the hammer blow count post-predictions of 5 open-ended piles from 5 locations (Port of Rotterdam, Eemshaven) in the Netherlands are presented (Figure 1, Figure 2, Figure 3). The modified Unified Method is denoted as UM (2020) SRD. It is stated that the piles of APM, RWG, SIF and HHTT terminals (Port of Rotterdam) were partially driven by a vibratory hammer (not examined in this paper), and later on the target depth was reached using hydraulic and diesel impact hammers. It is mentioned that the impact hammer energy was recorded during installation and was used as input into the driveability model, so that the outcome is mainly affected by the chosen SRD model. The results of the UM (2020) SRD are mainly compared to the most frequently used Alm & Hamre (2001) model, while for APM and RWG terminals, predictions were also made with the Stevens et al (1982) model. The AllWave-PDP driveability software was used for the purposes of this study.

5 CONCLUSIONS

Although this study is limited to pile diameters of 1.4 m (APM, RWG, SIF, HHTT terminals) and 0.76 m (EURIPIDES) it can be seen that the Unified Method, when slightly modified is capable of reproducing the hammer blows during installation. A way to assess the predictions made by the SRD models and the actual blow counts measured is through the Mean Absolute Percentage Error (MAPE) as a measure of average deviation between predicted and measured values. It was observed that the modified Unified Method has less deviation from the actual record of blows counts than the Alm & Hamre (2001) model in 13 out of 18 cases, whereas in 3 cases (out of 18) the modified Unified Method showed a slight over-under prediction, and in the remaining 2, both models showed the same deviation (Argyroulis (2022)). Despite that, the Alm & Hamre (2001) model is still very reliable model as can be seen in the figures below. The Stevens et al (1982) model, although it is a very practical and easy to use model, since it doesn't consider friction fatigue it tends to overpredict the number of blows (e.g., RWG terminal, Figure 1).

Further research is required to investigate the appropriate diameter range for which the modified Unified Method can be used, as well as variation in soil conditions (e.g., inclusions of soft clay layers).

Finally, the importance of collecting high quality driving records should be highlighted as the only way to improve the efforts made for more reliable driveability predictions, which may lead to minimization of installation risks and construction delays.

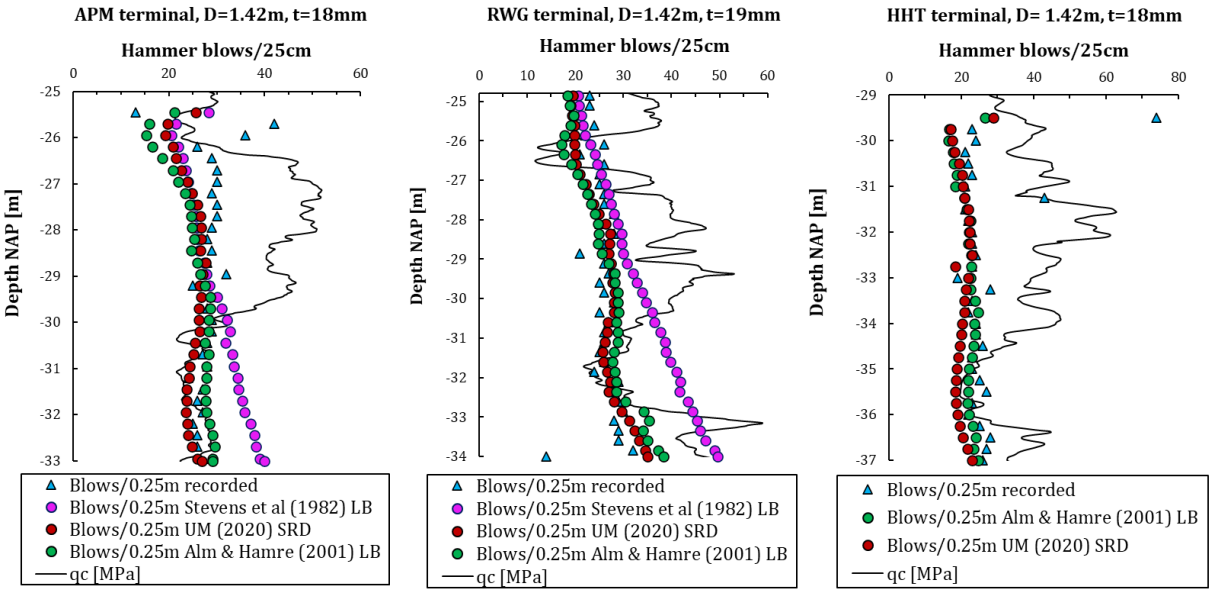

Figure 1. Post driveability predictions of hammer blow count profiles for terminals APM, RWG and HHTT at Maasvlakte, Rotterdam. Hydraulics hammers IHC S-200, IHC SC-200 and IHC S-280 were used.

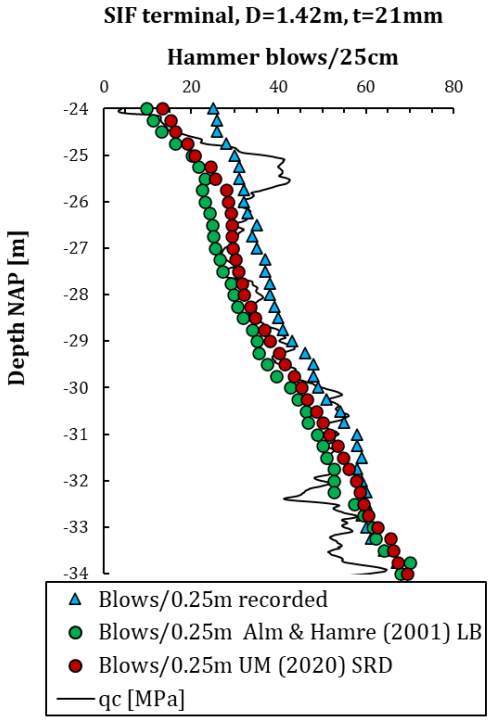

Figure 2. Post-predicted blow count profile for SIF terminal at Maasvlakte, Rotterdam. A Delmag D100-13 diesel hammer was used.

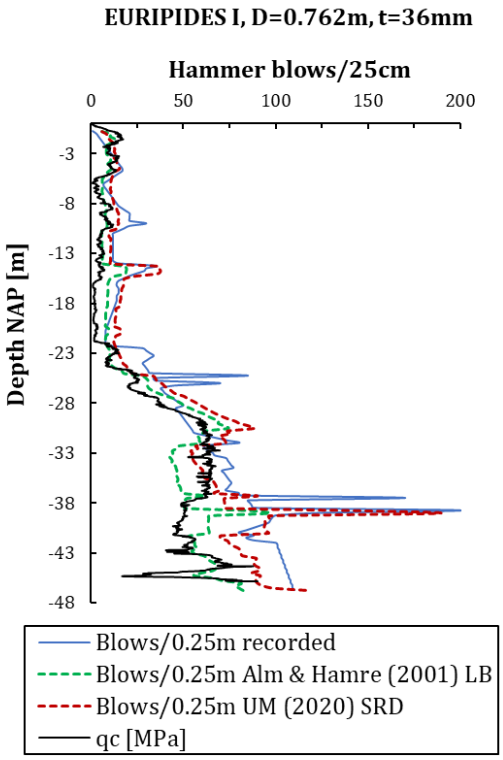

Figure 3. Post-predicted blow count profile for EURIPIDES project at Eemshaven. A IHC S-90 hydraulic hammer was used.

ABSTRACT: This study presents the results of a series of California Bearing Ratio (CBR) index tests aimed at investigating reinforced soil samples with woven and non-woven geotextile inclusions positioned at H/2 and 1/4H from the top of the specimens, compacted at standard Proctor energies. The samples used in the research are derived from a residual soil of a typical soil profile in the state of Minas Gerais, Brazil, classified according to the Miniature, Compacted, Tropical (MCT) methodology as non-lateritic clayey (NG'). The main conclusions of the research were: i) the occurrence of reinforcement mechanisms in soils due to inclusions was not observed; ii) geotextiles positioned at H/2 from the top of the specimens exhibited higher CBR values; iii) the CBR test does not reflect the real conditions of soil-geosynthetic systems in the layers of a reinforced road.

RÉSUMÉ: Cette étude présente les résultats d'une série d'essais d'indice de portance Californie (CBR) visant à examiner des échantillons de sol renforcés avec des inclusions de géotextiles tissés et non tissés, positionnés à H/2 et 1/4H du sommet des éprouvettes, compactés aux énergies normales de Proctor. Les échantillons utilisés dans la recherche proviennent d'un sol résiduel d'un profil de sol typique de l'État de Minas Gerais, Brésil, classifié selon la méthodologie Moisture, Compacted, Tropical (MCT) comme argileux non latéritique (NG'). Les principales conclusions de la recherche étaient: i) on n'a pas observé l'occurrence de mécanismes de renforcement dans les sols en raison des inclusions; ii) les géotextiles positionnés à H/2 du sommet des éprouvettes ont montré des valeurs de CBR plus élevées; iii) l'essai CBR ne reflète pas les conditions réelles des systèmes sol-géosynthétiques dans les couches d'une route renforcée.

Keywords: Tropical soil; CBR; geotextile; non-lateritic soil; inclusions.

1 INTRODUCTION

1.1 General considerations

Geosynthetic effectiveness as roads reinforce is strictly related to several factors as subgrade quality, embankment layers composition and thickness, base and subbase, besides the applied load and materials interaction as discussed by Perkins (1999) and Ghosh and Medhav (1994). Support capacity plays as a crucial element for pavements construction and depends on soil features and its compression characteristics.

Santos et al. (1988) declared preference for granular materials as sands and graded crushed rocks due to their potential to increase the California Bearing Ratio (CBR) of the foundation soil.

However, project economic viability may be compromised depending on materials acquisitions and transportation costs, especially when importation is necessary as highlighted by Jotisankasa and Rurgchaisri (2018).

It is usual to use CBR for measurements of soil support capacity. Thus, geotextiles using in non-pavemented roads are recommended when CBR values of the foundation soil are less than 10% aimed to increase subgrade support capacity and to mitigate side effects of erosive processes and wear and tear from road traffic. However, geotextile using in asphaltic pavements news is less common, being economically justified for thick cover layers and/or chemically stabilized bases, where geotextile detain the development and propagation of cracks on the road. These specificities reinforce the importance of comprehensive understanding about choosing and applying geotextiles in road projects.

1.2 Mechanisms occurring while performing CBR tests in reinforced soil tests

Mechanisms involved in the application of CBR tests to reinforced soil samples are fundamental to determining the bearing capacity of these soils. The evaluation may be achieved through load tests in real scale (*in situ*), in laboratory (Nini, 2019), field CBR (Ghosh et al., 2014), CBR laboratory tests using conventional cylinder (Ashik, 2017) or modified (Gor et al., 2013), besides analytic studies or numerical analysis (Ouria and Mahmoudi, 2018). Despite limitations, conventional CBR analysis performed in laboratory, is the most used technique to value roads paved or not, establishing an analogy between the behavior of reinforcements in the test specimen and in the layers of a generic pavement (Mehrpazhouh et al., 2019).

Figure 1 illustrates the behavior of two tests specimen compacted under the piston load of the CBR press. In the absence of reinforce (Figure 1a), load concentration can be observed at the point of application, resulting in major vertical tension to the underbed. In contrast, under the reinforced condition (Figure 1b), it is possible to observe a more balanced distribution of loading to the subgrade as discussed by Giroud et al. (1985) e Love et al. (1987).

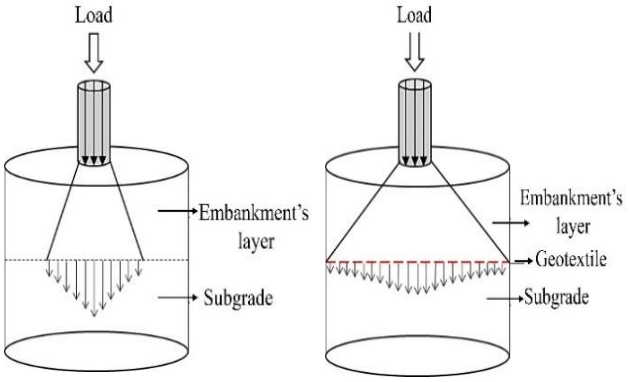

Figure 1. Stress distribution in soil layers within a CBR molded cylinder specimen.

The effects represented in Figure 1, involve in determining spread angle, denoted as β by adopting the trapezoidal model for the extension distribution in the embankment layer. This angle is more pronounced in reinforced structures compared to their unreinforced counterparts. Predictions about the behavior of reinforced soils based on β angle, are susceptible to mechanical properties changes affecting embarkment and underbed materials as discussed by Giroud et al. (1985) e Burd (2006). Burd (2006) observed that the magnitude of spread angle is greater to underbeds composed of soft soils compared to those underbeds composed of more rigid materials.

This research presents the results of CBR tests performed in order to investigate both the influence of different types of geotextiles and the insert position of this materials in the interaction among a tropical soil with non lateritic characteristics and the mentioned geotextiles.

2 MATERIALS AND METHODS

2.1 Materials

The material analyzed is a residual soil with transitioning characteristics among mature and juvenile. It composed by a significative percentage of clay being classified as silty sandy-clay. According to Transportation Research Board (TRB) and Unified Soil Classification System (USCS), is categorized as A-7-5(20) and MH, respectively. According to MCT (Miniature, Compacted, Tropical) methodology (Nogami and Villibor, 1981), it is classified as clay non-latelitic (NG'). In its mineralogy, primary (quartz and ilmenite) and secondary (kaolinite, goethite and hematite) coexist species coexist which reinforces its intermediate alteration feature.

To evaluation the bearing capacity parameters of the reinforced samples, two biaxial woven geotextiles made of polypropylene filaments were used, referenced in this study by the abbreviations T55 and T25, and a nonwoven needle-punched polyester geotextile represented by the abbreviation NT10. The main properties of these materials are presented in Table 1.

Table 1. Properties of geotextiles.

Properties		**T55**	**T25**	**NT10**
Nominal thickness (e), mm		0,93	0,66	1,99
Mass per unit area, g/m^2		244	117	210
Tensile strength, kN/m	longitudinal	55	25	10
	transverse	55	25	9
Deformation at nominal resistance, %	longitudinal	≤ 15	≤ 15	> 50
	transverse	≤ 15	≤ 15	> 50
Apparent opening of pores, O_{90}, mm**		0.20	0,25	0,13

2.2 Methods

In order to determine optimal compactation values (optimum moisture content – $W_{ót}$ and maximum dry apparent specific gravity - $\gamma d_{máx}$) from the studied soil at the standart Proctor correspondent energy, it was adopted procedures provided for the NBR 7182 (ABNT, 2016a).

Under the respective conditions of optimal soil compaction curves, the CBR tests were carried out, following the prescriptions of NBR 9895 (ABNT, 2016b), to obtain the California Bearing Ratio (CBR).

It was used four layers both without inclusions (Figure 2a) and reinforced samples, were compacted in four layers (for geotextile insertion) instead of five layers as NBR prescription, obviously remaining the same total compaction energy used in soils. For Proctor standard energy (560 kN.m/m^3) it was applied 15 coups per layer.

The geotextiles were cut to the diameter of the CBR cylinder (Figure 2) and inserted between compacted layers in two different configurations: after the second compacted layer (Figure 2b), that is, in the middle of the specimen (H/2), and after the third compacted layer (Figure 2c), located at ¼ of the top of the specimen (1/4H).

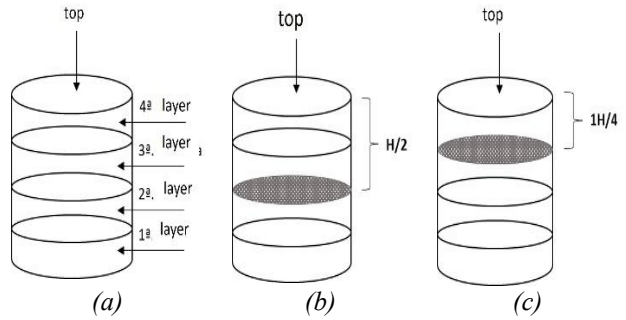

Figure 2. Positioning of the geotextile inside the specimen.

3 RESULTS AND DISCUSSIONS

Standard Proctor values of optimum moisture content ($w_{ót}$) and maximum dry apparent specific gravity were 33,82% e 12,82 kN/m^3, respectively.

Table 2 shows the results for compactation and CBR from the investigated sytems (soil and geotextiles), considering mean, standart deviation (SD) and coefficient of variation (CV).

The results of this research, suggest that geotextiles insertion did not increase CBR soil resistance, regardless of their type and position within the specimens. About reinforce position, changes in the geotextiles place directly affect the CBR values for the soil samples (ANOVA) being the H/2 position, the one in which the highest support capacity results were obtained between reinforced samples.

Figure 3 corresponds to the behavior of the reinforced samples in terms of stress spreading and its relationship with the location of the geotextiles within the specimen. Based on Love (1929) proposals it is estimated that, when the reinforcement material is positioned at half height of the test piece, the load applied by the piston reaches the geotextile in a proportion of approximately 19% (center of the loaded area) (Figure 3a), while, when located at ¼H, the vertical stresses spread with around 52% of the load request (center of the loaded area) (Figure 3b). It is also noted that, as the load approaches the edges of the geotextile, its intensity also decreases.

Table 2. Compactation and CBR results.

System	Geotextile position	Statistics	w (%)	g_d (kN/m^3)	CBR (%)
Soil	-	Média	33,03	12,79	6,33
		SD	0,23	0,10	0,34
		CV (%)	0,71	0,78	5,38
S – T55	H/2	Média	33,33	12,54	5,92
		SD	0,19	0,37	0,44
		CV (%)	0,56	2,93	7,44
	H/4	Média	33,18	12,58	5,71
		SD	0,16	0,20	0,44
		CV (%)	0,48	1,56	7,70
S – T25	H/2	Média	33,77	12,68	6,13
		SD	0,35	0,04	0,17
		CV (%)	1,03	0,30	2,72
	H/4	Média	33,52	12,66	5,20
		SD	0,21	0,24	0,25
		CV (%)	0,61	1,90	4,78
S – NT10	H/2	Média	33,27	12,73	6,03
		SD	0,24	0,14	0,46
		CV (%)	0,73	1,12	7,55
	H/4	Média	33,17	12,75	5,39
		SD	0,16	0,06	0,25
		CV (%)	0,47	0,48	4,56

Based on variance analysis (ANOVA) and on the Tukey test application, for all the soil-reinforce systems evaluated in this research, when the "type of reiforce" variable was not an influence factor, the incorporation of woven blankets was more effective in to increase the soil support capacity than the non-woven geotextile.

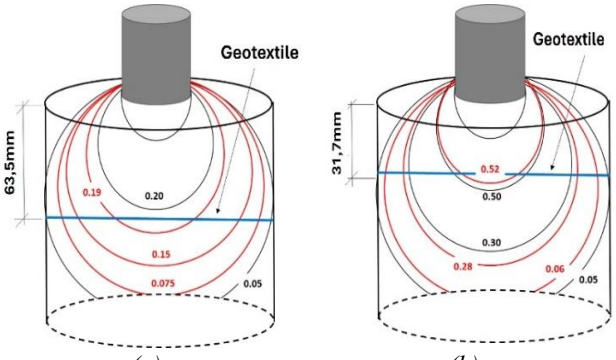

Figure 3. Stress spreading in the reinforced specimen.

The most important structural property of the geotextiles used as road reinforce is their rigidity. Gregory e Bang (1994) concluded that geotextiles fabrics impress a greater rigidity in the layers of a road compared to nonwoven geotextiles specially when underbed CBR is less than 11%.

4 CONCLUSIONS

The conclusions of this study highlight that the insertion of geotextiles, regardless of the type and position within the specimens, did not result in an CBR resistance increase of the soil.

Furthermore, results points that the soil-geotextile systems did not presents the expected support mechanisms, indicating that the CBR test may not be the most appropriate method to evaluate the support capacity of soils with inclusions.

The aforementioned situation can be explained based on Terzaghi (1943) proposition that if foundation pressures the ground, its pressure distributed over a region twice as large as the diameter of the foundation. Similarly, in the CBR test, where a 50 mm scope is used, the thickness distribution area is limited to the mold diameter of 150 mm. This suggests that the confinement of the standard CBR mold does not provide adequate space for the development of reinforcement mechanisms.

ABSTRACT: Enzyme-induced soil enhancement through carbonate precipitation is a widely utilized technique, however it releases ammonium into the atmosphere during the hydrolysis reaction. This paper introduces a novel and environmentally friendly sustainable method called Enzyme Induced Calcium Phosphate Precipitation (EICPP) for soil improvement, which can address the ammonium emission problem. The EICPP method involves the application of enzymes to facilitate the hydrolysis reaction of urea, resulting in the precipitation of Calcium Phosphate Compounds (CPCs). To ensure sustainability, this method incorporates tuna fish bones, which are typically considered food waste from the industry, can be repurposed to provide valuable source of calcium and phosphorus. By utilizing this readily available and renewable resource, EICPP reduces waste generation and promotes circularity within the food industry, aligning with Sustainable Development Goals (SDGs). Various analyses, including Unconfined Compressive Strength (UCS), X-ray Powder Diffraction (XRD), Scanning Electron Microscopy (SEM), SEM with Energy Dispersive X-ray Spectroscopy (SEM-EDS) were conducted to assess the effectiveness of EICPP for binding samples and examine the characteristics and composition of the precipitates. Different calcium/urea ratios were examined to determine the optimal ratio for the best outcome. The results reveal the presence of brushite with needle-like crystals in the improved samples of Toyoura sand, demonstrating the successful implementation of EICPP for strengthening silicate soil. EICPP method offers a promising solution for soil enhancement while mitigating the ammonium emission problem associated with traditional techniques. By repurposing tuna fish bones, this approach demonstrates the potential for sustainable resource utilization and supports the achievement of SDGs.

RÉSUMÉ: L'amélioration des sols par la précipitation enzymatique de carbonate est une technique couramment utilisée, cependant elle libère de l'ammonium dans l´atmosphère pendant la réaction d´hydrolyse. Cette publication présente l'approche Enzyme Induced Calcium Phosphate Precipitation (EICPP), une méthode éco-innovante pour l´amélioration des sols, répondant au problème d´émission d´ammonium. La méthode EICPP résout le problème d'émission d'ammonium en facilitant la réaction d'hydrolyse de l'urée par des enzymes, conduisant à la précipitation de Composés de Phosphate de Calcium (CPC). Pour assurer sa durabilité, cette méthode inclut l´utilisation d´arêtes de thon, qui sont considérées comme des déchets alimentaires classiques de l'industrie, offrant une source précieuse de calcium et de phosphore. En utilisant cette ressource disponible et renouvelable, l'EICPP réduit la production de déchets et promeut la circularité dans l'industrie alimentaire, en adéquation avec les Objectifs de Développement Durable (ODD). Des analyses diverses utilisant les méthodes RCNC, DRX, MEB, et MEB-EDS ont été menées pour évaluer l'efficacité de l'EICPP à lier les échantillons et examiner les caractéristiques et la composition des précipités. Différents rapports calcium/urée ont été examinés afin de déterminer le rapport optimal pour l'obtention du meilleur résultat possible. Les résultats montrent la présence de brushite sous forme de cristaux en forme d´aiguille dans les échantillons améliorés de sable de Toyoura, démontrant le succès de l'EICPP pour renforcer les sols silicatés. La méthode EICPP offre une solution prometteuse pour l´amélioration des sols tout en atténuant les émissions d'ammonium liées aux techniques traditionnelles.

Keywords: Soil improvement; calcium phosphate compounds (CPCs); enzyme induced calcium phosphate precipitation (EICPP); brushite; tuna fish bones.

1 INTRODUCTION

Soil enhancement techniques play a crucial role in modern construction sector, ensuring the stability and possibility of using those soils for further construction works. Among most widely utilized ecofriendly methods for improving soil, the use of enzymes to induce carbonate precipitation in soil, namely Ureolytic Induced Calcite Precipitation (UICP), has proven effectiveness and sustainability (Saif et al., 2022; Fu et al., 2023). These techniques apply urease for precipitation of calcite which binds soil particles and improve properties of material. However, UICP comes with an environmental concern. The hydrolysis reaction in this process results in the release of ammonia into the atmosphere, and ammonium into ground environment contributing to ecosystem disruption. In response to this issue, a novel and environmentally friendly approach known as Enzyme Induced Calcium Phosphate Precipitation (EICPP) for soil improvement were introduced.

The EICPP method, similar to UICP, employing enzymes to facilitate the hydrolysis reaction of urea, leading to the precipitation of Calcium Phosphate Compounds (CPCs), unlike Calcite in UICP. CPCs are inorganic substances mainly composed of calcium, phosphorus, and oxygen. They are commonly found in living organisms, primarily in the form of bones and teeth. CPCs exhibit solubility in acids while being insoluble in alkaline environments and its precipitation requires lower pH of environment to be solidified, therefore less ammonia will be released into the atmosphere (Prajapati, 2014; Dorozhkin, 2016).

This study investigates the improvement of fine sand quality by applying EICPP, introducing new method by exploring its practical application and environmental impact. In addition to its effectiveness in improving soil, the EICPP in this study utilizes tuna bones, a resource commonly considered food waste in industry, turning it into valuable components for soil improvement. In this way, EICPP not only offers a sustainable and environmentally conscious alternative, but also actively promotes circularity in the food industry, which is aligned with the main SDGs.

During the experiments, pH values were monitored daily to better understand ammonia and ammonium pollution in the atmosphere and ground environment, aiming to demonstrate the eco-friendliness of this method. Moreover, UCS, SEM, SEM-EDS and XRD practices were used to investigate in more detail binding soil samples. To ensure efficiency, different calcium/urea ratios were applied to determine the most favourable conditions for achieving the desired results.

2 MATERIALS AND METHODS

2.1 Sand

The present study is based on commercially available sand supplied by Toyoura Keiseki Kogyo Co., Ltd. Japan. This sand was checked for particle size distribution and was classified as poorly graded sand (ASTM D2487-17, 2020).

2.2 Fish bone meal and chemical reagents

To successfully precipitate CPCs, it is necessary to obtain a supply of calcium (Ca) and phosphate (P) ions. In this research, Tuna fish bones sourced from a local fish company were selected for this purpose.

The process of extracting Ca and P ions from the fish bones involved several steps. First, the fish was cleaned, removing fillet and skin parts. Then, it underwent a treatment process that included crushing and the removal of organic matter using a 2% NaOH solution at a ratio of 1:3 (w/v), followed by boiling for 30 minutes. After this treatment, the fish bones were filtered and dried. Subsequently, the dried fish bones were ground into a powder and completely dissolved in a 1% HCl solution at a ratio of 1:2.4 (w/v). The dissolution process was carried out by stirring for 60 minutes at 1000 rpm and resulting dissolved filtrate was used as part of the treatment solution for the study.

Furthermore, acid urease and urea, both essential components for current research, were sourced from Nagase & Co., Ltd. and Wako Pure Chemical Industries, Ltd., respectively, based in Japan.

2.3 Solidification test

Six 30 ml syringes were filled with Toyoura sand, and each was injected with 10 ml of a treatment solution containing fish bone solution with a Ca^{2+} ion concentration of 10,000 ppm and pH 2.7-3.3. The treatment solution was prepared based on fish bone meal, 2g/l of acid urease, and urea, with varying Ca^{2+}/Urea concentration ratios in samples 1 to 6, specifically: 0.15, 0.25, 0.5, 1.0, 2.0, and the last sample without the addition of urea. Samples were placed in a 25°C incubator, and the injections were performed daily for 21 days. The samples were prepared with three replicates, and the reported results represent the average values.

Upon the completion of the treatment period, the sand samples were thoroughly rinsed with water, dried in an oven maintained at 60°C, and subsequently subjected to UCS testing. Additionally, the samples underwent SEM, SEM-EDS, and XRD analyses.

Figure 1 illustrates the syringe solidification test model.

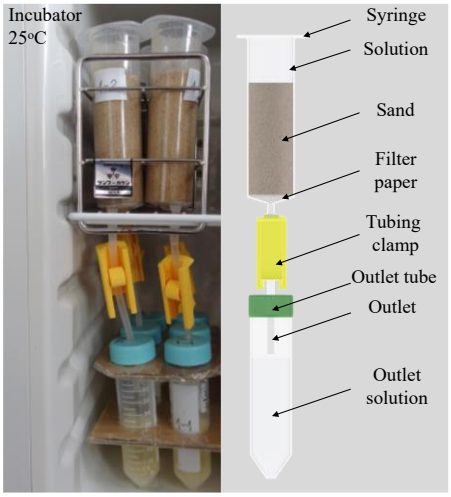

Figure 1. Visualisation of syringe solidification test model.

2.4 Measurements

The pH measurements were conducted using a pen-type pH meter, pH5S, manufactured by CEM Corporation in Tokyo, Japan. The UCS of the specimens was determined using a needle penetration test apparatus, SH-70, from Maruto Testing Machine Company in Tokyo, Japan. SEM and SEM-EDS analyses were performed using a JSM-IT200 Scanning Electron Microscope, manufactured by JEOL Ltd. in Tokyo, Japan. The microscope operated at an accelerating voltage of 15kV, and each sample was preliminarily coated with gold using a Sputter Coater DII-29010SCTR Smart Coater for 2 minutes. For the analysis of mineralogical composition, XRD was carried out using a MultiFlex X-ray diffractometer from Rigaku Corporation in Tokyo, Japan. The diffractometer utilized a Cu K-alpha source and operated at a scan rate of 6.5 degrees per minute, with a diffraction angle (2θ) ranging from 5 degrees to 70 degrees. The precipitation content was determined by calculating the percentage of dry weight loss after dissolving 1 g of the treated sample in 5 ml of 1% HCl solution.

3 RESULTS AND DISSCUSSION

3.1 Observation during treatment

Figure 2 shows treated samples after 21 days of EICPP with illustration of position of measuring UCS. Each sample solidified successfully, except for sample 6, without the addition of urea. The samples showed strong consolidation results with more precipitate on the top and less on the bottom. During treatment period samples 1 to 5 were showing pH in the range of pH 7-8.39. Sample 2 reached the highest pH 8.39 and sample 5 – lowest, 7.57.

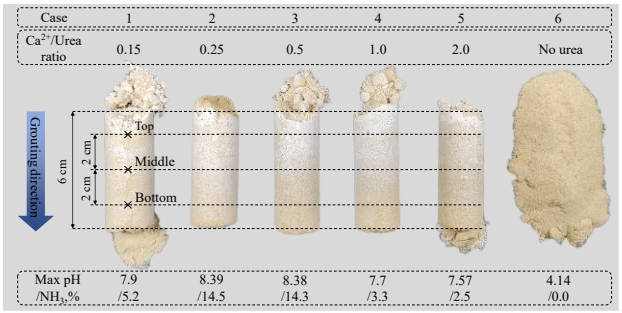

Figure 2. Illustration of the samples after treatment.

Based on the ammonium-ammonia conversion dependency (Prajapati, 2014), the maximum conversion rate to ammonia during the solidification of sample 2 and 5 was 14.5% and 2.5%, respectively. During conventional EICP pH increasing to the value pH 9 (Saif et al., 2022) resulting in converting 41.17% of ammonium into ammonia and uncontrollable pollution of atmosphere.

3.2 UCS and precipitation content

The mechanical properties were evaluated by conducting UCS tests, and the precipitation content was checked in experimental case samples. The results of these evaluations are shown in Figure 3.

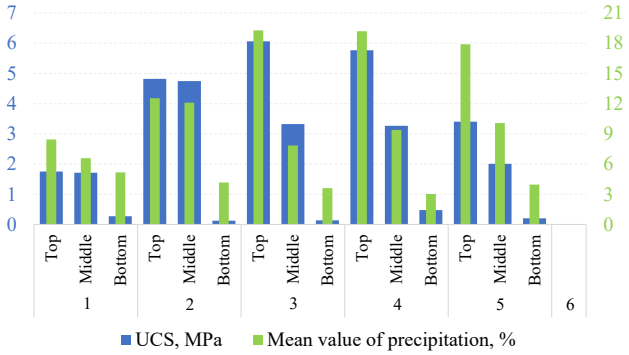

Figure 3. UCS results (blue bar, scale on the left) and precipitation content (green bar, scale on the right) of samples.

UCS results confirm the observations shown in Figure 2, indicating that a significant portion of the precipitation is concentrated in the upper and middle layers of the specimens, resulting in elevated values for both the UCS and the precipitation content. It is worth noting that specimen 3 showed the most remarkable results in terms of UCS and precipitation content, recording 6.05 and 19.27 % of CPCs precipitation in the top layer, respectively.

3.3 SEM and SEM-EDS

To further investigate the binding properties of the soil samples, SEM and SEM-EDS analysis were

performed and the results are shown in Figure 4. All samples showed inter-particle bonds, as well as a visible coating layer of sediment, except for sample 6 (without urea). SEM images were obtained from the middle of each sample, and SEM-EDS data showing sample 4.

In most cases, the needle-like crystals were observed approximately 100 nm in length. However, in case 5 a flower-shaped crystal was found. The SEM-EDS analysis showed the precipitates mainly covered the grains of sand and contained calcium and phosphorus, indicating the potential formation of CPCs.

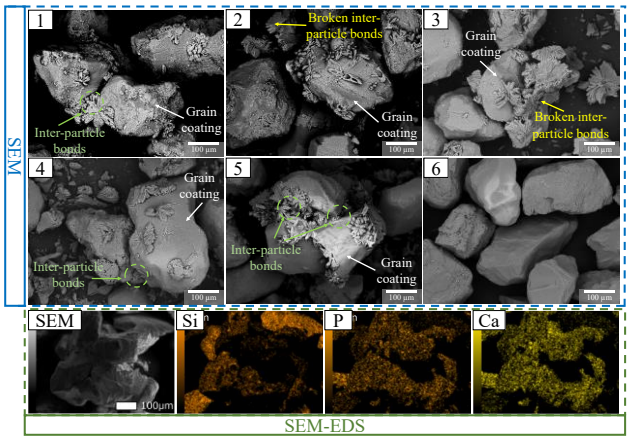

Figure 4. SEM images (blue rectangle) of samples 1 to 6 and SEM-EDS (green rectangle) results for sample 4.

3.4 XRD

The XRD results are shown in Figure 5, where clear peaks corresponding to brushite are observed in samples 2-5. In contrast, in case 1, there are only peaks associated with quartz and microcline, which are derived from sand, with no obvious brushite peaks.

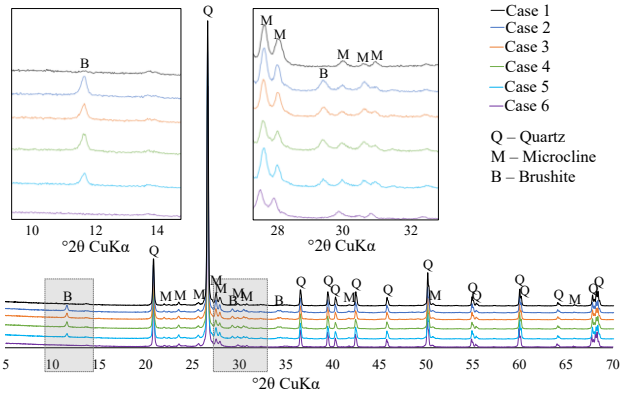

Figure 5. XRD analysis of samples 1 to 6.

Brushite, a member of the CPCs family, is known to precipitate easily in aqueous solutions in the pH range from 2 to 6. The formation of CPCs is strongly dependent on the pH and the Ca/P ratio in the medium. Taking into account the solubility characteristics of CPCs and their relationship with pH, brushite appears to be the most easily precipitated compound in the pH range mentioned above, which is confirmed by XRD analysis of the samples (Dorozhkin, 2016).

4 CONCLUSIONS

This study demonstrates the effectiveness and sustainability of EICPP for geotechnical applications involving fine sand. The improved sand exhibited strength, with UCS reaching 6 MPa, surpassing superior to conventional UICP while significantly reducing ammonia emissions to 3%.

Tuna fish bones, often discarded as food waste, proved to be an abundant source of calcium and phosphorus ions, addressing SDG challenges by repurposing these resources.

From a geotechnical point of view, it was determined that the most suitable calcium to urea ratios for soil improvement were 0.5 and 1.0 (samples 3 and 4). However, from an environmental point of view, maintaining a lower pH range is vital to ensure the method is environmentally friendly. The most optimal ratios were 1.0 and 2.0 (samples 4 and 5), which resulted in minimal ammonia emissions to the atmosphere - 3.3% and 2.5%.

Activating decarbonisation in the piling supply chain

Activer la décarbonation dans la chaîne d'approvisionnement des pieux

C.A. Barker*

J. Ly
Canary Wharf Group, London, United Kingdom

**chris.barker@arup.com*

ABSTRACT: Strategies to reduce embodied carbon for new developments have to date mostly been focused on the carbon emissions hierarchy of Build Nothing, Build Less, Build Clever and Build Efficiently from a developer/designer perspective. For some projects this approach can deliver significant reductions. However, for the many other projects, carbon reductions (if any) have been far more limited, and procurement processes have often not actively driven innovation for reduction of carbon. With a goal of reducing embodied carbon for all new developments at Canary Wharf, the role of carbon reduction within the piling supply chain was defined in the procurement approach. To actively decarbonise the piling contractor supply chain, direct engagement with piling contractors was done to measure and report embodied carbon consumption against a project target during construction. This paper shares the details of this carbon reduction supply chain engagement.

RÉSUMÉ: Jusqu'à présent, les stratégies visant à réduire le carbone incorporé pour les nouveaux développements se sont principalement concentrées sur la hiérarchie des émissions de carbone: Build Nothing, Build Less, Build Clever et Build Efficiently du point de vue du développeur/concepteur. Pour certains projets, cette approche peut entraîner des réductions significatives. Cependant, pour de nombreux autres projets, les réductions de carbone (le cas échéant) ont été bien plus limitées, et les processus d'approvisionnement n'ont souvent pas activement stimulé l'innovation en matière de réduction des émissions de carbone. Dans le but de réduire le carbone incorporé pour tous les nouveaux développements à Canary Wharf, le rôle de la réduction du carbone au sein de la chaîne d'approvisionnement des pieux a été défini dans l'approche d'approvisionnement. Pour décarboner activement la chaîne d'approvisionnement des entrepreneurs en battage, un engagement direct avec les entrepreneurs en battage a été réalisé pour mesurer et rapporter la consommation de carbone incorporé par rapport à un objectif du projet pendant la construction. Ce document partage les détails de cet engagement dans la chaîne d'approvisionnement en matière de réduction des émissions de carbone.

Keywords: Carbon; decarbonisation; sustainability; piles; construction.

1 INTRODUCTION

For many companies, supply chain-related emissions are their largest source of carbon emissions, and being outside their direct control, are the most challenging to reduce. Activating decarbonisation through supply chains is one of the most critical and effective pathways to reach net-zero (CDP, 2023).

However, with limited visibility and perceptions of limited influence on emission reduction measures, it can be challenging for many companies to bring the required change to their supply chain. Supplier engagement targets offer a way to influence decarbonization efforts within companies' supply chain when emissions data is challenging to track or unavailable.

Canary Wharf is forty hectares of land being progressively developed since the late 1980s on the site of the former West India Docks in East London, United Kingdom. It is the largest urban regeneration project in Europe containing commercial, retail and residential developments with many high-rise buildings and large basements.

In December 2020, Canary Wharf Group published its Net Zero Carbon Pathway, outlining its pathway for achieving net zero. A key aspect of the Pathway for new developments was supporting their supply chain in reducing carbon emissions and achieving their Science Based Targets.

This paper presents details of how the Pathway was implemented for the design, procurement and construction of new piled foundations for five new build projects.

2 DESIGN APPROACH

The five Canary Wharf projects presented in this paper are developments within a larger phased development. Foundation option selection process had determined piled foundations as the most suitable foundation solution. The subsequent carbon reduction approach during the design stages was one of reduction i.e. material selection and reducing material volumes. The principal ways this was achieved was through adopting lower partial factors in design permitted with preliminary and working pile load tests, which is further discussed in (Taggart and Barker, 2022) and by developing an efficient pile layout. This was achieved through maximising individual pile capacities within the capability of the piling industry while optimising the foundation layout through a geotechnical-structural iteration process to reduce the number of piles.

The scope of piling works was procured as contractor designed and for each of the five projects were:

Project A: comprised 500 No. 900mm and 1050mm diameter continuous flight auger (CFA) bearing piles with a typical pile length of 28m.

Project B: comprised 210 linear metres of 1200mm diameter hard-firm secant wall and 75 linear metres of 15m deep sheet pile wall and 7 No. 1500mm and 1800mm diameter rotary bearing piles with a typical length of 35m.

Project C: comprised 150 linear metres of anchored sheet piled dock wall and temporary cofferdam and capping beam with 26 No. 900mm diameter CFA anchor piles and 90 linear metres of 20m long 1200mm diameter hard-firm secant pile wall.

Project D: 300 No. 900mm diameter CFA bearing piles and 50 No. 900mm to 1800mm diameter marine piles.

Project E: comprised 120 No. 750mm CFA bearing piles typically 30m long, 80 No. 1050mm CFA bearing piles typically 32m long and 17 No. 1300mm rotary bearing piles with a typical length of 35m.

3 SUPPLY CHAIN ENGAGEMENT

With a goal of reducing embodied carbon in these new developments the role of embodied carbon was defined within the piling supply chain through the procurement process. Procurement, as shown in Figure 1, was historically on cost, quality and programme but for these projects embodied carbon was also now included.

To decarbonise the piling contractor supply chain, it was recognised that direct engagement with typically Tier 2 piling contractors was needed to calculate, measure and report embodied carbon consumption against a project target through the project delivery process, as shown in Figure 2.

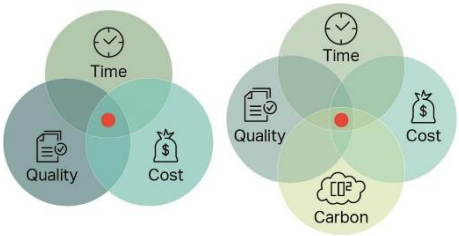

Figure 1. Historical and revised procurement values.

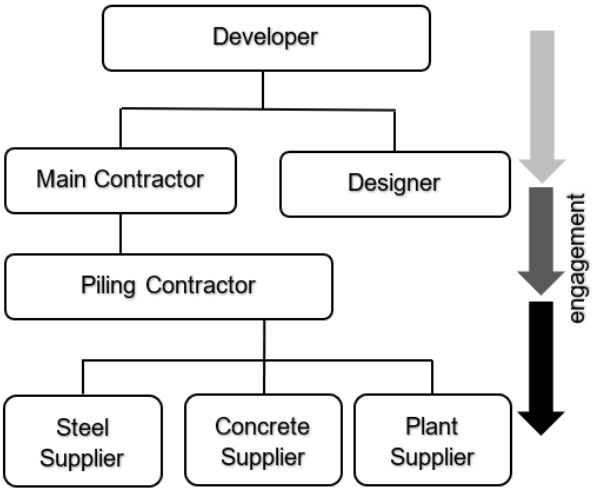

Figure 2. Supply chain engagement.

4 TENDER SPECIFICATION

To frame this approach new specification clauses were needed in the project piling specification. The two pages of new specification text (Barker, 2023) provide an aspirational embodied carbon target and requires all tendering piling contractors to use the free EFFC/DFI Carbon Calculator (EFFC and DFI, 2023) to estimate the embodied carbon in their tender design submissions. Concrete mix designs and any proposals for further embodied carbon reductions were also to be provided at tender. For the successful contractor, independently verified Environmental Product Declarations (EPD) were required for their construction materials and recalculating the estimated embodied carbon for their construction issue design was undertaken. Weekly reporting of embodied carbon consumption is provided by the contractor during construction. Also, at the end of construction, an as-built report is provided totalling the A1-A5 life cycle assessment modules (product and construction process stages) including waste emissions.

Table 1. Tender stage estimated embodied carbon (tCO2e).

	Project A	Project B	Project C	Project D	Project E
Target	*3000*	*2200*	*2600*	*4000*	*2160*
Contractor 1	2900	3300	3200	3300	2000
Contractor 2	3800	1300	-	3700	3800
Contractor 3	5800	1500	-	-	2400
Contractor 4	2500	-	-	-	2380
Contractor 5	-	-	-	-	2600

An EPD provides the independently verified carbon footprint of a product, e.g., concrete, diesel and steel reinforcement, in terms of Global Warming Potential (GWP) as measurable carbon dioxide equivalents (CO2e).

The calculation of embodied carbon consumption is easily undertaken during construction. Contractors are already routinely recording and reporting material volumes and resources. So, multiplying these quantities by a carbon factor is quite simple.

Table 1 presents the five separate contractor designed piling projects. The target embodied carbon was calculated and provided in the tender specification as an aspirational target assuming what a typical piling contractor was previously offering at tender. The remaining numbers are the calculated embodied carbon in contractor's tender returns. The piling industry's EFFC/DFI carbon calculator was specified as it was free, simple, easy to use and provided a common calculation method for all tenderers creating an equal tendering basis.

On the first project the range of estimates was quite large with a subsequent general trend of estimates reducing and the tender range narrowing.

5 CONSTRUCTION

Contractors were encouraged to engage with their suppliers to source low carbon materials and equipment. To drive beneficial changes in the supply chain, third party certified EPD carbon factors were preferred over published generic tables.

So as to not overburden construction administration, the weekly reporting format of carbon consumption during construction was decided by each contractor to best fit in with their established commercial monitoring processes. Typically, tables and plots were simply produced in Excel.

The principal areas of embodied carbon reduction are discussed below.

5.1 Concrete

Concrete is typically the most significant source of embodied carbon in piling. Typical piling tenders allow CEMIII/A with 40 - 50% GGBS (ground granulated blast furnace slag) cement replacement in piling concrete (210 kgCO2e/m^3). However, contractors can supply CEMIII/B piling concrete up to 70 - 80% GGBS cement replacement (163 kgCO2e/m^3). In unreinforced secant piles CEMIII/C can increase up to 95% GGBS cement replacement (49 kgCO2e/m^3).

While GGBS is an excellent supplementary cementitious material that helps displace clinker demand globally, it is a limited and constrained resource that is almost fully utilised globally. Therefore, whilst global supplies must continue to be fully utilised, locally increasing GGBS use at a project level is unlikely to decrease global emissions (Arnold *et al*, 2023).

Significant 52% carbon reduction shown in Table 2 were achieved in the secant wall on Project B, in part, through the use of high levels of GGBS in concrete mixes. This demonstrated the potential magnitude for carbon reductions in the future using new novel low carbon concrete mixes.

Tracking and reporting carbon consumption during CFA pile construction highlighted a +512 tCO2e increase over the target on Project A, the consequences, in part, of increased concrete wastage resulting from frequent concrete delivery delays.

5.2 Reinforcement cages

Suppliers of pile reinforcement source stock from steel mills both in the United Kingdom and the Europe Union and usually with high levels of recycled steel (>95%) which reduces carbon emissions. However, this may not always be the case, as on one project with two reinforcement suppliers their EPD showed significantly different values of 730 kgCO2e/t and 1100 kgCO2e/t steel. Adopting the circular economy principles in steel reuse is crucial.

5.3 Steel sheet piles

The introduction of an embodied carbon target in the Project C piling specification resulting in a tendering contractor to offer a 815 tCO2e saving by adopting 100% recycled steel sheet piles manufactured in an electric arc furnace (520 kgCO2e/tonne), for a cofferdam and new dock wall instead of more

Table 2. Measured as-built embodied carbon totals (tCO2e).

	Project A	Project B	Project C	Project D	Project E
Target	3000	2200	2600	4000	2160
Tender	2500	1300	3200	3300	2000
As-built	3512	1060	1400	tbc	tbc
Δ from target	+17%	-52%	-46%	tbc	tbc

typically procured steel sheet piles being source from blast furnace steel (2164 kgCO2e/tonne).

5.4 Fuel

A piling project at Canary Wharf (rigs, cranes, excavators, generators, pumps) can typically consume 80,000 to 150,000 litres of diesel (215 to 400 tCO2e).

Since 2012, Canary Wharf Group supply the estate and construction sites with certified renewable electricity being sourced from a mix of wind, thermal, solar and hydro. This enables the tendering process to engage contractors in transitioning piling plant and equipment from diesel fuel (2.68 kgCO2e/litre) to HVO biofuel (0.68 kgCO2e/litre) to renewable electricity (0 kgCO2e/kWh) or hydrogen.

5.5 Plant

Several of the projects have also achieved carbon reductions using electric crawler cranes, pumps and for site office power, HVO biofuel for plant as well as trialling electric piling plant. Contractors make significant capital investments in piling plant and the transition does benefit from active support in project procurement.

6 SUMMARY

Table 2 shows the five projects again but with the measured as-built embodied carbon total and difference from target. Projects D and E are still currently on site. The materials, fuel and plant carbon reductions achieved on Projects B and C illustrate what can be achieved from current 'normal' practice. The additional carbon consumed in Project A illustrates the significant additional carbon that can occur from concrete delivery delays.

7 CONCLUSIONS

Substantial embodied carbon reductions can be realised using currently available materials and methodologies and using the free the EFFC/DFI carbon calculator tool.

Activating decarbonisation in the piling supply chain can be readily achieved by specifying project embodied carbon targets for procurement followed by measuring and reporting embodied carbon consumption during construction. Such target setting is the step the industry now needs to take having identified baseline emissions and emission hotspots. Measuring and reporting data at a project level engages the whole supply chain: developer-consultant-contractor-suppliers and enables learning and continuous project improvements to be made by all parties.

Incorporating embodied carbon into the procurement and construction processes initiates a new level of engagement and learning for all parties. This is essential to drive change to enable the piling industry to capitalise on the coming opportunities in lower carbon materials and methodologies for a low carbon future.

Use of the Brazilian test and frost sensitivity test for determining the aptitude for earthworks of difficult soils stabilized by special lime-based binder

Utilisation de l'essai Brésilien et de l'essai de sensibilité au gel pour déterminer l'aptitude à utiliser des sols difficiles traités par liant à base de chaux pour les terrassements

L. Batali*, G. Andrieş

**loretta.batali@utcb.ro*

ABSTRACT: Strength, durability and stability of earthworks during service depend on the quality of soils they are made of, the execution technology and maintenance. Often, earthworks have to be built using poor quality soils that needs improvement or stabilization by using binders. For establishing the modifications brought by binder mixing and the long-term characteristics of the improved materials, laboratory tests are used, many of them being adapted, as the resulting material is sometimes away of the untreated soil properties. Therefore, research is still conducted for determining the best way of testing the properties of improved soils, especially considering the extensive use nowadays of these techniques. The paper, which continues a series of articles published on the subject, will determine the degree of sensitivity to frost in comparison with the durability performances to freeze – thaw cycles. The research studied the performances during time of a clay treated by special lime – based binder (3 and 4 %) by analysing the mechanical and frost sensitivity behaviour. Sample to be tested where produced in laboratory using 2 compaction energies – normal and modified Proctor. The mechanical behaviour during the time was studied by determining the compression strength and the indirect tensile strength (Brazilian test), while the frost sensitivity was established based on the swelling coefficient and the consistency state of the soil after freezing.

RÉSUMÉ: La résistance, la durabilité et la stabilité des ouvrages de terrassement en service dépend de la qualité des sols mis en œuvre, de la technologie d'exécution et de l'entretien. Souvent les terrassements doivent être construits avec des sols de mauvaise qualité qui doivent être traités, généralement avec des liants. Pour déterminer les modifications apportées par le traitement et les caractéristiques à long terme obtenues on utilise des essais de laboratoire adaptés, puisque le matériau résultant est souvent loin du matériau initial. Des recherches sont encore menées pour déterminer la meilleure méthode d'essai pour les sols traités, spécialement si on prend en compte leurs utilisation intensive de nos jours. L'article, qui continue une série de papiers publiés sur ce sujet, étudie le degré de sensibilité au gel par comparaison avec la durabilité au gel – dégel. La recherche a porté sur les performances à long terme d'une argile traitée par un liant à base de chaux (3 et 4%) en analysant le comportement mécanique et la sensibilité au gel. Les éprouvettes ont été produites en laboratoire en utilisant 2 énergies de compactage – Proctor normal et modifié. Le comportement mécanique a été étudié en déterminant la résistance en compression et la résistance à la traction indirecte (essai Brésilien), alors que la sensibilité au gel a été établie sur la base du coefficient de gonflement et l'état de consistance du sol après le gel.

Keywords: Lime; stabilization; clay; laboratory tests.

1 INTRODUCTION

Strength, durability and stability of earthworks during service depend on the quality of soils they are made of, the execution technology and maintenance. Often, earthworks have to be built using poor quality soils, not meeting the technical requirements in terms of quality and bearing capacity, that needs improvement or stabilization by using binders.

The paper is dealing with the performances of clayey soils after improving by using a lime-based binder and their study in the laboratory. It is part of a series of papers of this subject, all developed in the framework of the PhD thesis of PhD student Gabriela

Andrieș. The first results have been published at the ECSMGE 2019 (Batali et al, 2019), showing the performances for 3 admixtures (3%, 3.5% and 4% of lime-based special hydraulic binder) of a fat clay, after modified Proctor compaction. This paper showed the results of laboratory and in situ tests in terms of physical and mechanical properties, after 3, 7, 14 and 28 days of curing and the results of durability tests (stability to water and freeze-thaw cycles). The obtained results emphasized the modifications that the binder produced on the clay, due to changes in the intimate structure of the soil. The study also allowed the assessment of various working procedures for some of the laboratory tests, according to European and Romanian standards. In 2021 was published a second paper at the 20ICSMGE (Batali & Andrieș, 2021) which approaches the study of the behavior during time of a test field for a road embankment, with the same fat clay as previously, stabilized with special lime-based hydraulic binder (3% and 4%). The paper studied mainly the influence of the compaction energy on the physical, mechanical and durability properties. Also, various curing times have been tested, up to 60 days. As well, a mineralogical analysis was performed to assess the modifications in the clay structure.

The present paper is analysing how the lime-based binder treatment of active clays used for the active area of road earthworks is improving the following:

- the sensitivity to freezing by assessing the freezing swelling coefficient and the consistency index after thawing;
- the freeze / thaw behaviour by assessing the indirect tensile test (the Brazilian test).

2 FUNDAMENTAL PRINCIPLES

Water content and temperature variations lead to modifications of earthworks bearing capacity, therefore influencing the strength and stability of the road structure. To prevent degradation of earthworks due to freeze / thaw cycles measures have to be taken, often these being based on soil treatment by mixing it with hydraulic binders. Lime or lime-based binders are modifying the intimate structure of the clay: change of the texture, loss of water and mass for some minerals and apparition of a new phase in the clay being previously reported (Batali & Andries, 2021), changes which are leading to an increased durability.

Especially for the soils used in the active zone of the earthworks it is required to determine the sensitivity to freeze/thaw and based on this to establish the corresponding measures to be taken.

There is no unique European practice for testing stabilised cohesive soils for freeze/thaw, EN 16907-4 referring to local practices. Our experimental program was, among others, aimed to test various procedures, standardized or not, inspired by procedures for stabilised aggregates and trying to simulate as much as possible the real behaviour in site conditions.

3 MATERIALS AND METHODS

3.1 Materials

The experimental plot for which the experimental program has been carried out is a road to be built on a ground composed of a fat, black clay, with 51% clay fraction (< 2 μ), 42% silt and 7 % sand, with 2% organic matter, very high free swell (120 %), very high plasticity (PI = 40 %) and also very high swelling pressure (190 kPa). It was therefore decided to stabilize the clay using mixing with a high lime-content hydraulic road binder, with a total amount of CaO+MgO higher than 60%, having also a cement content in order to increase the bearing capacity at short term. The complete description of the clay and the laboratory experimental program, including the compaction parameters for normal and modified Proctor compaction energies can be found in (Batali et al, 2019; Batali & Andrieș, 2021).

Two admixtures were studied for the present paper, meaning the clay mixed with 3% and 4 % special lime-based road binder, for which were determined the physical and mechanical characteristics, as well as the durability ones.

3.2 Methods

For the assessment of the sensitivity to freezing were used the freezing swelling coefficient and the consistency index after thawing. For the determination of these indices was used the procedure described in the Romanian standard STAS 1709/2 and 3-90 which specifically applies to road works. The freezing swelling coefficient, C_u is calculated as the percentage ratio between the additional height of the compacted sample after freezing (Δh) and the frost penetration depth in the sample (Z). The temperature at the upper surface of the sample should be -8° for 7 days, while the temperature is positive on the other end of the sample. The consistency index (I_c) after thawing is calculated using the water content of the soil in the frozen area of the sample. Based on the values of these 2 indices the soil can be classified as insensitive (C_u <2 and I_c >0.75), sensitive (2<C_u<8 and 0.5<I_c<0.75) or very sensitive (C_u>8 and I_c<0.5).

The indirect tensile strength, R_{it} has been assessed according to the Belgian Code CRR (2010) and Technical guide LCPC SETRA in France (2000). This

value allows to verify the freezing resistance of stabilised materials, being imposed to have a minimum R_{it} of 0.25 MPa for compacted samples at the age corresponding to freeze apparition.

4 EXPERIMENTAL RESULTS

4.1 Freeze sensitivity

The results obtained in terms of freezing swelling coefficient (C_u) are shown Figure 1 for untreated soil and the 2 studied admixtures (3% and 4% lime-based special binder), for samples compacted at 98% of the optimum standard and modified Proctor (noted PN and PM, respectively).

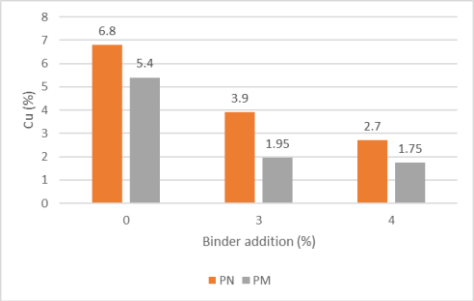

Figure 1. Freezing swelling coefficient vs binder addition.

For the analysed soil only samples compacted at modified Proctor had C_u values less than 2%, meaning insensitive to freezing. It can be seen that for modified Proctor compaction energy the C_u values are less than for standard Proctor, meaning that a stronger compaction brings less sensitivity to freezing. Also, the freezing swelling coefficient decreased by 42% for 3% addition and by 60% for 4% addition, compared to the untreated soil, for standard Proctor energy. In case of the modified Proctor energy, the reduction of C_u was of 64% for 3% addition and 74% for 4% addition. The decrease of the freezing swelling coefficient from 6.8% to 1.75% shows the attenuation of the clay activity when treated with lime-based binders, which reduces the swelling potential and increases the resistance to freeze/thaw.

In terms of consistency index after thaw, the results are shown Figure 2 and it can be observed that the values increased from 0.55 for the untreated clay to 0.66 and 0.71 for standard Proctor and from 0.62 % to 0.78% and 0.85 % for modified Proctor, for 3% and 4% binder addition, respectively. Also from this point of view the treated samples compacted at modified Proctor energy are insensitive to freezing, while all the others are classified as sensitive.

Although the treated samples compacted at standard Proctor energy are classified as being sensitive to freezing, in comparison with the untreated clay they are maintaining a high consistency after 7 days of freezing, increasing from 0.55 – 0.60 to more than 0.75 as the binder addition is increasing.

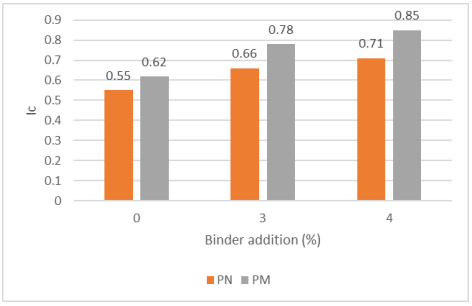

Figure 2. Consistency index after thawing vs binder addition.

The untreated samples exhibited destructuration and fissures after exposure to freezing (Figure 3a), while the treated samples remained compact, with no fissures (Figure 3b).

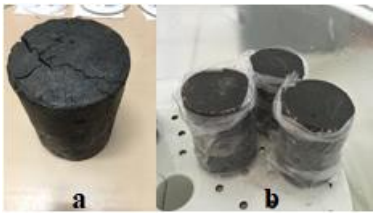

Figure 3. Samples after exposure to freezing.

4.2 Indirect tensile strength

The indirect tensile strength has been determined on samples of untreated clay (only for standard Proctor compaction) and treated clay with 3% and 4% lime-based binder addition, compacted at 98% of the optimum Proctor (standard and modified), at the optimum water content or at the optimum water content +2%. The test procedure was according to EN 13286-42, the samples being tested at 28 days of age, after being cured in the climatic chamber at 20°C and 95% humidity. All experimental values are shown Table 1.

Samples compacted at higher energy had indirect tensile strength values higher than 0.25 MPa, which is the criterion imposed in Belgium and France for freezing resistance. As well, it has been noted that increasing the compaction water content by 2% is not significantly influencing the results. In case of 4% addition and modified Proctor compaction energy there is a decrease from 0.32 MPa to 0.26 MPa, but in this case the value is satisfactory, remaining higher than 0.25 MPa. At least for this case it can be concluded that in-situ treatment with lime-base binders is ensuring the mechanical and durability properties, even when watered more than the optimum water content.

Table 1. Indirect tensile strength.

	Water content w (%)	Compaction degree Compaction energy	% binder	R_{it} 28 days (MPa)
Optimum	21.5	98% OPN	0	0.028
Proctor	23	98% OPN	3	0.13
water	24	98% OPN	4	0.2
content	19.2	98% OPM	3	0.27
(OPw)	20.2	98% OPM	4	0.32
Optimum	25	98% OPN	3	0.15
Proctor	26	98% OPN	4	0.21
water	21.2	98% OPM	3	0.25
content +			4	
2%	22.2	98% OPM		0.26

OPN – optimum standard Proctor, OPM – optimum modified Proctor.

The elasticity modulus and Poisson's coefficient were determined according to SR EN 13286-43 by using 4 LVDT transducers to measure the deformation of the horizontal diameter of the sample (0°) and the one of the diameter at 60° angle to the horizontal direction. The obtained curves have been analyzed to eliminate non-reliable values. After this selection still remained some values of Poisson's coefficient of 0.5 or even higher, which were not acceptable. The elasticity moduli were therefore corrected using ν = 0.25, value recommended by the Technical guidance LCPC SETRA (2000). All values, including the corrected ones are presented Table 2.

Table 2. Elasticity modulus and Poisson's coefficient.

	w %	Comp. degree Comp. energy	% add	E MPa	ν	E_{cor} MPa
OP	21.5	98% OPN	0	124	0.22	-
w	23	98% OPN	3	1523	0.22	1628

+	21.2	98% OPM	3	-	-	-
2%	22.2	98% OPM	4	6543	0.52	3720
	22.2	98% OPM	4	6616	0.52	3830
	22.2	98% OPM	4	5724	0.41	3710

5 CONCLUSIONS

The experimental study, continuing a series of tests already published, aimed at assessing other means for evaluating freeze/thaw durability of a fat clay treated with 3 or 4% lime-based road binder, meaning the freezing swelling coefficient, consistency index after thawing and indirect tensile strength. All these indices can be successfully used for assessing the durability.

The tests emphasized once more the influence not only of the binder addition and age, but also of the compaction energy, a higher energy offering better durability to freeze/thaw cycles.

The effect of the anisotropic state of stress on the normal force in a deep tunnel preliminary deformable lining

L'effet de l'état anisotrope de la contrainte sur la force normale dans un revêtement déformable préliminaire de tunnel profond

ABSTRACT: When deep tunnels are excavated in poor ground, squeezing conditions occur and the design of supports must follow the yielding principle. To this aim, special elasto-plastic elements embedded in the temporary support can be employed. The presence of the elastic-plastic elements radically modifies the ground-lining interaction mechanisms making necessary the use of numerical analyses. Particularly relevant is the case of anisotropic geostatic state of stress. The paper reports and discusses, some results from 2D numerical ground-lining interaction of deformable temporary support with initial non-isotropic stress field. Results of the classic rigid support are also reported and compared.

RÉSUMÉ: Lorsque des tunnels profonds sont creusés dans un sol de mauvaise qualité, des conditions d'écrasement se produisent et la conception des supports doit suivre le principe de flexion. À cette fin, des éléments élasto-plastiques spéciaux incorporés dans le support temporaire peuvent être utilisés. La présence d'éléments élasto-plastiques modifie radicalement les mécanismes d'interaction entre le sol et le revêtement, ce qui rend nécessaire l'utilisation d'analyses numériques. Le cas d'un état de contrainte géostatique anisotrope est particulièrement pertinent. L'article rapporte et discute certains résultats de l'interaction numérique 2D entre le sol et le revêtement d'un support temporaire déformable avec un champ de contraintes initial non isotrope. Les résultats du support rigide classique sont également rapportés et comparés.

Keywords: Tunnelling; yielding principle; soil-lining interaction; squeezing conditions; anisotropic state of stress.

1 INTRODUCTION

When deep tunnels cross poor grounds the so-called squeezing conditions happens. This leads to huge risks for the construction project, higher construction times and costs. Furthermore, in conventional tunnelling, extremely high convergences and overload of rigid preliminary lining can be expected. The best way to face these difficulties is to design the preliminary support following the so-called yielding principle (Kovári, 1998): the support must be highly deformable, allowing the ground deformations and, by so doing, reducing the stress acting on the lining. There are various technological solutions to introduce local deformations into the preliminary lining (Wu et al., 2021; Moritz, 2011). This paper is focused on circumferential elastic-plastic elements (EPE). TH steel ribs, hiDCon, LSC, hiDSte and Wabe are the most commonly used ones in conventional tunnelling.

There is limited literature on numerical modelling for the design of yielding supports in deep tunnelling under squeezing conditions (Yang et al., 2022; Barla et al., 2011; Tian et al., 2018; Radončić, 2011). Indeed, the ground-lining interaction (GLI) with a yielding lining has not been widely studied leaving a notable gap on the comprehension of tunnels' behaviour with this kind of supports. Furthermore, there is a lack of study on the effect of geostatic anisotropic state of stress, which is usually faced in squeezing conditions, on the interaction mechanism.

The aim of our work is to fill this existing gap. Our research was firstly driven by the embedment of high deformable elements in the steel ribs (Batocchioni et al., 2023). Whereas this paper aims at understanding the mechanical behaviour of a temporary lining following the yielding principle, under an anisotropic state of stress. Considering that in deep tunnelling the horizontal and the vertical stress can be quite far from equal for the combined effect of gravity and tectonic.

The methodology is developed by following a numerical approach. In order to highlight how the anisotropy of initial geostatic stress field affects the GLI, the results obtained for both rigid and yielding lining, starting from isotropic and then anisotropic geostatic conditions, are presented and discussed.

2 NUMERICAL MODEL

2D numerical analyses, modelling a cross section of a circular tunnel supported by temporary lining, have been developed with the aim of studying the peculiarity of GLI under an anisotropic stress field. The methodology is in line with the one used by Batocchioni et al. (2023), but with a focus on the relationship between lining's normal force, *N*, and the EPE's closure as relaxation increases. Indeed, study the effects on *N* give a first clear picture on the GLI mechanism. The analyses were developed through the FDM code FLAC2D (Itasca, 2011). The model reproduces only one quarter of the tunnel thanks to the symmetries (Figure 1). The mesh is composed of 4876 elements. The boundary constraints are the ones depicted in the Figure 1. Several analyses were carried out: the lining with (yielding) and without (rigid) the EPE, with an isotropic ($k_0 = 1.0$) and anisotropic ($k_0 = 0.5$) state of stress while keeping the average in-situ stress constant. For symmetry reasons, by neglecting the gravity and studying $k_0 = 0.5$ condition is equivalent to study also $k_0 = 2$ condition.

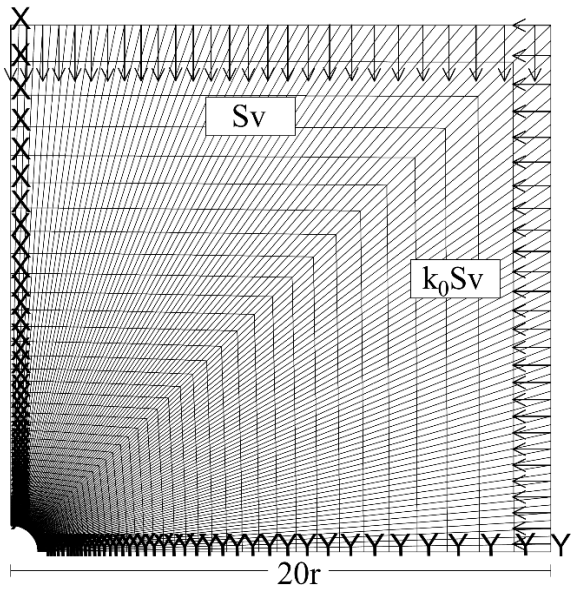

Figure 1. Numerical grid on FLAC 2D.

The mechanical behaviour of the ground has been modelled as isotropic elastic perfectly plastic with the parameters reported in Table 1. The severity of the conditions are quite high, in fact, the ratio between the uniaxial compressive strength and the mean in-situ stress is extremely low (≈ 0.06). Thus, leading to squeezing conditions (Ramoni and Anagnostou, 2010).

The excavation phase has been simulated with the well-known relaxation method, assuming the lining installation corresponds to a relaxation factor of 70%. The preliminary support has been modelled with one HEB240 steel rib per meter. For sake of simplicity, the presence of the shotcrete was neglected. The lining has been modelled with elastic perfectly plastic beam (yielding normal force of 2915 kN). Also the EPE has been simulated with the same beam elements, but with lower values of Young's modulus and yielding normal force. The EPE has been modeled as a generic yielding element, but akin to the hiDSte (the best solution to embed in the steel rib). Therefore the Young's modulus magnitude is the one obtained by compression in experimental analyses, whereas the yielding normal force has been set as half of the steel rib one. In the analyses, the EPE behave as a hinge, assuming a null value of the plastic moment of the beam. This is a reasonable simplification, because the capacity of withstanding bending moments of the EPE is quite small respect to the one of the steel rib. To simulate the controlled deformation of this kind of lining, a special FISH routine was written in FLAC. Thus making the EPE extremely rigid when they reach the 97% of its maximum deformation.

The lining is connected to the ground through an interface characterized by infinite compressive strength (elastic behaviour) and shear elastic-plastic behaviour with frictional Mohr-Coulomb criterion.

The accuracy of the numerical results is guaranteed by the high density and dimensions of the mesh (20 times the tunnel radius) and by the stringent convergence criterion set in the code (*sratio* equal to 10^{-5}). As well as by verifying the achievement of stationary conditions with the progress of calculation steps of the most relevant variables of the interaction problem.

Table 1. Parameters used in the numerical analyses.

	Ground	Steel Ribs	EPE	Interface
Friction angle (°)	30			20
Cohesion (kPa)	100			0
Normal and shear bond stiffness (MPa)				47e3
Average in-situ stress (MPa)	6.75			
Coefficient of earth pressure at rest, (-)	0.5, 1.0			
Young's Modulus (MPa)	1000	21e4	177	
Yielding Normal force (kN)		2915	1458	
Yielding Moment (kNm)		-	0	

3 RESULTS AND DISCUSSION

The Figure 2c reports the variation of *N* along the lining. As the relaxation increases, the *N* tends to incrase; the initial trend, higher at the sidewall, is a direct consequence of $k_0 < 1$ (arch effect). With further relaxation, the EPE start to close with progressively higher gradient (Figure 2b). As expected, initially the EPE at the sidewall ($\theta = 0° \; and \; 45°$) closes more than the rest. Thus, tending

to mitigate the strong *N* difference along the rigid lining (see Figure 2c dark-blue lines, rigid vs yielding at $\lambda = 0.8$). Continuing the relaxation, the closure gradient of the crown EPE ($\theta = 90°$) grows and at $\lambda = 0.98$ all the 3 EPE are close at the same level (around 80%). Whatching the *N* along the lining (Figure 2c, light green line), from this relaxation on until the first EPE reach the adimissible deformation, the trend is substantially the same with the istropic one (Figure 2c, black dotted line). This continue to emphasise the good benefit of the yielding lining on anisitropic mitigation. Indeed in these conditions, appear evident the effect of the EPE imposing the passage of the *N*-curve at their yielding value (1458 kN) and by so doing impeding the *N* value to rise more.

Whereas between the two EPE (in the rigid lining segment) the *N* rises because of the interface's shear strength, reaching the maximum value in the middle of the rigid segments (Radončić et al., 2009; Tian et al., 2018; Batocchioni et al., 2023).

The scenario changes when at $\lambda = 0.99$, the EPE in the crown is the first to reach the admissible deformation and finally at $\lambda = 0.995$ (Figure 2c, orange line) all the EPE are fully closed. In spite of such a small relaxation ($\Delta\lambda = 0.005$, Figure 2b), the effect on the *N*-curve is decisively clear: the interaction changes and inside all the lining with the close EPE (upper part of the tunnel) the *N* can rise. This difference of *N* (around 300kN) will remain constant until the end of relaxation considering that now on the lining behave as completely rigid (Figure 2c, red line). Therefore the final arrangement of the *N* is characterized by higher values at the crown. Unlike what was expected.

The explanation of these behaviours likely is in the different stress paths that experience the ground near the tunnel. Especially, looking at Figure 3, the first ground's element to reach the yielding (the only one before $\lambda = 0.7$, i.e. the installation of the lining) is the one at the sidewall; where the stress path induced by tynnelling tends to increase the mobilization of shear strength. The last to yield is the element in the crown (almost at the end of relaxation), where the deviatoric stress tends initially to reduce and after becoming isotropic, it tends to incrase, with an inversion of the principal stress direction. Thus, the plastic zone starts at the sidewall and then it extends to the upper part of the tunnel (Figure 2a).

In conclusion the effectiveness of the yielding lining can be highlighted by comparing the two dark-blue lines (Figure 2c, both thick and thin ones) representing the *N* on yielding and rigid lining (respectevely with and without the EPE) for the same level of relaxation ($\lambda = 0.8$). The *N* acting on the rigid

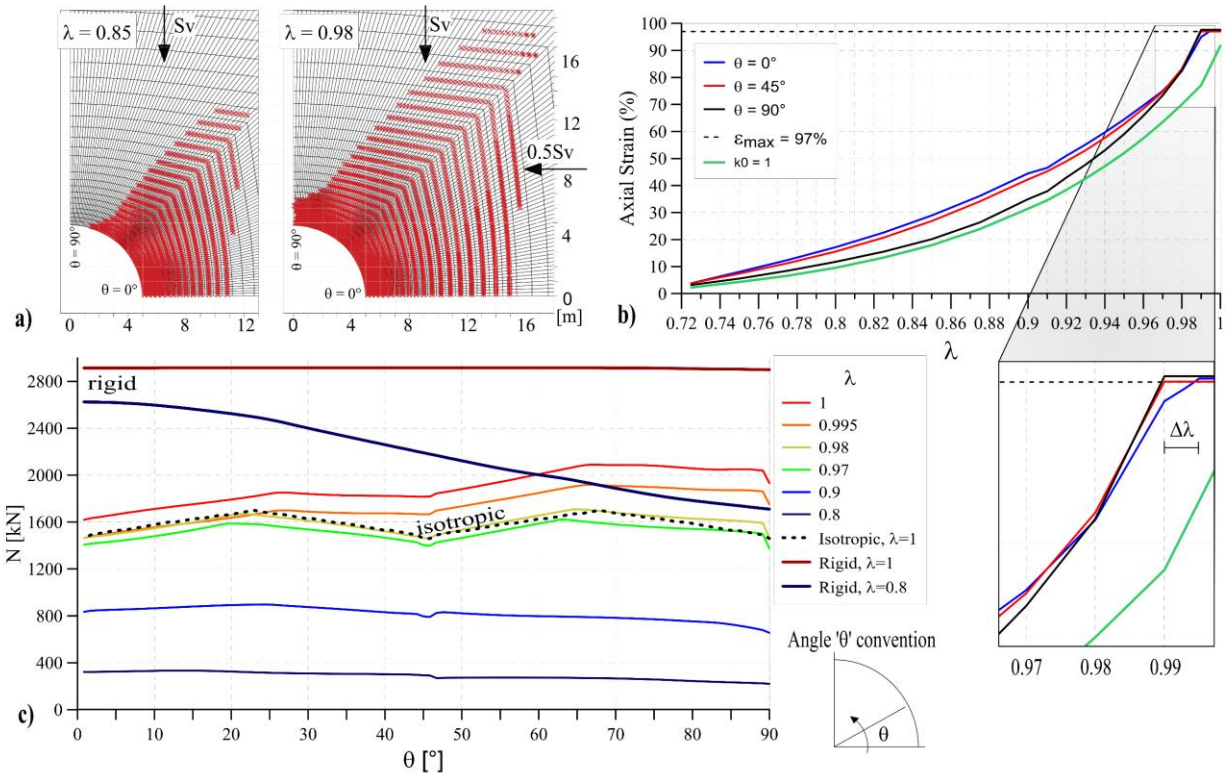

Figure 2. a) plastic zones around the tunnel with 2 different level of relaxation; b) EPE closure with the relaxation; c) normal force in the beam element along the tunnel (lining) with the relaxation.

lining are markedly higher than yielding one. Although less effectively than under isotropic stress field, the deformable lining is able to mitigate the effect of the anisotropic geostatic state of stress: the variation of *N* along the support is less pronunced respect to the rigid lining and the magnitude are rather lower.

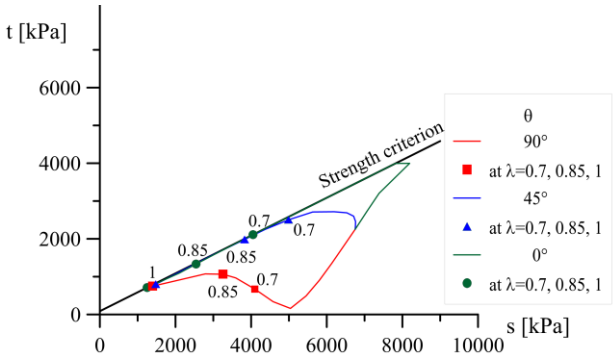

Figure 3. Stress path of different ground zone near the tunnel: green (θ=0°, sidewall), blue (θ=45°), red (θ=90°, crown) and black (strength criterion).

4 CONCLUSIONS

In the design of deep tunnel's preliminary lining squeezing conditions can be faced. In this case, a yielding lining must be conveniently employed. Moreover, due to the combined effect of gravity and tectonic, the initial stress state can be very far from isotropic.

In this paper, 2D numerical analyses have been developed with the aim of studying the interaction between temporary lining equipped with elasto-plastic elements and ground under geostatic anisotropic state of stress.

The main outcomes are the following:

- the study of the ground's plastic zones development is essential to understand the complex ground-lining interaction;
- if none of the elasto-plastic elements reach the admissible deformation, the yielding lining is able to minimize the effect of the anisotropic state of stress on the normal forces;
- if one or more elasto-plastic elements reach the admissible deformation, the most critic section turn out to be the one towards the maximum principal stress direction, differently from what happens with a rigid lining.

Regarding further development, in order to achieve a more complete picture of the ground-lining interaction of a yielding support under anisotropic state of stress, it will be necessary to consider the distribution and evolution of shear and bending moment, expected to be relevant.

ABSTRACT: Lot 2 of the Extension of the Yellow and Green Lines of the Lisbon Metro starts at the Santos Station and runs southwards across Av. D. Carlos I and Av. 24 de Julho up to the Cais do Sodré Station, connecting the Yellow Line to the Green Line. In this lot, several stages of prospection were carried out, resulting in an extensive set of field and laboratory works that enabled the preparation of the geological model and the geotechnical parameterisation of the lithological units considered in that model. In a length of only 665 m, several materials are crossed. In the survey campaign of the construction phase, among a wide range of works, 73 boreholes were driven for the geological-geotechnical, hydrogeological and geo-environmental components. Based on all information available from previous surveys and from historical and geological mapping, it was possible to draw up the geological model adopted in the Construction Design. Given the large number of results, statistical processing was used to limit and estimate the characteristic values of the parameters required in safety checks.

RÉSUMÉ: Le lot 2 de l'extension des lignes jaune et verte du métro de Lisbonne commence à la station Santos et se dirige vers le sud en traversant l'Avenue D. Carlos I et Avenue 24 de Julho jusqu'à la station Cais do Sodré, reliant la ligne jaune à la ligne verte. Dans ce lot, plusieurs étapes de prospection ont été réalisées, aboutissant à un vaste ensemble de travaux sur site et de laboratoire qui ont permis d'élaborer le modèle géologique et la paramétrisation géotechnique des unités prises en compte dans ce modèle. Sur une longueur de seulement 665 m, plusieurs matériaux sont traversés. Lors de la campagne d'étude de la phase de construction, parmi un large éventail de travaux, 73 forages ont été réalisés pour les composantes géologiques-géotechniques, hydrogéologiques et géo-environnementales. Sur la base de toutes les informations disponibles, provenant des études et campagnes précédentes et de la cartographie historique et géologique, il y a été possible d'élaborer le modèle géologique adopté dans les études d'exécution. Compte tenu de la grande quantité de résultats, il a été possible de limiter et d'estimer les valeurs caractéristiques des paramètres nécessaires pour les contrôles de sécurité à effectuer, grâce à l'aide de traitements statistiques.

Keywords: Lisbon; geologic model; geotechnical survey; geotechnical parametrisation.

1 INTRODUCTION

Lot 2 of the Extension of the Yellow and Green Lines of the Lisbon Metro begins at the Santos Station and extends for about 665 m until the Cais do Sodré Station. From a geomorphological and topographical perspective, the alignment is divided into two parts. The first part is located on the slope of the Madragoa neighbourhood, where the Santos Station is located, and the alignment mostly runs underground. It then transitions to the lower area along the riverfront, where it continues in a trench.

This lower area riverside evolution is presented in Figure 1.

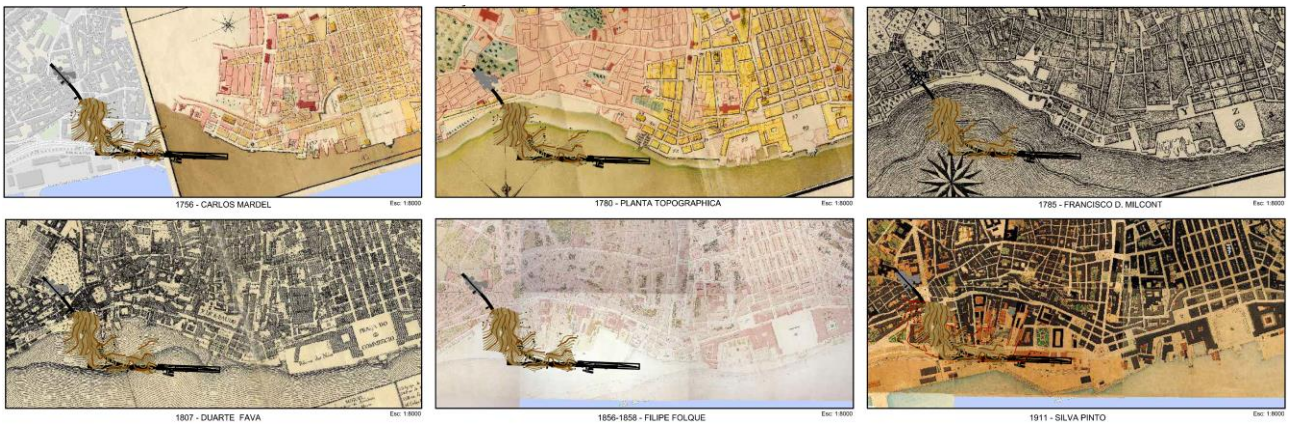

Figure 1. Maps dating from 1756 to 1911, showing the evolution of the riverside area of the Tagus River. The layout of the alignment shows that it lies partly on areas reclaimed from the river.

2 GEOLOGICAL MODEL

2.1 Geological and geotechnical zoning

In the initial part, the geological mapping is mainly composed of the Miocene unit of the Prazeres Clays (MPr), overlying materials from the Lisbon Volcanic Complex (CVL). In this area, in the upper part of the unit prevails basalt, often highly weathered and fractured and, in the lower part, tuffs and breccias. This complex overlies Cretaceous materials from the Bica Formation (mostly limestones). Approximately from Pk 1+575 onwards, the geology is dominated by the presence of alluvial soils underlying landfill deposits, as marked with lines in Figure 2. In this second part of the alignment, starting from the entrance into the Paleovalley (formed by a tributary of the Tagus and whose central zone broadly coincides with the designated Boavista landfill), it fits into an area with a flat surface morphology and the presence of alluvial deposits. In this zone, the geology is characterized, in the upper part, by the presence of landfill deposits – At, up to a depth of about 7.5 m (borehole SC22-Pz), beneath which prevail alluvial materials, predominantly sandy up to Pk 1+700, and predominantly clayey from there to the end of the trench section.

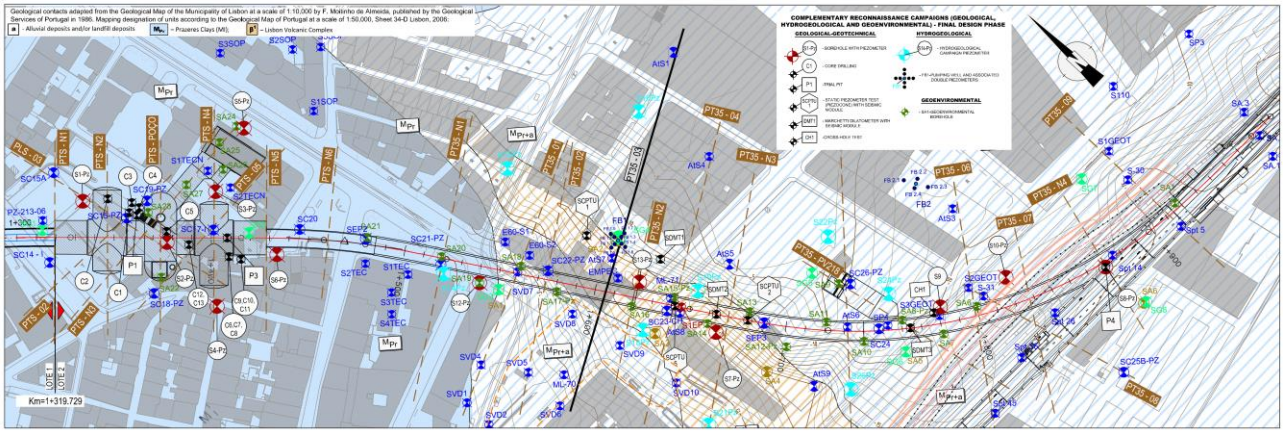

Figure 2. Geological map (adapted from geological mapping at a 1:10,000 scale). In blue, areas of the MPr-Prazeres Clays unit, and in brown, materials from the CVL-Lisbon Volcanic Complex ("line pattern" when under alluvial deposits). Contour lines indicate the topography of the substrate beneath the alluvial deposits in the paleovalley.

In the second section there is a noticeable rise of the Miocene substrate, reaching a maximum roughly between Pk 1+725 and 1+750, at the final of the paleovalley to the southwest. It is noteworthy that there is a prominence of the substrate in relation to the general base level trend toward the east throughout the alluvial/landfill area, with a positive differential of about 7 m. This substrate rise is attributed not only to the prominence of the former stream bank on the left side, but also because the alignment turns eastward here, running along the substrate. On the other hand, this local prominence of the substrate also marks, to some extent, the separation of alluvial deposits from the former stream (paleovalley) from those deposited

by the Tagus River. The overall structure of the Miocene monoclinal unit exhibits a general dip toward S-SE with strata dipping generally less than 15º, ranging from 5 to 10º, similar to the levels of the CVL. Despite the eventual faults in the second part of the alignment, it was decided not to represent them, as the model adopted allowed for the interpretation of the contacts between units without materializing disruptions caused by structural discontinuities. Another aspect worth noting in the model is its transversal variability, particularly around the paleovalley, as can be seen, for example, in the section at Pk 1+605, presented below in Figure 4

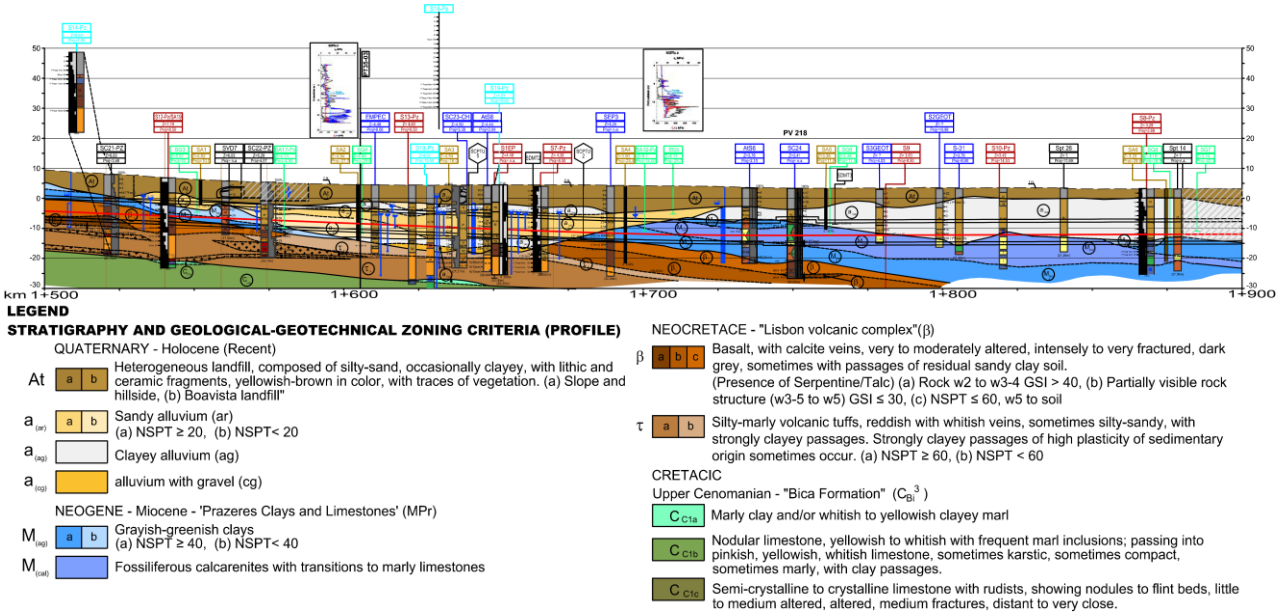

Figure 3. Geological model in the lower area, from pk 1+500 to pk 1+900. In the legend, stratigraphy and zoning criteria adopted in the geological and geotechnical model, in Bento et al. (2022).

The construction of the trench in the lower area, in an alignment that positions it as a barrier to the flow of groundwater along the paleovalley, also led to the need to carry out detailed hydrogeological studies. Taking into account the constraints arising not only by the trench to be built, but also by the basements and pumping systems of pre-existing buildings, these studies addressed the modelling of the current and post-construction conditions. These studies made it possible to design a solution for water to pass through the walls of the trench above the rail tunnel, achieved by drilling holes in the structure.

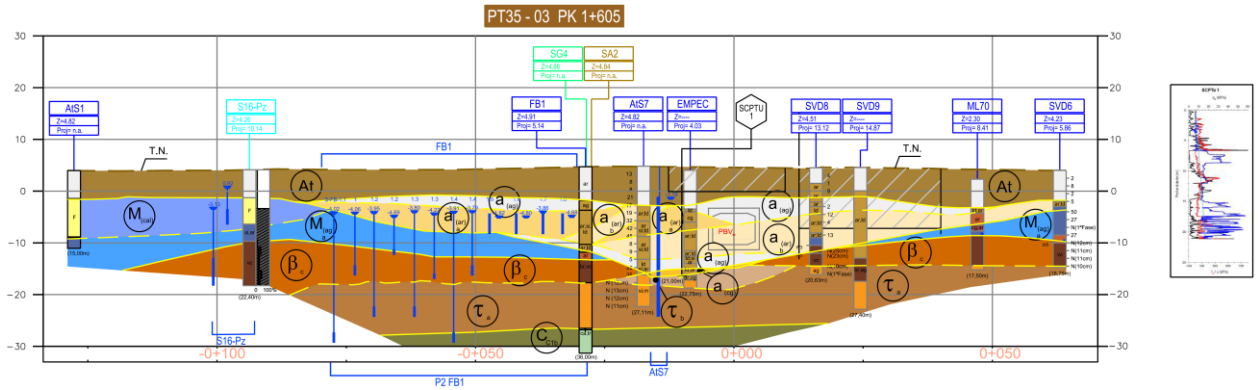

Figure 4. Profile PT35-03, geological model at pk 1+605, in the paleovalley area, in Bento et al. (2022). Particularly noteworthy are the piezometry results from borehole FB1 and the transversal variations of geologic strata. Profile PT35-05 location, at pk 1+600,5 signalled with black line in Figures 2 and 3.

The lithological units adopted in the geological model are part of the stratigraphic units, and different lithological units are considered depending on the type of soils found in each of the stratigraphic units. The

geologic model was primarily developed using geotechnical survey results, geological mapping, as well as ancient cartography, engravings and tile paintings. The geotechnical zoning adopted was based mostly on the analysis of the results of the geotechnical surveys carried out in the various ground investigation survey campaigns. All this data was weighed up against the type of works to be built. Regarding the geological units adopted, following the analysis of all the available data, it was decided to subdivide some of the lithological units in order to best tailor and optimise the solutions designed. This approach can be considered as geological and geotechnical zoning, primarily based on lithological criteria.

Thus, the zoning first identified a total of 6 distinct geologic units (Landfills, Alluvium, Miocene Complex, Volcanic Complex-Basalts, Volcanic Complex-Tuffs, and Cretaceous - Bica Limestones), as a result of which the different lithostratigraphic complexes crossed by the works were separated. In turn, some of these units were further first subdivided into lithological units and then in geotechnical zones, differentiating them according to their distinct mechanical properties.

In this context, in the alluvium geological unit, the sandy alluvial lithological unit was subdivided into $a(ar)_a$ and $a(ar)_b$, depending on whether the N_{SPT} value is greater or less than 20 blows, respectively.

The clayey Miocene unit was also subdivided into $M(ag)_a$ and $M(ag)_b$, depending on whether the N_{SPT} value is greater or less than 40 blows, respectively.

The basalts and tuffs of the CVL were also subdivided into β_a, β_b, and β_c, and τ_a and τ_b, respectively. The β_a basalts are low to moderately-highly weathered (W_2 to W_{3-4}) with GSI values > 40, the β_b basalts, while partially maintaining the rock structure, are moderately to highly weathered to decomposed (W_{3-4} to W_5) with GSI values < 25, and the β_c basalts consist of decomposed material (W_5) with N_{SPT} values $\leq$ 60 blows, commonly referred to as basaltic breccia in older campaign drillings. Tuffs τ_a and τ_b were subdivided based on N_{SPT} values equal to or less than 60 blows, respectively.

This process resulted in 17 geotechnical sub-zones, as presented in Figure 3.

2.2 Geotechnical survey

In addition to analysing and incorporating into the study the results obtained in 91 boreholes from previous campaigns, carried out both as part of previous phases of this project and other works in this densely populated area, a significant set of field and laboratory work was carried out as part of the studies. This included: 73 mechanical boreholes (17 geotechnical, 24 hydrogeological, and 32 geo-environmental); 13 core drillings; 3 inspection wells; 13 vane tests (FVT); 3 Marchetti dilatometric tests (DMT); 4 static penetration tests with seismic measurement (SCPTu); 39 Menard pressuremeter tests (PMT); 138 Lefranc permeability tests; 4 Lugeon permeability tests; collection of 30 undisturbed samples with a Shelby sampler for laboratory tests; Installation of 40 piezometers with a monitoring campaign; Laboratory tests for the physical and mechanical characterization of the soils, including particle size analyses, consistency limits, organic matter content, density of solid particles, volumetric weights, permeability tests, consolidation tests, and triaxial tests on soils; determination of bulk densities, unconfined compression tests, point load tests (PLT), and triaxial tests on rock; collection of water samples for laboratory analysis in environmental boreholes; pH, temperature, and electrical conductivity analyses in some piezometers; 4 pumping tests and 2 tide tests. The fieldwork is indicated on the plan in Figure 2.

3 GEOTECHNICAL PARAMETRISATION

3.1 Introduction

When possible, the estimation of the design geotechnical parameters for each geotechnical unit took into account the results of the work carried out in the various ground investigation campaigns available. When necessary, correlations established in the specialized literature were employed to convert the parameters obtained in the tests into design parameters.

The geotechnical field survey was parameterised using the following *in situ* tests: static cone penetration tests with seismic module (SCPTu's), Marchetti dilatometer tests with seismic module (SDMT's), Menard pressuremeter tests (PMT's), LNEC dilatometer tests (BHD's), Vane Tests (FVT) and permeability tests of the Lugeon and Lefranc types. Some results from laboratory soil tests were also used, namely uniaxial compression tests, determination of bulk density, and permeability determination obtained through triaxial tests. In addition, laboratory test results on rock samples were used, particularly uniaxial compression tests (UCS), point load tests (PLT), and determination of bulk density.

3.2 Methodology

Based on the mentioned tests, a statistical estimation of the possible characteristic values of the geotechnical parameters for the material of each considered unit was carried out.

Eurocode 7 recommends that "the characteristic value of a geotechnical parameter should be chosen to constitute a cautious estimate of the value that conditions the occurrence of the limit state under consideration." However, it is not specified what constitutes a "cautious estimate" of the value and how to calculate it.

As a contribution to the ongoing revision of EC7, Orr (2017), in Shen *et al* (2018), proposed the simplified equation (1), which was used as a preliminary calculation for the characteristic value of the geotechnical parameters:

$$X_k = X_{mean}\left(1 - 3aCOV/\sqrt{L_v}\right) \qquad (1)$$

After testing several approaches to determine the characteristic values, the project opted for equation (2), adapted from the simplified equation (1) proposed by Orr (2017):

$$X_k = X_{mean}\left(1 \pm 3aCOV/\sqrt{L_v}\right) \qquad (2)$$

where:

X_k –characteristic value of geotechnical parameter X;

X_{mean} –mean value of geotechnical parameter X;

a – factor responsible for the quality and extent of laboratory and field investigations. For high-quality and extensive investigations, a = 0.5; for average quality and extent of investigations, a = 0.75; and for values estimated from general experience or tabulated values, a = 1.

COV – coefficient of variation of geotechnical parameter X;

L_v –vertical dimension of the zone of influence.

The mentioned equation (2) was used, with a negative sign, whenever the number and consistency of tests allowed it, to calculate the characteristic values of the parameters undrained cohesion (c_u), effective friction angle (ø'), deformation modulus (E), and coefficient K_0, as these geotechnical parameters are more critical for the project the lower their values. On the other hand, for the unit weight (γ), saturated unit weight (γ_{sat}), and coefficient of permeability (k), which should be more critical for the project the higher their results, the equation was chosen with a positive sign.

The factor "*a*" and the coefficient of variation *COV* are important factors in these equations, as the first considers the quantity and quality of sampling, and the second, being a function of the standard deviation, reflects the dispersion of the data. For larger "*a*" and *COV* values, more cautious will the characteristic value obtained be.

A factor a = 0.5 was considered when the number of tests is greater than or equal to four, and a factor a = 0.75 when the number of tests is less than four.

The factor L_v is variable for each geotechnical unit, depending on the weighted thickness of the respective considered units, and also reflects the dispersion of the results. For a specific parameter with a certain range of results, the smaller the area in profile where this dispersion occurs, the lower the degree of confidence that these results provide. In other words, the lower the value of L_v, the more conservative the characteristic value obtained will be.

In the calculation of characteristic values, any results that significantly deviated from all others, i.e., those outside the overall pattern of a distribution (outliers), were excluded. For this purpose, the common method based on the interquartile range (IQR) was considered. This method involves identifying a result as an outlier if it is more than 1.5 times the IQR above the 3rd quartile (Q3) or more than 1.5 times the IQR below the 1st quartile (Q1)

It is important to note that, for almost all units, despite having few results to determine the characteristic value of some geotechnical parameters, which makes the estimate less valid from a statistical point of view, it was still decided to carry out this assessment, which serves as another element of careful analysis.

The data processing results for determining the characteristic value of undrained cohesion (cu) for the clayey alluvial unit a(ag) that occurs in the upper zone of the lower section of the alignment are presented in Figure 5. This unit is depicted in Figure 4 and is more extensively found in the alluvial deposits towards the end of the alignment.

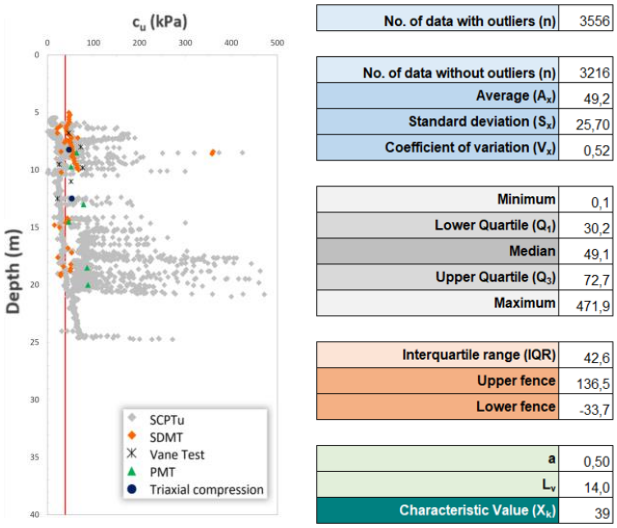

Figure 5. Alluvium a(ag) – Estimate of undrained cohesion (c_u).

For reference, the unit a(ag) is a clay, sometimes silty, with a characteristic value of N_{SPT} of 4 blows.

Table 1. Characteristic values for undrained cohesion (c_u) by test type in the clayey alluvium unit.

a(ag) unit	SDMT	SCPTu	PMT	Vane Test	Tri-axial
c_u (kPa)	41	39	62	40	47

The adopted characteristic value for c_u was 40 kPa. For this unit in particular, the need to consider different values in function of the depth, was also considered, being this variation obtained by the expression below the table in Figure 6.

Geotechnical Unit	γ (kN/m³)	γ_{sat} (kN/m³)	c_u (kPa)	E_u (MPa)	c' (kPa)	ø' (º)	E' (MPa)	K_0	k (m/s)	ν	σ (MPa) [rock]	E' (GPa) [rock]

Figure 6. Table of design parameters adopted for geotechnical safety checks, in Bento at al. (2022)

3.3 Design geotechnical parameters adopted.

Following the methodology explained above, naturally adapted to each testing type, geological unit material, location in depth, test quantity and previous experiences, it was possible to establish the geotechnical parameters presented in the table in Figure 6.

4 CONCLUSIONS

The extent of the ground investigation campaign, which complements previous campaigns, made it possible to gather the data that led to the development of the geological model adopted. At the date of the publication, this model has proven to be accurate in the ongoing works. The method of adopting characteristic values eased the systematic treatment of data (of varied nature and quantity) necessary for defining the design geotechnical parameters used in the development and safety verification of the construction works. Based on these characteristic values, the final adoption of parameters was naturally guided by the engineering practice and expertise, which are crucial in the process. developments.

ACKNOWLEDGEMENTS

The authors express their sincere gratitude for the support extended by the Owner (Metropolitano de Lisboa EPE) and the Construction Consortium (Metro Santos Sodré ACE), by allowing the publication of this article.

ABSTRACT: Use of stabilised soils in the construction of high-speed rail embankments is a desirable engineering solution as more site-won soils may be used locally thus reducing the volume and mass haul of imported and site-won materials. In the south of contract area C23, significant volumes of weathered structureless chalk will become available due to the construction of cuttings. However, presently there is little data available in the public domain to characterise the dynamic performance of a cement-stabilised chalk for use as high-speed rail embankment fill material. This paper presents the results of a field trial comprising in situ and laboratory testing of a large embankment constructed from three different chalk-cement mixes. By controlling pulverisation, stabilisation, and compaction procedures during construction, the observed variability of material grading, air voids, and density are presented in relation to the natural variation of the chalk, moisture content, added cement content, and stiffness of the supporting foundation. E_{V2} modulus values are shown to meet HS2 performance requirements but are highly sensitive to cement curing time. On the other hand, the Rayleigh wave characteristics are found to exceed HS2 criteria and the assumed shear value velocity for engineered fill, providing the justification for an increased value to be recommended for optimisation and efficiency.

RÉSUMÉ: L'utilisation de sols stabilisés dans la construction de remblais ferroviaires à grande vitesse est une solution d'ingénierie souhaitable pour HS2, car davantage de sols gagnés sur site peuvent être utilisés localement, réduisant ainsi le volume et le transport en masse de matériaux importés et gagnés sur site. Dans le sud de la zone contractuelle C23, d'importants volumes de craie altérée sans structure deviendront disponibles en raison de la construction de déblais. Cependant, à l'heure actuelle, il existe peu de données disponibles dans le domaine public pour caractériser les performances dynamiques d'une craie stabilisée au ciment destinée à être utilisée comme matériau de remblai de chemin de fer à grande vitesse. Cet article présente les résultats d'un essai sur le terrain comprenant des essais in situ et en laboratoire d'un grand remblai construit à partir de trois mélanges crayeux-ciment différents. En contrôlant les procédures de pulvérisation, de stabilisation et de compactage pendant la construction, la variabilité observée du classement des matériaux, des vides d'air et de la densité est présentée en fonction de la variation naturelle de la craie, de la teneur en humidité, de la teneur en ciment ajouté et de la rigidité de la fondation porteuse. Il a été démontré que les valeurs de module E_{V2} répondent aux exigences de performance HS2 mais sont très sensibles au temps de durcissement du ciment. D'autre part, les caractéristiques de l'onde de Rayleigh dépassent les critères HS2 et la vitesse de la valeur de cisaillement supposée pour le remblai technique, ce qui justifie une augmentation de la valeur recommandée pour l'optimisation et l'efficacité.

1 INTRODUCTION

1.1 Background

The High Speed Two (HS2) project is a High-Speed Railway Line currently under construction in the UK. Phase 1 of HS2 runs between London and Birmingham across the English Midlands

The scope of the C23 contract, which has been awarded to Eiffage, Kier, Ferrovial Bam Joint Venture (EKFB), includes 45 embankments and 30 cuttings supporting HS2 C23 mainline.

As per HS2 Technical Standard for Earthworks (TS-E) (HS2, 2019), the design of these mainline earthworks shall comply with challenging static and dynamic performance criteria, reflective of the high operational speed of the rail. Compliance needs to be verified during construction with testing. Both the Technical Standard for Earthworks (HS2, 2019) and HS2 Specification for Engineering Works 600 series – Earthworks (HS2, 2022), indicate that field trials are a prerequisite element of the design and construction control validation process.

For mainline embankments, large volumes of engineered fill are expected to be used as upper and lower embankment fill (UEF & LEF) and as foundation treatment, i.e. excavate & replace backfill. In this context and considering the complex logistics associated with this aspect of the scope, opportunities to maximise the use of the site won material generated during excavation for the formation of the mainline cuttings is continuously being sought.

As a result, the field trials scope has been extended to include assessment and validation of site won material performance for use as embankment fill and replacement fill for earthwork foundations.

1.2 Scope & objectives

The main objective of the Earthworks field trials was to demonstrate suitability of proposed unstabilised/stabilised soils for High-Speed Railway embankment fill, to provide earthworks control and verification to validate the performance of the earthworks during and following construction and to review suitable improvement options for re-use of any excavated materials for embankment fills.

This paper discusses the results of the embankment trial of Cement Stabilised Chalk which was performed at Great Missenden. The embankment was constructed using structureless Chalk (Class 3B1) stabilised using cement mix to produce a Class 9M1 fill material for use as UEF, LEF and foundation treatment. The trial's aim was to control, validate, and optimise the earthworks construction method to ensure that the Class 9M1 fill derived from the class 3B1 chalk could reasonably achieve the design requirements set out in the TS-E (HS2, 2019).

2 THE SITE

2.1 Trial location

The trial embankment site is located near Great Missenden, Buckinghamshire. The nearest mainline asset to the trial site is South Heath Cutting. The completed trial embankment is presented in Figure 1. The excavated fill was generally structureless Chalk. The trial site layout plan is shown in Figure 2.

Figure 1. Completed trial embankment.

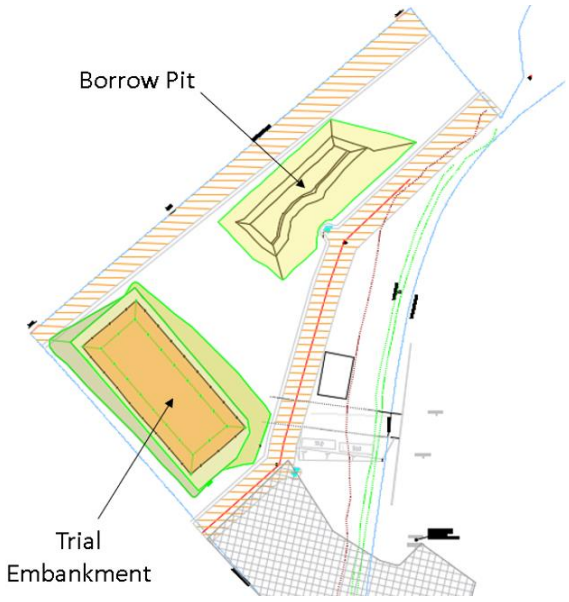

Figure 2. Trial Site Layout Plan and proposed testing locations.

2.2 Ground conditions

Based on the ground investigation at the borrow pit area, the site is characterised by structureless Chalk comprising 1m of grade Dm Chalk becoming grade Dc with depth (Figure 3). Localised zones of more structured Chalk (grades B & C) were also observed over the excavated depth.

Interpretation of available ground investigation data at the trial site indicated that the ground conditions below foundation platform level comprise grades Dm/Dc structureless Chalk over structured Chalk of Grades B/C. This is generally consistent with the ground conditions revealed at the borrow pit location.

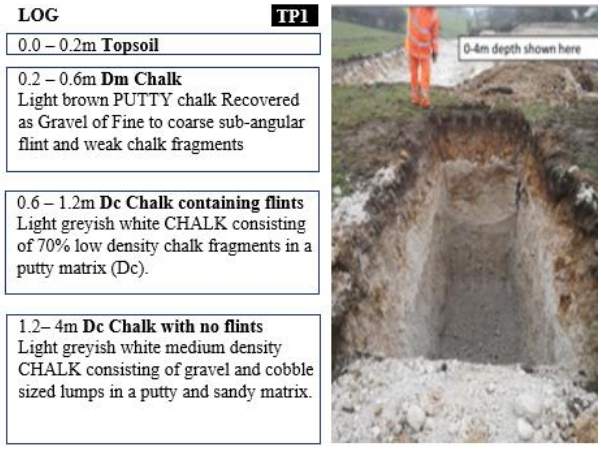

Figure 3. Photo of trial pit in the borrow pit area.

3 EMBANKMENT CONSTRUCTION

The Trial embankment was split into two areas (Area 1 and 2). Layers 1 to 3 of both Area 1 and 2 were constructed using Dm chalk mixed with 2% cement. Above layer 3, Area 1 and 2 were constructed with different binder contents, but both with Grade Dc white chalk. Area 1 used 2% cement for layers 4 to 8 and finished construction at layer 8. Area 2 used 3% cement for layers 4 to 8 and 4% cement for layers 9 to 13 and finished construction at layer 13. Individual layers were specified to achieve a compacted thickness of 250mm.

Due to variation in ground elevation, the trial location was levelled, using cut and fill within the hillside to form a basal foundation platform for the trial embankment. A 2% cement mix was used to stabilise the base.

Targeted in situ and laboratory testing were undertaken both during construction of the trial embankment and on completion to provide the necessary data for use in the assessment of the suitability of site won stabilised structureless Chalk Class 9M1 as HSR embankment fill.

4 PERFORMANCE REQUIREMENTS

4.1 Performance requirements for HSR fill

The performance requirements specified in the TS-E (HS2, 2019) are as follows:

4.1.1 Dynamic performance

The TS-E (HS2, 2019) (Table 4.2/1) specifies the performance criteria to be satisfied by the earthworks design and construction verification testing as a limiting Rayleigh wave velocity (V_R), measured at Formation Level:

$$V_R \geq 1.6 \times DS \quad (1)$$

where DS is the design speed, which for HS2 Contract C23 has been set at 360km/hr (100m/s).

This minimum V_R value is to be achieved over a frequency range of 10-50Hz.

In the beginning of the design, due to lack of information, a minimum V_S design value of 250m/s has been adopted for engineered fill forming embankments and earthwork foundation strata. This value is used for benchmarking the dynamic performance results from testing of the Class 9M1 material forming the trial embankment. The V_S design value has been revised to 300m/s at a later stage based on the evidence from field trials.

4.1.2 Static performance

TS-E specifies the minimum Deformation Modulus (E_{V2}) for Chalk when used as UEF to achieve static performance criteria:

$$(E_{V2}) \geq 45\text{MPa} \quad \text{(1m above LEF)} \quad (2)$$

$$(E_{V2}) \geq 60\text{MPa} \quad \text{(at surface of UEF)} \quad (3)$$

4.1.3 Layer thickness

The following requirements are set out in HS2 Specification, 600 series – Earthworks (2022):

- All fill materials - deposited in layers not exceeding 250mm uncompacted thickness.
- Cement stabilised materials - upper limit of 250mm may be increased depending on confirmation from field trials.

4.1.4 Testing and compaction requirements

Testing methods adopted for measuring in-situ dry density (DD) comprised: Nuclear Density Gauge (NDG), core cutter (CC), and sand replacement density (SRD). Only the NDG results were considered for assessing the material DD. The testing locations are shown in Figure 4.

Degree of compaction achieved is determined based on assessment of the DD as a proportion of maximum dry density (MDD), determined from a defined compaction test converted to a percentage. A similar method was adopted to measure the air voids (AV) in that the particle density (PD) determined from

the embankment trial was used together with the moisture content (MC) and DD readings to determine the AV.

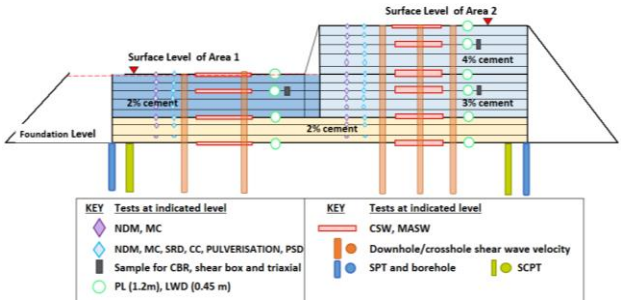

Figure 4. Testing locations and schedule for trial embankment.

Degree of compaction achieved is to be assessed against compaction data from either a standard (2.5kg) or modified (4kg) Proctor tests completed on sample of Chalk fill prior to construction. The Proctor test method used as a benchmark for the trial is determined based on the DD data obtained during compaction optimisation trials.

5 TESTING, RESULTS AND ANALYSIS

5.1 Design performance

5.1.1 Dynamic performance

Surface wave tests, comprising of Continuous Surface Wave (CSW) and Multi-channel Analysis of Surface Wave (MASW), were undertaken at foundation level and at different layers, as shown in Figure 4.

Additionally, Downhole and Crosshole seismic testing was conducted through the embankment fill and foundation strata to compare with the inverted values of Vs from MASW/CSW surveys.
The results are summarised in Table 1.

Table 1. Summary of Shear wave velocities obtained from Geophysical testing performed in Class M91 fill.

CSW (m/s)	MASW (m/s)	Downhole (m/s)	Crosshole (m/s)
400-500	500-600	400-600*	500-700

*Note - *Lower bound value is influenced by the averaging methodology considering the less stiff foundation material below the trial embankment.*

Surface wave geophysical methods are indirect ways of measuring Vshv, and therefore the VS derived from indirect methods (CSW and MASW) were benchmarked against direct methods (downhole and crosshole geophysics). Where surface wave geophysical methods were used, MASW results were considered superior in quality compared to CSW as lower variability was observed.

Benchmarking the testing results obtained from the four test types against the designed assumption of V-shv ≥ 250m/s showed mixed results throughout Areas 1 and 2 of the trial embankment. Nonetheless, all data obtained from all four test types demonstrated that the trial embankment formed of Class 9M1 fill with 2-4% cement contents exceeded the assumed Vshv value of 250m/s. A V_S of 570m/s was considered representative of 3% cement compared to 470m/s for 2% cement. A 2% cement content was considered sufficient to satisfy the dynamic requirement for the reuse of stabilised structureless Chalk Class 9M1 as embankment fill.

5.1.2 Static performance

To account for the depth of influence for a 600mm plate test (AFNOR, 2000), E_{V2} tests were performed within Layers 8 and 13. Also, to ensure that reliable and consistent results are obtained, only E_{V2} tests completed within 24hrs of compaction were assessed for each cement mix. The refined dataset, the results, the average value and percentage exceeding the Upper LEF and UEF requirements for Class 9M1 fill with 2%, 3% and 4% cement are presented in Table 2.

Table 2. Summary of E_{V2} testing results for different cement mix for Class 9M1 fill.

Fill Type	Range E_{V2} (MPa)	%Passing UEF Criteria (base)*	%Passing UEF Criteria (surface)
Class 9M1 (2% cement)	65-205	100%	100%
Class 9M1 (3% cement)	107-375	100%	100%
Class 9M1 (4% cement)	115-450	100%	100%

*Note - *: result represents tests at 1m above the top of the LEF.*

The testing results demonstrated that the static performance criteria for the use of Class 9M1 as UEF fill are met for all binder contents. Also, although E_{V2} values increased with higher cement contents, a 2% cement mix should be considered sufficient for the stabilised structureless Chalk to meet the static performance criteria when used as embankment fill.

5.2 Compaction assessment

5.2.1 Compaction optimisation

Compaction optimisation trials were performed to determine a suitable number of passes on layers 1, 2 and 3, with 9 No. NDG recordings taken after:

- 4, 6 and 8 passes on layer 1;
- 6, 8 and 10 passes on layer 2; and
- 8 and 10 passes on layer 3.

Variable MC were measured for each layer, ranging from 21% in layer 1 to about 22% in layer 2 and 25.5% in Layer 3. Therefore, compaction between layers could not be assessed collectively as MC skewed the degree of compaction and AV achieved. It was also noted that the material below 23% MC showed a reduced performance in AV, and therefore layers 1 and 2 were discounted from the compaction optimisation assessment.

From a review of the compaction optimisation trial results on Layer 3, presented as Figure 5, an increase in compaction was observed between 8 and 10 passes. Based on this, 10 passes using a 19t smooth drum roller traveling at <4kmph were adopted for the remaining duration of the trial.

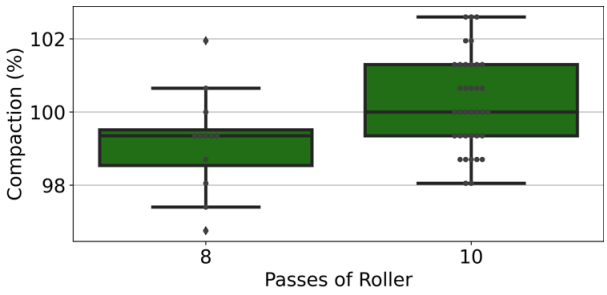

Figure 5. Trial Compaction Optimisation Results

5.2.2 Degree of Compaction and Air Voids

Based on the comparison between DD values achieved during compaction optimisation trials and laboratory Proctor tests, it was determined that the field dry density for the trial embankment compared closely to the standard (2.5kg) Proctor tests completed on 2% cement stabilised 9M1 material prior to construction. Therefore, compaction was benchmarked against MDD determined from standard Proctor tests.

Based on a comparative review of the Proctor tests, it was identified that Grade Dm chalk often produced a higher MDD than Dc Chalk by approximately 0.04Mg/m3. Based on the trial Proctor test data, MDD of 1.54Mg/m3 and 1.50Mg/m3 were determined for Dm and Dc Chalk, respectively, as Shown on Figure 6.

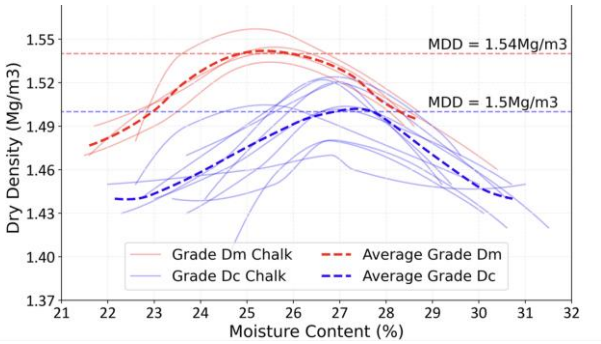

Figure 6. Trial Proctor Test Results

The degree of compaction of Dm and Dc chalk has been calculated against these respective MDD values. It is advised that compaction assessment for embankment fill during construction will need to be compared using locally determined MDD from asset specific Proctor tests for both Dm and Dc chalks used to produce Class 9M1 fill.

Optimum MC (OMC) was determined to be 25% for Grade Dm Chalk and 27% for Grade Dc Chalk. Based on average MC readings on each layer, 50% of the embankment layers (Layers 2,4,7 and 8) were dry.

Compaction data was screened to remove the following:

- Data points where cement content did not equate to 2%;
- Data points on layers where the number of passes of the roller did not equate to 10;
- Data points below an MC of 23% as the majority of this data did not achieve an AV<5%;
- Data points where NDG recordings were not recorded at 200mm depth.

When assessing the refined dataset for the trial embankment, 90% of the data exceeded a degree of compaction of 98.7% at the trial embankment, as shown on Figure 7.

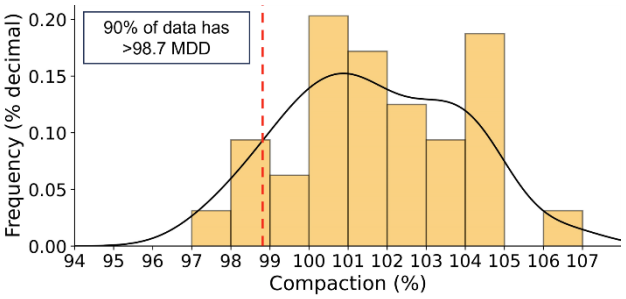

Figure 7. Histogram showing the distribution of degree of compaction for Class 9M1 fill.

The AV data from the revised dataset established showed that 90% of the data had an AV<6.1% as shown on Figure 8.

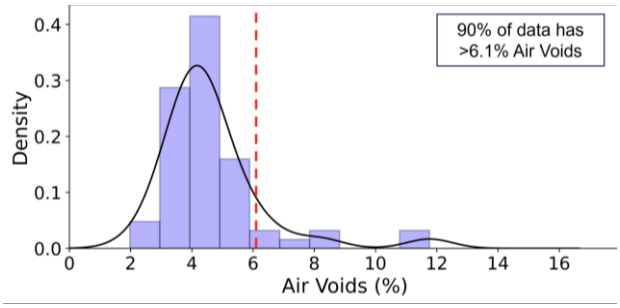

Figure 8. Histogram showing the distribution of air voids (AV) for Class 9M1 fill.

5.2.3 Pulverisation

Based on the trial data, the degree of pulverisation (DoP) ranged from 39% to 90% after the second pulverisation stage when cement was added. The three lowest values were considered outliers and, therefore, were excluded from the assessment. Based on the remaining dataset, a DoP of 60% was recommended after the second stage of pulverisation when adding cement.

5.3 Impact of layer thickness

The layer thickness during construction of the trial embankment ranged from 134-287mm, with six of the layers exceeding 250mm compacted thickness.

Compaction recordings were divided by the overall average compaction to normalise the data. From this, the average compaction of each layer was determined and plotted against the layer thickness.

The comparative review indicated that with increasing layer thickness, the normalised compaction tended to slightly decrease (albeit by less than 1% over a range of compacted layer thickness from 200-250mm). In light of the evidence from the trial, it is considered that layer thickness has a smaller impact on the degree of compaction compared to other variables (e.g. MC).

6 CONCLUSIONS

Based on the response of the structureless Chalk (Class 3B1) during trial embankment construction, pulverisation and testing, the following were identified as key requirements to ensure that the stabilised Chalk Class 9M1 fill meets the suitability criteria in terms the static and dynamic performance criteria:

- Class 3B1 Chalk should not be stockpiled due to drying effects reducing the materials ability to achieve the AV acceptability criteria (TRL, 1992).
- On classifying the chalk as either a grade Dm or grade Dc chalk, local Proctor testing should be undertaken to identify an appropriate compaction curve and MDD so that relative compaction can be assessed accurately for the asset specific embankment.
- The use of 2-4% cement during the trials have shown to not compromise static and dynamic performance requirements set in the TS-E. It is advised that the best percentage (by weight) of cement is 2%, as it has been shown to achieve the design performance criteria, whilst being the most sustainable percentage of cement to add.

The field trial results at Great Missenden have demonstrated that the site won structureless Chalk Class 3B1 can be improved to a Class 9M1, using controlled cement mix. They also demonstrated that the stabilised Chalk Class 9M1 met the static and dynamic performance criteria set by the TS-E (HS2, 2019) for use as HSR embankment fill subject to target construction requirements and trial compaction testing to determine an appropriate site specific maximum relative density.

Moreover, and based on a comparative review of results from various geophysical testing techniques, the dynamic performance in terms of Rayleigh wave velocity (V_R) was found to exceed the minimum assumed in design. An equivalent Vs design value of 300m/s is recommended for the Class 9M1 material.

ABSTRACT: This article presents an alternative solution for an excavation pit within a residential project in Târgu Mureș (Romania). Secant deep soil mixing columns in addition to CFA piles, proves to be a very effective, environmentally friendly (lower carbon footprint), cost and time saving solution, compared to traditional secant piles pit enclosure. Main challenge was to find an effective solution to build a proper dimensioned retaining wall considering not only the excavation depth, surrounding buildings, nearby streets and traffic but also restrained site dimensions. Given the non-cohesive soil layer, which is 2 metres thick, and due to the presence of ground water within, it was important just to seal this layer, to prevent water in-flow into the excavation pit. Deep soil mixing columns were 600 mm diameter and were done by the means of a special tool having three levels of mixing paddles. Calibration of grout flow, advancement speed and mixing rpms were very important for obtaining the proper BRN (blade rotation number) adapted to the soil conditions on the site. All criteria were monitored real-time using monitoring devices installed on the drilling rig and pumps. Design criteria, technology presentation and effective response of the solution are presented further.

RÉSUMÉ: Cet article présente une solution alternative pour une enceinte dans le cadre d'un projet résidentiel à Târgu Mureș (Roumanie). Par rapport à une enceinte traditionnelle, les colonnes DSM (deep soil mixing), en plus des pieux CFA, s'avèrent être une solution très efficace, favorable à l'environnement, économique et rapide. Le principal défi était de trouver une solution efficace pour construire un mur de soutènement aux dimensions appropriées, en tenant compte non seulement de la profondeur d'excavation, des bâtiments environnants, des rues avoisinantes et de la circulation, mais aussi des dimensions restreintes de la place. Compte tenu de la couche de sol non cohésive de 2 mètres d'épaisseur et en raison de la présence d'eau souterraine à l'intérieur, il était important de sceller cette couche pour empêcher l'eau de s'écouler dans l'enceinte. Les colonnes DSM avaient un diamètre de 600 mm et étaient réalisées par un outil spécial rotatif à axes verticaux à trois niveaux. L'étalonnage de l'écoulement du coulis, de la vitesse d'avancement et du régime de mélange était très important pour obtenir le BRN approprié aux conditions du sol sur le site. Tous les critères ont été surveillés en temps réel à l'aide de dispositifs de contrôle installés sur l'outil de forage et les pompes. Les critères de conception, la présentation de la technologie et efficacité de la solution sont présentés plus en détail.

Keywords: Excavation; pit enclosure; deep soil mixing; sealing.

1 INTRODUCTION

The proposed design had to give a technical and economical solution for the support of an excavation for a residential project, "DOX Apartments", located in Targu Mures city, Mures County, Romania.

Due to the limited space of approximately 780 sqm and the existing neighbouring buildings, the jobsite came with a lot of challenges regarding execution and design (Figure 1).

The scope of works was design and build of a pit enclosure, ensuring a 7,5 metres deep excavation in an urban environment.

Figure 1. Site layout.

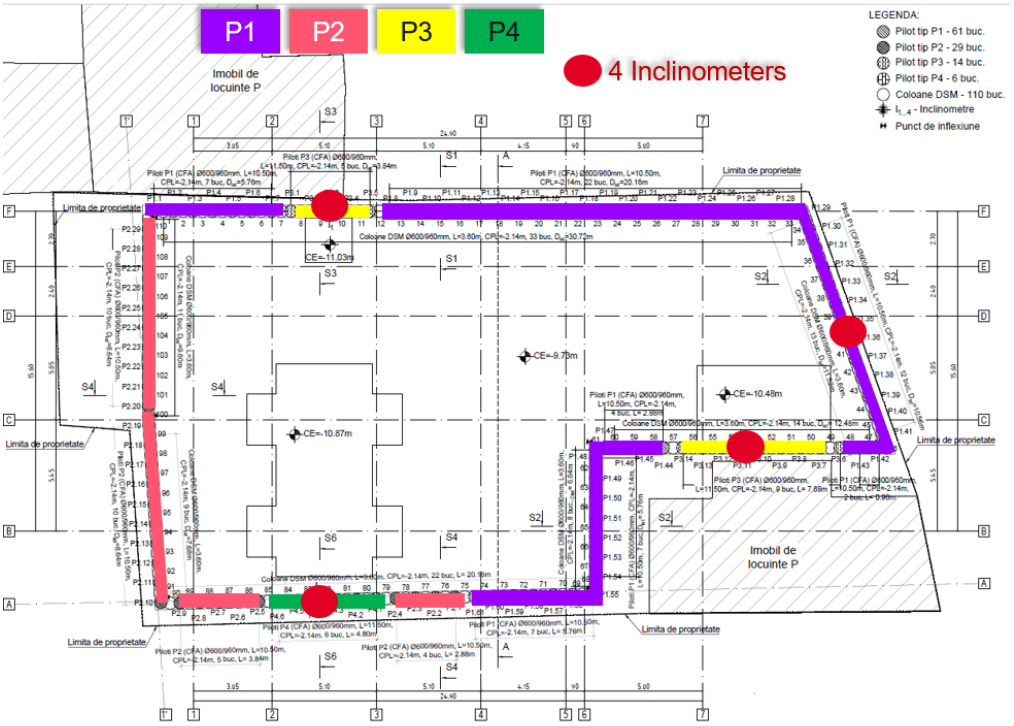

Figure 2. Pit enclosure layout.

2 SOLUTION

The soil stratigraphy encountered based on the geotechnical study was a succession of clayey sandy silt followed by a 2 metres thick non-cohesive layer, in which the water was embedded and finally a stiff marly clay.

The main solutions for properly ensuring the safe excavation until the designed level for the raft foundation consisted of making either a diaphragm wall or secant pile wall enclosure, supported by one strut level. But both diaphragm wall solution and secant piles were unable to achieve cost effectiveness, time schedule and CO2 carbon footprint as the hybrid solution presented further.

Due to the limitation of space and neighbouring buildings, the diaphragm wall solution was not feasible in this case, so the secant pile wall solution was further developed (Figure 2).

Taking into consideration the soil stratigraphy particularities in Targu Mures area, and the need to properly seal a relatively thin layer of non-cohesive soil of 2 metres, an alternative solution based on primary deep soil mixing (Colmix®) columns 600 mm and Secondary CFA 600 mm piles was proposed for this project (Figure 3).

With this solution, not only the execution schedule and the material quantities improved but also the environmental impact was lowered substantially, resulting in a much lower carbon footprint for the overall project.

Considering the purpose of the DSM columns, the most important characteristic of the treated soil was established to be the permeability and not the UCS strength, in order to properly seal the enclosure. The final mix was targeted to have low permeability (between 10^{-8} m/s and 10^{-9} m/s) and an average UCS of 1-2 MPa, to easily break through the mixed column with the CFA600 augers (secondary piles).

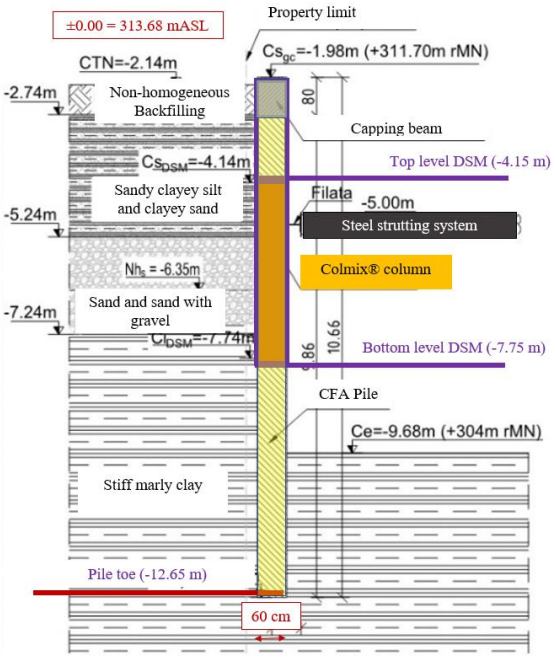

Figure 3. Characteristic section.

Bored piles give to the actual retaining wall bearing capacity, dimensioned in accordance with the loads, excavation depth and ground conditions.

Deep soil mixing columns were designed to be executed from natural ground level (-2.15 m) and embed 50 cm in the marly clay level (-7.75 m). Drilling length per one deep soil mixing column was 5.60 m with a diameter of 600 mm (Figure 4).

Figure 4. Construction site photo.

An important measure of the mixing energy imparted to the soil during deep soil mixing process is the blade rotation number (BRN), which requires a fine balance between thorough mixing and cost efficiency.

The targeted soil mixing index BRN was 360, with a permeability of 10^{-9} m/s (lower if possible) up to 10^{-8} m/s (maximum accepted to properly seal the non-cohesive layer).

Secondary piles, 600 mm diameter CFA, were done accordingly, between primary DSM columns, with specific drilling lengths as required by the design, resulting four different types of piles positioned depending on the distance to existing vicinities, on the difference of working platform levels or on locations of various sump pits.

Design approach and calculations were performed according to current regulations both Eurocode 7, (ASRO, 2004), corresponding national annex, ASRO (2007) and Romanian regulations regarding deep soil mixing and bored piles execution, ASRO (2005, 2015).

3 COLMIX® PROCESS

The Colmix® process is one of the deep soil mixing techniques and involves using a single or multiple tool to build soil mixing columns. Use of this tool requires to be attached to a capable piling rig (Figure 5).

Part of this solution is choosing the right tool and right machine for doing the process. In this case, it has been chosen a single tool having 3 levels of mixing paddles.

The tool is inserted into the ground, and it is being rotated, while the grout is injected into the soil. The tool is then raised, and the process is repeated until desired depth is reached.

The fact that this technique is relatively fast and efficient and is being also relatively environmentally friendly, made Colmix® the most suitable solution for this job. After setting up the suitable equipment, during design phase, according to site and ground conditions all construction parameters must be evaluated and selected.

Once the recipe of grout used for the mixing phase was designed, several preliminary drilling tests were performed, not only to validate proposed parameters but also to calibrate drilling speed, advancement and the quality of the mixing itself.

As required for reaching the desired blade rotation number (BRN) for local conditions, there have been established the volume of grout which needed to be incorporated by mixing, water cement ratio and, of course, the required quantity of cement.

Figure 5. Deep soil mixing tool.

After first preliminary drilling tests, it was concluded that, despite the fact that deep soil mixing was required only for 3,6 metres (from -4,15 down to -7,75 m), it was better to treat also the first two metres (from working platform level to -4,15 m), not necessarily for sealing purposes but to prevent nozzles from clogging and to reach the desired top level of actual DSM columns much more easily.

From that point down to designed bottom level of Colmix® columns, normal phase of treatment procedure – like rotation speed, tool advancement (vertical) speed and grout delivery - were followed.

Implementation of this deep soil mixing process is accompanied by real-time monitoring from a screen located in the cabin, allowing the operator to comply with the execution instructions and recording the main operating parameters during construction of each column.

An important issue is quality control which involves taking samples of the fresh soil-cement mixture to check the density of the mixture and eventually to get them tested for permeability and UCS values (Soletanche Bachy, 2013).

4 TEST RESULTS ON DSM SAMPLES

Core samples of the treated soil were collected from the spoil (the excavated material) created when the mixing tool was withdrawn from the ground after the mixing process was complete.

Laboratory testing was performed on three sets of samples, each set with three test cylinders from each DSM column, at 7, 14, and 28 days.

The tests included unconfined compressive strength (UCS) testing and permeability testing in consolidation cells.

On fresh samples collected on cylinders, permeability showed good values between 10^{-9} and 10^{-8} m/s (between targeted results) and UCS value at 28 days exceeded targeted value (2 MPa) with lower values at 14 days (about 1 MPa) and at 7 days (about 0,5 MPa).

Although UCS value exceeded the expected, primary DSM columns were easily drilled through by 600 mm CFA augers.

Core samples (Figure 6) were also tested from several columns and showed also good UCS values at an average of 1,8 MPa, with permeability values within the expected range.

Figure 6. Core samples from a DSM test column.

5 CONCLUSIONS

Deep soil mixing (DSM) columns are a proven and reliable ground improvement technique that offers several advantages over other solutions, including cost-effectiveness, sustainability, and efficiency.

The final solution for this project - combined retaining wall using deep soil mixing technique for the primary piles and CFA technology for secondary piles proved to be the perfect mix between tradition and innovation, resulting in a very successful project with an overall carbon footprint reduction of approximately 40 tons of equivalent CO2.

In other words, DSM columns are a versatile and sustainable ground improvement technique that can be used to achieve significant cost and environmental savings.

ABSTRACT: This paper describes the foundations solutions for the main stage for the World Youth Day in Lisbon 2023. The stage is located on an urban solid waste landfill that is sealed through a PEAD geomembrane, which made it impossible to use indirect foundations at an early phase. Underlying the deposits of municipal solid waste, emerges the alluvial formation composed of compressible soils, with weak mechanical characteristics, with variable thickness. In order to reduce the amplitude of differential displacements that could damage the structure, a preload landfill was carried out, in order to minimize the settlements that would occur at the time of the stage installation. During the time of permanence of the preload landfill, several reading campaigns of the instrumentation (topographic marks) were carried out in order to validate the initial assumptions. From the data collected from the instrumentation as well as from the tests carried out on site, the solution of the foundation for the stage was defined. The solution for the cover foundation was defined using ductile iron micropiles driven using the dry method, reinforced with self-drilling rod in the center, properly sealed in the miocene.

RÉSUMÉ: Cet article décrit les solutions de fondation pour la scène principale de la Journée Mondiale de la Jeunesse à Lisbonne en 2023. La scène est située sur une décharge urbaine scellée par une géomembrane PEAD, rendant impossible l'utilisation de fondations indirectes à une phase précoce. Sous les dépôts de déchets solides municipaux, émerge la formation alluviale composée de sols compressibles, aux caractéristiques mécaniques faibles, avec une épaisseur variable. Afin de réduire l'amplitude des déplacements différentiels susceptibles d'endommager la structure, un remblai de précontrainte a été réalisé pour minimiser les tassements qui se produiraient lors de l'installation de la scène. Pendant la période de permanence du remblai de précontrainte, plusieurs campagnes de lecture de l'instrumentation (repères topographiques) ont été menées afin de valider les hypothèses initiales. À partir des données collectées à partir de l'instrumentation ainsi que des tests réalisés sur place, la solution de fondation pour la scène a été définie. La solution pour la fondation de la couverture a été définie en utilisant des micropieux en fonte ductile en utilisant la méthode sèche, renforcés avec une tige autoperceuse au centre, correctement scellée dans le miocène.

Keywords: Micropiles; foundation solutions; preload landfill.

1 INTRODUCTION

For the World Youth Day event, a stage had to be set up in Parque Tejo, Lisbon. However, a challenge arose because the selected location was on a landfill of urban solid waste. Between this landfill and the competent Miocene substrate, there was a layer of sludgy materials with weak strength and high deformability characteristics. Consequently, a foundation solution had to be devised to meet the structural requirements of the installation. To address this, it was necessary to install a pre-loading embankment at the site where the stage would be supported by direct foundations. Part of the stage and its covering had to resort to indirect foundations due to an increase in the load.

To validate the solution, tests were conducted on self-drilling micropiles within the embankment.

Figure 1 shows the location of mentioned structure and their surroundings.

Figure 1. Location of the main stage.

2 MAIN CONSTRAINTS

2.1 Geological and geotechnical constraints

The target intervention area is located in a low and flat area on the right bank of the Tejo estuary.

The Main Stage will be founded on the Beirolas landfill, consisting of deposits of contaminated soils and urban waste, located on a heterogeneous landfill layer containing silty-clay materials mixed with sand and rubble of artificial origin. As the site approaches the river, the thickness of the 'artificial' landfill decreases until it disappears in the tidal zone. Beneath the artificial landfill layer, there is an alluvial formation composed of compressible silty mud soils, with highly variable thickness in the Beirolas landfill area. In the Stage area, the depth of silty mud soils increases from 2m to 25m towards the river, remaining nearly constant in the north-south direction. Underlying this layer of clayey mud, there is a Miocene formation consisting of sandstones, calcareous sandstones, and limestones, with variable presence of marly levels.

In Figure 2, we can see a schematic cross section of the main stage.

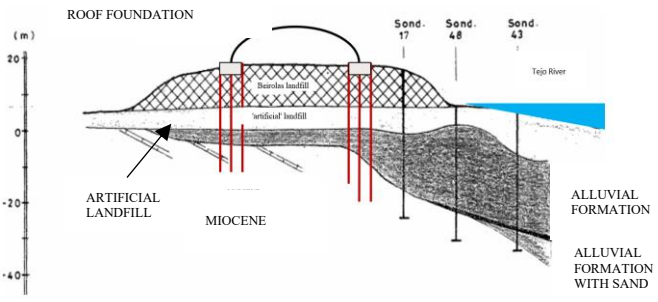

Figure 2. Cross section of the main stage. Roof foundations.

2.2 Constraints related to existing structures

To establish the foundation solutions for the stage, the initial concept was that indirect foundations were not viable due to the presence of the geomembrane protecting the landfill, making perforation impossible. Moreover, extracting the contaminated soil was not advisable. This premise applied to the entire intervention area, except for the rear zone of the stage – the southern zone – where indirect foundations were contemplated due to the magnitude of the loads to be transmitted to the foundation and the maximum permissible deformations.

2.3 Constraints related to the temporary nature of the structure

When establishing the foundation solutions for the stage, it was considered that the structure would be temporary and later dismantled. Consequently, a solution was selected for its ease of disassembly, allowing its components to be repurposed in the context of a future project.

3 ADOPTED SOLUTIONS

3.1 Pre-load embankment

The solution consisted of a pre-load embankment with a height of 3.20m in the Stage's implantation zone. The embankment was constructed with material with a bulk density of approximately 20kN/m3. The purpose of this pre-load embankment was to minimize settlements that would occur during the assembly and use of the Stage. The pre-load embankment remained in place for a period of 90 days, experiencing a maximum settlement of 25cm. To verify the design assumptions and anticipate settlements during the assembly of the stage, 16 settlement markers and 2 extensometers were installed during the pre-load phase. The outcomes for the marker A016 are illustrated in Figure 3. In Figure 4 we can see the location of all the settlement marks installed in the area of the pre-load embankment, with the identification of the marker A016.

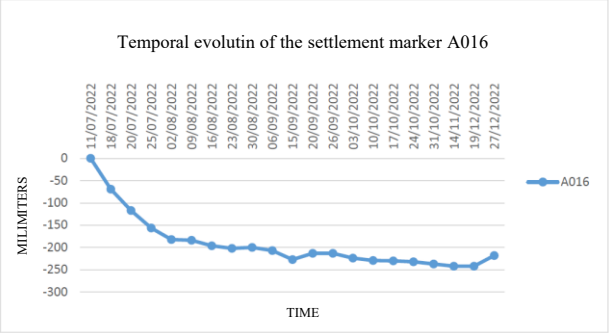

Figure 3. Time-Strain Graph. Instrumentation of the Pre-load Embankment Zone.

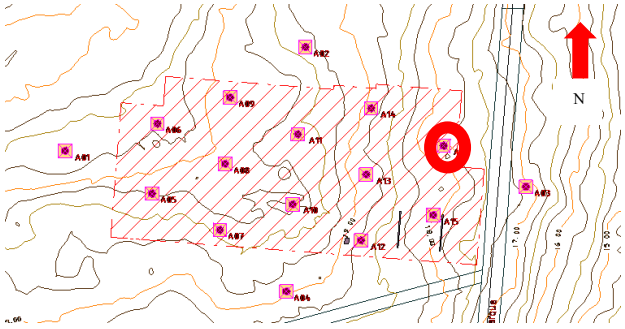

Figure 4. Location of the settlement marker A016.

3.2 Foundation

To maximize the uniformity of load transmission to the ground, the recommended solution involves the construction of a foundation slab consisting of precast hollow-core slabs with a minimum thickness of 30 cm. Due to the increased magnitude of loads in certain alignments and the irregular geometry of the foundation masses of the stage's roof, it was necessary to recommend an in-situ concrete foundation solution in these areas. Thus, the solution is divided into 4 different types:

- Current area: Solution with hollow-core slabs simply supported on precast peripheral beams with an L-shaped or rectangular section, depending on the existing level difference.
- Periphery of the stage roof foundation: Solution consisting of an in-situ concrete slab with a thickness of 30cm.
- Rear alignments – East and West zones: Solution consisting of an in-situ concrete slab with a thickness of 25cm.
- Rear alignments – central zone:

Foundation beam with a section of 1.65x1.20 m2 supported on ductile iron driven piles with a section of 170x7.5mm filled with C35/45 concrete and 3ø32mm bars inside. The foundation solution in this area was coordinated with the foundation solution of the stage roof, excluded from the scope of this article.

Figure 5 presents the 3D model of the entire foundation solution. Figure 6 and Figure 7 was taken during the construction phase and we can see the assembly of the hollow-core slabs. Figure 8 show the section of the ductile iron driven pile and the asse.

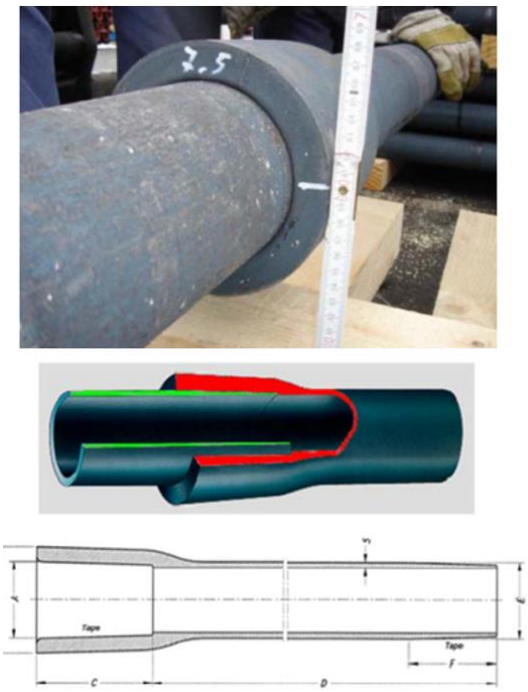

Figure 8. Ductile iron driven piles with a section of 170x7.5mm.

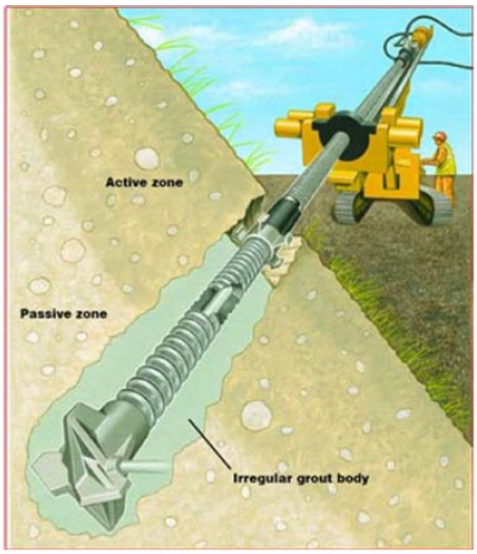

Figure 9. Self-drilling micropile system along the grout bonding legth. Solution for the stage roof foundation.

4 LOAD TESTS OF DRIVEN MICROPILES

Given the uncertainty associated with the behaviour of the micro piles executed in these materials, it was necessary to carry out load tests to validate the design assumptions. For this purpose, two full-scale load tests were conducted, one in compression and one in tension.

For both test micropiles, interior instrumentation was applied using strain gauges introduced with a ø16mm rod.

4.1 Tension load test

The reaction structure was materialized through a reinforced concrete mass, approximately 2.5m x 2.5m x 1m in size, as shown in Figure 9. The tested micropile had a length of 30.50m, reaching the Miocene substrate, and the self-drilling interior micropile had a length of 41.5m with an approximately 10m grout bonding length in the Miocene substrate (Bustamante and Doix, 1985). The planned test load was 850kN. The load test was conducted with four loading cycles up to the maximum load of 922kN. Additionally, a fifth loading cycle was performed up to 1598kN to test the load-bearing capacity of the sealing in the Miocene stratum. Even after reaching the load of 1598kN, no failure was observed.

Figure 10. Tension load test.

For the 922kN test load, a strong response was observed in all loading cycles, with a plastic deformation of approximately 13mm and a maximum deformation of 33mm. In the 5th loading cycle, a total deformation of about 59mm was observed, with a residual deformation of 20mm. A set of strain gauges was installed at depths of 2.5m, 10m, 20m, 26m, 30m, and 38.5m, particularly at the transition between the embankment and the alluvial stratum.

The consistency of results in the 4 loading cycles is noticeable, with pressure curves parallel to each other. It is clear that the top of the alluvial stratum is at an elevation of 20m, which is consistent with the results of the boreholes conducted on-site. It is observed that 50% of the load is transmitted to the embankment, and 30% of the grout bonding length was not engaged. However, due to the significant heterogeneity of the embankment material, it was considered that the sealing length should not be less than 10m (Bustamante and Doix, 1985), in order to accommodate the entire tensile load.

The main results of the conducted test are shown in Figure 10 and Figure 11.

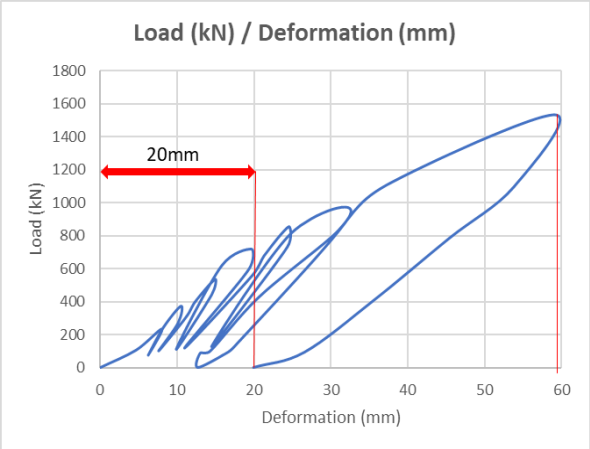

Figure 11. Load-displacement graph at the head. Tension load test.

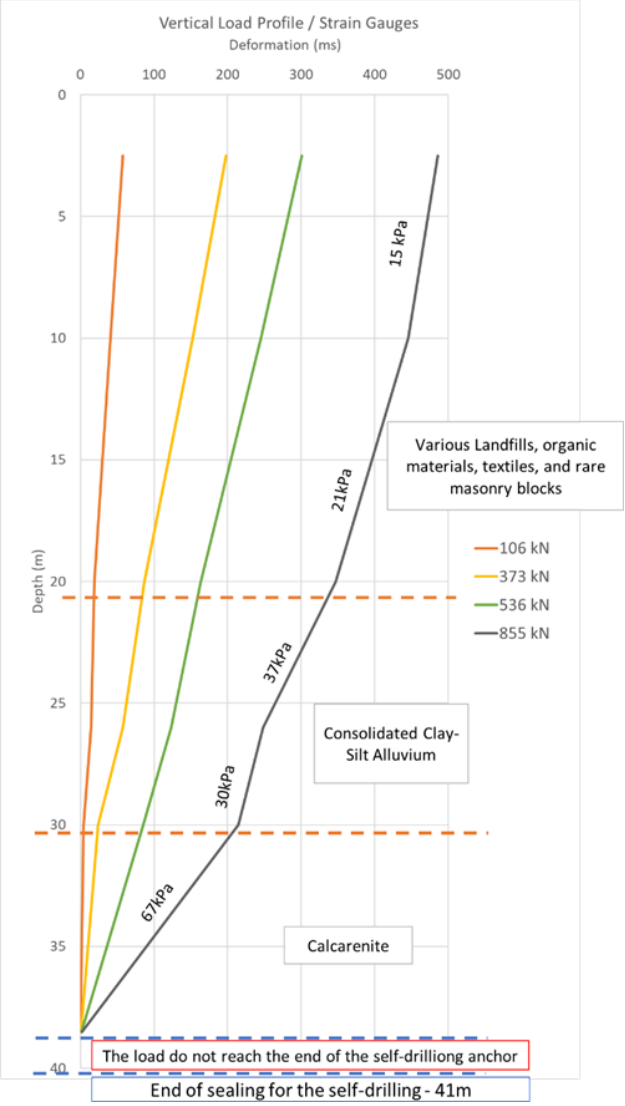

Figure 12. Strain gauges graph - Tension pre-test.

4.2 Compression load test

The reaction structure was constructed using a portal frame consisting of metal profiles supported on 4 micropiles similar to the micropile tested in tension. The structure is illustrated in Figure 13. The tested micropile had a length of 34.00m, reaching the Miocene substrate. The planned test load was 1820kN. Despite extreme care in aligning the jack with the axis of the micropile, instability of the micropile head mass was observed above a load of 1400kN with horizontal displacement of the mass to the west and north, as shown in Figure 14. Despite the rotation of the mass when the load exceeded approximately 1400kN, a continuous increase in load capacity of approximately 300kN was observed up to 1723kN.

Figure 13. Reaction structure for the compression load test.

The main results of the conducted test are shown in Figure 14 and Figure 15.

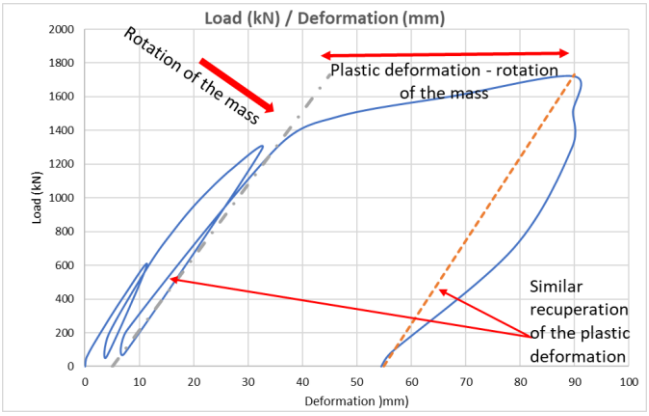

Figure 14. Load-displacement graph at the head. Compression load test.

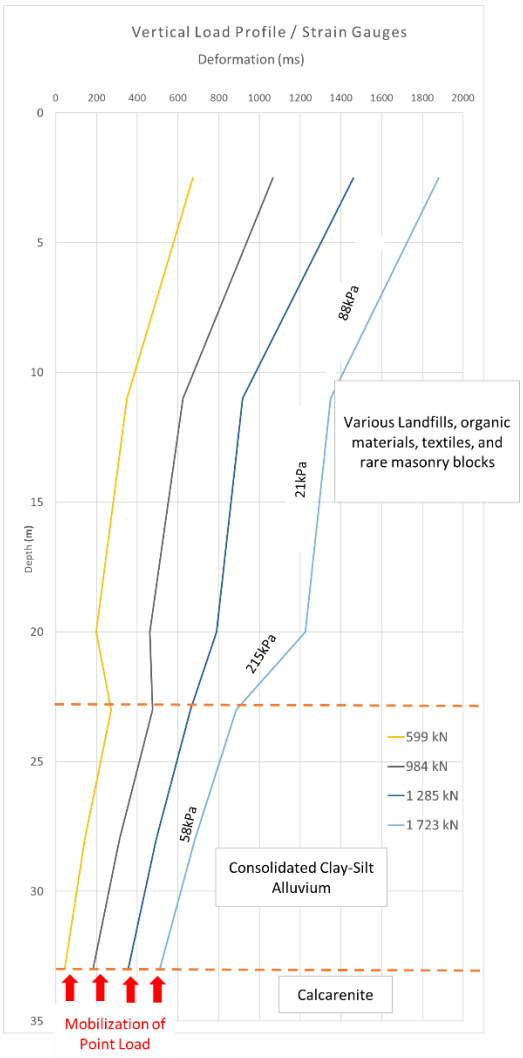

Figure 15. Strain gauges graph - Compression pre-test.

Figure 15 shows te measuring results of a set of strain gauges was installed at depths of 2.5m, 11m, 20m, 23m, 28m, and 33m, particularly at the transition between the embankment and the alluvial stratum. There is consistency in the results in the 4 loading cycles with pressure curves parallel to each other. It is clearly observable that the top of the alluvial stratum is at an elevation of 23m, which is consistent with information from boreholes conducted on-site. There was a significant load transmission capacity to the embankment with a firm response between 2.5m and 11m and a very good response between 20m and 23m depth. Between the depths of 11m and 20m, the load transmission to the embankment was negligible. The mobilized tip load is estimated to be around 600kN for a load on the order of 1700kN. It is estimated that the compressive capacity of the pile formed by the ductile iron outer micropile and the self-drilling inner bar is above 1800kN, with a plastic displacement of about 20mm and 40mm when subjected to a load of 1800kN.

5 CONCLUSIONS

The purpose of this article was to present the foundation solution for the main stage of the World Youth Day, highlighting the various constraints that influenced the choices and decisions made.

Based on the previously described constraints and on the results of the mentioned load tests, the adopted solution consists of a foundation slab made up of precast hollow-core slabs with a minimum thickness of 30 cm, which can be removed. In the heavily loaded alignments, the solution transitions from direct to indirect foundations using ductile iron driven micropiles, topped with foundation beams measuring 1.65x1.20m, connected by perpendicular beams with a section of 0.40x0.80m.

The possibility of removing the structures was taken into consideration, and whenever possible, solutions were adopted that would simplify demolition/dismantling, allowing the constituent parts of the structures to be potentially reused.

To validate the design assumptions of the foundation micropiles, two load tests were conducted at the stage location, one in compression and one in tension. The obtained results allowed for the early validation of the main design assumptions, ensuring the suitability of the solution to the local geological-geotechnical context.

The suitability of the solution to the implementation site was verified based on the results of the conducted tests and continuous monitoring of the construction work and the micropile driving results.

ABSTRACT: This article presents the earth retaining, underpinning and facades retaining solutions as part of the refurbishments works of the 260 years old Pedrosas (CTT) Palace, in Lisbon. To allow the construction of new basements, under the original foundations of the masonry building, it was necessary to design earth retaining and facades underpinning compatible solutions.The earth retaining solution consists of a reinforced concrete wall, built using the King Post Wall technique, temporary braced by ground anchors and steel struts. The underpinning and the temporary structures of the foundation were carried out using tubular micropiles. The main design criteria are presented, as well as the main monitoring and survey results.

RÉSUMÉ: Cet article présente les solutions de soutènement du terrain, de reprise en sous-œuvre et de maintien des façades dans le cadre des travaux de rénovation du Palais Pedrosas (CTT), avec 260 ans, à Lisbonne. Pour permettre la construction de nouveaux sous-sols sous les fondations d'origine du bâtiment en maçonnerie, il a été nécessaire de concevoir des solutions compatibles de soutènement du terrain et de sous-bassement des façades. La solution de soutènement consiste en une paroi avec la technique de King Post Wall, en béton armé, temporairement stabilisé par des ancrages au sol et des tirants en acier. Les travaux de fondation, de reprise en sous-œuvre et des structures temporaires ont été réalisés à l'aide de micropieux tubulaires.Les principaux critères de conception sont présentés, ainsi que les principaux résultats de surveillance et d'étude.

Keywords: Earth retaining wall; underpinning; façade retaining.

1 INTRODUCTION

In the scope of the redevelopment of Palácio das Pedrosas (CTT), located on São José Street in Lisbon, it was necessary to carry out a project involving excavation and peripheral earth retaining with facade underpinning. According to the aerial view presented in Figure 1, it is possible to identify the approximate layout of the construction, as well as some of the most relevant boundaries and constraints. The referenced area has boundaries to the north with an existing building that needs to be preserved.

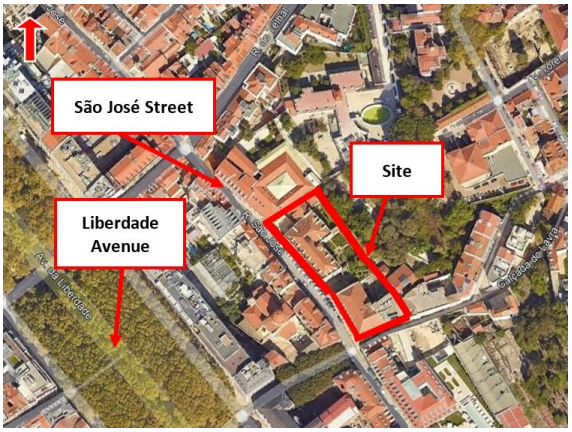

Figure 1. Site location.

The following figure shows the areas to be excavated beneath the existing structure.

Figure 2. Areas to be excavated under the existing structure.

As an old building, the solution to be adopted was conditioned by various factors, making this project quite challenging.

2 MAIN CONSTRAINTS

2.1 Constraints related to the building's boundaries

In this intervention, several underground floors will be executed, being adjacent to neighbouring buildings and roads. The proposed solutions must, therefore, be compatible with preserving the integrity of all structures and infrastructure located outside the perimeter of the construction site, ensuring their functionality conditions.

2.2 Constraints related to the need to preserve facades and structural walls.

Given the necessity to maintain the integrity of the majority of the main building facades, it is considered essential that the intervention be carried out in a way that minimizes its impact on their stability and appearance. Equally important was the adoption of construction solutions compatible with the use of equipment suitable for the available spaces and access, allowing the execution of the works while limiting the occurrence of vibrations and noise.

2.3 Geological and geotechnical constraints

According to the data collected during the geotechnical characterization campaign and considering the geology described in the geological map, the following lithological strata were identified on-site:

- Landfills: Detected in the superficial zone of all boreholes, with thickness ranging from approximately 0.20 to 0.50m. They are heterogeneous landfills with masonry fragments, primarily silty-clayey, and brownish.
- Prazeres Clays and Limestones: The Miocene levels are represented by alternating silty and clayey levels. The silty levels sometimes have transitions with fossil fragments and/or marly materials, with greenish to greyish tones. The more clayey levels often appear slightly micaceous and with darker tones. Generally, they exhibit plastic behaviour.

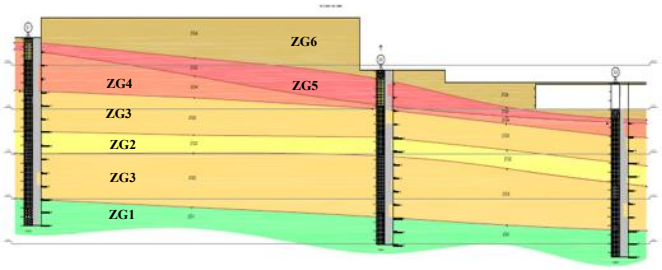

Figure 3. Soil profile.

Table 1. Geological and geotechnical parameters.

Geotechnical zone	N_{SPT}	Lithology	φ' (°)	C' (kPa)	γ' (kN/m3)	E' (MPa)
ZG6	-	Silt-sandy embankments with masonry fragments, all-in-one, concrete, and pavements	5 - 10	-	16 - 17	5 - 10
ZG5	2 - 9	Clayey silts and silty clays	10 - 15	5 - 15	17 - 18	10 - 15
ZG4	16 - 26 (16 - 18)*	Clayey silts and silty clays	15 - 20	15 - 20	18 - 19	20 - 25
ZG3	21 - 56 (21 - 42)*	Clayey silts and silty clays	20 - 25	20 - 30	19 - 20	30 - 40
ZG2	>60	Clayey silts and silty clays	25 - 30	40 - 60	20 - 21	50 - 60
ZG1	>60	Clayey silts, silty clays, calcareous marls/marly limestones	25 - 35	60 - 80	21 - 23	60 - 100

3 ADOPTED SOLUTIONS

The proposed solutions for the execution of facade underpinning and excavation with peripheral earth retaining are interconnected and are as follows:

- Excavation and peripheral earth retaining: to be carried out using the king post wall technology.
- Underpinning and earth retaining of preserved facades: to support the existing facades, it is proposed to install a steel structure for earth retaining and stabilization. The solution of the

facade containing structure is beyond the scope of this article.

The proposed solutions considered the necessary coordination between the two types of interventions described.

Concerning the structure of the peripheral earth retaining wall, considering the evaluation of the main constraints, it was proposed that, in general, the excavation of the underground floors be carried out under a peripheral earth retaining using the king post wall technology. The proposed construction technology for the 'king post wall' type earth retaining wall involves the phased execution, from top to bottom, of reinforced concrete panels supported by vertical micro-piles. These micro-piles, materialized by tubular profiles Ø88.9x9.0mm and Ø114.3x9.0mm with external joints, made of high-strength steel (fsyd > 560MPa), will also support the underpinning beams of the facade. These elements should be executed with the minimum possible distance from the facade and walls of neighbouring buildings, solidified through steel brackets.

The total length of the micro-piles will vary based on the elevation geometry, and the minimum of the sealing lengths (calculated by the Bustamante method) to be executed using the IRS system (repetitive and selective injection), employing a double plug and check valves, in competent soils with strength and deformability characteristics compatible with N_{SPT} greater than 35 blows and geologically stable concerning the excavation geometry.

This solution has the advantage of allowing the execution of the permanent wall during excavation. The number of temporary bracings (steel props and anchors), as well as excavation constraints, can be redefined during the construction phase based on the actual characteristics of the excavated soils and the results of the Instrumentation and Observation Plan.

In cases where underpinning the facade is necessary, a beam is required to have the capacity to transmit loads from the facades to the foundations, materialized by the micro-piles.

In the permanent phase, the structure of the slabs and foundation elements will be responsible for the stability of the earth retaining wall, and the temporary props will be removed after the completion of the said structure, and the anchors will be deactivated.

A 3D model is presented in Figure 4, where the existing facade elements to be preserved are represented in light blue, the underpinning beam to be executed in orange, and the earth retaining walls to be constructed for excavation work are shown in grey.

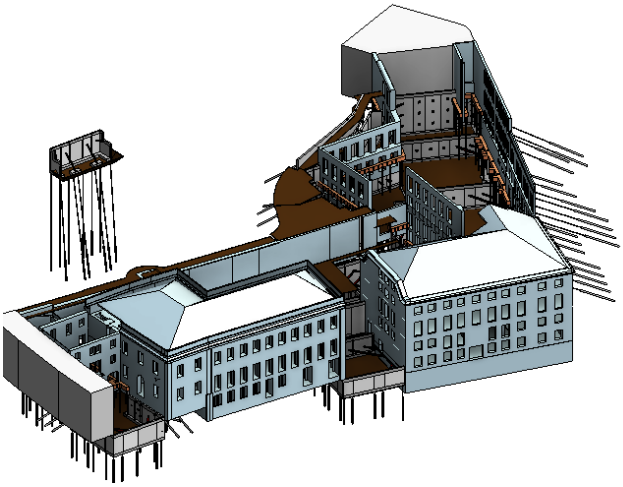

Figure 4. 3D view of solutions for excavation and peripheral earth retaining.

4 DESIGN

The finite element program Plaxis 2D was used for the design of the peripheral earth retaining walls to be executed using the king post wall technology.

Micro-piles and walls were modelled as "Plate" elements, sealing bulbs were modelled as "Embedded beam row" elements, and pre-stressing tendons were modelled as "Node-to-node-anchor" elements.

The forces are estimated considered the construction process, especially the excavation and construction phases of the peripheral earth retaining wall. Soil elements were modelled considering the previously presented geo mechanical properties and following the "Harding Soil" model.

Figure 5 shows the adopted model. This section corresponds to the maximum excavation height with the highest number of anchors in the whole retaining structure.

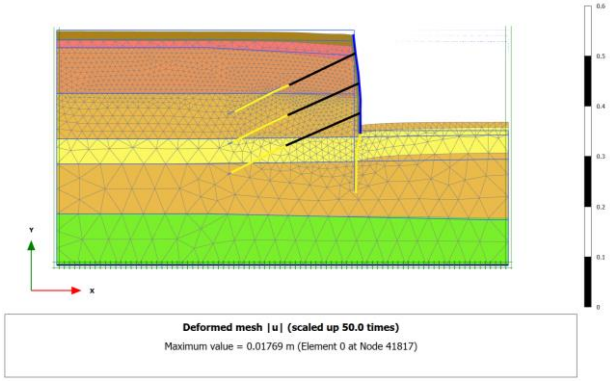

Figure 5. Total displacements – 1.7cm.

After the execution of the interior structure of the building, in the permanent phase, the bracing of the earth retaining is guaranteed by the structure of the underground floors. In the design of the peripheral

earth retaining, loads from the building structure were considered. For locations where the micro-pile is located outside the earth retaining wall, it was necessary to verify safety against buckling. In areas where the micro-pile is used simultaneously to support the peripheral earth retaining and for facade underpinning, the additional load from it was considered.

5 MONITORING AND SURVEY PLAN

As the construction is still in the early stages of demolition, the results of the monitoring and survey plan are not yet available. However, the proposed Monitoring and Survey Plan aims to ensure the safe and economical execution of demolition, excavation, and construction of earth retaining structures. It also involves the analysis of the behaviour of preserved facades and neighbouring structures and infrastructure during this construction phase. Thus, the proposed plan should allow the measurement, during excavation and construction of earth retaining structures and the underground floor, of the following parameters:

- Horizontal and vertical displacements of earth retaining structures.
- Horizontal and vertical displacements of neighbouring constructions.
- Measurement of tension/load at ground anchorages.
- Horizontal displacements in neighbouring structures and in the earth retaining.

The parameters described above will be measured using the following:

- Topographic targets for measuring parameters mentioned in a).
- Topographic targets for measuring parameters mentioned in b).
- Load cells in anchorages for measuring the parameter mentioned in c).
- Inclinometers for measuring the parameter mentioned in d).

6 FINAL REMARKS

The purpose of this article was to present the underpinning and peripheral earth retaining solutions adopted in a rehabilitation project to be carried out in the centre of Lisbon, in a densely urbanized area.

One can conclude that each work is unique, and even if the solution is conceptually the same, it should always be adjusted to the existing and exclusive constraints of each work itself. In this case, an attempt was made to define a solution that would better adapt to all mentioned constraints, from both technical and economic issues.

The use of foam glass for a lightweight fill and highway foundation on soft soil conditions

L'utilisation de verre mousse pour un remblai léger et une fondation d'autoroute sur des sols mous

J.W.R. Brouwer*, C.R. van Laerhoven
Geobest BV, Vianen, The Netherlands

**roel.brouwer@geobest.nl*

ABSTRACT: In soft soil conditions, the construction of embankments may cause significant subsidence during lifetime of the construction. The standard procedure to avoid large remaining settlements after project completion is pre-loading, often in combination with vertical drainage. However, this approach is time-consuming, costly, and has a considerable carbon footprint. For a highway in the province of Zeeland (The Netherlands), an alternative solution was found using foam glass as a lightweight fill material. The subsoil consists of highly compressible clay and peat layers with an average thickness of 8 m. Foam glass was also used to construct a stabilized foundation layer for support of the road construction. The stabilization consists of a mixture of foam glass, cement, in situ clay and the Geosta® additive. This innovative approach accelerates the building process and reduces the carbon footprint of the project considerably. Furthermore, the stabilized foam glass forms a foundation layer with considerable strength and stiffness, which may reduce the required asphalt thickness.

RÉSUMÉ: Dans des conditions de sol mou, la construction de remblais peut provoquer un affaissement important pendant la durée de vie de la construction. La procédure standard pour éviter les tassements importants après l'achèvement du projet est le préchargement, souvent associé à un drainage vertical. Cependant, cette approche prend du temps, est coûteuse et a une empreinte carbone considérable. Pour une autoroute dans la province de Zélande (Pays-Bas), une solution alternative a été trouvée en utilisant du verre mousse comme matériau de remplissage léger. Le sous-sol est constitué de couches d'argile et de tourbe hautement compressibles d'une épaisseur moyenne de 8 m. Du verre mousse a également été utilisé pour construire une couche de fondation stabilisée destinée à soutenir la construction de la route. La stabilisation est constituée d'un mélange de verre mousse, de ciment, d'argile in situ et de l'additif Geosta®. Cette approche innovante accélère le processus de construction et réduit considérablement l'empreinte carbone du projet. De plus, le verre mousse stabilisé forme une couche de base présentant une résistance et une rigidité considérables, ce qui peut réduire l'épaisseur d'asphalte requise.

Keywords: Stabilisation; Geosta®; foam glass; embankment; compressible.

1 PREAMBLE

The municipality of Borssele, located in the southern part of the Netherlands, intends to construct a new road around the village of Hoedekenskerke. This new road is required because of the increasing traffic in the centre of this village.

The new road will be built on an embankment on soft soil. The municipality, in collaboration with contractor Traas en Ovaa, sought to find an economical yet sustainable solution, where the carbon footprint is reduced using innovative solutions.

Traditionally, road construction in such areas would involve creating an embankment of sand, topped with an aggregate layer and asphalt. The soft soil conditions however would urge to pre-load the soil with sand or granular material. Preliminary assessments indicated that sand fills up to 8 meters high would be required to meet settlement requirements post-project completion. This approach would not only lead to significant delays but also result in a substantial carbon footprint, primarily due to the extensive need for sand transport. Additionally, concerns about traffic noise, vibrations, and pollution in the small village could potentially provoke considerable local protests. In response to these challenges, an alternative was found in the use of lightweight fill materials and a lightweight foundation layer but with a strength and stiffness larger than traditional foundation layers.

2 SOIL CONDITIONS

The geotechnical investigation for the proposed road construction in Borssele was comprehensive, involving Cone Penetration Tests (CPT), boreholes with undisturbed sampling, and an extensive laboratory testing program that included triaxial and oedometer tests. The CPTs were conducted using ISO 22476-1 Class 2 equipment. Figure 1 presents a typical CPT profile from the site, illustrating the subsurface stratigraphy. The results revealed soft, compressible soil layers extending to approximately 8 meters below ground level. These layers belong to the Holocene epoch and are primarily composed of normally consolidated clay, interspersed with organic material in some strata.

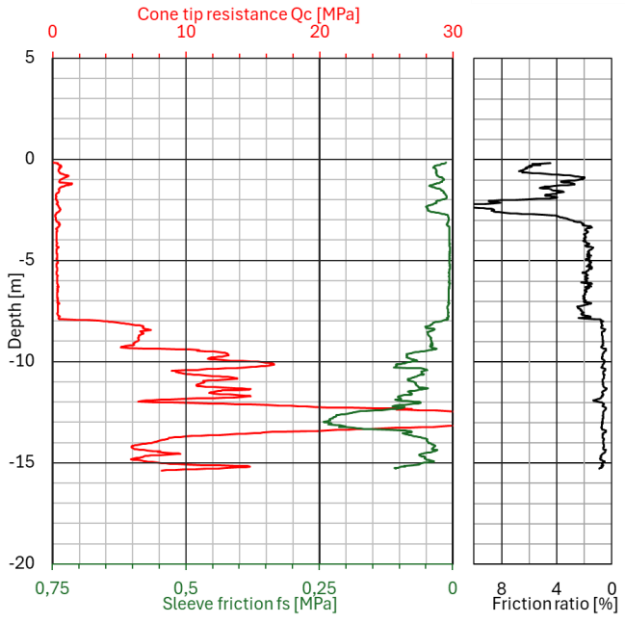

Figure 1. Typical CPT at project location.

3 DESIGN

3.1 The material foam glass

Foam glass is a porous glass foam material. It is made by heating a mixture of crushed or granulated glass and a blowing agent (chemical foaming agent) such as carbon or limestone. Near the melting point of the glass, the blowing agent releases a gas, producing a foaming effect in the glass. After cooling the mixture hardens into a rigid material with gas-filled closed-cell pores comprising a large portion of its volume. The grain shape of the material can be compared to natural sand.

Glass foam has a dry unit weight of 2 kN/m^3. The foam consists of closed cells, which prevents water attachment to the glass particles. In theory, the unit weight of the material in an embankment would remain at the original value. However, when placed below groundwater levels, some water intake may occur over the lifetime of the construction. This absorption can increase the unit weight of the material to approximately 7 kN/m^3. In this case study the foam glass was only used above groundwater levels, so this would not be a problem. As a safe approach, a unit weight of 4 kN/m^3 was adopted in the design of the embankment and the settlement calculations, which is still considerably lower than usually adopted sand as fill material (unit weight 18 kN/m^3 when compacted).

Foam glass is an environmentally safe material and causes no pollution when (in long term) used in embankments. The environmental aspects of the foam glass material are described in Rood and Klein (2014).

3.2 Embankment fill with foam glass

The practical experience with foam glass in the construction of embankments on compressible soils is described in Gold and Dietrich (2014).

The embankment for the new road utilizes foam glass as its primary fill material, capitalizing on its unique properties to address the challenges posed by the underlying soft soil. The key advantage of using foam glass in the embankment is its significantly lower unit weight compared to traditional fill materials, such as compacted sand or gravel. This reduced weight decreases the vertical stress exerted on the soft subsoil, minimizing the risk of excessive settlement and instability. Additionally, the closed-cell structure of foam glass offers excellent resistance to water absorption, maintaining its low weight and structural integrity even in varying environmental conditions.

In the construction of the embankment, careful attention was given to the layering and compaction of foam glass to ensure uniformity and optimal load distribution. The design also took into consideration the drainage and erosion control aspects, ensuring the longevity and durability of the embankment. By choosing foam glass, the project not only addresses the geotechnical challenges but also contributes to sustainability, as foam glass is often made from recycled materials.

3.3 Stabilised foundation layer

The foundation layer of the new road is a composite structure, stabilized with a mixture of foam glass, cement, in situ clay, and the Geosta® additive. This innovative approach creates a foundation layer with enhanced strength and stiffness, suitable for supporting the road structure while distributing loads evenly across the underlying soft soil.

The stabilization process involves thoroughly mixing the components, where the foam glass provides volume and reduces the overall weight, while cement

acts as the primary binding agent. The addition of Geosta® enhances the mixture's properties, improving flexibility and load-spreading behaviour, crucial for road foundations over soft soils. The use of in situ clay in the mix helps in achieving an eco-friendly solution by recycling existing materials and reducing the need for importing new fill materials.

The layer's design ensures it has sufficient bearing capacity to support the road and traffic loads without undergoing significant deformation or settlement. The stabilized foundation layer also contributes to a reduction in the required thickness of the overlying asphalt layer, leading to cost savings and a further reduction in the project's carbon footprint. This layer represents a fusion of traditional and modern construction techniques, resulting in a durable, resilient, and environmentally sensitive road foundation.

4 SOIL STABILISATION PRINCIPLE

4.1 Use of Geosta®

Geosta® is a mixture of inorganic salts, that in combination with hydraulic binders such as Portland cement or lime, is applied in soil stabilisation. By adding Geosta® to the cement a noticeable improvement of the soil stabilisation is realized (Omotosho, 2005), especially in flexibility and load spreading behaviour. Geosta® is a mixture of zeolites, oxides (aluminium, magnesium, and silicon oxide) or chlorides (magnesium, sodium, potassium and calcium chlorides). A regular formula is a mixture of 1.5 – 2.0 kg Geosta® with 100 kg cement per m^3 of soil.

Geosta® stabilised soil is applied as a hardstand foundation for several wind farms in the Netherlands (Brouwer and van der Veer, 2021).

4.2 Lime pre-treatment

In cases where the stabilization involves clayey soil, a pre-treatment with lime is often necessary. Clay particles tend to exhibit a delayed and often incomplete chemical reaction with cement and lime. Pre-treating the clay with lime leads to a more effectively stabilized product. This is attributed to the chemical interactions between lime and clay particles, as represented by the following reactions:

$$CaO + H_2O \rightarrow CA(OH)_2 \quad (1)$$

$$CA(OH)_2 + CO_2 \rightarrow CACO_3 + H_2O \quad (2)$$

where:

- CaO presents (quick) lime.
- H_2O is water.
- $Ca(OH)_2$ is hydrated lime.
- $CaCO_3$ is calcium carbonate.
- CO_2 is carbon dioxide.

This process leads to an upgrade of the clay material with considerably lower water content and a more granular-type behaviour.

5 TESTING

5.1 Laboratory

Prior to the design of the embankment and road foundation, samples were made in laboratory circumstances. Figure 2 shows 2 samples that were constructed. The mix consisted of clay, as found in the top layer at the project site, foam glass, cement and the Geosta® additive. The relation between the amount of foam glass and clay varied between 1:2 and 1:3.

Figure 2. Sample of stabilised foam glass.

The above mentioned samples were tested in the laboratory for compression strength. The results showed that the unconfined compression strength (UCS) varied between 1.9 and 2.1 N/mm^2. A clear distinction between the several used mixtures in terms of relation between foam glass and clay could not be made.

5.2 Test site

A test site was constructed by the contractor on a location close to the new road. Soil conditions at the test site were comparable to the final road location.

At the test site, a mixture was made (mixed in place) consisting of the locally available clay, Portland cement, Geosta® and foam glass. The ratio between clay and foam glass was initially set on 1:2. The mixture furthermore consisted of 150 kg Portland cement

and 1.5 kg Geosta® per m^3 soil/foam glass. The stabilised layer had a thickness of 400 mm and was constructed on top of the clayey subsoil.

Figure 3. Test site 1.

For the design of the road construction, the unconfined compression strength UCS and the static flexural stiffness $E_{stat,flex}$ was required. Plate load test according to DIN 18134 were carried out on the test site with a plate diameter of 300 mm to derive the static stiffness modulus. The results proved to be on the lower site. An average E_{v1} modulus of 85 MPa was derived, which is considered very low for a cement stabilised soil. This value was sufficient for the road deign design but insufficient to reduce the thickness of asphalt layers.

Additionally, cores were drilled to assess the strength of the layer in the laboratory. The drilled samples exhibited significantly lower unconfined compression strength (UCS) values, ranging between 0.4 N/mm² and 1.1 N/mm²

5.3 Comparison with literature and database

Numerous publications exist on the topic of the correlation between strength and stiffness of stabilised soils. A very large variation in correlations can be observed (Biswal et al, 2018).

The Geobest in-house database contains a large number of tests on Geosta® stabilised soil samples where UCS as well as flexural stiffness is determined in the laboratory. Based on these results, a correlation can be determined between both parameters. The results are graphically shown in Figure 4. A distinction was made between soil stabilisation with granular and cohesive materials.

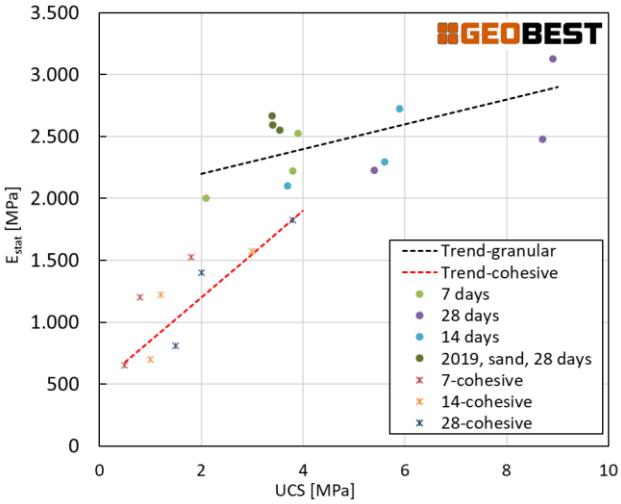

Figure 4. Static flexural E-modulus based on UCS tests.

Based on the correlation for cohesive soils, a stiffness of between 500 and approx 750 MPa could be expected. This is considerable higher than the above mentioned values form the plate load tests.

The large difference between the E_{v1} modulus determined in the field and the E-modulus in the correlation can be explained by a number of reasons:

- The modulus from the plate load test is a purely settlement related parameter and may be regarded as an short term oedometer stiffness rather than a flexural stiffness.
- The plate load test has an influence depth of 2D-3D, so in the worst case 900 mm. With a layer thickness of 400 mm, the compressible subsoil will influence the outcome significantly.
- The relationship from Figure 4 was derived under ideal laboratory conditions and therefore may not fully reflect the values that can be reached in practice.
- The execution of the test site was not ideal in terms of compaction, water saturation and particle size of the glass foam particles.

Based on these findings, it was decided that an additional test site was required and that further study on the flexural stiffness would be beneficial for the project.

6 CONCLUSIONS

This example demonstrates the potential of foam glass as a sustainable alternative for embankment construction in soft soil conditions.

The use of foam glass in a stabilised foundation layer is still an innovative and new solution. Additional research has to be performed towards the ideal mixing circumstances and the strength and stiffness parameters that can be obtained. The method is promising and may lead to a reduction of foundation and asphalt thickness, which is beneficial in terms of reduction of costs and carbon footprint.

At this moment the municipality of Borssele is in the process of decision making on this project. Construction of the road may take place in the second or third quarter of 2024. First step is to construct an additional test site, where the lessons learned from previous test sites are incorporated. The additional tests will lead to an upgraded design where all the benefits of this innovative method are included.

ACKNOWLEDGEMENTS

The authors would like to thank the contractor Traas en Ovaa BV and the municipality of Borssele for their cooperation for this paper.

Sensitivity analysis of load transfer curves in case of rigid inclusions

Analyse de sensibilité des courbes de transfert de charge dans le cas d'inclusions rigides

P. Burtin*
Menard, Chaponost, France

J. Racinais
Menard, Orsay, France

**pierre.burtin@menard-mail.com*

ABSTRACT: The soil reinforcement by rigid inclusions is usually a suitable solution in various projects such as shallow foundations, slab-on-grade, embankments, tanks, etc. In most cases, the settlement is a key point. The interactions between the rigid inclusion and the surrounding soil must therefore be well established, especially the behaviour laws along the shaft (skin friction) and at the tip (end-bearing). In France, the Frank and Zhao load transfer curves are often used to model those interactions. The input parameters are determined from the pressuremeter tests. Those tests are not always available, especially outside France. Some authors and standards have proposed other load transfer curves. This article summaries the main used interaction behaviour laws and presents sensitivity analysis, based on simulated load tests on isolated rigid inclusions and also based on regular design cases.

RÉSUMÉ: Le renforcement de sol par inclusions rigides est généralement une solution adaptée dans divers projets tels que fondations superficielles, dallages sur terre-plein, remblais, réservoirs, etc. Dans la plupart des cas, le tassement est un point clé. Les interactions entre l'inclusion rigide et le sol environnant doivent donc être bien estimées, notamment les lois de comportement en frottement latéral le long du fût et en pointe de colonne. En France, les courbes de transfert de charge proposées par Frank et Zhao sont souvent utilisées pour modéliser ces interactions. Les paramètres d'entrée sont déterminés à partir des essais pressiométriques. Ces sondages géotechniques ne sont pas toujours disponibles, notamment hors de France. Certains auteurs et normes ont proposé d'autres courbes de transfert de charge. Cet article résume les principales lois de comportement d'interaction utilisées et présente des analyses de sensibilité, basée sur des tests de chargement sur des inclusions rigides isolées mais aussi sur des cas de dimensionnement classique.

Keywords: Rigid inclusions; load transfer curves; skin friction; end-bearing; soil reinforcement.

1 INTRODUCTION

As a solution of soil reinforcement, rigid inclusions (RI) often serve as a valued engineered substitution to deep foundation techniques such as piles, and provide cost savings, shorter schedules, and high effectivity in difficult foundation conditions such as loose/soft fine-grained soils and organic soils (Magnan 1994, Briet & Plomteux 2010, Burtin & Racinais 2016, Sahyouni et al. 2021). The technique widely used today has experienced a great evolution in the number of projects carried out and the fields of application since the 1990s (Racinais et al. 2016). The fields of application cover all areas of construction: housing, industrial and commercial buildings, road embankments, railway embankments, storage tanks and finally onshore wind turbine (ASIRI 2013).

Rigid inclusions are an intermediate solution between shallow and deep foundations to reduce settlement and increase the bearing capacity and/or ensuring the stability (Figure 1). A load transfer platform (LTP) is generally placed or not in between the foundation and the rigid inclusion head, in both cases the important advantage is to be not linked to the structure.

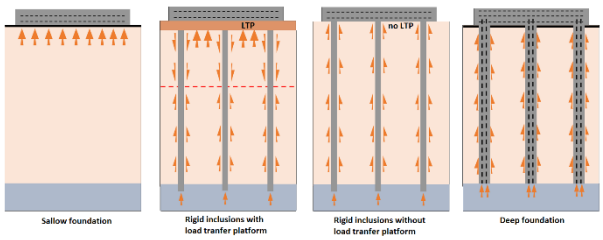

Figure 1. The various types of foundations.

The ground improvement by rigid inclusion consists in the transfer of a part of the load into the columns the other part going into the surrounding soft soil. The load transfer platform permits to share the load from the structure onto both elements at the level of column head. Then deeper, the contrast of the rigidity and loading generates a differential settlement and a load transfer from the soil to the columns is developed by negative skin friction along the shaft of the inclusion. At a certain elevation the settlement of the soil and the column is equal, that level is called "neutral plan". Below the column settles more than the soil, a load transfer from the column to the soil is generated by positive skin friction. At the toe of the rigid inclusion a load transfer occurs into the anchorage layer (end-bearing).

The interactions between the soil and the rigid inclusion are an important assumption and depend on the different load transfer especially along the shaft (skin friction) and at the tip (end-bearing). Several authors have proposed load transfer curves that are based on different approaches, return of experience such as static load test, etc.

During the design stage of a rigid inclusion project the designer should assume the above soil/inclusion interactions. The article proposes to present a part of the author propositions around the world in term of load transfer curves Then the settlement during a static load test on an isolated column will be predicted with the various approaches. In second part, the calculations of the slab-on-grade founded on the rigid inclusion will be presented and also with the different assumptions.

2 LOAD TRANSFER CURVES

The following list present various load transfer curves in term of load-displacement law. More details could be found in the respective referenced articles. In this section, the main information is shown and focus on analytical methods. Only the Frank & Zhao is based on the pressuremeter test.

2.1 Frank & Zhao / NF P 94-262 (2012)

In order to characterize the soil-structure interaction in a soil reinforced by columns, Frank & Zhao (1982) proposed two semi-empirical mobilization laws for skin friction at the interface of the column and for end-bearing at the toe of the column. This model is based on pressuremeter data.

The skin friction mobilization law is defined according to the relationship between the shear stress τ and the relative displacement $S_{(s-i)}$ between the rigid inclusion and the soil around the shaft of the column (Figure 2 left). This law depends directly on the limit value of skin friction q_s which could be correlated from the limit pressure p_l.

The end-bearing mobilization law is defined according to the relationship between the stress at the column toe q and the vertical displacement at the inclusion toe S_b in the anchor layer (Figure 2 right). This law depends directly on the limit value of the end-bearing resistance q_b, correlated from the limit pressure p_l.

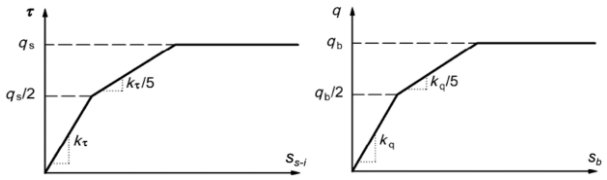

Figure 2. Semi-empirical mobilization law for skin friction (left) and for end-bearing (right) (NF P94-262).

The parameters of the slopes k_τ and k_q depend on the type of soil, the pressuremeter modulus E_m and the diameter of the isolated column B (Table 1).

Table 1. Parameters of the k_τ and k_q slopes of Frank & Zhao according to the type of soil.

Slope of the Trilines	Fine grained soil	Coarse grained soil
k_τ	$2\ E_m/B$	$0.8\ E_m/B$
k_q	$11\ E_m/B$	$4.8\ E_m/B$

2.2 American Petroleum Institute (2000)

The API recommendations in 2000 propose some load transfer curves about skin friction and end-bearing for clay and non-carbonate sand. The approach defines "point by point curves" such as one example below concerning the tip behaviour:

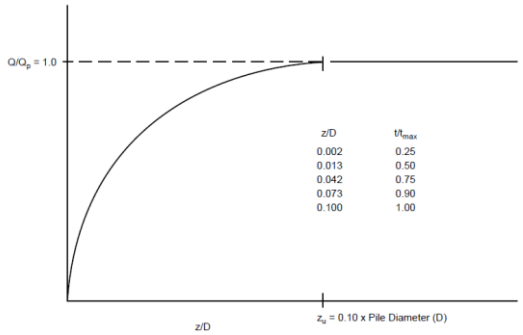

Figure 3. Pile tip load displacement curve (API 2000).

2.3 Bohn (2015)

According to the works, 2 mains load transfer curves were proposed: cubic root curves and hyperbolic curves. The 2 following figures present the laws.

		Mathematical expression	Curve shape
Cubic root curves	Shaft	$q_s = \min\left(\left(\frac{s_s}{s_{s,\lim}}\right)^{1/3} \cdot q_{s,ult}; q_{s,ult}\right)$		Tip	$q_b = \min\left(\left(\frac{s_b}{s_{b,\lim}}\right)^{1/3} \cdot q_{b,ult}; q_{b,ult}\right)$	
Figure 4. Proposed cubic root load transfer curves (Bohn).

		Mathematical expression	Curve shape
Hyperbolic curves	Shaft	$q_s = \frac{q_{s,ult} \cdot s_s}{M_s \cdot B + s_s}$		Tip	$q_b = \frac{q_{b,ult} \cdot s_b}{M_b \cdot B + s_b}$	
Figure 5. Proposed hyperbolic load transfer curves (Bohn).

The parameters $s_{s,lim}$, $s_{b,lim}$, M_s and M_b are defined either for mean or for conservative approach and fixed for all inclusion installations and ground types.

2.4 FHWA-IF-99-025 (1999)

Depending on the soil nature (cohesive or cohesionless soil), the shaft and the end-bearing load transfer curves are proposed. An example of the relationship is presented in the figure 6.

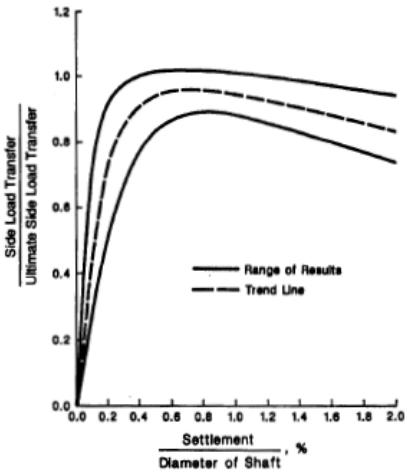

Figure 6. Normalized side load transfer for drilled shaft in cohesive soil. (FHWA-IF-99-025).

2.5 Fleming (1992)

This author proposed hyperbolic laws to estimate the load transfer soil/column interaction in both case shaft and end-bearing. Depending on the stiff or soft soil behavior some assumptions are defined. The young modulus of the anchorage layer is directly impacting the load-displacement equation.

2.6 Gwizdala & Krasinski (2016)

According to the analyses, root curves are defined with the following principle:

$$q = q_{bu} \cdot \left(\frac{z}{z_f}\right)^{\beta} \quad for\ z \le z_f \qquad (1)$$

$$q = q_{bu} \quad for\ z > z_f \qquad (2)$$

where:

- q: pile base resitance (kPa)
- q_{bu}: bearing capacity of the soil beneath pile base (kPa)
- z: pile head displacement (-)
- z_f: the displacement of the pile head, at with the soil bearing capacity under the pile base is mobilized (-)

The parameters β and z_f (and α and z_v about the skin friction) depend on the nature of the soil: cohesive or non-cohesive but also the methodology of the inclusion installation: driven, bored/CFA, vibro, etc.

2.7 Randolph & Wroth (1978)

Following to the method, the behavior of the shaft and the tip could be defined with:

- a linear part where the shear modulus of the soil has a direct impact.
- And then a limit equal to the maximum allowable skin friction and end-bearing resistance.

3 STATIC LOAD TEST

3.1 Presentation

The next section presents the impact of the load transfer curves when the static load test (SLT) on an isolated rigid inclusion is modelled. This test is a high-value quality control of the soil reinforcement technic. That consists in the loading, with generally a hydraulic jack below at reaction support, of the column head. The positive skin friction and the end-bearing of the inclusion is mobilized.

3.2 Sensitivity analysis

Considering all the above load transfer curves, the analysis assumes 3 different cases about soil profile

and soil parameters, inclusion installation type, diameter and length of the columns:

- Case 1: large and long rigid inclusion with soil displacement, anchored into a stiff layer.
- Case 2: RI with soil displacement, low end-bearing resistance in clayed condition.
- Case 3: RI with soil extraction in very soft soil above the gravel anchorage layer.

The following figures show the settlement predictions in function of the loading at inclusion top.

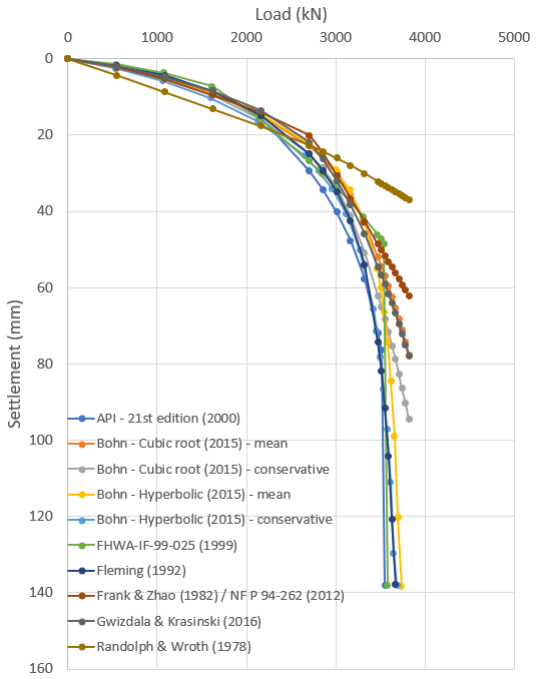

Figure 7. Settlement prediction for a static load test 1.

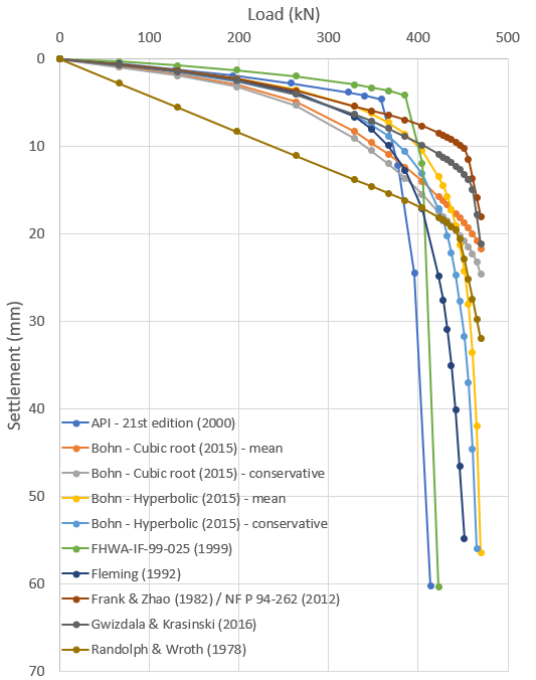

Figure 8. Settlement prediction for a static load test 2.

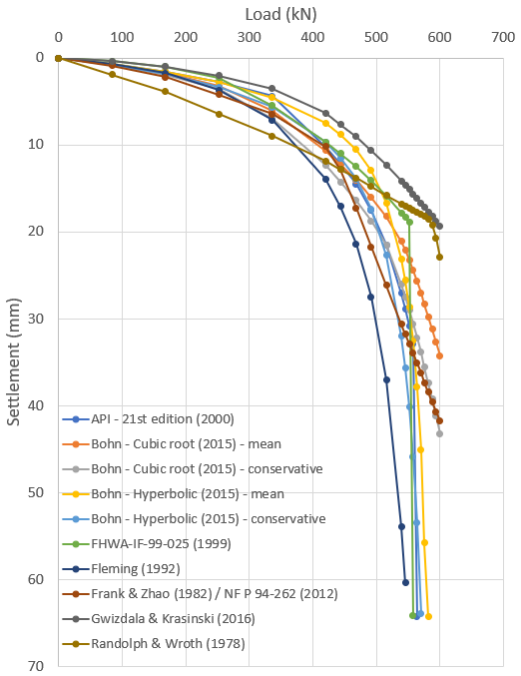

Figure 9. Settlement prediction for a static load test 3.

Closed the bearing capacity failure of the inclusion, the different methods present a large range of settlement predictions. However, at the creep load, the differences are limited. That is not obvious to define an author who over or under estimate the settlement prediction. Indeed depending on the percentage of the load, the curves intersect themselves and the final result at the RI head is a combination of different skin friction behavior of the multilayer and the end-bearing behavior.

4 UNIT CELL CALCULATION

4.1 Presentation

A design of a slab-on-grade over RI could consider the biphasic model which examines the interaction between the domain of inclusions and the complementary soil in a unit cell. That can be used to determine the distribution of forces and settlement profiles of the two domains (figure 11). The 2 domains are linked by load transfer curves.

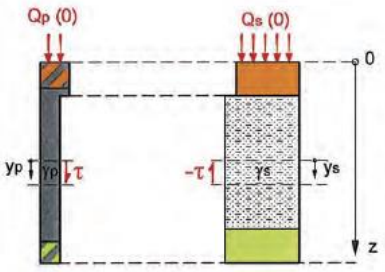

Figure 10. Biphasic model of the unit cell (ASIRI 2013).

4.2 Sensitivity analysis

Considering all the load transfer curves in section 2, the analysis assumes 3 different cases about soil profile and soil parameters, inclusion installation type, diameter and length of the columns:

- Case 1: large and long rigid inclusion with soil displacement, anchored into a stiff layer, with a high load in the slab.
- Case 2: RI with soil displacement, low end-bearing resistance in clayed condition and with no LTP between inclusion and slab.
- Case 3: RI with soil extraction into very soft soil over gravel anchorage layer.

The 2 following figures show the settlement (at the slab level, the punching into the LTP and the punching into the bearing layer) and loads into the RI (head, maximal, bottom) in function of different approaches for the case 1. The next table summaries the results in the 3 cases. The first line presents the average values of all the laws. The other lines show the variation in percent compared to the average. The cells should be read as "case 1" / "case 2" / "case 3".

The main design criteria for slab are typically the total settlement (in grey in figure 12 and 2nd column in table 2) and the maximal load into the RI (in grey in figure 13 and 6th column in table 2).

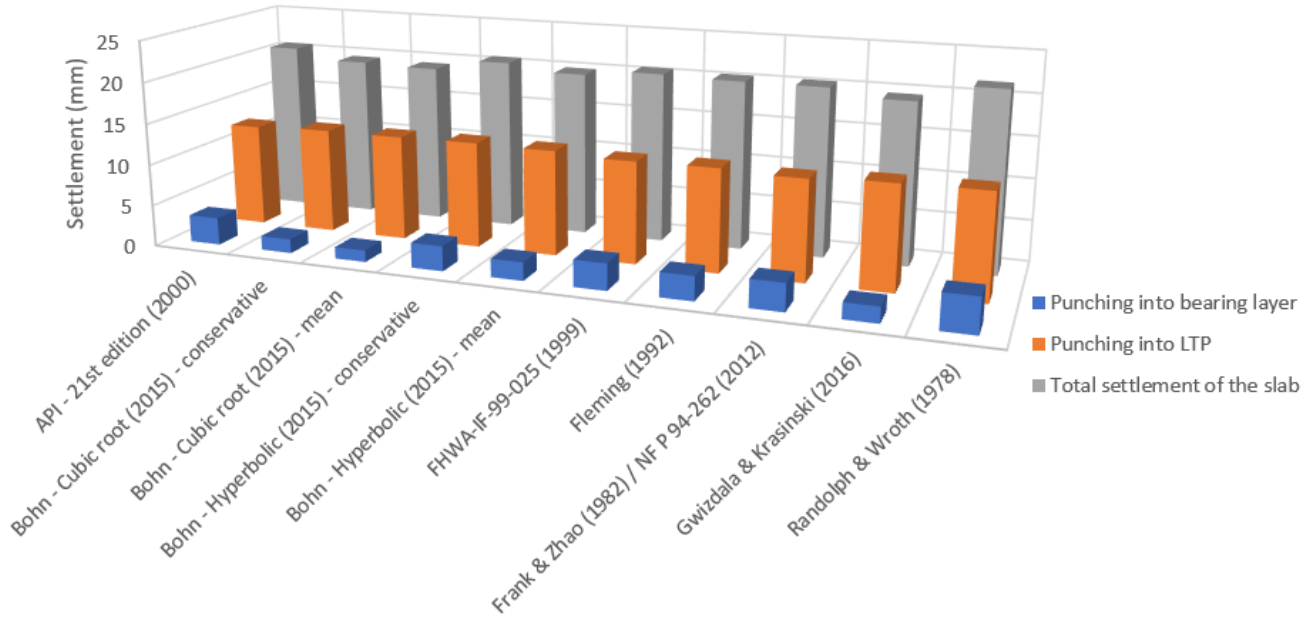

Figure 11. Settlement prediction for slab-on-grade loading - case 1.

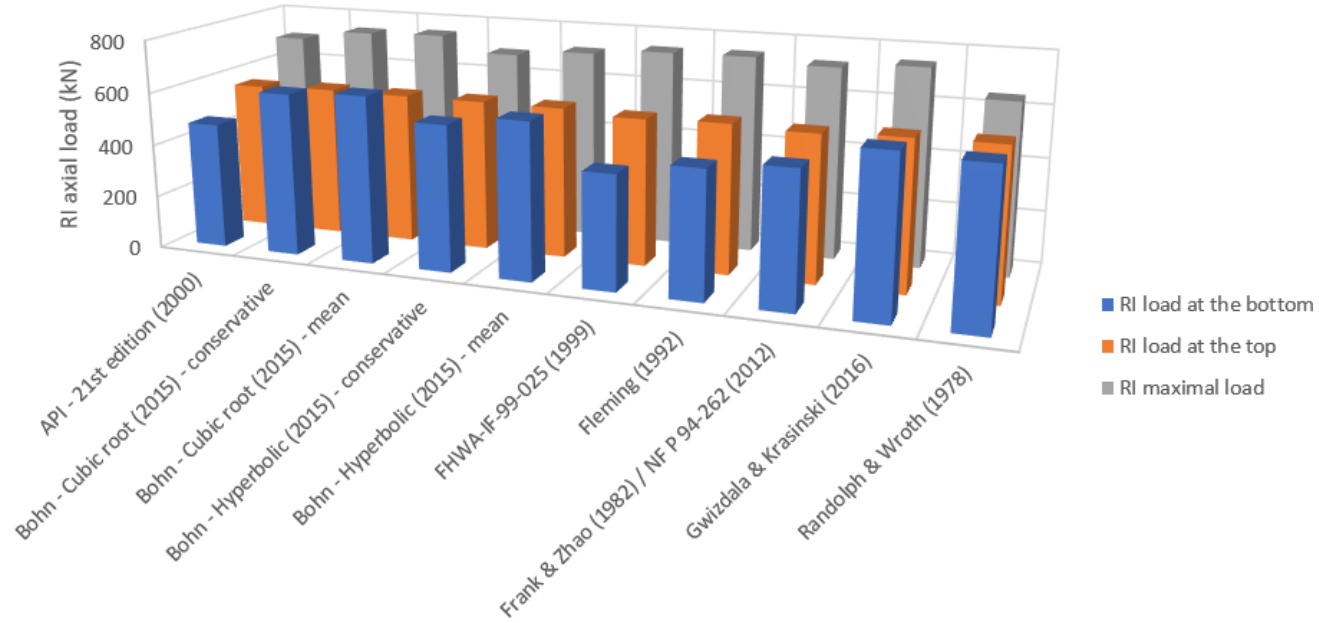

Figure 12. Load distribution into the inclusion for slab-on-grade loading - case 1.

Table 2. Summary of the results (settlement and load) about "case 1" / "case 2" / "case 3".

Load transfer curve	Settlement of the slab	Punching into LTP	Punching into bearing layer	RI load at top	RI load max	RI load at bottom
Average (in mm or kN)	***20/27/26 mm***	***12/0/23 mm***	***3/3/1 mm***	***562/93/41 kN***	***722/93/70 kN***	***541/28/48 kN***
API - 21st edition (2000)	**2/-2/1%**	-1/0/1%	19/-21/16%	0/0/0%	**-3/0/-2%**	-12/-12/-1%
Bohn - Cubic root (2015) – cons.	**-4/-1/0%**	2/0/3%	-38/-9/-77%	1/4/0%	**3/4/-2%**	14/14/21%
Bohn - Cubic root (2015) - mean	**-5/-2/-1%**	2/0/3%	-49/-15/-88%	1/7/0%	**4/7/-1%**	17/21/24%
Bohn - Hyperbolic (2015) – cons.	**2/-1/0%**	3/0/1%	9/-12/-7%	1/0/0%	**-4/0/-1%**	2/9/6%
Bohn - Hyperbolic (2015) - mean	**-2/-3/0%**	2/0/1%	-20/-27/-41%	1/0/0%	**0/0/1%**	9/23/12%
FHWA-IF-99-025 (1999)	**2/-5/1%**	-1/0/1%	16/-47/16%	-2/0/0%	**3/0/0%**	-21/1/-7%
Fleming (1992)	**1/2/0%**	-1/0/0%	5/20/-19%	0/0/0%	**3/0/0%**	-12/-60/-46%
Frank & Zhao / NF P 94-262	**1/-2/-1%**	-3/0/-4%	19/-18/62%	-2/0/0%	**1/0/3%**	-6/12/-15%
Gwizdala & Krasinski (2016)	**-4/-2/0%**	0/0/1%	-31/-15/-54%	0/5/-1%	**4/5/7%**	10/9/17%
Randolph & Wroth (1978)	**7/20/0%**	1/0/-4%	52/163/132%	1/-18/0%	**-10/-18/-7%**	7/-30/5%

The punching into the bearing layer presents important variations but that concerns a low value of displacement: 1 to 3mm. The law with the biggest gaps compared to the average is Randolph and Wroth. Indeed, a linear load transfer curve could be too simplified. About all the other, the variation is between -5 to +7% about the 2 mains criteria in bold text in the above table (settlement of the slab and maximal load into the RI).

5 CONCLUSIONS

When a rigid inclusions project is designed, the load transfer (stress/displacement) between the soil and the inclusions must be assumed. Various authors proposed load transfer curves depending in the nature and stiffness of the soil and the inclusions installation. This paper summarised a part of the different approaches and performed comparisons in typical cases of rigid inclusion applications.

The final design of rigid inclusions seems to be not significantly impacted by the different studied load transfer curves. However, the analysis is limited to 3 cases of static load test and 3 cases of slab-on-grade.

Benefits of finite element method analysis to the design of the Saint Maur Créteil caverns metro station

Apports de la modélisation numérique pour le dimensionnement des cavernes de la gare de Saint Maur Créteil

ABSTRACT: The Saint Maur Créteil metro station of the Grand Paris Express is the deepest one in France. It consists of a central shaft and two underground caverns located on either side. The caverns are carried out using Sequential Excavation Method in chalk with high groundwater pore pressure. Due to the dense urban environment, the design of theses caverns has been addressed by complex finite element method analysis to assess ground surface settlements. The caverns geometries are almost as wide as they are long: this unsual geometry requires to be considered to assess the settlements in a relevant way. Comparisons between plane strain modelling using the principle of superposition and the Attewell's formula, 3D "One step" modelling and full 3D modelling were performed and consistent results were obtained. Other FEM calculations allowed to define the execution procedures to control the groundwater pore pressures dissipation and the hydraulic gradient reduction, with the aim to ensure the lateral abutment stability of the caverns. In these calculations focusing on stability assessment, chalk specific behaviour, intermediate between rock and soil, were accounted for using different constitutive laws.

RÉSUMÉ: La gare de Saint-Maur Créteil pour le métro du Grand Paris Express est la plus profonde de France. Elle est formée d'un puits central et de deux cavernes souterraines de part et d'autre. Les cavernes sont réalisées en méthode traditionnelle, dans la craie avec une forte pression d'eau. La présence en surface d'une zone urbaine dense a nécessité la validation des solutions constructives par le biais d'une importante étude aux éléments finis pour évaluer les tassements de surface. La géométrie atypique des cavernes, presque aussi larges que longues, a dû être prise en compte pour évaluer les tassements de manière pertinente. Des comparaisons entre un modèle en déformations planes utilisant le principe de superposition et la relation d'Attewell, un modèle 3D stationnaire et un modèle 3D complet ont été menées. Des résultats cohérents entre les différentes approches ont été obtenus. D'autres modèles ont permis de définir les dispositions constructives pour contrôler la dissipation de pressions interstitielles et la réduction de gradients hydrauliques, avec l'objectif d'assurer la stabilité des culées des cavernes. Dans ces calculs orientés stabilité, le comportement particulier de la craie, à la frontière entre roche et sol, a été pris en compte via l'utilisation de lois de comportement différentes.

1 SAINT MAUR CRETEIL METRO STATION

Saint-Maur Créteil metro station is located southeast of Paris new metro line 15 and is part of the "Grand Paris Express". Initiated in 2017, the metro station should be finished by the end of 2025. The station is composed of:

- a central oblong-shaped shaft, 56 m long by 36.8 m wide and 58 m deep, sheltered by diaphragm walls with a thickness of 1.8 m.
- two underground caverns located on either side of the shaft, excavated using conventional methods, with a height of 13.6 m, a width of 21.3 m and a length of 30 m. 43 m of ground cover is found upon the vault (*cf.* Figure 1).

This new metro station is right underneath the existing surface RER-A train station: strong demands for limiting ground settlements were therefore needed, both in absolute and relative values.

This construction is carried out on behalf of the Société du Grand Paris by the joint venture of Eiffage and Razel-Bec. The project management is handled by Systra, and Terrasol is involved as an execution engineering firm for the design of underground caverns, the subject of this communication.

1.1 Geotechnical context

At South-east of Paris, project stratigraphy is typical of Paris Basin: Under the made ground, a first layer of coarse alluvium with a thickness of 10 m is found, followed by 3.5 m of fine sand covering a layer of 20 m of Ypresian Plastic Clay, softened in its upper part. This layer of Plastic Clay, overconsolidated and subjected to swelling, may exhibit weak mechanical properties, making it challenging to excavate underground sections using traditional methods. Underneath, a layer of 5 m of marl-limestone is encountered, covering the Campanian Chalk, partially altered in the upper part over approximately 5 m. The TBM and the caverns supporting the platforms, are entirely located in Campanian Chalk, which is a soft rock (σ_{ci}=6 MPa and GSI=57) with relatively low permeability (k=1.10^{-7} m/s).

Two water tables are encountered, the first in the alluvial deposits supported by Plastic Clays, and the second, slightly lower, in the chalk. For the design of the caverns, only the chalk water table is considered, corresponding to a pore water pressure of approximately 485 kPa at the invert of the caverns.

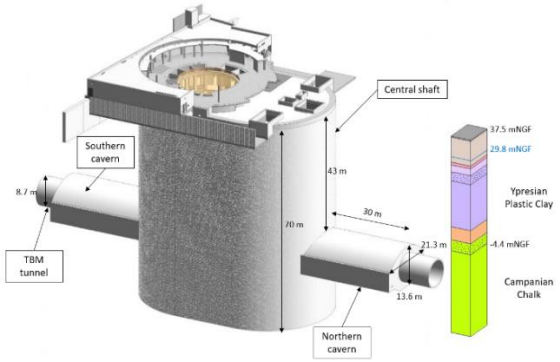

Figure 1. 3D View of the station and stratigraphy.

1.2 Execution procedures

The main tunnel was excavated using an Earth Pressure Balance Tunnel Boring Machine and has an internal section of 8.7 meters.

The excavation of the cavern is carried out with the Sequential Excavation Method aiming at minimize displacements by using rigid supports wherever possible as shown in Figure 2. At first the tunnel boring machine tunnel passes through the unexcavated shaft. Prior to the excavation of the caverns, a 5 m thick injection ring around the caverns is created from the segment lining tunnel through boreholes with Blow out Preventers. The tunnel is then backfilled with a self-compacting filling material "Regimix" (0). After that (1), superior abutments are excavated in parallel. Then (2), inferior abutments are bored. Abutments are then filled with concrete from bottom to top in two phases. Excavation of main gallery is then performed in two phases top-heading (3) and invert (5, each one followed by installation of definitive lining (4) (6). Let's note that each step of top-heading excavation was carried out in two steps: central part is excavated and supported before dealing with the lateral parts.

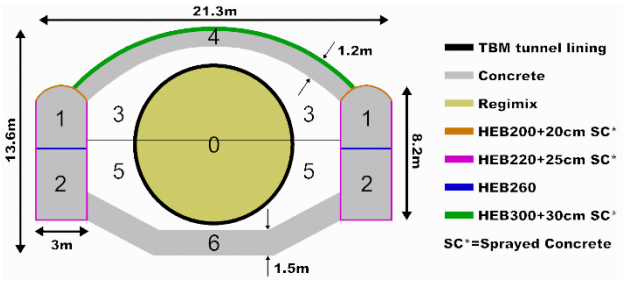

Figure 2. Sequential excavation of the cavern section.

The two underground caverns were excavated in parallel, and all the excavations were carried out continuously along their entire length. The start of the abutment galleries took place in May 2022 and Main gallery excavation began in late 2022, top-heading operations ended in early Spring 2023.

2 ASSESSING GROUND SETTLEMENTS

2.1 Results of geotechnical monitoring

To ensure that no critical damage is induced to buildings within the Geotechnical Zone of Influence (GZI), an extensive monitoring campaign has been performed. Various monitoring methods have been used: theodolites with reflector monitoring prisms, horizontal inclinometers above abutment galleries, oblique extensometers, from the surface to the caverns, electronic level indicators, piezometers, vibrating wire extensometers. As shown in Figure 1, most of the surface sensors have been placed near the RER-A station, since differential settlement could lead to important traffic disruptions.

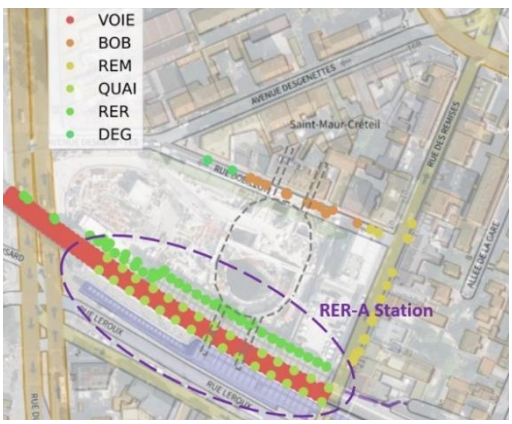

Figure 3. Optic sensors in the GZI.

Data from underground sensors were very unclear, with pikes corresponding to works at ground level near extensometer heads for instance. Chalk piezometer had problems during construction phase, and horizontal inclinometers provided values relatively close to what was expected, but with unexpected shape. Indeed, the maximum displacement is found at the final pass of the cavern, inconsistent with the distribution of surface settlements and every performed 3D FEM calculation (see Figure 9). Therefore, the authors chose to focus on data from surface settlement prisms shown in Figure 3. No clear tendency is visible on REM sensors: they are parallel to tunnel axis, but too far from it. Thus, five series of sensors were used:

- Rue Bobillot (BOB), from the angle with Rue des Remises to Avenue Desgenettes (included)
- Prisms beneath northern RER platform (Q01) and southern RER platform (Q02)
- Prisms along the wall common to RER and new metro station (RER) and Prisms on rail tracks, e.g southern rail of northern railway (V012).

If the first batch corresponds to a zone of residential buildings, with 2-3 floors, the others sensors are within the existing RER station, fixed on rigid structures (rails, concrete platforms, a wall 100m-long, …). The station itself is superficially founded, and long continuous walls give inertia to the structure, potentially perturbating the readings compared to a greenfield settlement trough.

To allow comparisons between measurements and results of numerical computations, Peck theory of gaussian settlement trough (Peck, 1969) has been used. Thus, if x denotes the transverse coordinate, the transversal settlement s is considered of Gaussian form:

$$s(x) = S_{max} \exp\left(-\frac{x^2}{2i^2}\right) \qquad (1)$$

with S_{max} the maximal settlement, and i the distance from tunnel axis to trough inflexion point. An algorithm has been used to get the two parameters' best fit, following a least squares procedure to assess errors. It also provides the covariance matrix, allowing the estimation of an elliptic joint confidence interval for each sector (Vugrin et al., 2007).

The procedure is illustrated with the case of Bobillot Street, and then applied to the four other series. First step corresponds to data cleaning: some sensors are reading irrelevant, chaotic data, while some others are missing months of data. Daily fluctuations are lessened using a moving average.

Data examination across the whole period reveals that if tunnelling boring machine passing through the unexcavated shaft induced quick oscillations of measures, it can't be accounted for any significant settlements.

The subsequent analysis is therefore limited to cavern excavation, divided in four phases: abutments excavation and filling with concrete, and then excavation of cavern upper part followed by permanent lining installation. Last phase of lower excavation isn't considered as no settlement was induced.

At the beginning of cavern excavation, all sensors registered a strong ascendant and unexplained displacement, independent of the ground injection. Over 19 sensors, 13 were kept after data cleaning. The white line on Figure 4 corresponds to tunnel face of the main gallery passing beneath Bobillot Street.

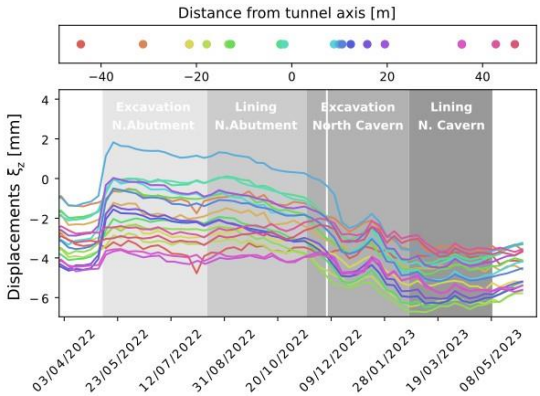

Figure 4. Time evolution of vertical displacements after data cleaning BOB (and rolling mean over 7 days).

Incremental ground displacements during abutment and main cavern operations along a transverse profile show Gaussian curve shape settlement trough (Figure 5). Let's note however that for abutment phase (May 2022 to Nov. 2022), best fit troughs are centred at fifteen meters from cavern axis, instead of the nine-meter distance expected from geometrical considerations.

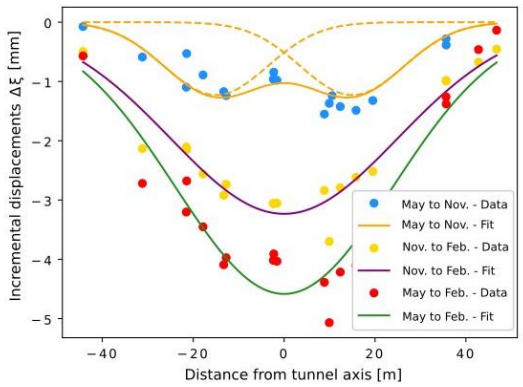

Figure 5. Incremental transverse trough along the Bobillot street for three periods: May-Nov 2022 (abutment construction), Nov-Feb 2023 (cavern excavation), Feb-May 2023 (cavern lining).

For other sensors, due to RER-A station rigidity, only final settlement through the whole period can be used. Procedure described earlier allows to get best fit parameters, and confidence ellipse at 90%, for each set of data (Figure 6).

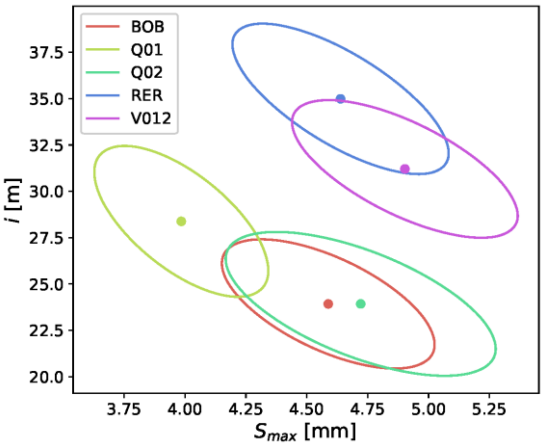

Figure 6. Elliptic joint confidence interval for each dataset.

According to Peck theory (Peck, 1969), greenfield trough width i defined earlier only depends on ground type. Therefore, its variability can be seen as a scale of the existing building stiffness: low stiffness for Bobillot Street to high stiffness for northern RER continuous wall. Maximum settlement also depends on distance from metro shaft and will be discussed later (cf.Figure 9).

2.2 Finite Element strategies

2.2.1 Integration from 2D calculation using Attewell's formula

When performing FEM numerical analysis, first step is 2D plane strain analysis. If deconfinement rate allows to consider excavation step's and distance to the tunnel face influence (Panet, 1995), the raw transversal trough obtained corresponds to an infinite tunnel excavation.

Attewell (1982) proposed a procedure to assess finite settlement trough considering that underground volume loss is punctual. This theory amounts to considering an incremental volume loss associated with each excavation step. After adapting Peck gaussian trough to radial coordinate in case of single point volume loss, a finite integration between points x_i and x_f leads to equation (2):

$$w(x,y) = \frac{V}{2\pi i^2}\int_{x_i}^{x_f} exp\left[\frac{-((x-x_0)^2+y^2)}{2i^2}\right]dx_0$$

where x is parallel to the tunnel centre line, y is normal to the tunnel centre line, i the trough width and $V = S_m\sqrt{2\pi}i$ the volume lost in surface trough per linear meter (linked to excavated volume by empirical relations). Therefore, after bidimensional computation, one only has to extract ground displacements and fit Peck parameters to predict the finite tridimensional surface trough.

However, finding the "right" deconfinement rate remains an issue. Theoretically, the convergence-confinement method (Panet, 1995) doesn't apply to sequential excavation since previous phases altered initial stress state (which in Campanian Chalk is supposed to be isotropic). In practice, the method is commonly applied using either a mean effective stress over the outline of tunnel section, or its value at face centre. Since tunnelling operations already decompressed part of the section, the deconfinement rate has been chosen with the mean effective stress. Deconfinement rate is thus calculated with an area-derived equivalent radius, and implicit method of (Nguyen-Minh & Guo, 1998) allows to consider lining stiffness influence over deconfinement at support installation.

2.2.2 Integration from 3D "one-step" computation

To avoid the issue of the choice of deconfinement rate while keeping calculation time reasonable, one can think of making use of the same notion of incremental loss in a 3D calculation, since excavation step is explicitly considered. Used since Corbetta (1990), the "one-step solution" consists in adding a finite number of incremental troughs corresponding to a single calculation: time integration is transformed into discrete space integration.

If this method allows to get quickly consistent results, without the intervention of deconfinement, the stationarity principle has strong limits. Indeed, it is impossible to consider any kind of aperiodicity regarding the loading (RER-A train station has finite dimensions) or the geometry (presence of the shaft).

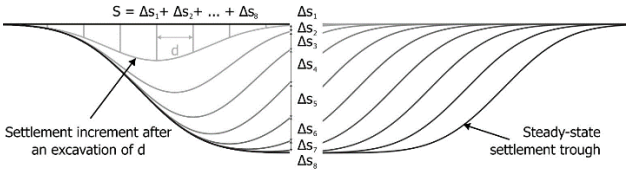

Figure 7. Principle of stationarity and "One-step" method.

2.2.3 3D complete computation

Finally, to grasp all the complexity of the problem, a full 3D study was performed. The shaft was explicitly modelled to account for the friction of the soil along its diaphragm walls, and surface loadings are located according to the position of RER-A station footings, as shown on Figure 8.

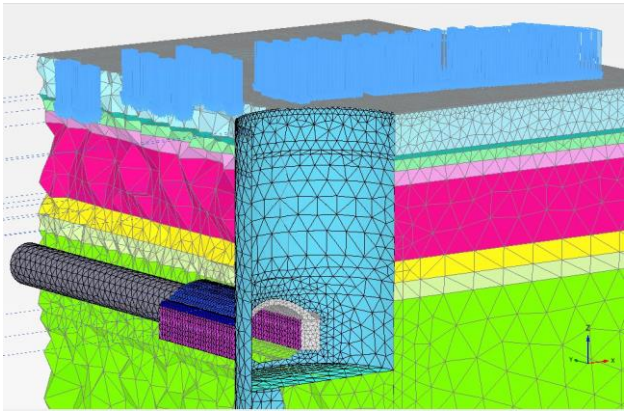

Figure 8. Plaxis 3D mesh.

A second model, considering only an average surface load, representative of the conditions encountered in the north, has also been produced. The results proved to be equivalent to the model representing the south, both in terms of maximum settlement and the location of the inflection point.

The simulation phasing of the underground sections closely follows, the sequence selected for the construction works, and two variants are tested: main gallery's permanent vault lining is installed either at the very end (a), or during excavation in (b), with five steps. During each excavation stage the effects of water flow are explicitly calculated considering a steady-state flow regime.

2.3 Conclusion on settlement estimation

The true behaviour is somewhere between (a) and (b): only vault lining steps 1 and 2 were completed before the whole excavation works was completed. Therefore, finding geotechnical monitoring results between 3D-Complete curves (a) and (b) appears to be satisfying.

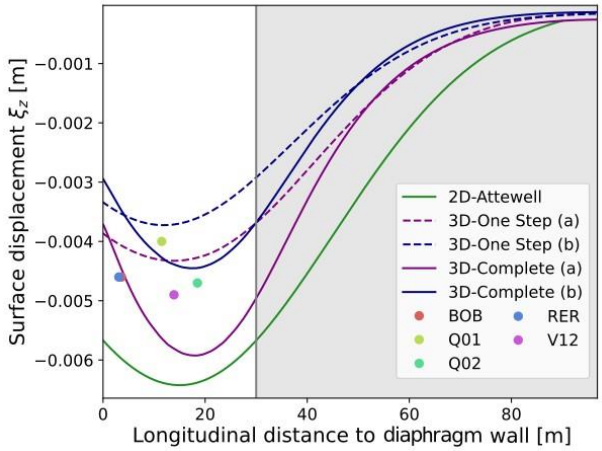

Figure 9. Longitudinal surface troughs.

Although all results seem to be in good agreement with the measurements, the "one step" 3D model tends to slightly underestimate settlements. This may be due the presence of the diaphragm walls of the shaft, the RER structures, and the excavation sequence, which does not comply the condition of stationarity on which the validity of the one-step method is based. On the contrary, Attewell's method seems to overestimate surface settlements. The cylindrical (instead of spherical) nature of the groundwaterflow leads to stronger tunnel convergence, which can probably be accounted for settlements' overestimation, along with hazardous deconfinement computation and limits to Attewell & Peck theories. However, it is interesting to note that integration from a simple 2D FEM computation gives settlements consistent with much more advanced 3D models.

Figure 10 allows to compare computed trough width to measured settlements. It appears that settlement troughs obtained from ground sensors, interpreted in terms of trough width with Peck, are well approached by full 3D calculation with support installation during excavation (scenario (b)).

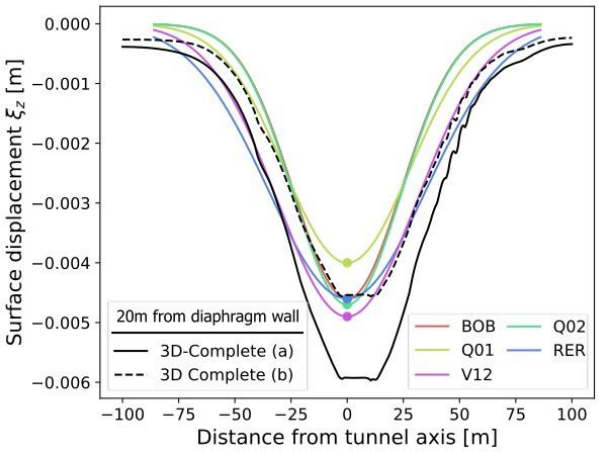

Figure 10. Comparison of monitored and computed transverse troughs.

3 ASSESSING STABILITY

The numerical models have also facilitated the choice of temporary construction arrangements. By installing a very rigid support, a significant part of the ground load moves to the structure and passes through the abutment galleries. Finite element deformations plane simulations have shown such result during the excavation of the Stross: instability due to punching of the abutment galleries could occur.

The low safety factors regarding the bearing capacity of the abutments resulted from a combination of various aspects: an eccentricity of the load acting upon the foundation, the presence of an adjacent "slope" to the structure, and water flow forces with very steep gradients (see Figure 11).

In a soft, low-permeability rock like Campanian Chalk, considering steady-state flow in models is likely pessimistic (homogeneous flows is considered in the matrix and not through potential fracture networks). Nevertheless, the consequences of the occurrence of the feared event were deemed unacceptable.

To adjust the construction arrangements to be implemented, two different hypotheses of constitutive laws were considered: an Hardening Soil Model with equivalent rock mass strength parameters defined in the contract, and a Hoek and Brown Model whose parameters were adjusted based on additional laboratory tests and survey of the abutment galleries face. Both types of constitutive laws have proven to be consistent, and additional construction measures adopted consisted of:

- Implementing, from the upper half-section, 5 rows of 3 sub-vertical passive drains per cavern.
- Creating an un-reinforced, 20 cm thick concrete protection slab during the Stross excavation progress.

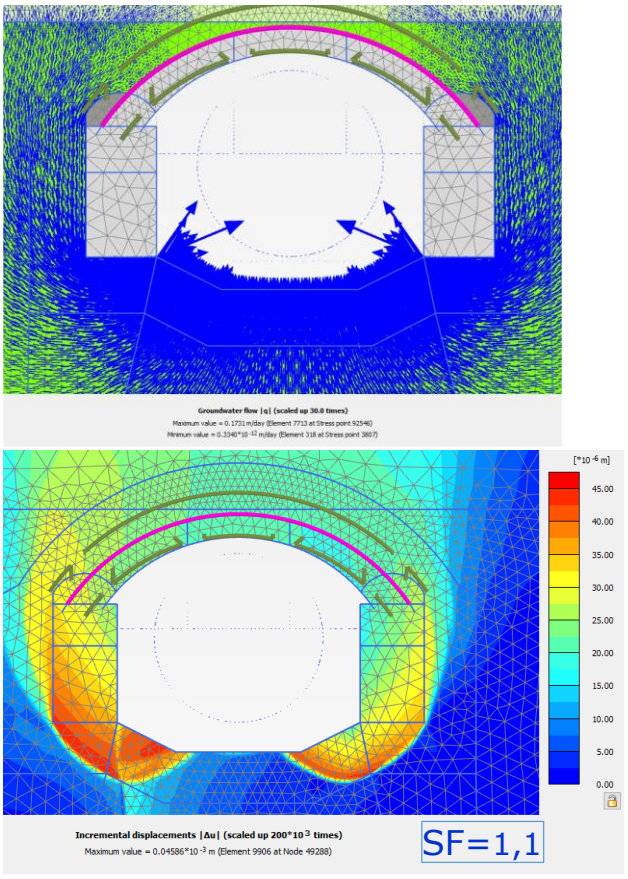

Figure 11. Ground water flow around the abutment galleries and highlighting the failure mechanism in a phase of c-φ reduction without additional measure.

These measures have thus ensured the confinement of the soil beneath the excavation bottom, reduced pore water pressures, increased the average effective stress, and consequently, the shear strength of the chalk.

As the natural permeability of Campanian chalk is low (k=1.10-7 m/s), the injection performed with bentonite/cement did not aim to further decrease its transmissivity but solely to ensure hydraulic homogeneity in the 5 m treated crown. The passive drains are used to control water inflows in this area, reduce flow forces, and prevent potential flushing phenomena.

Considering these additional construction measures, safety factors greater than 1.3 were consistently obtained.

4 CONCLUSIONS

The finite element simulations conducted during the execution phase of the Saint Maur Créteil station proved to be a valuable tool for designing the construction arrangements. The models, increasing in complexity, used to estimate surface settlements provided assurance to all stakeholders about controlling displacements below the specified thresholds. The models demonstrated good consistency with measurements. Regarding the evaluation of abutment stability during the Stross excavation phase, plane deformation models using different constitutive laws helped define additional construction measures that could be easily integrated into the chosen excavation process and were robust.

ABSTRACT: Monitoring plays an important role in what geotechnical works and investigation are concerned. Either for assessing stiffness on laboratory tests, or for evaluating forces or displacements in the field, instrumentation is of crucial relevance for a wide range of situations. Instrumentation provides critical data for subsurface characterization, determination of soil properties, assessment of groundwater conditions, monitoring of geotechnical structures, validation of design assumptions and research works. Over the last years, a number of different types of mechanical, electrical and optical sensors have been developed for geotechnical monitoring field. Among these, optical fibre sensors feature several important advantages, such as: durability; stability and insensitivity to external disturbances; embedding capability and possibility of distributed sensing over large distances and multiplexing of point sensors that are especially useful for long-term health assessment in geotechnical monitoring. Over time, the range of geotechnical parameters that can be measured using fibre optic sensors has expanded. Optical Fibre sensors are now utilized for monitoring a variety of geotechnical parameters, including strain, deformation, displacement, temperature, pressure, and even pore water pressure. Optical fiber sensors can be applied in slope stability monitoring, landslide detection, tunnel monitoring, foundation monitoring, and offshore geotechnical investigations, among other applications. This paper presents a comprehensive review of applications of optical fibre sensor for geotechnical monitoring.

RÉSUMÉ: La surveillance joue un rôle important en ce qui concerne les travaux et investigations géotechniques. Que ce soit pour évaluer la rigidité lors d'essais en laboratoire, ou pour évaluer des forces ou des déplacements sur le terrain, l'instrumentation revêt une importance cruciale pour un large éventail de situations. L'instrumentation fournit des données critiques pour la caractérisation du sous-sol, la détermination des propriétés du sol, l'évaluation des conditions des eaux souterraines, la surveillance des structures géotechniques, la validation des hypothèses de conception et les travaux de recherche. Ces dernières années, un certain nombre de types différents de capteurs mécaniques, électriques et optiques ont été développés pour le domaine de la surveillance géotechnique. Parmi ceux-ci, les capteurs à fibre optique présentent plusieurs avantages importants, tels que la durabilité, la stabilité et l'insensibilité aux perturbations externes, la capacité d'intégration et la possibilité de détection distribuée sur de grandes distances et le multiplexage de capteurs ponctuels qui sont particulièrement utiles pour l'évaluation de la santé à long terme en géotechnique surveillance. Au fil du temps, la gamme de paramètres géotechniques pouvant être mesurés à l'aide de capteurs à fibre optique s'est élargie. Les capteurs à fibre optique sont désormais utilisés pour surveiller divers paramètres géotechniques, notamment la déformation, la déformation, le déplacement, la température, la pression et même la pression interstitielle de l'eau, appliqués à la surveillance de la stabilité des pentes, à la détection des glissements de terrain, à la surveillance des tunnels, à la surveillance des fondations et aux enquêtes géotechniques offshore, entre autres applications. Cet article présente un examen complet des applications des capteurs à fibre optique pour la surveillance géotechnique.

Keywords: Fiber optic sensor; geotechnics; distributed sensors; optic point sensors.

1 INTRODUCTION

Geotechnical engineering covers a wide range of applications amongst which pile foundations, soil movements, stabilization anchors, mining and more. Due to the harsh environment, sometimes hard accessibility and long working period of geotechnical structures, monitoring methods are necessary to avoid accidental infrastructure failure that can cause human and economic losses. Over the last years, a variety of

mechanical, electrical and optical sensors have been developed and used for geotechnical engineering. Among these, optical fibre sensors are offering new monitoring possibilities. Using the advantages of optical fibre such as durability, lightweight, high sensitivity, stability and insensitivity to external disturbances associated with embedding capability (into soil or structure) and possibility of distributed sensing over large distances and multiplexing of several point sensors, it's possible to create a range of optical fiber sensors that can simultaneously monitor several parameters, such as strain, temperature, and deformation of the geotechnical structure (Soga et al. 2019, Wu et al. 2020, Singh et al. 2023).

The optical fibre sensors use changes in light parameters such as light intensity, phase, polarization state, wavelength, or frequency by the external parameters to monitor geotechnical structures.
This paper proposes a review of working principles and the application of optical fiber sensing technologies in geotechnical engineering.

2 WORKING PRINCIPLES OF OPTICAL FIBER SENSORS FOR GEOTECHNICS

The typical configuration of optical fiber sensor in represented in Figure 1. Light from a optical source is injected into the fiber system. After crossing coupler or a circulator is guided to sensing region. Depending on the sensing approach it is possible to detect the transmited or reflected spectrum.

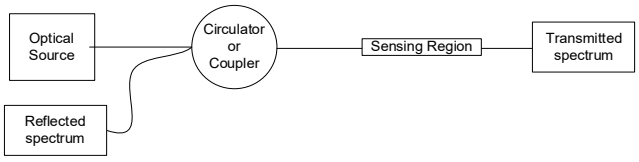

Figure 1.Generic configuration of optical fiber sensor.

The development of optical fiber sensors for geotechnics uses two approaches based in sensors head distribution, working principles and field of application (Ma et al. 2023):

(i) point sensor based in Fiber Bragg Grating (FBG), long period grating (LPG) or interferometric sensor configuration where the measurand was carried out in a specific point (Singh et al. 2023).

(ii) distributed sensors able to measure the parameters across the entire length of fiber based in Raman, Brillouin or Rayleigh scattering light (Bado and Casas 2021, Mohamad et al. 2023)

The FBG sensor is a well-established fiber optic-based point sensor. In this method, a tiny portion of the fibre core is subjected a periodical modulation of the refractive index by a powerful UV light (Hill et al. 2008). When broadband light with several wavelength passes through the fiber, the FBG reflected back one wavelength, called Bragg wavelength, while the remainder wavelengths pass through fiber (Figure 2). The Bragg wavelength is dependent on thermal changes or physical elongation of the sensors, and the Bragg wavelength shifts when subjected to an external parameter like temperature or strain. Measuring this change, allows to obtain the external parameter.

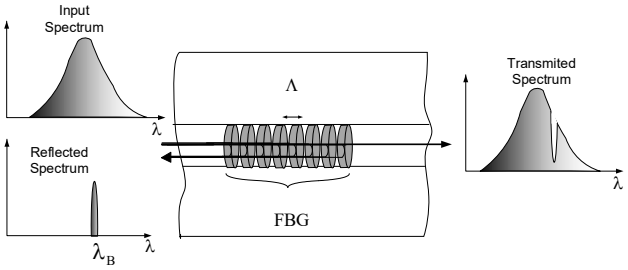

Figure 2. Fiber Bragg Grating.

The LPG is similar to the FBG but the modulation period is higher than FBG and couples some wavelength to the fiber cladding. The LPG couples a fraction of light to a specific cladding mode, whereas the remaining light keeps propagating in the fiber core. In this case, the transmissions spectrum presents some missing wavelengths that change the position when the LPG region is subjected to external parameters. The LPG can be fabricated using several techniques like UV light, using a CO_2 laser or the electric-arc technique (Rego et al. 2021).

The final point sensor is the in fiber interferometric sensor. In this case, the light from an optical source is divided into two beams: one beam is signal light and the other beam is reference light. Interference occurs when they meet. The interference spectrum changes by influence of external factors (Caldas and Rego 2021).

Distributed Sensors use the backscattered light of the optical fibre to feedback the performance of the optical fibre. When a light travels through an optical fibre, it interacts with the constituent atoms and molecules, and the light is deviated from a straight trajectory due to its non-uniformity. This deviation creates back scattering that brings a very small portion of the beam to go back to the source (Soga and Luo 2018).

The detected backscattered light power returned at various points along the length of the fiber contains information about external changes (strain or temperature change) along of fiber, which changes the characteristics of the back scattered beam (Figure 3). The distributed sensors use these changes in the recovered beam to quantify strain, temperature or vibration occurring along the standard optical fibre cable.

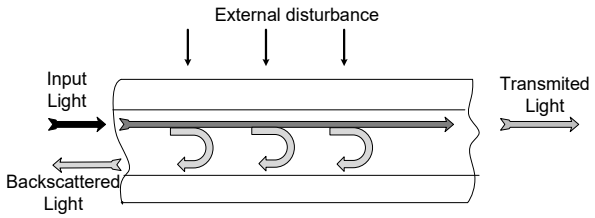

Figure 3. Backscattered light in distributed sensors.

In fact, the distributed system transforms an optical fiber cable into an array of virtual sensing devices when attached to a geotechnical structure or embedding, allow to monitor the changes of ambient parameters of the monitored object.

Using the point sensor or distributed sensors several applications has been developed in the last years. The next section presents the last applications of optical fiber sensor in Geotchnical engeneering.

3 APPLICATIONS

The optical fiber sensors are extensively used in various fields and given its small size, which allows it to be placed on the surface or embedded structures. In this section we focus in applications for geotechnical engineering based in point sensors and distributed optical fiber sensors.

One application of optical fibre sensors is the monitorization of health conditions of bridges (concrete, cables and suspenders) where the optical fiber sensors is an alternative for continuous real−time monitoring for identification, damage detection, safety condition assessment, and structural performance prediction (Costa and Figueiras 2012, He et al. 2013). In the case of crack detection in concrete, it is hard to monitor due to the complexity of the materials (Bao et al. 2010), but some solutions to determine the crack location and width evolution over time using distributed optical fiber sensors present accuracy equivalent to traditional electrical foil gauges (Berrocal et al. 2021).

The temperature and humidity changes of concrete are other important parameters for monitoring the structural health and providing information for maintenance, rehabilitation, repairing, upgradation or rebuilding of structures. Some optical fiber sensors using point detection based in FBG or interferometer configurations are proposed and the results are similar to the electronic sensors (Farhan et al. 2023).

Optical fiber sensors have also other applications for structural monitoring like tunnels, pipelines or wind turbine towers. Tunnels are complex: encompassing longer and wider tunnels, excavations through increasingly difficult ground conditions under densely populated zones or in seismic areas. Solutions using point or distributed sensors have been successfully applied in tunnels, to measure the displacement of a tunnel lining, monitoring its stability during the backfilling and traffic-operating periods or surrounding geotechnical and hydrological conditions (Gue et al. 2015).

Pipelines are one important and economic way to transport water, oil, natural gases and telecommunication cables across extensive distances. Maintenance and, in particular, health conditions of pipelines after earthquakes, or if pipelines are located in complex and hazardous environments, is important. The optical fiber sensors present an important advantage for pipeline leakage detection, corrosion or deformation along the time (Bang et al. 2012, Glisic and Yao 2012, Ye et al. 2013, Zhu et al. 2022).

Wind turbines are one of the most used renewable sources of power. The wind turbine structures are subject to several forces, dynamic or static, and vibrations. In the last years, the optical fiber sensors were performed for monitoring, in real time or not, the load/maximum strain and the load/maximum displacement profiles of wind structure or wind turbine blade bending and torsional loads (Z. H. Zhang et al. 2020).

Regarding the applications in geotechnical engineering, optical fiber sensor are applied in pile foundations, soil movements (landslides and soil subsidence), stabilization anchors, mining and more.
In pile foundations, the strain distribution of the pile under different scour effect, using point detection (Sang et al. 2020) based in FBG or distributed detection (Zhaohui Zhang et al. 2022) is possible using an optical fiber sensor pile strain profile.

Other applications include monitoring soil movements that are crucial for the prevention and control of disasters. For examples, in soil nails where the results using optical fiber sensors show that the rainfall infiltration and rise in groundwater pressures will lead to mobilization of tensile forces in soil nails. The obtained results demonstrate the capacity of optical fibre to measure strain of the soil nail under active and passive loading modes (Guo et al. 2019).

Optical fibre sensors also demonstrate great potential for dam health monitoring, especially fully distributed optical sensing technologies that are widely used for monitoring the deformation, stress, and leakage of dams (Zhou et al. 2019).

4 CONCLUSIONS

This paper reviews the application status of optical fiber sensors in geotechnical health monitoring with an emphasis on working principles, the detection

parameters and applications in geotechnical engineering. The results and recents papers published show that optical fibre sensors technologies are attracting more and more attention due to their excellent performance in this area.

ABSTRACT: Biocementation is an environmentally sustainable technique for soil improvement, in which the precipitation of calcium carbonate is promoted by using biological agents such as bacteria or enzymes. The precipitated calcium carbonate, or biocement, is responsible for soils strength and stiffness increment due to the bonds created between the particles, and for reducing the permeability caused by pore clogging. The shallow treatment of sandy soils to increase resistance to the formation of ravines is a new application. This treatment was carried out in a real case to avoid ravines caused by rain and is being monitored over time as part of an ongoing project of Instituto Superior Técnico funded by FCT (ref. PTDC/ECI-EGC/1086/2021). This case-study is an excavation slope in sandy soil on the A13 Motorway managed by Brisa. The treatment was carried out by Rodio Portugal, from the Soletanche-Bachy group, who provided the technology to inject into the soil the treatment fluids with bacteria. The first monitoring data are presented, consisting in the amounts of calcium carbonate measured right after treatment and after the first heavy rains, with encouraging results.

RÉSUMÉ: La biocimentation est une technique écologiquement durable d'amélioration des sols, dans laquelle la précipitation du carbonate de calcium est favorisée par l'utilisation d'agents biologiques tels que des bactéries ou des enzymes. Le carbonate de calcium précipité, ou biociment, est responsable de l'augmentation de la résistance et de la rigidité des sols en raison des liaisons créées entre les particules, et de la réduction de la perméabilité causée par le colmatage des pores. Le traitement superficiel des sols sableux pour augmenter la résistance à l'érosion par ravinement est une nouvelle application. Ce traitement a été réalisé dans un cas réel pour éviter les ravins causés par la pluie et est surveillé au fil du temps dans le cadre d'un projet en cours de l'Instituto Superior Técnico financé par FCT (réf. PTDC/ECI-EGC/1086 /2021). Cette étude de cas est une pente d'excavation en sol sableux sur l'autoroute A13 gérée par Brisa. Le traitement a été réalisé par Rodio Portugal, du groupe Soletanche-Bachy, qui a fourni la technologie pour injecter dans le sol les fluides de traitement contenant des bactéries. Les premières données de suivi sont présentées, constituées des quantités de carbonate de calcium mesurées juste après le traitement et après les premières fortes pluies, avec des résultats encourageants.

Keywords: Biocementation; excavation slope; ravines; monitoring; calcium carbonate.

1 INTRODUCTION

Biocementation is an environmentally sustainable technique for soil improvement, in which the precipitation of calcium carbonate is promoted by using biological agents such as bacteria or enzymes. The precipitated calcium carbonate, or biocement, is responsible for soils strength and stiffness increment due to the bonds created between the particles, and for reducing the permeability caused by pore clogging.

Non-pathogenic urease-producing bacteria are used for the treatment. The urease enzyme from the bacteria catalyses the hydrolysis of urea (Eq. 1), and calcium carbonate (biocement) precipitates in the presence of a source of calcium (Eq. 2):

$$CO(NH_2)_2 + 2H_2O \rightarrow 2NH_4^+ + CO_3^{2-} \quad (1)$$

$$Ca^{2+} + CO_3^{2-} \rightarrow CaCO_3 \quad (2)$$

This treatment is used in many geotechnical applications, for example to increase load bearing capacity of foundations, provide soil resistance to erosion and against liquefaction, and to reduce the collapse potential of soils (see for example Al Qabany *et al.* 2012). The shallow treatment of sandy soils to increase resistance to the formation of ravines is a recent application tested in small-scale laboratory tests (Fernandez and Cardoso, 2022), and was applied in a real slope in Portugal to investigate the durability of the treatment, in the scope of the ongoing project of Instituto Superior Técnico funded by the Portuguese Foundation for Science and Technology (ref. PTDC/ECI-EGC/1086/2021). This case-study is an excavation slope of the A13 Motorway, managed by Brisa. The treatment was carried out by Rodio Portugal, from the Soletanche-Bachy group, who provided the bacteria. The treatment applied in the slope and the first monitoring data are presented in this paper.

2 CASE STUDY

2.1 Overview

The slope treated (Figure 1) is located at A13 Motorway near Benavente, 40 km from Lisbon, Portugal. It was selected to meet the following criteria: excavated in a sandy geological foundation, maximum 6 m in height, slope smaller than 30º, no accentuated signs of ravine, and be accessible from the top.

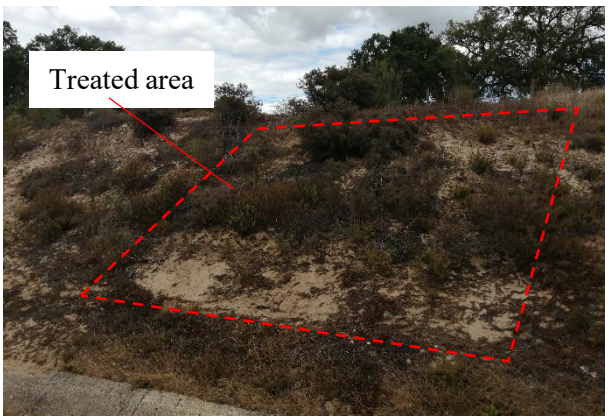

Figure 1. Slope before the treatment and treated area.

The soil of the treated area classifies as a well graded sand (SW) with 2% non-plastic fines and no gravel. The average dry unit weight is 15.5 kN/m^3 and the permeability measured was 2.4x10^{-4} m/s.

2.2 Bacteria and feeding solutions

Bacteria *Sporoscarcina Pasteurii* in lyophilized form were used, supplied by Soletanche-Bachy. They were mixed with tap water. The feeding solution was prepared also with tap water, using equal concentrations of urea and calcium chloride (0.5 M each).

2.3 Treatment

The area treated was the upper part of the slope (around 6 m × 6 m, see Figure 1), being left an untreated horizontal stripe (1 m width) in the bottom, which would receive the treatment fluids that would not be infiltrated in the treated area.

The treated area was divided into two vertical stripes to test two different methodologies: injection and irrigation was applied in the right side, and irrigation was applied in left side (Figure 2). The irrigation would treat only a surface layer, with a thickness expected to be between 0.08 and 0.10m. The injection was done using pipes (5 columns and 12 rows) placed at a depth of 0.5 m. The treatment protocol followed was identical for both methods. It was designed to reach the minimum percentage of calcium carbonate of 4%. The treatment was applied in September 2022 by Rodio Portugal and had the duration of 5 days.

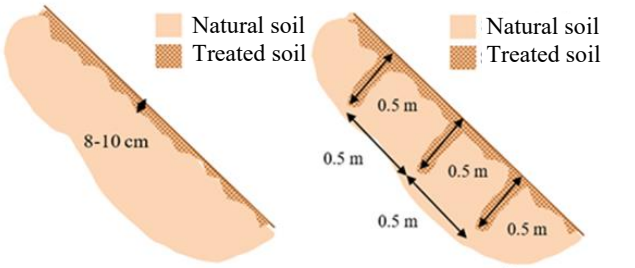

Figure 2. Treatment methods adopted for the two vertical strips of the slope.

The construction site was organized in the first day, being the slope surface levelled and the injection pipes installed (Figure 3). A plastic membrane was placed in the bottom to collect the effluent fluids during the treatment and from the final washing.

The treatment was applied in the following three days, with two applications in each day. It consisted in adding the bacteria solution to the soil followed, one hour later, by the addition of the feeding solution. These fluids were pumped from the mixer where they were prepared (Figure 3) into the injection pipes with valves. The injections were applied in the 5 pipes of each row, starting in the top of the slope, and were controlled pipe by pipe.

Figure 3. Installation of the injection pipes (left) and mixer used to prepare the bacteria and feeding fluids (right).

In the last day, the slope was washed with water through injection and irrigation and the plastic membrane at the bottom was removed.

2.4 Monitoring

The monitoring campaigns took place on average every two months, from September 2022 to July 2023, knowing that the treated slope will be observed for at least two years. A 5x5 grid, with dimensions 5.5 m x 5.5 m, was created to define the positions to extract small soil samples for measuring the percentage of calcium carbonate in the laboratory (Figure 4). These samples were extracted to 3 cm depth.

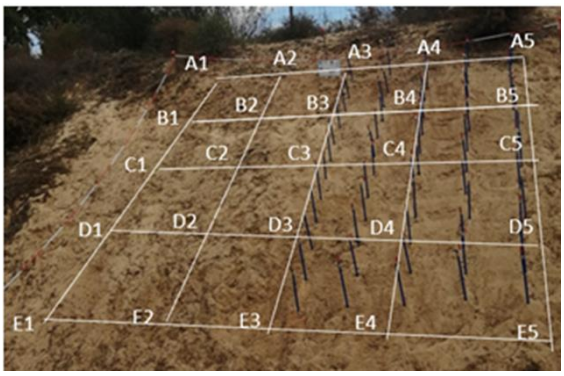

Figure 4. Grid defined for sampling during monitoring.

The percentage of calcium carbonate ($\%CaCO_3$) is given by Eq. 3., where m_{before} is the initial weight of the dried samples, and m_{after} is the weight of the same samples dried after being washed with hydrochloric acid (0.5 M):

$$\%CaCO_3 = \frac{m_{after} - m_{before}}{m_{before}} \quad (3)$$

3 CALCIUM CARBONATE DISTRIBUTION

The percentage of calcium carbonate measured in the samples collected allowed plotting the calcium carbonate distribution maps presented in Figure 5 using the Surfer® program (Golden Software, 2023).

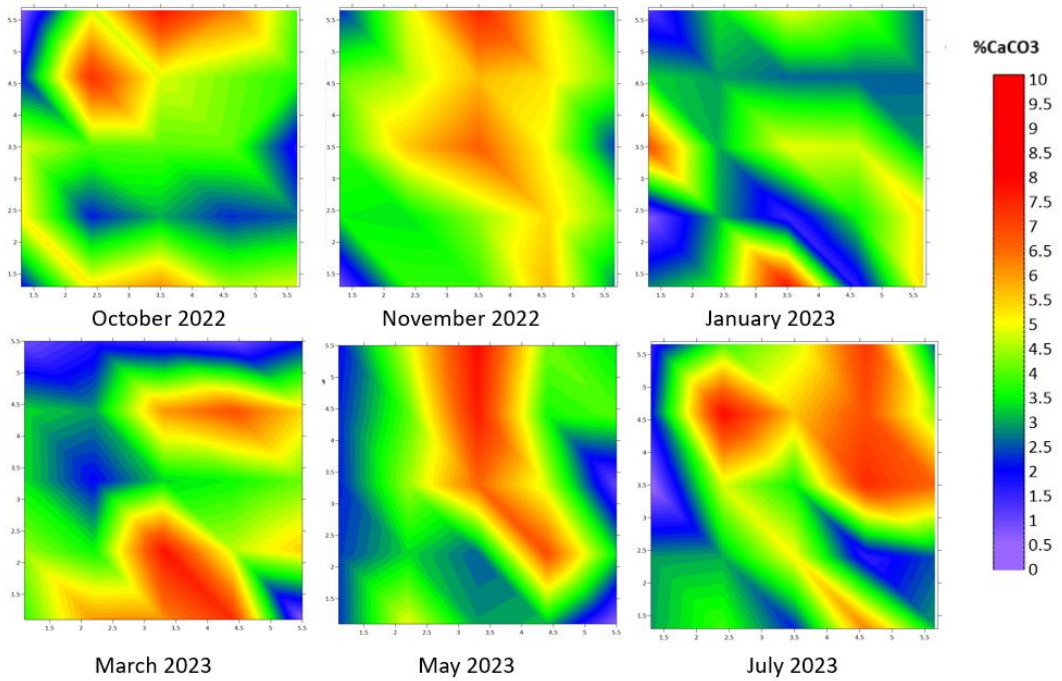

Figure 5. Distribution maps of the percentage of calcium carbonate in the treated area.

It can be seen that the treatment was heterogeneous and the $\%CaCO_3$ varied after successive sampling along time in each position. Some calcium carbonate was accumulated in the central zone, mostly at the top, where the treatment was applied by irrigation and injection. The temporal oscillations might be explained by some surface erosion caused by rain events. The $\%CaCO_3$ was not investigated in depth to avoid destroying the slope during the first year after the treatment.

The ravines formed in the treated slope surface were mainly caused by the treatment fluids and rain occurring during the treatment (see Figure 3) and they remained stable once they were formed. This can be seen in the photographs taken in October 2022 and in July 2023 (Figure 6). The ravines in the bottom are in the untreated horizontal strip. It can also be seen that vegetation is starting to appear in the top of the slope.

Figure 6. Photographs of the slope showing stable ravines in the treated area and the growth of a bush.

In general, the percentages of calcium carbonate measured were larger than the predicted value of 4%, as it can be seen in Figure 7, presenting its evolution along the horizontal alignment C in the middle of the treated area. The fact that the values are stable for the observed period suggests that the treatment is durable. Due to the dispersion of the results (Figs. 5 and 7) there is no obvious distinction between the zones where the two different treatment methodologies were used.

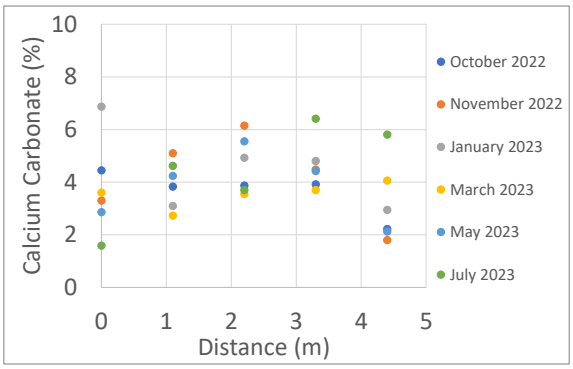

Figure 7. Values measured in horizontal alignment C.

Finally the presence of hard aggregates with high $\%CaCO_3$ is another evidence of the heterogenity.

4 CONCLUSIONS

The photographs of the slope surface during the monitoring period confirm the presence of ravines caused by water. This extreme form of surface erosion started during the treatment, appearing to become stable along the monitoring time. The values of the percentage of calcium carbonate measured in the different zones of the treated area presented some oscillation along the monitoring time, which was explained by some erosion caused by rain. Nevertheless, they were larger than the target value of 4% and remained stable, which indicates that the amount of biocement is stable, and therefore the treatment is being durable. The slope will be under observation for a longer period to understand better the durability of the treatment.

The results are inconclusive in what it concerns if the treatment by injection and irrigation can be more effective than just by irrigation. The ongoing investigation of the distribution of calcium carbonate in depth is fundamental to better evaluate each methodology.

Finally, the growth of a small bush in the top of the slope suggests that vegetation can grow in the presence of the biocement. This will also be confirmed with further observation of the slope.

Load-penetration response of a site-won soil reinforced with natural fibres. Application for unpaved roads

Réponse charge-pénétration d'un sol local renforcé avec des fibres naturelles. Application pour des routes non pavées

ABSTRACT: Unpaved roads are fundamental infrastructure worldwide. Forest roads provide access to forest areas to enable exploring the forest value chain products and access for firefighting. Usually, unpaved roads are formed using a superficial layer of unsealed gravel or aggregate, and often local soils or a mix of both materials. Reinforcements can be used to improve the mechanical properties of soil and aggregate, which enable reducing the quantities of good quality materials required for construction of these roads and delay the occurrence of defects leading to maintenance operations. Commonly, geosynthetics are used. However, alternative solutions can be defined, namely by applying locally available products. Resourcing natural reinforcements locally available can contribute to increasing the sustainability and decreasing the carbon footprint of the solutions adopted. Although natural materials tend to biodegrade, in areas such as forests where they are readily available, they can be a valid alternative. This study analysed the behaviour of a site-won fine soil reinforced with natural fibres from the forest value chain (pine needles), to assess the possibility of their use on unpaved forest roads. CBR tests were carried out to assess the load-penetration response of the soil and the soil-pine needles composite material. These tests and their interpretation have limitations, but they provide information commonly adopted in design methods for unpaved roads. The tests results allowed to conclude that the force-penetration response and CBR of the soil was improved by including pine needles; the greatest gain was observed for soil reinforced with 1% fibres, in mass.

RÉSUMÉ: Les routes non revêtues sont cruciales à l'échelle mondiale. Elles servent notamment les routes forestières permettant l'accès aux zones boisées pour explorer les produits de la chaîne de valeur forestière et prévenir les incendies. Généralement, sont composées d'une couche superficielle de gravier ou de granulats non scellés, souvent associés à des sols locaux. Les renforts améliorent les propriétés mécaniques du sol, réduisant le besoin de matériaux de qualité supérieure et retardant les défauts nécessitant des opérations d'entretien. Malgré l'utilisation courante des géosynthétiques, des alternatives locales, comme les renforts naturels, accroissent la durabilité et réduisent l'empreinte carbone. Les matériaux naturels, bien que sujets à la biodégradation, restent une alternative viable, notamment dans des zones comme les forêts, où ils sont facilement accessibles. Cette étude a analysé le comportement d'un sol fin obtenu sur site et renforcé par des fibres naturelles de la chaîne de valeur forestière (aiguilles de pin), afin d'évaluer la possibilité de les utiliser sur des routes forestières non revêtues. Des essais CBR ont été réalisés pour évaluer la réponse charge-pénétration du sol et du matériau composite sol-aiguilles de pin. Bien que ces essais aient des limites, ils fournissent des informations communément adoptées dans les méthodes de conception des routes non revêtues. Les résultats des essais ont permis de conclure que la réponse force-pénétration et le CBR du sol ont été améliorés par l'inclusion d'aiguilles de pin; le gain le plus important a été observé pour le sol renforcé avec 1% de fibres, en masse.

Keywords: Biodegradable reinforcement; unpaved roads; CBR tests; sustainability; percentage of incorporation.

1 INTRODUCTION

Unpaved forest roads are essential infrastructure worldwide, contributing to the economic, social, and cultural development of rural and forest areas, providing access to explore forest products. They have lower construction costs than paved roads and are an important part of the road network in many countries. They also play an important role in safeguarding and defending the forest against fires by ensuring access for preventive works, surveillance, or firefighting.

Usually, unpaved forest roads have low traffic volumes but are subject to high loads from heavy timber transport vehicles and forestry equipment. These roads are formed using a superficial layer of unsealed gravel or aggregate, and often local soils or a mix of the two types of material, placed above the foundation soil (roadbed). When subjected to traffic loads, the performance of these roads is influenced by

the quality of the construction materials used. Low-quality materials (e.g., materials with large quantities of fine particles) can decrease the resistance of the pavement, leading to deformations (in wet conditions) and dust (in dry conditions) (Pinard and Hongve, 2020). Repeated loads can cause the accumulation of plastic deformation and ruts, due to the reduction in aggregate layer thickness and owing to the deformation of the foundation (Dawson, 2001). Using good-quality natural materials (soils and aggregates often unavailable at the road site) has high extraction and transport costs and environmental impacts.

Alternative solutions can be used, for example applying locally available products or reinforcements to improve the mechanical properties of soils and aggregates. The main purpose is to reduce the quantities of good quality materials and to delay the occurrence of defects and the necessary maintenance operations. Pinho-Lopes (2022) and Magalhães et al. (2022) evaluated the use of industrial by-products and waste to improve the behaviour of soils for road applications. By-products from the forestry value chain (bottom and fly ashes) were used with the same purpose by Nienov et al. (2023) and Cepriá et al. (2021). Reinforcement with geosynthetics is a very popular solution to extend the useful life of these roads (Bräu and Vogt (2018), Al-Qadi et al. (2011)).

This work analyses the behaviour of a site-won soil reinforced with natural fibres (pine needles) from the forest value chain, to assess their use in unpaved forest roads. Although natural reinforcement materials may biodegrade, they can be a valid alternative in areas where they are readily available. To assess the load-penetration response of the fibre-reinforced soil composite, California Bearing Ratio (CBR) tests were carried out, analysing the influence of the percentage of fibres incorporated into the soil.

2 METHODOLOGY

2.1 Experimental programme

This paper includes results of CBR tests, carried out on a fine soil reinforced with pine needle fibres. The response of the soil, unreinforced and with fibre reinforcement, tested under the same conditions, was compared. The reinforced specimens analysed had different needles percentages of incorporation (NPI): 0% (unreinforced), 0.5%, 1.0%, 1.5%, 2.0% and 3.0%, in mass. Three specimens were tested per condition.

2.2 Materials

The fine soil used was collected from a salt pan wall in the Aveiro lagoon, Portugal, and characterised using laboratory tests. According to USCS, Unified soil classification system (ASTM D2487, 2011), the soil is ML - sandy silt. Additional characteristics of the soil: percentage of fine particles (<0.074 mm) 65.7%; average grain size (D_{50}) 0.023 mm; liquid limit (w_L) 35%; plastic limit (w_P) 25%; plasticity index (I_P) 10%; apparent unit weight (γ) 18.3 kN/m^3. The compaction characteristics of the soil, obtained from modified Proctor tests (ASTM D1557, 2012) are: maximum dry density (γ_{dmax}) 18.09 kN/m^3 and optimum water content (w_{opt}) 13.9%. Figure 1 illustrates the grain size distribution of the soil.

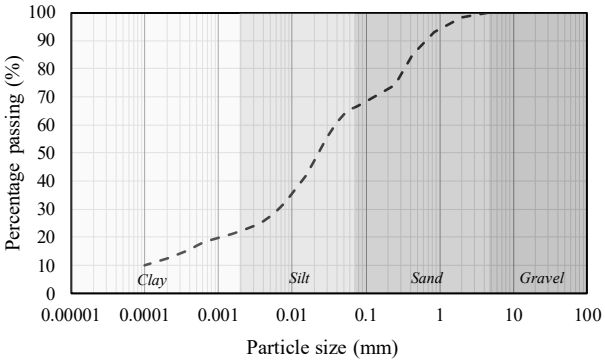

Figure 1. Grain size distribution of the soil studied (USCS, Unified soil classification system, soil fractions).

The pine needles were collected from a stone pine (botanical name *Pinus pinea*), also from the region of Aveiro, Portugal. Their geometric properties, namely length and width, were quantified using a 15 g sample. The pine needles ranged in length from 60 to 180 mm (mean value 117 mm and 42.4 mm standard deviation) and in width from 0.62 to 1.11 mm (mean value 0.87 mm and 0.15 mm standard deviation). The pine needles had a mean aspect ratio (length to width) of 134. The normalised length, L_N, and width, D_N, of the pine needles relatively to the average particle size of the soil (D_{50}) was 5087 and 38, respectively. The biochemical and mechanical properties of the fibres were not assessed. According to Dinesh et al. (2023), red pine needles contain 52-60% cellulose, 20% hemicellulose, 13-15% lignin and 5% of other extractives and have a maximum tensile strength between 35.8 and 36.94 MPa.

2.3 CBR tests

CBR tests were carried out following the procedure outlined in LNEC E198 (1967), which differs to ASTM D1883 (2007) on the imposed axial displacement rate only (1.00 instead of 1.27 mm/min).

Prior to the tests, the soil was dried, then its water content was adjusted to the required value (w_{opt}=13.9%). The soil was left to rest during 24 hours

under controlled conditions (temperature 20 ºC, relative humidity 65%); according to ASTM D1557 (2012), for ML soils this period should be longer than 16 hours. For the reinforced specimens, dry pine needles were added and mixed with the soil after the procedure referred, i.e., immediately before preparing the test specimens. The fibres were mixed with the soil in 5 portions, one per layer of the specimen.

A metal mould was used to produce cylindrical specimens (diameter 152 mm; height 125 mm). Each specimen was created by compacting 5 layers (25 mm high each) of soil or a mix of soil with needles with 25 blows of a rammer (4.54 kg; drop height 457 mm). Then, the specimens were soaked for 96 hours in an immersion tank filled with water. The swelling was registered; for specimens with NPI up to 1.0%, it stabilised after 96 hours; for specimens with NPI >1%, the soaking process was terminated after 96 hours (even if the swelling had not finished).

CBR tests were performed at an axial displacement rate of 1 mm/min., using a 50 mm diameter piston and a constant surcharge (by three annular plates, 24.52 N each) at the upper surface of the specimen.

3 RESULTS AND DISCUSSION

3.1 Summary of results

The force-penetration response for three specimens per condition (Figure 2) and the CBR of the specimens were defined. Herein the CBR was obtained from Equation 1, as the ratio of the force measured during the test for a value of penetration of 2.5 mm ($F_{2.5}$) to the corresponding force for a standard material ($F_{2.5S}$):

$$CBR = \frac{F_{2.5}}{F_{2.5S}} \times 100 \qquad (1)$$

The CBR values reported include mean values for 3 specimens prepared and tested under similar conditions (Table 1) and the corresponding 95% confidence intervals. Table 1 also includes the improvement ratio (IR) obtained for different values of NPI studied. The IR is the ratio between the CBR of reinforced specimens to that of the unreinforced soil.

Figure 3 illustrates changes in the soil density (ρ), water content, and swelling of the specimens after the compaction of the soil inside the mould (unsoaked), and after soaking (soaked). These parameters, which influence the behaviour of the composite material, depend on the incorporation rate NPI.

Reinforced specimens (Figure 4) exhibited agglomeration of fibres (overlapping in certain areas of a specimen) and fibres bent near the edge of the mould (for fibres longer than the mould diameter).

Table 1. CBR and improvement ratio (IR) for different NPI.

NPI (%)	CBR (%)				IR (-)
	Specimen				
	1	2	3	Mean value	
0	3.0	4.7	3.1	3.6 (±1.1)	-
0.5	6.0	5.4	3.4	4.9 (±1.6)	1.36
1.0	9.2	6.6	6.3	7.4 (±1.8)	2.06
1.5	6.5	7.6	5.3	6.5 (±1.4)	1.81
2.0	4.8	5.1	4.9	4.9 (±0.2)	1.36
3.0	4.5	3.7	3.9	4.0 (±0.5)	1.11

(95% confidence intervals in brackets)

3.2 Discussion

An important scatter of responses was observed (Figure 2, Table 1), without and with reinforcement. The force-penetration response varied, depending on the NPI considered, particularly for smaller values of penetration. Globally, the inclusion of pine needles led to a stiffer response for all values of NPI. A NPI of 1.0% and 1.5% led to responses much stiffer than that of the unreinforced soil; overall, the best response corresponds to NPI=1.0%. For NPI of 2.0% and 3.0%, the fibre benefit was less evident; relative to the average response, the fibres are detrimental for penetration up to ~0.6 mm (NPI=2.0%) and ~1.5 mm (NPI=3.0%); for larger values of penetration the addition of fibres was always beneficial.

The CBR increased with the pine needle reinforcement, for all NPI considered: 12% (NPI=3.0%) to 105% (NPI=1.0%). The specimens incorporating 1.0% of pine needles showed the best force-penetration response and CBR, with IR~2. For NPI >1.0%, the improvement in behaviour was less pronounced and eventually declined (IR between 1.1 and 1.8). Again, this suggests that the optimal NPI for this soil was 1.0%.

The improved response of the reinforced specimens can be ascribed to the redistribution of stresses and strains induced by the inclusion of fibres, through interaction mechanisms. The fibres have an effective effect on the soil when they are mobilised, i.e., subject to external forces and deform.

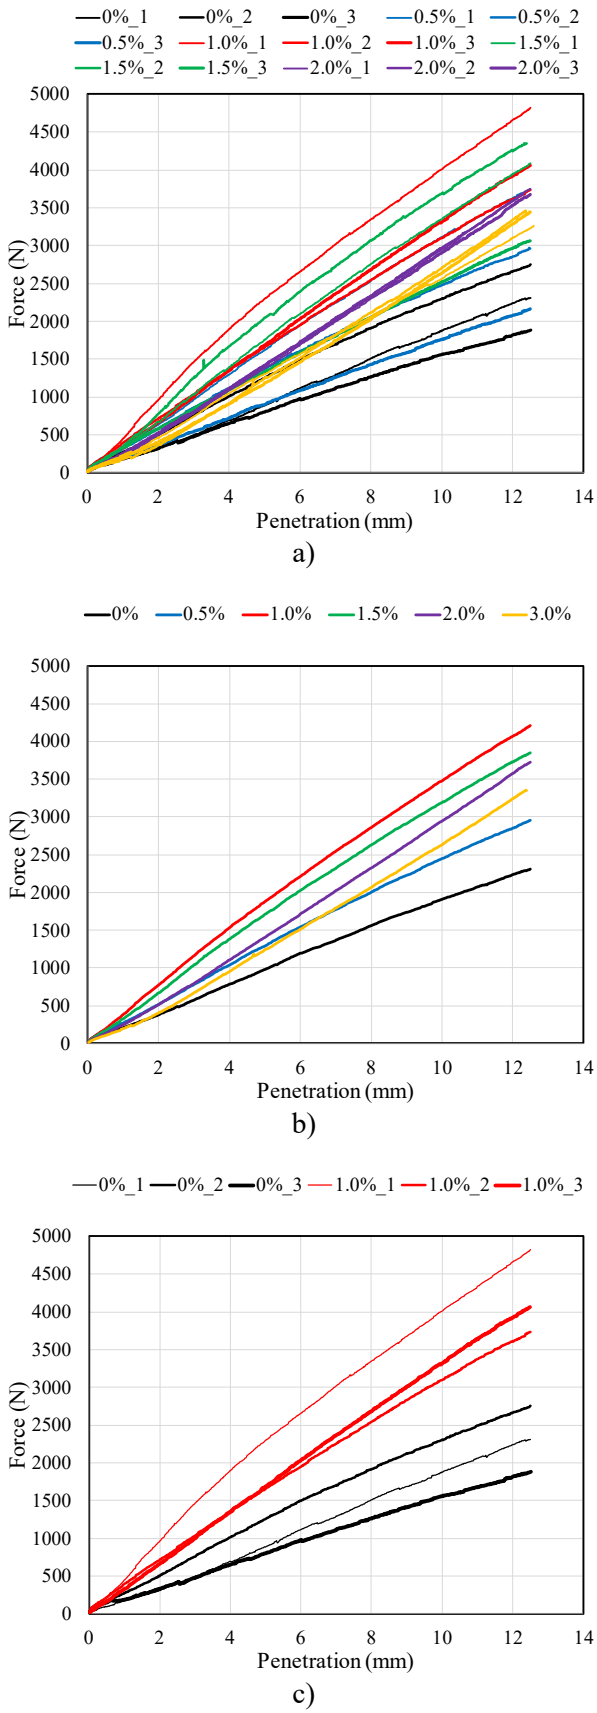

Figure 2. Force-penetration response for different percentages of incorporation (NPI): a) all specimens tested (3 specimens per condition); b) average for 3 specimens tested per NPI; c) optimal response (NPI=1%) and unreinforced specimens (NPI=0%), all specimens.

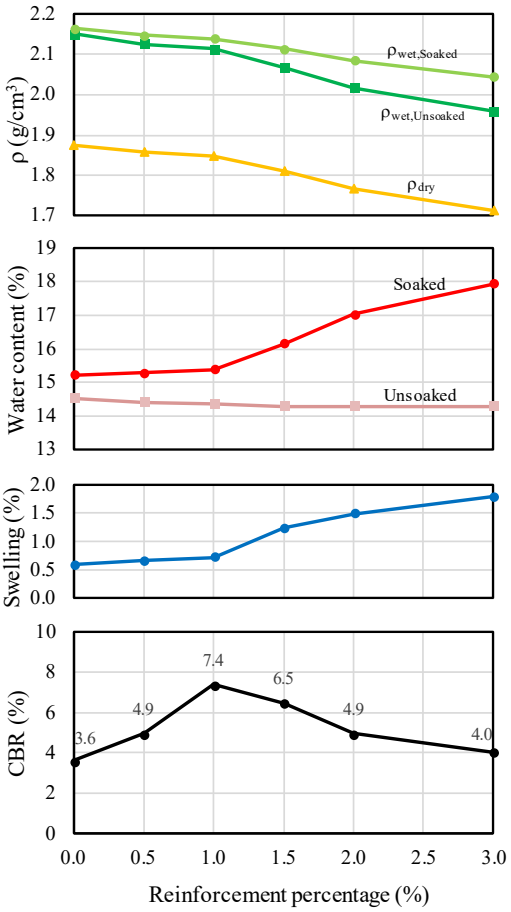

Figure 3. Influence of the pine needles percentage of incorporation, NPI, on the density (ρ), moisture content, swelling, and CBR (mean values for 3 specimens).

a) b)

Figure 4. Specimen of soil reinforced with pine needles: a) inside view (specimen cut along its height); b) outside view.

The soil skeleton was affected by the inclusion of fibres and, consequently, the distribution of stresses and strains inside the soil. The inclusion of fibres decreased the density of the specimens (Figure 3), especially above the optimum NPI (1.0%). This occurred because the fibres tend to restrict the soil grain packing, creating larger voids in their vicinity. The length of the pine needles used, in their natural state, (117 mm) was close to the diameter of the mould

(152 mm). This made the process of mixing the fibres into the soil difficult, resulting in heterogeneous orientation and spatial distribution of the fibres in the specimen (Figure 4). Therefore, the voids near the fibres tended to increase with larger percentage of incorporation of the fibres (NPI), and the amount of soil in the specimens reduced. In addition, the density dropped, because part of the specimen was occupied by fibres, less dense than the soil. The compaction process was also made more difficult due to the elastic behaviour of the fibres and due the voids created next to the fibres, which absorbed the impact forces generated by the rammer. Thus, among other causes, the decrease in the specimen density may have contributed to deteriorating the response of the material and lowering the CBR for larger NPI values.

The structure of the soil and of the soil-pine needles composite material was also modified during the soaking process because both materials (soil and fibres) absorbed water and underwent volumetric expansion (swelling). The inclusion of fibres increased the swelling and water absorption, mainly for NPI larger than 1.0%, illustrated by the variation of swelling and water content (Figure 3). The greater expansibility of the needles (hydrophilic material with high absorbent capacity) compared to the expansibility of the soil created preferential paths for water to flow through the soil, leading to an increase in the water content of the specimens. The increase in voids near the fibres also contributed to increasing the water flow into the specimens, raising the water content. Consequently, the increased water content led to a worse force-penetration response and reduced the CBR of the soil. This effect was particularly important for specimens with NPI larger than 1.0%.

The specimens exhibited agglomeration of fibres (overlapping in certain areas of a specimen) and some fibres were bent near the edge of the mould (Figure 4). This is related to the length of some fibres (longer than the mould diameter) and the compaction process. The resulting heterogeneity of the composite material was more important for higher NPI values. Many fibres were overlapping and could not be mobilised effectively during loading. Observation of the specimens after the tests showed that some fibres were bended or broken into smaller pieces. The reduced contacts between soil particles and fibres observed for higher values of NPI decreased the effectiveness of the mobilisation of the fibres.

In addition, the water incorporated into the specimens during the soaking process makes the interaction mechanisms at the interface between the materials less effective, since the water decreases the effective stresses, reducing frictional shear stresses and inducing sliding and ruptures at the interface.

The 95% confidence intervals for the mean value of CBR (Table 1) were rather high, showing some variability in the tests results. This may be caused by heterogeneity of the materials studied (soil, needles and composite material). Such heterogeneity is an intrinsic characteristic of soils, since they are natural materials. In this work, each specimen was prepared with new soil, so the soil in each specimen is a slightly different. The needles are also heterogeneous (section 2.2). Additional factors influence the heterogeneity of the reinforced soil specimens, such as the specimen preparation process. The specimens were prepared with soil reinforced with randomly distributed fibres, which suggests a certain degree of heterogeneity in the structure of the reinforced soil. The pine needles were used in one piece; many were longer (60 to 180 mm length) than the specimens (152 mm diameter and 125 mm height). The large volume filled with fibres (particularly for higher NPI) also made it difficult to mix the fibres with the soil, greatly increasing the heterogeneity of the specimens' structure.

The CBR test setup also does not guarantee that the reinforcement mechanisms mobilised during the test are realistic, since the tests are small-scale compared to real structures. The boundary conditions in the test can restrain the effect of the reinforcements. These limitations were mentioned before in several works about the force-penetration response of soils reinforced with several types of materials (geosynthetics, fibres).

4 CONCLUSIONS

The study analysed the behaviour of a site-won fine soil reinforced with natural fibres from the forest value chain (pine needles), to assess the possibility of their use on unpaved forest roads. CBR tests were carried out to assess the load-penetration response of the soil and of the soil-pine needles composite material. The results of the tests carried out allowed to conclude that:

- The force-penetration response and CBR of the soil improved with the inclusion of pine needles.
- Soil specimens with 1.0% of pine needles (in mass) led to an optimal response (force-penetration and CBR value).
- Percentages of incorporation larger than 1.0%, did not result in further improvement. The fibres affected the packing of the soil particles, as well as the swelling of the composite material.
- Due to water absorption capacity of the natural fibres, larger percentages of incorporation of fibres decreased the density and increased the water content and swelling of the specimens.

The effectiveness of the interface between both materials may also have been reduced.

- These parameters are linked, making it difficult, if not impossible, to reach a conclusion on which parameter has the most influence on the behaviour of the pine needle reinforcement.

Thus, further investigations should include the analysis of that the effect of fibres geometry (considering needles with different length), the effect of soaking process (comparing the behaviour of unsoaked and soaked specimens), and the effect of specimens' dimensions (using larger mould).

ACKNOWLEDGEMENTS

This study was funded by the PRR - Recovery and Resilience Plan and by the NextGenerationEU funds at Universidade de Aveiro, through the scope of the Agenda for Business Innovation "Transform - Transformação digital do setor florestal para uma economia resiliente e hipocarbónica" (Project no.34 with the application C644865735-00000007). This work was financially supported by FCT ("Fundação para a Ciência e a Tecnologia"- Portugal) through the project UIDB/04450/2020 (RISCO).

Assessment of stiffness parameters of stone columns

Évaluation des paramètres de rigidité des colonnes ballastées

ABSTRACT: This paper presents theoretical formulations for determining stiffness parameters of stone columns that can be evaluated from the results of load tests, such as: Young's moduli, confined moduli (oedometric), triaxial moduli and moduli of subgrade reaction. Theoretical examples and real load test measurements are presented, where different stiffness parameters of stone columns are compared, and recommendations are provided for proper characterization of these stiffness parameters, aimed to facilitate their use in numerical calculations with advanced constitutive models, as well as for simplified analytical calculations. As conclusions, based on these theoretical assessments and the experience, it is indicated that regardless of the installation method, the moduli of stone columns should be evaluated under triaxial conditions and adopting values from 20 to 100 MPa, approximately. Moduli higher than 120 MPa may imply risky overestimations.

RÉSUMÉ: Cet article présente des formulations théoriques pour déterminer les paramètres de rigidité des colonnes ballastées qui peuvent être évalués à partir des résultats d'essais de charge, tels que: les modules de Young, les modules confinés (œdométriques), les modules triaxiaux et les modules de réaction du sol de fondation. Des exemples théoriques et des mesures d'essais de charge réelles sont présentés, où différents paramètres de rigidité des colonnes ballastées sont comparés, et des recommandations sont fournies pour une caractérisation appropriée de ces paramètres de rigidité, visant à faciliter leur utilisation dans les calculs numériques avec des modèles constitutifs avancés, ainsi que pour des calculs analytiques. En conclusion, sur la base de ces évaluations théoriques et de l'expérience, il est indiqué que quelle que soit la méthode d'installation, les modules des colonnes ballastées doivent être évalués dans des conditions triaxiales et en adoptant des valeurs de 20 à 100 MPa environ. Des modules supérieurs à 120 MPa peuvent impliquer des surestimations risquées.

Keywords: Stone columns; triaxial modulus; load tests; settlements.

1 INTRODUCTION

Stone columns installed by deep vibrators have been used successfully in numerous of projects since the 1960s to reinforce soft or loose soil with high compressibility, speed up the consolidation process, decrease settlement, increase bearing capacity, and mitigate soil liquefaction. This deep vibro technique has a specific European Standard (EN 14731:2005, Ground treatment by deep vibration).

The so-called bottom-feed method consists of gravel insertion into the ground through a system of tubes attached to a vibrator coupled at the bottom. The whole rod is introduced into the ground aided by lateral displacement, vibration, vertical pull-down force and compressed air. Once the required depth is reached, the tubes stabilize the cavity and allow the gravel feeding. The general motions of deep vibrator compact the gravel by successive lowering and uplifting moves until the column is finished (Figure 1a). Other methodologies and equipment are also available, like the Rammed Aggregate Piers (RAP) firstly appeared during the 1990s. Figure 1b describes this method, which consists of extraction drilling and gravel feeding from the working platform. The compaction is only carried out vertically, through tamping by impact produced by a plate in contact with the gravel. The stability of the drilled cavity is highly important to implement this method, especially when the water table or very soft soil are found.

Attempts are usually made to evaluate the stiffness of stone columns by means of relatively quick plate load tests, where the induced settlements produced by the load increments are measured. Based on such results, the first approach to evaluate the column stiffness is the modulus of subgrade reaction (k_{col}),

defined as the ratio of the applied stresses to the measured settlements. Nevertheless, the determination of column moduli (stress - strain relationship) is a more complex procedure, strongly affected by the boundary conditions and loading procedure.

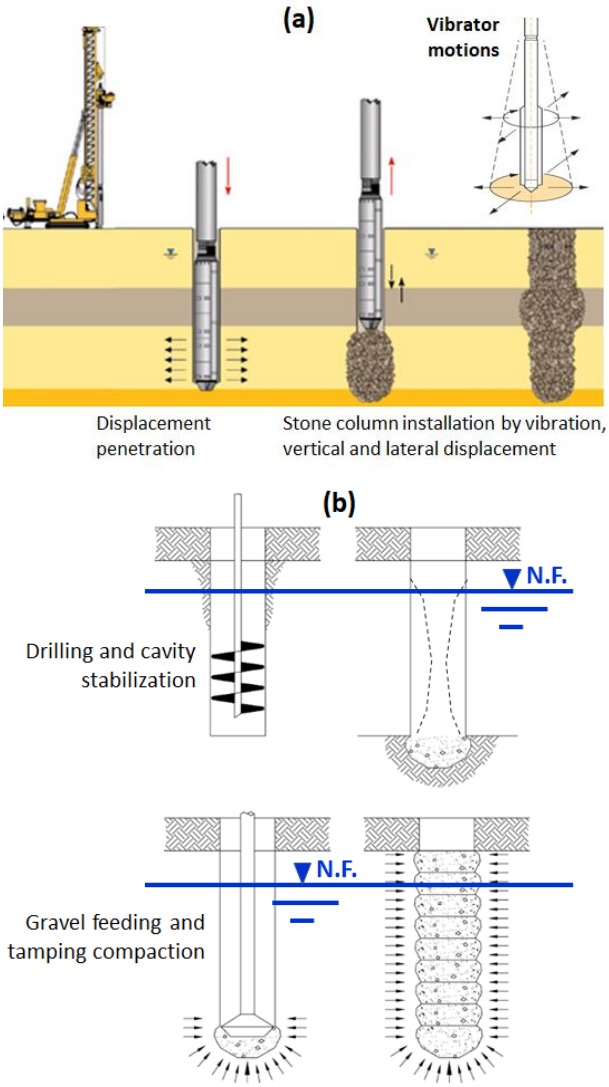

Figure 1. Methods: (a) vibro stone columns by bottom-feed; (b) Rammed Aggregate Pier with top-feed.

2 STIFFNESS EVALUATION

A range of moduli between 170 and 300 MPa is sometimes erroneously assumed for the stone columns. This assumption attributes abnormally high values for the moduli of stone columns, which is not in accordance with the actual values reported in the literature and practitioners' experience.

To properly assess the modulus of the stone columns, loading and boundary conditions must be correctly assumed. It is highly recommended to take reference values of moduli from the literature or conduct triaxial laboratory tests.

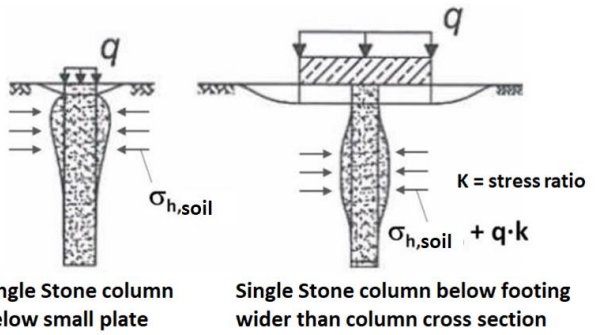

Figure 2. The triaxial conditions of stone columns below foundations and plate load tests.

Indeed, triaxial conditions correspond to the most representative state that stone columns undergo to support the foundation loading. Figure 2 shows the compression triaxial state usually produced in stone columns and surrounding soil under a foundation structure (similar to laboratory triaxial tests). Stone columns mainly deform through lateral bulging when subjected to compressive loading in triaxial conditions and are supported by the horizontal confining stress exerted by the surrounding soil. This behaviour has been demonstrated and extensively described by several researchers (Priebe, 1976; Priebe, 1995; Barksdale and Bachus, 1983; Goughnour and Bayuk, 1979; Wehr, 2004; Kirsch and Kirsch, 2010; Greenwood and Kirsch, 1983; Hu, 1995; Castro and Sagaseta, 2009).

The most common range of moduli values of stone columns in triaxial conditions varies from 20 to 100 MPa, approximately, according to many researchers who carried out comprehensive analyses by laboratory testing, field measurements, and numerical modelling (Han and Ye, 2001; Balaam and Booker, 1981; Castro, 2017; Bachus and Barksdale, 1983; Kirsch and Kirsch, 2010). The lowest moduli are obtained in the softest soils which offer the lowest confining stresses. It is worth mentioning that instead of the stone column stiffness, its friction angle and its diameter (i.e. the area replacement ratio) are the parameters with the largest impact on the improvement achieved with the treatment (Herle et al., 2007; Priebe, 1995).

Regarding the friction angle of stone columns, it is particularly interesting the investigation carried out by Duncan et al. (2007) about the same kind of material used for the stone columns (sizes 10–40 mm, approx.), which shows that moderately dense to very dense gravel may have a ϕ_{col} of approximately 55º for a very reduced level of lateral confining stress, of approximately 28 kPa (possibly in layers located at a depth of between 1.5 and 2.5 m); however, the same gravel with the same level of relative density experiences a significant decrease of ϕ_{col} to values between 40º and 47º, when the pressure is greater than

approximately 80 kPa (i.e., at depths of more than 4.5 to 7.0 m, approx.).

Figure 3 shows the degradation law of ϕ_{col} with the confining pressure, in accordance with the study by Duncan et al. (2007). It is particularly important to assess the risks that may arise if the design ϕ_{col} value is erroneously interpreted regarding the level of confining pressure to which they would be subjected, which not only depends on the initial stress state of the soil, but also on the stress state to which the soil and columns will be subjected due to the application of foundation loading.

Although the modulus in triaxial conditions (E_{TX}) is the most representative and widely used module to characterize stone columns, the subgrade reaction modulus, defined as the ratio between the vertical pressure applied on the foundation and the resulting settlement ($k_{col} = \Delta\sigma/s$), with density units (kN/m^3, t/m^3), is also usually considered.

Thus, based on the vertical pressures ($\Delta\sigma$) and the resulting settlement (s), it is possible to determine the subgrade reaction modulus of the columns (k_{col}) and the soil (k_s) by means of loading tests using small plates (0.30 to 1.0 m). For that reason, and because it is an affordable kind of test regarding execution times and costs, the execution of these plate loading tests is considered as an attempt to assess the stiffness of stone columns, or more precisely, of the soil-column system.

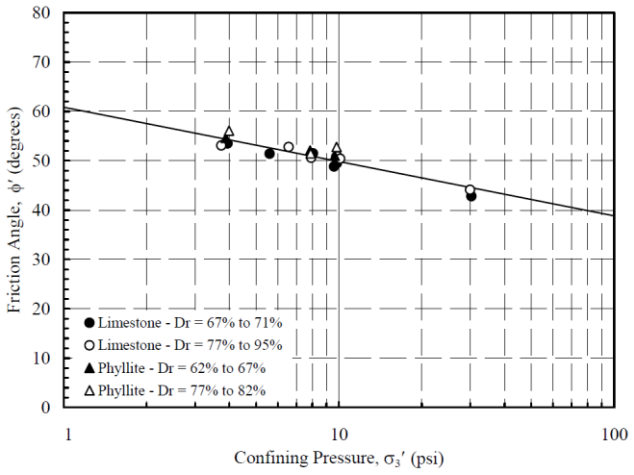

Figure 3. Duncan et al. (2007) investigation on internal friction angles on coarse aggregate type AASHTO #57.

However, these tests involve a number of limitations that complicate the proper assessment of column stiffness, such as: (i) small load plate tests only reach small depths (0.6 to 1.5 m); (ii) plate diameters usually only cover the column diameter, which limits the analysis of the real columns behaviour below the foundations which have greater area than the columns, Figure 2; (iii) plate tests are performed by fast loading and unloading procedures to complete the test in a few hours (e.g. NLT-357/98 or ASTM D-1143 Standards), therefore, the results mainly correspond to undrained conditions, which do not properly reproduce the elastic-plastic strains that govern the behaviour of stone columns and surrounding soil in the long-term; (iv) appropriate calculation procedures must be implemented to convert the measured reaction modulus (k_{col}) into the triaxial modulus (E_{TX}), as described in following sections.

Based on loading tests with a similar diameter to that of the stone columns, several researchers have compiled the "k_{col}" values, proposing empirical correlations between "k_{col}" and SPT blow-count, without the need of performing load plate tests. Figure 4 shows the correlation proposed by Sehn and Blackburn (2008), with recommended reaction modulus values for stone columns, considering both granular and cohesive soils around the columns.

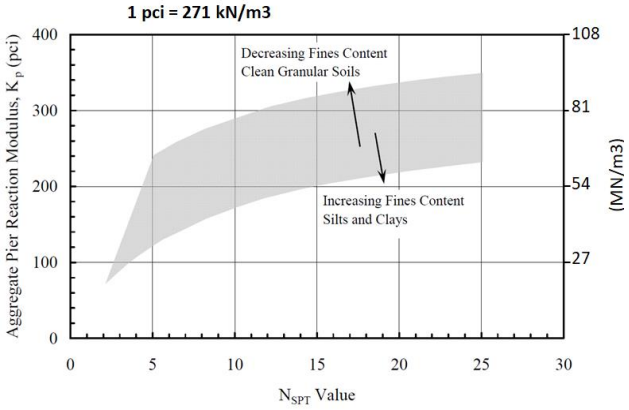

Figure 4. Correlation proposed by Sehn and Blackburn (2008) to estimate the reaction modulus for stone columns.

2.1 Stiffness formulation of stone columns

From the elasticity theory, a very simplified approach to estimate the settlement for a given soil element could be considered through Eq. (1):

$$S = \frac{\sigma_v}{E} . L \qquad (1)$$

where S is the settlement, E is the Young modulus of the column, L is the length of the considered element and σ_v is the axial stress applied.

Using the definition of reaction modulus (k_{col}) of a given soil element according to Eq. (2), it can be obtained a relationship between E and k_{col}:

$$k_{col} = \frac{\sigma_v}{S} = \frac{\sigma_v}{\frac{\sigma_v}{E} \cdot L} = \frac{E}{L} \; ; \; E = k_{col} \cdot L \qquad (2)$$

Then, under the simplified assumption that the induced stress during a field loading test has maximum value at the top of the element L, and reaches zero

stress at the bottom of the element, it can be considered that the average induced stress in the element is half of the applied stress at the top ($\sigma_{v,average} = \sigma_v / 2$). Thus, replacing σ_v by $\sigma_{v,average}$ in Eq. (2) the Eq. (3) can be obtained which represents a simplified relationship between the Young modulus (E) and the reaction modulus to evaluate the results from plate loading tests.

$$E = \frac{k_{col} \cdot L}{2} \quad (3)$$

More precisely, Boussinesq presented the closed-form solution to determine the settlement (S) under a rigid circular plate subjected to uniform load on an elastic and isotropic semi-space, as shown in Eq. (4).

$$S = \sigma_v \cdot R \cdot \frac{(1-\nu^2)}{E} \cdot I_a \quad (4)$$

where:
R: foundation radius
I_a: influence factor (in this case: $I_a = \pi / 2$)
σ_v: vertical stress
E: Young modulus ($E = \sigma_v / \varepsilon_v$; for $\sigma_h = 0$)
ν: Poisson's ratio ($\nu = \varepsilon_h / \varepsilon_v$)

From equation (4) the reaction modulus (k_{col}) can be determined as described in Eq. (5):

$$k_{col} = \frac{\sigma_v}{S} = \frac{E}{(1-\nu^2)} \cdot \left(\frac{2}{\pi}\right) \cdot \left(\frac{1}{R}\right) \quad (5)$$

Eq. (6) shows the relationship between Young's modulus (E) and the reaction modulus (k_{col}):

$$E = k_{col} \cdot (1-\nu^2) \cdot R \cdot \left(\frac{\pi}{2}\right) \quad (6)$$

Finally, looking back to the relationship between the oedometric and Young moduli (E_{oed} / E) based on Poisson's ratio (ν), depicted in Eq. (7), it is interesting to estimate the oedometric modulus both based on the simplified modulus (8) and based on the modulus derived from the Boussinesq's solution for rigid circular plate (9).

$$E_{oed} = E \cdot \left[\frac{1-\nu}{(1-2\nu)(1+\nu)}\right] \quad (7)$$

$$E_{oed} = \frac{k_{col} \cdot L}{2} \cdot \left[\frac{1-\nu}{(1-2\nu)(1+\nu)}\right] \quad (8)$$

$$E_{oed} = k_{col} \cdot R \cdot \left(\frac{\pi}{2}\right) \left[\frac{(1-\nu)(1-\upsilon^2)}{(1-2\nu)(1+\nu)}\right] \quad (9)$$

The relationships between k_{col}, E_{oed} and E from the Boussinesq's solution (Equations 6 and 9) include the implicit consideration of the influence depth of the foundation load, which may correspond to the plate load tests on stone columns in triaxial conditions and subjected to the confining stress of the surrounding soil. This implies a remarkable advantage over equations obtained from the simplified approach, because it allows the estimation of the moduli without the need of assigning arbitrary values to the original length of the soil element that needs to be studied (L), as is required with equations (3) and (8). Figure 5 shows the depth affected by the loads according to the Boussinesq's solution for homogeneous semi-space (one layer) and also shows the solution of Poulos and Davis (1974) for a bilayer model.

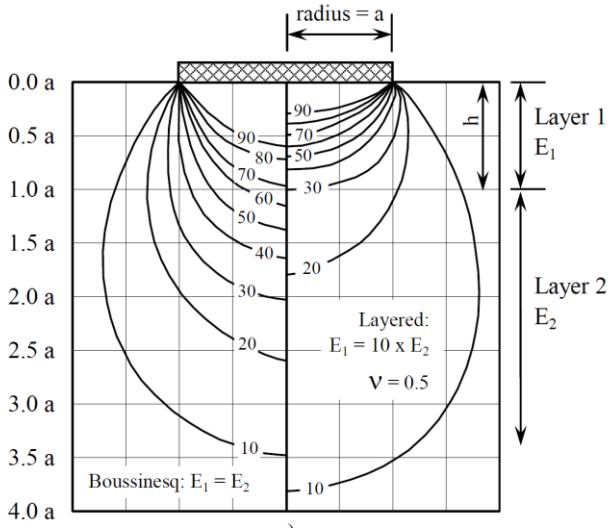

Figure 5. Influence depth of loaded rigid circular plate: (left) Boussinesq solution for homogeneous soil model; (right) Poulos and Davis (1974) for a bilayer model.

2.2 Example of moduli estimation

An example of moduli estimate for stone columns is shown, considering the following input data:

- Bearing plate diameter of 60 cm.
- Poisson's ratio of $\nu = 0.45$ for compacted gravel (Priebe, 1995).
- Reaction modulus, $k_{col} = 55$ MN/m^3. According to Figure 4, it could match a soil with SPT = 3–5; k_{col} could also be obtained from a plate load test on a column with 230 kN load (820 kN/m^2) and resulting settlement of 1,5 cm (820 kN/m2 /0.015 m) ≈ 55 MN/m^3.

Table 1 summarizes the results when using equations related to E_{oed}, E and k_{col}, from Boussinesq's solution. The results show a triaxial or Young modulus of 21 MPa and oedometric modulus of 78 MPa. These values are far from the aforementioned range of 170–300 MPa, showing that regardless of the execution

method, such values exceed the real stiffness of stone columns.

Table 1. Example moduli estimation of stone column.

Parameters	Bousinnesq (Equations 6 and 9)	Plain strain (Equations 3 and 8)
Influence depth, L	1.05 m	6.25 m
E_{oed}	78 MPa	652 MPa
E	21 MPa	172 MPa

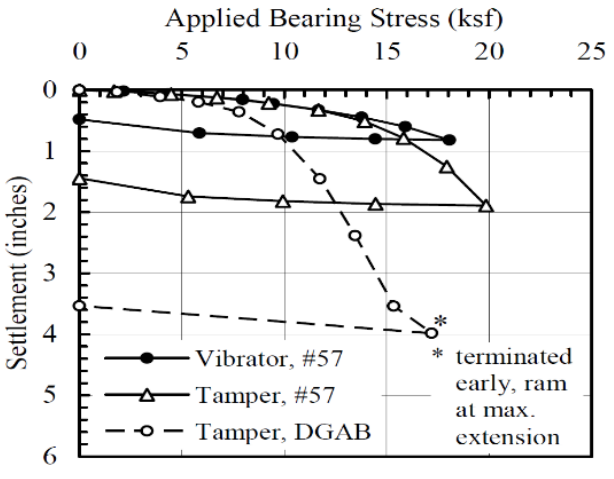
Table 1 also shows the results for the simplified approach, considering an influence depth of L = 6.25 m, which is necessary to obtain a modulus of the stone column of approximately E = 170 MPa.

This depth would be 20.8 times the radius of the foundation. In order to achieve E = 300 MPa it would be necessary to increase the influence depth to L = 11 m, which would be 37 times the radius of the plate.

2.3 Load tests on stone columns

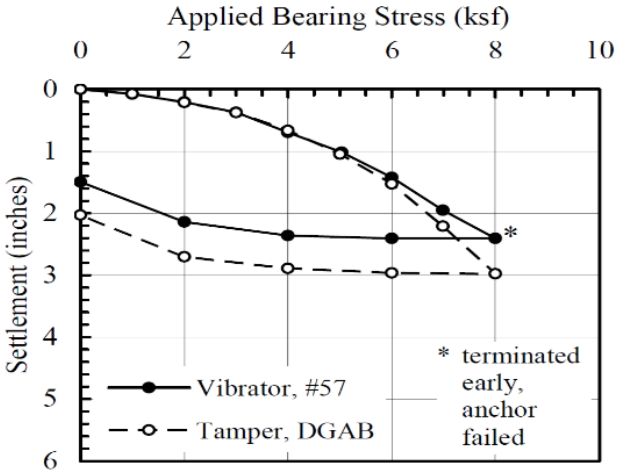
Stuedlein and Holtz (2008) performed an extensive study regarding the results of several load tests on small groups of stone columns (footings with 3 to 7 columns) and isolated columns with plate diameter of 76 cm.

Figures 6 and 7 show part of the results of this study, where very similar behaviour is observed in the columns performed with both methods (vibro bottom-feed and rammed aggregate piers).



a) 30-inch-diameter plate load tests

Figure 6. Plate Footing load tests on rammed aggregate piers (Tamper #57 and Tamper DGAB) and by bottom-feed deep vibrators (Vibrator #57), (Stuedlein and Holtz, 2008).



b) 9 ft x 9 ft footing load tests

Figure 7. Footing load tests on rammed aggregate piers (Tamper #57 and Tamper DGAB) and by bottom-feed deep vibrators (Vibrator #57), (Stuedlein and Holtz, 2008).

This similarity shows that the columns moduli are approximately the same for both execution methods, at least in the upper part of the columns, which can be assessed by plate load tests.

The dashed line in Figure 6 corresponds to a specific plate load test over one rammed aggregate pier, where relevant higher settlements is noticed. Further details of this specific load test can be found in Stuedlein and Holtz (2008).

3 CONCLUSIONS

Stone columns by deep vibrators, which are introduced into the ground by displacement and bottom-feed of gravel, have been successfully implemented for more than 60 years worldwide. This method has automatic control systems for execution parameters and one specific European Standard (EN 14731:2005).

Other procedures were developed around the 1990s, which include rammed aggregate piers as an alternative method, performed with extraction drilling, top-feed of gravel from working platform and compaction by vertical ramming.

The stone column moduli must be assessed under triaxial conditions. According to the experience and reported cases in literature the most common values of triaxial moduli vary from 20 to 100 MPa, the lowest moduli are obtained in the softest soils which offer lowest confining stresses. The consideration of column triaxial moduli higher than 120 MPa could imply a design overestimation regarding the reduction of settlement. Plate loading tests on isolated columns and small groups of columns show very similar behaviour in stone columns performed by both

methods. Tests on isolated columns with small plate diameters (30–60 cm) only allow assessments up to a depth of 1–1.5 m, so they do not represent the real behaviour of the entire column.

The Boussinesq's closed-form solution to determine the settlement (S) under a uniform loaded rigid circular plate on an elastic and isotropic semi-space can be considered for analytically interpretation of plate load tests, so that can be estimated the triaxial modulus of stone columns as a function of the measured reaction modulus during the test.

It is worth mentioning that instead of the stiffness, the friction angle and the diameter of stone columns present higher impact to maximize the improvement effects.

For adequate estimation of the friction angle of stone columns, it is essential to take into consideration the degradation law of ϕ_{col} with the confining pressure. This is particularly important to assess the risks that may arise if the design ϕ_{col} value is erroneously interpreted regarding the level of lateral confining pressure to which they would be subjected, which not only depends on the initial stress state of the soil, but also on the stress state to which the soil and columns will be subjected due to the application of foundation loading.

ABSTRACT: A case history is presented to describe the application of the "S-Alpha hydraulic Dive" system for the installation of stone columns offshore. This system comprises equipment able to be dived in the sea up to a maximum water depth of approximately 25 m, allowing to reduce the effective weight of the whole system and thus allowing the execution of deeper treatments of stone columns with dry bottom-feed method until approximately 70 m depth. It is described the soil improvement to support the foundation of one abutment for the San Ignacio bridge built over the Bilbao estuary in Spain. As conclusions, the satisfactory application of the "S-Alpha hydraulic Dive" system for the installation of stone columns offshore in very soft soils is highlighted, as well as the capacity of the improved soil to consolidate and increase the shear strength required to carry out this type of marine works.

RÉSUMÉ: Un cas historique est présenté pour décrire l'application du système "S-Alpha Hydraulic Dive" pour l'installation de colonnes ballastées en mer. Ce système comprend des équipements capables d'être plongés dans la mer jusqu'à une profondeur maximale d'environ 25 m, permettant de réduire le poids effectif de l'ensemble du système et permettant ainsi l'exécution de traitements plus profonds de colonnes ballastées avec méthode d'alimentation par le fond sec jusqu'à environ 70 m de profondeur. Il est décrit l'amélioration du sol pour soutenir la fondation d'une culée du pont de San Ignacio construit sur l'estuaire de Bilbao en Espagne. En conclusion, on souligne l'application satisfaisante du système "S-Alpha Hydraulic Dive" pour l'installation de colonnes ballastées offshore dans des sols très meubles, ainsi que la capacité du sol amélioré à consolider et à augmenter la résistance au cisaillement nécessaire pour réaliser ce type de travaux maritimes.

Keywords: Stone columns; deep vibrators; offshore; S-Alpha system; soft silts.

1 INTRODUCTION

Stone columns installed by deep vibrators represent a well-known ground improvement method with long history of development since 1960s (Kirsch and Kirsch, 2010). Recently significant advances regarding the installation of stone columns have been developed. This work attempts to address several of those improvements, essentially corresponding to the execution of stone columns for offshore sites considering that the literature about this kind of technology is still limited compared with the literature about the conventional execution of stone columns onshore (Carvajal and Mora-Rey, 2014).

Furthermore, the typical soil conditions to be improved in maritime works, which usually need large improvement depths and columns installation in very soft layers below seabed suppose an additional challenge for the execution technologies. Thus, the development of equipment able to assure the treatment objectives and proper quality control is of great interest. Particularly, the implementation of some relevant developments related to the execution and control systems of maritime works by stone columns are presented for the construction of abutment structures which support the San Ignacio bridge over the Nervion river in Bilbao, Spain.

2 STONE COLUMNS OFFSHORE

Before describing the advances for the installation of offshore stone columns, it is important to tackle some of the conventional methods. The oldest method consists of placing a bed of gravel on the seabed, thereafter, the gravel is crossed by means of deep

vibrators coupled to their whole system of rods (vibrator, extension tube, couplings), so that the gravel could fall into the cavity generated when the vibrator is lowering with the depth.

(a) (b)

Figure 1. Conventional system of stone column execution offshore: (a) gravel bed method on the seabed, (b) method of mechanically gravel feeding.

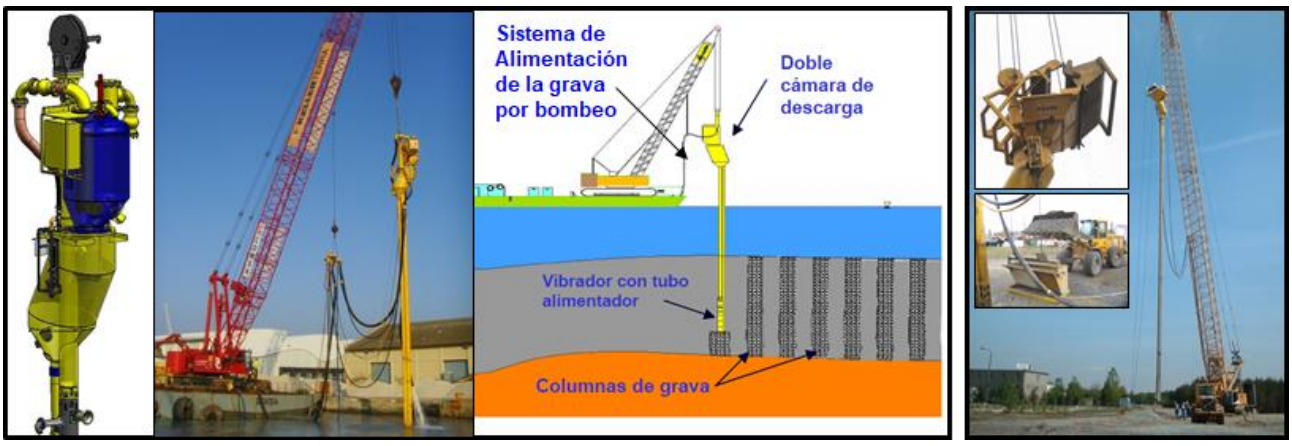
The deep vibrators in this system are aided by a water jet which enable their capacity to penetrate the different layers. Figure 1 shows a sketch of this methodology.

One of the most used methods, and which represented an important advance at the time, consists of "feeding gravel mechanically" or using the Hopper Method. In this case, the use of two barges is usually necessary; one for the crane with the vibrator hanging from an auxiliary crane, and the second with the gravel collection and an extendable arm excavator that feeds the hopper on top of the vibrator.

This system includes a double compartment chamber between the hopper and the vibrator where a mixture of compressed air and gravel is used to transport the gravel to the tip of the vibrator. The gravel is then compacted in the usual way by raising and lowering the vibrator. This method is illustrated in Figure 1b. The most recent technological development of special equipment for stone columns has allowed the treatment of very deep soft soils, both in marine and onshore works.

Figure 2a shows an execution system that represents a new generation of development. This is the so-called "alpha hydraulic system", consisting of a circuit to propel the gravel by pumping to a discharge chamber connected to the feeder tube through which the gravel flows until its final discharge into the ground through the lower part of the vibrator.

Figure 2b shows the "mechanical alpha system", where the gravel is deposited by a loader directly into the hopper. After filling the hopper with gravel, it is raised by wire rods until the top of the feeding tube, from where it is poured until it outflows by the bottom of the vibrator. In both alpha systems (hydraulic and mechanical), the whole rod composed by the hopper, feeding tube and vibrator is usually coupled to the arm of a crane (crane boom), to enable the execution of treatments at very deep depths up to app. 60 m.



(a) (b)

Figure 2. S-Alpha systems for installation of stone columns: (a) hydraulic, (b) mechanical.

3 NEW SYSTEM S-ALPHA DIVE

As a part of the continued development of the new generation of equipment for offshore stone column, significant improvements have been made to the Alpha hydraulic system. Figure 3 shows the new "S-Alpha hydraulic Dive" system, which consists of an equipment capable of diving in the sea to a maximum depth of approximately 25 m, allowing the effective weight of the entire system to be reduced and thus facilitate the execution of deeper treatments of stone columns with bottom-feed procedure, up to approximately 70 m deep. This method significantly improves the execution conditions of the entire system, making possible a very similar procedure as the well-known bottom-feed and dry system of stone column usually performed in onshore conditions. The possibility of submerging the system also facilitates the optimization of the capacity required by the cranes and increases the production rates. One of the most important aspects of the "Hydraulic S-Alpha Dive" system consists of obtaining a compact integration of all the components of the gravel feeding and diving system to the vibrator.

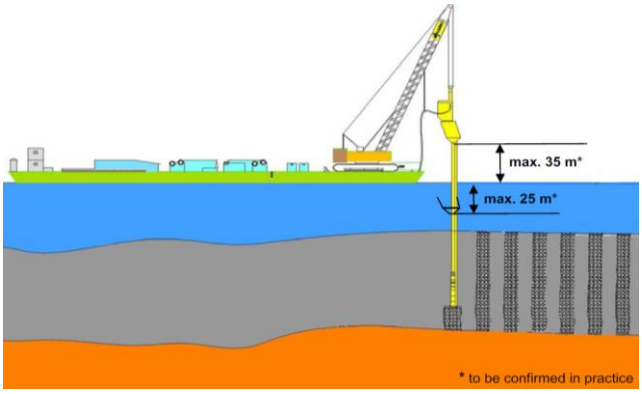


Figure 3. New system S-Alpha dive.

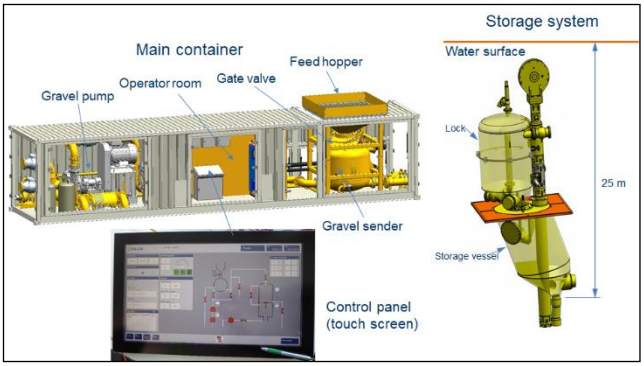

Figure 4. Components of S-Alpha dive system.

As can be seen in Figure 4, in a single type of container structure with approximately 12 m in length, where are deployed the gravel delivery pumps, the hopper for accumulation and dosing of the volumes of gravel supplied to the vibrator, as well as a control room where the panels are located that show the most important parameters of the power system. Additionally, another smaller container is considered where compressors, auxiliary pumps and a generator are placed.

As this new system can reduce the space and weight of all the necessary infrastructure, it also allows the system to require small barges or pontoons.

As a part of the execution procedure of this new system, it is necessary to use an auxiliary crane to transport the gravel from its general stockpile site to the hopper located in the main container. In some cases, for nearshore treatments, both the storage and auxiliary crane can be located on the land side, and when the treatments are located offshore, the storage must be located either on the main barge or on an auxiliary barge.

4 CASE HISTORY: SAN IGNACIO BRIDGE

Figure 5 shows a plan view and typical section of a treatment using offshore gravel columns, for the foundation of an abutment corresponding to the San Ignacio bridge, to be built on the Bilbao estuary (Spain). Basically, the stone columns installed with the system "S-Alpha hydraulic Dive" are aimed to consolidate and reinforce the soft silty soils with low-plasticity, which are located until maximum depths of 8 to 15 m below the seabed and represent an important risk of instability and non-allowable long-term settlements for both the abutment foundation and the adjacent embankments. These soft silts have undrained shear strengths in the order of 10 to 50 kPa, which pose a significant challenge to achieve the installation of the stone columns and meet the design objectives. In this case the crane, the main container and the barge used to carry out the works occupied an area of approximately 470 m2.

Figures 6 shows photographs of the work environment, where can be seen the auxiliary crane located next to the gravel storage, on the land side, and one front view of the S-Alpha dive system.

It is important to highlight that with this new system a more continuous feed of the gravel is achieved than that obtained by the conventional methods, due to the continuous drive system located in the main container, which is located a few meters from the main crane that supports the system of tubes connected to the vibrator. Figure 7a shows a typical log of the execution parameters of offshore stone columns using conventional systems. In this case, the vibrator penetrates to the desired depth, and then in

successive phases it incorporates gravel and compacts it, for which it must spend some time when finishing each stage of gravel compaction, to install the amount of gravel corresponding to each column segment.

Figure 7b shows this procedure using the new "S-Alpha Dive" system. The penetration phase of the equipment into the ground is similar, but in the phase of gravel feeding and its compaction with the vibrator, a continuous process is followed. These improvements represent a significant increase in the production rate, and therefore reductions in execution times. In both cases, the execution parameters are recorded continuously and automatically from the monitoring systems. Likewise, in both cases a GPS positioning system is used.

Figure 6. S-Alpha system at San Ignacio bridge site.

5 CONCLUSIONS

The satisfactory application of the "S-Alpha hydraulic Dive" system for the installation of stone columns offshore in very soft silts is highlighted, as well as the capacity of the improved soil to consolidate and increase the shear strength and reduce the soil compressibility required to carry out this type of marine works to build the west abutment of San Ignacio Bridge in Bilbao. Moreover, the new S-Alpha dive system comprises a number of operations easier, safer, faster and more effective than the older offshore methods, including: handling, assembly-disassembly of equipment, production rate, improvement depth, smaller barges and smaller cranes.

ABSTRACT: Stone columns are vertical inclusions in soft soils formed by gravel. In very soft soils, they may be wrapped typically with a geotextile to increase its lateral capacity. In the latter case, they are usually named encased stone columns. Their critical or optimum length may be defined as the one where further lengthening of the column provides a negligible improvement and it is therefore not cost-effective to build columns longer than it. Besides, for encased stone columns, the optimum length of the encasement is also relevant. In previous finite element analyses, the authors have studied the column and encasement critical length considering a uniform soft soil layer with a linear elastic perfectly plastic behaviour for simplicity. For those cases, the optimum column length is around 1.5-2.0 times the footing diameter for encased stone columns, and slightly lower for ordinary stone columns, namely around 1.5. These critical lengths should be related to the loaded area and not to the column diameter. Here, the authors extend those previous analyses using a constitutive model that considers a stress-dependent soil stiffness, namely the Hardening Soil model. The results are very similar, but columns are slightly more effective when considering stress-dependent stiffness and the optimum column length is slightly lower. Finally, the critical length of the encasement is found to be slightly lower than the critical column length.

RÉSUMÉ: Les colonnes ballastées sont des inclusions verticales dans les sols mous, composées de gravier. Dans les sols très mous, elles peuvent être enveloppées dans un géotextile pour augmenter leur capacité latérale. Dans ce dernier cas, elles sont généralement appelées colonnes ballastées enveloppées. Leur longueur critique ou optimale peut être définie comme celle où un allongement supplémentaire de la colonne apporte une amélioration négligeable, donc il n'est pas rentable de les construire plus longues. En plus, pour les colonnes ballastées enveloppées, la longueur optimale du géotextile est également importante. Dans les analyses précédentes, les auteurs, pour simplifier, ont étudié la longueur critique de la colonne et du géotextile en considérant, une couche de sol uniforme avec un comportement élastique parfaitement plastique. Dans ces cas, la longueur optimale de la colonne est d'environ 1.5-2.0 fois le diamètre de la semelle pour les colonnes ballastées enveloppées, et légèrement inférieure pour les colonnes ballastées classiques, à savoir environ 1,5. Ces longueurs critiques devraient être liées à la surface chargée et non au diamètre de la colonne. Ici, les auteurs étendent ces analyses précédentes en utilisant un modèle de comportement du sol qui prend en compte leur rigidité en fonction des contraintes, le modèle Hardening Soil. Les résultats sont très similaires, mais les colonnes sont légèrement plus efficaces lorsque l'on considère une rigidité dépendante de la contrainte, et la longueur optimale est légèrement inférieure. Enfin, la longueur critique du géotextile est légèrement inférieure à la longueur critique de la colonne.

Keywords: Finite element analyses, encased stone columns, critical length, settlement.

1 INTRODUCTION

Ground improvement using stone columns, also known as granular piles or aggregate piers, is a widely spread technique to improve soft soils for foundation of embankments or structures (e.g. Barkdale and Bachus 1983; Kirsch and Kirsch 2010). In very soft soils, stone columns may suffer of lack of lateral confinement ($c_u \leq 5 - 15\ kPa$) (e.g., Wehr, 2006). In those cases, stone columns are usually encased with geotextiles or other geosynthetics (e.g., Alexiew and Raithel, 2015; Almeida et al., 2019)

Ordinary or encased stone columns (OSC or ESC) may reach a rigid substratum (end-bearing columns) or may be embeded just on a soft soil layer (floating columns). For the latter case, the length of the columns is an important design parameter to be chosen. In some cases, it may be more cost-effective to add additional columns than increase the length of the columns. In this way, the concept of the optimum or critical length of stone columns appear. For columns longer than the optimum length, the improvement achieved with stone columns does not notably change or increase. Although the load transfer mechanisms are different from piles, the concept of optmimum or critical length is equivalent (e.g., Fleming et al., 2009). The authors have also applied this concept to dynamic problems (Fernández-Ruiz et al., 2021).

Some existing proposals for the column critical length include those by Hughes and Withers (1974), McKelvey (2002) and Black et al. (2011), amongst others. The authors (Castro et al., 2019; Miranda et al., 2021) have analysed them and have shown that the column critical length should be expressed in terms of the footing width or diameter (B, D) because the column length to diameter ratio, L/d_c (slenderness of the column), has a minor influence (second order effect) on the ground improvement achieved with stone columns.

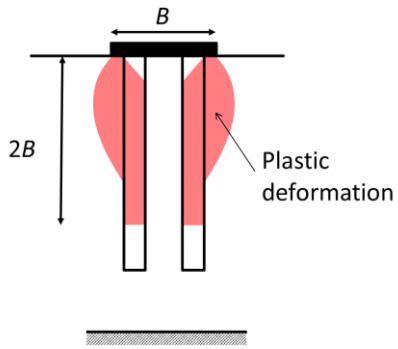

Figure 1. Justification of critical column length in a homogeneous soil layer.

Muir Wood et al. (2000) pointed out the importance of the deformation mechanism beneath the footing. Castro (2017) conceptually showed that the critical column length for bearing capacity depends on the failure mechanism and the critical column length for settlement reduction is related to the extension of the pressure bulb beneath the footing. Since the critical length is larger for settlement reduction, this is the one that is normally used. The pressure bulb is a useful concept, but it is strictly only valid for an elastic behaviour, which is not usually the case for an efficient design of OSC or ESC. The authors (Castro et al., 2019; Miranda et al., 2021) have shown that the critical column length is related to the extension of plastic deformation in the soil and column (Figure 1).

The concept of optimum column length is useful only for footings or small groups of columns because for large loaded areas (e.g., embankments), the critical length is larger than the soft soil layer thickness and then, there is no critical length in practise (e.g., Yoo, 2010).

Here, the authors extend their previous work on column critical length (Castro et al., 2019; Miranda et al., 2021), which considered a simple linear elastic perfectly plastic model ("Mohr-Coulomb", M-C) to reproduce the soil and column behaviour, to cases where a more advanced constitutive model is used to reproduce the soil behaviour, namely the Hardening Soil Model (HSM) (Schanz et al., 1999).

2 NUMERICAL MODEL

The finite element code Plaxis 2D 2023 (Brinkgreve et al., 2023) was used to represent a simplified 2D axisymmetric model of only one centred column beneath a rigid circular footing (Figure 2). This is the same 2D simplified model used in previous analyses by the authors (Castro et al., 2019; Miranda et al., 2021) and provides similar values of the footing settlement than those of a full 3D model of a group of columns with the same area replacement ratio and the same encasement stiffness to column diameter ratio (J_g/d_c). The area replacement ratio (a_r) is the ratio between the area of the columns and the loaded area.

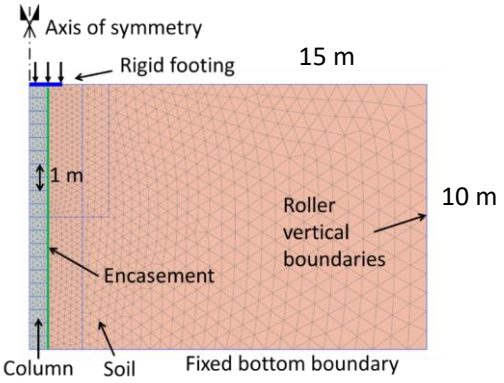

Figure 2. Numerical model and finite element mesh.

As a starting point, the same reference case as in previous analyses was used. The footing diameter, D, was 2.5 m and the column diameter (d_c=1.37 m) was chosen to give an area replacement ratio of a_r=30%. The soil profile was simplified to only one homogeneous soil layer, with a thickness of H=10 m (Fig. 2). The rigid footing was assumed as perfectly rough and modelled as a very stiff plate (EA = 10^{10} kN/m and EI = 10^{12} kN m^2/m) that

produces uniform settlements. Drained conditions were assumed for all the process, i.e. no excess pore pressures were generated. Geostatic initial stresses were generated using the effective soil unit weight (γ') and the coefficient of lateral earth pressure at rest, K_0=0.6. For simplicity, the ground water level was assumed to be at the ground surface and an effective unit weight of γ'=10 kN/m^3 for soil and column was directly considered without modelling pore water pressures. The applied pressure on the footing, p_{app}, was 100 kPa.

The column length was varied from L =10 m (end-bearing column, L/H=1) to L=0 m (no column) in steps of 0.5 m (Figure 2). The critical column length was identified from the variation of the settlement reduction factor with the column length. The settlement reduction factor (β) is the ratio between the settlement with columns and the settlement without columns (s_z/s_{z0}). Some mesh sensitivity (of around 3%) was observed between different cases, but the same mesh was used to identify each critical column length, i.e. for each case with different column lengths.

Table 1. Column and soil parameters using M-C.

Material	E (MPa)	ν (-)	c (kPa)	ϕ (º)	ψ (º)
Soil	2	0.33	5	25	0
Column	30	0.33	0.1	45	10

In previous analyses (Castro et al., 2019; Miranda et al., 2021), the soil and column were modelled using the M-C model (Table 1). Here, the column constitutive model and parameters were kept, but the soil is modelled using the HSM to be able to reproduce, for example, its stress-dependant stiffness. A reasonable common set of parameters that gives a similar settlement as in previous calculations was adjusted (Table 2). The reference pressure for the stiffnesses values is p_{ref}=100 kPa. Since stone columns are commonly employed in clays, the stress-dependant stiffness parameter was chosen equal to m=1 (oedometric behaviour).

Table 2. Soil parameters using HSM.

E_{50}^{ref} (MPa)	E_{oed}^{ref} (MPa)	E_{ur}^{ref} (MPa)	ν_{ur} (-)	c (kPa)	ϕ (º)	ψ (º)
8.7	8.7	26.1	0.2	5	25	0

3 NUMERICAL RESULTS

3.1 Influence of soil constitutive model

The results of the non-encased case for different a_r values are summarized in Figure 3. The value of a_r was varied by varying the column diameter. The settlements without column for the MC and HSM are the same and equal to 121 mm because the HSM stiffness parameters (Table 2) were calibrated to provide the same settlement. With column, the settlement reduction factor is slightly lower for the HSM than for the MC model because columns are more effective in a soil which stiffness increases with depth, than for a uniform stiffness, even more for short columns and large area replacement ratios.

The column optimum length is approximately indicated around 1.5D because the settlement reduction beyond that depth is negligible. A detailed analysis indicates that the column optimum length slightly decreases for larger values of a_r and for the HSM.

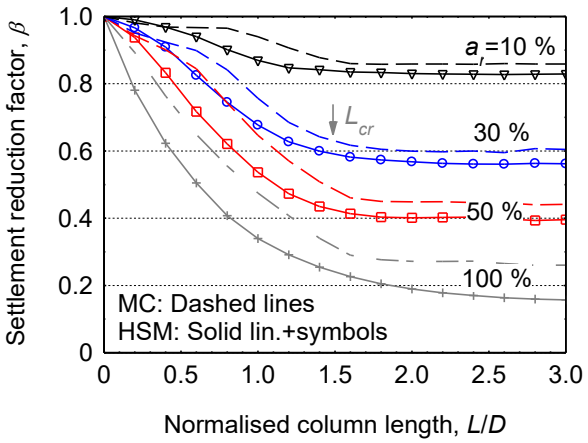

Figure 3. Settlement reduction factor for different column lengths, area replacement ratios and soil constitutive models.

3.2 Encasement critical length

Here, the numerical results considering an encasement with a circumferential stiffness of 0.5, 2 or 5 MN/ml are presented. A null Poisson's ratio is assumed for the geosynthetic encasement (ν_g=0) because it is assumed to have two major directions (radial and longitudinal), which behave independently.

Just as there may exist a column optimum length, there may exist an encasement optimum length. To systematically analyze them, both the column and the encasement lengths were varied (please, refer to Miranda et al., 2021 for details).

Table 3. Values of optimum column and encasement length for different area replacement ratios and geotextile encasement stiffnesses.

J (MN/ml)	a_r=10%	a_r=30%	a_r=50%
0.5	1.7D / 1.4D	1.6D / 1.3D	1.5D / 1.1D
2	1.8D / 1.5D	1.7D / 1.3D	1.6D / 1.1D
5	2.0D / 1.7D	1.8D / 1.3D	1.6D / 1.2D

The optimum column and encasement lengths for different a_r and J values are summarized in Table 3. It may be observed that the optimum encasement length slightly increases with higher geotextile stiffnesses, as the applied load is transmitted deeper. On the other hand, the critical encasement length reduces with the increment of a_r. Both trends are similar to the ones of the optimum column length (Table 3), but the values of the optimum encasement length are slightly lower. Therefore, from these numerical analyses, the optimum encasement length is slightly lower than the critical column length. Leaving the column tip without encasement could also contribute to create an enlarge column tip (Dash and Bora, 2013), whose effect has not been considered in the presented numerical simulations. On the other hand, leaving the column tip without encasement has disadvantages for the column construction process and consequently, it is not generally cost-effective. Thus, encasing the full column length is usually the best option. When partial encasement could be calculated as beneficial (e.g. Murugesan and Rajagopal, 2006), it will be more economical in most cases to reduce the whole column length and keep the full encasement of the column.

4 CONCLUSIONS

Previous analyses by the authors of the optimum column length are here extended using a constitutive model that considers a stress-dependent soil stiffness, namely the Hardening Soil model. The results show that the optimum column length for the analyzed cases (without encasement) is around 1.5 times the footing diameter (loaded area). Besides, the column optimum length slightly decreases for larger values of a_r and for the HSM when compared with the cases using the MC model. Finally, the critical length of the encasement is found to be slightly lower than the critical column length.

ABSTRACT: Current methods for calibrating the end bearing component of soil resistance to driving (q_u) in sand are based on factoring or capping the cone tip resistance (q_c). Results of a detailed back analysis of driving behaviour of large diameter piles in sand using a large database of pile driving data from several windfarm sites are presented. Self-weight penetration (SWP) records are assessed indicating q_u/q_c~0.5. Signal matching for piles in the PAGE JIP indicated unit end bearing <0.2q_c. Back analysis of three large windfarm sites revealed q_u in the range 0.13-0.25q_c with the lower value being more reliable. Differences between SWP and dynamic end bearing are explained in terms of drained and undrained soil resistance. The undrained resistance is much lower than the drained resistance because the operational undrained shear strength is affected by the effective stresses around the pile tip during dynamic penetration which in turn are governed by hydraulic fracture and cavitation.

RÉSUMÉ: Les méthodes actuelles de calibration de la composante en pointe de la résistance du sol au battage (q_u) dans les sables sont basées sur un facteur de réduction ou le plafonnement de la résistance à la pointe du cône (q_c). Les résultats d'une analyse à postériori détaillée du comportement de battage de pieux de grand diamètre dans le sable à l'aide d'une vaste base de données de battage de pieux provenant de plusieurs parcs éoliens sont présentés. Les mesures de pénétration sous poids propre (SWP) sont évaluées et indiquent q_u/q_c~0,5. L'analyse par calage de signaux sur les pieux effectués dans le cadre du PAGE JIP a indiqué une résistance unitaire de pointe <0,2q_c. L'analyse à postériori de trois grands parcs éoliens a révélé que q_u se situait entre 0,13 et 0,25q_c, la valeur la plus faible étant la plus fiable. Les différences entre le SWP et la résistance en pointe dynamique s'expliquent en termes de résistance du sol drainée et non drainée. La résistance non drainée est beaucoup plus faible que la résistance drainée parce que la résistance opérationnelle au cisaillement non drainé est fonction des contraintes effectives autour de la pointe du pieu pendant la pénétration dynamique qui, elles-mêmes, sont régies par la fracture hydraulique et la cavitation.

Keywords: Pile; driveability; end bearing; cone resistance; undrained.

1 INTRODUCTION

Current pile driveability methods do not always provide good predictions for large diameter monopiles and various authors and groups are addressing this problem (Stergiou et al, 2023, Yenigul et al, 2023; Jones et al, 2020; Vergote et al, 2022; Cathie et al, 2020). The two components of the Soil Resistance during Driving (SRD) are shaft friction and annulus end bearing. The end bearing component is the subject of this paper. Starting with static end bearing assessed from self-weight penetration, the study investigates the end bearing using a detailed back analysis of driving data over the full range of penetration depths and correlation to the cone penetration resistance, q_c.

Three major monopile installation projects are considered in this paper with a total of 190 locations. Pile diameters were 6.7 – 7.8m OD and pile tip wall thickness 56 – 85mm. All sites were in the North Sea in predominantly fine to medium sand, although some locations contain layers of dense silt and clay (which do not dominate the SRD but are useful to indicate rapid changes in end bearing).

An independent approach to assessing unit end bearing is also reported using signal matching of dynamic pile monitoring measurements.

2 END BEARING ASSESSMENT

2.1 Previous work

Methods of assessing the annulus end bearing resistance during driving of offshore tubular piles (q_u) in sand are widely based on the cone tip resistance (q_c) using a ratio q_u/q_c. Alm and Hamre (2001) proposed q_u = 0.15 q_c* where q_c* is $(q_c/\sigma'_{v0})^{0.2}$, which lead to approximately q_u/q_c of 0.35-0.55, while Maynard et al (2019) found q_u/q_c=0.1. Schneider and Harmon (2020) studied three well documented cases and found q_u/q_c =0.35-0.45. Jones et al (2020) adopted q_u/q_c =0.6 for all soils.

Others have assessed end bearing driving resistance by adapting the static end bearing capacity (Byrne et al, 2012; Lehane et al, 2022). Lehane et al consider the mobilisation distance for end bearing and select q_u=0.4q_c in their adaptation of the Unified method. How the raw cone resistance profile is smoothed is important for most methods, for example by considering ±1.5D* (where D* is the equivalent diameter) above and below the pile tip (Lehane et al, 2022).

Independent back analysis of a large quantity of driving data by Stergiou et al (2023) led to a correlation: $q_u = (0.15 + 0.35A_r)q_c$. For the monopiles used in the present study, the area ratio, A_r is in range 0.03-0.04 leading to q_u/q_c~0.16.

Cathie et al (2020) in a detailed signal matching study for a large diameter monopile (7.8m OD) imbedded in a very dense sand layer (qc > 100MPa) at 30m depth, in a water depth of 30m, revealed a unit end bearing in the range 6 – 7.5MPa. Using a q_c limit of 50MPa indicated q_u/q_c of 0.12 - 0.15 which was considered to be constrained by cavitation of the pore water during dynamic penetration.

Based on strain measurements during penetration, White (2002) showed that for drained penetration in sand significant grain crushing and particle breakage occurs just below the pile tip in a "nose cone" with zones of vertical compression/horizontal extension, horizontal compression/vertical extension and dilation. Rapid loading tests of piles in sand in a centrifuge by Hölscher et al. (2012) confirm the different zones of contraction and dilation as measured by the excess pore pressure response either positive or negative (suction). The pore pressure response was also dependent on the partial dissipation which occurs during the rapid loading test.

When using CPT data for driveability studies, the pile embedment depth into a stronger layer and the effects of a weaker layer below influence the correlation between q_c and q_u. In dense sand, a "critical depth" to achieve "quasi-stationary" penetration resistance is between 10 – 20 times the governing dimension – either the cone diameter, or the pile diameter for closed or plugged piles (Puech and Foray, 2002). For unplugged piles, the pile wall thickness at the tip may be considered the relevant dimension, which is the case for all piles considered in this paper. Thus, pile penetrations into stronger layers require 1.0-1.5m to develop full quasi-static resistance.

Whether the pile tip response is drained or undrained may be a key consideration for assessing end bearing. The normalised velocity $v.d/c_v$ where v is the pile velocity, d the pile wall thickness, and c_v the coefficient of consolidation of the sand), may be used: when $v.d/c_v$<0.1 drained conditions may be assumed whereas for $v.d/c_v$>30 undrained conditions apply (White et al, 2018). Considering a pile wall thickness of 75mm and a rate of penetration of 2m/s (rise time of about 5ms, penetration 0.01m), c_v limits for drained and undrained conditions are >1.5 or <0.005 m^2/sec, respectively. Many dense fine to medium sands will fall between these limits (partially drained) while dense fine silty/clayey sands may well respond undrained. This may explain the uncertainty which currently exists on the appropriate end bearing resistance.

Accumulation of excess pore water pressure may develop around the shaft in fine sands due to partial drainage under typical blow rates of 30-100 blows/minute. However, this is less likely around the pile annulus despite the highly variable strain field with areas of contraction and dilation (White, 2002). Nevertheless, particle breakage will occur due to the very high stresses associated with driving in dense sand which cause contraction and average pore pressure increases and lower operational undrained shear strength.

Finally, the need to consider the spatial variability of the cone resistance in the vertical direction has led to the various methods developed to smooth the cone resistance for pile resistance calculations (see Lehane et al, 2022). However, the spatial variation of the cone resistance around the perimeter of a large monopile will also be significant. A discussion on spatial variability is outside the scope of this paper and may be considered a scale effect of using the CPT cone resistance as an indicator of end bearing resistance.

2.2 Penetration rates

During initial pile installation (pile stabbing), the pile penetration velocity is a similar order of magnitude to the penetration rate of a standard cone penetration test (0.02m/s) and the normalised penetration rate lies in the drained region for sand. Therefore, this self-weight penetration (SWP) resistance is considered a static,

drained resistance. Back analysis of the SWP of piles during stabbing provides a reliable benchmark (drained) resistance for performing back analysis during driving.

During pile driving, the average penetration rate is approximately 0.01m/s during normal driving (25 blows/0.25m) and 0.001m/s during hard driving (125 blows/0.25m) depending on the blow rate indicating drained end bearing response during multiple blows even if the single blow response is partially drained or undrained.

In current SRD assessment methods (Alm & Hamre, 2001; Maynard et al, 2019, Stergiou et al, 2023) the (drained) cone resistance (q_c) is used to estimate the (potentially undrained) pile annulus resistance. This has led to applying limiting values to the measured q_c to avoid overestimating the unit end bearing (Cathie et al, 2020).

3 END BEARING RESISTANCE DURING SELF-WEIGHT PENETRATION

The measured SWP under either pile weight or pile plus hammer weight provides a direct measure under essentially static conditions of the soil resistance. At low penetrations in sand, the soil resistance is dominated by end bearing. By reducing the pile and hammer weight by the estimated shaft resistance, the unit end bearing (q_u) can be evaluated with some confidence.

In this study, the SWP for pile and hammer together has been used since all the studied projects involved scour protection and not all piles punched through the scour protection under their own weight. The additional overburden pressure caused by the scour protection increases the effective stresses in the soil and thus the soil resistance. An overburden correction was applied to the raw CPT data (collected in the absence of scour protection) considering the additional stress increment using elastic theory and the effect of this increase on cone tip resistance using the correlations of Krogh et al (2022). As noted above, the cone resistance was smoothed over a 1m interval (+-0.5m from the depth considered).

The shaft resistance to be deducted from the overall pile plus hammer weight to give the end bearing component was obtained using the Alm and Hamre (2001) method after demonstrating in a preliminary study that the SWP was well predicted.

Figure 1 shows the measured SWP plotted against the calculated unit end bearing, normalized by the cone tip resistance (q_u/q_c) at the pile tip depth. q_u/q_c appears to reduce slightly with depth but is generally within the range 0.4 – 0.6.

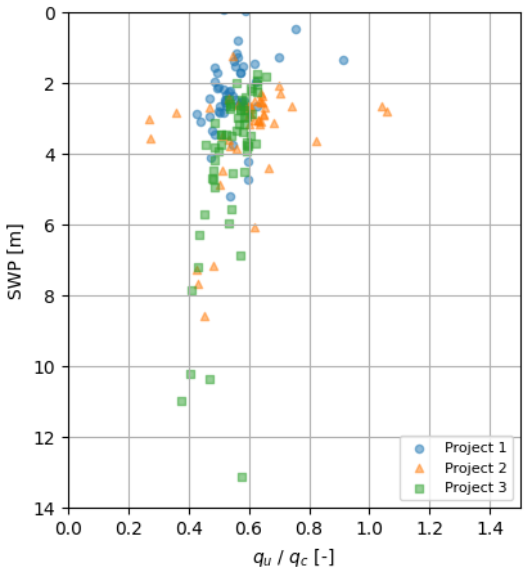

Figure 1. Normalised unit end bearing from self-weight penetration results.

Considering the pile tip wall thickness (t) for the projects in this study, the quasi-static end bearing resistance should be achieved after a penetration of about 1.6m (20*t). Since almost all points exceed this criterion, a correction for shallow penetration is not necessary and therefore the depth dependency is not due to shallow penetration into a layer.

The depth dependency in q_u/q_c appears to be related to the vertical effective stress and the depth dependency disappears when using the Alm and Hamre (2001) formulation for the unit end bearing: $q_u = s_1\, q_c\, (q_c/p_0')^{0.2}$ where p_0' is the effective overburden pressure.

A best fit value s_1=0.15 was derived from this data set which confirms the original formulation of Alm and Hamre is quite appropriate for SWP assessment of large diameter piles although the simpler use of q_u/q_c~0.5 is also satisfactory.

4 END BEARING RESISTANCE DURING DRIVING

4.1 Unit end bearing from signal matching

Since no pile monitoring data was available for the monopile driving for the 3 test sites, the end bearing from the PAGE JIP have been used to provide an independent indicator and backdrop for this study. The PAGE JIP (Cathie et al, 2023) analysed 25 high quality dynamic pile load tests at End of Drive (EoD) and during Restrike by signal matching for piles with diameters between 1.3 - 3.4m. The signal matching process yields the shaft resistance and end bearing at

the time of driving. Although signal matching is not as reliable as static measurements or SWP data to assess end bearing, it still provides a realistic estimate of the end bearing resistance for large diameter piles during driving and is the best data available at the present time. End bearing derived from signal matching includes not only the annulus resistance but a component of the shaft resistance very close to the pile toe which cannot be resolved in the wave equation model. In the data presented below, no attempt has been made to correct for the shaft resistance component and therefore the results should be considered a high estimate of the annulus end bearing.

From the PAGE dataset, the unit end bearing is plotted as a function of the cone tip resistance in Figure 2. Cone tip resistance in this figure is the average q_c over +-1.5D from pile tip. The best fit q_u/q_c is 0.20 for the signal matching results.

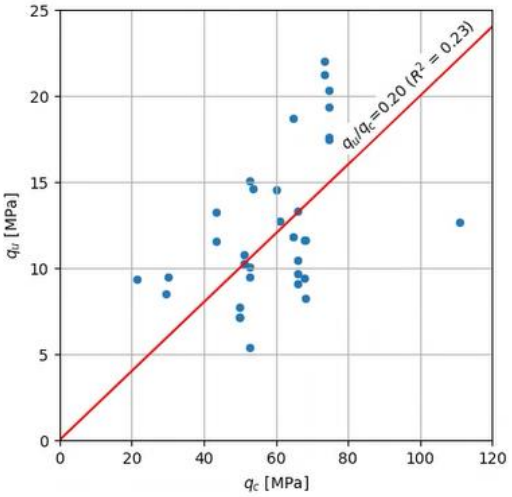

Figure 2. Unit end bearing from signal matching.

4.2 End bearing resistance from back-calculated SRD

Performing a back analysis using a wave equation solution of the three study projects using measured blowcounts, hammer energy and taking account of energy losses due to submergence (Vantomme et al, 2019) leads to a continuous back figured SRD v depth. In the back analysis, a fixed set of quake and damping factors was adopted (quake: 2.5mm, damping shaft and toe: 0.5s/m) to give consistency of SRD with that found from signal matching in sands.

Using the continuous SRD v depth plots, the change in SRD when transitioning from a stronger to a markedly weaker layer may be used to approximately assess the annulus end bearing change (Figure 3). While the shaft resistance is cumulative and only changes relatively gradually with depth, the end bearing resistance reduces rapidly as it penetrates a stronger or weaker soil. The reduction in SRD (ΔQ) is primarily due to a change in end bearing (although a small component of this change is due to the incremental increase in shaft resistance due to the additional penetration and the decrease due to friction fatigue). This can be compared to the reduction in cone resistance (Δq_c) at the layer change, which can be used to develop the approximate relation between Δq_u / Δq_c where $\Delta q_u = \Delta Q/A$ and A is the pile annulus area.

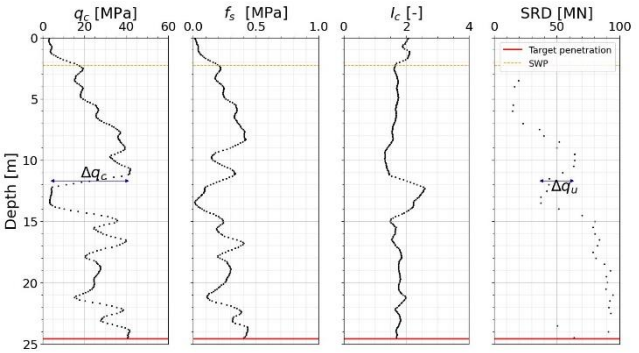

Figure 3. Example of back analysis results and selection of Δq_c and Δq_u.

A manual approach selecting clearly defined cases, and an automatic approach were undertaken. For the manual approach, the main criteria adopted for selecting the locations and depth windows included a) a well-defined change in q_c (typically at least 20MPa), and a sufficiently deep layer of weaker material that the annulus end bearing during driving would reach a quasi-static value (taken as 2m). An example is shown in Figure 3.

There is some subjectivity in the selection of data points in the manual procedure. To exclude any bias, the whole dataset was analysed numerically comparing $\Delta q_u/\Delta q_c$ over a 2m window (selected to obtain a significant change in q_c and q_u, but not too large to be unduly affected by the change in shaft resistance. For the same reason, the dataset was filtered on the soil behaviour index, selecting only cases for Ic>2.4 at the bottom of the window, and Δq_c<-10MPa. The two sets of results are shown on Figure 4 and the histograms on Figure 5.

The manual approach on a much smaller dataset took account of depth mismatches between changes in q_c and q_u, indicates a median $\Delta q_u/\Delta q_c$=0.25, i.e. q_u=0.25q_c. Quite a large scatter of Δq_u may be seen including some locations where there is very little change in SRD despite cone resistance changes in excess of 30MPa.

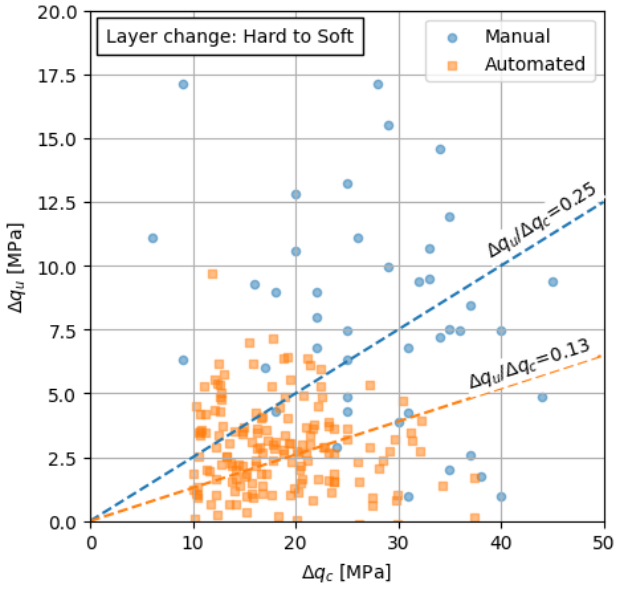

Figure 4. Change in cone resistance and end bearing for reducing q_c (absolute values plotted)

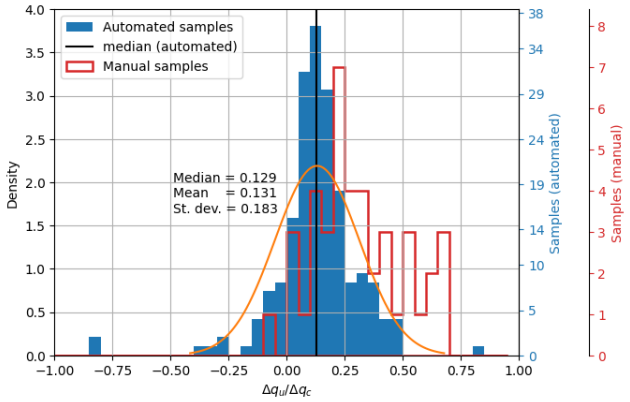

Figure 5. Change is cone resistance and end bearing for reducing q_c (sand into silt/clay) using 2m window applied to full dataset

The automated approach did not account for a depth mismatch between CPT and SRD data but overall, a clearer trend is found compared to the manual method with q_u= 0.13q_c being the best fit. Both approaches assume that the CPT data is representative for the entire pile diameter.

5 DISCUSSION

Based on the static resistance during SWP, the q_u/q_c ratio found for the sand profiles in this study approaches 0.4 below 10m penetration. From signal matching the ratio is less than 0.2, while from back analysis we have 0.13 - 0.25, with the lower 0.13 corresponding to the better data set. The difference between static and dynamic penetration are believed to be due to the different mechanisms occurring during drained static penetration (pile during SWP and CPT) and undrained or partially drained dynamic penetration (pile). In soft clays, House et al (2001) demonstrated a factor of 3.4 difference between drained and undrained penetration resistance while recently Carotenuto et al (2022) have shown by variable rate penetration testing in silts a ratio between cone resistance in drained and undrained conditions respectively of 3.0. Both studies are for contractive soils. In contrast, White et al (2018), in considering free-fall penetrometers, suggests higher undrained resistance for all but very loose sands due to dilation-induced suction pressures based on theoretical considerations.

Applying the White et al undrained strength model for a silica sand with relative density of 90% leads to a mean effective stress at failure of 7.2MPa, an undrained shear strength of 4.7MPa, and q_u of 35MPa. This is not consistent with the results of this study.

The White et al model does not take account of pore water cavitation during driving as discussed by Cathie et al (2020). If the cavitation limits are respected, at 30m penetration and 30m water depth, the mean effective stress at failure is limited to 0.99MPa, the undrained shear strength 0.63MPa and q_u 4.8MPa which is well aligned with the back analysis results.

Lower undrained end bearing during driving in sand may also result from extremely high instantaneous hydraulic gradients around the pile tip. Carotenuto et al (2022) indicated pressure differences between the cone tip and shaft that exceeded u/σ'_{v0} of 3 at a penetration rate of 0.1m/s and could exceed 4-5 during a blow (2m/s). This would translate to upward hydraulic gradients far greater than needed for hydraulic fracturing of the soil and temporary relief of the effective stresses around the pile tip area as the pressure wave in the pore water propagates outwards from below the pile tip. Such pore pressure gradients can also be inferred from the high volumetric strain rate gradients around a pile tip observed by White (2002) during drained penetration.

6 CONCLUSIONS

Based on the methods and data used in this study for large diameter piles in sand, the annulus end bearing observed during self-weight penetration (SWP) was between q_u/q_c = 0.4-0.6. During driving, the ratio was much lower due to undrained (or partially drained) conditions with the data pointing to q_u/q_c<0.2 by signal matching and q_u/q_c~0.13 (for the most reliable results) from global back analysis of the driving logs.

Differences between the drained SWP results and the driving back analysis results are due to the undrained or partially drained conditions operating

during a single blow, and the shear strength dependence on a) pore pressure cavitation, and b) hydraulic fracture in dynamic conditions near the pile toe.

Further work is required to evaluate these effects and to test theoretical concepts on databases such as the one used in this paper.

Degradation mechanisms of the hydro-mechanical behaviour of a lime-treated clay exposed to wetting and drying cycles

Mécanismes de dégradation relatifs à l'altération du comportement hydromécanique d'une argile traitée soumise à des cycles hydriques

ABSTRACT: The present experimental study is focused on analysing the degradation processes of the mechanical performances of a lime-stabilised expansive clay exposed to wetting/drying cycles of various amplitude. Fully cured specimens were exposed to several wetting and drying cycles with suction-controlled techniques, and the maximum suction applied during the cycles ranged from 0.30 MPa to 95 MPa. This study highlighted that the main deterioration mechanism of lime-treated expansive soils exposed to cyclic wetting and drying is connected to micro-structural changes whose intensity were controlled by the amplitude of the cycles. The improved understanding of these mechanisms, as provided by this work, has the potential to more effectively forecast the conditions that could promote durability of lime-stabilised expansive soil.

RÉSUMÉ: L'objectif de cet article est d'évaluer les processus d'altérations relatifs à l'exposition d'une argile traitée à des cycles de séchage et d'humidification. Des éprouvettes traitées à la chaux ont été exposées à des cycles hydriques d'amplitudes allant de 0,30 MPa à 95 MPa. L'étude a permis de montrer que le mécanisme principal de dégradation du comportement mécanique des éprouvettes était la formation de fissure dont l'intensité était contrôlée par l'amplitude de succion appliquée. Ainsi, l'altération observée est principalement mécanique et résulte d'un endommagement des liaisons cimentaires, ce qui permet d'expliquer le rôle primordial de l'amplitude des cycles hydriques sur le comportement à long terme des sols argileux traités.

Keywords: Soil stabilization; durability; wetting and drying cycles; expansive soils; compressibility; microstructure.

1 INTRODUCTION

The alteration of mechanical performances over the service life of treated soils when exposed to seasonal wetting and drying cycles is one of the major concerns of the improvement technique. Indeed, several studies showed that wetting and drying cycles can alter the beneficial effects of treatments on soil performances (e.g., Khattab et al., 2007). Various methodologies have been employed to simulate the wetting and drying cycles during laboratory experiments. The major importance of the experimental protocol to impose the wetting and drying cycles has been highlighted by some authors. Stoltz et al. (2014) studied the impact of the amplitude of wetting and drying cycles on the mechanical behaviour of an expansive clay treated with lime, evidencing a progressive increase of swelling associated to strength reduction for increasing suction levels. They employed osmotic suction-controlled techniques to impose different wetting and drying amplitudes to the specimens. The results evidenced a progressive increase of the swelling properties associated to a loss of strength with higher suctions applied upon drying. Therefore, a key factor in the degradation of the mechanical performance of lime-stabilised soils exposed to wetting and drying cycles is the amplitude of the wetting and cycles. Nevertheless, only very few studies investigated the role of the amplitude of the cycles.

In addition, the degradation mechanisms associated to wetting and drying cycles are still poorly understood. Indeed, most of the available studies on the impact of wetting and drying cycles are based on results obtained at the macroscopic scale, without deciphering the different microstructural processes occurring during cycles. Thus, the mechanisms responsible for the degradation of lime-stabilised soils exposed to wetting and drying cycles still need to be

identified. Tang et al. (2011) provided some evidences that the bonding induced by lime-treatment could be altered by successive wetting and drying, with a significant modification of the microstructure along the cycles. There is thus a limited knowledge on the mechanisms involved in the alteration processes triggered by the exposure to successive wetting and drying cycles, and the relative importance of each process.

In this context, a laboratory study has been performed to understand the link between wetting and drying amplitude, micro-scale changes in fabric and the modification of the mechanical behaviour of a lime-treated expansive soil exposed to wetting and drying cycles. Lime-stabilised specimens were exposed to successive wetting and drying cycles of different amplitudes. The hydromechanical behaviour of the expansive soil was then determined using oedometer tests. The microstructure was also evaluated to identify the alteration mechanisms involved. In this paper, the characteristics of the lime-stabilised expansive soil specimens employed in this study are first provided. The experimental techniques are then successively exposed. The effect of the number of cycles and their amplitudes on the mechanical behaviour of the lime-stabilised soil and on the microstructure are then discussed. This work provides new understandings of environmental-driven alteration of lime-stabilised expansive soils that is discussed in the last section.

2 MATERIAL AND METHODS

2.1 Tested soil

The soil employed in this study was a clayey soil classified as CH according to the Unified Soil Classification System, mainly composed of clay minerals such as illite, muscovite, and montmorillonite, along with the presence of quartz and feldspars. The geotechnical characteristics of this soil can be found in Table 1. The shrinkage potential of the untreated soil, initially prepared at optimum moisture content, equal to 14.1 %, while the addition of 1% quicklime reduced the shrinkage potential to 0.1% (Stoltz et al., 2012).

Treated specimens were retrieved from the internal part of an experimental embankment built in 2010 with this expansive soil treated with 4 % quicklime by vertical coring. The embankment was thoroughly studied by Chabrat et al. (2023), who showed that the internal part of the structure was not affected by significant alterations due to environmental-driven processes.

Table 1. Geotechnical properties of the studied soil.

Parameters	Values
Passing sieve 80 μm (%)	90
Clay size content (<2 μm) (%)	70
Specific gravity Gs (-)	2.675
Liquid limit (%)	71
Plastic limit (%)	29
Plasticity index (%)	42

2.2 Experimental techniques

To prepare the specimens from the cores, a dicing saw equipped with a diamond wire was employed. Water was used to avoid heating of the sample during the cutting process. The specimens were subsequently carefully trimmed to a diameter of 70±0.1 mm and a height of 12 ± 2 mm. Two specimens were exposed to the same combination of suction amplitude and number of cycles. One of the specimens was used to determine the compressibility of the material while the other was employed for the microstructural analysis. The different experimental techniques employed are successively introduced in this section.

2.2.1 Drying-wetting experimental procedures

One of the main goals of the study was to assess the impact of the range of suction applied during wetting and drying tests on the behaviour of the treated specimens. For this purpose, two different methods were chosen to apply different ranges of suctions. The first method employed osmotic suction-controlled oedometers. The cycles were applied between saturation (s = 0 MPa) and suction values ranging from 0.30 MPa to 8.00 MPa were applied to the specimens following the protocol developed by Stoltz et al. (2014). The second method employed climatic chamber to control the relative humidity of the soil. This method, also derived from the one developed by Stoltz et al. (2014), was chosen to simulate high-amplitude cycles, with H_R = 50% corresponding to s = 95 MPa and H_R = 80% corresponding to s = 30 MPa. During the cycles, the dimensions of the specimens were monitored to evaluate their swelling and shrinkage potential along the cycles.

2.2.2 Tests procedures

Following the drying and wetting cycles, some specimens were subjected to oedometer testing under saturated conditions. These tests involved saturating the specimens and loading them by increment. For microstructural analysis, cubes with approximate dimensions of 10±2 mm were cut from a sample after

the cycles. The samples were dried using the freezing/drying method. The specimens were first immersed in liquid nitrogen at a temperature of -196°C. They were then placed in a vacuum chamber to undergo water sublimation. Observations with Scanning Electron Microscopy (SEM) were performed using the Hitachi SU5000 microscope. Prior to observations, a gold coating was applied to the sample on a fresh fracture surface. SEM images were taken at different magnifications of x1000 and x5000.

3 RESULTS

The axial deformation during the cycles was first analysed (Figure 1). After 2 wetting and drying cycles, the extent of variation in swelling and shrinkage behaviour appeared closely related to the maximum suction imposed during the cycles, ranging from less than 1% during drying at 0.30 MPa of suction up to 8 % when drying at a suction level of 95 MPa (Figure 1). The initial drying phase upon all the ranges of suction applied consistently led to irreversible shrinkage. Subsequently, during the wetting stage following the first drying, limited swelling occurred, resulting in irreversible shrinkage strains by the end of the first cycle.

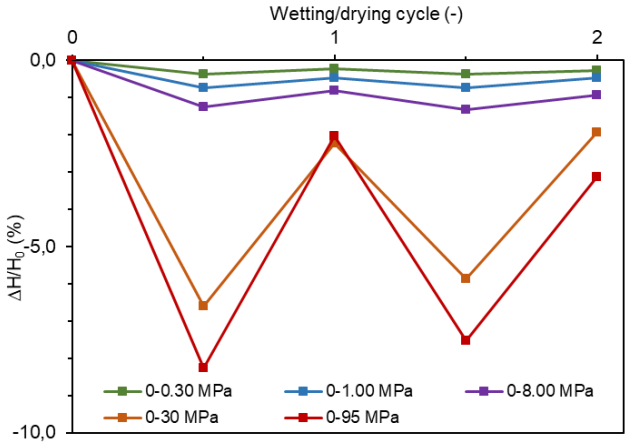

Figure 1. Volumetric variations obtained during 2 wetting and drying cycles.

Following the imposition of the suction cycles, the specimens were subjected to loading tests to determine their compressibility, and thus assess the impact of treatment (Figure 2). The compression curves obtained were compared to the one of the treated sample unexposed to wetting and drying periods (corresponding to N=0). The difference between the hydromechanical behaviour of the untreated and the treated soil suggests that the addition of lime effectively improved the mechanical performances of the soil. The compressibility of the specimens collected *in situ* was similar to the compressibility of specimens prepared in the laboratory. The impact of the cycles on the mechanical behaviour can be assessed by analysing the compressibility curves (Figure 2). After the first two cycles, it can be seen that the higher the suction applied during the drying phase, the larger the degradation of the mechanical behaviour. Up to an applied suction of 8.00 MPa, the compressibility is still significantly impacted by the lime treatment, as the yield stress of the soil was higher than 900 kPa. Beyond 8.00 MPa, the effect of lime stabilisation vanished, with values of yield stress lower than 100 kPa.

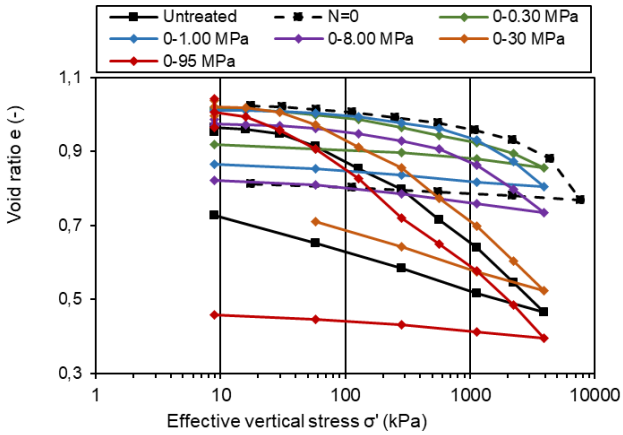

Figure 2. Compression curve of lime-treated specimens exposed to 2 wetting and drying cycles with different ranges of suctions.

Thus, for all amplitudes of wetting and drying periods, the first cycle induced plastic shrinkage deformation while only elastic deformation was generated during the subsequent cycles (Figure 1). The yield stress and the stress sensitivity were plotted as a function of the moisture content variation applied during the cycles (Figure 3). Extent of degradation was rather limited when the cycles were performed between 0.30 MPa and full saturation while the most significant mechanical degradation was observed when the applied suction during the cycles was larger than 8.00 MPa.

The microstructure was observed with SEM for the stabilized material unexposed to wetting and drying periods (Figure 4a), and then to specimens experimenting different ranges of suction applied (Figure 4b, c, d, e and f). The clayey particles observed on the unaltered specimen appear to be grouped together in aggregates bounded by macropores of about 1 µm wide, with a length higher than 10 µm. A coating on the surface of the particles was also observed that can be attributed to the precipitation of hydrated gel (i.e. C-S-H gel) as a result of the development of pozzolanic reactions (e.g., Vitale et al., 2020).

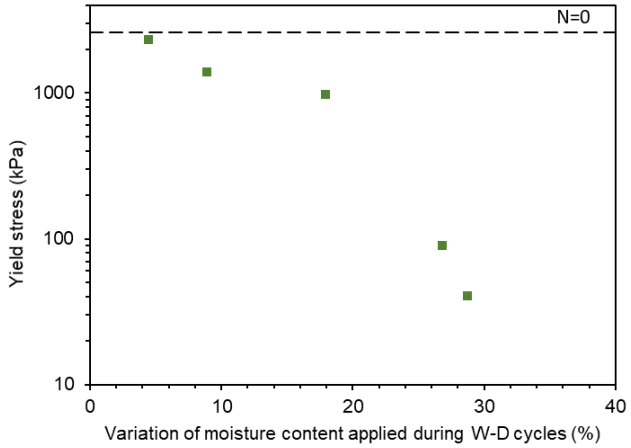

Figure 3. Effect of suction-controlled wetting and drying cycles on the yield stress of the quicklime-treated materials.

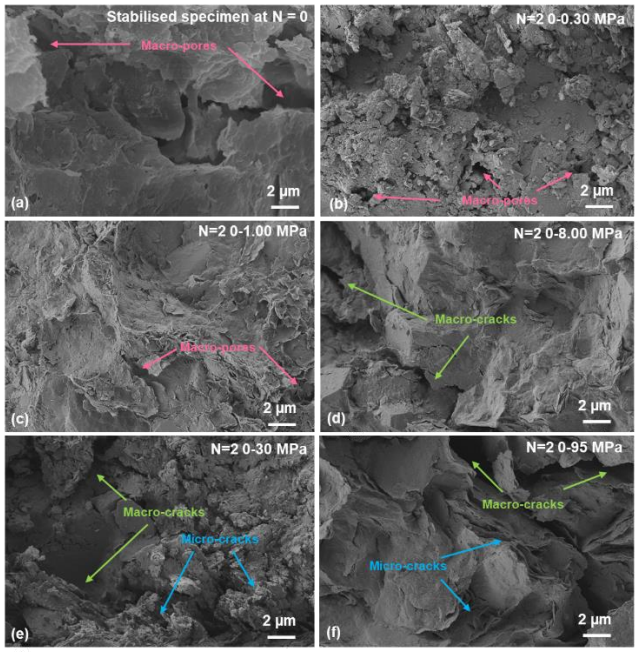

Figure 4. SEM pictures from specimens exposed to 2 wetting and drying cycles with different ranges of suctions.

Observations made on specimens exposed to a suction of 0.30 MPa (Figure 4b) showed low differences with the observations made on the unaltered treated soil (Figure 4a). The coating of the clayey particles is still visible and no significant evolution of the structure of the material could be observed. Specimens exposed to a suction of 1.00 MPa during the drying phase exhibited some longitudinal macro-cracks with a width of about 1 µm (Figure 4c). At the micro scale, the fabric of the specimens appeared to be massive and similar to the stabilised specimen unexposed to wetting and drying conditions. The newly formed macro-pores were even more present at an applied suction of 8.00 MPa, while the C-S-H gels were still visible on soil aggregates (Figure 4d). At 30 MPa and 95 MPa, macro-cracks could also be observed (Figure 4e and f). It was however possible to identify individual clay particles separated by pores smaller than 1 µm. Thus, a significant degradation of the microstructure was evidenced with the formation of macropores after the cycles when the maximum suction applied during the cycle was higher than 1 MPa. Beyond an applied suction of 8.00 MPa the cycles induced an additional alteration of the microstructure that led to the individualization of clay particles.

4 DISCUSSION

The purpose of this section is to explore the relationship between the modification of the microstructure, the amplitude of the wetting and drying cycles and the degradation of the compressibility. When the applied suction during wetting and drying periods was 0.30 MPa, the mechanical degradation of the material was very limited (Figure 2 and Figure 3), and the fabric of the soil seemed unaltered by the cycles. The height variation of the specimens occuring during wetting and drying cycles was also limited to 1% (Figure 1). When the maximum suction during the cycles was comprised between 1.00 and 8.00 MPa, newly formed macro-cracks were observed (Figure 4c and d). For suctions higher than 8.00 MPa, a complete change of the structure of the soil was evidenced, as both micro-cracks and macro-cracks were visible (Figure 4e and f). This rearrangement of the microstructure was associated to a complete degradation of the compressibility of the material.

The formation of cracks has been recognized as a key factor to explain the degradation of naturally cemented soft rocks containing clay exposed to wetting and drying cycles. Indeed, wetting-drying cycles can cause cyclic expansion and contraction of the clay minerals, and this repeatedly act on soil microstructure, resulting in fatigue damage, leading to a mechanical degradation of the material (e.g., Liu et al., 2020). The amount of cracks is likely related to the shrinkage experienced by the specimens during the cycles. Therefore, these observations demonstrate that a key damage mechanism could be associated to the formation of cracks during the cycles, indicating a degradation of the bonds between the soil particles associated to the pozzolanic reactions induced by the lime addition.

5 CONCLUSION

The main objective of this study was to analyse the impact of the wetting and drying cycles amplitude on

the behaviour of lime-stabilised samples, and to understand the associated degradation mechanisms. Fully cured specimens were exposed to several wetting and drying cycles. The amplitude of the cycles was controlled using suction-controlled techniques, and the maximum suction applied during the cycles ranged from 0.30 MPa to 95 MPa. The height variation was monitored during the cycles, and the compressibility of the soil was determined through oedometer tests. Structural modifications at the micro-scale were evaluated through scanning electron microscopy.

The study demonstrated that the compression behaviour of the treated material could be significantly altered by wetting and drying periods. The alteration of the material was mainly explained by the formation of cracks upon drying. The number and intensity of the newly formed cracks in the stabilised material were promoted by the increase of the maximum suction applied. The improved understanding of these mechanisms, as provided by this work, has the potential to more effectively forecast the conditions that could promote durability of lime-stabilised expansive soil.

ACKNOWLEDGEMENTS

The study presented in this paper is a part of the first author's PhD thesis that has been funded by Ginger CEBTP. The authors gratefully thank Dr. Michel Khatib from Ginger CEBTP for their valuable support and fruitful discussions. Dr. Abner Colella, Dr. Claudia Di Benedetto and Dr. Roberto De Gennaro are gratefully acknowledged for their valuable support in conducting microstructural investigations.

The project has received funding from the European Union's Horizon 2020 research and innovation program under the Marie Skłodowska-Curie grant agreement No 778120.

Deformation characteristics of existing three-line tunnels with connected aisle induced by three-line mechanized tunnels under-crossing

Caractéristiques de déformation des tunnels à trois lignes existants avec allée connectée induites par le passage sous les tunnels mécanisés à trois lignes

ABSTRACT: Deformation characteristics of exiting tunnel induced by tunnel under-crossing is crucial for the safety of existing tunnel. A combination of manual low-frequency monitoring and wireless sensing high-frequency monitoring was used for an under-crossing case. The case is existing three-line tunnels under-crossed by new three-line mechanized tunnels and there is a connected aisle between two existing tunnels. The monitoring measured settlement and deformation of existing tunnels. Settlement monitoring results show that the settlement of existing tunnel during under-crossing experienced 2 stages: (i) heave, (ii) subsidence. The settlement profiles of the existing tunnels induced by the second tunnel under-crossing were found to be asymmetric with respect to the second tunnel line and the location of maximum settlement point deviated toward the center of the first under-crossing tunnel and the second under-crossing tunnel. For the third tunnel under-crossing, the situation is similar but the offset is not as much. Besides, the connected aisle also caused a longitudinal asymmetric distribution of deformation. Rotational deformation monitoring results show that the deformation of existing tunnel is more complex. When the cutter of tunnel boring machine (TBM) is right below the existing tunnel, the existing tunnel heaved during TBM advancing and subsided during TBM halting. When the shield tail is 0.4D in front and behind the existing tunnel in horizontal direction where D is the diameter of TBM, the existing tunnel heaved at most of time while subsided if the grouting volume is insufficient.

RÉSUMÉ: Les caractéristiques de déformation de la sortie du tunnel induites par le passage sous le tunnel sont cruciales pour la sécurité des tunnels existants. Une combinaison de surveillance manuelle à basse fréquence et de surveillance à haute fréquence par détection sans fil a été utilisée pour un cas de passage souterrain. Il s'agit de tunnels existants à trois lignes traversés par de nouveaux tunnels mécanisés à trois lignes et d'une allée connectée entre deux tunnels existants. Le contrôle a mesuré le tassement et la déformation des tunnels existants. Les résultats du contrôle du tassement montrent que le tassement du tunnel existant pendant la traversée a connu deux étapes : (i) le soulèvement, (ii) l'affaissement. Les profils de tassement des tunnels existants induits par la traversée du deuxième tunnel se sont révélés asymétriques par rapport à la ligne du deuxième tunnel et l'emplacement du point de tassement maximal s'est écarté vers le centre du premier tunnel traversant et du deuxième tunnel traversant. Pour le troisième tunnel, la situation est similaire, mais le décalage n'est pas aussi important. En outre, l'allée connectée a également provoqué une distribution longitudinale asymétrique de la déformation. Les résultats du contrôle de la déformation rotationnelle montrent que la déformation du tunnel existant est plus complexe. Lorsque la fraise du tunnelier se trouve juste en dessous du tunnel existant, ce dernier se soulève lors de l'avancement du tunnelier et s'affaisse lors de l'arrêt du tunnelier. Lorsque la queue du bouclier se trouve à 0,4D devant et derrière le tunnel existant dans la direction horizontale, D étant le diamètre du tunnelier, le tunnel existant s'est soulevé la plupart du temps et s'est affaissé si le volume d'injection est insuffisant.

Keywords: Wireless sensing; shield tunneling; under-crossing.

1 INTRODUCTION

With the development of underground space, more and more tunnels are constructed in city area. The construction of new tunnel will affect the surrounding environments, like existing tunnels, pipelines, buildings. For the case of under-crossing existing tunnels, it is important to ensure both the serviceability of the existing tunnel and the safety of the new tunnel

(Fang et al., 2015). The earth balanced pressure shield (EPBS) machine under-crossing existing tunnels at close distance causes considerable deformation and devastating additional stress, especially in water-rich sand or silt stratum (Chen et al., 2018).

Many methods have been applied to study the effects of adjacent tunneling on existing structures, including empirical or semiempirical methods (Peck, 1969; Lai et al., 2017; Chen et al., 2018), physical model experiments (Byun et al., 2006;), numerical methods(Do et al., 2014; Avgerinos et al., 2017; Li et al., 2022), analytical methods (Liu et al., 2022), and field observations (Fang et al., 2022; Li and Yuan, 2012). Field observation provides the monitored data for all other methods. The models, assumptions need the field observation to be validated. Thus, field observation is the basis for other methods and is the most direct and reliable method.

The studies about tunnel-induced ground settlement have focused on complex crossing situations, such as new twin-line tunnel under-crossing existing single line (Lai et al., 2020), new twin-line tunnel under-crossing existing twin-line (Chen et al., 2018). In this paper, a more complicated crossing situation, new three-line tunnels under-crossing existing three-line tunnels, is studied by field monitor method to investigate the deformation characteristic of the existing three-line tunnels.

Traditional field method applied total station, level and other manual equipment for settlement measurement. These manual methods are time-consuming and less frequent. The monitoring results are often more difficult to reflect the deformation pattern of the existing tunnel during the under-cross process, i.e., deformation of the existing tunnel due to each construction cycle of the shield machine during under-crossing is difficult to be monitored. Thus, in this research, a new monitoring method, wireless sensing network (WSN) is combined with manual level for settlement measurement in the existing tunnels.

2 SITE MONITORING INFORMATION

The project is a new three-line tunnels under-crossing existing three-line tunnels in China. The relative positions between the tunnels are shown in Figure 1. Tunnel 1#, 2#, 3# are existing tunnels, Tunnel 4#, 5#, 6# are new constructing tunnels. The horizontal distance between Tunnel 1# and Tunnel 2# is 8.3 m. The horizontal distance between Tunnel 2# and Tunnel 3# is 10.3 m. The distance between Tunnel 4# and Tunnel 6# is 4.0 m. The distance between Tunnel 5# and Tunnel 6# is 4.0 m. The new constructing tunnels cross silty clay and clayey silt. The stratum between the existing tunnel and the new constructing tunnel is clayey silt. The properties of the stratum can be found in Table 1. The overburden of existing tunnel is around 22.0 m for Tunnel 1#, 2# and 19.65 m for Tunnel 3#. The vertical distance between the existing tunnels and new constructing tunnels is 3.6 m. The outer diameter of the tunnels is 6.6 m, the thickness of the tunnel lining is 0.35 m and the width of segmental ring is 1.5m.

The direction of construction progress is from north to south. Tunnel 1# is the first tunnel to be under-crossed. Tunnel 2# is the second tunnel to be under-crossed. Tunnel 3# is the third tunnel to be under-crossed. Tunnel 4# is the first to be constructed, then Tunnel 5# begin construction, and Tunnel 6# is the last to be constructed. After Tunnel 4# under-crosses Tunnel 3#, Tunnel 5# begins to under-cross Tunnel 1#. After Tunnel 5# under-crosses Tunnel 3#, Tunnel 6# begins to under-cross Tunnel 1#.

The monitored sections are shown in Figure 2. There are 35 settlement monitoring cross-sections in Tunnel 1#, 35 settlement monitoring cross-sections in Tunnel 2# and 43 settlement monitoring cross-sections in Tunnel 3#. The distance between two adjacent cross-sections of settlement monitoring is 2 m. WSN nodes are installed on the segmental ring of Tunnel 2# and the Ring No. are 478, 479 and 481, which are right above the Tunnel 6#. The installation of WSN nodes is shown in Figure 3 (a). Four tilt WSN nodes are installed on the segmental lining with the angle of 45° and 120° from vertical direction. The WSN nodes are installed in the position to reduce the effect of the deformation of segments (). The accuracy of manual level is 0.002mm, the accuracy of the tilt nodes is 0.01°. The monitoring frequency of manual level is 1~1/15 days^{-1} and that of WSN nodes is 1/3~1/10 minutes^{-1}. The WSN nodes on site is shown in Figure 3(b).

3 MONITORED DATA OF MANUAL LEVEL

The three typical relative position between tunnel boring machine (TBM) of new constructed tunnel and existing tunnel are shown in Figure 4. For position 1, the cutterhead of TBM is just about to enter directly below the existing tunnel. For position 2, the TBM has just passed directly below the existing tunnel. For position 3, the TBM is already 30 m away from the existing tunnel in horizontal direction. The monitored data from manual level at the three positions is shown in Figure 5 and the dashed line represents the center of the newly constructed tunnel. In Figure 5 (a), the existing tunnel is Tunnel 1# and the new constructed tunnel is Tunnel 4#, i.e., M equals to 1 and N equals to 4. For others: (b) M=1, N=5; (c) M=1, N=6; (d) M=2, N=4; (e) M=2, N=5; (f) M=2, N=6; (g) M=3, N=4; (h) M=3, N=5; (i) M=3, N=6.

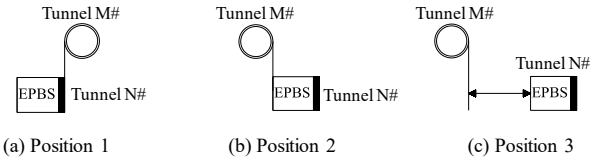

Figure 4. Three typical relative position between TBM of new constructed tunnel and existing tunnel.

At position 1, the existing tunnels heave. At position 2, the existing tunnels continue to heave and the troughs of settlement appear. At position 3, the settlement troughs of the existing tunnels have formed. During all nine under-crossing process the exsiting tunnels showed a deformation pattern of heave followed by settlement, although the final shape of the settlemnet troughs is different. The settlement troughs are “V” shape when the existing tunnels under-crossed by the first tunnel, “W” shape when under-crossed by the second tunnel, and “V” shape when under-crossed by the third tunnel.

The change of settlement over time is shown in Figure 6. S18 in Tunnel 1#, S18 in Tunnel 2# and S21 in Tunnel 3# are the sections directly above the newly constructed Tunnel 6#. The ranges between two adjacent straight lines in Figure 6 represent the under-crossing process of Tunnel 4#, 5#, 6#. During the under-crossing process, the existing tunnels heave firstly and then settle. However, the frequency of manual level monitoring is too low to display the deformation details of existing tunnels during under-crossing process. Thus, WSN is applied with a high monitoring frequency (Chang, et al., 2022).

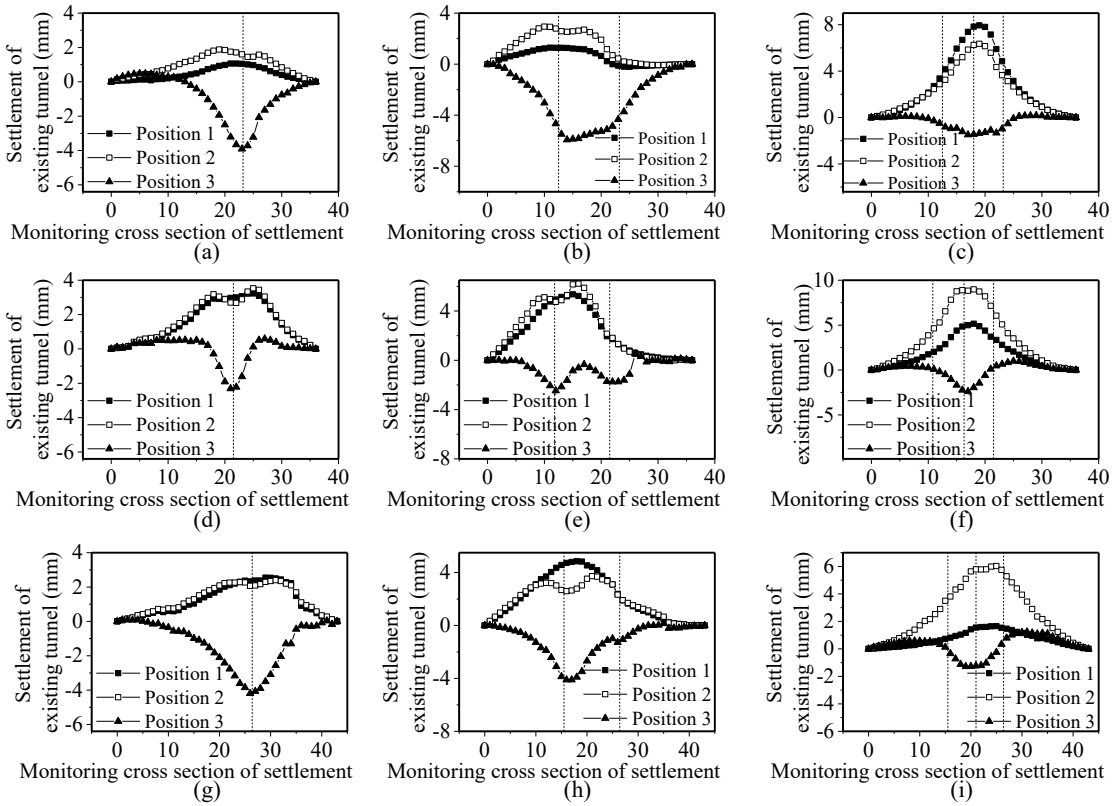

Figure 5. Monitored data from manual level.

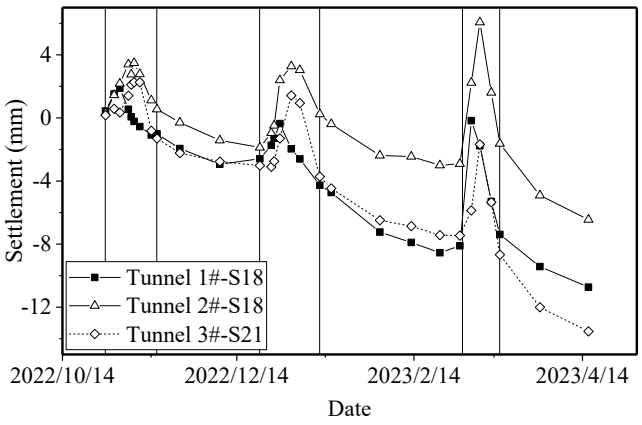

Figure 6. Data of manual level over time.

4 MONITORED DATA OF WSN

The monitored data of WSN is shown in Figure 7. There are 3 monitored sections, i.e., Ring 478, Ring 479 and Ring 481. In each section there are 4 WSN nodes. The monitored sections are in Tunnel 2# and are located directly above the newly constructed Tunnel 6#. According to the previous research (Wang et al., 2020), the convergence of horizontal diameter of segmental lining can be calculated by the data from WSN as:

$$\Delta D = L \cdot (\Delta\theta_1 - \Delta\theta_2) \cdot cos\ \alpha \qquad (1)$$

where L is the distance from point A to point B in Figure 3 (a); A is at the joint between segment B1 and segment D; B is at the horizontal side of segmental ring; $\Delta\theta_1$ is the tilt change of WSN node DR; $\Delta\theta_2$ is the tilt change of WSN node DL; α is the angle between vector AB and vertical direction as shown in Figure 3 (a). Using equation (1), the convergence of horizontal diameter of segmental lining can be calculated as shown in Figure 8. The increase in convergence value represents a decrease in diameter, i.e., a vertical ovalization deformation. The decrease in convergence value represents an increase in diameter, i.e., a horizontal ovalization deformation. The changing trend of diameter convergence is similar with the data from manual level. Comparing Figure 6 and Figure 8, horizontal ovalization and heave occur simultaneously, while vertical ovalization and settlement occur simultaneously. Using the least squares method, the relationship between convergence and settlement can be got as:

$$y = -2.68x + 2.40 \qquad (2)$$

where y is the settlement monitored by manual level and x is the convergence calculated by data from WSN on Ring 479. The results of the fitting are shown in Figure 9.

Thus, the deformation of existing tunnels including the diameter convergence and settlement with high

monitoring frequency can be obtained by WSN monitoring. The monitored results during the under-crossing process of Tunnel 6# is shown in Figure 10. The data is from UR node on Ring 479 of Tunnel 2#. The increase of data represents vertical ovalization and settlement of existing Tunnel 2# while the decrease of data represents horizontal ovalization and heave of existing Tunnel 2#. The gray boxes represent the advance process of TBM, while the other parts represent the halt process of TBM. During advance process, the data decreases so the existing Tunnel 2# shows horizontal ovalization and heave deformation because of the soil pressure on face and grouting pressure. The deformation of the existing tunnel induced by the under-crossing process is divided into 3 stages here:

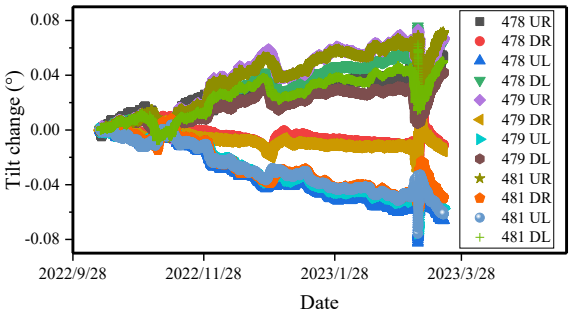

Figure 7. Monitored data of WSN.

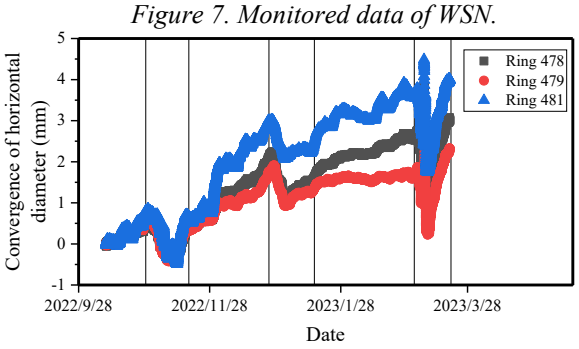

Figure 8. Convergence of horizontal diameter of segmental lining.

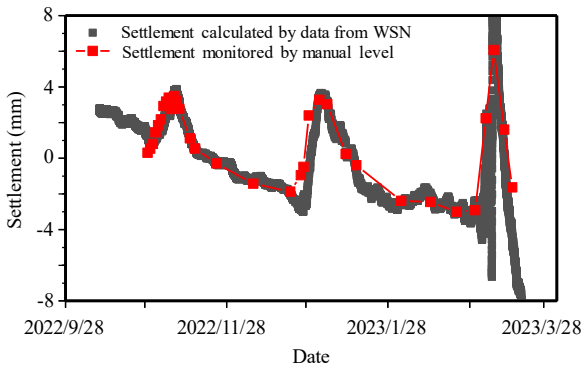

Figure 9. Settlement calculated by convergence of horizontal diameter and monitored by manual level.

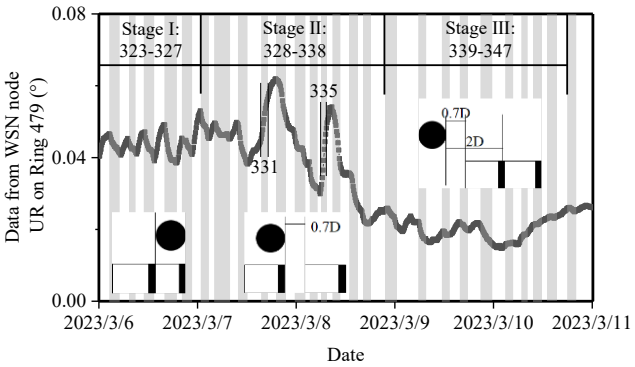

Figure 10. Deformation of existing tunnel monitored by WSN.

Stage I: During the construction of Ring 323 to Ring 327 of Tunnel 6#. At this stage, the cutterhead of TBM of Tunnel 6# is right below the existing Tunnel 2#. When TBM advances, the negative soil pressure on face causes the increase of pore water pressure in the stratum between Tunnel 2# and Tunnel 6#. As shown in Figure 1, the stratum between them is clayey silt and its permeability coefficient is relatively high compared with clay. Thus, in this stage, the heave and horizontal ovalization induced by TBM advance will disappear when the TBM halts because the excess pore water pressure decreases quickly.

Stage II: During the construction of Ring 328 to Ring 338 of Tunnel 6#. At this stage, the shield tail is no further than 0.7D from the existing Tunnel 2# in horizontal direction where D is the diameter of TBM. When shield advance, the grout is injected into the soil through the shield tail. The heave and horizontal ovalization of existing Tunnel 2# are mainly caused by the injection of grouting. Thus, the recovery of deformation during TBM halts is small at this stage. It should be noted that during the construction process of Ring 331 and Ring 335 of Tunnel 6#, the grouting volume is significantly insufficient, thus leading to significant settlement in the existing Tunnel 2#.

Stage III: During the construction of Ring 339 to Ring 347 of Tunnel 6#. At this stage, the shield tail is from 0.7D to 2D from the existing Tunnel 2# in horizontal direction. At this stage, the heave and horizontal ovalization caused by grouting decreases and the existing Tunnel 2# begins to settle again.

5 CONCLUSION

A complicated under-crossing construction case: newly constructed three-line tunnels under-crossing existing three-line tunnels is studied in this research. Manual level monitoring is combined with WSN monitoring. The results show that the connected aisle will decrease the heave of the first tunnel being under-

crossed and increase the heave of the second tunnel being under-crossed. The shape of settlement troughs after the first under-crossing are “V” shape, the shape of settlement troughs after the second under-crossing are “W” shape and the shape of settlement troughs after the third under-crossing are “V” shape. Because the third newly constructed tunnel is in middle of the first and second tunnel. The settlement can be calculated by the WSN monitoring data. The WSN data show that there are three stages of deformation of existing tunnels during under-crossing. In the first stage when the cutterhead is directly below the existing tunnels, the existing tunnels show heave and horizontal ovalization deformation during TBM advances because of the soil pressure on face. But when TBM halts, the heave and horizontal ovalization recover. In the second stage when the TBM tail is no further than 0.7D from the existing tunnels in horizontal direction, the existing tunnels show heave and horizontal ovalization deformation during TBM advances because of tail grouting. And when TBM halts, the heave and horizontal ovalization do not recover. In the third stage when the TBM tail is from 0.7D to 2D from the existing tunnels in horizontal direction, the influence of tail grouting decreases gradually and the existing tunnels begin to settle.

Fluid rheology and its implications for flow and cuttings transport in horizontal directional drilling (HDD) bores

Rhéologie des fluides et ses implications pour l'écoulement et le transport des déblais dans les forages de forage dirigé horizontal (FDH)

ABSTRACT: Common misconceptions about the appropriate fluid properties for horizontal directional drilling (HDD) often lead to inefficient hole cleaning strategies increasing the risk of hydrofractures, ground heave and mud loss, with significant cost and programme implications. This paper explores the fundamentals of flow behaviour in HDD showing that in-bore flow rates and hence fluid shear strain rates are so low that the traditional Bingham fluid model based on 300 and 600 rpm data from a Fann-type direct indicating viscometer is not valid. An example involving HDD bores for cable landfall of an offshore windfarm is discussed to illustrate the practical consequences of the cuttings transport processes. Analysis of rare annular pressure monitoring data has provided valuable insights into the cuttings behaviour in the bore. The importance of fluid property and pressure monitoring, and having a coherent hole cleaning strategy are highlighted. The paper concludes with recommendations to minimise the risks of hydrofracture and bore blockage.

RÉSUMÉ: Les idées fausses courantes concernant les caractéristiques fluides appropriées pour le forage dirigé horizontal (FDH) entraînent souvent des approches inefficaces de nettoyage du trou, augmentant ainsi le risque de fractures hydrauliques, de soulèvement du sol et de perte de boue, avec des conséquences significatives en termes de coûts et d'implications sur le programme. Cet article explore les principes fondamentaux du comportement de l'écoulement en FDH. L'article montre que le taux d'écoulement dans le forage et par conséquent les taux de cisaillement du fluide sont si faibles que le modèle traditionnel de fluide de Bingham basé sur des données à 300 et 600 tr/min provenant d'un viscosimètre direct de type Fann n'est pas acceptable. Un exemple impliquant les forages FDH pour les câbles sous-marins d'un parc éolien offshore est présenté afin d'illustrer les implications concrètes des processus de transport des déblais. L'analyse de données de surveillance de la pression annulaire, bien que peu fréquentes, ont livré des précieuses observations sur le comportement des déblais à l'intérieur du forage. L'importance des caractéristiques du fluide, la surveillance de la pression et avoir une stratégie de nettoyage du trou cohérente sont soulignées. L'article se termine en offrant des recommandations visant à réduire les risques de fractures hydrauliques et d'obstruction du forage.

Keywords: Horizontal directional drilling (HDD); drilling fluid; rheology; cuttings transport; hydrofracture.

1 INTRODUCTION

Horizontal directional drilling (HDD) was initially developed in the 1970s and is now widely used. Global challenges to mitigate climate change impacts through increased reliance on renewable energy and improved infrastructure resilience have increased the attractiveness of HDD technology. The technique is now capable of installing pipelines of up to 1.5 m diameter and up to 5.2 km length (Yan et al., 2019; Underground Construction, 2018). HDD is ideally suited to crossings beneath natural and man-made obstacles and offers substantial cost, safety and environmental benefits, as compared to alternative methods of pipeline and cable installation. However, despite the now wide use of HDD, there remain concerns regarding project risk in certain situations.

Key to HDD success is good management of the drilling fluid (often referred to as the mud), and the avoidance of excessive mud loss. Fundamental risks in HDD drilling arise from pressure build-up in-bore leading to hydrofracturing of the ground, heave of the overburden and mud loss – either to formation, subsurface infrastructure or up to the surface.

Table 1. Summary examples of mud use and shear rates in Europe in clayey ground. For shear rates using Bingham and Herschel-Bulkley models, parameters in Figure 2 have been assumed. P = pilot bore, R = fully reamed bore.

Category	Bore diameter (P & R)/ drill rod diameter (m)	Min/ max flow velocities in annulus (m/s)	Nominal Newtonian Shear rate range (s^{-1})	H-B shear rate range (s^{-1})	Bingham shear rate range (s^{-1})
Energy landfall HDD (efficient mud recycling ~1km+)	P:0.356 - 0.476; R:0.610 - 0.635/ 0.168	P:0.106/ 0.357; R:0.062/ 0.154	P:4.1 - 22.8; R:1.7 - 4.2	P:8.6 - 43.9; R:3.7 - 8.7	P:48.7 - 120.6; R:30.5 - 48.9
Long urban crossings (basic recycling ~500m+)	P:0.203 - 0.254; R:0.508 - 0.661/ 0.089	P:0.057/ 0.096; R:0.022/ 0.071	P:4.1 - 10.1; R:0.64 - 5.2	P:8.6 - 20.1; R:1.5 - 10.6	P:48.6 - 77.7; R:18.7 - 54.5
Short urban crossings (no mud reuse, ~200m)	P:0.153; R:0.457 - 0.559/ 0.089	P:0.105/ 0.262; R:0.007/ 0.016	P:19.8 - 49.5; R:0.17 - 0.52	P:38.3 - 92.9; R:0.45 - 1.2	P:111.6 - 185.6; R:9.5 - 16.8

In addition to ground heave, these problems can lead to slow progress rates, high mud consumption and risk of equipment damage or loss. Once hydrofracture has been initiated, fracture re-opening is easy and achievable in-bore pressures become limited, thereby constraining the available operational pressure range.

Poor cuttings transport can trigger bore blockage, generate hydrofracture and crystallise the above risks. At mud flow rates used in practice, hydrofractures can propagate significant distances in the ground before bore blockage is identified and mitigated.

These operational challenges are most severe for landfall HDD bores such as that shown in Figure 1 where drilling starts at a clifftop and descends to punchout in the sea. In-bore pressures before punchout are elevated by the hydrostatic head of the drilling fluid from the clifftop entry pit.

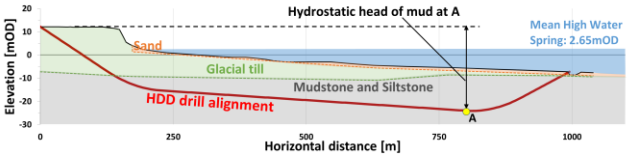

Figure 1. Example HDD vertical alignment for cable landfall (note expanded vertical scale, typical inclination of the entry section is about 9°).

2 THE DRILLING FLUID

For an HDD fluid key issues include: (a) carriage of the cuttings from the cutter head in the bore to the drill pit at the surface, (b) minimising the pressure required for cuttings carriage so as to minimise the risk of hydraulic fracture, and (c) limiting fluid loss from the bore. This discussion will focus on modelling the rheology and pumping pressure which are necessary precursors to the consideration of cuttings transport.

Typically in the UK the drilling fluid used for HDD works will be a bentonite-based slurry with an array of additives available including thinners, viscosifiers, agents to improve cuttings carriage, fluid loss control agents and fibrous materials to seal voids and fractures. Polymer fluids without bentonite have yet to achieve the prominence in UK HDD which they have achieved for piling world-wide.

Both bentonite slurries and polymer fluids are non-Newtonian fluids as indeed will be any fluid laden with soil cuttings. For these fluids, shear stress will be a non-linear function of the applied shear rate as can be seen from the data points in Figure 2 which are the average of many sets of shear stress - shear rate data for a bentonite-based fluid from an HDD bore. It can be seen that the data are strongly non-linear at low shear rates. Therefore when modelling non-Newtonian fluid behaviour it is essential to consider the operational shear rate.

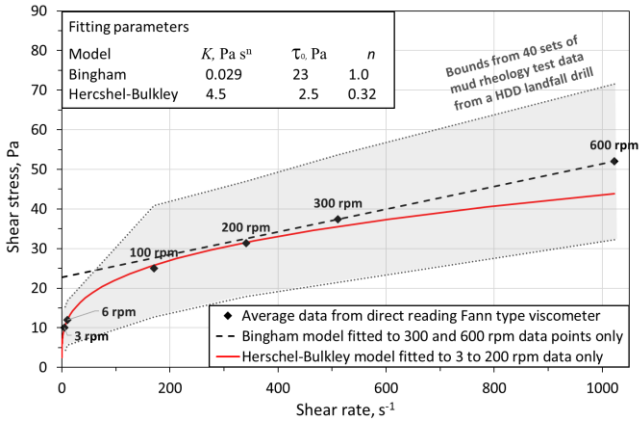

Figure 2. Shear stress - Shear rate data for a bentonite based slurry used in landfall HDD. Data obtained with a direct indicating viscometer of the Fann-type.

For a Newtonian fluid flowing with average velocity v in an annulus of external diameter d_o, and inner diameter d_i the shear rate at the wall $\dot{\gamma}$ is:

$$\dot{\gamma} = 12v/(d_o - d_i) \qquad (1)$$

For a circular pipe the same formula applies except that the number 12 is replaced by 8 and $(d_o - d_i)$ by the pipe diameter. For non-Newtonian fluids modelled wall shear rates will be higher than the nominal

Newtonian wall shear rate by a factor which will depend on the rheological model used, the selected model parameters, the flow rate, and the bore diameter (see for example, shear rates in Table 1). By way of an example of the significance of Equation 1, if the flow rate in an HDD bore is 1600 litre/min and the bore and drill pipe diameters are 0.356 and 0.168 m (14 and 6.625 in) then the nominal Newtonian shear rate will be 22 s^{-1} which will drop to 2.3 s^{-1} if the bore is reamed to 0.635 m (25 in).

Now the typical six-speed Fann-type viscometer used for assessing drilling fluids has a shear rate range of 5.1 to 1022 s^{-1} (3 to 600 rpm). Thus for HDD operations the in-bore shear rate is likely to be towards the lower end or below the range of shear rates that can be obtained with this type of viscometer (see Table 1 for typical examples and Figure 2). The best that can be done is to interpolate/extrapolate the low shear rate data (which themselves can be rather unsteady because of the low readings).

Two models have been used to fit the data in Figure 2, the Bingham and Herschel-Bulkley models. Both can be represented by the equation:

$$Shear\ stress = K\dot{\gamma}^n + \tau_0 \qquad (2)$$

where n is the power law index, K the consistency coefficient (Pa s^n) and τ_0 the yield stress (Pa). For the Bingham model $n = 1$.

It can be seen that the Bingham model based on the 300 and 600 rpm readings (511 and 1022 s^{-1}) gives entirely erroneous results at low shear rates. It predicts that there should be no flow below a shear stress of 23 Pa (y-axis intercept) whereas the measured data show flow at lower shear stresses. Despite this the Bingham model based on the 300 and 600 rpm data is the most widely used in the industry (Yan et al. 2020, Caenn et al. 2017, Lam et al. 2015). Indeed some Fann-type viscometers have only two speeds, 300 and 600 rpm. Whilst of no value for HDD flow modelling, the 300 and 600 rpm data can be useful for quality control as typical values are widely reported.

For all fluid modelling it is essential to adopt a model appropriate to the shear rates. For HDD this must be a model which can fit the low shear rate data, for example, the Heschel-Bulkley model (Chhabra and Richardson, 1999) and to use a viscometer capable of providing data at the relevant shear rates.

2.1 Pressure drop during drilling

Typically the drill rods may lie at the base of the bore but for order of magnitude pressure assessments it is convenient to assume that the bore is an annulus with central drill rods. Based on this assumption, Figure 3 has been developed to show the required pumping pressure per metre of bore for two bore diameters as a function of flow rate using the model parameters shown in Figure 2.

From Figure 3 it can be seen that for the Bingham model based on the 300 and 600 rpm data, flow rate has little effect on the pressure drop which is dominated by the inappropriately high modelled yield stress. The Herschel-Bulkley model fitted to the 200 to 3 rpm data gives greater sensitivity to the flow rate as the data fitting results in a lower yield stress but a much higher relative consistency coefficient.

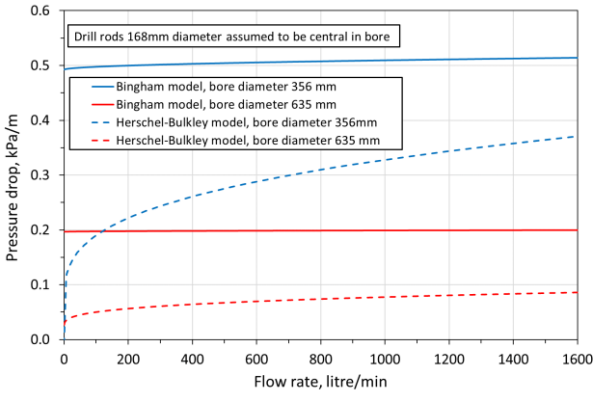

Figure 3. Modelled Pressure drop-Flow rate plots using Bingham and Herschel Bulkley Models.

However, a striking feature of both models is that the predicted pressures are low, much lower than those observed in the field with the clear implication that bores are not being effectively cleaned by the fluid flow and/or that the fluid discharged from the bore is not representative of the fluid in other parts of the bore. Indeed by way of comparison, the predicted pressures are much lower than the hydrostatic pressure which will be at least 10 kPa per metre vertical distance from cutter head to discharge pit.

2.2 Carriage of cuttings

Experience with slurry tunnelling machines suggests that a minimum velocity of about 3 m/s is necessary to carry the spoil in the pipeline from the cutter head. In HDD bores velocities are unlikely to reach 1 m/s (see Table 1). HDD cutter heads therefore must be designed and operated so as to cut the soil into pieces small enough to be carried by the fluid flow, sizes which can be expected to be of the order of 1 mm or less. This brings with it substantial demands with respect to soil-slurry separation. However, it must be recognised that in HDD, cuttings have to settle only the short distance across the bore to become part of a bed load which may be kneaded into a paste by the drill pipe and which may adhere to the pipe and/or walls of the bore so tending to block the bore. Good cuttings carriage will be

particularly important during reaming as the enlarged bore diameter will result in lower annular velocities potentially coupled with high solids loadings.

3 CUTTINGS LOAD FROM STATIC PRESSURE MEASUREMENTS

3.1 Background

Multiple HDD bores, each 1 km long, were drilled at a site off the UK east coast to enable the cable landfall of an offshore windfarm. The geology of the site comprises marine sand and glacial till overlying a mudstone bedrock. A bentonite-based drilling fluid with the average rheology shown in Figure 2 was used.

The initial phase of the HDD work was to form a pilot bore. The typical downhole assembly (DHA) used for pilot drilling is shown in Figure 4. It consists of a drill bit, a mud motor, and a gyro, behind which drill pipes are attached. The gyro measures the inclination and azimuth to determine the position of the drill downhole. The gyro unit also provides real-time measurements of fluid pressure both inside the drill pipe and in the annulus behind the mud motor. The annular pressure, which is reflective of conditions of the bore downhole, forms a focus of this paper.

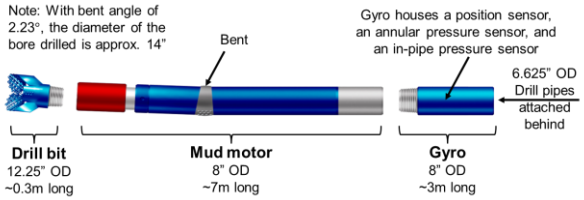

Figure 4. Schematic configuration of a pilot downhole assembly (DHA).

As discussed in earlier sections, hydrofractures and hole cleaning issues are key challenges in HDD. Current practice to mitigate hydrofracture risks involves careful monitoring and control of drilling parameters, particularly the dynamic annular pressure while drilling. On the other hand, the static annular pressure, which is the pressure of the mud plus cuttings suspended in the mud when there is no flow in the annulus, is rarely discussed or monitored. This paper sets out a novel and unique approach for tracking the cuttings content along the HDD bore, using the static annular pressure measured by the gyro.

3.2 Methodology

Following typical HDD site practice, after each pipe is drilled, the mud pump is turned off, the drill string is disconnected from the drill rig along with the internal electrical cable that transmits the signal from the gyro to the control cabin, a further pipe is inserted, cable reconnected, mud pump restarted and drilling resumed.

During pipe connections, opportunity was taken to capture the static annular pressure downhole after the mud pump was turned off, but before the disconnection of the signal cable. Such readings are rarely recorded in practice, although not difficult to obtain.

With the mud pump turned off, the annular pressure in the annulus should equilibrate to hydrostatic conditions. Hydrostatic pressure of fluid in the bore is calculated based on the density of mud returns exiting the bore at surface, and the depth change from the bore entry point to the annular sensor position, reflecting the current bore location. The density of mud returns measured at surface ranges from 1.01 to 1.2 kg/L. This range forms an envelope of hydrostatic pressures within which the static annular pressure measurements are expected to fall.

3.3 Results and findings

Figure 5 shows an example of the static annular pressures recorded during pilot drilling of a HDD bore in virgin ground. The measurements were compared to the expected range of hydrostatic pressures calculated based on the density of mud returns.

The static annular pressures are generally higher than hydrostatic from the first bend of the drill alignment where the bore path becomes flatter (at ~215 m from entry). This could be attributable to suspended cuttings not being effectively carried out to the surface, resulting in a higher in-bore mud density than that measured at surface. Cuttings will be held-up in the bore as they will tend to settle back so that their net velocity is less than that of the mud during their ascent to surface along the inclined section of the bore. However, as the excess pressures are more apparent in the horizontal section than the inclined, it seems that a more significant mechanism is the formation of blockages in the bore, which choke the flow and trap pressure within the bore. The trapped in-bore pressures take time to dissipate from the drilling conditions to hydrostatic.

In either case, the measurements indicate that cuttings were being held up and/or the bore blocked, which highlights the need for improved hole cleaning by optimising cutter head design, and/or mechanical hole cleaning coupled with attention to mud rheology. Not surprisingly, the highest concentration of trapped cuttings appears to coincide with the lowest point of the alignment before the ascent (~820 m from entry).

During the works, as drilling progressed to Pipe 53 (~510 m from entry), the front part of DHA (including

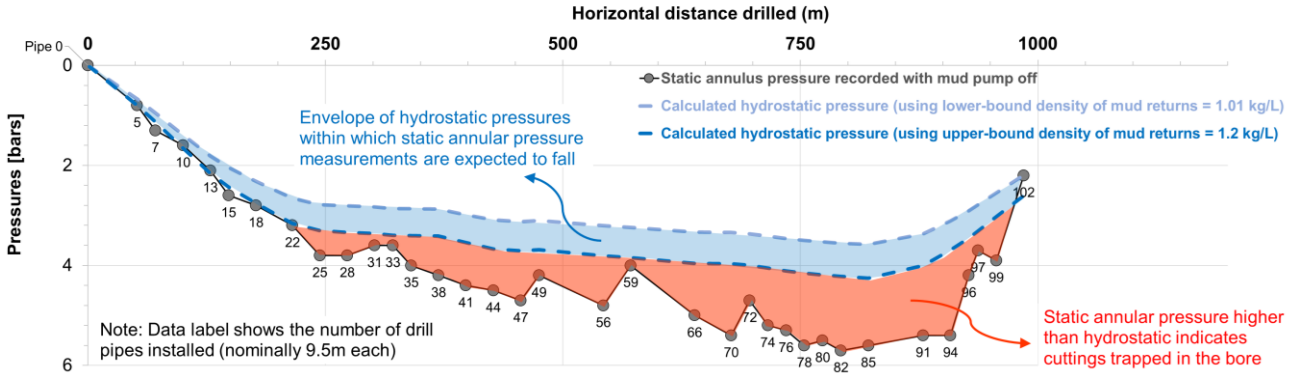

Figure 5. Comparison of static annular pressures with calculated hydrostatic pressures.

the drill bit and the mud motor) sheared off from the system and was lost downhole. A fishing operation was performed using a 11.25" diameter overshot housing a grappler. The lost tool was successfully retrieved and was tripped out to the surface. This tripping out was essentially also a mechanical hole cleaning. Cuttings in the form of large clay "sausages" were observed being tripped out (Figure 6). This confirmed that cuttings were trapped within the bore, as indicated by the high static annular pressures measured, which would not have been cleaned had the tripping out not been performed. Static annular pressures were also recorded for another HDD bore, and these findings were repeated, with high annular pressures indicating the presence of trapped cuttings. It is proposed that the monitoring of static annular pressures should be employed regularly as a simple and insightful means to inform the bore cleanliness, increase the confidence of hole cleaning performance and improve quality control.

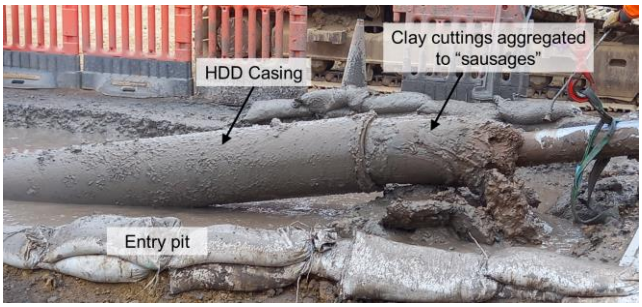

Figure 6. Photo of large "clay sausages" tripped out.

4 DISCUSSION AND CONCLUSIONS

The key issue from this brief analysis of HDD flow behaviour is that it is fundamental to: (i) consider the relevant shear rate for the process under consideration, (ii) use a fluid model appropriate to the shear rate and (iii) use a viscometer with which relevant data can be obtained. A Bingham fluid model based on the 300 and 600 rpm readings (shear rates of 511 and 1022 s^{-1}) on a direct indicating Fann-type viscometer will not be appropriate for HDD processes, as these shear rates are too high and the results will be dominated by the high modelled yield stress.

The Hershel-Bulkley model can better fit the data for bentonite slurries at the low shear rates of HDD processes and indeed the shear rates for all civil engineering applications of support fluids.

However, for HDD, both models show much lower pressures than are typically observed in the field demonstrating that pressures are controlled by constrictions/ blockages in the bore or zones of stiffer mud (sausages) and this needs to be addressed.

When designing fluids and additives for HDD it is essential to consider the low shear rate rheology and to be prepared to ignore 300 and 600 rpm data.

Static annular pressure measurements, which are rarely recorded in practice, were shown in this paper to provide valuable insights into the bore cleanliness. Static readings higher than hydrostatic indicate the presence of trapped cuttings in the bore, demonstrating that improved hole cleaning is required, either by optimising cutter head configuration and drill mud rheology, and/or mechanical hole cleaning. As these readings are not difficult to acquire, it is recommended that they are measured and monitored more regularly.

Experience has shown that HDD hydrofracture and heave risk may be of most significance in urban applications, where movement-sensitive infrastructure is crossed. Planning, pricing and constructing of such crossings requires careful consideration of drilling-induced ground movements, including both settlement and heave risks. Mitigation of ground movement risks hinge on good hole cleaning and mud management strategies, as discussed in this paper.

A hazard associated with hydrofracturing, which is well recognised in oil drilling but poorly appreciated in the HDD field, is "ballooning" ground or "well breathing" (e.g. Baldino et al., 2019). This is a phenomenon where drilling-induced ground hydro-fracturing, as well as engagement and opening of pre-

existing natural discontinuities, results in large mud loss to the formation during drilling with circulation. However, when drilling stops, large fluid flowback from the ground to the surface occurs. As no flow is expected when circulation pumps are off, this is often perceived as an unexpected occurrence. Flowback in ballooning ground is due to a network of fractures which are inflated during drilling, and are subsequently deflated by geostatic stresses at pumps-off when the in-bore fluid pressures fall. Ballooning may occur in grounds where an extensive fracture network is induced/ exists in which drilling fluid can be stored, but which is insufficiently extensive and open to drain the fluid away permanently. HDD project experience in the UK indicates that in ballooning ground, daily mud losses can reach 300 m^3/ day, of which about 25 - 85% can be recovered as daily flowback. In addition to other issues, this requires that sufficient mud storage capacity is available.

5 RECOMMENDATIONS

At HDD planning and design stage, ground investigations (GIs) should be carried out to provide detailed information on the fabric of the soil and rock formations to be transversed, and obtain information on hydrofracture and clogging risks. GIs should include borehole logs with detailed descriptions, accurate logging of pre-existing discontinuities and, where possible, judiciously designed in-situ hydrofracture tests outside the HDD alignment.

When developing HDD muds and other civil engineering support fluids, their rheology should be studied using equipment with sufficient precision at the relevant shear rates.

During HDD works, the actual shear rates should be considered, these will be lower than the standard shear rates historically adopted from the oil industry and applied to HDD.

During HDD drilling, downhole static annular pressures should be measured, monitored and analysed regularly to inform bore cleaniness and hole cleaning strategy.

To optimise the chances of project success, a good mud management strategy should be considered which is cognisant of the actual hole cleaning capability of the mud at the flow rates employed. Supplementary hole cleaning processes (such as periodic cleaning trip-outs) are helpful, but if overused in some geological settings there are risks of damage to or deviation from the already drilled bore.

Vigilant and documented monitoring of the mud returns is important for mitigating hydrofracture risk and should be embraced by the whole site team as an important quality control tool.

In some ground conditions, excessive hydro-fracturing, possibly coupled with opening of pre-existing natural discontinuities, can lead to ballooning ground with both large fluid losses and large flowbacks. This hazard is not well known in the HDD industry and is highlighted here.

ACKNOWLEDGEMENTS

The project experience reflected in this paper comes from a large number of projects, each of which has only been possible due to the work of a large group of people too numerous to list individually. The authors are grateful to all. Special thanks go to Andy Barwise and Phil Cowlishaw of RWE and Amandine Brosse and Jerry Love of GCG.

Enhancing soil-cement mixture's performance with GGBS

Améliorer les performances du mélange sol-ciment avec GGBS

Indian Institute of Technology Indore, India

**lalitborana@iiti.ac.in*

ABSTRACT: A soil-cement composite, comprising a thoroughly blended mix of soil, cement, and water, has played a crucial role in the construction of various civil infrastructures like bridge foundations, tunnels, highway embankments, foundations for port and harbour structures, and many more. Though efficient, traditional high-cement formulations pose severe environmental concerns, leading to the exploration of alternative materials that can bring sustainability to construction practices. This study focuses on utilizing "Ground-Granulated Blast-Furnace Slag" (GGBS) to explore its impact on the engineering characteristics of soil-cement mixtures. In this investigation, clay soil is blended with 20% of OPC and varying proportions of GGBS (20%, 30%, and 40% by weight of cement) as a replacement for OPC. The composite mixture is subjected to several Unconfined Compressive Strength (UCS) tests to assess the undrained shear strength of soil-cement-GGBS mixtures at distinct curing intervals (7, 14, and 28 days). Field emission scanning electron microscopy (FE-SEM) is also employed to examine the microstructure of the soil-cement composite, revealing the arrangement of particles, pore structures, and the distribution of cementitious materials. The results show that the composition having clay soil and 20% cement, replaced with 20% GGBS, yields maximum strength among all tested compositions with a significant increase of 24% compared to the conventional soil-cement mixture of clay soil and 20% cement only.

RÉSUMÉ: Un composite sol-ciment, comprenant un mélange soigneusement mélangé de terre, de ciment et d'eau, a joué un rôle crucial dans la construction de diverses infrastructures civiles telles que les fondations de ponts, les tunnels, les remblais d'autoroutes, les fondations de structures portuaires et bien d'autres. Bien qu'efficaces, les formulations traditionnelles à haute teneur en ciment posent de graves problèmes environnementaux, ce qui conduit à l'exploration de matériaux alternatifs susceptibles d'apporter de la durabilité aux pratiques de construction. Cette étude se concentre sur l'utilisation du « laitier de haut fourneau granulé moulu » (GGBS) pour explorer son impact sur les caractéristiques techniques des mélanges sol-ciment. Dans cette étude, un sol argileux est mélangé avec 20% d'OPC et des proportions variables de GGBS (20%, 30% et 40% en poids de ciment) en remplacement de l'OPC. Le mélange composite est soumis à plusieurs tests de résistance à la compression sans confinement (UCS) pour évaluer la résistance au cisaillement non drainé des mélanges sol-ciment-GGBS à des intervalles de durcissement distincts (7, 14 et 28 jours). La microscopie électronique à balayage par émission de champ (FE-SEM) est également utilisée pour examiner la microstructure du composite sol-ciment, révélant la disposition des particules, les structures des pores et la répartition des matériaux cimentaires. Les résultats montrent que la composition contenant un sol argileux et 20% de ciment, remplacée par 20% de GGBS, donne une résistance maximale parmi toutes les compositions testées avec une augmentation significative de 24% par rapport au mélange sol-ciment conventionnel composé d'un sol argileux et de 20% de ciment uniquement.

Keywords: Soil-cement; ground-granulated blast-furnace slag (GGBS); unconfined compressive strength (UCS); scanning electron microscopy (SEM).

1 INTRODUCTION

There has been a significant advancement in using soil-cement mixtures in geotechnical engineering. Dry or wet cement is combined with clayey soils to create a durable composite material called soil-cement mixture, which has several advantages over traditional building materials like cement concrete. The soil-cement mixture is considered a cost-effective remedy for soil stabilization in construction projects due to the economic benefit of utilizing locally accessible materials and minimizing dependency on costly imported materials mix (Solihu 2020; Choudhary et al. 2023). Ordinary Portland Cement (OPC) is the key component in soil-cement mixtures that serves as a fundamental binder, and it is readily used as a chemical additive in soil stabilization due to its several advantages like easy availability, low cost, durable end products, resistance towards acid and chemical attacks and many more. However, the extensive use of OPC leads to negative environmental consequences, primarily due to the high energy consumption during production and significant carbon dioxide emissions (Gupta and Chaudhary 2020). To mitigate this negative environmental impact, several researchers

attempted to find appropriate substitutes and cement alternatives that can provide appreciable strength. Out of all the conventional supplementary cementitious materials (SCM), Ground-Granulated Blast-Furnace Slag (GGBS) is considered one of the best cement substitutes. When added in a certain proportion, GGBS enhances the strength and endurance of the cement hydration products. GGBS is a by-product obtained from the blast furnaces used in the iron and steel manufacturing, exhibiting inherent pozzolanic properties. The addition of GGBS enhances the physical and mechanical characteristics of soil-cement mixtures by reacting with calcium hydroxide (lime), produced during the early stages of cement hydration, forming additional cementitious compounds like Calcium Silicate Hydrate (C-S-H) gel, Calcium Alumino-Ferrite (CAF), and Calcium Hydroxide (CH) which reduces the void spaces in the soil-cement matrix. Recently, some studies have shown the possible utilization of industrial waste-based SCMs to improve the engineering properties of clay soils (Åhnberg et al. 2003; Horpibulsuk et al. 2012; Singh et al. 2021). However, very few researchers have studied the utilization of SCMs to replace a part of lime and cement in soil stabilization. D.D. Higgins et al. (1998) conducted several laboratory tests such as UCS, CBR, swelling index, and many more on GGBS mixed lime-clay mixtures to analyze the changes in the engineering characteristics of clay soil. The results obtained revealed that the addition of GGBS considerably increased the clay soil's compressive strength. Arulrajah et al. (2018) studied how industrial waste by-products like fly ash (F) and slags (S) can enhance soft soil treatment using deep soil mixing methods. The study conducted laboratory experiments on test samples with varying water content levels (0.75, 1.0, and 1.25). The results showed appreciable improvement in the strength and stiffness of soft clay soils with an optimal binder content of 20% and an ideal mix of 5% F class and 15% S class fly ash. Du et al. (2017) conducted a comparative study on lightweight cement-treated soil with lightweight geopolymer-treated soils by performing several tests like UCS, mercury intrusion porosimetry (MIP), hydraulic conductivity, SEM images, and thermogravimetric analysis (TGA). They found that lightweight geopolymer-treated soils improved the permeability and strength properties and provided better engineering performances than lightweight cement-treated soils.

This study explores the strength gain characteristics by blending clay soil with 20% cement (by weight of dry soil) and varying proportions of GGBS (20%, 30%, and 40% by weight of cement) by conducting UCS tests. SEM was employed to observe the microstructure of the soil-cement composite, revealing the arrangement of particles, pore structures, and the distribution of cementitious materials.

2 MATERIALS AND METHODOLOGY

The clay soil used in this study is sourced from a test pit at the IIT Indore campus, located in Madhya Pradesh (India). The raw clay soil is sieved through a 2 mm Indian Standard (IS) sieve, dried in a hot air oven for 24 hours, and kept in an air-tight container. OPC and GGBS were obtained through collaboration with industrial partners. Using the Unified Soil Classification System (USCS), as adopted from ASTM D-2487-98, the soil is categorized as highly expansive clay soil. The grain size distribution curve (GSD) is illustrated in Figure 1. The basic properties of the clay soil are listed in Table 1.

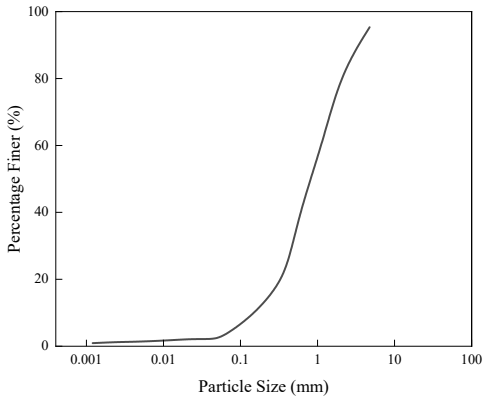

Figure 1. Grain size distribution (GSD) curve of clay soil.

Table 1. Basic properties of clay soil.

Property	Value
Natural water content (%)	15.38
Specific gravity	2.71
Liquid limit (%)	81.05
Plastic limit (%)	36.44
Optimum moisture content (%)	29
Maximum dry unit weight (kN/m^3)	1.425
Shrinkage limit (%)	11.20
USCS soil classification	CH

In this study, prepared raw clay soil was added with 20% of cement (specific gravity G_s = 3.10) and appropriate water content to obtain slurry-type consistency. The major constituents, including clay soil, cement, GGBS, and water, were thoroughly mixed with the help of a mechanical mixer.

Sixteen samples of soil-cement-GGBS compositions were prepared using high polymer

density molds (HPDM) with an internal diameter of 44 mm and a height of 98 mm. The soil was mixed with a cement content of 20%, and cement was subsequently substituted with 0%, 20%, 30%, and 40% by weight of dry cement. To preserve the consistency in the mixtures and provide adequate hydration, the amount of water added was 1.5 times the liquid limit of the soil (Choudhary et al. 2023). Each mixture was then carefully poured into the molds, and the sample was air-free with the help of a mechanical stirrer. The freshly molded mixtures were left for 24 hours at room temperature to achieve appreciable strength. After 24 hours of sample preparation, the samples were removed from the molds and placed in a curing tank, where they underwent a continuous curing procedure in a submerged condition. Afterward, a series of UCS tests were conducted to evaluate the mixture's undrained shear strength and unconfined compressive strength at 7-days, 14-days and 28-days of curing. Following the completion of UCS testing, SEM imaging was also utilized on the tested samples to provide insights into microstructural details.

3 RESULTS AND DISCUSSION

3.1 Unconfined compressive strength

The UCS test, conducted following ASTM D7012-23, was employed to evaluate the undrained shear strength and unconfined compressive strength of soil-cement-GGBS mixtures. A compression load at the strain rate of 1.25 mm per minute was applied to the specimens during the UCS test. The test includes samples with varying mixture combinations and curing times. The test results demonstrated increased compressive strength of all mixes correspondingly with longer curing times. An optimum content of 20% of cement has often been considered in previous studies, which showed significant strength and stability in the soil-cement mixture (Pham et al. 2021; Solihu 2020). Figure 2 (a), (b), and (c) show that the strength gain variation of samples with varying constituents increases for varying curing times of 7-days, 14-days, and 28-days, respectively. Moreover, it has been experimentally determined that specimens subjected to a 28-day curing period exhibit maximum compressive strength gain among all the compositions.

A soil mixture with 20% cement and 20% GGBS blend shows maximum values of 0.41925 N/mm^2 and 0.2096 N/mm^2 for undrained shear strength and unconfined compressive strength, respectively. The strength of the specified composition is 24% higher in comparison to that of the traditional soil-cement mixture with 20% cement content. The obtained results greatly emphasize the importance of GGBS in improving the strength qualities of combinations while encouraging the use of sustainable materials.

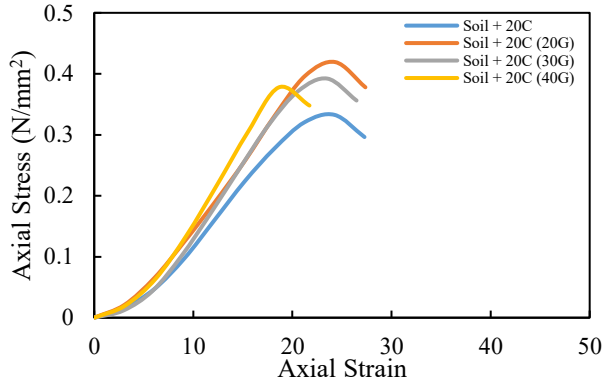
(b)



(c)

Figure 2. Stress-Strain curve of soil-cement-GGBS mixture with varying GGBS percentage for a curing period of (a) 7-days, (b) 14-days, and (c) 28-days.

3.2 Scanning electron microscopy

In this work, FE-SEM was conducted using FE-SEM Supra 55 (Carl Zeiss, Germany) with a magnification of 500X on a sample of GGBS blended soil-cement mixture having 20% cement with 20% GGBS as replacement of cement cured for 28 days as illustrated in Figure 3. The SEM image confirms bond formation and development of hydration products such as

calcium aluminate hydrates (CAH), calcium silicate hydrates gel (C-S-H gel), and Ettringite. Hydration production is confirmed by the creation and dispersion of these products, which helped develop the strength of composites. The angular shape of the GGBS particles also helps in better interlocking and strength development. The SEM images provide crucial insights into the interfacial connection of GGBS and soil-cement particles.

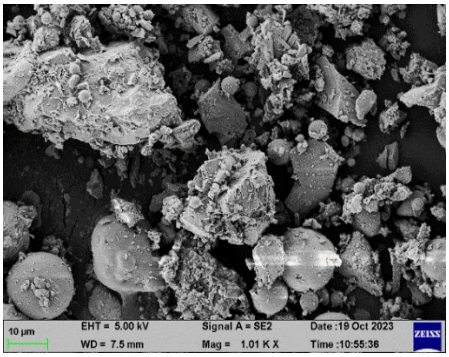


Figure 3. SEM image of Clay Soil + 20% cement + GGBS (20% of cement) at 28-days of curing.

4 CONCLUSIONS

The current study illustrates the strength properties of soil-cement-GGBS mixture with varying compositions for different curing times. The conclusions drawn from the results are as follows.

- It exhibits a strong reaction with calcium hydroxide ($Ca(OH)_2$), a by-product of cement hydration, leading to the formation of additional cementitious compounds., reducing the cavities and improving the overall strength and durability of the soil-cement mixture.
- The mixture of clay soil with 20% cement and 20% GGBS blend cured for 28 days shows a significant increase in the values of undrained shear strength and unconfined compressive strength of 0.41925 N/mm^2 and 0.2096 N/mm^2 respectively, as compared to other compositions. This composition exhibits a 24% increase in strength compared to the conventional soil-cement mixture with 20% cement content.

It is worth mentioning that this experimental study emphasizes mainly the strength development of clay soil mixed with 20% cement, and the cement proportion is replaced with GGBS at varying ratios. However, there are more areas in which further investigation is required to improve the current understanding of various parameters, such as optimization of mix ratios, the effect of curing conditions, long-term performance, time-dependent stress-strain behaviour, field scale validation, and many more.

Consolidating existing road structures using self-drilling bars

Consolidation des structures routières existantes à l'aide de barres autoperceuses

I.A. Ciocaniu*, A.C. Onescu, S. Manea
Technical University of Civil Engineering of Bucharest, Bucharest, Romania

GEOSOND SA, Bucharest, Romania

**ionut.ciocaniu@geosond.com*

ABSTRACT: The article presents design methods and execution technologies for consolidating geotechnical structures and roads in mountains areas of Romania, considering the specific conditions for each site. The design process took into consideration the difficult site conditions respectively , the working space - the consolidation and drainage works must be strictly performed within the road area (approximately 9m wide) and the execution phases – the works must be executed in such a way that traffic can proceed safely. The paper will present several situations encountered in different locations in Romania, with their respective geotechnical and hydrogeological characteristics and the specific technical solutions chosen at the design stage and implemented throughout the execution. Detailed solutions will be offered for the drainage system and the surface and underground water, as well as for the restoration of existing structures. The degradation over time of the road-associated structures is a widespread problem and it is influenced, among others, by geotechnical conditions and water action. Such deterioration compromises traffic safety leading to partial failure with impact to the usual traffic and even to complete failure. The pressing need for safety usually demands an emergency intervention plan, with technical solutions that can be quickly executed in the event of a major hazard. With this innovative approach, roads can be made safer and more resilient against future deterioration caused by changing geotechnical conditions or other environmental factors.

RÉSUMÉ: L'article présente des méthodes de conception et des technologies d'exécution pour consolider les structures géotechniques et les routes dans les zones montagneuses de Roumanie, en tenant compte des conditions spécifiques de chaque site. Le project a pris en considération les conditions difficiles du site, respectivement l'espace de travail - les travaux de consolidation et de drainage doivent être strictement effectués dans la zone routière (environ 9 m de largeur) et les phases d'exécution - les travaux doivent être exécutés de manière à ce que la circulation puisse se dérouler en toute sécurité. Le document présentera plusieurs situations rencontrées dans différents endroits de Roumanie, avec leurs caractéristiques géotechniques et hydrogéologiques respectives et les solutions techniques spécifiques choisies lors de la phase de conception et mises en œuvre tout au long de l'exécution. Des solutions détaillées seront proposées pour le système de drainage et l'eau de surface et souterraine, ainsi que pour la restauration des structures existantes. La dégradation au fil du temps des structures associées aux routes est un problème répandu et elle est influencée, entre autres, par les conditions géotechniques et l'action de l'eau. Une telle détérioration compromet la sécurité routière, entraînant une défaillance partielle avec un impact sur la circulation habituelle et même une défaillance complète. Le besoin urgent de sécurité exige généralement un plan d'intervention d'urgence, avec des solutions techniques qui peuvent être rapidement exécutées en cas de danger majeur. Avec cette approche innovante, les routes peuvent être rendues plus sûres et plus résistantes à la dégradation future causée par les changements des conditions géotechniques ou d'autres facteurs environnementaux.

Keywords: Self-drilling bars; micropile; anchors; consolidating structures.

1 INTRODUCTION

Recent changes in construction work sector and the creation of special, modern equipment have allowed the development of new solutions for applied geotechnics.

One of these relatively recent technologies is the self-drilling bars, used as soil anchors and also as micropiles for deep foundation works, which is successfully applied in Romania in projects for consolidation and foundation works for road construction, slope protection structures and landslide stabilization etc., in difficult soil and space conditions.

Consolidating existing road structures is a crucial aspect of infrastructure development, especially in mountainous regions. The challenging terrain and specific geological conditions in these areas require specialized design methods and execution technologies to ensure the stability and longevity of

the road structures. One approach to consolidating road structures in mountainous regions is using self-drilling bars. These self-drilling bars provide a cost-effective and efficient solution for reinforcing the geotechnical structures and stabilizing the road foundations. Consolidation significantly influences soil strength and the stability of structures. Accurate prediction of consolidation and settlement is essential for the construction, design, and safety of engineering projects in mountainous regions. Over the past ten years, many road construction projects in Romania encountered difficulties that heightened the vulnerability to landslides.

In every situation, it was needed to use small but strong equipment that could change according to work conditions.

2 CONSOLIDATION WORKS FOR EXISTING RETAINING WALLS IN THE MOUNTAIN AREA

The high traffic in the city of Brasov, situated in a mountain area in the center of Romania, led to the accentuated degradation of some structures and traffic restriction in the area.

The existing structures were made of raw stone and cyclopean concrete, with a poor strength plain concrete foundation. The walls dimensions were variable as follows: widths between 0.60 m and 3.00 m at the base of the wall, lengths between 40.00 m and 80.00 m and heights varying from 0.90 m up to 10.00 m.

A visual inspection of the retaining walls was performed prior to the consolidation works design which revealed existing degradations such as cracks, displacements, settlements, that endangered the stability and resistance of these structures, the degradations being mostly still an active process. Some of the retaining walls had drainage systems, but due to the degradation of the roadway water infiltration took place and led to the collapse of one part of the walls and road, and also affected some houses downstream. These situations with degraded structures and signs of loss of stability have led to the restriction or even stop of road traffic, requiring immediate interventions to ensure stability of the area. The lithology in the site consisted of conglomerate layers that represent the bedrock, and on top of the bedrock, the soil was formed by soft reddish-brown, yellowish-brown clayey silt or silty clay representing the Quaternary age alteration blanket and contains fragments of rocks in variable percentages.

Consolidation works (Figure 1) consisted of micropiles executed by drilling vertically into the body of the structure, with two stage injection, which were connected at the top by a reinforced concrete beam. In addition, the walls were supported by inclined micropiles executed on two levels, respectively at the top and center of each wall height, with 45º inclination and lengths of 12.00 – 15.00 m. Furthermore, the consolidation works involved the restoration of the drainage system, where existing, or otherwise, execution of a new drainage system.

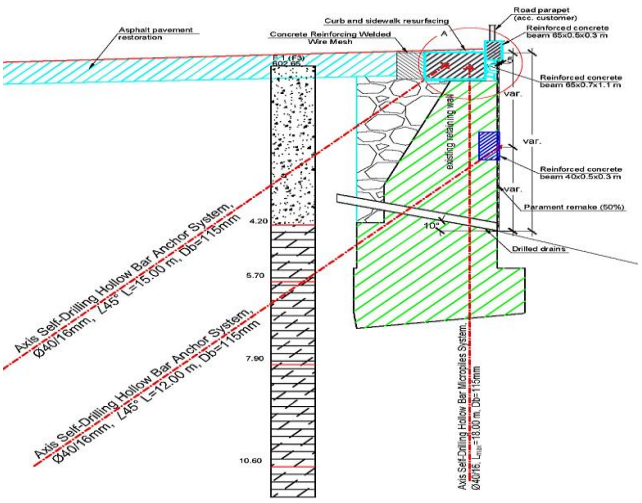

Figure 1. Characteristic section - designed solution for consolidation of the retaining wall.

The works were executed in well-defined steps as the consolidation of the retaining walls had to be done under traffic, on narrow streets and without changing the specific architectural aspect of the area (Figure 2). The geotechnical design of the structures rehabilitation was carried out in accordance with the requirements of European and Romanian standards.

Figure 2. Picture from the site during execution.

The structure was modeled in 2D design software, using both the limit equilibrium method and the reaction coefficient method, and verifications were

performed at the ultimate limit states: structural (STR) and geotechnical (GEO), considering normal and seismic design situations.

The geotechnical design was verified for the following ultimate limit states:

- internal failure or excessive deformation of the structural elements, in which the material strength contributes significantly to ensuring the resistance (STR);
- failure or excessive deformation of the soil, in which the foundation soil parameters contribute significantly to ensuring the resistance and global stability (GEO);

The main consolidation elements were the self-drilling bars. Their sizing was done preliminarily with the formula (1) below, then by automatic calculation the influence of these as a group effect on consolidation and displacement reduction was verified.

$$L = \frac{T_w * F_s}{\pi * D * T_{ult}} + l \qquad (1)$$

where T_w is the design force (kN); F_s is the safety factor equal to 2, dimensionless; D is the design diameter of the anchor/micropile (m); T_{ult} is the lateral friction resistance of the injected micropile (kPa); l is the free length (m).

The equilibrium conditions were verified in the first step, through which the dimensions and geometry of the micropiles were determinate to ensure the stability of the system under the action of the soil pressures and other external loads. Then, in the second step, the structural design, the necessary sectional strength characteristics were established for the new system to be able to safely take all the loads and stresses (bending moments, shear and axial forces).

3 CONSOLIDATION WORKS FOR LANDSLIDES ON A NATIONAL ROAD

On a national road in Romania, in the mountain area, with high traffic accentuated degradation and instabilities were discovered with fast evolution accentuated by the rainy condition. Thus, from day to day, the degree of damage was greater, which endangers road traffic without taking urgent rehabilitation measures (Figure 3).

Figure 3. Photo of the affected road area

The geotechnical investigation, including inclinometer measurements (Figure 4), showed a first layer of soft sandy clay and loose sand to a depth of approx. 6.00 m over a layer of consolidated marl clay. Groundwater was intercepted at depths between 0.40-4.10 m, sometimes having a under presure character, due to clay intercalations in the first layer that locally block groundwater flow and generate springs locally.

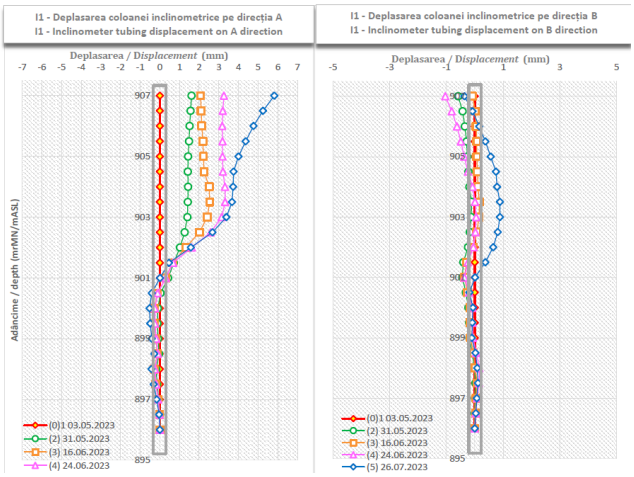

Figure 4. Inclinometer measurement that show the evolution of displacement at different time intervals

Following the stability analyzes performed, it resulted that the soil is stable in dynamic and static conditions only when the soil layer is not saturated.

Thus, through the project, works were foreseen to ensure the controlled flow of surface water and groundwater, the consolidation of soft ground and ensuring the general and local stability of the site.

The engaging was the condition that the consolidation and drainage works must be strictly performed within the road area (approximately 9m wide) and the execution phases – the works must be executed in such a way that traffic can proceed safely.

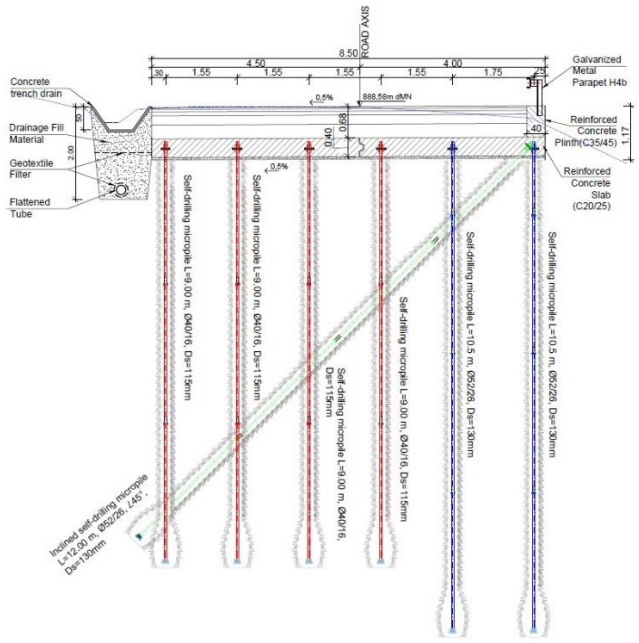

Figure 5. Section with the designed solution

In this case it was designed a complex solution with self-drilling micropiles, vertical and inclined, that ensures the soil improvement where difficult soil conditions were encountered and load transfer to the deeper layers and also the stability of the area (Figure 5).

The advantage of this solution is that it is based on a fast and efficient execution technology because the self-drilling bars allow dynamic grouting during drilling. In addition to significantly reducing execution time, it also allows efficient injection of soil near the micropiles.

The execution of the proposed works will eliminate the need to occupy surfaces outside the road and through the proposed execution solution, does not require closing traffic, because the equipment involved in the implementation of the works has small size an weight and the time required for execution is very reduced, reducing the inconvenience caused by single-wire traffic.

For groundwater drainage, an infiltration water collection system was provided consisting of a perforated rifled tube, wrapped in a geotextile filter, mounted at about 2.00m depth and drainage filling, on the route of the concrete channel projected on the left side of the road, in the direction of increasing mileage.

4 CONCLUSIONS

According to the specific conditions of the site, it is important to choose the consolidation solution for both structural damage of structure and soil degradation that appears due to the actions of natural or anthropic factors, it is very important to be minimally invasive and highly effective. Dynamic grouting during drilling process offers the advantage of improving the near soil by injection, also the execution can be performed with modern small dimensions equipment. The use of self-drilling bars for consolidation and foundation works it is a modern and efficient solution that which can be applied in cases.

The possibility of execution of both inclined and vertical self-drilling bars can ensure the soil improvement and also the stability of the area.

The solution was successfully applied in many projects in Romania associated with drainage works.

ACKNOWLEDGEMENTS

This paper was developed from the projects designed and executed by the company Geosond SA, Bucharest, Romania.

ABSTRACT: This article presents design phases, special foundation works, and technology used for construction of an electrical power station, with two basements, in a crowded area of the city. The surface of the underground structure is 700 sqm. Both effective design solution and technology standards cope with challenging demands such as neighbour buildings, high traffic area and restrained site area. As for environmental concerns, this project used low carbon concrete, which significantly reduced carbon footprint of the entire construction. Pit enclosure consisted of CFA piles and one row of horizontal steel struts. Further challenges such as limited water in-flow, due to electrical equipment installed inside the basements were coped by infrastructure design and execution, as well. To assure safe excavation works at the depths of -10 meters and -11.50 locally and then to build the reinforced concrete raft and infrastructure, retaining wall piles was required. Based on site characteristics, soil conditions (silty clay and ground water level at approx. -7,50 m, distanced CFA piles of 60 cm and 40 cm diameter were built. Considering the architectural and structural configuration proposed, the building's foundation system consists of a general raft. Infrastructure consists of columns, beams, walls made of reinforced concrete and slabs. The perimeter structural walls of basements are 25-30cm thick with additional waterproofing requirements applied. Optimised solution proved to be effective for both civil and geotechnical works, delivering the project on time.

RÉSUMÉ: Cet article présente les phases de conception, les travaux de fondation spéciales et la technologie utilisée pour la construction d'une centrale électrique avec deux sous-sols, dans un quartier surpeuplé de la ville. La surface de la structure souterraine est de 700 m². La solution de conception efficace et les normes technologiques répondent aux exigences difficiles telles que les bâtiments voisins, la zone à fort trafic et la zone de site restreinte. En ce qui concerne les préoccupations environnementales, ce projet a utilisé du béton bas carbone ce qui a considérablement réduit l'empreinte carbone de toute la construction. L'enceinte se compose de pieux CFA et d'une rangée d'entretoises horizontales en acier. D'autres défis tels que le débit d'eau limité, en raison de l'équipement électrique installé à l'intérieur des sous-sols, ont également été relevés par la conception et l'exécution de l'infrastructure. Des pieux de mur de soutènement ont été nécessaires afin d'assurer la sécurité des travaux d'excavation à des profondeurs de -10 mètres et -11,50 localement, puis pour construire la base et l'infrastructure en béton armé. Etant donné les caractéristiques du site et les conditions du sol (argile limoneuse et niveau des eaux souterraines à env. -7,50 m), des pieux CFA de 60 cm et de 40 cm de diamètre ont été construits. Compte tenu de la configuration architecturale et structurelle proposée, le système de fondation du bâtiment se compose d'un radier général. L'infrastructure se compose de poteaux, de poutres, de murs et de dalles en béton armé. Les murs structurels de périmètre des sous-sols ont une épaisseur de 25-30 cm et des exigences d'étanchéité supplémentaires sont appliquées. La solution optimisée s'est avérée efficace pour les travaux civils et géotechniques, livrant le projet à temps.

Keywords: Excavation; pit enclosure; urban; electric station.

1 INTRODUCTION

Being built on a crowded area of the city of Bucharest, the new electrical power station which is designed for electrical power supply to the new Promenada Mall extension, needed the right solution to cope with the local ground conditions, multiple requirements by the electrical system supplier and with restrained site area.

The location is in northern side of the city and quite a restrained space was handed over, a working space

which required proper coordination, right technology to be chosen and a tight time schedule to fit in.

The project required design and build solution for a safe deep excavation, in an urban area, for two basements with an excavation depth from 9.72 metres to 11.52 metres, locally.

Being a deep excavation surrounded by adjacent structures, close enough to current project property limits, it was particularly important to follow up a rigorous and sensitive monitoring programme.

2 PROJECT HIGHLIGHTS

2.1 Vicinities

Total surface of the construction site is just 1000 sqm and it has several neighbour buildings such as an office building on North-West with 1 basement and 7 stories height, at the South with another office building with 4 basements and 10 stories. At East it is one of the busiest avenues (Barbu Văcărescu) especially on rush hours (Figure 1).

Figure 1. Pit enclosure vicinities.

2.2 Ground conditions

Prior ground investigation, through its two 35 meters long boreholes, revealed relatively homogenous ground lithology, but with various widths and compressibility characteristics for each layer (Table 1).

The ground is mainly characterized by alternance of cohesive with non-cohesive layers, the ground water being found within the second layer at approximately 7 meters below natural ground level.

2.3 Service state requirements

The structure by its purpose – as an electrical power supply station – needed to bear the active pressure, overloads caused by neighbour buildings and to limit as much as possible any ground water infiltrations which might occur during the electrical power station service state.

Therefore, besides usual design approaches for these kind of structures, special attention was paid to the waterproofing solution of the infrastructure.

Table 1. Ground conditions.

Layer	Level	Width	Description
I	GL … -1,20 m	0,90 m … 1,00 m	Brown clayey sand, gravel and waste construction materials
II	-1,20 m … -15,00 m	14,00 m	Clay / silty clay / sandy grey clay, firm to stiff
III	-15,00 m … -19,40 m	4,50 m	Clayey sand / compact silty greyish sand
IV	-19,40 m … -29,50 m	10,00 m	Clay / sandy grey clay, stiff
V	-29,50 m … -32,80 m	3,50 m	Clayey sand / grey sand, compact
VI	-32,80 m … -35,00 m	2,00 m	Grey clay, stiff

2.4 Retaining structure solution

Because of the constrained site space required for the works, the chosen solution was a contiguous pile wall supported by one level of steel struts and locally, an additional level where the excavation level was the deepest.

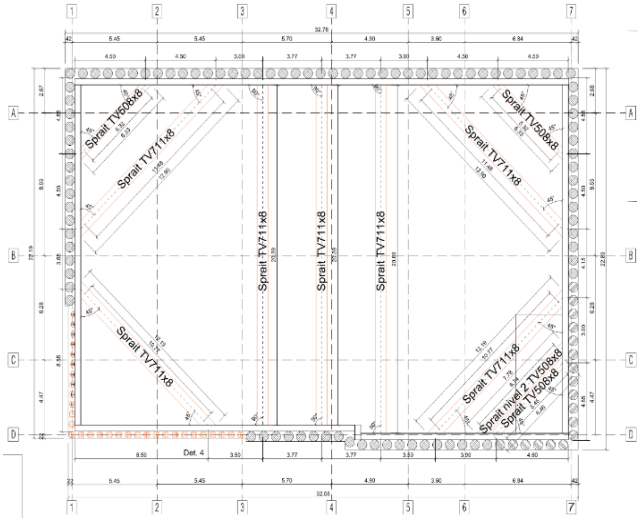

Figure 2. Contiguous pile wall and steel struts layout.

For the temporary retaining wall (Figure 2), there can be distinguished three different sections characterized by different supporting solution.

The first one, contiguous pile wall with one level of steel struts supporting system. (Figure 3 – left).

For a single area where the excavation was deepened with about 2 meters, for the sump pits, an additional steel strutting level was installed (Figure 3 – middle).

For both characteristic sections of the pit enclosure, 60 cm diameters CFA piles with a spacing of 80 cm, were designed.

The section of the pile wall near the existing neighbour building's diaphragm wall – part of the 4 ground floors office building, was dimensioned accordingly, 40 cm diameter CFA piles with a spacing of 60 cm (Figure 3 – right).

The entire pile wall is solidarized by a reinforced concrete capping beam.

The building's foundation system consists of a general raft. Reinforced concrete columns, beams, walls and slabs are part of building's infrastructure. The perimeter structural walls of basements are 25 -30 cm thick with additional waterproofing elements applied.

3 EXECUTION STAGES

Regarding execution sequence, prior to retaining wall execution, a safe, stable, and solid enough working platform was prepared at approximately -1.00 m level. To limit deviations of the piles and to ensure a proper drilling position, guide walls were cast in place. Piles were then made using CFA technology, following the guiding walls perimeter, changing the auger type from 600 mm to 400 mm diameter in the vicinity of the neighbour building's existing diaphragm wall.

After the piles concrete has reached the specified strength, piles were trimmed down to the designed level and the interior guide wall was demolished to make the formwork, install the rebar and pour the concrete in the capping beam.

The operational team proceeded then with a general excavation down to -4.00 m, to install the main steel strutting system at -3.00 m.

After all the elements were safely put in place, confronting also monitoring results in sequent stages, final excavation has been performed and secondary strutting system was installed on the corner side, where the excavation level went almost 2 meters deeper. After finishing the pit enclosure, waterproofing works and power station's infrastructure (reinforced concrete raft, vertical and horizontal structural elements) were done.

Monitoring works were confirming the results obtained by the design, ensuring a smooth continuation of the works in highly safe conditions.

4 DESIGN

Retaining walls dimensions were established considering the limitation of deformations, as well as for technological reasons, aiming to obtain a quasi-impermeable pit enclosure, by assuring the embedment in the lower layers of clay with low permeability.

Design was made using the Eurocode's DA1, Combination 1, DA1 Combination 2, complying also with Romanian regulations.

Design situations followed up different approaches, such as the regular design situation, accidental situation considering an additional excavation and the calculation in the hypothesis of seismic action, according to SR EN 1998-5:2004 (ASRO, 2004).

To obtain the efforts in the retaining wall, the support system was modelled using two-dimensional numerical calculation, in a plane stress and plane strain.

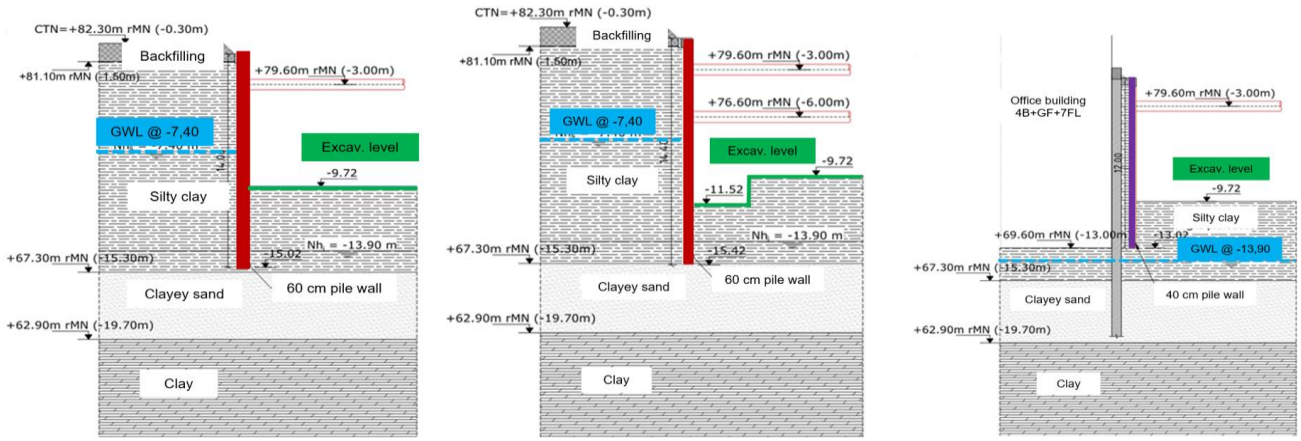

Figure 3. left: characteristic section 1, middle: characteristic section 2, right: characteristic section 3

The calculation is based on the finite element method, through Plaxis 2D software.

Maximum horizontal displacement of the retaining wall, calculated, towards inside pit area, was 25 millimetres (Figure 4).

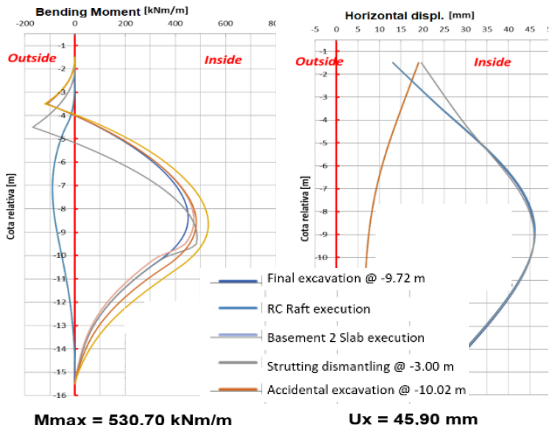

Figure 4. Contiguous pile wall and steel struts layout.

5 MONITORING

To conduct proper monitoring works both for the new infrastructure works and for the neighbour existing buildings, there were installed two inclinometers and used new and existing settlement monitoring marks on both two buildings.

Monitoring works were conducted according to a specific programme which followed each key step of new infrastructure construction.

Measurements were compared to displacement values obtained within design phase to confirm the design assumptions, and, if it is the case to take corrective actions as quick as possible.

Monitoring reports revealed a maximum horizontal displacement of the retaining wall of about 10 mm, less than the one provided by design and vertical displacement of neighbour buildings within required parameters (Figure 5).

Figure 5. Inclinometer measurements and working stage.

6 CONCLUSIONS

This project was a particularly challenging one, not necessarily due to the technology used for the infrastructure works, but since the works required a deep excavation in a congested urban area, in a particularly narrow working space and being surrounded by buildings that must not be affected in any way with the newly power station execution works. In this way, it is once again noted the importance of preparing and conducting monitoring works, both for newly built structure and for vicinities also (Figure 6).

Compressibility transition between a marine onshore clay to artificial carbonate silt soil behaviour

Transition de compressibilité entre le comportement d'un sol argileux marin onshore et le comportement d'un sol limoneux carboné artificiel

A. Conrado-Palafox*, T. Newson, A. Ahmed
Geotechnical Research Centre, Department of Civil and Environmental Engineering, University of Western Ontario, London, Ontario, Canada

*aconrado@uwo.ca

ABSTRACT: Wind turbines are rapidly moving to offshore environments to lessen onshore land use, reduce visual impact, and take advantage of higher and more constant wind speeds. A clear example is the Gulf of Mexico and its surroundings, which have a high potential for offshore wind farms. The most attractive offshore areas have shallow water depths, such as Florida, the Yucatan shelf, and the Bahamas, which are characterized by crushable carbonate sediments. Since it is expensive to obtain *in situ* carbonate sediment samples, the creation of an artificial simulant consisting of calcite particles and clay soil was used for this research. Compressibility tests were carried out to identify the compression responses of several clay – calcite and silicate silt mixes were used to provide an initial screening of suitable materials. The results show an improvement in the void index with addition of silica and calcite particles to the reconstituted clay, and although both forms of silt particles decreased the compression index; the calcite mixtures with higher than 85% of calcite particles reached and exceeded the C_v of the reconstituted clay. Moreover, the calcite particles decreased the liquid limit to a lesser extent than the silicate mixtures.

RÉSUMÉ: Les éoliennes se déplacent rapidement vers les environnements offshore pour réduire l'utilisation des terres terrestres, réduire l'impact visuel et tirer parti de vitesses de vent plus élevées et plus constantes. Un exemple clair est celui du golfe du Mexique et de ses environs, qui présentent un fort potentiel pour les parcs éoliens offshore. Les zones offshore les plus attrayantes ont des eaux peu profondes, comme la Floride, le plateau du Yucatan et les Bahamas, caractérisées par des sédiments carbonatés écrasables. Comme il est coûteux d'obtenir des échantillons de sédiments carbonatés in situ, la création d'un simulant artificiel composé de particules de calcite et de sol argileux a été utilisée pour cette recherche. Des tests de compressibilité ont été effectués pour identifier les réponses à la compression de plusieurs mélanges d'argile – calcite et limon silicaté afin de fournir un premier criblage de matériaux appropriés. Les résultats montrent une amélioration de l'indice de vide avec l'ajout de particules de silice et de calcite à l'argile reconstituée, et bien que les deux formes de particules de limon diminuent l'indice de compression ; les mélanges de calcite avec plus de 85 % de particules de calcite atteignaient et dépassaient le Cv de l'argile reconstituée. De plus, les particules de calcite diminuent la limite de liquidité dans une moindre mesure que les mélanges de silicates.

Keywords: Compressibility; carbonate silt; artificial offshore marine sediments.

1 INTRODUCTION

This study focuses on the geotechnical properties of soils in the near offshore carbonate areas of the Gulf of Mexico and Caribbean, more specifically on the Yucatan Shelf, Florida Shelf, Bahamian Platform and Gulf of Batabano in Cuba. These areas are of great interest because they are adjacent to existing offshore oil industry areas, such as the Campeche Bay or the continental shelf of Texas, and they have reasonable wind capacity factors (~40%) making them potentially viable for future offshore wind farms. The capacity factor is determined based on raw wind data obtained from the ERA-5 and MERRA-2 wind climate estimations and standard wind turbine power curves, enabling estimates of the energy production. It should be noted that the average capacity factor currently achieved offshore in Europe was 45% in 2018 (Hernández Galvez et al. 2022).

These offshore areas are characterized by either extensive shallow water depths with low wave energy, e.g. Florida Bay, Bahamian Platform and the Gulf of Batabano (because of their protected shelf lagoon singularities), or high energy wave environments with open, deeply submerged shelves, e.g. the West Florida Shelf and Yucatan Shelf (Logan et al. 1969).

The carbonate sediments in the Gulf of Mexico are generally formed from coral reefs, sands and mud

materials, whose composition depend on wave energy and carbonate precipitation. The sediments are found to transit from sand and lime sands to lime muds, with increasing mud composition (clay size particles), for greater water depth and lower wave energies (Logan et al. 1969; Purdy 1963; Ginsburg 1956; Hoskins 1964).

There are four main particle size distribution (PSD) types in the carbonate areas of the Gulf of Mexico (See Figure 1). These are: 1) sand material with less than 12% silt and <5% clay particles; this is characterized by skeletal carbonate materials, such as mollusk grains or non-skeletal grapestone particles (shown with brown lines); 2) silty sand sediments with around 20% silt particles and <10% clay size particles, with the skeletal portions coming from coral algae particles, angular molluscan fragments and foraminifera, and the oölitic portion from non-skeletal particles (shown with red lines); 3) lime muds with 50% silt material with less than 20% clay size particles (shown with green lines); 4) carbonate mud sediments formed with clay size particles around 50% and less than 25% sand particles (shown with yellow lines). The carbonate silt and mud sediments are mostly non-skeletal silt grains, such as faecal pellets, peloids and ooids, while clay size grains are often aragonite precipitated particles and some terrigeneous clays close to Campeche bay, the Texas shelf and southeast Cuba, (Logan et al. 1969; Purdy 1963; Ginsburg 1956; Hoskins 1964).

As can be seen in Figure 1, although these materials are generally all carbonate in nature, there is a significant range of particle size distributions along the Gulf of Mexico, e.g. carbonate muds (4) can be found on the Yucatan Shelf with Campeche Calcilitutie, as well as in Florida and Bahamas, with Cudjoe Keys and South Bright, respectively. Whilst silty sands (2) are in Progreso, Yucatan, Florida Bay and the Bahamas.

Most geotechnical investigations for carbonate soils have been carried out with sand or silty sands (e.g. Coop 1990; Wang et al. 2020) to determine the crushability influences of these weak particles, leaving a gap in the literature with very few carbonate silts and mud samples being investigated and particularly those of the Gulf of Mexico. This paper describes a study of the variations in compression behaviour observed and other basic geotechnical properties of an artificial offshore sediment made from a high sensitivity terrigenous clay with additions of crushable carbonate silt particles. These carbonate silt-clay mixtures are also compared with similar silicate silt-clay mixtures to determine any behavioural differences due to the calcite minerals. Thus, this paper investigates the transition behaviour between lime mud or Marquesa Lagoon sediments to the Cudjoe keys or South Bright carbonate mud sediments, as shown in Figure 1.

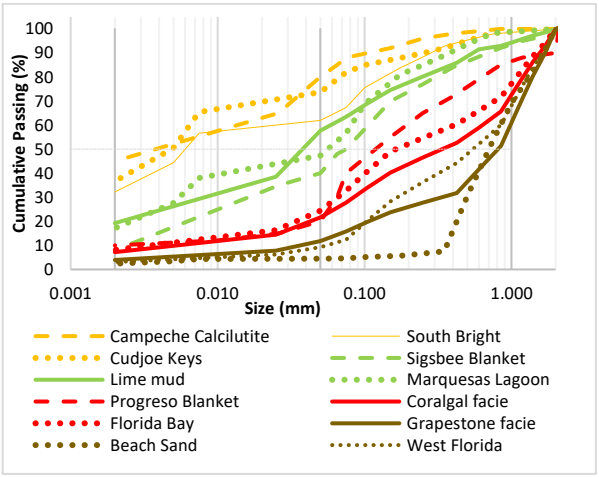

Figure 1. PSD of carbonate sediments in the Gulf of Mexico.

2 MATERIALS AND METHODS

Since it is expensive to obtain offshore marine *in situ* sediments and because carbonate minerals have high sensitivity values from 2 to 50 leading to significant disturbance during sampling, some researchers have attempted to better understand calcareous and carbonate soils based on artificial soils (e.g. Chen et al. 2013; Liu et al. 2016). In this paper, the same approach has been taken as a first step to creating realistic simulants for artificial offshore carbonate clayey-silt materials and provides a good screening tool to assess the most promising materials.

The clay material used to make the soil mixtures is an onshore clay from Eastern Canada (Ottawa), which was selected as a reference material due to its glaciolacustrine sediment characteristics (Nader 2014); comparable in relation to its sedimentation processes to some marine sediments. This high plasticity clay (CH) has a liquid limit of 55%, plastic limit of 26% and a plastic index of 29%.

2.1 Calcite and silicate mixtures

Artificial calcite particles were created in a chemistry laboratory at Western University based on Na_2CO_3 and $CaCl_2$ adjusting the pH to 10 with HCl, to produce a uniformly graded carbonate silt material. SEM images of these particles show them to have hexagonal and rhombohedral shapes, a tendency to aggregate and a crushability index Br of 0.54 (Conrado-Palafox et al. 2023). The silicate silt is a commercial Sil-Co-Sil-106 sub-angular ground quartz (Schmidt 2015).

Both types of silt particle were mixed with the Ottawa clay soil at different percentages: 25%, 50%, 75%, 87.5% and 93.5%, to obtain the resulting compressibility and other basic geotechnical behaviour of the clay. Figure 2 shows that the pure artificial calcite particle size distribution (PSD) has a

generally uniform grading, while the silicate silt material has a more well-graded curve (Table 1 shows d_{50} values), with 25% of the particles smaller than 0.002mm. The Ottawa clay soil has 70% of its particles smaller than 0.002mm.

The carbonate silt mixtures show better graded curves for 25% and 50%, while the curve with 75% calcite lies closer to the uniform distribution; the corresponding d_{50} and uniformity coefficients (C_u) are shown in Table 1. This is important because the particle sized distribution in the sample plays a significant role in the compressibility behaviour.

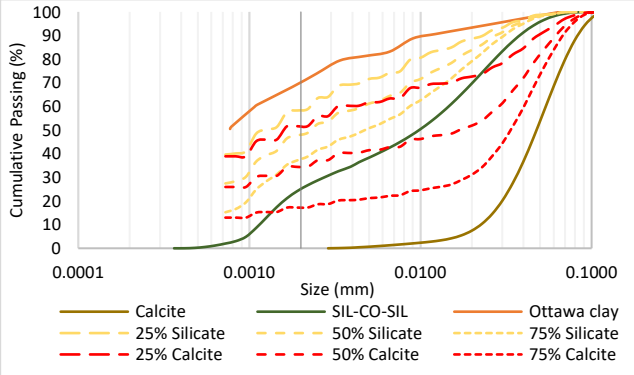

Figure 2. PSD of silicate silt, calcite, and Ottawa clay mixes.

Table 1. PSD characteristic parameters.

Soil sample	Silt (%)	d_{50} (mm)	C_u
Reconstituted clay	0	0.0080	
Silicate	25	0.0015	2.65
Silicate	50	0.0022	5.18
Silicate	75	0.0050	10.48
Silicate	100	0.0100	
Calcite	25	0.0018	5.18
Calcite	50	0.0180	36.14
Calcite	75	0.0340	48.19
Calcite	100	0.0500	

2.2 1-D oedometer test

Oedometer tests were carried out with reconstituted samples formed at 1.5 times their liquid limit, to determine the compressibility variations (void ratio vs stress) due to the calcite and silicate admixtures. To visualize any potential bonding and structure behaviour of our mixes, the intrinsic compression line (ICL) and sedimentation compression line (SCL) after Burland (1990) was determined using the void index (I_v) approach with the following equations (1 – 3) and compared to the void index relationships of the different mixtures;

$$I_v = \frac{e - e_{100}}{C_c*} \quad (1)$$

$$e_{100} = 0.109 + 0.679e_L - 0.089e_L^2 + 0.016e_L^3 \quad (2)$$

$$C_c* = 0.256e_L - 0.04 = e_{100} - e_{1000} \quad (3)$$

where e_L is the void ratio at the liquid limit and e_{100}, e_{1000} are the void ratio at 100 kPa and 1,000 kPa.

3 RESULTS

3.1 Compression behaviour

The initial void ratios (e_0) and void ratios at 25 kPa (e_{25}) for the intact clay and reconstituted clay are e_0 = 2.07, 1.39 and e_{25} = 2.04, 1.27 respectively. The silicate mixtures presented initial void ratios from 1.46 to 0.76, decreasing with higher silicate % and their e_{25} range are from 1.25 to 0.67; while e_0 of the calcite mixtures are 2.03 to 1.18 and e_{25} are 1.87 to 1.01.

Figure 3 (a) shows the 1-D oedometer compression curves of the calcite-clay mixtures, while 3 (b) shows the results of silicate-clay mixtures. The void ratio (e) was normalized by the void ratio at 25 kPa (e_{25}). Two distinct behaviours are seen, with calcite compressibility curves moving upwards (increasing e/e_{25}) with increasing silt %, while the silicate mixes went downwards (reducing e/e_{25}), in comparison to the reconstituted Ottawa clay material reference.

The compressibility indices (C_c) of the silicate materials show a reduction with silicate percentage increases, while the C_c values for the calcite mixes keep increasing until 93.5%, where it actually exceeds the reconstituted clay value. On the other hand, the swelling index decreased with both the addition of the silicate and calcite minerals; the silicate mixes reduce their C_s with higher percentages of silicate, while the calcite mixes presented lower C_s values with lower calcite percentages (see Table 1).

Figure 4 shows compressibility index (C_c) with liquid limit (LL). As expected, LL decreases with silicate or calcite addition. However, the silicate reduced the LL more than the calcite. It can be seen in Figure 4 that LL of the calcite mixes range from 35-42%. Intact samples from Mexico and other offshore regions show higher LL, thereby increasing their compressibility indices. This is likely to due to the minerology and chemistry of the offshore materials.

Figure 5 shows the ICL and SCL developed by Burland (1990) obtained with a meta-study of natural clay results. According to Cotecchia and Chandler (2000) the sensitivity can also be determined with the SCL and ICL curves. Therefore, the SCL obtained by Burland (1990) with intact clay samples shows a sensitivity of approximately S_t=5 in respect to its ICL. The undisturbed Ottawa clay is far above the SCL

meaning that the clay tested has a sensitivity higher than 5 at lower stresses. At a vertical effective stress (σ'_v) above 500 kPa, the line converges on the SCL, while for reconstituted Ottawa clay void index (I_v) lies between the SCL and ICL lines, showing the influence of structure on the intact clay compression behaviour.

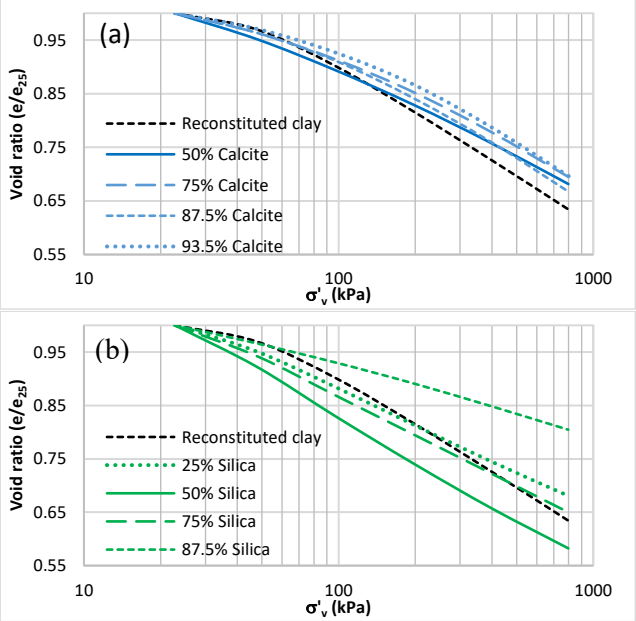

Figure 3. Normalized compression curves of calcite (a) and silicate (b) mixes with Ottawa clay.

Table 2. Compression index (C_c) and swell index (C_s).

Soil sample	Cc	Cs
Reconstituted clay	0.348	0.036
25% Silicate	0.263	0.027
50% Silicate	0.251	0.016
75 % Silicate	0.146	0.011
87.5% Silicate	0.091	0.010
50% Calcite	0.222	0.016
75% Calcite	0.269	0.018
87.5% Calcite	0.325	0.024
93.5% Calcite	0.455	0.026

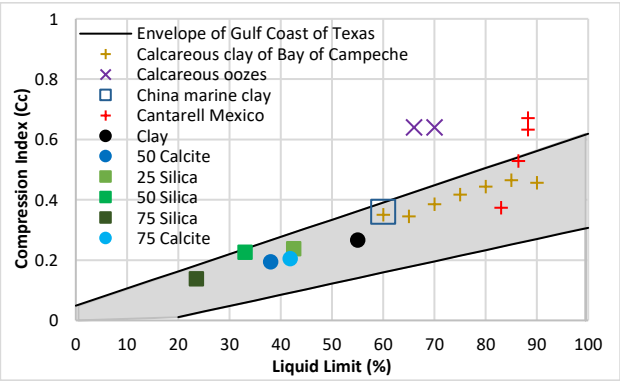

Figure 4. Compression index with limit liquid.

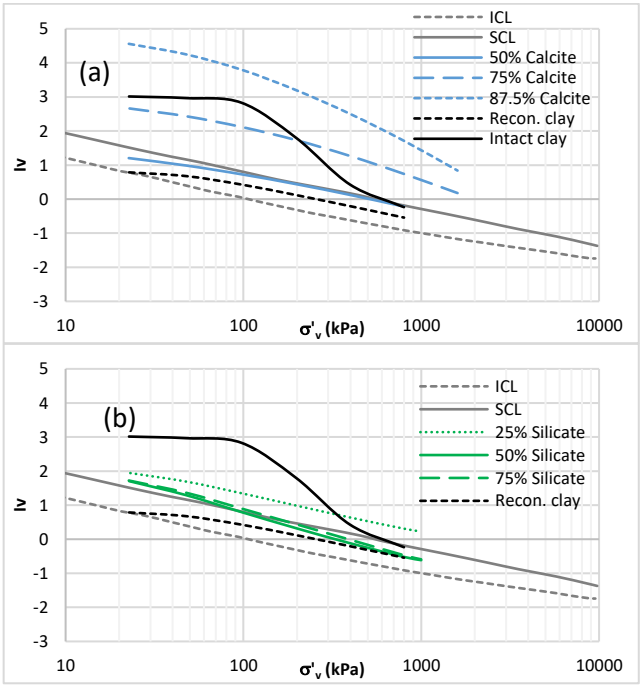

Figure 5. Void indices (I_v) of clay and calcite (a) and silicate (b) mixes.

The calcite mixture curves have increased void index values with calcite % increases, lying well above the reconstituted clay curve. At higher calcite contents (>75%), the calcite curves reach the undisturbed clay curve and eventually exceed it. In contrast, the silicate mixtures with less than <75% present similar curves laying around or beneath Burland's SCL, reproducing the similar behaviour to the very low % calcite mixes.

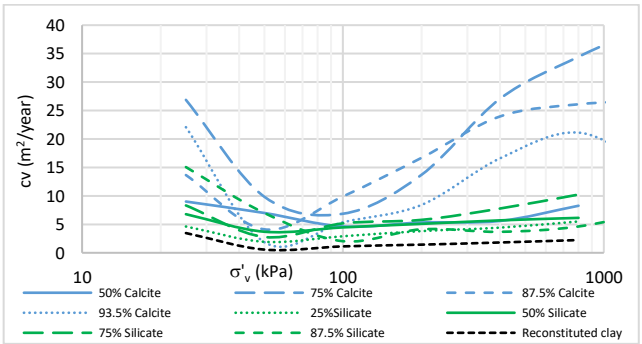

Figure 6. Coefficient of consolidation (C_v) with stress.

The values of coefficient of consolidation (C_v) are shown in Figure 6 and show lower values for silicate mixtures compared to the calcite. The 50% calcite mixture presents the lowest C_v in comparison with the other mixtures. The highest C_v values are the calcite mixtures greater than 75%, although at 50 kPa the values are about the same as the silicate or 50% calcite.

4 CONCLUSIONS

This study shows the changes in basic geotechnical behaviour of a high plasticity terrigenous clay due to the addition of precipitated calcite particles and manufactured silicate particles. Firstly, the addition of 50%, 75% of silicate and 50% calcite shows PSDs similar to the upper limits found in the Gulf of Mexico marine sediments. Adding more calcite particles (75% and 87.5%) provides PSD curves similar to the Coral facies or Progresso Blanket curves. The clay – silicate mixes are less compressible than the clay – calcite mixes, and sediments with more than 85% of calcite particles present compressibilities and void ratios higher than a structured intact high plasticity clay. Moreover, the calcite particles do not reduce the clay plasticity as much as silicate particles, and the calcite addition increases the coefficient of consolidation more than the silicate material. Although not tested in the study, it is expected changes in the shear strength and sensitivity of the silicate and calcite mixes will occur, based on the ICL and SCL curves of the clays. Further testing using more sophisticated stress-strain approaches will be used to further validate the obtained materials.

Development and laboratory testing of a low-cost wireless in-place inclinometer prototype

Développement et tests en laboratoire d'un prototype d'inclinomètre sans fil à faible coût

R. Correia dos Santos*, J. Marcelino
Laboratório Nacional de Engenharia Civil, Lisboa, Portugal

**ricardos@lnec.pt*

ABSTRACT: This paper introduces a low-cost in-place inclinometer tailored for geotechnical engineering applications, specifically designed for monitoring lateral (transverse) deformations in embankments, retaining walls or natural slopes. The developed system utilizes Micro-Electro-Mechanical System (MEMS) accelerometers, which are pivotal in tilt measurement, offering precise and compact solutions for monitoring inclinations in geotechnical applications. The hardware configuration involves connecting multiple accelerometer sensors in series, interfacing them with small low-cost microcontrollers. These sensors communicate data wirelessly to a central master node. The master node further transmits the collected data to the web infrastructure. The software architecture of the system is developed to achieve real-time data processing and analysis. This integration enables efficient storage, retrieval, and visualization of the displacement data, empowering geotechnical engineers with accurate, timely, and actionable insights. Laboratory testing and validation of this inclinometer system demonstrates that it may be useful in providing general information for slope stability assessments, excavation safety, and foundation integrity evaluations. The MEMS accelerometer used is quite low-cost, with a mere 10-bit output resolution, and, thus, may not meet the requirements for high-risk projects. Plans are underway to explore alternative MEMS that offer enhanced precision and accuracy for tilt measurement while still maintaining affordability.

RÉSUMÉ: Cet article présente un système d'inclinomètre à faible coût conçu sur mesure pour les applications de génie géotechnique, spécifiquement élaboré pour surveiller les déformations latérales (transversales) dans les remblais, les murs de soutènement ou les pentes naturelles. Le système développé utilise des accéléromètres à système micro-électromécanique (MEMS), cruciaux pour la mesure de l'inclinaison, offrant des solutions précises et compactes pour la surveillance des inclinaisons dans les applications géotechniques. La configuration matérielle implique la connexion en série de plusieurs capteurs d'accéléromètre, en les interférant avec de petits microcontrôleurs économiques. Ces capteurs transmettent sans fil les données à un nœud central maître. Ce nœud maître transmet ensuite les données collectées à l'infrastructure Web. L'architecture logicielle du système est conçue pour permettre un traitement et une analyse des données en temps réel. Cette intégration permet un stockage, une récupération et une visualisation efficaces des données de déplacement, fournissant aux ingénieurs géotechniciens des informations précises, opportunes et exploitables. Les tests de laboratoire et la validation de ce système d'inclinomètre démontrent qu'il peut être utile pour fournir des données cruciales pour les évaluations de la stabilité des pentes, la sécurité des excavations et l'intégrité des fondations. Le capteur MEMS utilisé est assez économique, avec une résolution de sortie de seulement 10 bits, et pourrait ne pas répondre aux exigences des projets hautement significatifs et à haut risque. Des plans sont en cours pour explorer des capteurs alternatifs offrant une précision et une précision accrues pour la mesure de l'inclinaison tout en maintenant un coût abordable.

Keywords: Fixed-in-place inclinometer; low-cost; MEMS acceleration sensors; ground movement; embankments.

1 INTRODUCTION

Inclinometer monitoring is a geotechnical technique used to measure and track the changes in inclination of a natural slope, retaining wall, or embankment, over time. This method typically involves the use of a metal or plastic pipe (casing) with inner grooves in two orthogonal directions that is installed into a borehole drilled within the ground being monitored (Dunnicliff, 1982; Stevens and Zehrbach, 2000). By regularly measuring the inclinations of that casing at specific depths, engineers and geotechnical experts can determine the lateral deformations in two directions and assess the stability of slopes, tunnels, excavations, dams, and other geotechnical structures (Ding et al., 2000; Stark and Choi, 2008; Uhlemann et al., 2016).

Inclinometer monitoring provides valuable data on ground movements, enabling also early detection of potential issues and allowing for timely remedial

actions to prevent accidents or damage to structures (Stark and Choi, 2008).

The most used instrument type, the transversing inclinometer probe, which uses a servo-accelerometer sensor, was introduced to the industry in the late 60s (Green and Mikkelsen, 2008). Servo accelerometers measure acceleration based on force balance and inertial principles, and are known for their high precision, robustness, durability, and ability to withstand harsh environments. The casing's shape is established through consecutive manual measurements, usually placing the transversing probe at 50 cm intervals, which is the typical distance between the wheels that guide the probe along the casing grooves. These measurements yield a profile of the casing in two orthogonal directions. Machan and Bennett (2008) presents a detailed description of the procedures involved in the measurement and data collection using the transversing inclinometer probe.

One notable drawback of servo accelerometers used in such probes is their relatively high cost. Other limitations, which can cause measurement errors if not properly accounted for, include sensitivity to temperature changes and limited frequency response (high frequency readings may result in feedback loop that can introduce phase lag). These limitations make servo accelerometers less suitable and prohibitive for applications that require the use of a fixed In-Place Inclinometer (IPI) solution, or automatic acquisition and remote access of high-frequency reads.

IPI involve the installation of multiple sensors at discrete depths along the tube casing and are useful when frequent monitoring of ground movement is essential or when site accessibility is limited (Uhlemann et al., 2016). This approach saves valuable time and labour that would otherwise be spent on manual measurements using the transversing inclinometer probe. Additionally, it enables the seamless collection of regular data through the utilization of automated data acquisition equipment, providing valuable information on the ground deformation vector and rate of movement.

Micro Electro-mechanical Systems (MEMS) accelerometers have gained prominence in the last decade (Li et al., 2014), supplanting the traditional servo accelerometer, and finding a growing application in IPI.

The principle of MEMS accelerometers relies on detecting changes, for example, in capacitance, piezoelectricity, or thermal conductivity caused by accelerative forces (Niu et al., 2018). When the accelerometer undergoes acceleration, these microstructures move, leading to a change in capacitance or other quantifiable properties. This change is then converted into an electrical signal, which can be analysed and used to ascertain the acceleration applied to the sensor.

Ground movements are typically deemed quasi-static. Thus, by measuring the components of the gravitational acceleration vector along a three axis MEMS accelerometer, mathematical algorithms can be applied to ascertain the sensor's orientation relative to Earth's gravitational field.

The rapid advancements in MEMS technology as led to significant reductions in sensor cost, size, and energy consumption of inclinometer solutions. At present, some companies, including, SISGEO.com, GEOSENSE.co.uk, SIGNALQUEST.com, MEASURAND.com and SOILINSTRUMENTS.com, have their own commercially available IPI solutions.

Those solutions use a series of accelerometers housed within rigid bodies that are somewhat interconnected by flexible joints enabling relative tilt movement between each sensor. Each available solution features its joint mechanism and rigid body design. Some are specifically designed for insertion into traditional grooved casings, whereas others offer greater versatility, allowing placement inside unguided casings. The IPI from MEASUREMENT don’t require any centring of the rigid bodies within the casing, relying on the casing’s wall for the support of the flexible joints. Full information about the MEMS accelerometers used in commercial solutions is not disclosed by the companies. Recently, Freddi *et al.* (2023) presented laboratory testing of prototypes and preproduction samples of a lightweight IPI solution, using carbon fibre rods for the rigid body.

These solutions can result in relatively expensive IPI systems, specially, for use cases where many inclinometers, with a high sensor count, are necessary. Often, to reduce costs, only a minimal number of sensors are placed, or they are installed far apart from each other (Allasia et al., 2020). Also, all of them transmit data from sensors through wires, using a serial wired communication protocol (e.g., RS485 or SDI-12).

A prototype of a low-cost IPI system, designed for budget-constrained scenarios, is presented. A notable aspect of the developed system is the wireless transmission of data from each sensor to a master node. This minimizes the need for extensive wiring and connections and results in cost savings.

While there is an inherent acceptance of reduced tilt precision and accuracy in comparison with available expensive commercial solutions, the system's design should be tailored to maintain its utility and reliability across typical geotechnical monitoring applications.

2 MATERIALS AND METHODS

The IPI prototype comprises four sensor nodes and a master node. Each sensor node wirelessly transmits angle data obtained from its accelerometer to the master node. The master node forwards this data to a web-based timeseries database at predetermined time intervals.

2.1 Hardware components

Sensor nodes comprise an accelerometer board (HW-86C) and a microcontroller (ESP8266 D1 mini R2), both readily available at affordable prices (< 3 euros per unit). A custom-designed PCB board manages power distribution and ensures seamless communication between the microcontroller and the accelerometer with no wiring. Figure 1(a) shows the main components of each sensor node.

The sensor board employs the consumer-grade ADXL345, a triple-axis MEMS accelerometer with 10-bit digital output, providing a wide measurement range and low power consumption. Table 1 shows an estimate of the main source of error and the corresponding tilt errors. After compensation of some errors, through calibration, the ideal performance corresponds to a tilt error of 0.1º. Despite being 10 to 100 times less accurate than servo-accelerometers, this error level, if achieved, could be adequate for some less demanding cases.

Table 1. ADXL345 error source estimate (Analog Devices).

Sensor parameter	Performance	Condition/Note	Tilt Error
Noise density	290 *u*g/√Hz	Bandwidth at 6.25 Hz	0.05º
Bias drift	-	10 days	0.057º
Initial offset	35 mg	No compensation	2º
		With compensation	0º
Total error	No compensation	Bandwidth at 6.25 Hz	2.1º
	With compensation	Bandwidth at 6.25 Hz	0.1º

The electronic components of each sensor node are enclosed within a stainless-steel pipe (probe) with about 30 mm outer diameter and 10 mm length. Node sensors are powered by an 5V parallel circuit source. Each one operates at around 50 mA when active and can peak at a maximum of 300 mA (during 1 to 5 milliseconds) wireless transmission. Wireless transmission occurs in a staggered manner, one sensor at a time, with intervals of about 100 miliseconds, to prevent current overload.

The connection between each sensor probe is established using multi-layer ½ inch (PVC?) pipes and compression pipe fittings typicaly used in fluid applications. Figure 1(b) shows the prototype setup prior assembly with the four node sensors. A flexible joint is omitted, because laboratory testing is conducted using an apparatus with a rigid casing (Figure 1(c)). The goal is to eliminate potential errors arising from joint movements, focusing exclusively on assessing the accuracy and precision of sensor‘s angle measurements. To ensure a precise fit and centering in the rigid casing, 3D printed PLA elements are affixed at the extremities of each probe.

Figure 1. (a) sensor node components; (b) inclinometer prototype setup; (c) calibration rigid casing used in tests.

2.2 Software of nodes and acquisition system

Each sensor node's microcontroller is programmed in C++ using Arduino IDE to: (i) retrieve gravitational forces (g_x and g_y) from the accelerometer via the I2C protocol, (ii) compute the corresponding angles (a_x and a_y), (iii) employ a low-pass filter for enhanced accuracy, and (iv) wirelessly transmit this data to the master node. Each ESP device has a unique MAC address which is used to identification purposes. The transmission occurs at regular intervals controlled by a user variable. In the laboratory tests, data was transmitted every 10 s. Wireless transmission is achieved using the ESP-NOW protocol. ESP-NOW enables direct, fast, and low-power communication among multiple ESP microcontrollers over long distances (up to 400 m) without the need for a router.

The master node acts as an acquisition system and an internet gateway, being composed by two ESP8266 microcontrollers. The first microcontroller receives

data wirelessly from the node sensors, stores the readings in an array, and sends the aggregated sensor data in JSON format over Serial at regular intervals (30 seconds interval has been set in lab tests). Its code also features a timeout mechanism to ensure data transmission, even if not all sensors have provided readings within a specified time frame. The second microcontroller establishes a secure Wi-Fi connection, receives incoming JSON data from the Serial port (containing measurements from all sensors), and forwards it to a remote broker using the MQTT (Message Queuing Telemetry Transport) protocol. This microcontroller operates as an MQTT client, publishing data to a specific topic (with a name defined by an inclinometer code).

A free MQTT broker has been established using HiveMQ's cloud service (hivemq.com), which controls and aggregates all messages published.

A local server with Telegraf, InfluxDb and Grafana docker containers was established. Telegraf systematically gathers data from MQTT topics. This data is seamlessly relayed to an InfluxDB timeseries database, wherein a timestamp is attributed to each message, forming a robust backend infrastructure. Finally, the visual representation of the acquired data is facilitated through integration with a Grafana dashboard viewer, enhancing the overall monitoring and visualization capabilities of the system.

2.3 Setup of laboratory testing

The inclinometer prototype underwent testing utilizing an apparatus equipped with a top-mounted pivot, enabling a rigid casing to rotate within a range of +/- 20º along a vertical plane. Each sensor probe was manually aligned to ensure that the accelerometer's X and Y axes corresponded with the orthogonal grooves on the casing. A portable tiltmeter (servo accelerometer from Slope Indicator with a tilt error of approximately 0.011º) was positioned on a tilt plate installed perpendicular to the casing. All readings from the sensor probes and tiltmeter were zeroed with respect to the vertical position of the casing to eliminate any potential zero-g bias offset errors.

The angles computed from the sensor probes were then compared with those recorded by the tiltmeter. The prototype was placed into the casing with two different orientations to assess the angles of rotation along the sensor's X and Y axes (a_x and a_y). Readings from the sensor and tiltmeter were taken at regular intervals of about 0.5º within a range of about ±15º, under an ambient temperature of 18ºC.

3 RESULTS AND DISCUSSION

Figure 2 shows the results obtained when the X-axis of the accelerometers is aligned with the casing tilt motion. Results for the other prototype orientations are omitted due to space limitations, as they align closely with the findings presented here.

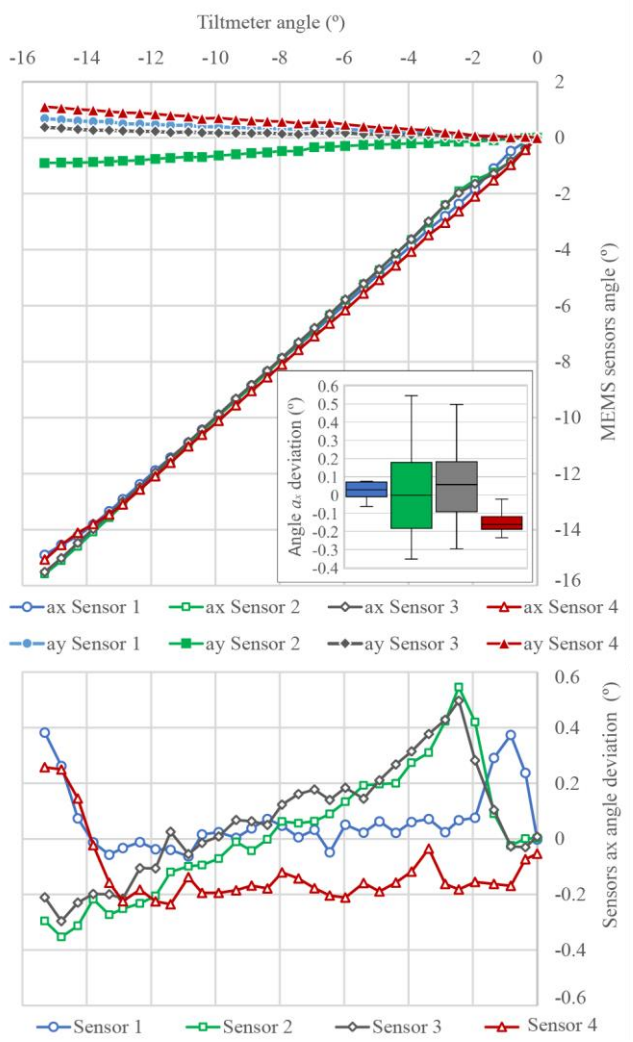

Figure 2. Results from the inclinometer prototype, with the X-axis sensors aligned to the casing rotation (-15º to 0º).

The top plot displays the relative angles resulting from each sensor probe (a_x and a_y) against the relative angles computed from the uniaxial tiltmeter. The bottom plot depicts the deviation of a_x relative angles from sensors in relation to those provided by the tiltmeter. The points of these plots derived from an average of not less than ten measurements for each sensor at every casing tilt position. The boxplot shows the interquartile range between the first and third quartiles, and the median of the deviation angles a_x of the sensors in relation to the tiltmeter for the entire range of rotation tested.

The results shown in Figure 2 allow for the following main findings:

- Average a_x angle deviations of sensors are within ±0.2º for the most of the tested range; Higher deviations, up to 0.5º, are observed in Sensor 1 within the tilt range [0.5º; 1.5º], and in Sensors 2 and 3 in [2º; 4º]; All sensors exhibit increasing a_x deviations for tilt angles greater than 14º but remain below 0.4º.
- All sensors show non-null relative a_y angles, demonstrating an almost linear relationship with the casing tilt angles; At a tilt angle of 15º, the sensor's a_y deviations range between ±1º; This suggests a misalignment of the accelerometers' actual axes, wherein the casing's tilt motion induces an undesired roll movement of the sensors (a_y).

Median values of a_x deviations for the entire tested range are 0.028º, -0.0006º, 0.057º and -0.163º for sensors 1, 2, 3 and 4, respectively; Sensors 1 and 4 show narrow interquartile range for the a_x deviations (less than 0.06º), when compared with sensors 2 and 3 (up to 0.35º).

As anticipated, owing to the extremely low-cost of the tested accelerometers, which are based on the consumer-grade ADXL345, the angle deviations are considerably higher when compared to force balanced sensors used in the transversing inclinometer probes.

Observed errors exceed the advertised total error of 0.1º for this sensor. This discrepancy may arise from certain limitations in the way angles are compared within the testing apparatus and misalignment due to the zero-g offset of sensors in relation to the casing orientation. The uniaxial tiltmeter used as reference also exhibits some error, with an expanded uncertainty of 0.011º/º (e.g., an error of 0.055º for a 5º tilt). Future enhancements to the testing apparatus and the calibration of sensor probes, ensuring their precise alignment within the casing tube, are required to yield reduced errors.

Results also suggest that precision and accuracy of the ADXL345 vary among different batches of the sensor. This variation is likely attributed to microstructural imperfections, resulting from the sensor's manufacturing process or other factors. It is also noted that errors due to temperature drift have not been addressed (the datasheet indicates a variation of 0.02º/ºC).

MEMS accelerometers of greater sensitivity, accuracy, and precision than the ADXL345 are available. For instance, the ADXL355 is promoted with a total angle error that is about 20 times lower, but it also comes with a 20-fold increase in cost, and a larger chip form factor. In ongoing developments, alternative MEMS featuring newer technologies and manufacturing processes will be assessed, all of which incur only a slight additional cost compared to the ADXL345.

4 CONCLUSIONS

This paper presents a prototype for a low-cost in-place inclinometer system, integrating MEMS accelerometers, and wirelessly transmitting its data to a master node acting as an acquisition system and a gateway to the internet.

Laboratory test results suggest that an in-place inclinometer based on this prototype may offer a general understanding of ground movements in low-risk scenarios, where total errors of about 0,4º are acceptable. Compared to pricier existing IPI systems, this specific equipment offers a cost-effective alternative. Its use is however not advised in high-risk works where extreme precise inclinometer monitoring is critical.

Investigations are ongoing to incorporate the optimal commercial MEMS accelerometer from other manufacturers in the developed prototype, with a focus on achieving the best price-to-quality ratio.

Compared to pricier existing IPI systems, this specific equipment offers a cost-effective alternative.

ABSTRACT: The continuous development of urban areas has had implications in how the planning and management of the cities is performed. In that regard, it comes up the need to take advantage of underground spaces, as well as to repurpose the built heritage. In this article, a study is intended to be conducted covering the urban and geotechnical limitations that lead to the decision of adopting earth retaining structures, specifically diaphragm walls, along with their structural analysis. This research also aims to display practical cases of civil works where the assessments of the technical support team during the execution phase will be approached. The studies realized are mainly based in the information gathered through instrumentation and monitoring, along with the geological and geotechnical surveys realized locally. The case presented reveals to be characteristic of a familiar reality in the daily work of an enterprise dedicated to the field of geotechnical engineering, where sometimes the unpredictability of the ground can lead to modifications in design during the construction works. The need to solve singular and imponderable situations, using convenient and effective alternatives of execution, contributes to an endless development of the geotechnical knowledge and the evolution of the technique.

RÉSUMÉ: La croissance continué des zones urbaines a entraîné des graves conséquences sur la planification et la gestion du territoire des villes. En ce sens, il est nécessaire profiter des espaces souterrains et de réutiliser le patrimoine bâti. L'ingénierie civil, en particulier la géotechnie, a joué un rôle clé dans le développement de technologies qui répondent aux défis structurels, géologiques et géotechniques et aux contraintes d'excavation en milieu urbain. Avec cet article, nous avons l'intention de présenté une étude sur les contraintes géotechniques et urbaines qui conduisent à la décision d'adopter des structures de soutènement des terres, du type paroi moullée, ainsi que son analyse structurelle. Cette analyse se reflète également dans la présentation d'un cas pratique d'un ouvrage de cette nature, où seront abordées les études de suivi technique réalisées pendant la phase d'exécution des travaux, résultant d'incidents ayant entraîné une modification de la conception et des procédures constructives. Les études ont été principalement basées sur des recherches géologiques et géotechniques réalisées localement. Le cas présenté caractérise une réalité familière au travail quotidien d'une entreprise dédiée à la Géotechnie, où l'imprévisibilité du comportement des terrains conduit parfois à l'analyse et à la modification du projet au cours des travaux. La nécessité de résoudre des situations singulières et impondérables avec des alternatives d'exécution rapides et efficaces conduit à une connaissance géotechnique continue et au développement de la technique.

Keywords: Earth retaining structures; diaphragm walls; civil works; geotechnical characterization; instrumentation.

1 INTRODUCTION

For the construction of diaphragm walls (Soletanche Bachy, 2011) there are essentially two kinds of excavating tools, grabs composed by mechanical cables (Figure 1) or hydraulic systems, and the Hydrofraise (Figure 2). The former is implemented for drilling and excavation of loose soils with low resistance, even though it can be suitable for higher resistances by implementing pre-drilling techniques with the aid of some other tools, like a chopping bit.

On the other hand, the Hydrofraise allows for excavation of ground with higher resistances, without the need of pre-drilling tools. The system is composed by two counter-rotating drums on horizontal axes fitted with cutting teeth. It allows for the penetration of the ground, as well as for its extraction, using reverse circulation of the drilling fluid.

The drilling system of the Hydrofraise, due to its reliance on more complex procedures and more robust and powerful equipment, has been rarely used in Portugal. For this reason, the article is dedicated to a

project currently underway at the time of submission in the city of Porto, whose drilling and excavation processes uses the mentioned technique for retaining walls.

Figure 1. Grabs for diaphragm wall.

Figure 2. Hidrofraise.

2 CASE STUDY

2.1 Location

The mentioned project is in the city of Porto (Figure 3), and it will be incorporated as part of the of the subway network, enabling to close the loop of several lines in the metropolitan area in a circular manner. The purpose of this project is to enhance the sustainability of mobility and relief the center of the city from congestion.

Figure 3. Project location, in Praça da Liberdade, at the end of Av. dos Aliados and extending up to São Bento Station and Largo dos Lóios.

2.2 Project

The retaining structure is a diaphragm wall ranging between 11,5 and 23 meters of depth, for an excavation height between 9 and 20 meters The shoring system consists in the execution of slabs from the final structure using a Top-Down procedure.

2.3 Geological and geotechnical characterization

The project is situated in a geological context characterized by granitic rock with varying degrees of weathering (Figures 4 to 7).

The available geotechnical data before the beginning of the works (Metro do Porto, 2019a), allowed for the identification of a granitic rock material with variable weathering across the soil profile. The overall geotechnical cross-section of the metro line allowed for the identification of the lowering of the weathered rock in the valley where the construction of the future Estação Liberdade – São Bento is expected.

According to the geotechnical profiles available (Figure 8), the drilling equipment would reach the geotechnical zones between G2-G7, being G5-G7 soil materials, G2-G4 rock type materials from low to high weathering. The technical design report of the project, based on the information presented previously, didn´t identify the presence of an intersection with geotechnical zone G1. Moreover, even though G2 was indeed identified, it was only present in the deeper layers of soil or as an isolated granite block.

Figure 8. Summary of Geotechnical Characterization (Metro do Porto, 2019a).

3 WORKS EXECUTION AND CONSTRUCTION PROCEDURE

Given all the constraints and limitations inherent in a project of this scale and in an urban environment, the execution procedure led to the use of a Compact Hydrofraise. This equipment, being smaller in size than the typical Hydrofraise, made excavation work possible and allowed other activities related to the project to occur simultaneously, without hindering the normal progress of the work.

The construction sequence (Figure 9) considered the execution of primary and secondary panels with cutting back into the concrete of the previously executed panel ("bite"). Figure 10 illustrates some general photos of the construction works.

4 CHALLENGES & SOLUTIONS

4.1 Observations during works

An interesting detail of the excavation with the Hydrofraise is the need to control the verticality of the drilling (Rodio Portugal, 2022), which can be corrected thanks to the devices incorporated in the equipment, enabling the recovery of possible deviations in real time.

However, due to the celerity and localized nature of the deviations, it is not possible to avoid them when the root is the stiffness of the ground. In these cases, it is only possible to rectify them by re-drilling to regain the desired position. For this reason, specific characteristics of the drilled ground can result in an increase of difficulty when correcting deviations, like the ones identified during the works by Rodio. Figure 12 illustrates some important elements to consider while working with a Hydrofraise.

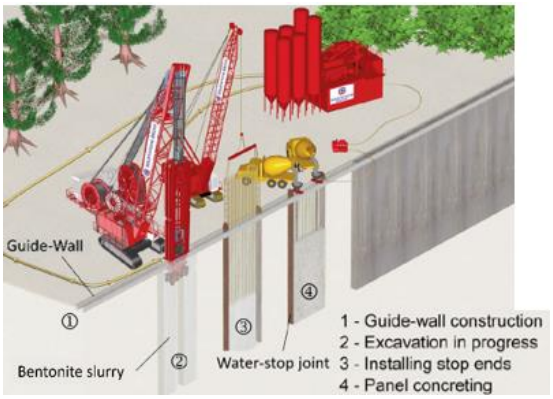

Figure 9. Representation of the Execution Process (Soletanche Bachy, 2011).

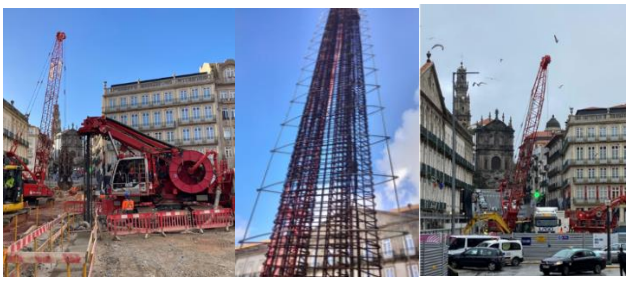

Figure 10. General Photos of the Construction Site.

During the hydrofraise drilling, in the area of *Largo dos Lóios* and *Praça da Liberdade,* abnormally high rock resistance was observed compared to what would be expected for that location and working depths. The increased hardness of the granitic rock caused not only slight deviations in the panels but also a decreasing of the expected drilling yields.

However, the uniaxial compressive strength (UCS) tests conducted on samples collected from the site's boreholes showed values below 45 MPa in all samples

located at depths higher than the base of the Diaphragm Wall. These resistances were consistent with the estimated yields for excavation during the project's study phase.

4.2 Followed approaches

To understand the reason behind the difference between the expected yields and the actual drilling performance during the works, multiple additional boreholes were executed, and samples were collected for laboratory tests, along with supplementary geotechnical studies.

The reports from these supplementary studies (ENGGEO, 2023), provide geological and geotechnical information for 20 boreholes, including sample extraction, analysis, and uniaxial compression tests. A total of 59 uniaxial compressive strength (UCS) tests were conducted in these campaigns.

An analysis was conducted on the uniaxial compression tests performed before and during the construction. From this analysis, the representation of the obtained total strength values resulted in a Strength vs. Depth graph, illustrated in Figure 11.

The results presented in the graph reveal the occurrence of slightly weathered granitic rock with high resistance at much shallower depths than what could be inferred from the project's prior information.

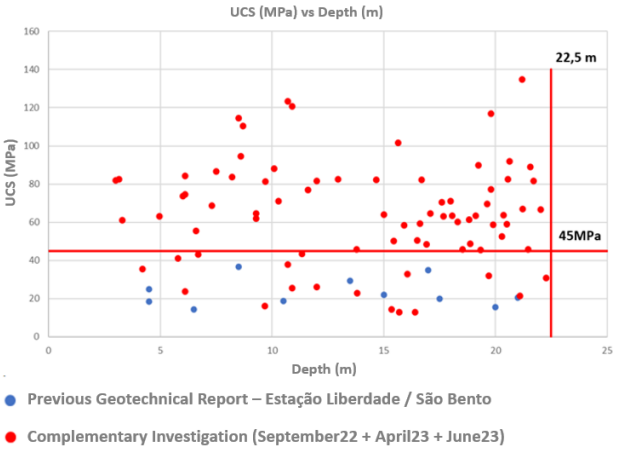

Figure 11. Strength vs Depth representation of the initial and complementary surveys.

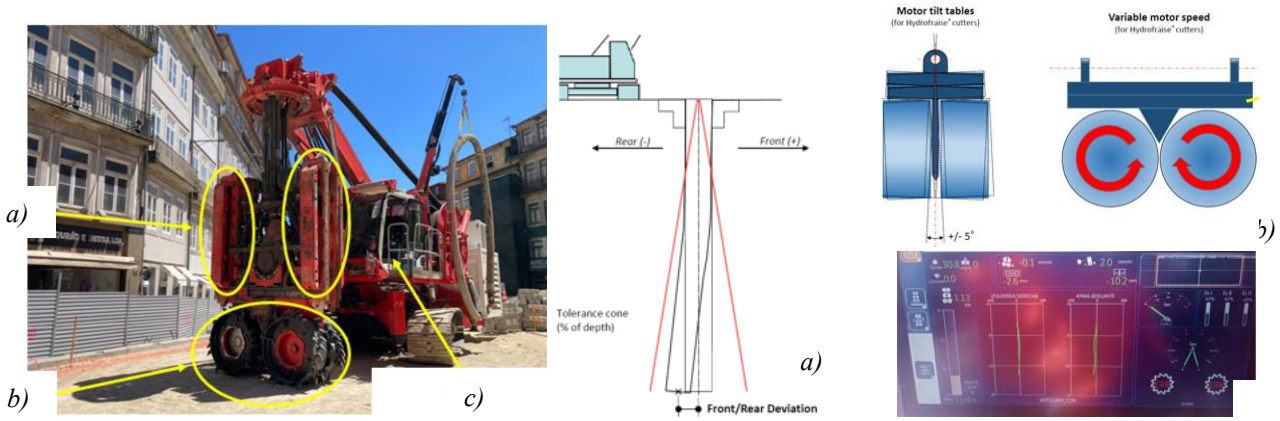

Figure 12. Details of the Hydrofraise: vertical control (a), counter-rotating drums (b) and monitoring system (c).

5 CONCLUSIONS

Being Hydrofraise a less common technique in the execution of diaphragm walls, it is estimated that the case studied is the second application in Portugal. Given the geological and geotechnical constrains, as well as the limited space and location, it has proven to be an important contribution to a better understanding of these type of geotechnical solutions.

Regarding the resistances of the intersected rock, in general, and up to the present date, the project's base information significantly differs from reality. It can be observed that, initially, in any part of the initial geotechnical information, soils with resistances below 45 MPa were predicted. However, after conducting additional geotechnical boreholes, an extraordinarily high percentage of samples with resistances exceeding 45 MPa (78%) was observed.

As for remaining challenges, the project was proactively executed, looking to improve the performance of the panels day by day and to solve the incidences and issues that have been occurring, as stated in this article, leading to an elevated prior preparation of the works so they could be developed as efficiently as possible.

ACKNOWLEDGEMENTS

The aknowledgements extend to the construction owner Metropolitano do Porto, to the general contractor and client of Rodio, Ferrovial-ACA conglomerate, and to the ENGGEO company, author of the complementary geotechnical survey study.

Shear wave velocity and permeability evolution of MICP-treated carbonate bearing sand

Vitesse des ondes de cisaillement et évolution de la perméabilité des sables carbonatés traités au MICP

G. Das*, S. Joshi, M. Judge, F. McDermott, M. Long, S. Donohue
University College Dublin, Dublin, Ireland

**geetanjali.das@ucd.ie*

ABSTRACT: Microbially induced calcite precipitation (MICP), a promising method developed for soil stabilization, demonstrates potential as an eco-friendly approach capable of significantly improving the geotechnical properties of soil. However, research indicating the evolution of permeability requires further investigation to substantiate the effectiveness of MICP treatment in enhancing permeability. In this aspect, this study investigates the evolution of shear wave velocity (V_s) and permeability (k) in MICP-treated carbonate bearing sands. Compacted specimens were subjected to MICP-treatment using 5ml/min and 10ml/min injection flow velocities. Injection velocities of 5ml/min produced heterogeneous $CaCO_3$ precipitation across the sample, with maximum precipitation near the injection point after 6 cementation cycles. This led to clogging near the injection point, resulting in a decrease in k by an order of magnitude and a constant V_s, showing a maximum value of 554.2m/s. On the other hand, specimen subjected to a 10ml/min injection velocity showed a relative homogeneous $CaCO_3$ distribution throughout. This resulted in a consistent permeability and V_s continued to increase beyond 6 cementation cycles and reached a constant value of 950m/s after 13 cementation cycles. Thus, injection flow velocity is an important variable to be considered when investigating permeability modifications in MICP treated soils.

RÉSUMÉ: La précipitation de calcite induite par voie microbienne (MICP), une méthode prometteuse développée pour la stabilisation des sols, démontre son potentiel en tant qu'approche respectueuse de l'environnement capable d'améliorer de manière significative les propriétés géotechniques des sols. Cependant, la recherche indiquant l'évolution de la perméabilité nécessite une étude plus approfondie pour prouver l'efficacité du traitement MICP dans l'amélioration de la perméabilité. Dans cette optique, cette étude examine l'évolution de la vitesse des ondes de cisaillement (V_s) et de la perméabilité (k) dans des sables carbonatés traités au MICP. Des échantillons compactés ont été soumis à un traitement MICP en utilisant des vitesses d'injection de 5ml/min et 10ml/min. Des vitesses d'injection de 5ml/min ont produit une précipitation hétérogène de $CaCO_3$ dans l'échantillon, avec une précipitation maximale près du point d'injection après 6 cycles de cimentation. Cela a conduit à un colmatage près du point d'injection, entraînant une diminution de k d'un ordre de grandeur et une V_s constante, montrant une valeur maximale de 554,2m/s. D'autre part, l'échantillon soumis à une vitesse d'injection de 10ml/min a montré une distribution relativement homogène du $CaCO_3$ dans l'ensemble de l'échantillon. Cela a entraîné une perméabilité constante et V_s a continué à augmenter au-delà de 6 cycles de cimentation et a atteint une valeur constante de 950m/s après 13 cycles de cimentation. Ainsi, la vitesse d'injection est une variable importante à prendre en compte lors de l'étude des modifications de perméabilité dans les sols traités au MICP.

Keywords: MICP-treated sand; flow velocity; shear wave velocity; permeability; calcium carbonate precipitation.

1 INTRODUCTION

MICP is a biocementation method in which microbial activity drives the precipitation of calcium carbonate at within and/or around soil particle to improve engineering properties (Fu et al., 2023; Tang et al., 2020).

Several laboratory studies have shown the efficacy of MICP treatment in improving the strength, stiffness, and bearing capacity of soils (Lui et al., 2021; Fu et al, 2023). However, studies investigating the impact of MICP-treatment on the soil permeability have demonstrated a range of effects (Jian and Soga, 2017; Martinez et al., 2013; Sharma et al., 2021; Whiffin et al., 2007). For example, Sharma et al. (2021) documented the permeability evolution in MICP treated sands after 6, 12, and 18 days of treatment. They reported a maximum decrease of 91% in the coefficient of permeability (k) after 18 days in MICP-treated sand compared with an untreated specimen. This reduction in 'k' was attributed to the decrease in porosity resulting from calcium-carbonate ($CaCO_3$) precipitation. Similarly, Martinez et al. (2013) reported a decrease in 'k' of up to two orders in

magnitude with an increase in shear wave velocity (V_s) of about 1000 m/s in MICP treated Ottawa 50-70 sands. On the other hand, Whiffin et al. (2007) reported that the 'k' value of MICP-treated sand remained almost unchanged, though a significant development in the soil's strength and stiffness occurred. Likewise, Jiang and Soga (2017) reported a limited impact of cementation on the reduction of 'k' in MICP-treated sand-gravel mixture. The impact of MICP-treatment on 'k' has been attributed to several factors. Zamani and Montoya (2016) showed that the reduction in 'k' with increase in cementation level is governed by soil grain size. Other studies reported that the concentration of cementation solutions has a significant impact on the reduction of 'k' (Harkes et al., 2010; Tang et al., 2020). These uncertainties motivated the present study to investigate further the impact of selected MICP-treatment parameters on the permeability evolution of sands.

This study aims to investigate the 'V_s' and 'k' evolution in MICP-treated carbonate-bearing sands subjected to different flow rates of solution injections. The first part of the study presents the 'V_s' and 'k' monitored throughout the MICP-treatment process and in the second part, the variability in $CaCO_3$ precipitation throughout the specimens were measured to provide an interpretative framework for the observed results.

2 MATERIALS AND METHODOLOGY

2.1 Soil and solutions properties

Fine sand, sampled from Blessington quarry, Ireland, with a fine content (< 0.063mm) of 35% and initial carbonate content of 20% was used. Four types of chemical solutions were prepared. To mimic the field's groundwater, artificial groundwater (AGW) was prepared for preparation and saturation of the specimens. Yeast (Y), Biostimulation (BS), and Cementation (CM) solutions were prepared for the MICP-treatment. Further details of these solutions are presented in Table 1.

2.2 Sample preparation

Air-dried sands were placed in soil columns of 5cm diameter, and 10cm height. The placement was made in three layers, with each layer tamped 15 times to reach the minimum void ratio of 0.53. Specimens were then fully saturated by pumping 1 pore volume flow (PVF) of AGW into the specimen from beneath.

Table 1. Chemical solutions.

Solutions	Composition and concentrations
AGW	Potassium Nitrate: 0.04mM; Magnesium sulphate: 0.45 mM; Calcium chloride: 1.75 mM; Sodium Nitrate: 0.04 mM; Sodium Bicarbonate: 1.10mM; Potassium Bicarbonate: 0.06mM
Y	Yeast extract: 0.2g/L; Sodium acetate trihydrate: 42.5mM
BS	Yeast extract: 0.2g/L; Sodium acetate trihydrate: 42.5mM; Urea: 350mM; Ammonium chloride: 100mM
CM	Yeast extract: 0.2g/L; Sodium acetate trihydrate: 42.5mM; Urea: 350mM; Ammonium chloride: 12.5mM; Calcium chloride: 250mM

2.3 MICP-treatment and shear wave velocity measurement

Saturated specimens were subjected to MICP treatment through biostimulation. This initially involves the injection of Y solution to enhance the growth of native ureolytic bacteria present in the soil. Then, 4 cycles of BS solutions (BS1-BS4) were injected to allow the bacteria to induce ureolytic reactions, thus producing carbonates. This was then followed by cementation cycles using cementation solutions to allow the precipitation of $CaCO_3$ (Tang et al., 2020). Throughout the cementation cycles, V_s was measured to monitor the stiffness evolution of the soil using bender elements, as per ASTM D8295-19 (2019). The cementation cycles continued until a constant V_s was reached to ensure that no further precipitation of $CaCO_3$ were possible.

2.4 Permeability measurement

All chemical solutions were injected through the inlet present at the base of the soil columns. Effluents were collected from the outlet located at the top of the column. The chemical solutions were injected at two different flow rates, i.e., at 5ml/min and 10ml/min using a pump. A constant hydraulic gradient is maintained throughout the injection between the pump and the injection point. The coefficient of permeability is calculated using Darcy's equation. In the following sections, specimens subjected to MICP treatment processes involving injection of solutions at 5ml/min and 10ml/min are represented as SP1, and SP2, respectively. Thus, SP1 is the specimens subjected to relatively slower MICP treatment than SP2.

2.5 Calcium-carbonate measurement

At the end of cementation cycles for SP1 and SP2, specimens were sampled from top, middle, and bottom

parts of the samples to check the spatial distribution of calcite precipitation. Calcite was measured as per ASTM D4373-02 (2017).

3 RESULTS AND DISCUSSIONS

Figure 1 presents the V_s evolution throughout the cementation cycles in specimens SP1 and SP2. SP1 reached a V_s of 554.2m/s after the 6 cementation cycles. With further injection of cementation solutions, V_s showed no change. This indicates that no further $CaCO_3$ precipitations can occur, as the increase in V_s is reported to be directly related to the $CaCO_3$ precipitations (Lui et al., 2021). Thus, the injection was stopped after the 8th cementation cycle. By contrast, the V_s value obtained after 6 cementation cycles in SP2 was slightly lower and reached the same value as SP1 after the 8 cementation cycles. This V_s increased further with further injection of cementation solutions and reached about 950m/s after 13 cementation cycles. This value remained constant with further injection of cementation solutions up to 15 cementation cycles.

Figure 2 presents the permeability evolution in specimens SP1 and SP2. The initial value of 'k' in specimen SP1 is lower than specimen SP2. This is attributed to the difference in flow velocity maintained in specimens SP1 and SP2, since the rate of discharge of solution is directly proportional to 'k' at a given hydraulic gradient as per Darcy's law. Further, with incremental cementation cycles in SP1, the magnitude of 'k' reduced by an order of magnitude, which corresponds to the constant value of V_s reached after 6 to 8 cementation cycle (Figure 1). However, for specimen SP2, where the cementation cycles continued up to 15 cementation cycles, the magnitude of 'k' remained in between 6.8×10^{-6} to 5.7×10^{-6} m/s, thus, showing no significant change.

Table 2 presents the percentage increment in $CaCO_3$ measured in the specimens sampled from the three layers of SP1 and SP2, at the end of 8 and 15 cementation cycles, respectively. The percentage increment is represented with respect to the untreated sand. At the end of cementation cycle, the weight % $CaCO_3$ was 6% higher in the bottom sampled specimen of SP1, near the injection point compared to the top and middle sampled specimens. Such heterogeneity in $CaCO_3$ distribution has been a concern in several MICP studies (Fu et al., 2023; Tang et al., 2020). However, in specimen SP2, the distribution of $CaCO_3$ is relatively homogeneous irrespective of position in the column (Table 2). Such differences in $CaCO_3$ distribution between specimens SP1 and SP2 highlight the fact that the low flow velocity (5ml/min) in SP1 caused maximum deposition of $CaCO_3$ near to the injection point. This caused clogging, which was confirmed after observing white thick precipitation between the porous stone and the specimen near the injection point. This probably restricted the flow of calcium ions to the middle and top region of SP1 beyond 6 cementation cycle. This phenomenon results in a decrease of permeability (Figure 2) and restricted further increase in V_s with further injection of cementation solutions (Figure 1).

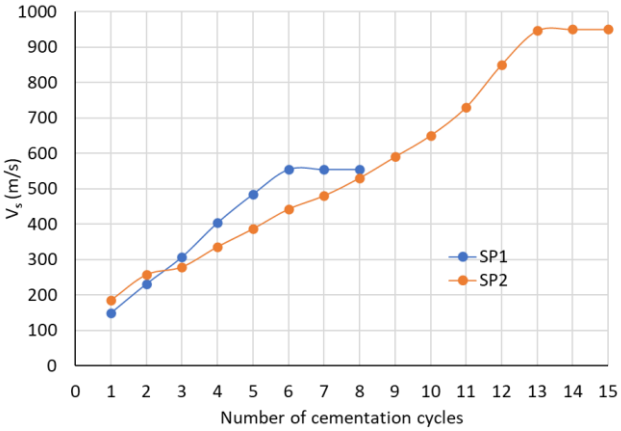

Figure 1. Shear wave velocity evolution in SP1 and SP2.

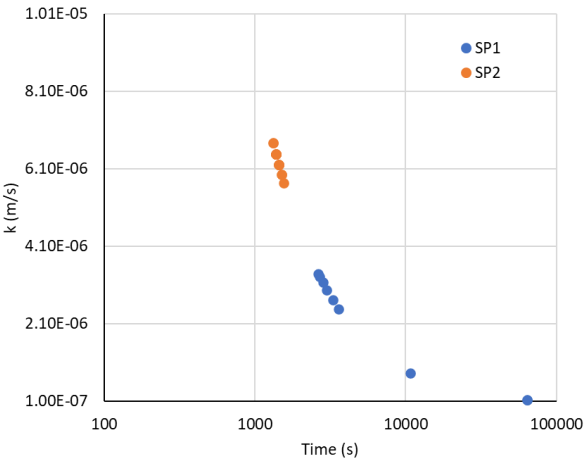

Figure 2. Permeability measured in SP1 and SP2.

A higher flow velocity of 10ml/min in SP2 enabled uniform calcium dispersal throughout the sample uniformly beyond the 6th cementation cycles, resulting in a more homogeneous $CaCO_3$ distribution (Table 2). This phenomenon increases the V_s beyond the 6th cementation cycles (Figure 1). A homogeneity in $CaCO_3$ distribution prevented clogging near the injection point. This led to no significant change in the permeability (Figure 2), unlike SP1.

Table 2. $CaCO_3$ percentage in SP1 and SP2.

Specimens	$CaCO_3$ (%)		
	Top	Middel	Bottom
SP1	10	10	16
SP2	12	12	13

4 CONCLUSIONS

The study investigated the shear wave velocity and permeability evolution in a MICP-treated carbonate bearing sand column subjected to different flow velocities. The main conclusions are:

1) A greater flow velocity (10ml/min) produced a more homogeneous $CaCO_3$ distribution throughout the MICP-treated specimen. compared with that subjected to 5ml/min flow velocity.
2) Deposition of $CaCO_3$ near the injection point in specimen subjected to low flow velocity MICP treatments, led to clogging of specimens. This restricted the uniform flow of calcium ions throughout the specimen, thus, restricting further increase in shear wave velocity. For the same type of compacted specimens, specimen subjected to 10ml/min flow velocity showed a increase in shear wave velocity up to 13 cementation cycles, while that subjected to a 5ml/min flow velocity did not show an increase in shear wave velocity after the 6th cementation cycles.
3) Clogging of the specimen near the injection point led to a decrease in permeability. The k value decreased by an order of magnitude in the specimen subjected to flow velocity of 5ml/min, whereas it remain unchanged in the corresponding specimen subjected to a flow rate of 10ml/min.

This study highlights that flow velocity is an important parameter that needs to be considered which investigating the stiffness and permeability evolution in MICP treated sand columns.

The practice of testing ground nails

La pratique des essais de clous

M. de Carvalho
National Laboratory for Civil Engineering (LNEC), Lisbon, Portugal
**marc@lnec.pt*

ABSTRACT: The soil nailing construction technique is often used to stabilise a ground mass by installing reinforcing elements (nails). The European Standard EN 14490:2010 defines general principles for execution, supervision, testing and monitoring of soil nailing. This paper presents tests results obtained in several ground nails executed in recent geotechnical works. These tests were carried out in sacrificial nails, before and during the works. As shown in this paper, the execution of the nails, the test system and test procedures affect their results quality. Thus, a critical analysis of the tests results is performed to assess the behaviour of the ground nails, framed by EN 14490:2010, in accordance with the design and contract specifications.

RÉSUMÉ: Le clouage est une technique de construction utilisée pour améliorer la stabilité d'un massif du terrain par la mise en place d'éléments de renforcement (clous). La norme européenne EN 14490:2010 établit les principes généraux pour la construction, les essais, le suivi et les contrôles d'exécution des ouvrages avec clouages. Cet article présente les résultats d'essais obtenus sur des clous exécutés lors de travaux géotechniques récents. Ces tests ont été réalisés sur des clous sacrificiels, avant et pendant la construction. Comme s'expose dans cet article, l'exécution des clous, le système de test et les procédures des essais affectent la qualité des résultats obtenus. Ainsi, une analyse critique des résultats des essais est réalisée afin d'évaluer le comportement des clous, encadrée par la norme EN 14490:2010, conformément aux spécifications du projet et du contrat.

Keywords: Nail; load test; proof load; sacrificial nail.

1 INTRODUCTION

Ground nails mobilise frictional forces along their entire length, which contributes to improve the ground stability if the stability conditions are adverse.

The stability is achieved by inserting reinforcing nail elements into the ground. To validate the ground nail resistance, to assess their behaviour or design considerations, nail load tests shall be carried out.

The test procedures and locations of a nail test shall be validated. Previously, the tests program shall be defined, all the elements presented, evaluated, and confirmed. The contractors equipment and their calibration certificates shall be evaluated and identified for each test.

This paper presents the results of sacrificial nail tests, obtained in recent geotechnical works.

The sacrifitial nails were instaled in the same way as the production nails, only to establish the pullout capacity, and do not forming a part of the ground nail structure.

Based on the collected data, recorded in the tests sheets, this paper presents tests results analysis in accordance to EN 14490:2010 specifications. Conclusive synthesis and recommendations are presented.

2 GROUND NAIL LOAD TESTS

The EN 14490:2010 recognizes two distinct types of static load tests: i) in sacrificial nails; and ii) in production nails. Testing requirements are stated in EN 14490:2010.

Normally, a sacrificial nail test involves loading the test nail to failure, or to the characteristic value of the resistance anticipated in the design.

It is essential that the test nail be axially loaded. The facing system or the load test reaction system cannot influence the test results.

Static load testing can be used for a variety of purposes, including to verify the nail ultimate bond resistance, used in the design, and to demonstrate the satisfactory nail performance.

3 EQUIPMENTS AND PROCEDURES

3.1 Layout of the nail test system

In the nail load tests presented in this paper, the load was measured directly, with a load cell, and indirectly, with a calibrated pressure gauge monitoring the pressure of the hydraulic stressing jack (Figure 1).

Figure 1. General view of a ground nail load test layout.

To control the bar and wall movements, the displacement monitoring system was installed in an independent support. The jack extension was also monitored.

The equipment has been previously calibrated.

3.2 Tests programs and procedures

The test programmes were designed in accordance with EN 14490:2010 requirements, considering two cycles, with the first cycle up to the load of $0.5P_p$ and the second up to the proof load, P_p.

The sacrificial nail test intends to verify the ultimate pullout resistance and creep characteristics of the nail. Concluded the load test program, when the bond length had not reached the failure, it was recommended a second load test phase to evaluate the nail load capacity (according EN 14490:2010, C.3.3.3). The second program test phase presented in this paper, was defined considering the tensile capacity of the nail bar, which consists in a single steel bar with 25 mm of diameter. In the geotechical works presented, the nails bond length varies between 2 m and 8 m.

The presented ground nailing work was done in 71 granitic slopes stabilization works with various weathering levels and joint patterns (Figure 2). These works had technical assistance from the paper author.

Figure 2. Examples of slope stabilisation in granitic rock masses that have different weathering levels and joint patterns.

4 TESTS RESULTS

45 sacrificial test nails have been done but, in this paper, only five examples of test results are presented, represented by diagrams of the displacement evolution with applied load. The results are presented for two different monitoring systems: (i) load cell and bar displacement (Cell-Bar); (ii) load pressure gauge and stressing jack displacement (pressure gauge-jack extension). These diagrams also present the evolution of elastic and plastic displacements with load of the reinforcing element (δ_e; δ_p), the datum load (P_a) and the proof load (P_p). Figure 3 to Figure 7 represent the results of the in-situ sheets data tests of the contractors' reports.

The theoretical value of the elastic displacement of the bar (δ_{et}) is obtained by:

$$\delta_{et} = \frac{\Delta P L_{lt}}{E A_t} \quad (1)$$

considering E=200 (kN/mm^2); the nail steel cross section A_t= 490.87 (mm^2); the total de-bonded length $L_{lt}=L_l+L_e$ (mm); and the theoretical value of the difference between the proof load (P_p) and the datum load (P_0), as in the program test ($\Delta P=P_p-P_0$).

5 REQUIREMENTS

It is necessary to ensure that the nail has the pullout capacity to support the P_p and comply with the standard EN 14490:2010 criteria, namely:

a) In a sacrificial nail test the creep rate (k_s) must be less than 2 mm at P_p unless the design defines a lower value.
b) In a load test, the extension measured in the nail head, at P_p, is not less than the expected elastic extension (δ_{et}) for the nail de-bonded length.

The quality of the data field registrations, a correct equipment installation and an adequate test program are primordial to achieve the test goal.

6 RESULTS ANALYSIS

6.1 Monitoring with redundancy

Monitoring with redundancy is not a standard requirement of the EN 14490:2010. However, the redundancy of recording loads and displacements data results in important benefits, namely the possibility to

clarify doubts and confirm aspects associated with the nail behavior, if necessary.

Figure 3 and Figure 4 present the values obtained in the same test for two diffent systems. One of the systems consists of monitored the values by the load cell and the bar displacements gauge. The other system is composed by the pressure gauge pump and by the extension jack, to monitor the load and displacement, respectively.

The data obtained with both systems shows a diferent mechanical behaviour (Figure 3), namely a diferent elastic behaviour in each cicle. However, in Figure 4 the behaviour diferences are smaller.

Other advantage of the redundancy, is the possibility to conclude the test if a device has problems during the test.

6.2 Creep rate (k_s)

The creep rate, k_s (mm), is defined as (eq. 2):

$$k_s = \frac{d_2 - d_1}{log_{10}(t_2/t_1)} \quad (2)$$

where d_1 and d_2 are the measured displacements (mm) at time 1 and 2 (minutes), respectively.

The value obtained for k_s, in the successful nail tests, was smaller than 0.5 mm, So, the creep rate respects the statements of EN 14490:2010.

6.3 Mechanical behaviour

The results obtained on the nail nº4 indicate an adequate mechanical response (Figure 3a) and Figure 4), satisfying the design and standard EN 14490:2010 requirements.

In the test nail nº3b and 4.1 (Figure 5a, and Figure 6a, respectively) the bond failure was reached. In these cases, the nails do not have lateral resistant capacity to support P_p. So, the test does not meet the conditions to be considered valid, the procedures of the nail construction shall be reviewed and / or the design reanalysed.

The nail nº3b reached the failure in the beginning of the 1st cycle (Figure 5a), and also presents a high deformability from the datum load, P_a, which indicates that the nail has: (i) execution deficiencies; or (ii) the bond length may be insufficient; or (iii) the ground, eventually, does not have the design resistance characteristics estimated for that location.

However, in the case of the nail nº 4.1 (Figure 6a), given the value reached, the failure could have occurred in the sealed area or in the nail steel bar.

At the beginning of the nail nº8 test (Figure 5b) signs of test execution deficiencies were shown. These anomalies could be related, amongst other possibilities, to the equipment assembly, with the displacement's measurement, for instance due to movements of the fixed reference, or the occurrence of gaps or friction, which were not eliminated before the beginning of the test. These deficiencies outcomes in difficulties that do not allow the reliable determination of displacements and, consequently, the determination of the corresponding value of k_s, and / or the evaluation of the nail mechanical behaviour, namely the accurate value of the permanent and elastic displacements, for example, for the test nail nº8 (Figure 7a) those displacements do not comply the EN 14490:2010 requirements.

The results obtained in the nail test 4.2 (Figure 6b), show a pronounced hysteresis, particularly in the 2nd cycle. This hysteresis may be related with the prestressed system or with the nail mechanical behaviour, as it only has 2 m of bond length. However, it appears to have the capacity to withstand the proof load and the test results (Figure 7b) fulfil the EN 14490:2010 requirements.

Deficiencies are often observed in nail tests. In these cases, the tests do not exhibit quality, have unsuccessful results and they do not meet the requirements to consider the ground nail work valid.

In this context, it should be noted that the test quality depends on the previous preparation of the operational procedure for carrying out the nailing works and their tests, the previous equipment calibration, and their approval, as well as on the workers quality, equipment installation control, data registration quality, amongst other aspects.

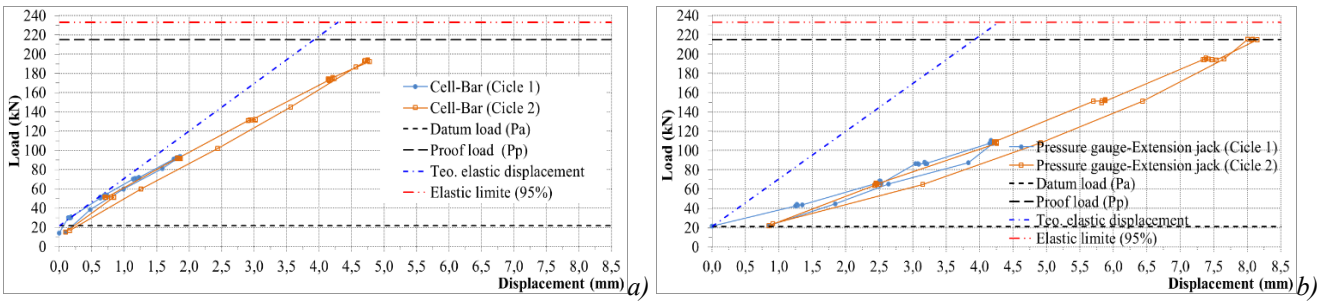

Figure 3. Nail nº4. Evolution of the displacements with load: a) cell-bar; and b) pressure gauge-jack extension.

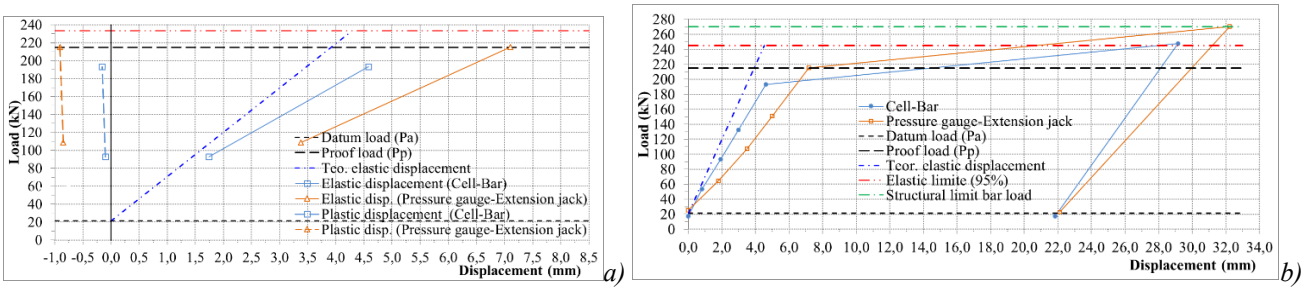

Figure 4. Nail n°4. Results obtained in both monitoring systems. Evolution of the plastic and elastic displacements with load (a), and evolution of the total displacement with load, in the 2d test phase (b).

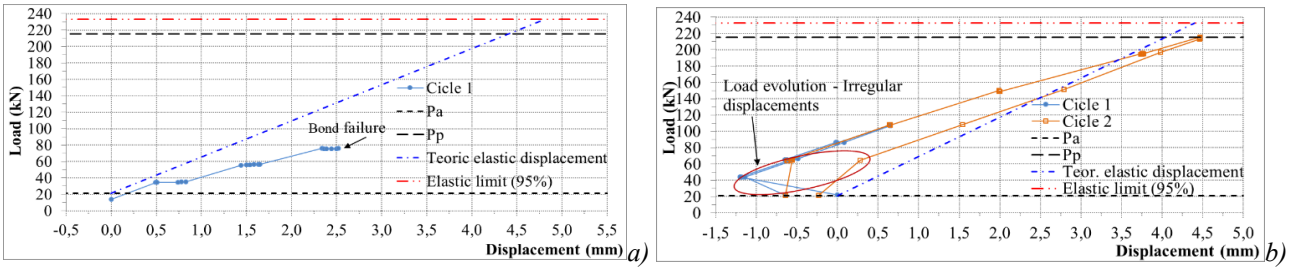

Figure 5. Evolution of the displacements with load, of the nails n° 3b (a) and n° 8 (b).

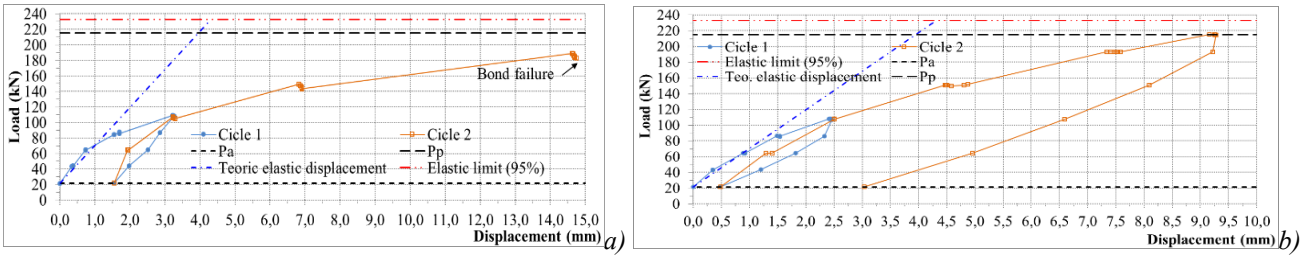

Figure 6. Evolution of the displacements with load, of the nails n° 4.1 (a) and n° 4.2 (b).

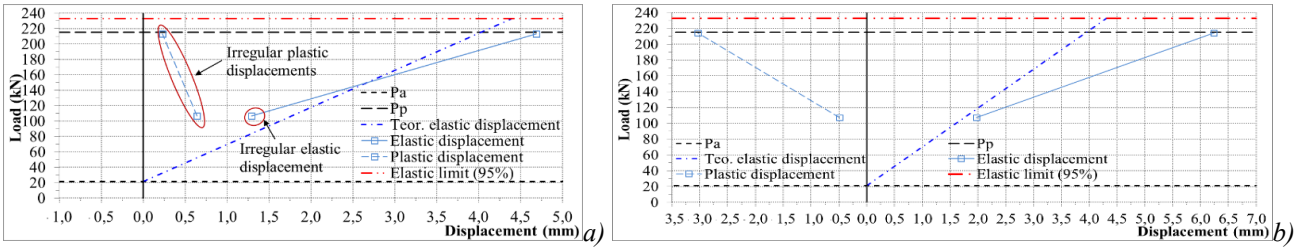

Figure 7. Evolution of the plastic and elastic displacements with load of the nails n° 8 (a) and n° 4.2 (b).

7 CONCLUSIONS

Some tests results do not comply the EN 14490:2010 criterions, either due to the occurrence of permanent displacements manifestly greater than the elastic ones, or by because of the abnormally reduced values of elastic displacement and, also, because there are tests where negative permanent displacements were recorded. These cases may be related to anomalous circumstances, nail failure, tests lack quality, which present inconsistent data, such as displacement reduction as the load increases, among other events. To allow to understand the nail behaviour, the tests quality should be warranted.

The creep values (k_s), like expected for granites, was low so, regarding the creep behaviour, they are not constraints in the geotechnical areas where tests results comply the EN 14490:2010 requirements.

In each ground conditions, the sacrificial nail test intend to allow to: i) validate the construction method; ii) ensure that the required nail design capacity is guaranteed; and iii) ensure that the nails mechanical behaviour is adequate. The production nail test allows to demonstrate that the nails installation methods and the ground conditions encountered result in satisfactory nails behaviours, at the proof load.

It is clearly relevant the necessity of doing tests in ground nailing works, either in soil or rock.

Studying impact of reclamation technique on vibrocompaction performance

Analyse de l'impact du vibrocompactage selon la technique de remblaiement d'un terre-plein gagné sur la mer

A. Debaize*, T. Pille, K. Dedecker
JAN DE NUL GROUP, Aalst, Belgium

**antoine.debaize@jandenul.com*

ABSTRACT: The process of creating new lands from seas or riverbeds is an efficient and pragmatic approach responding to an increasingly growing global demand for commercial exchanges. The material is dredged and reclaimed via dumping, rainbowing or pumping ashore. In almost all cases, the newly reclaimed site can be enhanced using soil improvement (such as Rapid Impact Compaction, Dynamic Compaction or Vibrocompaction) and consolidation techniques (such as Prefabricated Vertical Drains with a preloading surcharge). In this paper, vibrocompaction data in a reclaimed silica-based clean sand, with 12% fines maximum, and less than 2% of 2µm clay particles, has been analysed for a jobsite located in South America. On this project, unexpected difficulties were encountered. Correlating the needle's amperage with 150 pre and post-CPTs (Cone Penetration Tests), the descending and ascending phases of vibrologs have been split and studied independently. The influence of grid size and the number of passes has been investigated. The resulting in-depth data analysis identifies clear differences in soil improvement performances depending on the reclamation technique. The article also includes an analysis of the ageing effect after a 100-days resting period by means of CPTs.

RÉSUMÉ: Le processus de création de nouvelles terres à partir des mers ou des lits de rivières est une approche efficace et pragmatique répondant à une demande mondiale croissante en matière d'échanges commerciaux. Le matériau est dragué et déposé par déversement, par largage en arc-en-ciel ou par pompage. Dans presque tous les cas, le site nouvellement crée et gagné sur la mer peut être amélioré en utilisant des techniques d'amélioration du sol (telles que le Compactage par Impact Rapide, le Compactage Dynamique ou le Vibrocompactage) et des techniques de consolidation (telles que les Drains Verticaux Préfabriqués avec surcharge). Dans cet article, le vibrocompactage d'un sable à base de silice, avec 12% de fines au maximum et moins de 2% de particules d'argile (2µm) est analysé pour un chantier situé en Amérique du Sud. Là-bas, nous avons fait face à de nombreuses difficultés. En corrélant l'ampérage de l'aiguille vibrante avec 150 pre & post CPTs, les phases descendantes et ascendantes des enregistrements de paramètres ont été séparées et étudiées indépendamment. L'influence du maillage et du nombre de passes a été étudiée. L'analyse de données qui en résulte met en évidence des différences claires dans les performances d'amélioration du sol, fonction de la technique de remblaiement du sable. L'article inclut également une analyse de l'effet du temps après une période de repos de 100 jours par mesures de pénétrations statiques (CPTs).

Keywords: Reclamation technique; vibrocompaction; data mining; grid size; ageing effect.

1 INTRODUCTION

The study project is located in South America where 1,080 points were vibrocompacted. To verify the actual improvement of the ground, 150 pre- and post-CPTs were conducted. After analysis, the upper part of the sand reacted perfectly to compaction, while the lower part showed only slight improvement.

This article focusses on the used reclamation techniques (rainbowing and dumping) and compares how they influence vibrocompaction performances. Usual state-of-art parameters (such as the spacing grid, the number of passes and the ageing effect) are also studied using a statistical analysis.

2 METHODOLOGY

The study considered the following key aspects:

Needle Amperage Analysis: The descending and ascending phases of vibrologs were studied independently to correlate needle amperage with soil improvement. This analysis aimed to identify trends in amperage changes during the vibrocompaction process.

Influence of Grid size: Different grid sizes were used during the vibrocompaction process. The study examined how grid size influenced the rate of soil improvement.

Number of Passes: In some cases, a two-pass approach was utilized during vibrocompaction. The research investigated the impact of the number of passes on soil improvement.

Ageing effect: An essential aspect of the study involved analyzing the soil's response to vibrocompaction after a 100-day resting period. CPTs were conducted to assess changes in soil strength over time.

3 DREDGING AND RECLAMATION SEQUENCES

- **Step 1:** Depending on the area of the quay, the *in-situ* clay is removed using a Cutter Section Dredger (CSD) down to depths of -26.50mCD to -31.00mCD,
- **Step 2:** Sand is dredged from a borrow area by a Trailing Suction Hopper Dredger (TSHD),
- **Step 3:** The dredged sand is dumped by opening bottom doors up to -10.00mCD to -14.50mCD,
- **Step 4:** The sand is reclaimed using rainbowing up to target level,
- **Step 5:** Vibrocompaction works are performed up to -26.50mCD to -31.00mCD, depending on the area.

4 AMPERAGE

During vibrocompaction works, the needle vibrates during the entire process. The production is split into three main parts: a descending phase, an ascending phase and a stationary phase. The descending phase is done in one continuous movement while ascending and stationary phases are alternating.

Thus, the descending phase represents the soil behaviour before compaction.

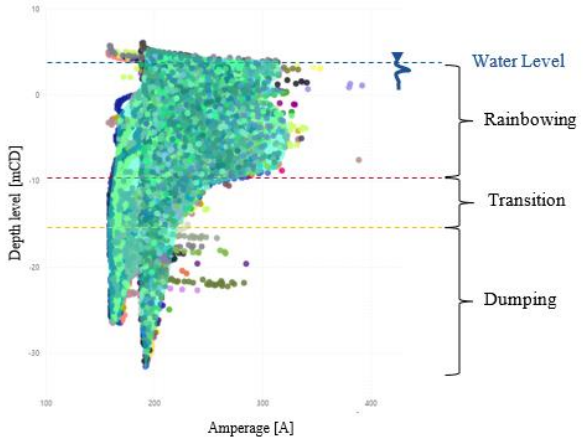

Figure 1. Descending phase compared to the reclamation technique.

As shown in Figure 1, the recorded amperage in the rainbowed sand varies significantly, ranging from 190A to 330A, whereas the amperage in dumped sand falls in the range of 190A to 230A.

This difference comes from the placement method and disposal circumstances: under water, a rainbowed sand is naturally more compacted than a dumped sand.

5 POST SOIL IMPROVEMENT ANALYSIS

5.1 Grid patterns

On site, several grid sizes were tested, including among others: a triangular grid pattern in 4.40x4.40 m² (1 and 2 passes), and a rectangular pattern in 5.00x5.00 m² (2 passes).

Comparing both patterns requires a unified geometric model. A converted axisymmetric model centred on each vibrocompaction point is applied, as defined below:

$$R = \sqrt{\frac{Area\ of\ the\ grid}{\pi}} \quad (1)$$

where R (m) is the radius of influence, depending on the Area of the grid (m²).

Table 1. Radius of influence for each grid.

Grid pattern	Radius [m]
Triangular 4.40x4.40 m² - 1 pass	2.096
Triangular 4.40x4.40 m² - 2 passes	1.632
Rectangular 5.00x5.00 m² - 2 passes	1.994

5.2 Influence of grid on the improvement degree

For each grid, we compared the average of pre-CPTs with the average post-CPTs (after vibrocompaction) after 30 days of resting period.

5.2.1 Triangular grid pattern (4.40x4.40 m² - 1 pass)

As Figure 2 illustrates, pre-CPTs show a homogeneous q_c profile apart from the first 4 m, where the ground was compacted and levelled with excavators and graders.

CPTs after vibrocompaction (also called post-CPTs) show a q_c value which is 82% higher on average. We also notice that the improvement is higher in rainbowed sand when compared to dumped sand.

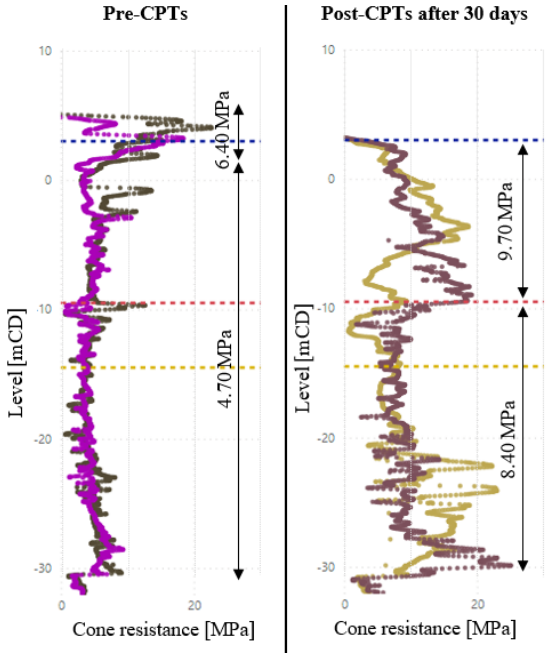

Figure 2. Triangular grid - 1 pass - R=2.096m - Pre&Post-CPTs comparison.

5.2.2 Triangular grid pattern (4.40x4.40 m² - 2 passes)

Based on pre-CPTs introduced in Figure 3, we can't see a clear difference between dumped and rainbowed sand. Over the first 3 to 4 m, the sand is more compacted.

Vibrocompaction improved the entire average profile by 108% in a homogeneous way. The hard top layer is no longer visible. There is also a clear difference between improved rainbowed sand and improved dumped sand.

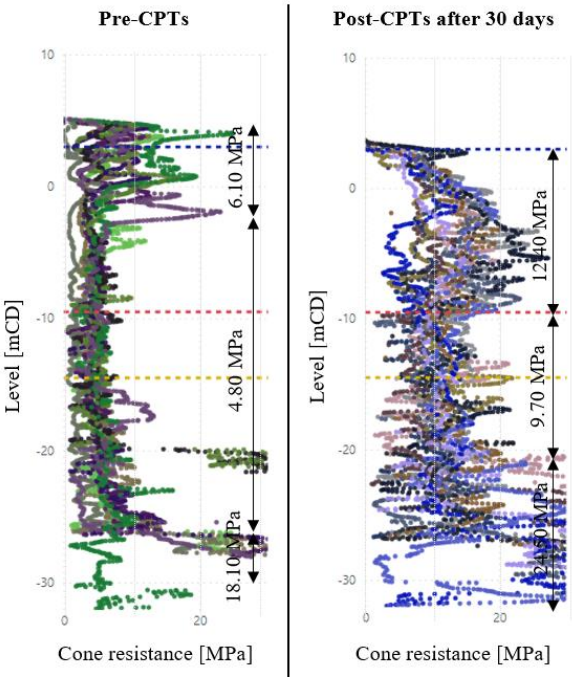

Figure 3. Triangular grid - 2 passes - R=1.632m - Pre&Post-CPTs comparison.

5.2.3 Rectangular grid pattern (5.00x5.00 m² - 2 passes)

Looking at pre-CPTs (Figure 4), we can see again the hard top layer.

The vibrocompacted soil presents a global improvement of 81% on average. Cone resistance in a vibrocompacted rainbowed sand is almost two times higher than a vibocompacted dumped sand.

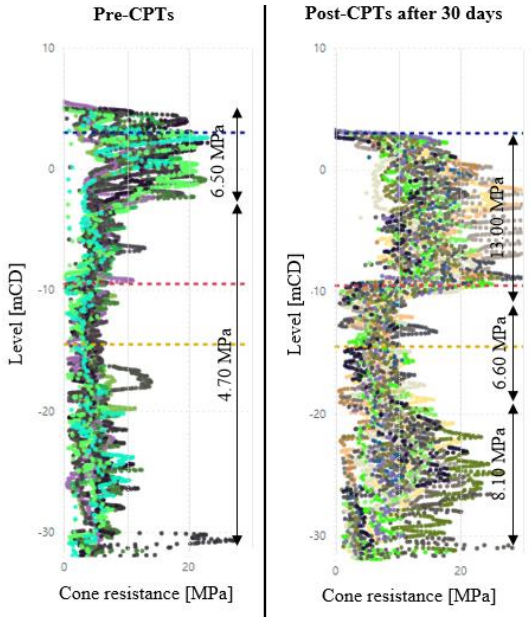

Figure 4. Rectangular grid - R=1.994m - Pre&Post-CPTs comparison.

5.2.4 Comparison of vibrocompaction performances

- (A), (B), (C): The global improvement is directly linked to the radius of influence. Thus, the narrower the spacing between each point, the better the improvement will be. The improvement is higher in a rainbowed sand as compared to a dumped sand.
- (A) & (B): The improvement increases with a second pass by 26%.
- (A) & (C): The radius of influence is near-identical, and as a result, the global improvement as well. Using either two passes or an equivalent one-pass shows equivalent result.

Table 2. Performances measured for each grid.

Reference	Grid pattern	Radius [m]	Global improvement (30 days)
(A)	Triangular 1 pass	2.096	82%
(B)	Triangular 2 passes	1.632	108%
(C)	Rectangular 2 passes	1.994	81%

6 AGEING EFFECT

CPTs performed too soon after the completion of compaction show pessimistic results due to pore water pressure, the rearrangement of particles and the possible presence of temporarily trapped release air. When CPTs are repeated after a resting period, an improvement is observed. This is called the ageing effect.

Thus, 150 CPTs where performed from 0 to 195 days after the first point compacted.

We studied the ageing effect over two approaches: by comparing grid patterns, and by comparing the improvement above, and below -10.00mCD (corresponding to the interface between rainbowing and dumping).

6.1 Influence of the grid

As illustrated on Figure 5, the improvement degree is higher with a triangular grid (the smallest radius of influence), reaching 114%.

In both rectangular and triangular grids, at least 60% of improvement is observed four days after the completion of the first pass. Then, tests performed the same day as the second pass show an effective loss of 10 to 20% in improvement.

After the second pass, the rectangular grid zone improves by an additional 30% and the triangular grid zone by 55%.

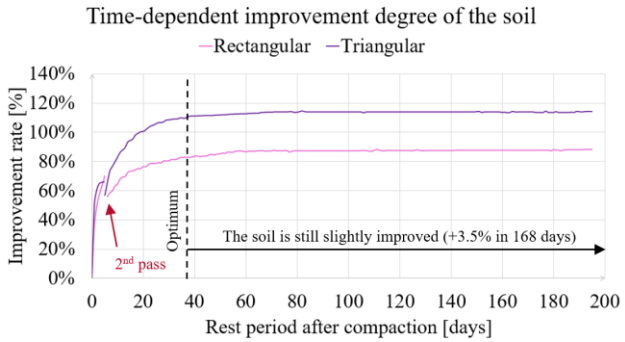

Figure 5. Time-dependent improvement rate of the soil - Rectangular & Triangular grids.

Based on these results, the optimum ageing time seems to be reached between 25 to 30 days after the second pass. Beyond this point, the soil will carry on its improvement over time but the delta between rectangular and triangular grid remains constant.

6.2 Influence of the reclamation technique

As previously shown, the measured amperage differs whether we are in rainbowed or dumped sand. In order to determine if the post-compaction results are different, we have separated the results at the -10.00mCD threshold.

Thus, above -10.00mCD refers to the rainbowed sand, while below -10.00mCD corresponds to the dumped sand. The transition zone is included in the dumping cycle, but does not influence the results.

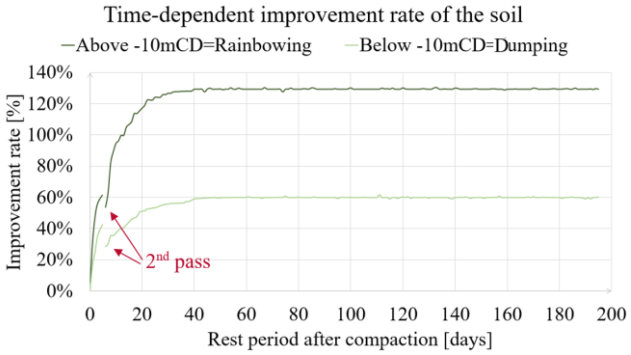

Figure 6. Time-dependent improvement rate of the soil - Above & below -10.00mCD.

Figure 6 clearly shows that the improvement rate is 70% higher in the rainbowed vibrocompacted sand as compared to the dumped vibrocompacted sand.

This difference likely arises from the dumped sand capturing sedimentation layers, which are then mixed together by vibrocompaction, resulting in a lower but consistent effectiveness of the compaction.

This phenomenon depends on the length of the dumping cycle and the presence of sediments in the water.

7 CONCLUSION

While the upper layer reacted as expected, unusual results were observed in the lower part of the fill. For the first time, we encountered difficulties in compacting the dumped layer. After analyzing the various effects discussed in this article, we believe this is likely due to fines in the sand matrix captured during each dumped load, resulting in a mixed soil layer with a high fines content.

To address these issues, a two-pass triangular approach yielded the best results. The amperage seems to be the best parameter to analyze the first soil response. Thence, a dumped soil presents lower post improvement values than a rainbowed sand. On this project, a second pass of compaction, or an equivalent narrow first pass appears to be the most efficient solution to improve the dumped soil.

Finally, depending on soil's properties, q_c values are improved by 60%, 4 days after the 1st pass. The ageing effect can improve the *in-situ* soil by an additional 25% after at least 30 resting days.

ABSTRACT: The Nordhavnstunnel, located in the Nordhavn region of Copenhagen, Denmark, extends the existing Nordhavnsvejtunnel over 1,4 km, passing below the Svanemøllehavn and in the Nordhavn area. It is designed as a rectangular reinforced concrete cut and cover tunnel constructed between anchored retaining walls. A successful design and construction in the challenging location and ground conditions require a series of preliminary sheet pile driveability tests and anchor investigation tests. This paper presents a comprehensive summary of the test results, offering valuable insights and recommendations. Furthermore, it delves into the implications of these findings on the updated design of the tunnel's retaining system and uplift anchors. The conclusions drawn from this study provide crucial insights pertinent to the Nordhavnstunnel but also offer valuable lessons for future projects in Copenhagen encountering similar geotechnical conditions.

RÉSUMÉ: Le Nordhavnstunnel, situé dans la région de Nordhavn à Copenhague, au Danemark, s'étend sur plus de 1,4 km depuis le tunnel existant de Nordhavnsvejtunnel jusqu'à la mer, passant sous le Svanemøllehavn et la zone de Nordhavn. Il est conçu comme un tunnel rectangulaire en béton armé construit entre des murs de soutènement. La conception et la construction à cet emplacement et dans ces conditions géotechniques difficiles nécessite une série de tests préliminaires de faisabilité d'enfoncement de palplanches et d'ancrages. Cet article présente un résumé des résultats des essais, offrant des informations précieuses et des recommandations. De plus, il explore les implications de ces résultats sur la conception mise à jour du système de soutènement du tunnel et des ancres de soulèvement. Les conclusions tirées de cette étude fournissent des informations cruciales qui ne sont pas seulement pertinentes pour le Nordhavnstunnel, mais offrent également des leçons précieuses pour les projets futurs à Copenhague rencontrant des conditions géotechniques similaires.

Keywords: Road tunnel; retaining wall; uplift anchor; limestone; investigation test.

1 INTRODUCTION

The new Nordhavnstunnel extends the existing Norhavnvejtunnel to the east in the Nordhavn region of the Copenhagen, Denmark. The project owner is Danish Road Directorate (Vejdirektoratet) and design and build contract is awarded to Besix & MT Højgaard joint venture with design support from Niras (all permanent works), Jacobs UK (M&E design) and Besix Engineering Department (all temporary works).

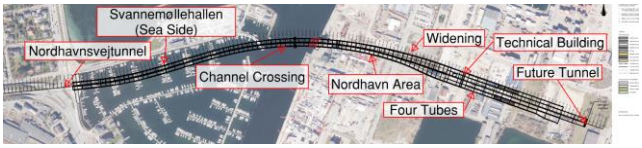

Figure 1. Plan view of the Nordhavnstunnel.

The tunnel is 1.4 km long. It is connected at its west end to the existing Nordhavnsvejtunnel. A 800 m long part of the tunnel passes under the existing harbour of Svanemøllen and crosses the access channel to the Nordhavn quays. After construction, the harbour and

the access channel will be reinstated. The channel must maintain a width of 40 m all along the construction period. East of the channel crossing, the tunnel continues under the Nordhavn Area, which is intended to be further developed in a nearby future. The Nordhavnstunnel will be extended by a future Eastern tunnel that will connect the Nordhavn area to the Copenhagen airport.

The section in the Svanemøllehavn and channel crossing is a two-tube rectangular section of constant width. East of the harbour and the channel crossing, in the Nordhavn area, the tunnel widens to consist of four tubes: the two outer tubes will act as a ramp for Nordhavn area, and middle two tubes will be kept as blind tunnel for connection to Eastern Ring Road.

The clearance height between the bottom and slab is 6.65 m, allowing for a 4.65 m high traffic clearance profile, 1 m high mechanical and electrical installations profile above traffic and a pavement and ballast concrete layer of about 1m. The width of the tunnel tubes starts from 9 m and increases up to 19 m at the widening section.

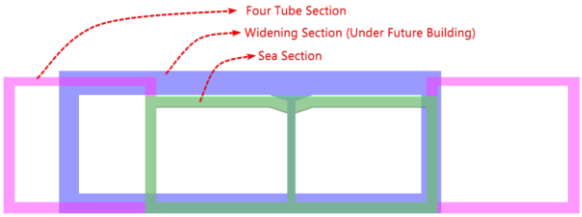

Figure 2. Various Cross-section used in Nordhavnstunnel.

The project includes the design and construction of two large pumping stations along the tunnel as well as a main technical building located on top of the tunnel in the Nordhavn area, as well as various road infrastructure and upgrades of existing tunnel structures and buildings.

The geotechnical conditions at the project location consist of following (simplified) layering (from bottom to top):

- Copenhagen Limestone at starting at level -12 to -16 m DVR 90. The limestone is highly indurated in its upper meters, low fractured except at the east end of the project due to the presence of the Svanemolle fault zone.
- Greensand, thickness 2 to 3 m. The Greensand is not found in the Nordhavn area.
- Glacial till, of quite variable thickness 4 to 8 m over the project location. The glacial till can be described as a clayey silt to silty clay.
- Interbedded layers of melt sand in the glacial till at Nordhavn
- The top 2 to 4 m at Nordhavn consist of man-made sandy and very heterogeneous fill

The values of the geotechnical parameters are shown in the Table 1 and Table 2.

Table 1. GIR Parameters (simplified mean value - ½ std dev).

Soil type	γ_b kN/m³	S_u kPa	φ'_{pl} °	c kPa	E_{50} MPa	E_{ur} MPa	σ'_{pc} kPa
Existing fill -sand	20	-	32	0	25	75	0
Existing fill -clay	20	65	29	5	15	45	0
Clay till	22	400	33	35	30	90	>1000
Glacial Sand	20		37	0	30	85	>1000
Greensand	21	500	32	50	65	200	>1000

Table 2. Limestone properties (Hoek-Brown properties transformed into equivalent Mohr Coulomb properties).

Soil type	γb kN/m³	UCS MPa	GSI	m i	D	φ'_{pl} °	c kPa	E_{50} MPa
Limestone (passive)	22	15	65	7	0	45	100 (450)	1200
Limestone (vertical)	22	30	70	7	0	55	900	1200

** Limestone properties for vertical capacity were upgraded based on preliminary vertical bearing capacity estimations through dynamic testing (see discussion in 4.3).*

The limestone has a separate, potentially artesian, hydrological regime compared to the above layers.

The tunnel is secured against uplift by means of post tensioned bar anchors fixed in the limestone. 50 cm toe is used throughout the tunnel to increase the uplift resistance.

The tunnel is constructed by the cut and cover method, from a hydraulic fill forming a temporary working platform in the Svanemøllen harbour, and from the existing ground in the Nordhavn area. The tender documentation provided "for information" by the Road Directorate to the tenderers proposed a secant pile wall retaining system with multiple anchor levels. The depth of the secant pile wall was determined by the geotechnical and hydrological design to reduce the water discharge by dewatering. The proposal of secant pile wall was in-line with the retaining system that had been used for the Nordhavnsvejtunnel. The Contractor decided to adopt a sheet pile retaining wall system in combination with grouting to create a water cut off. This solution was considered to bring in significant productivity and potentially sustainability related benefits to the project. An indicative cross section of the excavation pit and the retaining wall system in the marine area is illustrated in Figure 3.

Risks related to driveability of the sheet piles through the clay till/greensand and in the limestone were identified and from the early design stages different scenarios with various penetration depths in the limestone were assessed. Early driveability testing

was placed in the planning, to allow early risk mitigation and design improvement.

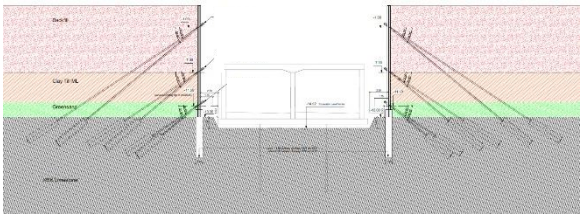

Figure 3. Temporary works cross-section in the marine area, illustrating the excavation pit: sheet pile wall with multiple anchor levels, grout injection, berm support of sheet pile.

This paper presents the results of the investigation tests of uplift anchors and sheet piles performed at the initial phase of the project. To optimize the design, a set of uplift anchor investigation tests, anchors with bond length in the clay till, and sheet pile driveability tests have been carried out. Additional test data and project information are also shared to document the various know-hows obtained during the early phases of the project.

2 UPLIFT ANCHORS

2.1 Design against uplift

Uplift checks of the tunnel have been performed as per the Client's Requirements and DS EN 1997. The requirements are summarized below for completeness.

Load combinations for UPL in Danish annex have been separated into two to consider the additional risks related to frictional resistance. If frictional resistance and tensile elements such as anchors are used, Table A.4-1 should be used: 0.9 x Favourable - 1.1 x K_{fi} x Unfavourable. If only self-weight is used to resist against uplift, the factors are lowered due to reduced uncertainty: 1.0 x Favourable - 1.05 x K_{fi} x Unfavourable (Water). Since a very conservative friction between concrete and backfill is included in all cases, only Table A.4-1 is used in Nordhavnstunnel. Therefore, the overall safety factor against uplift can be calculated as 1.35, considering K_{fi}=1.1 as per the Client's Requirements.

Additional requirements by Client includes future excavations in certain areas, artesian pressures that create additional water pressure from the bottom of tunnel, requirement of post-tensioning the anchors.

The typical failure mode of the anchors (see figure 4) has been checked throughout the design process.

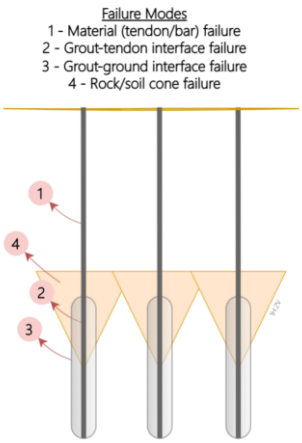

Figure 4. Anchor failure modes.

Following criteria are considered for the definition of anchor lengths:

- All bond lengths should be embedded in the limestone with minimum of 1 m from the top of the limestone.
- Free length = Minimum 4 m

Since the anchors are embedded in the limestone, main design criteria become the material failure (failure mode 1). To be able to increase the anchor spacings, S670/800 MPa bar anchors are considered in the design. As per the DS EN 1997-1, material capacity is $R_{t;d} = A_{anchor} \cdot \min\{k_1 \cdot f_{pk}; k_2 \cdot f_{p0.1k}\}$. In this equation, k_1=0.8 and k_2=0.95. The steel bar should be able to carry the proof load. The proof load is determined as the 1.43 x design load. Therefore, the capacity $R_{t;d}$ is reduced by 1.43 to reach the design capacity. Due to conservative requirement on the $R_{t;d}$, the limitation as per the EN 1993-5 does not govern – as the requirement to check for proof load is only for $R_{t;d}$. With these assumptions, Ø50, Ø57.5 and Ø63.5 S670/800 anchors result in $R_{t,d}$ of 874 kN, 1156 kN and 1410 kN, respectively.

2.2 Investigation tests uplift anchors in limestone

The typical bond strength (referring to failure mode 3) assumption for Copenhagen limestone has been increasing over the years from 650 kPa to 900 kPa – the latter value is being used widely in the latest projects.

Considering that the number of anchors in Nordhavnstunnel is more than 700, even a slight increase in the capacity optimizes the project significantly. More importantly, ensuring that the problems during the construction and testing phase is critical, also considering that 10% of the anchors will be suitability tested, and acceptance test load is increased to same level with suitability test load, i.e. 1.43 x design load.

Uplift anchor tests have been carried out in two different locations on the land-side of the project. In total, 8 anchors were tested. The anchor data are summarized below:

Bond length = 3 and 5 m

Top of anchor – top of limestone = 1 m and 2 m

Strand anchor to reach the capacities.

Proof load: 3350 kN – corresponds to 2090 kPa adhesion for 3 m bond length.

Test Method 1 is used in Denmark. The interpretation method for anchor failure in Denmark is the creep rate method. The methodology is described in DS/EN ISO 22477-5:2018. The creep rate is the rate of increase in deformation under constant load with logarithm of elapsed time. As per the DS EN 1997-1, creep rate limits are 2 mm/log(min) for acceptance and suitability tests and 5 mm/log(min) for investigation tests. Based on this methodology, the success vs. failure will be implemented as shown below:

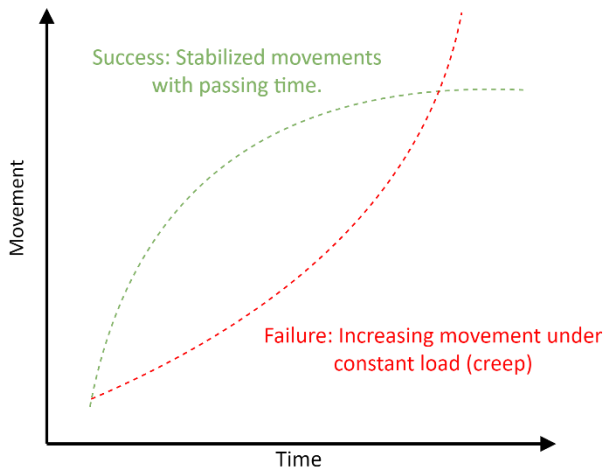

Figure 5. Success vs. failure of anchor test.

The data has processed in a way that all durations starting from t=1 min are checked for maximum creep rate, i.e. b/w 1-3 min, 1-5 min, 1-10 min, 1-15 min, 1-30 min, 1-45 min, 1-60 min. Although ISO recommends using the last stabilized portion of the curve, most critical creep rate has been found from test results conservatively.

The test results have shown that all the creep values were significantly below the 5 mm level for failure. To make sure the results are correct, all individual measurement points are used separately to calculate the creep rate. The results are summarized for adhesion (kPa) – which is the applied load per surface area of the bond.

The highest creep rate observed in the tests were 2.13 mm/log(min) – and not at the highest adhesion. The highest creep is observed for an anchor with 861 kPa loading.

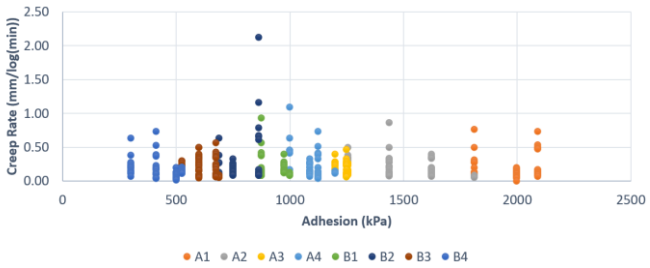

Figure 6. Creep rate vs. adhesion.

The highest anchor loads (in terms of adhesion) are shown in table 1. For a load (friction) of 2091 kPa, the creep rate is less than 1 mm/log(min). Therefore, the failure has not been reached even at the maximum adhesion of 2091 kPa.

Table 3. Creep rates at highest proof loads.

Name	Region	Load (kPa)	Duration (min)	Bond Length (m)	Friction (kPa)	Creep Rate (mm/log(min))
A1-3350-3	A1	3350	3	3	2091	0.73
A1-3350-20	A1	3350	20	3	2091	0.53
A1-3350-15	A1	3350	15	3	2091	0.51
A1-3350-30	A1	3350	30	3	2091	0.49
A1-3350-5	A1	3350	5	3	2091	0.48
A1-3350-10	A1	3350	10	3	2091	0.47

B2-3350-30	B2	3350	30	3	2091	0.14
B1-3350-20	B1	3350	20	3	2091	0.13
B2-3350-20	B2	3350	20	3	2091	0.13
B2-3350-15	B2	3350	15	3	2091	0.13

2.3 Comparison with literature

Several papers in the literature (Kristensen et. al., 2000, Roesen & Trankier, 2021, Lyse, 2022) discuss bond of anchors in the Copenhagen limestone. The maximum tested adhesion was reported by Lyse (2022) as high as 2060 kPa. None of the studies have reported failure in the Copenhagen limestone. Therefore, it can be concluded that the Nordhavnstunnel test results increased the number of tests above 2000 kPa, reaching a new limit.

2.4 Design decisions for uplift anchors in the limestone

To reduce the risk to an acceptable level, an adhesion of 1200 kPa has been selected. Using a common drilling diameter of 150 mm. this resulted in 3.6 m bond length for 63.5 mm diameter anchor to sustain the design uplift load of 1410 kN.

3 ANCHORS IN THE GLACIAL TILL

A series of anchor investigation tests with the anchor grout body in the clay till was set up during the design phase.

16 inclined investigation tests were performed on inclined anchors at two specified test sites adjacent to the tunnel location on land (Nordhavn area). These anchors were all made to investigate the anchors' suitability for the glacial clay till. The test anchors were inclined by 35 degrees to the horizontal plane, drilled in OD Ø170 mm dimension using a Ø152 mm casing, and each was installed with 12 No. of 0,62" Y1860 strands. The test proof load was 1600 kN. 12 anchors with bond length 6,9 and 12m were installed with primary injection during installation and using 6 to 7 bar grout pressure when extracting the casing around the tendon bond length. 4 anchors with 9m bond length were post grouted using two reinjection tubes.

Anchors with no post grouting could take a load between 720 and 960kN, without reaching failure, however a creep rate of 2 mm per time decade was reached even at the lower end of the mentioned loading range.

Post grouted anchors could undertake test loading up to 1440 kN for a 9 m bond length (displacement criterion $\Delta s=s_b-s_a<0.5$mm was exceeded at the last step of 1600kN or creep rate of 2mm per time decade was reached).

The investigation tests confirmed that anchors in the clay till with post grouting have a resistance of approximately 265kPa (the corresponding adhesion factor α would be equal to 0.65 assuming S_u=400kPa and adhesion=α x c_u). This resistance, however, was not sufficient for the current project demands.

As the sheet pile wall design requires proof load tests ranging up to 1600 to 1800 kN, it was decided not to go forward with the anchors bond in the clay till, but to adopt a grout body in the limestone.

4 TEMPORARY WORKS - RETAINING STRUCTURE

4.1 Design summary

The construction sequence in the Svanemøllehavn foresees a hydraulically installed working platform from which the sheet piles and vertical anchors are installed passing through the fill, clay till, greensand to the limestone. In the Nordhavn area, retaining walls and vertical anchors are to be driven from the existing ground level. Grouting is to be performed to extend the water cut-off role of the sheet piles into the limestone over 2 to 9 m depth. Dewatering (with re-injection) is installed to allow staged dry excavation and installation of the grout anchors at one to three levels depending on the depth of the building pit. The retaining height reaches up to 15 m in the deepest parts. (see Figure 3). In the Svannemolen area, the bottom slab of the tunnel is up to two meters below the limestone top. As the sheet piles do not reach the depth of the bottom slab in these areas, a berm will be left below the toe of the sheet pile to reach full excavation depth.

An extended driveability campaign at 5 locations with different hammers and modifications (e.g. driving shoe at the toe of the sheet pile, pre-trenching/relaxation of the soil) was performed. Heavy duty U-sections with flange thickness around 20 mm, were selected from the beginning and used on all test piling locations. Testing was done, using panel driving of three double piles at each testing location, to simulate the piling process for the production sheet piles, that are properly interlocked. These sheet piles were considered more likely to be driven through the hard underground thanks to their shape and stiffness.

4.2 Sheet pile driveability tests

A variety of hammers were used for the sheet pile driveability tests, including a 9-ton free fall hydraulic hammer along with hydraulic accelerated hammer types IHC S-120 and S-150, both representing equivalent drop weights of 12 ton and 15 ton, respectively. The result of the driveability tests was that the free fall 9 ton hammer proved to be adequate for sheet pile driving to the limestone, as well as the IHC hammers.

Potential benefits from pretrenching/loosening the soil of upper layer were not observed. A driving shoe was found to have benefits (stress reduction during driving) but given the sheet pile section selected (the sheet pile section could also be installed without a driving shoe), a driving shoe was not deemed necessary.

Through the campaign it was proven possible to drive the U-shaped sheet piles smoothly through the glacial till and greensand layers to the top of limestone. However, penetration in the limestone could not be demonstrated. Some sheet piles were extracted at the end of campaign to witness toe damage. Sheet piles in general demonstrated acceptable minor or no damage. However, there were cases where sheet pile toe got damaged to force sheet piles into limestone (Figure 7).

As multiple inclined anchors are necessary for the support of the wall, it is easily understood that the vertical load on the sheet pile is high and vertical bearing capacity is thus critical. The initial design has been adapted to sheet piles stopping with refusal to the top of limestone. The end bearing capacity will have to be confirmed by dynamic testing: PDA-measurements and CAPWAP-analysis and by the introduction of a reliable set criterion when installing

the sheet piles. Preliminary dynamic testing allowed for an estimation of an unfactored toe bearing resistance of 4514kN/m (or factored as per DS EN 1997-1 approximately 2257kN).

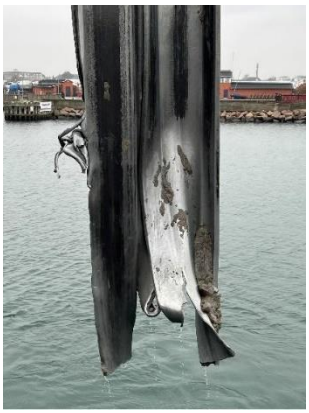

Figure 7. Damaged sheet pile toe as retrieved.

4.3 Limestone berm support at pile toe level

Where excavation extends deeper than the toe of the sheet piles, a berm at the sheet pile toe is provided to ensure sufficient end bearing capacity. This design includes a purpose specific assessment of the effective limestone strength accounting for its anisotropy in the given the loading conditions.

By including anisotropy of the limestone, in combination with the nature and circumstances of the load from the retaining wall onto the limestone berm, two different sets of equivalent strength properties can be attributed to the limestone due to the different failure mechanisms. Thus, one set of strength parameters was used for the vertical capacity and berm stability, and a specific set of values was used for the determination of horizontal passive resistance in the earth pressure calculations.

The design strategy furthermore foresees site assessment of the limestone conditions and properties based on face logging results at the centre of the excavation before excavation towards the sheet piles is continued. Rock bolts are foreseen as mitigation measure in case of unfavourable geological and geotechnical conditions (e.g. unfavourable fissuring).

5 CONCLUSIONS

Uplift anchor investigation tests, inclined anchors investigation tests in the clay till and sheet pile driveability tests have been carried out to validate and optimize the design of the Nordhavnstunnel.

Uplift anchor tests reached confirmed adhesion as high as 2091 kPa and the anchors did even not come close to failure. Therefore, traditional 650-900 kPa values should not be used anymore, and higher values should be adapted in Copenhagen. Nordhavnstunnel design adopts 1200 kPa – while higher values are open to explore. Preliminary anchor testing allowed a refinement of the anchor grout body length, contributing to financial optimisations.

The benefits of post grouting of anchors in the clay till could be demonstrated. An increase of capacity by minimum 60% was reported, with post grouted anchors of 9m grout body in the clay till demonstrating a capacity around 1440kN.

U-shape heavy duty (20mm web thickness) sheet piles were found to be able to be smoothly driven in the clay till and greensand layers of Copenhagen, but no penetration in the limestone could be demonstrated.

Placing the driveability campaign early in the project allowed for an in-time design refinement and risk mitigation and enabled the adoption of a sheet pile solution instead of a traditional secant pile wall. The very good collaboration between design and execution team, the contractor and the client allowed preliminary investigation tests, taking calculated risks/opportunities, and led to an improved productivity and potentially sustainability related performance during design and execution.

6 ACKNOWLEDGEMENT

The authors would like to express their gratitude to VejDirektoratet for their support during the project and for their approval of the paper.

Acceleration of embankment construction on soft soils of Salamanga using wick drains and counterweight fills

Accélération de la construction de remblais sur sols mous de Salamanga à l'aide de drains verticaux et des remblais de contrepoids

H. Dete*, C. Quadros
TÉCNICA – Engenheiros Consultores Ltd., Maputo, Mozambique
**hans.brigido@gmail.com*

ABSTRACT: The construction of embankments on soft soils is an inevitable solution in the case of roads crossing thick clayey alluvial deposits. In such cases, consolidation acceleration techniques can be adopted, in order to prevent excessive settlements to occur as a result of the stress increase induced by the embankment or causing it to fail due to insufficient shear strength of the foundation. This paper evaluates technical solutions for accelerating the construction of embankments on soft soils using wick drains and counterweight fills. This solution was implemented on the construction of a 9.6 m high embankment between the years 2016 and 2017, along the Maputo River floodplain, in Salamanga District. The construction was preceded by an extensive geotechnical investigation, including in situ and laboratory tests, which identified the existence of a 39 m thick deposit of soils that were not only highly compressible and of low permeability, but also had a low shear strength, reason why counterweight fills were adopted to prevent failure of the embankment during the staged construction. Because of the uncertainties involved in the characterization of soft soils, related to the sedimentation process, and spatial variation of their properties, and in predicting their behavior when loaded, an instrumentation and monitoring plan of the construction was implemented, whose results were used to calibrate the geotechnical model. From the collected data, it was concluded that the designed solution performed satisfactorily and the project assumptions regarding the allowable residual settlements and stability of the embankment were met before laying the pavement.

RÉSUMÉ: La construction de remblais sur sols mous est une solution incontournable dans le cas de routes traversant des alluvions argileuses épais. Dans ces cas, des techniques d'accélération de la consolidation peuvent être adoptées, afin d'éviter que l'augmentation des contraintes induite par le remblai ne produise des tassements excessifs ou ne provoque pas sa rupture en raison d'une résistance au cisaillement insuffisante de la fondation. Cet article évalue des solutions techniques pour accélérer la construction de remblais sur sols mous à l'aide de drains verticaux préfabriqués et des remblais de contrepoids. Cette solution a été mise en œuvre pour la construction d'un remblai de 9,6 m de hauteur entre 2016 et 2017, le long de la plaine inondable du fleuve Maputo, dans la région de Salamanga. La construction a été précédée d'une vaste investigation géotechnique, y compris des essais in situ et en laboratoire, qui a identifié l'existence d'un dépôt de 39 m d'épaisseur de sols qui étaient non seulement hautement compressible et de faible perméabilité, mais avaient également une faible capacité portante, raison pour laquelle des bermes à contrepoids ont été adoptées pour éviter la rupture du remblai lors de sa construction par étapes. En raison des incertitudes liées à la caractérisation des sols mous, à cause de leur nature sédimentaire et à la variation spatiale de leurs propriétés, et à la prédiction de leur comportement en charge, un plan d'instrumentation et de surveillance de la construction a été établi, dont les résultats ont été utilisés pour calibrer le modèle géotechnique, à partir duquel il a été conclu que les hypothèses du projet concernant les tassements résiduels admissibles et la stabilité du remblai étaient respectées avant la construction de la chaussée.

Keywords: Acceleration of embankment construction; soft soils; wick drains; counterweight fills.

1 INTRODUCTION

Among several factors, the design of a highway is constrained by the topography, geology and hydrology of the site.

Indeed, in the cases where a road layout crosses a river valley, it is frequent to build embankments adjacent to the bridge abutments to avoid overtopping of the roadway during extreme floods.

In such cases, the viability of such construction must be very well analysed, for the river valleys are generally composed of saturated alluvial soils, of low bearing capacity and high compressibility, requiring the use of non-conventional construction methods to prevent excessive settlements of the infrastructure during the service phase.

According to Almeida & Marques (2010), the choice of the most adequate method depends on the

geotechnical characteristics of the deposit, use of the area, including the neighbourhood, as well as construction deadlines and costs involved.

Therefore, this paper presents the use of wick drains with surcharge loading and counterweight fills (berms) as an alternative method for the construction of embankments on soft soils.

2 TECHNIQUES TO ACCELERATE THE CONSTRUCTION OF EMBANKMENTS ON SOFT SOILS

2.1 Wick drains with surcharge loading

The construction of road embankments on deep soft soil deposits is usually done by preloading the ground through an additional depth of fill, during a period long enough to allow most of the consolidation settlements to occur before laying the pavement.

Due to the low permeability of soft soils, the consolidation period might be too long (Terzaghi et al., 1996), thus not complying with the construction deadlines.

In such cases, the preloading is combined with wick drains (Figure 1), which are installed relatively close to each other to reduce the drainage distance up to 1 to 2 meters, therefore accelerating the consolidation (Espinoza et al., 2020).

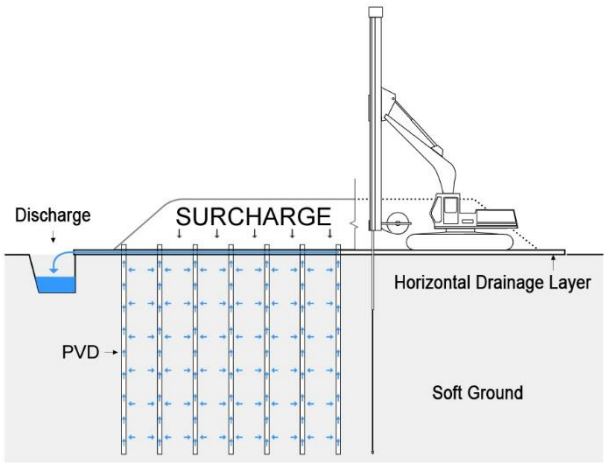

Figure 1. Preloading embankment combined with wick drains. (Source: Prefabricated Vertical Drains, 2017).

2.2 Counterweight fills

Despite the fact that the construction of embankments on soft foundation must account for excessive settlements, it is also necessary to ensure that the embankment height will not cause failure of the foundation due to its low undrained strength.

According to (Jakobson, 1948), if the required embankment height does not comply with the foundation shear strength, counterweight fills (loading berms) can be adopted to decrease the shear stress along the critical failure surface (Figure 2).

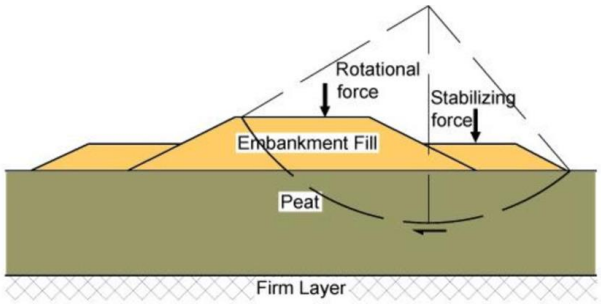

Figure 2. Effect of counterweight embankment on the stability of the embankment. (Muhammad, 2018).

3 CASE STUDY

3.1 Project description

The new Maputo – Ponta do Ouro road crosses an alluvial floodplain within the Salamanga District, near the Maputo River.

Since the ground level was +3.0 m and the design flood level was +8.054 m, it was necessary to build an embankment to enable the safe vehicle circulation during extreme floods.

After an extensive geotechnical survey along the road alignment, it was observed that the foundation mainly comprised fat clay with sand (CH) along 3.6 km up to a maximum of 39 m deep, as illustrated on Table 1A and Table 1B (CRBC, 2018).

Table 1A. Soil profile characterization.

Layer (depth, m)	**Soil**	***c* (kPa)**	**ϕ (°)**	**γ (kN/m³)**	**e_0 (-)**
1 (0.0 – 3.8)	CH	12	14	14.6	2.298 3.412
2 (3.8 – 9.3)	SC	12	13.4	14.5	3.412 2.487 2.547
3 (9.3 – 18.6)	CH	12	14	14.2	2.607 2.619 2.619

Table 1B. Soil profile characterization (cont.).

Layer (depth, m)	**Soil**	***c* (kPa)**	**ϕ (°)**	**γ (kN/m³)**	**e_0 (-)**
4 (18.6 – 33.6)	CH	17	22.4	16.1	0.722 2.165 1.852 1.645
5 (33.6 – 39.0)	CH	17.9	17.8	18.3	0.948 0.946 0.949

As per the geotechnical investigation results, the foundation soil has a very low shear strength and is highly compressible (compressibility index between 0.973 and 1.864), requiring special construction methods prior to the final loading.

In this context, the engineering design adopted a solution based on the consolidation process, which consisted of installing wick drains (prefabricated vertical drains). Additionally, counterweight fills (loading berms) were adopted to increase the factor of safety against the slope failure, during the staged construction.

A general scheme of the adopted engineering solution is presented on Figure 3.

For this study, a road section with 379 m of length was considered. On this section, the design height of the embankment was 6.7 m, the top width was 11.5 m and 1:1.5 slopes. The counterweight fills were 3 m high and 15 m of width on both sides of the main embankment.

The wick drains were installed up to 30 m deep, under a triangular pattern.

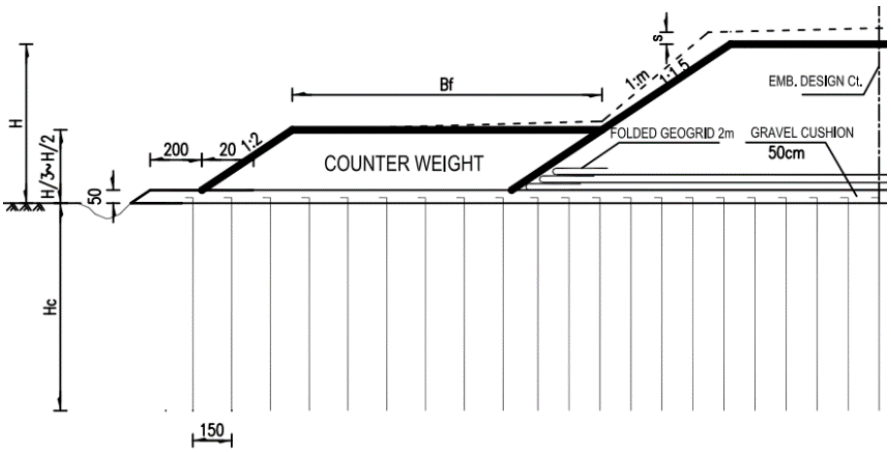

Figure 3. General scheme of the adopted engineering solution (all the dimensions are in centimetres).

3.2 Settlement prediction and design criteria

Settlements were predicted using the horizontal consolidation coefficient (c_h) determined by the Asaoka's observational method, as per the settlements measured until 5.3 m height of the embankment (Figure 4). Further calculations indicated that the consolidation settlements with respect to the design embankment is 2.6 m.

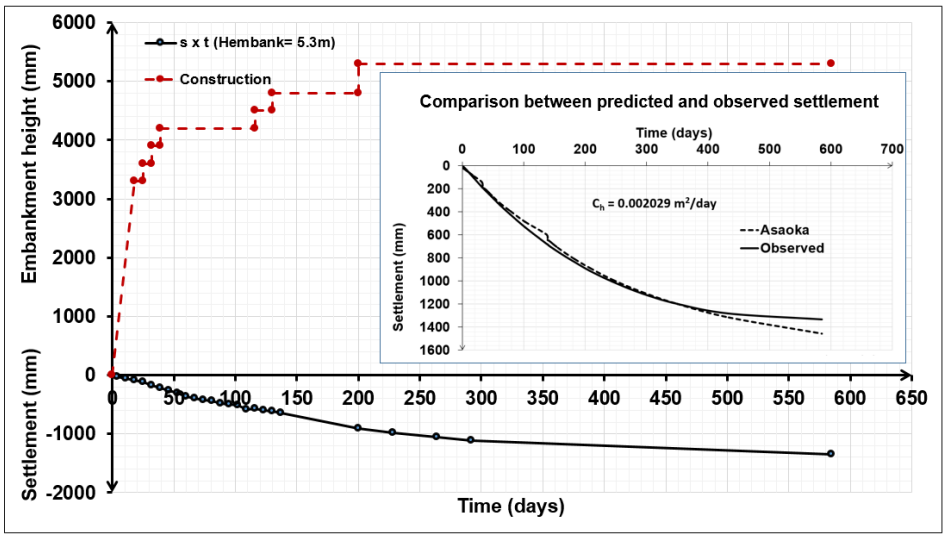

Figure 4. Observed and predicted settlement of the embankment during construction.

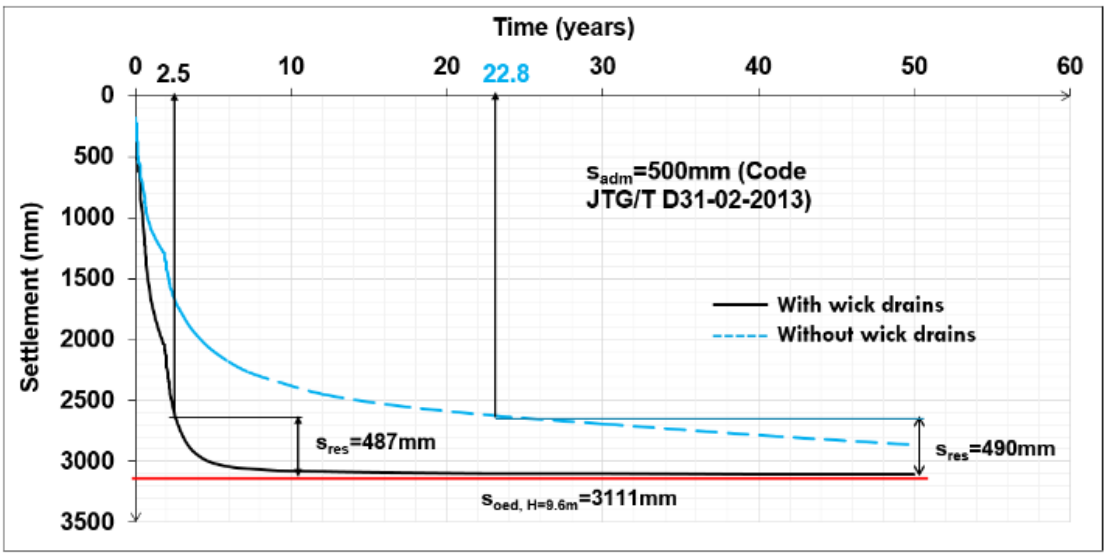

Figure 5. Settlement vs. time curve of the foundation with and without wick drains.

In order to comply with the design height of the embankment and thus, of the road elevation, an additional surcharge fill of 2.9 m was prescribed for the construction stage. Therefore, the total height of the fill was 9.6 m, which would cause a total consolidation settlement of 3.1m (Figure 5).

The construction took 26 months and, according to JTG/T D-31-02-2013, the residual settlement should not exceed 500 mm on the transition section between the embankment and the box culverts (piled foundation with almost no settlement).

Moreover, it was expected that the consolidation process would end 4 years after the construction, reason why maintenance measures such as refilling the pavement on critical sections were prescribed in order to provide good driving conditions.

4 CONCLUSIONS

This paper presented the engineering solution adopted to accelerate the construction of the road embankment accross the Maputo River floodplain, in Salamanga District.

From the study, it is concluded that the installation of wick drains led to a significant acceleration of the consolidation process, keeping the residual settlements within the pavement allowable settlement. In fact, the settlement-time curve presented on Figure 5 shows that without this technique, that process would last for almost 22 years, what is clearly unfeasible.

Finally, it is important to note that the success of the described solution relies not only on the extensive geotechnical investigation, but also on the evaluation of the settlement measurements acquired during the construction monitoring.

The sustainable future of vertical drains

L'avenir durable des drains verticaux

J.W. Dijkstra*
Cofra B.V., Amsterdam, The Netherlands

R. Bodamer
Geotechnics, Amsterdam, The Netherlands

**Jeroen.Dijkstra@cofra.com*

ABSTRACT: Vertical drains are a common technique for accelerating consolidation in soft compressible material and improving soil strength for a variety of applications, such as embankment construction for infrastructure. They also help reduce the residual settlements of green- and brownfield developments and mitigate liquefaction risks. The sustainable future of vertical drains for ground improvement is a rapidly developing area of research. The objective of this paper is to explore the current trends in the use of sustainable vertical drain systems, with a focus on environmentally friendly materials, innovative construction processes, and potential design implications. Biodegradable or recycled materials have started to replace the traditional synthetic materials. Additionally, construction processes are being refined to reduce waste and minimize the ecological footprint. The use of sustainable vertical drain systems benefits the environment while also having potential design implications, requiring different approaches to soil improvement in some cases. In summary, the sustainable future of vertical drains for ground improvement requires a holistic approach to design, construction, and materials selection. The continued development of innovative and sustainable solutions will ensure that vertical drains remain a valuable tool for geotechnical engineers. This paper provides an overview of the latest trends, innovations, and potential design implications for sustainable vertical drain systems.

RÉSUMÉ: Les drains verticaux sont une technique courante pour accélérer la consolidation des matériaux souples et compressibles et améliorer la résistance du sol pour diverses applications, telles que la construction de remblais pour les infrastructures. Ils contribuent également à réduire les tassements résiduels des développements en milieu urbain et rural et à atténuer les risques de liquéfaction. L'avenir durable des drains verticaux pour l'amélioration des sols est un domaine de recherche en plein essor. L'objectif de cet article est d'explorer les tendances actuelles dans l'utilisation de systèmes durables de drains verticaux, en mettant l'accent sur les matériaux respectueux de l'environnement, les processus de construction novateurs et les implications potentielles en matière de conception. Les matériaux biodégradables ou recyclés commencent à remplacer les matériaux synthétiques traditionnels. De plus, les processus de construction sont affinés afin de réduire les déchets et de minimiser l'empreinte écologique. L'utilisation de systèmes durables de drains verticaux bénéficie à l'environnement tout en ayant des implications potentielles en matière de conception, ce qui nécessite parfois d'adopter des approches différentes pour l'amélioration des sols. En résumé, l'avenir durable des drains verticaux pour l'amélioration des sols nécessite une approche holistique de la conception, de la construction et de la sélection des matériaux. Le développement continu de solutions novatrices et durables garantira que les drains verticaux restent un outil précieux pour les ingénieurs géotechniciens. Cet article offre un aperçu des dernières tendances, innovations et implications potentielles en matière de conception des systèmes durables de drains verticaux.

Keywords: Vertical drains; sustainability; ground improvement; consolidation.

1 INTRODUCTION

Vertical drains are extensively used in the consolidation of low permeable and weak soils, such as clay and peat deposits. The drains offer several advantages, including reduced construction time, improved control of residual settlements, and accelerated soil strength development. Typically composed of an oil-based plastic core surrounded by an oil-based PP or PET geotextile sleeve or sheet, vertical drains, also known as prefabricated vertical drains (PVD), band drains, or wick drains, have been widely implemented in many projects all over the world. Every year, hundreds of millions of meters of drainage material are installed to remain in the ground.

While the discussion on environmental impact of plastics has mainly focused on consumer goods, it has started to reach the civil engineering sector as well. Manufacturers in the field of geosynthetics are feeling the urge to provide green alternatives and promote sustainability. The establishment of the European

Association of geosynthetic product manufacturers (AEGM) exemplifies their collective effort to promote the use and their sustainable practices on a European scale.

Vertical drain manufacturers are also actively seeking new materials that reduce the overall environmental impact, such as the carbon footprint and material usage, motivated by the impending introduction of CO_2 taxes and the growing popularity of environmental impact assessment tools in certain countries.

To provide a comprehensive understanding of the current state of vertical drain technology, this paper aims to address the evolving environmental awareness and provide an overview of the currently available sustainable alternatives.

2 THE USE OF VERTICAL DRAINS

The vertical drain plays a crucial role in facilitating the short consolidation period during the construction of embankments, typically within a year. These drains are designed to expedite the process of soil consolidation, while ensuring stability and durability of the embankments. However, once the intended functional period is complete, the vertical drains remain embedded in the soil beneath the groundwater level.

Unlike other plastic products that contribute to environmental pollution, vertical drains have minimal impact in terms of microplastic pollution. They rarely come into contact with the environment, as they are situated beneath the pavements or structures. Their exposure to the environment occurs only during soil excavation. Additionally, a significant portion of the drains extracted during excavation are reused in other construction projects or required to be removed, further minimizing waste.

From a technical and environmental standpoint, vertical drains are considered to be safe and sustainable. Therefore, when civil engineers are questioned about the future of vertical drains, concerns about their impact on the environment are often non-existent. This is however slowly changing.

3 ENVIRONMENTAL AWARENESS

Despite the relatively low environmental impact and functional application, there is a growing awareness among civil engineers about the potential environmental consequences and potential consequences for future generations. In the Netherlands, a shift is ongoing towards the use of environmentally friendly alternatives, which has prompted ongoing research into the use of biobased and compostable/degradable materials as substitutes for the current materials used.

The research is particularly focusing on materials compatible with common PVD extrusion devices in relation to the specific characteristics that a PVD needs to possess. The material should be strong enough to withstand ground pressures, flexible enough to accommodate settlement and the installation processes, and have a low creep component to ensure long-term discharge and performance.

Finding biodegradable materials that meet all of these criteria has been challenging. After years of testing, at least three types of PVDs made from (partly) biobased plastics have now entered the market that meet the aforementioned characteristics. Several successful projects have already been executed in the Netherlands. These drains, based on biobased plastics, will be called biodrains in the remainder of the paper.

In addition to these recent developments with biodrains, there is another type of natural drain, the fiber drain, that has been available for over 30 years but has not gained widespread popularity due to the higher costs and lower discharge properties compared to the regular PVD. This drain is manufactured using jute and coconut materials, making it 100% biobased. The production mainly takes place in South East Asia and India, and while this drain has been used in projects across Asia, it has yet to be adopted on other continents except through research programs (Nguyen 2020).

The following chapters will separately discuss both types of drain: The biodrain and the fiber drain.

4 BIODRAINS

Drains made of biobased plastics are now available from various PVD manufacturers. These drains are degradable under industrial conditions, typically at temperatures of around 60 degrees Celsius. However, claims that these drains are fully compostable can be misleading, as they are often left underwater after construction, not exposed to UV radiation, and subject to low oxygen and low temperatures. In such conditions, the drain will retain its form, similar to other plant materials found in organic soils. Some degradation, especially strength (Borelbach et al 2023) may occur due to bacteria, but it can generally be assumed that the drains will remain in the ground for the required service life.

Biodrains, due to the use of the same extrusion production process as regular PVDs, have a similar look, feel, and functionality. All biobased PolyLactic Acid (PLA) drain types contain various additives in addition to the PLA base. These additives, which can

be oil-based or of different natural origins, are necessary to improve extrusion characteristics, provide sufficient strength during installation, and meet compression, flexibility, and creep requirements to ensure adequate discharge capacity over the drains' lifespan. However, the additives and properties of PLA are not as optimized for PVD production compared to other polymers. Consequently, the current versions of biodrains are often thicker and heavier than regular oil-based drain types.

As a result of their increased weight and changed material properties with a higher stiffness and lower creep, biodrains tend to over-perform in terms of discharge capacity. In some cases, they can provide 300% to 400% higher discharge compared to regular PVD types, depending on testing pressures and increasing with a greater confining pressure due to the material properties. Refer to Table 1 for testing results of one of the biodrain types available in the market.

Table 1. Measured discharge capacity in the laboratory of Geotechnics in Amsterdam under 120kPa loading and 0.1 gradient after 28 days.

Drain type	Discharge capacity [ml/s]

Corrugated biodrain	220
Fiber drain	8

5 NATURAL PREFABRICATED VERTICAL DRAIN OR FIBER DRAINS

Natural vertical drains, which were initially patented by NUS and researched by Professor Chew in Singapore, are currently manufactured in India, Bangladesh, and Indonesia. These drains typically consist of two materials: coconut ropes/coir encased by jute filters. Unlike regular drain types, natural fiber drains do not have free flow channels but rely on the natural fibers, or the space between the coirs to facilitate water drainage. As a result, the discharge capacities of these drains are generally lower compared to conventional PVD or biodrains (refer to Table 1).

Several researchers have published studies on the use of fiber drains, including Lee et al. (1994), Venkatappa Rao et al. (2000), Kim and Cho (2008), Lekha and Kavitha (2006), Vinod and Minu (2010), and Artidteang et al. (2015). Nguyen (2018) summarized the development of multiple drain types over the years, ranging from round drains to drains with 4 to 16 coir strands to a coconut coir mat wrapped in a jute filter. Despite the research conducted, all fiber drain types have achieved more or less similar discharge capacities, with no significant improvement over time. Reported values range between 5 and 15ml/s, depending on the confining pressure. This aligns with the measurements presented in Table 1. Researchers are still trying to find the best way to draw clear conclusions on the most optimal type for the market due to the complex mix of parameters influencing the success, such as drain costs in relation to manufacturing efficiency, confusion regarding the best material and structure options, natural variations in material, and uncertainty about biodegradation over time (Nguyen, 2018).

Field observations have shown rapid degradation of jute drains in some cases (Kim 2008), while other instances demonstrate no significant biodegradation during soil consolidation. This was confirmed by a field trial conducted in Australia and described by Nguyen et al in 2020. Despite the large differences in discharge capacity and concern on the biodegradability, the fiber drain performed remarkably well compared to the regular drain type, with similar settlement rates during the process of consolidation.

When a PVD type with a very low discharge manages to achieve similar settlement rates and results compared to an already well-optimized regular PVD, it raises two possibilities. Either the discharge capacity of the regular PVD type used in the test is very low, making it behave similarly to the fiber drain, where discharge is not highly affected by kinking, or the discharge capacity of regular PVD types is highly over dimensioned. To gain a better understanding and further optimize PVD types or explore drains made of natural materials, additional trial fields and a deeper understanding of PVD behaviour in relation to the consolidation process are required. An additional test is therefore currently being performed by the authors in the Netherlands where different biobased drain concepts are tested on their performance in a large field test.

6 THE CO2 TAXED FUTURE IN EUROPE

As CO_2 emissions will be taxed in the future in the European Union, it is also essential to evaluate the CO_2 balance of the PVD. The European Union is planning to tax emissions with rates mentioned as high as 125 euros per ton of CO_2. Similarly, the municipality of Amsterdam is considering to price the CO_2 contribution as high as 418 euros per ton in their tenders.

Regular PVDs have a CO_2 footprint of approximately 0.15 to 0.2 kg per meter of drain. This translates to a CO_2 tax of 2.5 cents for the European tax rate of 125 euros per ton of CO_2 and 8.4 cents according to the Amsterdam calculation model. These

numbers provide additional insight into the cost differences that may arise between regular drains and alternative options, such as biodrains, when CO_2 costs will be incorporated into tender processes.

The tested biodrain type demonstrated a reduction of over 35% in CO_2 footprint. This reduction is valued at 3 cents. It also means that when CO_2 costs are incorporated, the biodrain can only be 3 cents more expensive in the Amsterdam model to arrive at the same cost price. When it is more expensive, the regular drain with CO_2 costs included will be cheaper.

Fiber drains, on the other hand, exhibit a negative CO_2 footprint due to the storage of CO_2 in the plant-based material. These drains can be valued at and may become easily 10 cents or more expensive when CO_2 costs are included.

Therefore, it is crucial for future projects to consider the CO_2 costs and emissions associated with different drain options as part of their overall sustainability assessment and decision-making processes. By incorporating these factors, companies can make more informed decisions and contribute to a greener and more environmentally responsible construction industry.

It is up to manufacturers, however, to find ways to make the biobased solutions also financially attractive and to expand their research.

7 CONCLUSION

In order to meet the needs of the present without compromising the ability of future generations to meet their own needs, clients and the market must make informed choices regarding the available drain options. Suppliers and installers have already taken steps to offer clients a range of PVD types, from traditional polymeric PVDs to alternatives such as fiber drains. At the same time, they are actively working towards reducing the current price gap, making their environmentally friendly products more affordable. The adoption of different drain types will vary from country to country, depending on environmental awareness and regulations such as the CO2 tax being implemented in Europe.

By considering the CO2 footprint, material usage, and the overall environmental impact of different drain options, the construction industry can contribute to a sustainable future. Making responsible choices in drain selection will not only help mitigate climate change but also align with the growing demand for environmentally friendly construction practices.

The sustainable future of vertical drains relies on finding a product with the lowest CO_2 footprint and material usage, while maintaining a competitive price compared to conventional drains. Further research is therefore necessary to gain a better understanding of the discharge capacity of fiber drains in relation to current standards. For the biodrains it is key to reduce on the material usage and find ways to arrive at similar discharge capacities within the boundaries set in this paper. This will ensure that biodrains and fiber drains can become a mature green alternatives that eliminates the use of plastic in conventional PVD types.

ABSTRACT: The use of recycled 6F5 aggregate is widely seen as a necessary option in civil engineering projects to meet carbon offset targets. This material is used for a range of applications such as load distribution platforms, capping layers, sub-bases and general backfill. It can consist of fresh aggregate or recycled components and its engineering characteristics can, therefore, vary widely. Independent of the application, it is important to characterise accurately the material properties of the aggregate in order to guarantee safe, economical solutions. The angle of friction is often the main parameter required for geotechnical design and usually obtained by direct shear tests. However, when using standard laboratory equipment there is an upper limit to the size of particle that can be tested, rendering such apparatus inappropriate for obtaining the shear parameters of 6F5 aggregate, which has a specified size fraction of 0-125 mm. The paper describes the design of a series of giant shear box tests, with a shear plane area 2.25 m^2, on recycled 6F5 together with details of the testing procedure and the results of these full-scale tests.

RÉSUMÉ: L'utilisation de granulats 6F5 recyclés est largement considérée comme une option nécessaire dans les projets de génie civil pour atteindre les objectifs de compensation carbone. Ce matériau est utilisé pour une gamme d'applications telles que les plates-formes de répartition des charges, les couches de forme, les sous-couches et le remblai général. Il peut être constitué de granulats frais ou de composants recyclés et ses caractéristiques techniques peuvent donc varier considérablement. Quelle que soit l'application, il est important de caractériser avec précision les propriétés mécaniques du granulat afin de garantir des solutions sûres et économiques. L'angle de frottement est souvent le principal paramètre requis pour la conception géotechnique et est généralement obtenu par des essais de cisaillement direct. Cependant, lors de l'utilisation d'un équipement de laboratoire standard, il existe une limite supérieure à la taille des particules qui peuvent être testées, ce qui rend un tel appareil inapproprié pour obtenir les paramètres de cisaillement de l'agrégat 6F5, qui a une fraction granulométrique spécifiée de 0 à 125 mm. L'article décrit la conception d'une série d'essais en boîte de cisaillement géante, avec une surface de plan de cisaillement de 2,25 m^2, sur du 6F5 recyclé, ainsi que des détails sur la procédure d'essai et les résultats de ces essais à grande échelle.

Keywords: Piling platforms; full-scale testing; carbon reduction.

1 INTRODUCTION

During large infrastructure projects, such as the rail infrastructure project HS2 (one of the largest and most complex infrastructure projects ever undertaken in the UK), to facilitate the construction of the permanent works contractors must utilise temporary civil engineering structures (e.g. load distribution platforms, capping layers, sub-bases and general backfill). In the UK, the material widely used to create these structures is "recycled 6F5 aggregate". 6F5 is defined as any recycled aggregate made up of crushed hardcore materials including crushed concrete. In general, this crushed material ranges in size from 0 to 125 mm (BSI, 2018). The description accompanying material of this strength is "specified well-graded material laid and fully compacted to DoT Specification and protected below with geotextile". A characteristic angle of friction, φ', is required for determining the thickness of these tracked plant platforms. The recognised range that the industry usually assume is generally between 30°-45° degrees. BRE 470 (2004) recommends a maximum value of 45° for "strong" (rock compressive strength, q_c > 50 MPa) particle strength materials. An alternative industry practice guide, TWf (2019), states that values of φ' > 45° can

only be used if suitably high quality controls for design, inspection and maintenance are in place. However, this can only be achieved if it is possible to obtain reliable values of the shear strength of the fill.

The inherent issues of both variability and particle size associated with 6F5 aggregate present significant challenges in measuring its characteristic shear strength parameters. It is not possible to obtain these parameters using standard apparatus because the particle size is too great. Even commercially available "large" direct shear boxes, which have plan dimensions of 300 mm x 300 mm, are too small to meet box diameter to particle size ratios recommended in both ASTM Standards (D3080, 2011) and BSI (1990). The heterogeneity of 6F5 aggregate results in it not being possible to use the technique of testing samples of the material in which the grading curve has been scaled down to allow testing in standard apparatus (Tanghetti, 2021). Therefore, to obtain reliable values of the shear strength parameters of 6F5 aggregate it is necessary to test the material in suitably large – non-standard –shear apparatus.

This led to a collaboration between SCS Railways (Skanska, Costain, STRABAG S1 & S2 Joint Venture) – one of the joint venture organisations constructing HS2 - and City, University of London to develop a reliable method to measure the characteristic shear strength parameters of 6F5 aggregate. This study was based on testing 6F5 aggregate obtained from a number of HS2 sites in a series of direct shear tests using the Giant Shear Box facility developed at City, University of London, Tanghetti *et al.* (2019, 2021).

2 TEST DETAILS

2.1 Giant Shear Box facility

The City, University of London Giant Shear Box facility (Figure 1) has been described in Tanghetti *et al*. (2019 and 2021). A series of comparative tests reported by Tanghetti (2021) provided confidence in the use of the large shear box for testing large (≤ 100 mm) particle size materials at higher values of normal stress, which are consistent with the range of stresses typically encountered in engineering practice. The facility comprises of a large split box (internal dimensions 1.5 m x 1.5 m x 1 m) constructed from 254x254x132 UC steel sections. The upper half of the box is prevented from moving horizontally during shear by a reaction frame, while the bottom half is free to move horizontally in order to shear the sample. To minimise friction between the top and bottom of the box during shearing, Acetal sheets are fixed to the lower and upper flanges of the top- and bottom-halves of the box, respectively. Prior to testing standard machine grease is applied to these sheets to provide additional lubrication.

The system to facilitate the movement of the bottom half consists of three I-beams, which are firmly attached to a strong floor in the laboratory and have the role of providing runways in which machine skates can slide. This arrangement retains the bottom half of the shear box laterally to ensure horizontal movement occurs in the direction of shear only.

The shear force is applied to the sample through four 500 kN hydraulic jacks (maintained in position by a reaction frame), which push the bottom section of the box in a horizontal direction creating a horizontal shear plane. The normal load is applied by a single 5 MN hydraulic jack fixed to a beam that is bolted to the reaction frame. The vertical stress is applied to the sample via a platen comprising a stiffened 30mm thick plate designed to minimise deflections even at the maximum applied stress.

During testing potentiometers measured vertical displacement in four positions on the loading platen and the horizontal displacement in two positions on the bottom half of the box. Two load cells mounted between the inside of the reaction frame and the top half of the box measured the horizontal force applied to the shear plane during shear and resisted by the stationary top-half of the box. In addition, an in-line pressure transducer also recorded the hydraulic pressure required to move the bottom-half of the box by the hydraulic jacks. All measurements were recorded on a bespoke LABVIEW data logger.

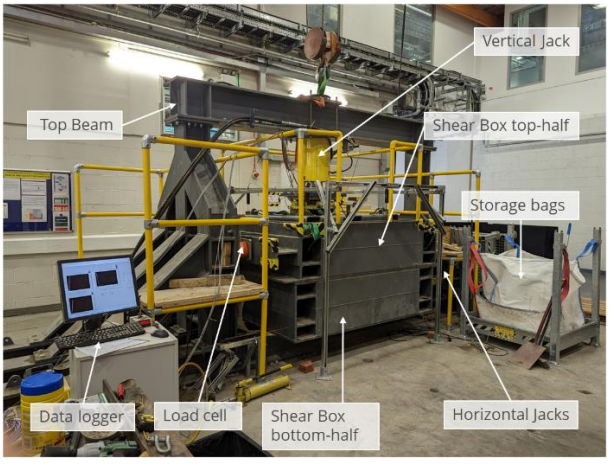

Figure 1. View of Giant shear box facility.

2.2 Material

The recycled 6F5 aggregate reported in this paper was described as "medium level control". This description referred to both the particle size distribution and the constituent materials in the aggregate. The distribution by weight of the constituent parts of this aggregate

together with the particle size distribution are presented in Figures 2(a) and 2(b), respectively. This data was obtained by sampling, conducted by SCS Railways, directly from the construction site prior to the material being bagged for transporting to City, University of London for testing.

The specified limits for the grading of the material are plotted in Figure 2(b) together with the grading curve for the material sampled for testing. From this it can be seen that the "medium control" material is within the contractually agreed limits for recycled 6F5. However, there is still considerable variation within these limits. The constituents of the batches of 6F5 from which material was taken for shear testing, presented in Figure 2(b), indicate that the aggregate consisted of 45-55% "concrete or concrete products" and roughly 25% "clay masonry units" but only 20% "unbound aggregates". In Figure 2(a) the constituents given are; R_c - "Concrete, concrete products & concrete masonry", R_u - "Unbound aggregate, natural stone & Hydraulically bound aggregates", R_b - "Clay masonry units (i.e. bricks & tiles), calcium silicate masonry units & aerated non-floating concrete, calcium silicate", R_a - "Bituminous Material", R_g - glass, X - "Other: Cohesive (i.e. clay & soil), gypsum plaster, miscellaneous - metals (ferrous & non-ferrous), non-floating wood" and FL - "Floating Particles - given as the percentage remaining".

2.3 Sample preparation

Material was delivered to City, University of London in five 1 m^3 capacity full drop flap discharge bulk bags. Each bag was filled with approximately 800 kg of material but was weighed prior to being placed in the shear box to obtain the exact mass of the sample.

Samples were prepared by compacting the 6F5 aggregate in the box in layers after having first removed any aggregate over 125 mm or metal rebar components. To ensure each layer was uniform it was compacted using a small wacker-plate that was passed over the material layer for 2 minutes. The sample was formed of five compacted layers with an average thickness of approximately 200 mm. Because of the size of the box, the first two layers were first prepared in the bottom half before the top half was put in position. Once the box was fully assembled the three further layers could be prepared. In this way, one of the layers spanned the interface between the two halves of the box.

Following the compaction of each layer its thickness was determined. The sum of the thicknesses together with the sum of the mass of each layer allow calculation of the voids ratio and density of the complete specimen to be determined. Once the fifth material layer had been prepared the loading platen was lifted into place and the vertical loading system assembled.

2.4 Testing

Following compaction of the samples and completion of the assembly of the apparatus. All samples were first loaded to a vertical stress of 500 kPa (at this stress level the force applied to the top cap was 1125 kN). This gave all samples the same pre-consolidation stress and therefore similar stress histories. Six samples were included in this series of tests. Three were sheared following the application of the peak vertical stress of 500 kPa and the other three following unloading to a vertical stress of either 200, 300 or 400 kPa.

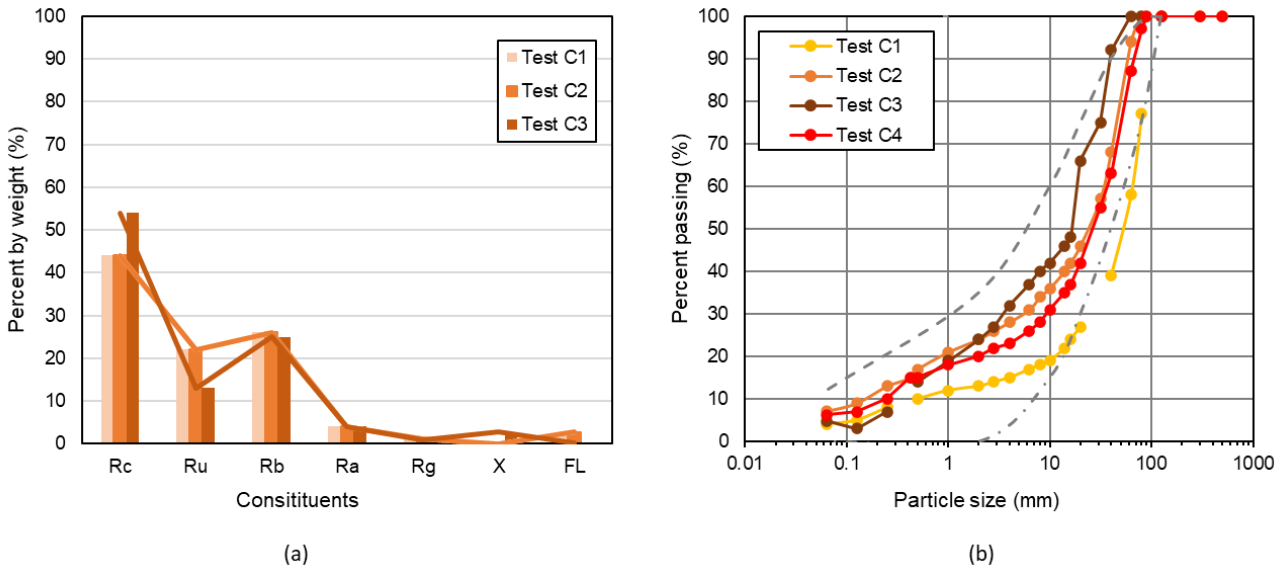

Figure 2. Recycled 6F5 (a) Constituents report and (b) Particle Size Distribution plot with acceptance limits.

Shearing commenced once all displacements following compression or unloading, as appropriate, had reached a plateau. The shear force was applied by increasing the pressure to the horizontal jacks at a constant rate causing the bottom-half of the Giant Shear Box to move. The test was stopped once both the horizontal potentiometers measured displacements greater than $\Delta h = 300$ mm (for a typical sample height $z = 1000$ mm this corresponded to a shear strain, γs, of $\Delta h/z = 30\%$). In most cases this allowed significant post peak shear strength behaviour of the samples to be observed

3 RESULTS

3.1 Application of vertical stress

Figure 3 shows the average settlement for one of the six samples, obtained from the measurements of the four vertical potentiometers, when the sample was subjected to an increased normal stress via the vertical jack. The loading was increased in a number of steps with settlement allowed to stabilise before the next increment of loading was applied. As indicated above, all six tests were pre-loaded to 500 kPa.

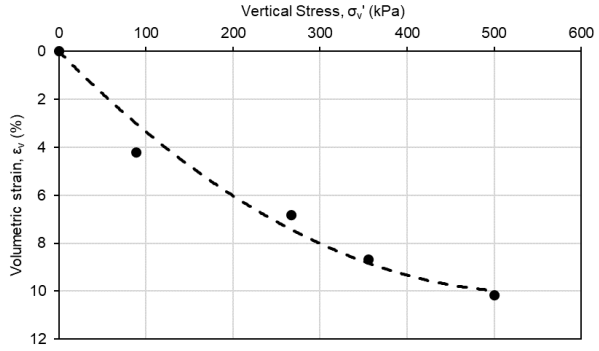

Figure 3. Sample behaviour during compression.

3.2 Shearing

In direct shear box tests the area of the shear plane decreases with displacement and, consequently, although the normal force acting on the top cap of the specimen remains constant, the stress acting on the shear plane will increase. Similarly, in the analysis of the result of direct shear tests the variation of the area of the shear plane with displacement is accounted for in the calculation of shear stress. Therefore, to quantify the relationships during shear between shear stress and shear strain, γ_s, or volumetric strain, ε_v, values of shear stress, τ, should be normalised by the vertical stress, σ', at the same displacement.

Figure 4 shows the results of a shear test conducted at an initial vertical stress (i.e. before shearing commenced) of 200 kPa having been initially compress to and unloaded from 500 kPa. As would be expected from a soil that has been compressed to a significantly higher value of stress than its *in-situ* state, this sample displays a "dense" (or "dry of critical") response to shearing. This is manifest by dilation and a distinct peak value of normalised shear stress. Post peak the rate of dilation decreases and at the end of the test both the normalised shear stress and the volume of the specimen were approaching a steady state. At this stage the Giant Shear Box had reached the end of travel and so it was not possible to achieve critical state.

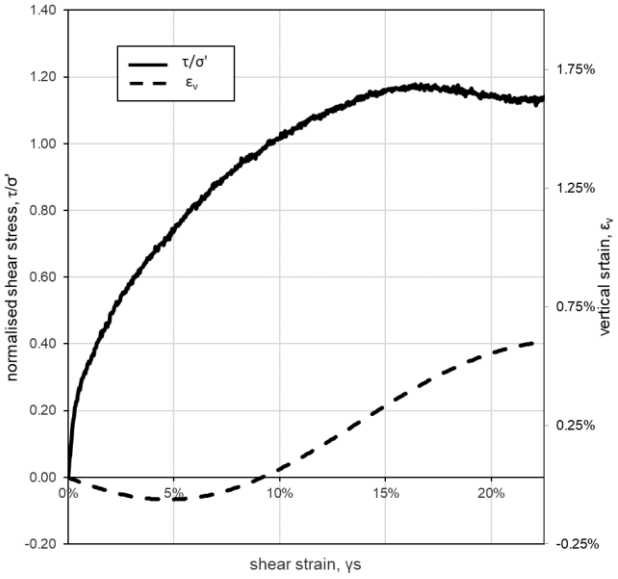

Figure 4. Sample behaviour during shearing.

3.3 Determination angle of friction, φ'

The peak shear stress and vertical effective stress for each of the six tests are plotted in Figure 5 from which it is possible to calculate the angle of friction for the 6F5 aggregate material. A line of best fit has been drawn (passing through the origin) and this yields an angle of friction of $\varphi' = 47.6°$. The coefficient of determination, R^2, of this line is 0.9923. Given the scale and variability of the material over the six tests this is considered to be a very good fit to the Coulomb friction model. This is demonstrated further by a confidence interval of $\varphi_{90}' = 47.6° \pm 2.1°$ at the 90% confidence level, which is also plotted in Figure 5.

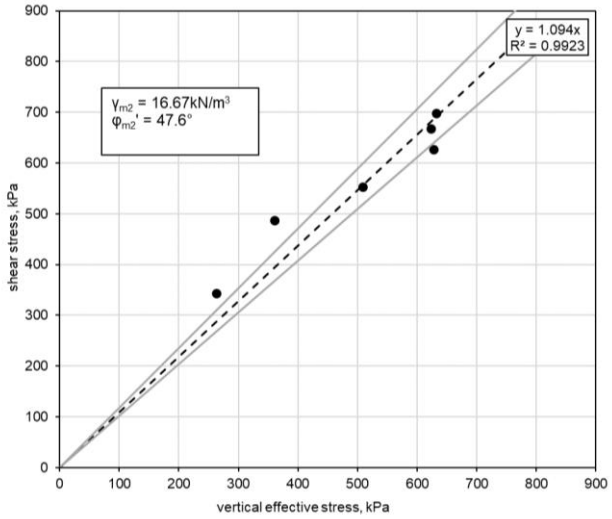

Figure 5. Peak angle of friction from six Giant Shear Box tests.

4 CONCLUSIONS

In geotechnical design it is important to characterise accurately the material properties of any aggregate to guarantee safe, economical solutions. In this paper a series of Giant Shear Box tests were carried out at City, University of London with SCS Railways to ascertain the characteristic angle of friction, φ', of recycled 6F5 aggregates.

Six tests were conducted at a range of vertical stresses on the recycled 6F5 aggregate taken from some HS2 construction sites. Each test used approximately 3.5 tonnes of material and showed a very consistent set of results.

The results indicate the characteristic angle of friction, φ', was found to be 47.6° and with a confidence interval of $\varphi_{90}' = 47.6° \pm 2.1°$ at the 90% confidence level. Although the quality of the material was considered to be a "medium" level of control (i.e. test results reviewed by designer together with regular inspection and maintenance, as specified in TWf, 2019), the material showed a higher value than the 45° generally accepted as the maximum value specified in current guidance. This angle of friction, φ', if adopted during the design phase, has the potential to reduce the tracked plant platform thickness and potentially have a saving in terms of material, cost and carbon.

ABSTRACT: The effective design, specification and construction of geotechnical assets or Special Geotechnical Measures (SGMs) is critical to the efficient operation of the National Highways Strategic Road Network (SRN) in England. Given the required performance of the SRN in terms of resilience, reliability, redundancy and recovery it is essential that SGMs are themselves reliable in terms of performance and life; resilient to external conditions such as earthworks deterioration and extraordinary conditions (e.g. climate change). Around 100 different types of SGMs are used on the SRN and the early installations of some SGMs are approaching the end of their design life and the design, specification and application of many of these techniques is based on limited studies. A series of forensic examinations of gabion walls in various settings on the SRN was undertaken and the results used to develop advice on the design, construction, inspection, maintenance and decommissioning of such structures and to make a series of recommendations on their future use. Principle amongst these is that the evidence suggests that when properly designed, specified, constructed and maintained, including an appropriate inspection regime, Gabion Walls can meet the required design life of such SGMs.

RÉSUMÉ: La conception, la spécification et la construction efficaces d'actifs géotechniques ou de mesures géotechniques spéciales (SGM) sont essentielles au fonctionnement efficace du réseau routier stratégique national (SRN) en Angleterre. Compte tenu des performances requises du SRN en termes de résilience, de fiabilité, de redondance et de récupération, il est essentiel que les SGM soient eux-mêmes fiables en termes de performances et de durée de vie; résistant aux conditions externes telles que la détérioration des terrassements et les conditions extraordinaires (par exemple, le changement climatique). Environ 100 types différents de SGM sont utilisés sur le SRN et les premières installations de certains SGM approchent de la fin de leur durée de vie et la conception, la spécification et l'application de bon nombre de ces techniques sont basées sur des études limitées. Une série d'examens médico-légaux des murs de gabions dans divers contextes sur le SRN a été entreprise et les résultats ont été utilisés pour élaborer des conseils sur la conception, la construction, l'inspection, l'entretien et le démantèlement de ces structures et pour formuler une série de recommandations sur leur utilisation future. Le principe parmi ceux-ci est qu'il n'y a aucune preuve convaincante que lorsqu'ils sont correctement conçus, spécifiés, construits et entretenus, y compris un régime d'inspection approprié, les murs de gabions ne peuvent pas respecter la durée de vie requise de ces SGM.

Keywords: Geotechnical; asset; retaining; wall; gabion.

1 INTRODUCTION

This paper provides a brief summary of a study that investigated gabion walls. Typically, Gabion Walls are used on the Strategic Road Network (SRN) as relatively low height (generally less than 5m high) retaining walls at the toe of embankments, often to reduce land take. They are often, but not always, adopted during the construction phase to deal with unforeseen site constraints as they arise. This can lead to rapid decision-making and an apparent lack of design and/or construction control and supervision.

This work forms part of a wider study (Duffy-Turner et al., 2022a) of the performance of geotechnical asset types, known as Special Geotechnical Measures (SGMs), including gabion walls (Duffy-Turner et al., 2022b), block walls (Winter et al., 2022), counterfort drains (Nettleton et al, 2022) and soil nails (Duffy-Turner et al., 2022c).

An account is given of issues identified from gabion wall inspections on the SRN along with issues for their design, construction, inspection, maintenance and recommendations for their future use.

2 ISSUES IDENTIFIED

Two types of gabion baskets were observed on the network: woven gabions and welded mesh gabions. Welded mesh gabions were more prevalent with nine out of 13 identified during the inspections. A wide variety of issues were identified with both types of gabion walls, and these included but were not restricted to the issues that follow.

A wide range of stone fill materials was observed, ranging from a granite, that clearly conformed to the requirements of the Manual of Contract Documents for Highway Works (MCHW), to a shale (argillaceous) that did not and was showing significant signs of deterioration. Other seemingly unsuitable fill materials observed included chalk and waste-derived concrete, asphalt and brick.

The fill used in the gabion baskets pictured in Figure 1 is also oversized compared to the allowable limit in the MCHW. This undoubtedly contributed to the overall unsatisfactory condition of the baskets which were observed to be barely containing the fill due to distortion and breakage of both the wire and the fastenings. The embankment slope retained by the gabion wall was observed to be moving which may be, in part, attributed to loss of support from the gabion below.

Figure 1. Oversize concrete fill leading to large voids within the gabion baskets. The oversize fill also means that the gabions have been unable to be properly sealed along the top, instead they are secured at pinch points where the fill allows (A42).

Other than where carefully placed, the use of oversized stone was associated with significant voids; voids were also associated with undersized material that could be readily removed from the baskets.

One issue that was observed for welded mesh baskets, but is relevant to both types, is that large voids can be created if filling of the baskets is not undertaken with great care. This can lead to movement of the fill within the basket during the service life putting undue strain on the mesh and the system used to join the panels of the baskets.

Significant corrosion was observed in a series of baskets that were placed in a marine environment. The damage was significant and in places the loss of fill exceeded 80% rendering the SGM ineffective in fulfilling its support function (Figure 2). While gabions can be used in marine environments care is required, especially in active tidal areas which can be challenging for all SGMs, and this indicates the importance of the correct specification selection for gabions and the materials they are formed from.

Figure 2. Gabions used within a marine environment leading to significant corrosion and loss of fill. (A27/M3 Junction).

Both galvanised and plastic-coated corrosion protection were observed and both good and bad instances were observed of each. The poor examples showed damage (possibly caused during transport, construction or in service) to the galvanised and plastic corrosion protection and on some of the welded baskets this could be peeled off using the observer's fingers without difficulty (Figure 3). Corrosion or damage to the corrosion protection was not observed on any of the woven baskets, albeit that the majority of the baskets inspected were of welded mesh. Clearly the loss of corrosion protection, is something of a problem in terms of durability and resilience with both the level of protection offered and the expected life of the wire reduced.

Significant apparent vandalism was also observed at two separate locations; vandalism was observed where the mesh appeared to have been cut and this had led to loss of fill and corrosion of the wire. Similarly, vehicle overrun appeared to be the cause of the damage

to another gabion wall (Figure 4) which was located in a layby alongside a dual carriageway.

Figure 3. Coating peeling away from the mesh on a welded gabion basket (A453).

Figure 4. Vehicle overrun appears to be the primary cause of the significant damage to low height Gabion Wall at this location (A453).

Notwithstanding the issues outlined above, gabion walls can be a resilient form of structure and can be beneficial in terms of the accommodation of movements without reaching either their serviceability or ultimate limit states. In the majority of cases, even where issues were observed, the overall gabion walls were performing as intended and this is one of the strengths of such SGMs.

3 DESIGN

The most comprehensive source of design guidance for gravity retaining walls (UK) is the British Standard BS 8002 the Code of Practice for earth retaining structures (BSI, 2015). When it comes to specifications the guidance is clear, with several sources of information for mesh products and geotextiles being available.

Design of gabions needs to take into account a number of different elements and these include layout of the baskets, type of gabion required (i.e. woven or welded), details of the wire and corrosion protection, type and size of fill and how it should be placed, the use of filter geotextiles and the environmental setting.

4 CONSTRUCTION

Some construction guidance is available for Gabion Walls in the British (BSI, 2015) and MCHW; however, this is not particularly comprehensive as it typically refers to the manufacturer's installation instructions. The manufacturer's instructions tend to be detailed and further guidance is readily available from them if required. The majority of manufacturers will also provide on-site advice.

Gabion units should be constructed to maintain tightness of mesh and, if woven, should be laced securely with wire. During construction, internal tie wires (bracing) should be inserted, and units tensioned in accordance with the manufacturer's instructions; failure to do can result in deformed gabions.

The rock fill placed in a gabion basket is integral to the durability of the wall and filling must be undertaken with care so as not to damage the baskets and the associated corrosion protection and also to ensure that the fill is placed such as there are no significant voids and that materials cannot escape or be removed from the exposed mesh face(s): e.g. baskets have been observed with incorrectly secured panel joins and significant voids.

Adequate and competent personnel for construction and supervision are essential for what is often an artisanal form of construction.

5 MAINTENANCE AND INSPECTION

Inspection and maintenance (and demolition) of the structure or SGM should be considered throughout the design, specification and construction process and plans should be prepared and incorporated into handover documentation.

Visual assessments will, in almost all cases, be the most likely mode of inspection and will require the application of sound engineering judgement. Gabion Walls shall be assessed qualitatively; however, it is noted that quantitative judgements are difficult since conditions will vary greatly with the quality of fill used, type of basket, age, subsoil conditions, drainage, geometry, weathering factors and local expectations. Things to inspect should include, but not be limited to, condition of the baskets and stitching or clips, type of corrosion protection and its condition, type and condition of the fill including weathering details, signs of bulging, leaning or spilling, existing loads and the condition of the retained slope, presence of vegetation

and environmental stresses such as vehicle impacts or surface water.

6 CONCLUSIONS AND RECOMMENDATIONS

Based on the walls inspected, which ranged from eight to 46 years old, the evidence suggests that when properly designed, specified, constructed and maintained, including an appropriate inspection regime, Gabion Walls can meet the required design life (120 years) of such SGMs. This is especially so when manufactured gabions are used in accordance with the manufacturer's recommendations.

Advice in standards and other related documents for Gabion Walls is well defined in some areas (such as specification) and limited in others (such as construction), which rely heavily on the manufacturer's own guidance. Through the course of this work a number of key issues have been identified and these are set out as recommendations below:

Recommendation 1: The most appropriate Gabion Wall type (woven or welded mesh) is selected for its application.

Recommendation 2: That the use of a filter/separator behind the wall should be required in all cases unless specific conditions allow for its omission.

Recommendation 3: That modifying gabion baskets on site shall be reserved for only those instances in which recognised manufacturers cannot produce a prefabricated suitable solution. Any modifications should be done in accordance with manufacturer's instructions and will require agreeing as part of the technical approvals process.

Recommendation 4: As part of the technical approval process, it should be ensured that a Gabion Wall solution is the most appropriate for the environment. This includes careful consideration before designing Gabion Walls within marine and especially tidal environments; adjacent to public footpaths where vandalism is a possibility; and low-height gabions placed in location where vehicle over-run is likely.

Recommendation 5: Gabion fill which does not meet the requirements of the MCHW should not be used on site unless there is a specific aesthetic requirement. Any deviations, including materials potentially susceptible to weathering, should be discussed in advance and agreed as part of the approvals process.

Recommendation 6: Issues identified during the site inspections highlighted that double corrosion protection was not always used and that the wire may be thinner than required; therefore, it is apparent that further enforcement of the specification is required by the Works Examiner.

Recommendation 7: Contractor self-certification of SGMs is not recommended. Observations on the SRN and of the wider UK infrastructure portfolio have found the self- certification process to be suboptimal.

Recommendation 8: Any inspections for the acceptance of constructed Gabion Walls should be undertaken prior to the site becoming fully operational and while items are visible and remedial measures can be readily implemented; and it is recommended that provision for early inspection should be built into the contract.

Numerical modelling of suction bucket foundations subjected to axial loading

Modélisation numérique de fondations à godets aspirants soumises à un chargement axial

ABSTRACT: In multi-caissons foundations, the overturning moments are crucial for the design. The foundation resists to those moments through compression and tension. The tensile capacity of the upwind caisson should be considered in the design. To investigate this tensile behavior, numerical analyses are performed in PLAXIS 2D using a constitutive model which combines a Mohr-Coulomb failure criterion with the concept of state-parameter for sands. Initially, the tensile capacity of the suction bucket in fully drained and undrained conditions is investigated. The suction bucket is pulled out by applying small displacements, until its ultimate capacity is reached. Different values of densities are examined to monitor their effect on the ultimate capacity of the foundation. A parametric coupled consolidation analysis is then performed to study the impact of the permeability of the soil and of the pull-out rate. It is observed that the fully drained and undrained conditions constitute, respectively, the lower and upper boundaries of the ultimate tensile capacity of the foundation. The higher densities lead to higher tensile capacities. With faster loading rates and lower permeabilities, the response of the suction bucket approaches the undrained capacity, as suction is developed beneath the bucket.

RÉSUMÉ: En ce qui concerne les fondations à caissons multiples, les moments de renversement sont cruciaux pour la conception. La fondation résiste à ces moments par la compression et la tension. Cette capacité de traction du caisson en amont doit être prise en compte. Pour étudier ce comportement de traction, des analyses numériques sont effectuées dans PLAXIS 2D, en utilisant un modèle constitutif qui combine un critère de défaillance de Mohr-Coulomb avec le concept d'état-paramètre pour le sable. Premièrement, la capacité de traction du caisson dans des conditions entièrement drainées et non drainées est étudiée. Le caisson est retiré en appliquant de petits déplacements, jusqu'à ce que sa capacité ultime soit atteinte. Différentes valeurs de densités sont examinées pour surveiller leur effet sur la capacité ultime de la fondation. Une analyse paramétrique de consolidation couplée est ensuite réalisée pour étudier l'impact de la perméabilité du sol et du taux d'arrachement. Il est observé que les conditions entièrement drainées et non drainées constituent, respectivement, les limites inférieure et supérieure de la capacité de traction ultime de la fondation. Les densités plus élevées conduisent à des capacités de traction plus élevées. Avec des taux de chargement plus rapides et des perméabilités plus faibles, la réponse du caisson se rapproche de la capacité non drainée, étant donné qu'une aspiration se développe sous le godet.

Keywords: Suction bucket; suction caisson; offshore wind turbine, axial loading; tensile.

1 INTRODUCTION

Climate change constitutes one of the most challenging problems that our world has to deal with. Most of the countries have set the ambitious target of a net zero carbon footprint by 2050, in order to contribute to sustainability and to environmental protection. This target leads more and more to the use of renewable sources of energy as a replacement to fossil fuels. Offshore wind energy has gained in popularity during the last decades. The most common type of offshore foundation is a monopile, particularly for relatively shallow waters. Alternatively, a suction caisson, which is essentially an upturned bucket, can be used as part of the foundation system for offshore wind generators. In effect, in deeper waters, where the loads are higher and the turbines are larger, multiple caisson foundations can be used in tripod or tetrapod structures which include, respectively, three or four caissons. For offshore wind generators, the most important loads are the horizontal forces from waves, currents and wind and the overturning moments that these loads apply to the foundation. The latter are resisted by developing tension and compression forces

on the upwind and downwind legs of the structure (Byrne et al., 2002). In this paper the tensile behaviour of the upwind bucket is investigated by conducting parametric numerical analysis in PLAXIS 2D.

2 NUMERICAL MODEL

2.1 Geometry of the problem and ground conditions

The dimensions of the foundation were chosen so as to depict a realistic structure. The diameter (D) of the caisson is 8 m, while the length (L) of the skirt is equal to 4 m (L/D = 0.5). The thickness of the lid (t_{lid}) is 0.2 m and that of the skirt (t_{skirt}) is chosen as 0.05m. The skirt's thickness to diameter t_{skirt}/D ratio is, therefore, 0.625%. Due to the geometry and loading characteristics of the problem, axisymmetric numerical models were used in PLAXIS 2D.

The region modelled extends 44m (5.5D) from the axis of symmetry, while the bottom boundary of the domain is located at a distance of 40 m (10L) below the tip of the skirt. Such dimensions were observed to eliminate any boundary effects. The soil domain was discretised using 15-noded triangular elements, whereas the bucket was simulated using plate elements. The soil-structure interaction was modelled using interface elements, where the normal and shear stiffness values were adopted as $K_N = K_S = 10^6\ kN/m^3$. A Mohr-Coulomb failure criterion was employed to describe the strength of the interface, with an angle of shearing resistance matching that of the soil at Critical State, i.e. $\phi_{interface} = \phi_{CS} = 32°$ (see section 2.2).

A single layer of Dunkirk sand (see Zdravkovic et al. (2020) for additional information on this material) with the groundwater table at the surface (to correctly modelled the effective stress) was considered. The coefficient of earth pressure at rest, K_0, was assumed to be 0.47 ($= 1 - \sin\ \phi_{CS}$).

2.2 Materials and constitutive modelling

The soil was simulated using the IC MAGE M02 model (Taborda et al., 2021), implemented as a PLAXIS User-Defined Soil Model. This model combines a non-associated Mohr-Coulomb failure criterion with the state-parameter framework proposed by Been and Jefferies (1985). Thus, the strength and dilatancy of the material are direct functions of the state parameter, defined as $\psi = e - e_{CS}$ where e_{CS} denotes the void ratio at Critical State for the current mean effective stress level. According to this model, for denser-than-critical samples, i.e. $\psi < 0$, the peak strength of the material is larger than that at Critical State, with the material exhibiting plastic dilatancy. As the sample approaches Critical State, $\psi \to 0$, the available strength reduces to that at Critical State (quantified simply by ϕ_{CS}) and the dilation decreases to 0. Full details on the formulation of this model are given in Taborda et al. (2022). Within the elastic region, soil behaviour is defined by a hypoelastic model, according to which the shear modulus depends on void ratio, mean effective stress and deviatoric strain (Equation 1).

The selected constitutive model was calibrated for Dunkirk sand and validated by successfully reproducing the field tests on large diameter monopiles performed as part of the PISA project. The full set of parameters is listed in Table 1. The suction bucket's material is steel, with a unit weight of γ_{steel} = 78.5 kN/m^3, Young's modulus of E_{steel} = 200 GPa and a Poisson's ratio of ν = 0.3. It is assumed that it behaves elastically.

$$G_{max} = G_0 \frac{1.0}{0.3+0.7 \cdot e^2} \left(\frac{p'}{p'_{ref}}\right)^{0.5} \qquad (1)$$

Table 1. IC MAGE M02 parameters for Dunkirk sand.

Parameter	Value	Parameter	Value
Plastic behaviour		*Elastic behaviour*	
$e_{CS,ref}$	0.91	G_{ref}	88.6 MPa
λ	1.05	m_G	0.5
ξ	0.19	ν	0.17
ϕ_{CS}	32°	a	4E-04
k_1	1.5	b	1.40
k_2	-0.2	R_G	0.10
l_1	4.3	p'_{ref}	101.3 kPa
l_2	0.2		

2.3 Loading and type of analysis

The suction bucket is pulled upwards by applying a prescribed displacement at the centre of the lid until the maximum capacity is reached.

At first, fully drained and undrained elastoplastic analyses were performed to characterise the response of the suction bucket under these two limiting conditions. Different values of relative density (D_R = 60%, 75% and 90%) were also examined to assess the effect of the density on the tensile capacity of the foundation. Following that, a set of coupled consolidation analyses were performed. These analyses were performed for D_R = 75% and different values of permeability (k = 10^{-3}, 10^{-4}, 10^{-5} and 10^{-6} m/s), which were combined with various pull–out rates, in order to assess how close each combination of parameters was to drained and undrained conditions.

3 RESULTS

3.1 Drained and undrained conditions

The capacity curves for both drained and undrained conditions are depicted in Figure 1. As expected, the capacity in the undrained cases (dashed lines) is higher than that in the drained cases (solid lines) because in the latter the basic resistance of the suction bucket to the upward moving derives solely from the side friction developed inside and outside the skirt (Houlsby, Kelly & Byrne, 2005). As a result, the full capacity mobilises at very small displacements, with the lid of the suction bucket quickly losing contact with the foundation soil. Conversely, in undrained conditions, the resistance of the suction bucket to the upward movement is controlled by the suction within the soil that develops due to the tensile loading, which in this case was limited to a maximum negative pressure of 100 kPa. Therefore, the full separation between the bucket and the soil requires considerably larger displacements than those observed for the drained analysis, with a much higher capacity being mobilised. Clearly, the effect of the relative density of the soil is almost unnoticeable when the strength of the interface is assumed to be independent of the characteristics of the surrounding soil. This is in agreement with the fact the tensile axial capacity is controlled predominantly by the strength of the interface. Additional analysis, where the value of $\phi_{interface}$ was adjusted to reflect the changes in peak strength resulting from increases in relative density, showed a considerable spread in tensile capacity (Figure 2). These are described in Eleftheriou (2021) but are not reported herein for brevity.

3.2 Coupled consolidation analysis

3.2.1 Effect of pull-out rates

Fully coupled consolidation analyses were also conducted as part of this study, which required the definition of hydraulic boundary conditions. These consisted of considering the axis of symmetry as 'closed', thus preventing flow through it, whereas the top of the soil mass was assumed to remain at constant head, implying that water could flow across it as needed. Assuming a relative density of 75% and a relatively low value of soil permeability ($k = 10^{-6}\ m/s$), 6 different coupled consolidation analyses were performed. In each analysis, the maximum vertical displacement applied was 20 mm, with the duration per loading phase controlling the pull-out rate in mm/s, which varied between 0.000012 mm/s (or 1 day/mm) and 0.14 mm/s (or 0.00008 days/mm).

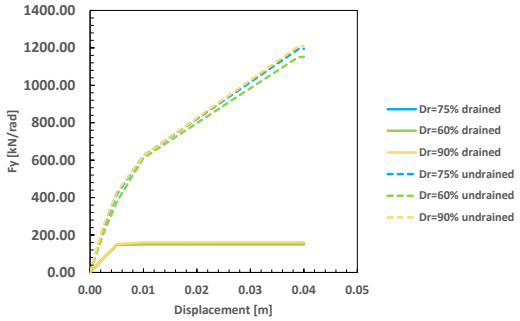

Figure 1. Comparison of capacity of drained and undrained conditions for different values of density.

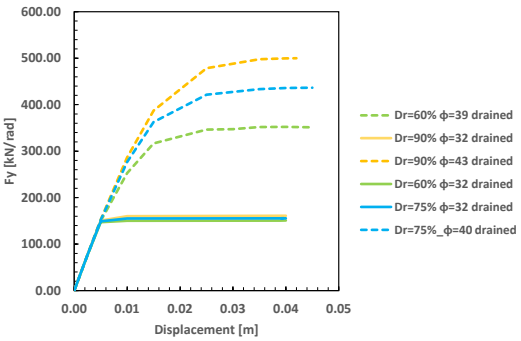

Figure 2. Capacity curves of the buckets for different values of density and different values of angle of shearing resistance at the interface – drained conditions.

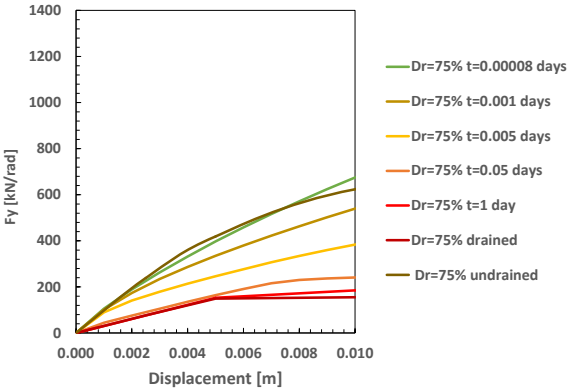

Figure 3. Tensile capacity of the suction bucket for different pull-out rates and a permeability of 10^{-6} m/s.

As shown in Figure 3, when the bucket was pulled out at the fastest rate (green line), the modelled response was similar to that of the fully undrained analysis. As the rate of loading decreases, the behaviour of the foundation approaches that observed for drained conditions (dark red line). Clearly, the tensile capacity increases as loading rate increases, while a higher displacement is needed in order for the tensile capacity to be fully mobilised.

3.2.2 Effect of permeability

Clearly, the transition from drained to undrained is not solely a function of the loading rate, with the permeability having a crucial role. For two distinct

pull-out rates (0.002 mm/s or 0.005 days/mm, and 0.14 mm/s or 0.00008 days/mm) different values of permeability were examined, covering the range typically observed for sand deposits: 10^{-6} m/s, 10^{-5} m/s and 10^{-4} m/s.

The obtained results are shown in Figure 4 (slow pull-out rate) and Figure 5 (fast pull-out rate). It is interesting to note the combined effects of the permeability and loading rate: for the larger pull-out rate, a permeability of 10^{-6} m/s was sufficiently low to guarantee undrained conditions. However, for the lower pull-out rate, this value of permeability leads to a response between those observed in the drained and undrained analyses. Similar patterns can be observed for the other values of permeability.

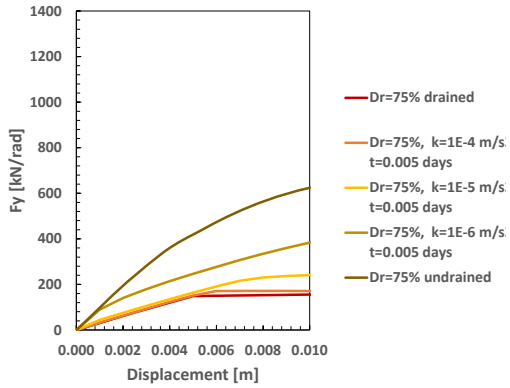

Figure 4. Tensile capacity of the suction bucket for different values of permeability (loading rate = 0.002 mm/s).

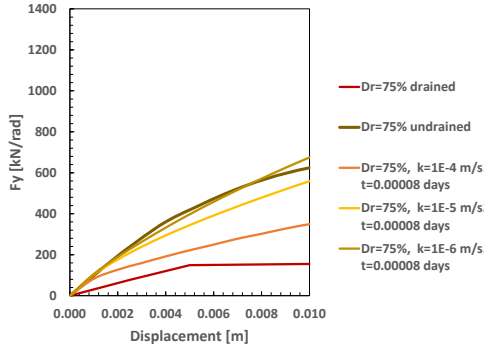

Figure 5. Tensile capacity of the suction bucket for different values of permeability (loading rate = 0.14 mm/s).

4 CONCLUSIONS

The objective of this paper was to determine the role of density, loading rate and permeability in the tensile capacity of a suction bucket, founded on a dense sand (Dunkirk sand). The obtained results show that the tensile axial behaviour of the suction bucket is primarily controlled by the characteristics of the interface. As a result, the density of the soil has negligible effect on the modelled response unless the changes in soil strength are reflected on that of the interface. As expected, the simulated behaviour is highly affected by the drainage conditions, with the undrained response being characterised by considerably higher capacity. Therefore, the balance between pull-out rate and permeability needs to be considered carefully as the two control the ability to prevent the build-up of negative pore water pressures below the lid. Both low pull-out rates and high permeability provide opportunity for water to flow around into the area beneath the lid, leading to conditions closer to those in drained analyses.

ABSTRACT: The cyclic behavior of pile foundations is studied using the Discrete Element Method (DEM) through simulated centrifuge experiments. The centrifugal acceleration enables reproducing real-scale problems on reduced models, while DEM provides access to microscopic information on the particles-structure interactions. First, a discrete model based on spherical particles involving elasticity, friction and rolling resistance is calibrated against monotonic, drained triaxial tests to reproduce the behavior of Fontainebleau NE34 sand. Then, the cyclic response of the material is evaluated by means of cyclic triaxial tests. Finally, the model is applied to a quasi 2D simplification (semi-infinite plate with periodic boundary conditions) of the behavior of a pile foundation. After an investigation of the effect of sample size and boundary conditions, the study tests different pile jacking techniques, monotonic and cyclic strokes, exploring their impact on the total of the shaft and tip resistance of the pile. The importance of installation velocity is investigated for each technique. The geometry of future experiments in the geotechnical centrifuge is presented in this work and used as a basis for the numerical simulations. In conclusion, this research provides important information about the impact of different modes of installation on pile foundation behavior.

RÉSUMÉ: Le comportement cyclique des fondations sur pieux est étudié à l'aide de la méthode des éléments discrets (DEM) au moyen d'expériences simulées en centrifugeuse. L'accélération centrifuge permet de reproduire des problèmes à échelle réelle sur des modèles réduits, tandis que le DEM donne accès à des informations microscopiques sur les interactions particules-structure. Dans un premier temps, un modèle discret basé sur des particules sphériques impliquant élasticité, frottement et résistance au roulement est calibré sur des essais triaxiaux drainés monotones pour reproduire le comportement du sable de Fontainebleau NE34. Ensuite, la réponse cyclique du matériau est évaluée au moyen d'essais triaxiaux cycliques. Enfin, le modèle est appliqué à une simplification quasi 2D (plaque semi-infinie avec conditions aux limites périodiques) du comportement d'une fondation sur pieux. Après une étude de l'effet de la taille de l'échantillon et des conditions aux limites, l'étude teste différents types de techniques de fonçage de pieux, à coups monotones et cycliques, en explorant leur impact sur la résistance totale du fût et de la pointe du pieu. L'importance de la vitesse d'installation est étudiée pour chaque technique La géométrie des futures essais dans la centrifugeuse géotechnique est présentée dans ce travail et sert de base aux simulations numériques. En conclusion, cette recherche fournit des informations importantes sur l'impact des différents modes d'installation sur le comportement des pieux.

Keywords: DEM simulations; pile jacking; fontainebleau sand NE34; centrifuge modelling.

1 INTRODUCTION

Wind turbines play a significant role in the generation of renewable energy and have several important advantages. However, it is essential to recognize the challenges that arise throughout the implementation process. One technique that is often used for the installation of such structures is pile jacking. Applying quasi-static stress cycles to jack the pile in the ground is one method of installation. Studies on different techniques for pile jacking using centrifuge model testing are previously done by El Haffar et al. (2017); Blanc et al. (2019). Interesting results revealed a significant difference between piles installed at 1g and at 100g. Three times higher resistance in compression

was recorded for piles jacked at 100g. Differences were also seen between piles jacked monotonically and those jacked cyclically (by a series of strokes). The tip capacity in compression decreased, while the pull-out capacity showed a clear tendency to increase with the increasing number of installation strokes.

Numerous studies have explored the effects of cyclic loading using discrete element method (DEM) (Cundall and Strack, 1979) simulations such as the work by Jiang et al. (2019); Zorzi et al. (2017), that studied the behavior of model sands during a cyclic triaxial loading path. Other studies have demonstrated the ability of DEM to model soil-structure interactions (Ciantia et al., 2019; Arroyo et al., 2011). Moreover, Zhang and Wang (2015) used DEM to simulate monotonic pile jacking at increased acceleration to simulate and compare with experiments in the geotechnical centrifuge.

The capability and constraints of DEM for simulating soil structure problems need to be fully explored through further research. For this purpose, this work studies the effect of sample and particle size as well as the installation speed on the response of a quasi-two-dimensionally simplified pile foundation installed under centrifugal acceleration, with monotonic and cyclic strokes. The geometry of experiments from the geotechnical centrifuge are shown as a basis for the numerical simulations that will later be used for similar experiments aiming to confirm the validity of the DEM model.

2 EXPERIMENTAL SETUP

The experimental setup of the centrifuge model, which is used as a reference for the simulations, is detailed in Figure 1. The setup comprises a container of dimensions 800x450x200mm with one transparent side made of plexiglass enabling the visual observation of the soil during installation followed by PIV analysis. To allow this observation around the pile as well as the comparison with the numerical model, a wall is taken as a quasi 2D pile of width 16mm, depth of 224mm and thickness of 200mm. Dry Fontainebleau NE34 sand is deposited in the container by air pluviation, aiming to achieve a relative density (D_r) of 68% up to a depth of 400mm. The material properties of NE34 are documented in Andria-Ntoanina et al. (2010).

During the tests, a centrifugal acceleration of 25 times gravity is applied. The model wall is installed at a velocity of 0.1 mm/s. Both the wall and the soil are instrumented with sensors to measure the total stress exerted within the system during the tests.

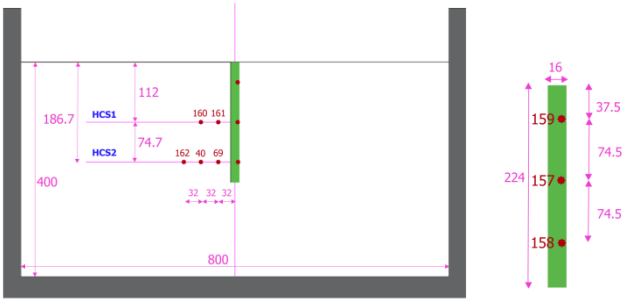

Figure 1. Experimental setup showing the model wall and the positions of total stress sensors in the sand and on the wall shaft.

3 DEM MODEL

A quasi 2D model pile is installed in a material that is calibrated to reproduce the behavior of NE34 using YADE, an open-source software developed by Kozicki and Donze (2009). The numerical model used is a classical linear contact law with Mohr-Coulomb plasticity surface and a moment that resists rolling to account for real particle shape when using spheres. The model description and calibration process are found in Ezzeddine et al. (2023), while the parameters used are presented in Table 1.

Table 1. Calibrated parameters of the contact model.

E (MPa)	α	φ (°)	α_r	η_r	Density (kg/m^3)
500	0.3	24	0.1	0.4	2650

The sample is generated with periodic boundary conditions on the horizontal directions and a rigid wall serving as a boundary at the bottom of the sample depth while keeping a free surface at the top. To enhance computational efficiency, the particle size distribution of NE34 is multiplied by a scaling factor denoted as "F". Particles are initially generated within a confined box and left to settle under the influence of gravity. Once they settle and the forces stabilize, a sample of dimensions L, w, and h is prepared as shown in Figure 2. In order to be able to obtain samples with different values of initial porosity, the inter-particle friction angle φ set in YADE is decreased during the preparation process to obtain denser samples.

4 PILE JACKING SIMULATIONS

In order to establish sample boundaries that effectively mitigate any finite size effects, a systematic investigation is done, examining the influence of sample dimensions and particle size.

Samples with varying L and F are generated at a constant $\varphi = 10°$ during preparation. φ is then changed

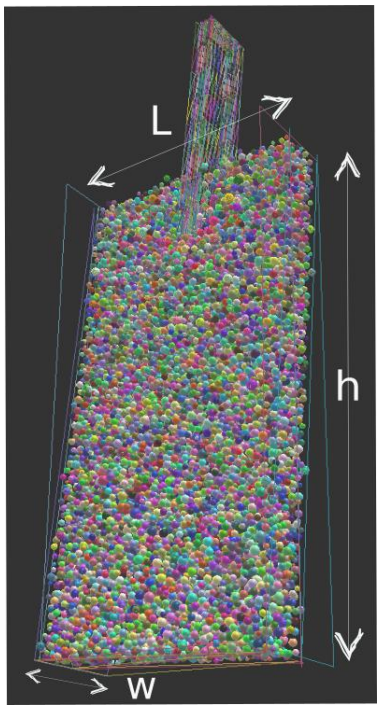

Figure 2. Numerical sample dimensions and boundaries.

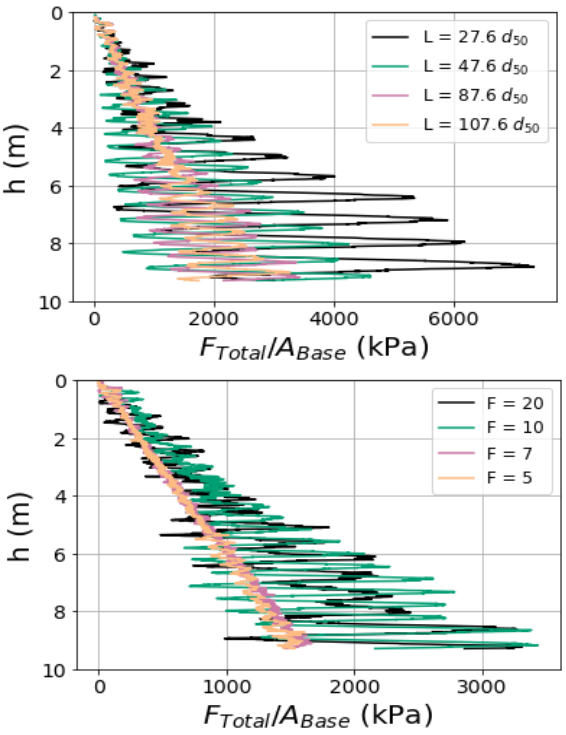

Figure 3. Total normalized force on the wall with depth for varying a) normalized length L/d_{50} b) factor F.

to its calibrated value in Table 1. The resultant average porosity of the sample is maintained at 0.44. The model wall has a width of 16mm, depth 100mm and is infinite on the periodic direction w whose value is taken as the width of the sample $10d_{50}$. To select an appropriate value for w two values, $10d_{50}$ and $20d_{50}$, are initially examined and found to give close results. It is then installed at a velocity v_p such that the ratio of inertial forces to confining forces is $I < 10^{-2}$ for quasi-static conditions (Janda and Ooi, 2016), under an acceleration of 100g, effectively simulating conditions similar to those in a centrifuge experiment. Results are compared in terms of total (tip and shaft) unit resistance to assess the influence of each variable. The results are presented in prototype scale. The total force is normalized by the area of the tip to obtain the unit resistance.

4.1 Effect of dimension L

Four values of L are compared: L/d_{50} = 27.6, 47.6, 87.6, 107.6, where F = 10 and d_{50} = 2.1mm. The results are shown in Figure 3, where it is evident that in the sample with the smallest dimension L, the distance between the walls within the periodic sample is insufficient to avoid their interaction, leading to noticeable fluctuations in the results. As L increases, these fluctuations diminish. Furthermore, it can be observed that the effect of L on pile resistance is more pronounced at greater depths, owing to the fact that the zone of influence of the pile extends with increasing depth. The test with L/d_{50} = 87.6 seems to avoid any significant boundary effects while maintaining a reasonable computational time Let's denote this value of L as «L_1» in further analysis.

4.2 Effect of F

Additional tests are done keeping L_1 and varying F = 5, 7, 10, 20 to investigate the influence of particle size on the pile's response. Strong fluctuations are seen for F = 10, 20. With the decrease of F from 10 to 7, a variation of the pile to grain size ratio shows a clear influence on the behavior. When further decreasing F to 5, no effect is seen.

4.3 Effect of v_p: monotonic and cyclic strokes

The sample with L_1 and F = 7 constituting of 249254 spheres is selected as the reference configuration for the subsequent tests. Three values of jacking velocity (v_p = 0.1, 0.5, 1 m/s) are compared for two cases: monotonic installation and by strokes of 10 mm (1 m prototype scale). The effect of the velocity in the monotonic case is only noticeable at the starting point. It is clearly more crucial for the installation by strokes, where the high fluctuations seen for v_p = 1 m/s, particularly at higher depths decrease but stay visible at v_p = 0.5 m/s, and diminish at v_p = 0.1 m/s. This suggests that, in cyclic jacking, conditions that are more restrictive may be imposed on the criterion for choosing the velocity than in monotonic loading, since jacking by subsequent strokes can induce important force fluctuations.

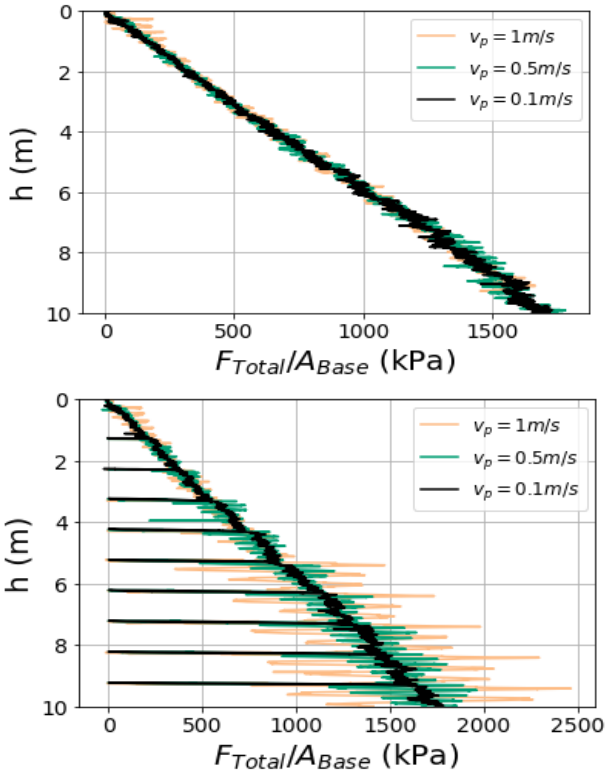

Figure 4. Effect of velocity on the total normalized force on the wall with depth for a) monotonic b) cyclic case.

5 CONCLUSIONS

In this study, the installation of pile foundations is investigated through simulated DEM centrifuge experiments. A simplified 2D representation of a pile is modelled and the effect of model and particle size on the behavior of the quasi 2D model during installation are explored. After deciding on the suitable model dimensions, the effect of jacking velocity on the pile's resistance is checked for the monotonic and cyclic jacking techniques. This work aims to explore the effect of various parameters on DEM's ability to simulate complex geotechnical soil-structure interactions. In the very next future, numerical simulations of the jacking and pullout of the model pile, with the parameters identified in this work, will be performed and compared to the corresponding centrifuge model tests.

ACKNOWLEDGEMENTS

The authors would like to thank the high-performance computing centre of Pays de la Loire (CCIPL) and the European project GEOLAB for their valuable support during the course of this research. The acknowledgments are further extended to Gustave Eiffel University and the Region Pays de la Loire for their financial support through thesis grants.

Mechanical behavior of Ypresian plastic clays

Comportement mécanique des argiles plastiques de l'Yprésien

S. Fanelli*, L. Makki, E. Bourgeois, F. Szymkiewicz, P. Reiffsteck
Université Gustave Eiffel, Champs-sur-Marne, France

**sonia.fanelli@univ-eiffel.fr*

ABSTRACT: Ypresian plastic clays are formations with a complex behavior, particularly due to their anisotropy and their swelling properties, which can make it difficult to interpret the results observed during laboratory or in situ tests campaigns. It is therefore sometimes necessary to use different methods to better understand their mechanical behavior. This communication presents the results of tests carried out in laboratories as part of several projects in the Paris region on Ypresian Clay formation. The soils studied come from deep core drillings taken between 20 and 70 m deep during various geotechnical investigation campaigns. The tests include both static and dynamic tests, making it possible to observe the mechanical behavior evolution of the material according to the stress path used. The different results were achieved using the cyclic triaxial, the resonant column, the shear wave propagation measurements from the Bender Elements, the stress paths and K_0 measurements at the triaxial. An analysis of the decrease in the shear modulus is then carried out, which will feed a rheological model and calibrate it according to the confining pressure.

RÉSUMÉ: Les argiles plastiques de l'Yprésien sont des formations au comportement complexe du fait, notamment, de leur anisotropie et de leur caractère gonflant qui peuvent rendre difficile l'interprétation des résultats obtenus lors de campagnes d'essais en laboratoire ou in situ. Il est donc parfois nécessaire d'avoir recours à différentes méthodes pour mieux comprendre leur comportement mécanique. Cette communication présente les résultats d'essais réalisés en laboratoire dans le cadre de plusieurs projets de la région parisienne sur les formations de l'Yprésien argileux. Les sols étudiés sont issus de sondages carottés profonds prélevés entre 20 et 70 m de profondeur lors de différentes campagnes de reconnaissance géotechnique. Les essais regroupent à la fois des essais statiques et dynamiques qui permettent d'observer le comportement mécanique du matériau en fonction de la sollicitation utilisée. Les différents types d'essais ont été réalisés à partir du triaxial cyclique, de la colonne résonante, des mesures de propagation des ondes de cisaillement aux Bender Elements, des chemins de contraintes et des mesures de K_0 au triaxial. Une analyse de la diminution du module de cisaillement est ensuite réalisée, ce qui permettra d'alimenter un modèle rhéologique et de le calibrer en fonction de la pression de confinement.

Keywords: Ypresian clay; shear modulus; laboratory tests.

1 INTRODUCTION

In urban environnements, modern practices of building construction or large structures can lead to new problems of interaction between soils and structures, particularly when using more fragile materials that can tolerate less strains.

The structures are mainly designed from methods incorporating mechanical characteristics defined by a single type of test and therefore only one mode of loading. However, depending on the actual stress path in the soil, the stiffness observed during the tests may not be realistic. Indeed, depending on the soils properties, the type of structure and its location, applied loads can be different and induce different mechanical responses. In order to identify the most representative test for in situ stresses, it is necessary to compare different methods for evaluating the mechanical parameters of materials. The improvement of the design of the structures through a better evaluation of the response of the soils to low-intensity loads is therefore an important issue.

Since several years, a database of tests carried out on Ypresian plastic clays, concerning Grand Paris Express worksites and other construction projects in the Parisian region, has been collected.

After a brief presentation of the geological context and the location of the sites studied, this communication will present the results of tests that have provided an overall view of the mechanical behavior of these plastic clays. These tests include controlled deformation and stress path triaxial tests, tests to define the earth pressure coefficient at rest K_0, resonant column tests, cyclic triaxial tests and wave propagation velocity measurements with Bender

Elements. We carried out nine monotonic triaxial tests under drained conditions (three specimens each) and 27 under undrained conditions, 15 cyclic undrained tests, 15 resonant column tests, 12 bender element tests, 23 triaxial tests following a specific stress path (drained and undrained), and five tests under K_0 condition.

The results which are presented in the following paragraphs will enable us to define a modulus degradation curve and different mechanical parameters. Then these parameters will be implemented in a finite elements numerical model which will be able to reliably represent the mechanical behavior of the soil nearby a structure.

2 GEOLOGICAL CONTEXT

Plastic clays are part of an impermeable geological formation of fluvio-lacustrine origin identified at the base of the Ypresian (Lower Eocene), called the Sparnacian, which also includes the upper sands, false glaises and Auteuil sands (Filliat et al., 1981).

This formation is framed by Campanian flint chalk (Upper Cretaceous) and Lutetian coarse limestone (Middle Eocene). The plastic clays or "argiles bariolées" are very compact and composed of clays sometimes marbled with various colors ranging from red to gray, bluish, black or yellowish (figure 1). They vary in thickness from 8 to 12 m depending on their location.

Figure 1. Plastic clay samples (Paris15e).

Their main characteristics are their high plasticity (plasticity index over 50) and their sensitivity to water, which gives them a swelling behavior that requires certain precautions to be taken, particularly when sampling them and carrying out experimental studies in the laboratory.

3 LOCATION OF STUDY SITES

The sites studied are part of the Grand Paris Express project, which involves the construction of several metro lines and stations in the Paris region (figure 2). The plastic clays that are the subject of this article are located on line 15 west at La Défense and line 14 south at Paris 13e.

Two other sites are also being studied, related to other construction projects in Paris 15e and Paris 12e.

Soil samples were taken at depths ranging from 20 m to 70 m, depending on location.

4 EXPERIMENTAL ANALYSIS

Various tests were carried out in the laboratory: the drained monotonic triaxial, the cyclic undrained triaxial, the resonant column, measurement of shear wave propagation velocity at the Bender Elements, stress paths in drained and undrained conditions and measurements of the earth pressure coefficient at rest K_0 at the triaxial.

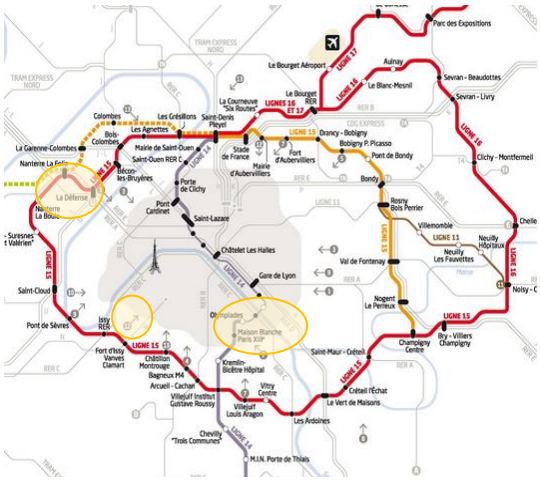

Figure 2. Location of sites studied in Paris region (source www.societedugrandparis.fr).

4.1 Consolidation and swelling of specimens

Assembly, saturation, measurement of Skempton B coefficient and consolidation were carried out in the same way for all specimens except those in the K_0 test, where a cell pressure corresponding to the vertical stress in place was applied with taps closed, in order to limit swelling due to water absorption before the saturation phase. A value of 800 kPa of back pressure was applied.

Consolidation phases were stopped once constant back volume had been achieved. Consolidation times varied from several hours to several days. Tests were then carried out with confining pressures ranging from 200 to 920 kPa, depending on the depth of the samples.

4.2 Triaxial drained and undrained tests

Drained consolidated tests were used to obtain mechanical parameters such as long term cohesion, angle of internal friction and Poisson's ratio with the variation in specimen volume. The results give an

average of 20 kPa for effective cohesion, 15° for the effective internal friction angle, and 0.45 for Poisson's ratio.

4.3 Cyclic triaxial tests

Cyclic tests were carried out with force control and global strain measurement. A loading program was established with 9 loading phases ranging from 2 to 500 kPa, each consisting of 5 cycles starting from a minimum effective axial stress equal to the consolidation stress plus 10 kPa. Some results are shown in figure 3.

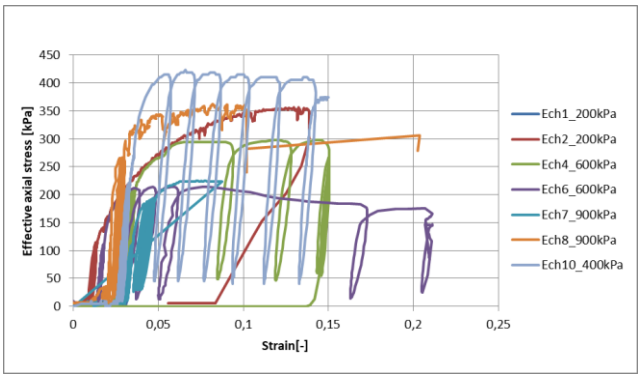

Figure 3. Example of cyclic tests at different confinement.

4.4 Resonant column tests

Resonant column tests were carried out at various confining pressures ranging from 200 to 920 kPa. Shear modulus results were obtained at strain values between 10^{-3} and 10^{-6}. A shear modulus degradation curve was established from the various tests (figure 4).

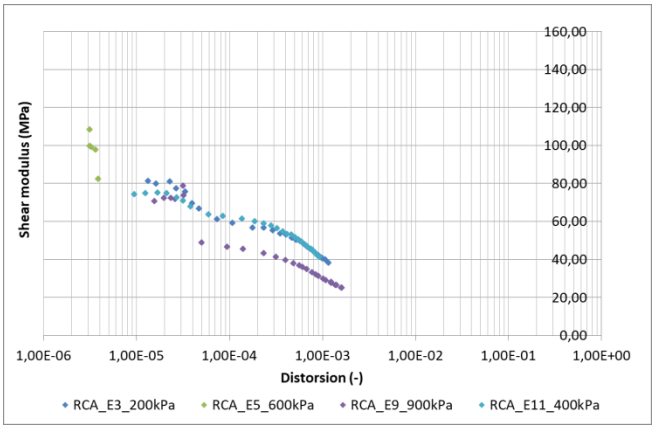

Figure 4. Shear modulus degradation curve for four samples.

4.5 Shear wave propagation tests

Shear wave propagation tests were carried out using a set of Bender Elements at confining pressures ranging from 0 to 900 kPa. Measurements at 0 kPa correspond to the stage before saturation just after installation in the cell. The figure 5 shows an example of a wave propagation test result.

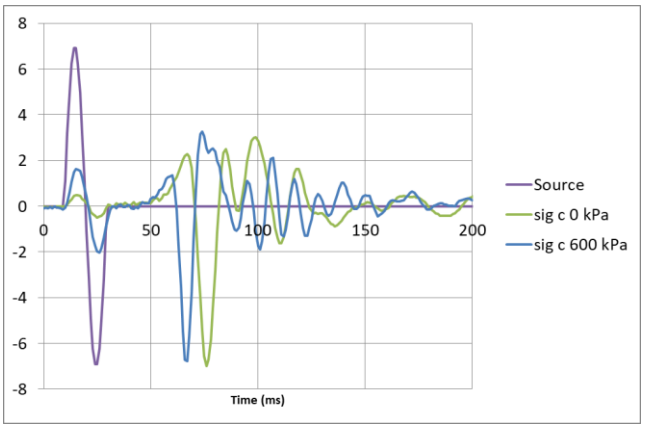

Figure 5. A specimen test results with the Bender Elements.

4.6 Stress paths

Specimens were tested along deviatoric paths according to mean stress p and deviator q in drained and undrained conditions. Two types of path were used for stress path testing. The first one describe the path tests in line with simulations and the life of the structure. The different stages are defined below:

1: geostatic stress state
2: existing loads (loading)
3: unloading/reloading cycle
4: simulation of earthworks (excavation)
5: end of project stresses
6: creep (long term condition)

The second type of stress path test has the same four stages as the first type but the deconfinement is realized until failure.

The curves shown in figure 6 represent the degradation curves of secant modulus observed during these tests.

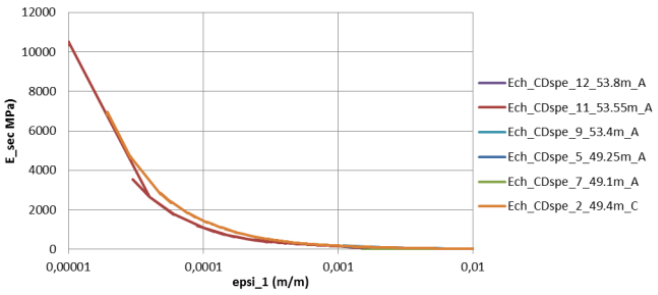

Figure 6. Secant modulus degradation curve for different stress path tests.

4.7 K_0 tests

The earth pressure coefficient at rest K_0 has been extrapolated directly from laboratory tests by imposing a condition of no radial displacement of the specimen. The cell pressure is increased and the axial force is controlled to limit diameter variation.

The figure 7 shows four tests. The K_0 value is close to 1 for three specimens. Another specimen, for which swelling was observed at saturation, shows a higher K_0 value, which then decreases to 1 as it approaches in-place stress.

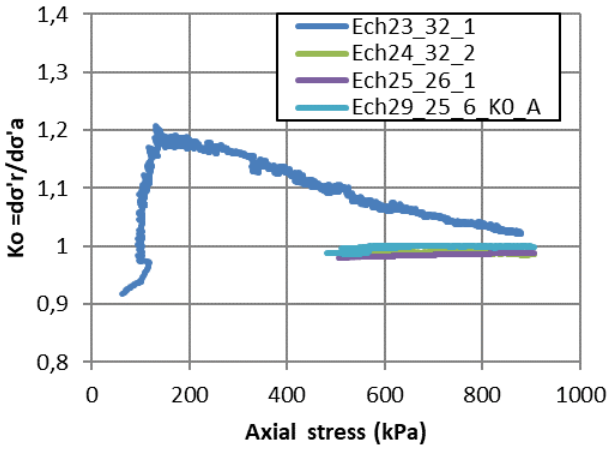

Figure 7. Results of four K_0 tests.

5 RESULTS SYNTHESIS

The different laboratory tests carried out eneabled us to obtain a degradation of the shear modulus, normalized with the G_0 modulus at very low strains, as a function of distortion for each site studied.

The figure 8 shows results of Bender Elements, resonant column and cyclic triaxial tests carried out for the site located in Paris 15^e. It shows a marked decrease in shear modulus for strains of between 0.001% and 0.1%.

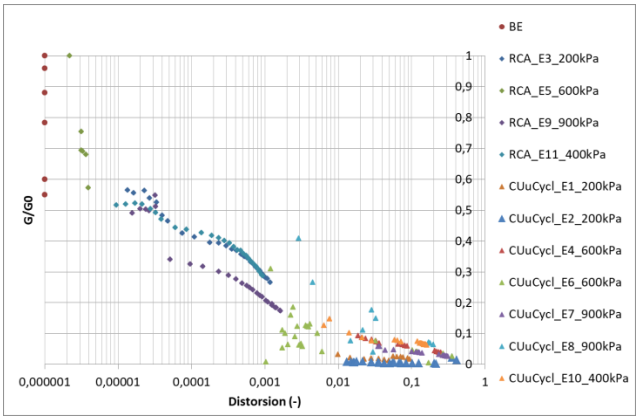

Figure 8. Shear modulus degradation curve on the site Paris 15^e.

The modulus degradation curve will be used to feed a rheological model and calibrate it as a function of confining pressure.

6 CONCLUSION

The tests presented here are used to determine the parameters of a model specifically developed to improve the representation of displacements in finite element simulations of the behavior of specific structures in the Grand Paris station projects, in particular vertical displacements around the structures. At present, it is difficult to know which models are really suitable for modeling structures. The simplest models sometimes provide vertical ground displacements that do not necessarily reflect ground movements observed in reality. It is therefore important to be able to propose a model that aims to take better account of ground behavior on unloading stress paths. The parameters obtained from these tests will then be used to feed a rheological model and calibrate it as a function of confining pressure.

ABSTRACT: The new Lisbon metro line will cross a densely urbanized part of the city, connecting Rato station located at one of the hills of the city and Cais do Sodré station at the Tagus River right bank. Thus, the underground excavation intersects a wide range of materials, from rock mass to soft soils. The new Santos Station will be located partially beneath XIX century buildings with a cover depth of about 15 m, being these structures highly sensitive to differential settlements given its masonry and timber composition with multiple structural pathologies. Given the building conditions, its heterogeneous soil foundation and the level of surface settlements induced by NATM excavation, an underpinning solution was needed aiming to mitigate the buildings potential damages. Hence, high length micropiles, concrete reinforced beams and walls were executed from the building ground floor aiming to transfer buildings loads to the soils located underneath the tunnel excavation. This paper presents an overall description of the adopted solutions, how they were implemented and the buildings' behaviour during the underground works.

RÉSUMÉ: La nouvelle ligne de métro de Lisbonne traversera une partie densément urbanisée de la cité, reliant la gare de Rato, située sur l'une des collines de la cité, et la gare de Cais do Sodré, sur le Tage fleuve. Ainsi, l'excavation souterraine recoupe une large gamme de matériaux, de la masse rocheuse aux sols meubles. La nouvelle station de Santos sera située en partie sous des bâtiments du XIXe siècle avec une profondeur de couverture d'environ 15 m, ces structures étant très sensibles aux tassements différentiels compte tenu de sa maçonnerie et du bois avec de multiples pathologies structurelles. Compte tenu des conditions du bâtiment, de l'hétérogénéité de la fondation du sol et du niveau de tassement de surface induit par l'excavation NATM, une solution de reprise en sous-œuvre était nécessaire afin d'atténuer les dommages potentiels du bâtiment. Par conséquent, des micropieux de grande longueur, des poutres et des murs renforcés en béton ont été exécutés à partir du rez-de-chaussée du bâtiment dans le but de transférer les charges des bâtiments vers les sols situés sous l'excavation du tunnel. Cet article présente une description globale des solutions retenues, de la manière dont elles ont été mises en œuvre et du comportement des bâtiments lors des travaux souterrains.

Keywords: Metro; underpinning; centenary buildings; excavation.

1 INTRODUCTION

The new Lisbon circular metro line will include a new Station in Santos that will be partially located beneath some XIX century buildings with a cover depth of about 15 m, being these structures highly sensitive to differential settlements given its masonry and timber composition while presenting already multiple structural pathologies.

The underground excavation of this tunnel, using the technology known as New Austrian Tunnelling Method, was analysed with numerical models and surface settlements were estimated considering the geological scenario previously accessed. This information was used to evaluate the building vulnerability to those settlements also considering their structural condition and it was concluded the deficient structural conditions of those structures to support the estimated settlements without major damage. Given this scenario, a buildings underpinning solution was proposed mitigating the impact of the underground excavations on those centenary buildings.

2 AFFECTED BUILDINGS

Considering the vulnerability analysis conducted, two buildings with masonry walls and timber floors were classified with a moderated potential damage induced by the underground excavation. Those XIX century buildings have 3 and 5 upper floors and had a superficial foundation (see Figure 1).

Figure 1. Centenary buildings located above de tunnel.

The buildings are located on a hillside on the area where a monastery collapsed due to a strong magnitude earthquake that took place in 1755. Therefore, is it possible that the superficial foundation is located on top of debris fills which worsen its foundation conditions and can justify the differential settlements that were already visible.

Considering this scenario and the settlements estimation from the underground excavation numerical analysis, using Burland's (1997) classification it was concluded that those building, without reinforcement, would potentially suffer moderate to severe damage.

3 MAIN CONSTRAINS

3.1 Geological-geotechnical constrains

The geological investigation campaign included the execution of multiple boreholes that allowed the characterization of the soil units underneath the buildings (see Figure 2). It was possible to confirm that its superficial foundation was on top a 10m thickness Anthropocene fill layer. Bellow that layer, Miocene and Lisbon Vulcanic Complex materials were found showing satisfactory resistance and deformation characteristics.

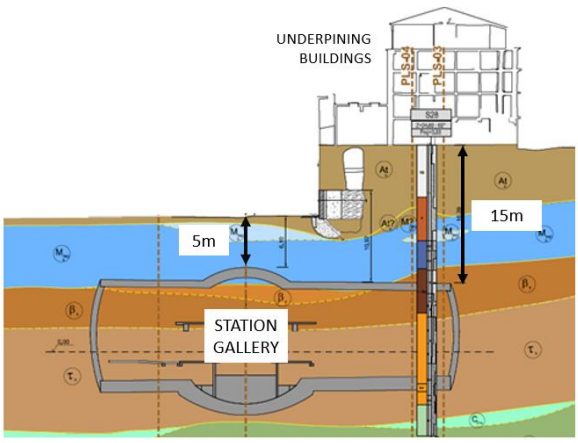

Figure 2. Geological scenario.

3.2 Constructive technologies constrains

The reinforcement solutions must respect the local constraints regarding the accessibility of equipment. Considering the need to work inside the buildings, the solutions must be compatible with equipment that can operate with a minimal ceiling height of about 2,5m.

3.3 Underground works constrains

Underground works consider the excavation using the NATM method which include the use of reinforcement elements such as umbrella soil nails and geodrains that go beyond the tunnel section. The position of those elements must be considered on the underpinning solution to avoid intersection of those elements.

4 UNDERPINNING SOLUTION

To materialize the solution of buildings underpinning, it was proposed the execution of the following elements at the ground floor level:

- Reinforced concrete beams grid, connected to the masonry walls with prestressed threaded bars to promote an effective load transfer do micropiles (see Figure 3) [concrete beams 60cmx80cm | ϕ32mm GEWI bars];

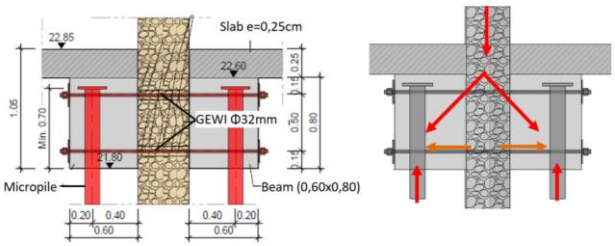

Figure 3. Underpinning solution – Load transfer beams.

- Reinforced concrete lining walls connected to the masonry peripheral walls with stell bolts to promote an effective load transfer [30cm thickness wall];
- Reinforced concrete slab on beam grid for materialization of the ground floor, overall rigidification of the solution and control of torsional forces in the beams [25cm thickness slab];
- Application of sprayable reinforcement mortars reinforced with carbon fibre meshes on internal masonry walls for their confinement and structural reinforcement [S&P ARMO-mesh | S&P ARMO-crete w] (see Figure 4);

Figure 4. S&P ARMO system application.

- Micropiles, vertical and sub-vertical, executed in the alignments of the walls and connected to the beams grid. Its 6m bond length materialized with repetitive selective injection (IRS) is placed outside the excavation influence area, in materials from the Lisbon Volcanic Complex geological unit (see Figure 5) [N80 tube 127x9mm].

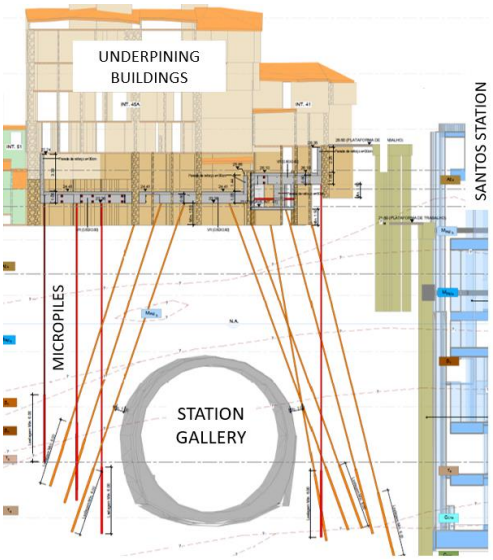

Figure 5. Underpinning solution - Cross section.

The underpinning solution was design to transfer the totality of the buildings load to Lisbon Volcanic Complex competent materials through micropiles with lengths from 20m to 25m, totalling about 4000m of micropiles tubes. That load transfer will occur when the underground works induces a settlement at build foundation level so it is expected that the load transfer can occur gradually with the tunnel excavation progress.

5 SOLUTION DESIGN

The underpinning concrete beam grid was designed using structural models within the SAP2000 software. The grid joint support was placed on micropiles location considering its inclination and using a spring to simulate the axial stiffness of the micropile free length. Those models made it possible to estimate beams structural forces as well as its elastic deformation (see Figure 6).

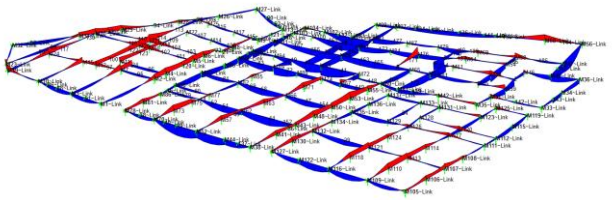

Figure 6. Beams grid SAP2000 analysis – Bending moments.

Considering the joint support springs on the structural model, the maximum design axial load on each micropile was estimated, allowing the safety validation of those steel elements. Since the micropiles free length is placed on influence excavation area it was necessary to account for second order effects so a 20mm as the maximum eccentricity a micropile can be subjected and therefore its design accounted for axial-bending moment verification. A numerical model considering NATM excavation phasing allowed the confirmation of displacements on micropiles to be less than 20mm (see Figure 7).

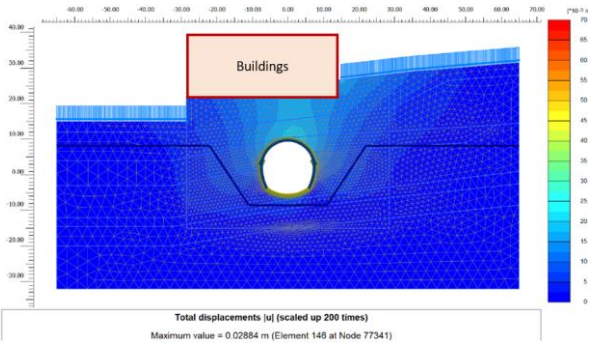

Figure 7. Plaxis 2D – Total displacements.

6 MONITORING AND SURVEY PLAN

Given the highly complexity of the present solution as well as the geotechnical substantial risk scenario a reinforced monitoring plan was implemented. Regardless of the underground excavation typical monitoring plans, at surface inside and outside the underpinning buildings multiple devices were installed such as inclinometers, topographic targets, tiltmeters, crack meters and liquid level sensors. Automated total stations (ATS) were used to access data daily aiming the access of in real-time building behaviour while the underground excavation is implemented and allowing for risk mitigation measures promptly if needed (see Figure 8).

The monitoring and survey plan the establishment of threshold values included for each monitoring

device. The numerical analyses results were used to determine reference values for measured parameters that were used to set warning and alarm values, considering warning alarms thresholds as 80% and 120% of the reference values, respectively. Thus, the reach of warning limit means the approximation of the estimated behaviour and alarm means it was surpassed by 30% and therefore the works must stop, and reinforcement measures must be taken.

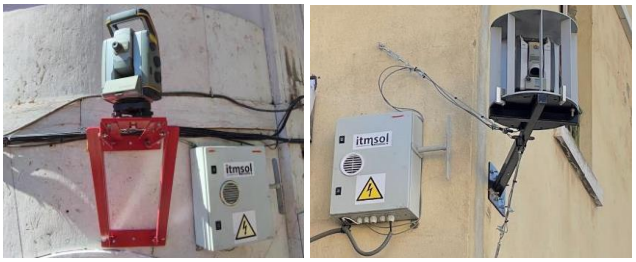

Figure 8. Automated total stations.

Up to this date, the monitoring survey plan has been implemented with daily measures and the buildings behaviour during the underpinning works and later with underground excavation has been proven as expected, with low settlements reaching a maximum of 3mm (see Figure 9).

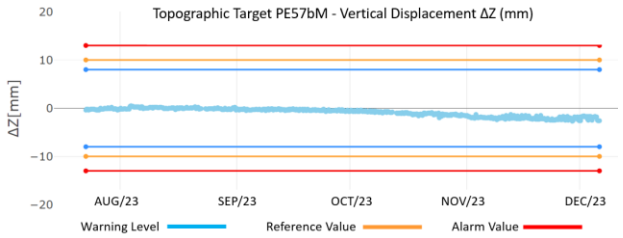

Figure 9. Topographic target - Vertical displacement.

Since the underpinning buildings are located on a hill the mass movements of the soil were also a concern since the station and tunnel underground excavations are taking place at the hill bottom. Thus, inclinometers with 35m long were installed behind those buildings to access deep horizontal soil movements that cloud indicate any global stability issue (see Figure 10).

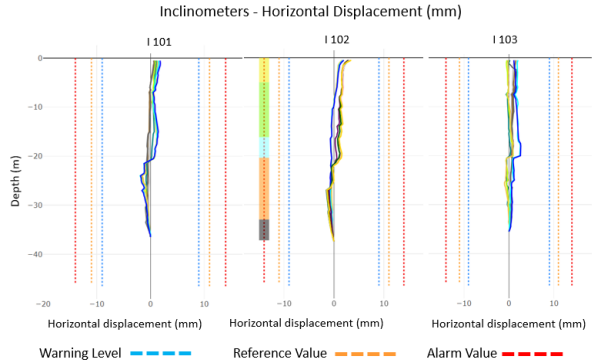

Figure 10. Inclinometers - Horizontal displacement over.

7 CONCLUSIONS

Underground excavations can lead to surface settlements that can impact the structural safety of buildings, particularly centenary buildings were multiply pathologies can already be observed. The use of numerical models for settlement estimation combined with Burland's method to access a buildings potential damage is crucial to determine the necessity of additional reinforcement measures. For extreme scenarios, such as the one presented, an underpinning solution can be most suitable way to maintain the building integrity despite this type of solution often as multiple constrains regarding equipment access and operation (see Figure 11). An adequate monitorization plan is essential to confirm an effective load transfer to the underpinning system while the underground excavation take place.

ABSTRACT: The use of cement in the treatment and stabilization of soils *in situ*, using high-power equipment, allows the optimization of the existing natural resources from the sites, resulting in less expensive suitable technical solutions. Given the performance of these new technologies, it becomes necessary to have innovative methods for quality control of built-up layers in addition to the traditional laboratory tests, which are performed on site laboratories, in order to ensure the binomial deadline-quality of the construction in effective terms. This paper presents both the solution adopted in the design phase and the methodology applied in the Quality Control during the construction of large embankments (with a maximum height of approximately 70 m) on the stretches of the motorway A4 that access to the Marão tunnel, in the North of Portugal. This solution made it possible to incorporate an important volume of materials obtained from the excavation works of the line and the tunnel, and to optimize surface occupation, due to the fact of being possible to adopt steeper slopes with the cement treatment of the embankment. The solution adopted in the construction of these embankments is deemed sustainable since it maximises the usage of local resources (excavation volumes) and is better integrated in the natural landscape.

RÉSUMÉ: L'utilisation du ciment dans le traitement et la stabilisation des sols in situ, à l'aide d'équipements de forte puissance, permet d'optimiser les ressources naturelles existantes des sites, aboutissant à des solutions techniques adaptées à des conditions financières avantageuses. Compte tenu des performances de ces nouvelles technologies, il devient nécessaire de disposer de méthodes innovantes de contrôle qualité des couches bâties en plus des essais traditionnels en laboratoire, qui sont effectués dans les laboratoires de chantier, afin d'assurer le binôme délai-qualité de la construction en termes efficaces. Cette communication présentera la solution adoptée dans la conception et la méthodologie utilisée dans la perspective du contrôle de qualité pour la mise en œuvre de grands remblais, d'une hauteur maximale d'environ 70 m, sur les tronçons de l'autoroute A4 qui accède au tunnel du Marão, au Nord du Portugal. L'adoption de cette solution a permis d'incorporer un volume important de matériaux provenant des excavations de la ligne et du tunnel, en maintenant une occupation raisonnable du terrain grâce à la possibilité d'adopter de fortes pentes dans le remblai, constituant ainsi une solution durable compte tenu de la rentabilité des ressources locales et intégrées dans le paysage.

Keywords: Embankments; soil-cement; road works; soil stabilization.

1 INTRODUCTION

In this article it is presented the solution adopted in the design and construction of the large embankments (with a maximum height of approximately 70 m) located in the stretches of the A4 motorway that approach the Marão tunnel, in the North of Portugal.

This solution, based on the use of cement in the treatment and stabilization of the embankments, was developed for the construction of the embankments that approach the East and West portals of the Marão Tunnel. It was applied in 4 places, having been designated as walls M14, M24, M40A and M41. The solution consisted in executing reinforced backslopes with soil-cement (with a cement rate of approximately 4%) with a slope of a 1:1 (V:H) and benches at every 15 m in height. The maximum heigh obtained for these embankments was 69 m.

The adoption of this solution made it possible to incorporate an important volume of materials obtained from the excavation works of the line and the tunnel while allowing a lower surface occupation due to being possible to adopt steeper slopes in the embankment face. The maximisation of the reusage of local resources (excavated volumes) and the better

integration in the natural landscape makes it a sustainable solution.

Figure 1 shows a photograph with an overview of the M24 reinforced embankment after the completion of the works, highlighting its good landscape integration.

Figure 1. General view of the M24 embankment, reinforced with soil-cement.

This case study also intends to present a synthesis of the methodology used in the perspective of Quality Control, which was defined in the design phase and implemented during the construction stage.

2 GEOLOGICAL SETTING

The A4 motorway is mainly located in eruptive terrains of a granitic nature and metamorphic terrains that are essentially schist. The first occurs from between the beginning of the motorway up to about km 12, where the embankments concerned on this paper are located. Metamorphic terrains are predominant in the remaining motorway length. Both eruptive and metamorphic terrains can provide sub-rocky embankment materials (soils rich in rock fragments/blocks), suitable for the construction of embankments.

The granites are interwoven by multiple joint families and posess thick layers of residual soils which are derived from a deep weathering of the rock.

From a geotechnical point of view, and according to the nomenclature of the International Society for Rock Mechanics (ISRM), schists are moderately weathered (W3), and intensely fractured (F4-5).

3 DESIGN SOLUTION

The design solution was developed for the construction of the embankments that approach the East and West portals of the Marão Tunnel. The solution was applied in 4 sites, designated as walls M14, M24, M40A and M41. In general, the solution included the execution of embankments with 1:1 (V:H) slopes, presenting along its development 1 to 5 embankment slopes separated by 3 m wide benches and at every 15 m of heigth. For slope stabilization, a mixture of soil-cement with a cement rate of approximately 4% was employed.

Figure 2 shows a typical section of the solution adopted.

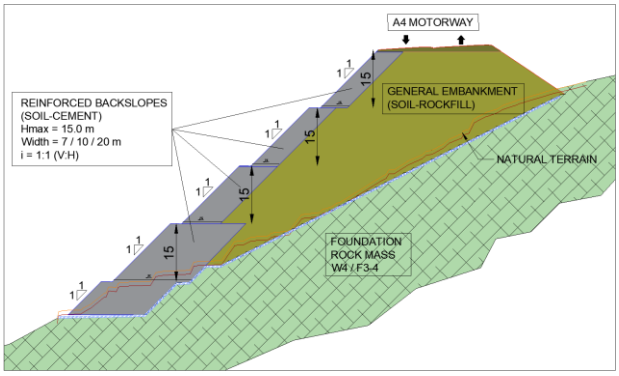

Figure 2. Typical section of the solution.

Table 1 shows the main characteristics of each of the embankments considered in the present case study.

Table 1. General characteristics of the executed soil-cement embankments.

General Characteristics	Embankment			
	M14	**M24**	**M40**	**M41A**
Length (m)	558	413	304	336
Max. height (m)	69	55	24	52
Nº of benches	4	3	0	2
Max. Side slope width (m)	20	16	7	10
Soil-cement volume (m3)	175.000	125.000	30.000	85.000
Embankment volume (m3)	510.000	175.000	20.000	210.000

Regarding the embankment foundation, a 1m deep over-excavation of the natural terrain was required in order to obtain good support conditions (W4 rock or better) throughout the embankment area.

It was considered the need to reinforce the backslope foundation whenever, after over-excavation, W4 and F3-4 rock mass (or better) was not detected. This reinforcement consists of over-excavation of about 2 m in the width of the backslope and later filling with cyclopean concrete and / or a concrete slab with two vertical nailing alignments.

4 CONSTRUCTIVE ASPECTS

4.1 Materials

The characteristics of the embankment materials, mainly soil-rockfill mixtures derived from schists and granites, should comply with the requirements of the Design's Technical Specifications. Additionally it was defined that the values presented in Table 2 must be achieved after the compaction of treated and untreated embankments.

Table 2. General characteristics of soil-cement embankments.

Parameters	Embankment	
	Soil-rockfill	Soil-cement
Friction angle (º)	36	38
Specific weight (kN/m^3)	20 – 22	20 – 22
Cohesion (kPa)	5	200
Passing the #200 sieve (ASTM) (%)	< 25	< 25
Max. Diameter (m)	0.25	0.25
Uniaxial compressive strength (MPa)	N/A	1.0 (7d) 2.0 (28d)
Diametral compressive strength (MPa)	N/A	0.25 (28d)
Deformation modulus (MPa)	N/A	2000 (28d)

The control of these parameters was carried out during the quality control process defined for the construction phase, using laboratory and *in situ* tests.

5 QUALITY CONTROL

Special attention was given to the definition of the quality control for the execution of embankments right from the design phase (with a large emphasis on the reinforced zones). Thus, the 2 main phases to ensure proper execution of the design solution were identified in the Design phase:

- Study Phase;
- Construction Phase.

The studies, methodologies and tests to be carried out in order to guarantee the strength parameters that guarantee the stability and safety of the structure were defined in the Design phase.

5.1 Study phase

During the study phase, in order to define the mixture of cement soil to be applied on site, as well as its application technique, the following methodology was adopted (*Figure 3*).

5.1.1 Mixing study

Before commencing work, a laboratory study was carried out to formulate the mixture to be applied *in situ*.

This study, which should contain at least 3 different cement dosages, presented:

- Grain size distribution curve of the material resulting from the action of the "recycler";
- Cement content and its characteristics;
- Water content, which should be optimized in order to ensure maximum mechanical resistance;
- Results of the modified Proctor test on the "soil (aggregate) / cement" mixture;
- Proctor density corresponding to the water content of the installation;
- Results of strength tests on moulded test specimens with a degree of compaction of 98%, referring to the modified Proctor test;
- Simple and diametral compression tests at 7 and 28 days (or 90 days for CEM II);
- Workability period.

The study of the mixture was carried out, considering specimens composed by schist and granitic materials, with 3 different dosages of cement. The different mixtures were then subjected to simple and diametral compression tests at 7, 28 and 90 days, in order to assess whether the values obtained were in line with the design reference values.

The results showed that, in general, the use of materials of a schist-grade nature, made it possible to meet the established requirements, even for a 3% cement dosage.

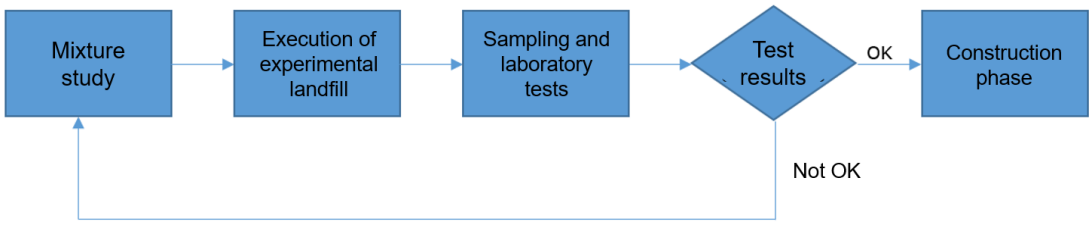

Figure 3. Methodology to be applied in the Study Phase to define the mixture.

In contrast, with the use of materials of a granitic nature, the minimum strength values defined were only achieved with a minimum cement dosage of 4%.

5.1.2 Experimental embankment

After the study of the mixture, the phase of experimental embankment construction began, which allowed the design and study assumptions to be confirmed. It was particularly important to evaluate the obtained strength for the percentage of cement added and its temporal evolution, particularly in the early days.

The results obtained in samples from the experimental embankment tests confirmed the values obtained in the study of the mixture.

It was defined that the soil-cement mixture should contain a minimum cement rate of 4%, in order to obtain the desired resistance parameters, namely when the reinforced embankment is being carried out using materials of a granitic nature.

5.2 Construction phase

5.2.1 In situ and laboratory tests

After the study and definition of the soil-cement mixture to be used, the construction of the reinforced embankments begins according to the assumptions defined during the study phase.

During the construction phase, the quality control carried out was based on the comparison between laboratory tests and on-site tests, when possible.

Thus, in addition to the tests that are usually caried out in order to ensure that the embankment is properly built, the following tests were carried out to validate the design parameters:

- Uniaxial compressive strength – Obtained by testing samples in a hydraulic press, in laboratory;
- Diametral compressive strength - Obtained by testing samples in a hydraulic press, in laboratory;
- Deformation modulus – Evaluated *in situ* with a portable impact deflectometer - PRIMA 100.

It is important to mention that, during the construction phase, it was essential to adjust the time necessary for carrying out the tests and obtaining the respective results to the production needs and on-site efficiency.

In order to solve this issue, it was defined that the laboratory tests to be carried out, namely for the evaluation of simple and diametral compressive strength, would be performed at young ages (≤ 7 days). Then, through the calibration obtained during the study phase, it was possible to carry out the projection of the results for the most advanced ages (28 and 90 days).

5.2.2 Monitoring

In addition to the Quality Control works, the monitoring with geotechnical instrumentation (topographic marks / targets and inclinometers) allowed to evaluate in real time the response of the embankment, by controlling its deformations at the surface and in depth.

Throughout the construction work, and after its completion, the instrumentation showed a good behaviour of the embankments.

6 CONCLUSIONS

The solution developed for the stabilization of the M14, M24, M40 and M41A embankments, located in the stretches of the A4 motorway that approach the east and west portals of the Marão tunnel, allowed to incorporate an important volume of materials obtained from the excavation works. The use of reinforced backslopes in soil-cement allowed steeper slopes, which reduced surface occupation.

The combination of these two important initial premises resulted in the development of this innovative technique, allowing the execution of large embankments, both in height and in length. Thus, it was possible to make the best use of local resources and achieve a better landscape integration, resulting in an economically and environmentally sustainable solution.

The quality control of the construction works was, in our understanding, the main condition for the success of the Project's execution. The proposed methodologies guaranteed not only the quality of execution and consequent stability of the embankment but also the fulfillment of the established deadlines, especially since it is an innovative solution and, therefore, on which there was little experience and knowledge.

ACKNOWLEDGEMENTS

ABSTRACT: This paper describes the main design and execution criteria for peripheral earth retaining solutions required to construct a multi-family residential building on Avenida Conde Valbom in Lisbon. The building covers approximately 200m², encompassing three underground and seven elevated floors. The excavation area is bordered by a 10-floor building with one underground level to the north and an 8-floor building with five underground stories to the south. Geological findings indicate a groundwater level of around 4 meters. Soil investigations reveal clayey fill materials, rocky fragments, and other elements atop dark gray clays, followed by Miocene formations named "argilas e cálcarios dos prazeres" and "Formação de Benfica" from the Eocene-Oligocene era. For excavation and containment, the proposed method involves utilizing the "king post wall" technique horizontally supported by a slab strip. This approach includes phased construction of vertically reinforced concrete panels, supported by micro-piles. The slab strip provides load-bearing support and incorporates HEB140 double shorings where necessary. This solution permits a thinner wall (0.30m) and simultaneous execution during excavation. To ensure stability against soil pressures during excavation, concrete pouring of panels directly into the ground is planned, with support from the slab strip and metallic shorings at existing floor levels. Monitoring and survey plan aims to execute excavation and containment structures safely and economically while assessing the behavior of neighbouring structures during construction. It addresses identified constraints and quantifies risks associated with the construction phase.

RÉSUMÉ: Le document décrit les principaux critères de conception et d'exécution des solutions périphériques de retenue des terres nécessaires à la construction d'un immeuble résidentiel multifamilial sur l'Avenida Conde Valbom à Lisbonne, couvrant une superficie d'environ 200m² comprenant trois étages souterrains et sept étages surélevés. La zone de fouille est délimitée par un bâtiment de 10 étages avec un sous-sol au nord et un bâtiment de 8 étages avec cinq sous-sols au sud. Les résultats géologiques indiquent un niveau d'eau souterraine d'environ 4 mètres, tandis que les investigations du sol révèlent des matériaux de remplissage argileux, des fragments rocheux et d'autres éléments sur des argiles gris foncé, suivis par des formations du Miocène appelées "argilas e cálcarios dos prazeres" et "Formação de Benfica" de l'ère de l'Éocène-Oligocène. Pour l'excavation et le support, l'approche proposée implique l'utilisation de la méthode "king post wall" soutenue horizontalement par une bande de dalle. Cette méthode comprend une construction par phases de panneaux en béton armé verticalement soutenus par des micro-pieux. La bande de dalle assure le support de charge et intègre des étais doubles HEB140 là où nécessaire. Cette solution permet un mur plus mince (0,30m) et une exécution simultanée pendant l'excavation. Pour assurer la stabilité contre les pressions du sol pendant l'excavation, la coulée de béton des panneaux directement dans le sol est prévue, avec le soutien de la bande de dalle et des étais métalliques aux niveaux de sol existants. Le plan d'instrumentation et d'observation vise à exécuter les structures d'excavation et de retenue en toute sécurité et de manière économique, tout en évaluant le comportement des structures environnantes pendant la construction. Il aborde les contraintes identifiées et quantifie les risques associés à la phase de construction.

Keywords: Earth retaining wall; slab strip; king post wall; monitoring and survey plan.

1 INTRODUCTION

The present article describes the solutions adopted for the excavation and peripheral soil containment, necessary for the construction of the 3 underground floors of a multi-family residential building located on Avenida Conde Valbom nº21-25, in Lisbon. In Figure 1, the location of the construction site is presented, highlighting the following boundaries for the excavation area:

- Conde Valbom Avenue side: The terrain is approximately at the level of floor 0.
- Northern side: Existing building with 10 floors and 1 basement floor.

- Southern side: Existing building with 8 elevated floors and 5 basement floors.
- Rear side: Boundary with the existing backyard.

Figure 1. Aerial view of the intervention site (images taken from Google Earth).

The building to be constructed has a footprint area of approximately 200 square meters, comprising three underground floors and 7 elevated floors plus a rooftop.

2 MAIN CONSTRAINTS

2.1 Neighbourhood conditions

The excavation and peripheral containment solutions must be compatible with preserving the proper functionality of all structures and infrastructures located near the excavation area. The Figure 2 illustrates the plan view of the neighbourhood main constrains.

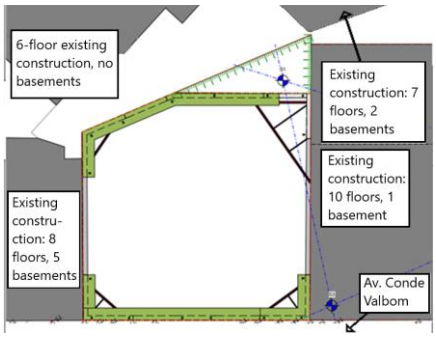

Figure 2. Plan view of the neighbourhood constrains.

2.2 Geological and geotechnical conditions

The geological-geotechnical survey encompassed three boreholes for SPT tests and sample collection. Reported groundwater levels approximate 4 meters. Survey results reveal primarily brown clayey fill materials to a depth of about 3.0 meters. Subsequently, Miocene formations display whitish-gray silts, and lower layers exhibit clayey and silty sands, attributed to the Eocene-Oligocene.

The findings categorized three geotechnical zones: ZG1 (NSPT 7-15) for recent cover deposits, ZG2 (NSPT 18-45) for uncompressed in situ masses, and ZG3 (NSPT 45-60) representing the more robust "Formação de Benfica".

3 EXCAVATION AND PERIPHERAL EARTH RETAINING SOLUTIONS

In the design of the adopted peripheral earth retaining solutions, the objective was to maintain crucial principles such as: (a) Manage soil deformation and safeguard neighbouring structures and infrastructures against excavation-related impacts; (b) Minimize disruptions to adjacent structures and infrastructures as much as possible.

Considering the existence of various conditioning factors, the excavation and peripheral containment were executed using the "king post wall" technology, coupled with the installation of a slab strip as illustrated on Figure 3.

The construction approach for the "king post wall" type containment wall involves a phased assembly, from top to bottom, of reinforced concrete panels supported by vertical micro-piles. The profiles are inserted into holes and sealed along the sealing bulb length using the IGU injection system in competent terrain. The slab strip integrates a section of the final slab to bear soil loads, while double shorings are deployed in areas where the slab strip isn't possible to execute. Provided the assumptions hold, panels will be directly concreted into the ground to stabilize the containment wall against soil pressures during excavation, supported by the slab strip and metallic shorings at existing floor levels (0, -1, and -2). The following figures represents the plan view of the -1, -2 and -3 floor. To minimize soil decompression, strict adherence to the proposed construction phasing is important, notably ensuring a 24-hour maximum gap between excavation and concreting. In the definitive phase, floor slabs at levels 0, -1, and -2 will themselves ensure the containment wall's stability, transitioning temporary props to permanent upon completing the mentioned structure.

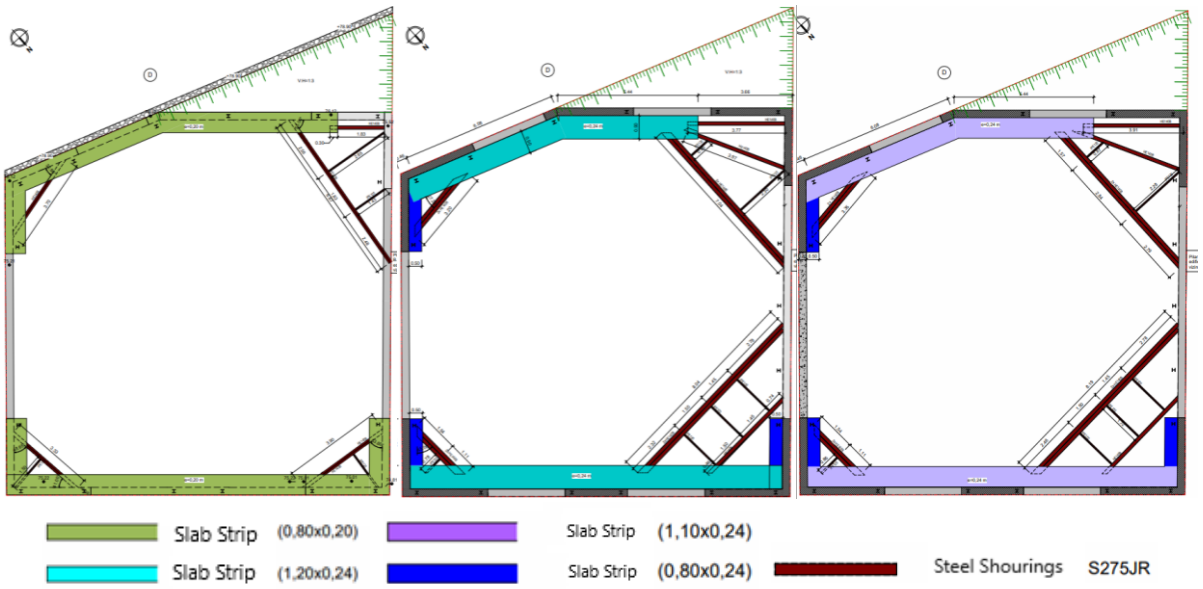

Figure 3. Design plan view of the peripheral earth retaining solution at levels 0, -1 and -2.

4 GEOTECHNICAL AND STRUCTURAL DESIGN

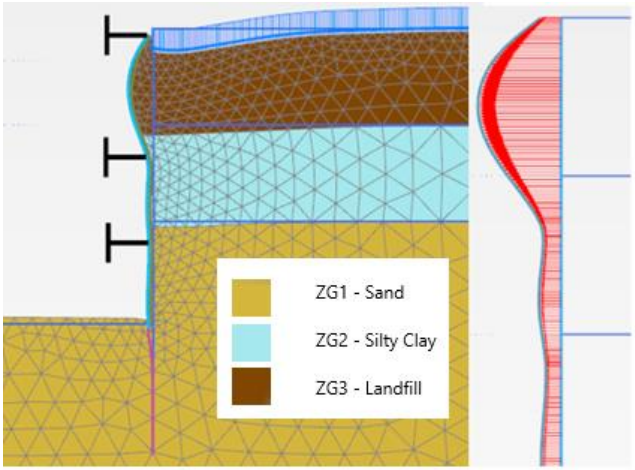
The evaluation of the proposed methods for the peripheral earth retaining solutions in terms of forces and deformations encompassed a comprehensive analysis across construction phases. This assessment utilized dedicated finite element program PLAXIS 2D, purpose-built for this specific task. A constitutive model was developed to mimic the behaviour of "Hardening Soil," considering nonlinear constitutive relationships and variations in soil stiffness under differing stress states. These outlined parameters from Table 1 were then implemented in PLAXIS 2D to accurately model the behaviour of the soils.

Table 1. Geotechnical soil parameters.

Soil Type	ZG_3	ZG_2	ZG_1
N_{SPT}	7-15	18-45	45-60
Υ [kN/m^3]	18	18	20
Φ [°]	27	30	38
E_{50}^{ref} [MPa]	10	40	90
E_{ur}^{ref} [MPa]	30	120	270

ZG_1 – *Loosely compact clay fill*; ZG_2 – *moderately compact silt soil and clayey sandy soil;* ZG_3– *compact clayey sand soil.*

In these models, the "king post wall" and the vertical micropile were represented using "plate" elements exhibiting elastic behavior. Meanwhile, the slab strip and the steel struts were simulated as "anchors." The behaviour of the peripheral retaining structure underwent analysis, evaluating design aspects such as containment structure forces, deformations, stress conditions, and soil stability. Figure 4 showcase specific displacement results derived from these developed models.



u	*16,34 mm*	u_x	*15,82 mm*

Figure 4. Expected maximum total displacements (u) and maximum horizontal displacements (ux).

5 MONITORING AND SURVEY PLAN

Based on the complex framework of the site, a Monitoring and Survey Plan (MSP) was established to ensure safety and optimal functionality during excavation and the construction of geotechnical structures, as well as for neighbouring structures and infrastructures. Within this plan, the following instruments were installed: (a) 20 topographic targets positioned along the earth retaining solution and placed along neighbouring infrastructure; (b) 1 inclinometer placed behind the peripheral containment wall.

Alert and alarm criteria were established for all instruments and monitored structures based on the conducted modelling. Overall, the readings consistently remained below the defined alert and alarm criteria outlined in the project. Figure 5 and Figure 7 illustrates the schematic locations of the instrumentation devices along with some of the most noteworthy results.

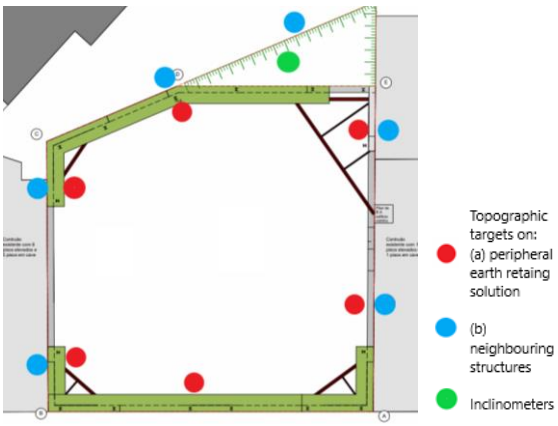


Figure 5. Instrumentation and monitoring plan.

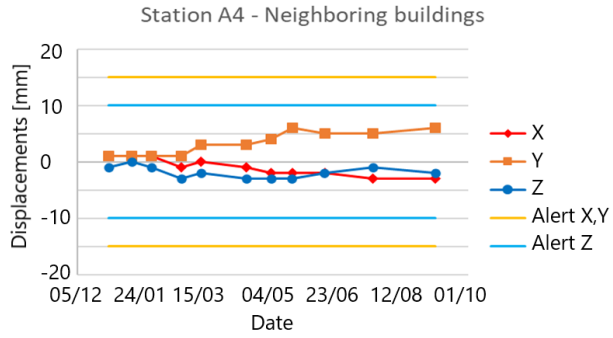

Figure 6. Maximum displacements on neighbouring structure (station A4).

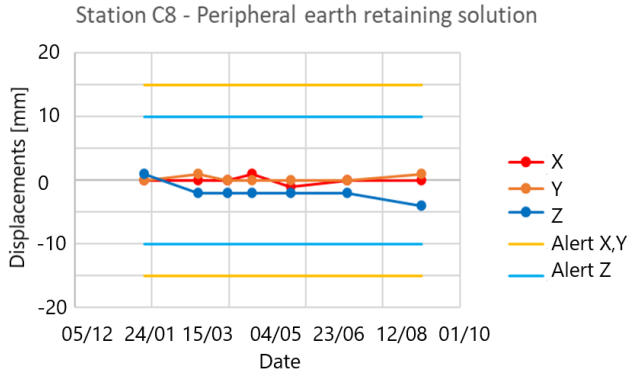

Figure 7. Maximum displacements on peripheral earth retaining solution (station C8).

In general, maximum displacements of about 6mm were recorded for neighbouring structures, and approximately 3mm for the peripheral containment solution, values well below the alert and alarm criteria set at the beginning of the excavation, which were 15mm and 30mm, respectively. As for vertical displacements, a maximum value of around 4mm was registered, equally well below the alert and alarm criteria of 10mm and 20mm, respectively. The apparent discrepancy between estimated and observed deformations can be attributed to several factors, notably the geomechanical attributes of the soils involved. Specifically, the Miocenic formations exhibit superior characteristics compared to those initially considered in the design calculations.

6 CONCLUSIONS

In the scope of this article, it was possible to demonstrate the technical efficiency of king post wall braced by various structural elements such as struts, and slab stripes. The peripheral earth retaining solution presented actual displacements lower than those estimated in project and displayed a highly stable behaviour during the excavation works. Additionally, the use of slab bands not only overcame the encountered limitations due to the excavation´s site proximity to the technical gallery and the future underground parking lot, but also incorporated elements of the final structure, enhancing the economic efficiency of the solutions. One of the most daunting hurdles encountered throughout the project was the limited space available for the construction site. Situated within a densely urbanized environment, the work site posed significant challenges, primarily due to its restricted area. This spatial constraint significantly impacted various aspects of the construction process, from material storage to site infrastructure and the removal of excavated soil.

Effects of soil improvement on the axial load capacity of drilled displacement piles – a CPT based case history analysis

Effets de l'amélioration du sol sur la capacité de charge axiale des pieux forés à déplacement – une analyse historique de cas basée sur le CPT

ABSTRACT: Pile installation is known to affect the surrounding soil, its mechanical properties, and consequently its performance under any type of loading. Data from 11 construction sites, where Cone Penetration Tests (CPT) were performed before (CPT_{PRE}) and after (CPT_{POST}) pile construction, was used to analyze the change in soil resistance surrounding the Drilled Displacement Piles (DDP). Six of the 11 project sites included static axial load tests, allowing for a comparison between axial pile load predictions using CPT_{PRE} data, load test results during field testing, and analytical capacities obtained through CPT_{POST} data. This paper will first present a comparison of post-installation soil improvement observed at all 11 sites. The improvement ratio was defined as the CPT tip resistance post-installation ($q_{c.post}$) divided by the pre-installation resistance ($q_{c.pre}$). Hereafter, the axial load capacity is analytically estimated using soil resistance parameters before and after the pile construction. Results do not differ considerably when using CPT parameters for stratified soil profiles but showed notable analytical improvement (by a factor of 1.4) for cohesionless soils. However, when comparing analytical estimates using CPT-post data to in-situ failure loads observed from axial load tests, the use of post-installation CPT-based soil parameters for design was deemed premature. While field improvement is evident, its benefit is not correctly reflected in the predicted pile performance, primarily attributed to the uncertainty of capacity predictions for these specialty type of foundations. For cohesive sites, the analytical pile capacity estimated with the CPT_{POST} and the axial load test data did not show a consistent trend.

RÉSUMÉ: L'installation de pieux est connue pour affecter le sol environnant, ses propriétés mécaniques et, par conséquent, ses performances sous tout type de chargement. Les données de 11 chantiers de construction, où des tests de pénétration du cône (CPT) ont été effectués avant (CPT_{PRE}) et après (CPT_{POST}) la construction des pieux, ont été utilisées pour analyser le changement dans la résistance du sol entourant les pieux forés à déplacement (DDP). Six des 11 sites du projet comprenaient des tests de charge axiale statique, permettant une comparaison entre les prévisions de charge axiale des pieux à l'aide des données CPT_{PRE}, les résultats des tests de charge lors des essais sur le terrain et les capacités analytiques obtenues grâce aux données CPT_{POST}. Cet article présentera d'abord une comparaison de l'amélioration du sol après l'installation observée sur les 11 sites. Le taux d'amélioration a été défini comme la résistance de la pointe CPT après l'installation ($q_{c.post)}$ divisée par la résistance avant l'installation ($q_{c.pre}$). Ci-après, la capacité de charge axiale est estimée analytiquement en utilisant les paramètres de résistance du sol avant et après la construction du pieu. Les résultats ne diffèrent pas considérablement lors de l'utilisation des paramètres CPT pour les profils de sols stratifiés, mais ont montré une amélioration analytique notable (d'un facteur 1,4) pour les sols sans cohésion. Cependant, lors de la comparaison des estimations analytiques utilisant les données CPT-post aux charges de rupture in situ observées lors des essais de charge axiale, l'utilisation de paramètres de sol basés sur le CPT après l'installation pour la conception a été jugée prématurée. Bien que l'amélioration sur le terrain soit évidente, ses avantages ne sont pas correctement reflétés dans les performances prévues des pieux, principalement attribuées à l'incertitude des prévisions de capacité pour ces types spéciaux de fondations. Pour les sites cohérents, la capacité analytique des pieux estimée avec le CPT_{POST} et les données des tests de charge axiale n'ont pas montré de tendance cohérente.

Keywords: Displacement piles; axial load test, CPT; soil improvement; pile installation.

1 INTRODUCTION

Drilled Displacement piles (DDPs) are unique in their ability to displace and compact soil around the pile during installation, with the potential to improve the pile's load-bearing capacity. Numerous elements, including soil type and its mechanical characteristics,

the construction tool, the configuration of the displacement body, as well as the arrangement and geometry of the piles, collectively influence the extent of soil enhancement and the load-bearing capacity of the piles.

Researchers have observed cohesionless soils to experience a considerable improvement of soil resistance after pile installation; an inverse relationship between the level of improvement and the initial resistance was found by Siegel *et al.* (2007). Meng *et al.* (2015) studied the installation of DDPs in cohesive soils by measuring the lateral soil displacement and the pore water pressure dissipation, both were found to be highly dependent on time. Maximum displacements were observed after pile concreting, and a reduction of around 50% of the deformations was measured after 15 days.

Semi-empirical methods for estimating axial load capacities of DDPs have been formulated through case history data accompanied by finite element models. CPT-based methods include Brettmann and NeSmith (2000; 2005) and Bustamante and Gianeselli (1993;1998). Basu and Prezzi (2009) developed an axial pile capacity method grounded in lateral earth pressure concepts, and Park et al., (2013) predict axial load capacities through the t-z spring method. All the above-mentioned methods utilize soil properties prior to the pile installation without accounting the soil change due to the pile construction. Consequently, these methods frequently yield conservative predictions of pile capacity and pile design.

The complexity of the DDP installation techniques and its influence on the axial pile capacity was further evidenced by Moshfeghi and Eslami (2018), who studied the reliability of CPT- based predictions for axially loaded DDPs. Moshfeghi and Eslami found the accuracy of the predicted pile capacity to be dependent on the drilling tool; for instance, the capacity of Atlas piles was best predicted by the Brettmann and NeSmith (2005) method. The study also showed that for some CPT direct methods, the axial load capacity results are highly conservative for clayey soils. Figueroa *et al*. (2021) evaluated the predicted accuracy of CPT and SPT based direct methods in estimating axial pile load capacity for DDPs in sand-like, clay-like, and mixed soil sites. Results showed that among all CPT-based methods used to predict axial pile capacities, the closest agreement between measured and analytically predicted failure load in sands was obtained with Brettmann and NeSmith (2000; 2005). The closes agreement in mixed soils was obtained using Bustamante and Gianeselli (1993;1998), and clayey soils were best predicted using Eslami and Fellenius (1997).

This paper aims to present the change in soil properties following pile installation and its influence on the pile bearing capacity. DDP's CPT-based analytical capacity was obtained with CPT_{PRE} and CPT_{POST} data to be later compared with the experimental results of static axial load tests.

2 DDP CASE HISTORIES

The project data is summarized in Table 1 showing the site location, Ground Water Table (*GWT*) depth, and soil categorization (SC)- i.e., (1) homogeneous cohesionless soil profiles, (2) homogeneous cohesive soil profiles, and (3) stratified soil profiles. The pile diameter (*D*), pile length (*L*), and DDP pattern and spacing (*S*), expressed in terms of pile diameter *D* (if applicable) are also listed. Furthermore, Table 1 provides the number of CPT_{PRE} and CPT_{POST} at each site along with the distance between CPT_{POST} and DDP in terms of the pile diameter (*D*). A total of 53 CPTs (15 CPT_{PRE} and 38 CPT_{POST}) were analyzed. The sites consisted of either homogeneous cohesionless or cohesive sites, or mixed soils with strongly stratified sand, silt, and clay layers. The number of days between pile construction and CPT_{POST} testing is also detailed. The number of Static Axial Load Tests (ALT), compression (C) or Tension (T) are listed for every project site. The nominal shaft diameter varies from 40.6 cm to 45.7 cm (16 to 18 in). The embedment length of the piles ranged from 6 m to 15 m (19.7 ft to 50 ft). Figure 1 shows a representative project site CPT tip resistance (q_c) for each site category.

As detailed in Table 1, among the 11 project sites, 6 of them included axial load tests. The in-situ axial load that triggered plunging behavior (high deformation with a low increase of the load) was either obtained directly from the load test ($Q_{f.in\text{-}situ}$) or estimated using Van der Veen's Criteria, 1953 when the plunging behavior was not reached experimentally ($Q_{f.int}$).

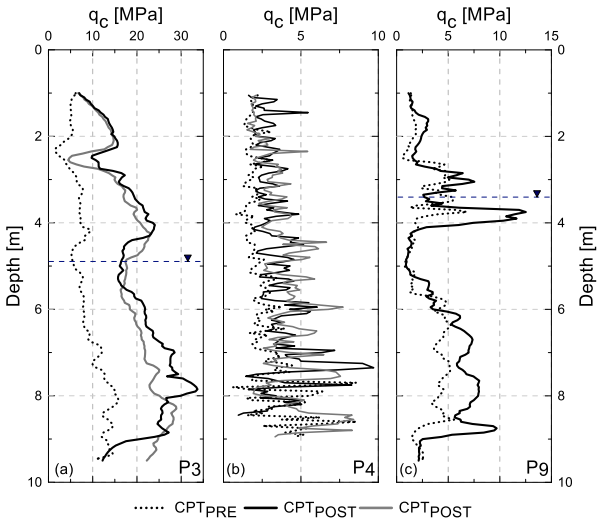

Figure 1. CPT tip resistance (q_c) before and after pile installation for (a) cohesionless, (b) cohesive, and (c) stratified soil profiles.

In addition to identifying the pile failure loads, the axial load that triggers a settlement equal or higher than 10% of D ($Q_{\Delta=10\%D}$) was also determined (whenever pile settlements reached that level of deformation). The maximum load ($Q_{max.test}$) and corresponding settlement (Δ_{max}) were also collected for further analysis.

Table 1. Overall information of each project site and tested piles.

3 DATA ANALYSIS

3.1 CPT_{PRE} and CPT_{POST} data analysis

An initial assessment of raw CPT measurements, i.e., tip resistance (q_c) and side friction (f_s), showed that for homogeneous soil profiles the improvement in q_c and f_s can be easily noticed and the improvement of both resistances are closely associated. For stratified soil profiles, the change in CPT measurements was observed to be smaller and cannot be easily quantified by visual inspection, unless a substantially large uniform layer is present, as exemplarily depicted in Figure 1(c) from 6 m to 8 m depth.

The CPT tip resistance improvement ratio was calculated as $q_{c.post}/q_{cpre}$ and plotted against the tip resistance prior to pile installation (q_{cpre}) for all site categories. Figure 2 shows the improvement ratio vs, q_{cpre}. Results suggest an inverse relationship between achievable improvement and soil resistance prior to pile installation.

Figure 2(a) suggests nearly immediate improvement for homogeneous soil profiles with mostly clean sands and sand-like soil types. Homogeneous cohesive soil layers, as shown in Figure 2(b), have the time-dependent capability to enhance their resistance due to a low initial soil resistance. The data points in Figure 2(b) showing an improvement ratio higher than 5 come from CPT_{POST}s executed 11 days after pile installation. For stratified sites, the change in the CPT tip resistance was not visually quantifiable. Nearly $q_{c.post} \cong q_{cpre}$ or a reduction of the q_{cpre} ($q_{c.post}/q_{cpre}<1$) can be observed. Improvable layers (e.g., sand layers within a stratified profile) only showed visible improvement when a sufficient layer thickness (> 0.7 m) was available. The beneficial effects of soil homogeneity on the achievable

improvement can also be observed in Figure 1(c) from 6 to 9m depth.

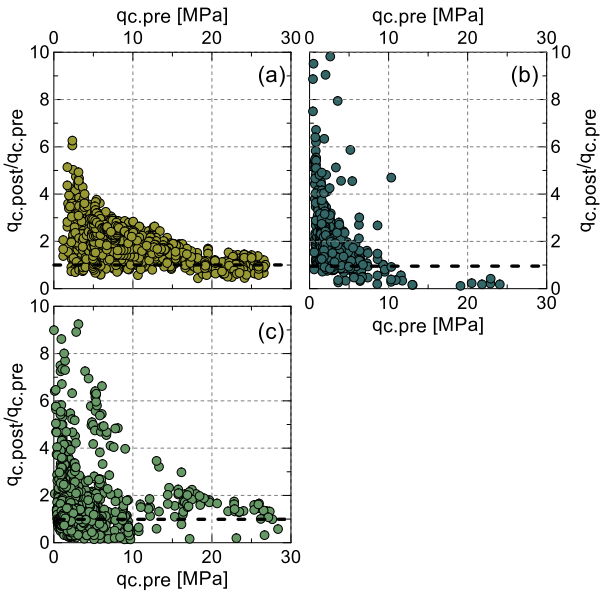

Figure 2. CPT tip resistance ($q_{c.pre}$) vs. $q_{c.post}/q_{cpre}$ for (a) cohesionless, (b) cohesive, and (c) stratified soil profiles.

Further analysis showed that the level of soil resistance improvement is contingent upon several other parameters, including the pile arrangement, separation between the piles (S) and the location where the improvement is being assessed; consequently, it cannot be predicted solely based on the initial soil resistance. A more detailed analysis by the authors with recommendations to predict the expected soil improvement following DDP installation is currently in review (see Figueroa *et al*. 2024).

3.2 Comparison of axial load capacities estimated with CPT_{PRE} and CPT_{POST} data

An improvement in soil behavior surrounding the DDP as observed in the case studies listed beforehand could suggest a potential increase in axial pile load capacity as benefit of the unique installation technique. The CPT data obtained before and after pile construction was utilized to predict the axial load capacity of the DDP. Brettmann and NeSmith (2000; 2005), Eslami and Fellenius (1997), and Bustamante and Gianeselli's (1993;1998) analytical CPT methods were employed for cohesionless, cohesive, and stratified soil profiles, respectively. Since Bustamante and Gianeselli (1993; 1998) estimate the load corresponding to the settlement of 10%D, Eslami and Fellenius (1997) method was employed for stratified soil sites where the $Q_{max.test}$ corresponding settlement is lesser than 10%D. This theoretical exercise helped visualize how installation effects, i.e., the change in raw soil resistance data, could translate into potential changes of overall pile capacity.

The bar chart of Figure 3 separates the axial pile resistance into the analytically estimated toe resistance (Q_{toe}, Figure 3(a)), side friction (Q_{side}, Figure 3(b)), and the total, ultimate load (Q_u, Figure 3(c)) based on before and after soil data. Except for P4, all sites maintain or improve their analytical tip resistance and indicate similar or higher toe capacity. Similar observations can be made for the cumulative shaft resistance shown in Figure 3(b). Except for P7, which is mostly composed of silt-like and clay-like soils, all piles maintained or increased their side friction due to the installation technique. The CPT_{POST} for P7 was performed 2 days after the pile construction, hence potential improvements are likely not captured.

For homogeneous cohesionless sites, the total pile axial load capacity analytically increased by a factor of 1.3 to 1.7 when using CPT_{POST} vs. CPT_{PRE} data. Almost all mixed soil type projects (P7, P8, P9, P10 and P11) showed ratios of post vs. pre ultimate pile capacities near 1.0, deeming its improvement benefit negligible.

More importantly, is the comparison of analytically predicted axial load capacities with experimentally observed failure loads. The in-situ axial load that triggered plunging behavior ($Q_{f.in\text{-}situ}$), the interpreted failure load ($Q_{f.int}$), the axial load that triggers a settlement equal or higher than 10% of the pile diameter ($Q_{\Delta=10\%D}$) and the maximum load during the test ($Q_{max.test}$) are also presented in Figure 3 to assess the pile behavior more completely. Projects P2, P3, P9, and P11 do not have axial load test data, therefore the comparison between the analytical capacity and experimental failure load was not possible for these sites. When the red and blue dashed lines are next to each other, the axial load test reached plunging failure and the failure load equals the max applied load accordingly. This was the case for P6, P8, and P10.

Results presented in Figure 3(c), suggest the data and methods to be assessed more closely, making it difficult to draw general conclusions given the limited availability of data. Projects P4 and P8 show very good agreement between the in-situ pile load failure, and the capacity analytically estimated with the CPT_{POST} data. Both projects were analyzed using Eslami and Fellenius method. The analytical predictions for P1(Δ_{max}=2.0 cm) and P6 (Δ_{max}=2.4 cm) notably overestimate the actual pile load capacity. P1 consists of clean sand and sand-like materials, and the use of CPT_{POST} data overestimates the expected pile capacity. Project P6, a highly mixed site, analyzed with Eslami and Fellenius shows similar trends, the analytically estimated capacity (using both, CPT_{PRE} and CPT_{POST}) being unconservative. Given the broad spectrum of

comparative results, a generalized conclusion is nearly impossible and warrants the plea for future testing or sharing of existing results that encompass a wide range of axial load tests in various soil types with before-after testing.

4 LIMITATIONS OF THIS STUDY

Factors affecting a 1:1 comparison of CPT_{PRE} and CPT_{POST} measurements include the non-horizontality of the soil layers that can produce a wrong comparison between the pre and post measurements. The "thin-layer effect" in comparing CPT data arises from the load cell of the testing instrument sensing the next soil layer before reaching its depth, thereby impacting soil resistance measurements, especially in highly stratified soils.

Simultaneously, the analytical methods are limited by their empirical derivation. While the Brettmann and NeSmith (2000; 2005) method was developed for DDP, the DDPs consisted of Augered Pressure-injected Drilled Displacement Piles (APID). Likewise, Bustamante and Gianeselli (1993; 1998) method was developed based on Franki-Atlas, De Waal, Omega, and Spire DDP. The difference between the installation tool may alter the level of soil displacement and therefore the pile behavior.

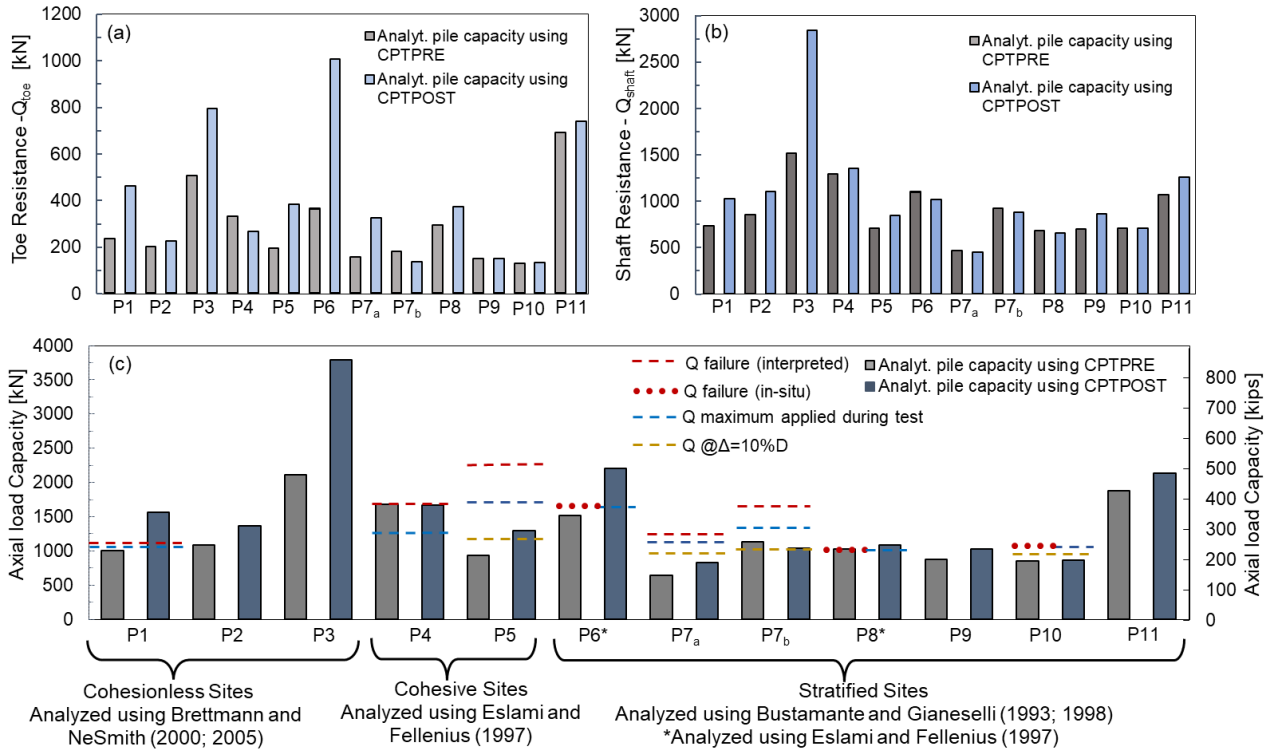

Figure 3. Analysis of the axial load capacity of the DDP using the CPT_{PRE} and CPT_{POST} data. (a) Analytical Q_{toe} capacity, (b) Analytical Q_{shaft} capacity, (c) Total capacity Q_u showed in bars, $Q_{failure}$, $Q_{max.test}$, and $Q_{\Delta=10\%D}$ showed with dashed lines.

5 CONCLUSIONS

An initial assessment of raw CPT data showed clear (and nearly immediate) improvement for soil profiles with homogeneous clean sands and sand-like soil types. Cohesive soils were found to improve recognizably when the soil profiles consisted of thick and homogeneous layers. The number of days between the DDP construction and CPT_{POST} execution suggested a strongly time-dependent improvement for cohesive soils. For stratified or cohesive soil profiles, with no thick homogeneous soil layer, the change in the CPT tip and side friction was not visually quantifiable, and in some cases lower resistances were measured.

For all site categories, the CPT-based soil resistance ratio ($q_{c.post}/q_{c.pre}$) was found to be dependent on the initial soil resistance, and follows an inverse relationship, i.e., the lower the initial resistance (q_{cpre}), the higher the achievable improvement. For cohesive soils with low initial tip resistances, q_{cpre}, improvement ratios of up to 6 times the initial resistance were observed, when continuous, thick homogeneous soil layers were present.

Available axial load test results were compared to analytical predictions. Best agreement between

analytically predicted pile capacity obtained with the CPT_{POST} data and in-situ failure loads was achieved for primarily homogeneous soil profiles. For projects with the pile toe resting in a strong sand layer, the analytical methods appear to overestimate the in-situ pile capacity of the elements, while for projects with thin sand layers between clayey soils, the analytical pile capacity underestimated the axial load pile capacity in the field.

While important trends could be identified with the data sets available to the authors, the need for future field testing became critically apparent. Particularly well-designed field programs that include spatial, time, and geometric aspects of DDPs as well as more diversified field instrumentation is recommended to gain additional insight into the soil improvement due to the installation technique and pile load-behavior. Similarly, the assessment of short term vs. long term improvement aspects of the installation technique remains unexplored to date.

ACKNOWLEDGEMENTS

This work was supported primarily through the National Science Foundation, Grant CMMI 1752303, and supported in part by the DFI ACIP Technical Committee Project Fund. We extend our sincere appreciation to the following professionals for their support on this project and their generous willingness to share data: Sam Warren (Farrell Design-Build, Inc.), Morgan NeSmith (Berkel and Company), Peter Faust (Malcolm Drilling), and Derek Deutscher† (formerly Condon Johnson).

ABSTRACT: In order to reduce the environmental impact generated in the manufacture of products and applications in civil construction and geotechnical works, there is an increasing search for alternative materials to conventional ones, such as cement, which can reduce emissions of harmful gases into the atmosphere, such as CO_2, and energy consumption in their production. With this in mind, this study proposes the use of a natural inorganic binder, which has the function of absorbing CO_2, in the stabilization of iron ore tailings in order to improve their mechanical properties. To this end, a dosage test was carried out to define the best levels of the product in the tailings, using simple compressive strength tests. The tests evaluated the application of 3%, 4% and 5% of the binder in relation to the dry mass of tailings and showed that the three dosages showed significant gains in terms of peak strength and deformations when compared to the virgin sample of tailings, with 3% of the product already showing significant results. Therefore, the use of the product proved promising in the stabilization of tailings, helping to improve both the mechanical characteristics, which are important in geotechnical works projects, and to reduce the environmental impacts of these processes.

RÉSUMÉ: Afin de réduire les impacts environnementaux générés par la fabrication de produits et d'applications dans la construction civile et les travaux géotechniques, on recherche de plus en plus des matériaux alternatifs aux matériaux conventionnels, tels que le ciment, qui peuvent réduire les émissions de gaz nocifs dans l'atmosphère, tels que le CO_2, et la consommation d'énergie lors de leur production. Dans cette optique, cette étude propose l'utilisation d'un liant inorganique naturel, qui absorbe le CO_2, pour stabiliser les résidus de minerai de fer afin d'améliorer leurs propriétés mécaniques. À cette fin, un test de dosage a été réalisé pour définir les meilleurs niveaux de produit dans les résidus, en utilisant des tests simples de résistance à la compression. Les essais ont évalué l'application de 3 %, 4 % et 5 % du liant par rapport à la masse sèche des résidus et ont montré que les trois dosages présentaient des gains significatifs en termes de résistance maximale et de déformations par rapport à l'échantillon vierge de résidus, 3 % du produit montrant déjà des résultats significatifs. Par conséquent, l'utilisation du produit s'est avérée prometteuse pour la stabilisation des résidus, en contribuant à améliorer les caractéristiques mécaniques, qui sont importantes dans les projets de travaux géotechniques, et à réduire les impacts environnementaux de ces processus.

Keywords: Mining tailings; natural inorganic binder; stabilization.

1 INTRODUCTION

The mining sector, which is extremely important for the Brazilian economy, accounting for around 4% of the country's GDP (ANM, 2023), faces the constant challenge of reconciling its significant growth with the pressing need to reduce the environmental impacts associated with traditional tailings disposal practices. Faced with this reality, the dry stacking technique has emerged as a promising alternative to dam structures, as it proposes the deposition of tailings in the best compaction conditions for stacking, thus reducing instabilities in these structures and risks of liquefaction. However, even this technique is prone to instability and ruptures, especially during heavy rainfall events. For this reason, it is often necessary to stabilize the tailings to improve their mechanical characteristics and optimize the processes, the most common currently being the use of Portland cement. The biggest problems associated with cement are its high energy demand in production and high emissions of harmful gases into the atmosphere (CARVALHO et al., 2016), which is why there is an increasing search for ecological and effective alternatives in the stabilization processes of mining tailings for piling.

This study proposes an innovative approach in the search for sustainable practices in the geotechnics of mining tailings, using an inorganic cementing agent HPA PLUS to replace traditional cement. This agent

seeks to promote the chemical stabilization of iron ore tailings, aiming not only to improve the mechanical properties of these materials, but also to reduce the environmental impacts associated with cement production.

2 MATERIALS AND METHODS

The study included the physical and mechanical characterization of iron ore tailings from a mining company in the Iron Quadrangle in Minas Gerais, as well as the tailings mixtures with the addition of the HPA Plus product. For physical characterization, tests were carried out on the grain size, specific mass of the grains, Atterberg limits and compaction of the tailings.

For mechanical characterization, the unconfined compressive strength test was carried out on both the pure tailings samples and the mixtures with the addition of 3%, 4% and 5% HPA Plus. These levels were used to obtain the optimum dosage and all the tests were carried out in duplicate to improve the reliability of the results.

2.1 Iron ore tailings

The iron ore tailings used in this research come from a mine in Minas Gerais, Brazil. Figure 1 shows an image of the material.

The tailings sample collected went through the mining processes until the final dewatering stage, when it had the consistency of pulp and 22.93% moisture.

Figure 1. Iron Ore Tailings used in this research.

2.2 Cementing agent - HPA plus

HPA Plus is part of a range of new products offered by Fonntes Geotécnica for different geotechnical solutions. It acts as a cementitious agent when added in appropriate dosages to the tailings matrix, where the material is chemically stabilized through alkaline activation processes, improving its mechanical properties. Figure 2 below shows the material used in the research.

Figure 2. HPA Plus.

HPA Plus is made up of a mixture of oxides of silicon, aluminum, magnesium, among other elements, and for this reason it acts as a cementing agent in the mixture, because the ions present in its formulation are attracted to those of the tailings, there is cation exchange, and so the whole alkaline activation process takes place, such as agglomeration between the particles, hydration and pozzolanic reactions arising from the hydration stage of the mixture, forming C-S-H and C-A-H gels, which make the structure of the material more cohesive, obtaining a more rigid material that is less susceptible to shrinkage and expansion (WILKINSON et al. , 2010).

The oxides present in HPA Plus can trap CO_2 through a process called carbon mineralization or CO_2 mineralization. The oxide reacts with atmospheric CO_2, transforming it into a stable carbonate that is harmless to the environment.

Table 1 below shows some of the product's characteristics.

Table 1. Characteristics of HPA Plus.

Charactheristics	Correspondents
Color	White
Format	Powder
Odor	Odorless
Bulk Density	0.3 g/cm³
Solubility	Practically insoluble in water
pH	10,3 (20°C)

2.3 Methodology

In order to properly assess the effect of the cementing agent on the matrix, characterization and mechanical tests were carried out on the pure tailings and the mixture of tailings with the addition of HPA at dosages of 3%, 4% and 5%.

The laboratory tests were carried out in accordance with the specific norms and standards in force in Brazil. In summary, the samples were prepared and the tests carried out in accordance with the criteria recommended by the Brazilian Association of Technical Standards (ABNT).

3 RESULTS

3.1 Characterization of the tailings sample

The particle size curve obtained for the tailings is shown in Figure 3. It shows 16.1% clay, 75.1% silt, 8.4% sand and 0.5% gravel. The tailings were therefore classified as clayey silt with little sand.

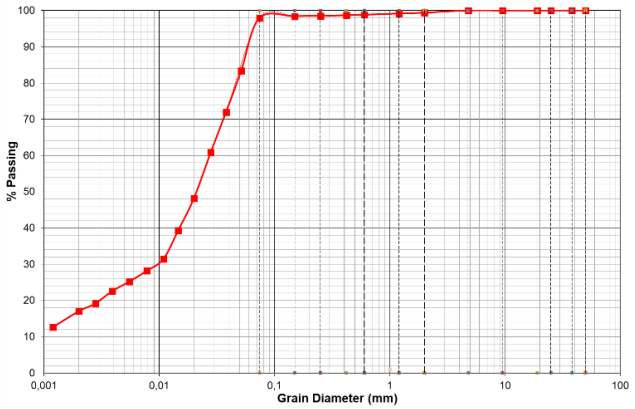

Figure 3. Iron ore tailings granulometry.

The specific mass of the grains obtained was 3.34 g/cm³. With regard to consistency limits, a liquidity limit (LL) of 22% and plasticity limit (LP) of 18% were obtained for the tailings sample.According to the Plasticity Index (PI) of 4, the material was classified as slightly plastic.

Papini et al. (2018) evaluated an iron ore tailing belonging to the same mine as this study and obtained results of 2.98 g/cm³ specific mass of the grains. X-ray diffraction analysis showed the presence of quartz, hematite, magnetite, goethite, kaolinite and gibbsite, the latter three being finer minerals, which corresponds to the fine fraction seen in the grain size results. In this study, chemical analyses were also carried out, showing a composition of 13.79% iron, 67.57% silica, 1.20% alumina, 0.22% manganese and 0.03% phosphorus in the global tailing's samples.

3.2 Normal Proctor

The compaction test was carried out on the virgin tailings, and the results obtained were 14.9% optimum humidity and 2.069 maximum dry specific mass. Figure 4 shows the compaction curve obtained.

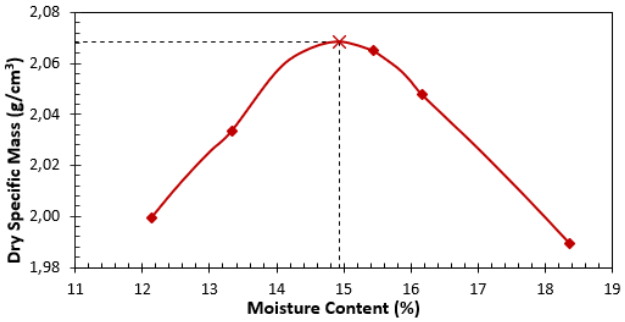

Figure 4. Iron ore tailings compaction curve.

3.3 Unconfined compressive strength

Figure 5 shows the graph with the results of the unconfined compressive strength (Axial Stress versus Axial Deformation) of the virgin samples and those treated with the addition of 3%, 4% and 5% HPA.

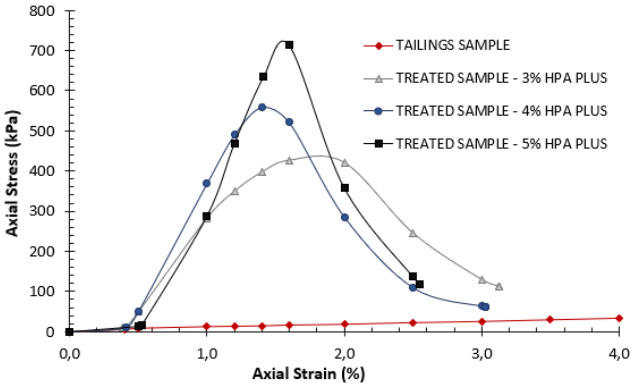

Figure 5. Unconfined compressive strength test results.

Table 2 shows the results of the tests carried out with HPA Plus. It should be noted that the results are an average of the duplicates carried out.

Table 2. Unconfined compressive strength test results.

SAMPLES	Umidity (%)	Compressive Strength (kPa)	Strain (%)
Tailings Sample	22.30	44.90	5.00
Treated Sample – 3% HPA Plus	16.70	466.83	1.60
Treated Sample – 4% HPA Plus	16.85	537.86	1.50
Treated Sample – 5% HPA Plus	16.80	676.00	1.80

The results presented show that the dosage of HPA Plus was directly proportional to the increase in Simple Compression Resistance, however, with the addition of 3% of the product, there was already a significant increase in simple compression resistance, which led to this content being defined as the optimum for the product. Regarding the deformation of the

samples, there was a significant reduction when the product was added, which indicates that HPA Plus gives the tailings rigidity, which was expected due to its properties as a cementitious agent.

4 CONCLUSIONS

In summary, the results of this study show that the addition of the inorganic cementing agent HPA Plus to iron ore tailings substantially increased simple compressive strength and reduced axial deformation, indicating a significant improvement in the material's geotechnical properties. The potential for expressive gains with doses as low as 3% highlights the effectiveness of HPA The environmental relevance of the study is emphasized by the favorable comparison with conventional cement, suggesting that HPA Plus not only improves mechanical properties, but also represents a more sustainable alternative, contributing to the reduction of CO_2 emissions associated with the stabilization of iron ore tailings in the mining industry.

ACKNOWLEDGEMENTS

To Fonntes Geotécnica for their full support of the research and the use of the HPA Plus product and to the clients for providing the iron ore tailings samples.

The influence of partial saturation on the engineering properties of a metakaolin-improved sand

L'influence de la saturation partielle sur les propriétés techniques d'un sable amélioré au métakaolin

ABSTRACT: Ground improvement by injection of sustainable binders and geopolymers is generating much interest. The use of these products in foundations, landslides, excavations, retaining structures and tunnel applications is being progressively considered in geotechnical standards. This fact would require consideration of material evolution under mechanical or environmental action, including changes in the hydraulic state of the ground. An extensive laboratory investigation was conducted on sand specimens treated with a metakaolin-based geopolymer to evaluate the effect of different saturation conditions on the main properties required for ultimate and serviceability limit states for ground improvement works. Curing the treated samples under partially saturated conditions dramatically affected the stiffness characteristics at low strains, the shear strength under unconfined and axisymmetric conditions, and the response to cyclic loading. In any case, the geopolymer satisfactorily avoided liquefaction initiation within the number of cycles investigated. A decrease in water permeability was observed as a function of the degree of filling of the voids with the binder and an increase in retention capacity and air-entry value compared to the untreated material. Mercury intrusion porosimetry and micro-CT provided microstructural insight into these phenomenological observations.

RÉSUMÉ: L'amélioration des sols par injection de liants durables et de géopolymères suscite un grand intérêt. L'utilisation de ces produits dans les fondations, les glissements de terrain, les excavations, les structures de soutènement et les tunnels est progressivement prise en compte dans les normes géotechniques. Cela nécessiterait de prendre en compte l'évolution des matériaux sous l'action mécanique ou environnementale, y compris les changements dans l'état hydraulique du sol. Une étude approfondie en laboratoire a été menée sur des échantillons de sable traités avec un géopolymère à base de métakaolin afin d'évaluer l'effet de différentes conditions de saturation sur les principales propriétés requises pour les états limites ultimes et de service pour les travaux d'amélioration du sol. Le durcissement des échantillons traités dans des conditions partiellement saturées a considérablement affecté les caractéristiques de rigidité à faibles déformations, la résistance au cisaillement dans des conditions non confinées et axisymétriques, ainsi que la réponse aux chargements cycliques. Dans tous les cas, le géopolymère a évité de manière satisfaisante l'initiation de la liquéfaction dans le nombre de cycles étudiés. Une diminution de la perméabilité à l'eau a été observée en fonction du degré de remplissage des vides par le liant et une augmentation de la capacité de rétention et de la valeur d'entrée d'air par rapport au matériau non traité. La porosimétrie par intrusion de mercure et la micro-CT ont fourni un aperçu microstructural de ces observations phénoménologiques.

Keywords: Sand improvement; metakaolin; partial saturation; geotechnical properties.

1 INTRODUCTION

Ground improvement aims to increase the mechanical properties of soils and rocks while decreasing permeability in engineering applications.

The traditional Ordinary Portland Cement (OPC) is used for ground improvement. However, other materials, known as non-conventional binders, are used as an alternative to OPC for ground improvement purposes, such as colloidal silica, resins, micro-fine cement, and geopolymers (e.g., Anagnostopoulos and Sapidis, 2017; Salvatore et al., 2020; Spagnoli et al., 2022; Fraccica et al., 2022).

It is critical to analyse the hydro-mechanical behaviour of non-conventional binders that could be used as an alternative to OPC in sustainable

engineering practices. When exposed to acid solutions, geopolymer materials outperform OPC (e.g., Bakharev, 2005).

This work has focused on Soil Deep Mixing (SDM)-adaptable binder (metakaolin-based geopolymer - MK). To the authors' knowledge, no commercial applications of MK-based binders for ground improvement are known. Most laboratory studies on geopolymer-treated soils focus on volcanic ash, fly ash, or ground blast-furnace slag (e.g. Verdolotti et al., 2008; Rios et al., 2017). Metakaolin-based geopolymers have received little attention for soil treatment and have typically been used with other geopolymers or OPC (e.g. Kolovos et al., 2013). Furthermore, in many laboratory investigations, soil and geopolymer precursor powders are combined dry before the activator is applied, and the samples are compacted (e.g. Zhang et al., 2013). However, this does not reflect how SDM is often performed in situ because already-activated slurries are combined with wet soils and no compaction is performed (Yaghoubi et al., 2018). Consoli et al. (2011) and Spagnoli et al. (2022) have demonstrated that the soil structure obtained after compaction (final porosity and amount of binder) has a significant impact on the strength and stiffness of the treated material.

Finally, few studies have been conducted to investigate the combined impact of extreme dry curing conditions and lengthy curing times on soil binder performance (e.g. Rios et al., 2017).

The current paper focuses on the permeability, static and cyclic strength of sandy soils treated with a metakaolin-based geopolymer after curing in dry and wet conditions at a relative humidity RH = 50% and 100%, respectively.

2 MATERIALS AND METHODS

The base material used in this study is a medium quartz sand (Holcim 0.2–0.6 mm), while the binder is an alkali-activated metakaolin. The metakaolin is activated with a water solution of potassium silicate. Potassium silicate solution, water and metakaolin are mixed in equal masses, leading to a geopolymer with a fluid/metakaolin mass ratio of 2:1 and a mass ratio between dry metakaolin and dry sand of 5.2% and 13% for initial slurry volumetric void filling F_{MK} values of 40% and 100%, respectively. Specimens were prepared by pouring the pure sand or the sand+geopolymer mixture into moulds. Specimens for Unconfined Compression (UC) tests are 70 mm in diameter and 164 mm in height. In contrast, those for cyclic and monotonic triaxial undrained compressions (CTX, STX) are 38 mm in diameter and 96 mm in height. After an initial 3-day common stage in the casting mould (at 20°C and RH = 50%), some specimens were cured at 20°C in dry conditions and some in wet conditions, at a relative humidity RH = 50% and 100%, respectively. The last condition was achieved by submerging the samples in water after three days of curing. The following nomenclature identifies the specimens: S, sand; MK, geopolymer; SMK, geopolymer+sand. The F_{MK} achieved is indicated between parenthesis; the curing condition is indicated by a letter (W: water immersion, D: curing at 50% RH) and a number indicating the curing time in days. For example, SMK(100)D7 indicates sand+geopolymer, with a F_{MK} = 100%, dry-cured for 7 days. D or W is not indicated for specimens at 3 days curing as they were submitted to a common preparation stage.

3 HYDRO-MECHANICAL TESTS

3.1 Microstructural observations

Treated soil's microstructure was investigated using mercury intrusion porosimetry (MIP), X-ray tomography, Field Emission Scanning Electron Microscopy (FESEM) and paraffin tests (Spagnoli et al., 2022; Fraccica et al., 2022). An increase in macro-pores was observed in the dry-cured specimens by MIP, resulting from micro-cracks formation in the geopolymer and detachment at the grain/geopolymer contact (FESEM). X-ray and paraffin tests revealed a decrease in dry density with dry curing (void ratio $e \approx 0.42$ after three days and $e \approx 0.47$ after 100 days).

3.2 Hydro-mechanical properties

After evaluating the bar wave velocity v_b in dry- and wet-cured samples through an ultrasonic pulse velocity tester (Proceq Pundit Lab Lab+, see Spagnoli et al., 2022), the small-strain Young's modulus was calculated as follows:

$$E_0 = \rho(t_c) v_b^2 \quad (1)$$

where $\rho(t_c)$ is the bulk density at a given curing time. At similar curing times, lower stiffness values were observed on dry-cured samples than on wet-cured ones (Table 1).

UC tests were conducted at a 0.5%/min axial deformation rate on specimens with a height/diameter ratio between 2 and 2.5. Lower Unconfined Compression Strengths (UCS) were observed in dry-cured samples, with a slight decreasing trend with curing time (Table 1).

Isotropically consolidated undrained triaxial compression (TXCIU) tests were performed under monotonic and cyclic conditions. After saturation, the water permeability was evaluated under steady-state conditions by imposing a back pressure of 200 kPa at the bottom and 10 kPa at the top cap. The treatment progressively contributed to decreased soil water permeability as the F_{MK} and the curing time increased due to void clogging and the solidification of geopolymers (Figure 1).

Table 1. Mechanical properties of treated sand under dry and wet curing.

Specimen	E_0 (GPa)	UCS (MPa)
SMK(100)3	-	1.44
SMK(100)3	-	2.07
SMK(100)D7	0.59	1.18
SMK(100)W7	3.44	2.05
SMK(100)D28	0.71	1.10
SMK(100)W28	5.40	1.51

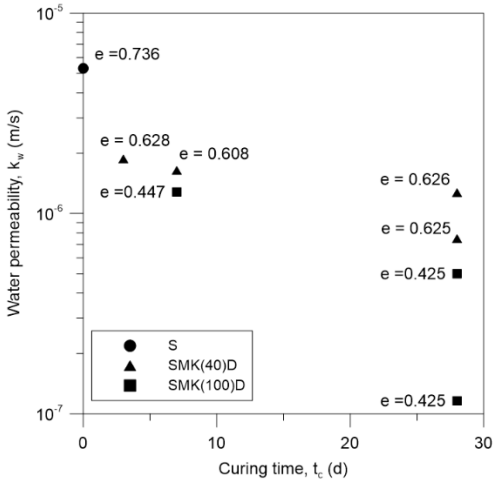

Figure 1. Water permeability of geopolymer-treated sand at different curing times. Void ratio as labels.

Consolidation was induced under isotropic stresses p'_0 = 200 and 600 kPa. The shearing phase was carried out with a back-pressure of 500 kPa under stress-controlled conditions (47 kPa/min). Increasing F_{MK} resulted in more dilatant, stiffer and stronger specimens (Fraccica et al., 2022). Similar to what was observed for UC tests, samples with longer dry curing periods presented slightly lower shear strength starting from similar isotropic consolidation pressures (Figure 2). The different treatments of F_{MK} increased soil cohesion with no changes in the friction angle.

Cyclic undrained triaxial compressions (CTXCU) were performed; consolidation was carried out under K_0 = 0.5 until reaching σ'_1 = 250 kPa. Cyclic shearing was imposed through 600 cycles (1 Hz) at a cyclic stress ratio CSR = 0.25 and a back pressure of 400 kPa (Fraccica et al., 2022). The untreated sand underwent large strains (i.e. higher than 5%) after the first ten cycles with a fast increase in r_u (Figure 3) and liquefaction. The treatment reduced strains (i.e. lower than 0.07%), cyclic stiffness degradation and excess pore pressures.

Small treated soil subsamples (~300 mm^3) were extracted from dry-cured specimens to evaluate their water retention properties. A dew-point psychrometer measured total suction while gravimetric water content was assessed by oven drying at 105°C. Results from MIP tests were converted into Soil Water Retention Curves (SWRC) through the procedure explained by Romero (1999). The main drying curve of the treated sand was evaluated starting after 28 days of dry curing (Figure 4).

The soil's air-entry value rose after the treatment. The soil's ability to retain water decreased with greater total suctions, as seen by a sharp decline in the degree of saturation S_r.

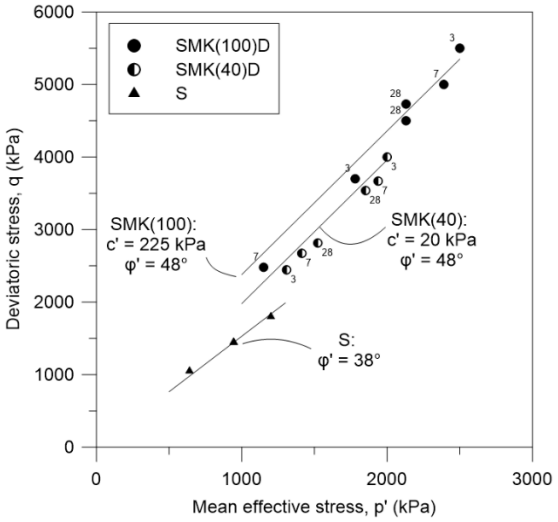

Figure 2. Shear strength envelopes for untreated and treated sand. Curing days as labels.

4 DISCUSSION AND CONCLUSIONS

Dry curing impacted the microstructure and hydro-mechanical behaviour of the metakaolin-treated sand.

Compared to wet-cured samples, microcracks and grain-binder detachments led to a decrease in stiffness and strength over time and an increase in the void ratio. Unlike untreated conditions, void clogging, filling ratio, and binder solidification helped reduce permeability and boost shear strength.

The treated soil's higher stiffness contributed to lower strains and excess pore pressures in the CTXCU, avoiding liquefaction. The almost saturated material showed a very high air-entry value due to the higher void filling with fine clayey material; this behaviour

was likely caused by the microstructural changes previously noted. The S_r value then sharply decayed. Therefore, when assessing the effects of such a ground improvement technology on geotechnical parameters in partially or saturated soils, consideration should be given to slurry void filling, curing duration, and *RH* conditions.

Muck identification and anomaly detection in earth pressure balance shield based on multi-task deep learning

Identification des déblais et détection des anomalies dans le bouclier à pression de terre basée sur l'apprentissage profond multi-tâches

ABSTRACT: A lack of understanding of geological conditions and improper muck disposal often leads to serious accidents, such as ground settlement or machine damage, during shield tunneling. The image data of muck on the conveyor belt reflects the general soil type of the excavated strata and the discharge condition, providing abundant and valuable information for EPB shield construction decisions. This paper aims to use a multi-task deep learning method to establish an image recognition model that can track the type and location of the muck and estimate whether the muck is discharged smoothly at the same time. The first task is an object detection task and the second is an image classification task. A convolutional neural network for a multi-task learning setting has been designed, and then used to build a multi-task muck recognition model using a specially constructed labeled muck dataset. The mAP for the muck identification task reaches 92.72%, and the accuracy for the anomaly detection task reaches 96.26%. The model is applied to Metro Line 14 in Shanghai, and the results show that the model performs well on both target tasks, meeting the real-time requirements at 45 frames per second.

RÉSUMÉ: Le manque de compréhension géologique et une élimination inadéquate des déblais peuvent entraîner des accidents graves, tels que l'affaissement du sol ou des dommages aux machines lors du creusement de tunnels avec un bouclier. Les images du tapis roulant reflètent le type de sol et la condition de décharge, offrant des informations cruciales pour les décisions de construction. Cet article utilise une méthode d'apprentissage profond multi-tâches pour créer un modèle de reconnaissance d'image suivant le type et l'emplacement des déblais, estimant simultanément la décharge correcte. La première tâche est la détection d'objets, la seconde est la classification. Un réseau neuronal convolutionnel est conçu pour un environnement d'apprentissage multi-tâches, utilisé pour construire un modèle de reconnaissance de déblais avec une APM de 92,72% pour l'identification des déblais et une précision de 96,26% pour la détection d'anomalies. Appliqué à la ligne 14 du métro de Shanghai, le modèle répond aux exigences en temps réel à 45 images par seconde, montrant une performance exceptionnelle sur les deux tâches.

Keywords: Muck identification; anomaly detection; multi-task deep learning; earth pressure balance shield.

1 INTRODUCTION

The shield method, with its safe, efficient, and labor-saving nature, is widely adopted in urban tunneling projects. Understanding the soil condition and discharging the muck smoothly play an essential role in reducing the disturbance to the environment and ensuring construction safety. Information about the soil type at the excavated face facilitates the adjustment of current construction decisions. When operating an earth pressure balance (EPB) shield machine, the muck produced by the machine and discharged by the screw and belt conveyor reflects the general soil type of the strata being excavated. Valuable information such as the soil condition ahead of the cutters and the muck discharge condition can all be obtained through the images of the muck on the conveyor belt. However, the number of experienced drivers is far from the needs of hundreds of shield tunneling projects. Furthermore, the manual vision-based inspection of the muck is comparatively subjective, uncertain, time-consuming, and labor-intensive. Nowadays, with the rapid development of artificial intelligence, especially deep learning (DL), automatic extraction of muck information

using computer vision presents an opportunity to automate the investigation of muck conditions.

DL has been applied to learn from muck images of tunnel boring machines (TBM) to estimate the size and shape of rock chips (Zhou et al., 2021) and grade the rock fragments in TBM construction (Yang et al., 2021). For soil muck generated by an EPB shield, which is more challenging than rock muck, Zhang et al. (2023) have tried to identify soil types based on muck images and achieved good results. Nevertheless, previous models can only extract a single aspect of information from muck images, while there is a lot of construction information that technicians care about in the muck images. If multiple similar tasks can be completed in one model, that should be very beneficial for the practical deployment and application on site. In this study, the authors aim to establish a multi-task deep learning-based model that can not only identify muck types but also simultaneously estimate whether the muck is discharged smoothly only using the site closed circuit television data. The method presented in this paper can be used to further develop more feature-rich visual recognition models of muck.

2 METHODOLOGY

2.1 Multitask learning

Multitask learning (MTL) is an inductive transfer mechanism whose principal goal is to improve generalization performance (Caruana, 1997). MTL can leverage the domain-specific information contained in all the related tasks. Useful information learned from any task will be shared across all tasks by training them in parallel using a shared representation.

MTL can not only help to train a model for completing multiple tasks simultaneously, but also there may be an useful improvement of generalization in the model resulting from the use of MTL. Moreover, training a single model for all the tasks using MTL can considerably enhance computational efficiency and conserve computational resources compared with training models for each task separately.

2.2 Network architecture

Owing to the exceptional performance of deep learning on image data processing, this study develops a convolutional neural network to train a multi-task recognition model for muck images.

The convolutional neural network architecture constructed in this study is shown in Figure 1. The network is composed of three parts, backbone, classifier, and detector. The backbone of Darknet53 (Redmon et al., 2018) is the shared layers which are responsible for extracting common useful features for both tasks. The classifier and detector are the task-specific layers for the two tasks. These layers are designed to further select and integrate features based on the characteristics of different tasks, achieving better performance on each task. The classification task is much easier than the object detection task. So the classifier consists of only a few simple layers, used for extracting global features, while the detector is the detection head of YOLOv3 (Redmon et al., 2018), which is excellent in the speed and accuracy of detecting objects of varied sizes and aspect ratios.

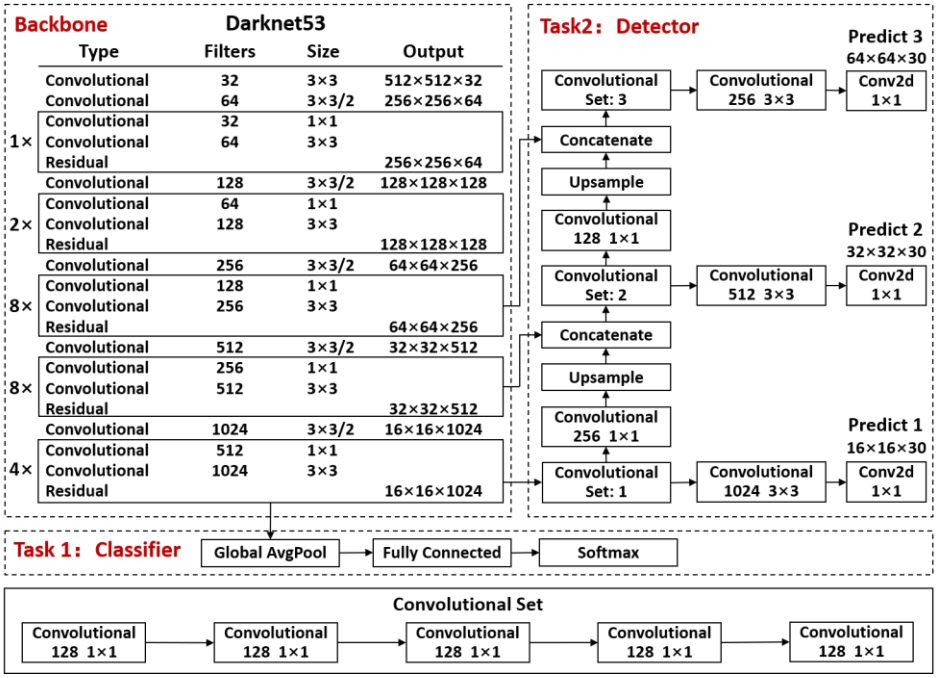

Figure 1. Architecture of the muck recognition network.

2.3 Evaluation metrics

Mean average precision (mAP) is used to evaluate the performance of the model on the muck-type identification task. Average precision (AP) is the averaged precision across all values of recall between 0 and 1, and it can be obtained by calculating the area under the precision–recall curve (i.e., *P*-*R* curve; Everingham et al., 2010) as shown in Equation 1:

$$AP = \int_0^1 P(R)dR \quad (1)$$

The average value of the APs over all categories is the mAP of the model as shown in Equation 2:

$$mAP = \frac{\sum_{n=1}^{C} AP(n)}{C} \quad (2)$$

where C is the number of categories, P and R are precision and recall respectively, and $P(R)$ represents the *P*-*R* curve.

Accuracy is used to evaluate the performance of the model on the task of determining whether the muck is discharged normally. Accuracy calculates the proportion of images correctly classified by the model out of the total number of images. The formula for accuracy is shown in Equation 3:

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (3)$$

TP is the correct prediction count for positive samples, TN is the correct prediction count for negative samples, FN is the count of positive samples incorrectly predicted, and FP is the count of negative samples incorrectly predicted.

Frames per second (FPS) is frequently used to evaluate the inference speed of a model. In general, a model can achieve real-time detection when FPS reaches 30 (Ma et al., 2020).

3 DATASET

3.1 Data collection and preprocessing

Above the shield machine's conveyor belt, a surveillance camera monitors muck discharge. Video footage from this camera serves as the primary data for our muck dataset. In this study, muck image data is collected from three tunnel intervals excavated by the EPB shield machine of Metro Line 14 in Shanghai.

Surveillance video, being low in information density, requires preprocessing. Initially, stable excavation stages in valid videos are identified, and muck images are extracted at regular intervals. Muck images exhibiting significant changes in morphology and construction scenes are selected while pixelated and redundant images resulting from video lag are eliminated.

3.2 Dataset establishment

Following preliminary data processing, 2080 high-quality muck images were obtained from collected videos. Among these, 1200 images depict normal muck discharge, while the remaining 880 showcase abnormal discharge. The collected muck images from Shanghai encompass five types: soft clay, normal clay, hard clay, silty sand, and mixed soil. The 1200 images of normal muck discharge equally represent each muck type at 240 images per type, while the abnormal discharge images specifically focus on soft clay.

Each image in the dataset is assigned corresponding labels for the two tasks. For the object detection task identifying muck types, LabelImg (Tzutalin, 2015) was used for manual annotation, stored in Pascal VOC format with XML files. For the image classification task determining normal muck discharge, the 1200 normal discharge and 880 abnormal discharge images are segregated into folders labeled "normal" and "abnormal," respectively.

4 IMPLEMENTATION AND RESULTS

4.1 Model development

All the experiments were executed on a workstation with an Intel Core i7-10700K CPU, an NVIDIA GeForce RTX 3080 with 16GB memory, and a Ubuntu 20.04 operating system. The neural network was constructed using Python 3.7 and PyTorch 1.7.0.

Hyperparameter settings: Original images were resized to 512 × 512 pixels for network input, with a batch size of 8. Stochastic gradient descent optimized the network parameters over 120 epochs. The initial learning rate was 0.001, linearly decreasing to 0.0001 with each epoch. Momentum and weight decay were set at 0.9 and 0.0005, respectively.

4.2 Model evaluation

The model was evaluated on the testing set. The performance of the model on the muck detection task is presented in Table 1. The detector has quite high accuracies on all five classes of muck, and the model achieves 92.72% mAP on the VOC metric (IOU = 0.5). The AP of soft clay is the highest, followed by normal clay and mixed soil, and finally hard clay and silty sand. The larger number of images for the soft

clay type may be one of the reasons for its optimal performance. Besides, soft clay is the type most easily recognized even by the naked eye, so it might be the same for the model. The morphological and texture characteristics of silty sand and hard clay will change with the application of soil conditioners, so the values of the evaluation indexes of these two categories are relatively low.

Table 1. The AP values for each muck type.

	Soft Clay	Normal Clay	Hard Clay	Silty Sand	Mixed Soil
AP	94.83%	93.43%	91.10%	90.17%	94.08%

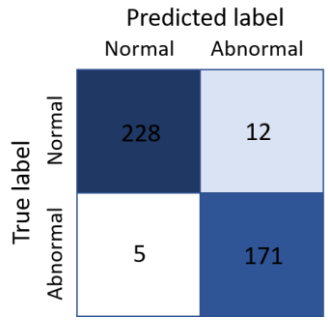

Figure 2. Confusion Matrix.

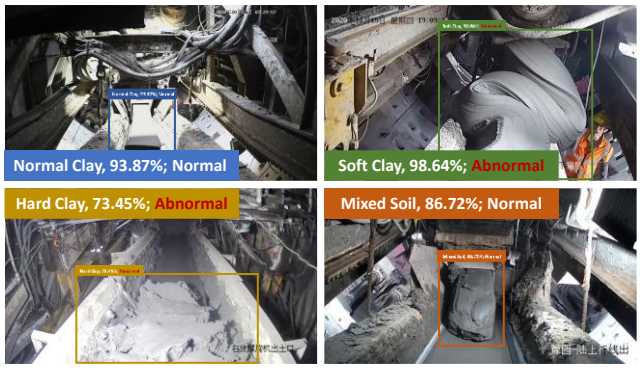

Figure 3. Muck recognition results.

The model achieves a 96.26% accuracy in anomaly detection. Figure 2 displays the confusion matrix for the binary classification task. It reveals that most misclassifications involve normal muck discharge cases mistakenly identified as abnormal, reflecting a conservative judgment less likely to impact tunneling safety. Figure 3 shows the detection and classification results of the model with four muck images. The model performs well on both tasks. The muck type is well-identified and the location of the muck is predicted accurately. The situation of muck discharge is also correctly discriminated, and abnormal muck discharge is highlighted in red. The model can process 45 frames of muck images per second, which can meet the real-time requirements.

5 CONCLUSION

This study developed a multitask-deep-learning-based model that can simultaneously accomplish two muck image recognition tasks in real time. The model can identify the muck type and locate the muck position precisely, reaching 92.72% in mAP. In the image classification task to determine whether the muck is discharged smoothly, the model achieves an accuracy of 96.26%. The model has the potential to increase the safety and steady tunneling rate of shield projects. The method used in this paper to build a multi-task muck recognition model could also be extended to build other models enabling the automation of different muck recognition tasks.

Reconstitution of samples for the study of mechanical behaviour of sulphide-rich soils

Reconstitution des échantillons pour l'étude du comportement mécanique des sols riches en sulfures

N. Garcia*, P. Gunnvard, Q. Jia, J. Laue
Luleå University of Technology, Luleå, Sweden

**nelson.garcia@ltu.se*

ABSTRACT: Sulphide-rich soil, a prevalent soft alluvial type along the Baltic Sea coast, is characterised by its sulfur content, low strength, high compressibility and significant organic components. Common practice involves replacing this soil with more resilient subgrade materials; however, excavated sulphur-rich soil necessitates to be treated as environmentally hazardous, due to its oxidation potential, leading to increased construction expenses. If instead, sulphide-rich soil is going to be used as subgrade, it becomes crucial to define its cyclic mechanical properties. This requires representative samples, which may not always be available through conventional undisturbed sampling methods. In this paper, the slurry deposition method was adopted to generate reconstituted samples of sulphide-rich soil for static triaxial testing. The method provided consistent samples and captured the characteristics of the natural soil. The triaxial results are the first step towards the understanding and definition of the cyclic behaviour of sulphide-rich soil.

RÉSUMÉ: Les sols riches en sulfures, un type alluvial mou prévalent le long de la côte de la mer Baltique, se caractérisent par leur teneur en soufre, leur faible résistance, leur grande compressibilité et leur teneur significative en matières organiques. La pratique courante consiste à remplacer ce sol par des matériaux de sous-fond plus résilients. Cependant, le sol riche en soufre excavé doit être traité comme dangereux pour l'environnement en raison de son oxydation, ce qui entraîne des coûts de construction accrus. Si, au contraire, le sol riche en sulfures doit être utilisé comme sous-fond, il devient essentiel de définir ses propriétés mécaniques cycliques. Cela nécessite des échantillons représentatifs, qui ne sont pas toujours disponibles par le biais de méthodes d'échantillonnage classiques non perturbées. Dans cet article, la méthode de dépôt de boue a été adoptée pour générer des échantillons reconstitués de sol riche en sulfures en vue d'essais triaxiaux statiques. Cette méthode a fourni des échantillons cohérents et a capturé les caractéristiques du sol naturel. Les résultats triaxiaux constituent la première étape vers la compréhension et la définition du comportement cyclique du sol riche en sulfures.

Keywords: Slurry deposition; sulphide-rich soil; triaxial testing.

1 INTRODUCTION

The construction of roads and railways in regions characterised by sulphide-rich soil deposits, particularly prevalent along the Baltic coastal areas of Sweden and Finland, presents a pressing geotechnical challenge. This unique fine-grained soil is known for its soft properties and high natural void ratio, with voids containing high amounts of water, organic matter, and sulphides, resulting from its anaerobic sedimentation during the last glaciation in tranquil brackish estuaries (Pousette et al., 2008). The soft nature of sulphide-rich soil, defined by low undrained strength and high compressibility and viscosity (e.g. Yu, 1993; Westerberg et al., 2005), implies significant obstacles to geotechnical structures leading to a common practise of excavating and replacing this soil. In addition, the sulphide-rich sediment produces acidic leachate when oxidised. Hence, excavated sulphide-rich soil is treated as environmental hazardous waste, increasing project costs and transportation emissions.

Recent advancements in soil stabilization and reinforcement techniques offer potential solutions for utilising sulphide-rich soil as a subgrade material. The subgrade of a road or railway embankment may not require a high bearing capacity, but it is subjected to high-cycle loads, characterised by large numbers of cycles with small amplitudes. Accurate predictions of deformation and pore pressure development are needed to ensure the long-term performance of the transportation network. However, the cyclic behaviour of sulphide-rich soil, with its unique properties, is not well studied.

Representative samples are needed to define the behaviour of a soil by laboratory testing. The softness of sulphide-rich soil prevents, in most cases,

undisturbed sampling. Making conventional sampling techniques, such as piston sampling, impractical or potentially disruptive. Disturbed samples can be reconstituted into representative samples instead. The slurry deposition method was initially devised for the reconstitution of sandy soils with fines. The method can also be applied to reconstitute silts and clays (Liu et al., 2017). However, its applicability on the reconstitution of organic fine-grained soils, such as sulphide-rich soil, needs to be investigated.

The aim of the research project is to investigate the cyclic behaviour of sulphide-rich soil and provide valuable insights for the design and construction of roads and railways in regions abundant with this distinctive soil type. Prior to cyclic triaxial testing, it is necessary to conduct static triaxial testing to obtain basic strength parameters of the soil and establish optimal test conditions. This paper covers the application and suitability of the slurry deposition method for the static triaxial testing of reconstituted samples of sulphide-rich soil.

2 SAMPLE RECONSTITUTION

The reconstitution of samples is a common practise in laboratory investigations of silts. Various techniques have been proposed for this purpose, such as moist tamping methods, water or air pluviation, and slurry deposition (Ladd, 1978; Kuerbis and Vaid, 1988; Carraro and Prezzi, 2008). Evaluations of the merits and drawbacks of these different reconstitution techniques can be found in Bradshaw and Baxter (2007) and Reid et al. (2022). When dealing with sulphide-rich soil, some challenges arise: the inability to dry the soil due to cementation and potential oxidation, the need for homogeneous reconstitution to the desired conditions, and disturbances by preparing the sample directly within the triaxial cell. The most fitting of the considered techniques, meeting all stipulated criteria, is the slurry deposition method. As the name suggests, the method involves consolidating the sample to the desired conditions starting from a slurry.

2.1 Soil Characteristics

The soil used for this study is a clayey silt, sourced from a landfill of freshly excavated soil from the Northern coastal area of Sweden. An overview of the basic parameters of the soil can be found in Table 1.

Table 1. Basic Soil Properties.

Property	
Clay Content	10 %
Silt Content	60 %
Sand Content	30 %
Organic Content	4 %
Specific Gravity	2.76
Water Content	40 %
Liquid Limit	33 %

2.2 Sample Preparation

The following equation by Liu (2017) is used to determine the amount of slurry needed for one sample,

$$m_{slurry} = (\pi \cdot h \cdot r^2) \cdot \rho_{dry} \cdot (1 + \omega_{slurry}) \quad (1)$$

where m_{slurry} corresponds to the mass of slurry to be poured, h is the height of the final sample, r denotes the radius of the final sample, ρ_{dry} corresponds to the target dry density, and ω_{slurry} is the water content of the slurry. Figure 1 shows the procedure followed for the sample reconstitution:

a) Assembly of the latex membrane, split mould, and bottom filter onto the triaxial base plate. Talc powder is applied to the mould exterior to prevent adhesion of the membrane.
b) Three strips of filter paper are placed inside the membrane to quicken the slurry consolidation.
c) A rubber support is fixed to the upper section of the split mould with two clamps.
d) An extension tube is inserted into the rubber support and fastened using the two clamps.
e, f) A funnel with an elongated nozzle is used to pour the predetermined m_{slurry}. As the slurry is gradually poured, the funnel is slowly raised with the nozzle end following the slurry surface.
g) A top filter and plug are positioned at the uppermost section of the extension tube. The consolidation process is initiated with a surcharge load atop the plug and vacuum pressure at the base. Both the surcharge and vacuum are maintained at pressures lower than the minimum confining pressure applied during the triaxial test. Water is added at the top to ensure that the sample remains fully saturated.
h, i) When the defined sample height h is reach, the surcharge load and vacuum pressure are removed, and the rubber support and clamps are detached. The soil sample is then cut at the top of the split mould. The part of the sample remaining in the extension tube is used to determine water content and soil density.
j) The prepared sample is mounted onto the triaxial apparatus following the standard procedure.

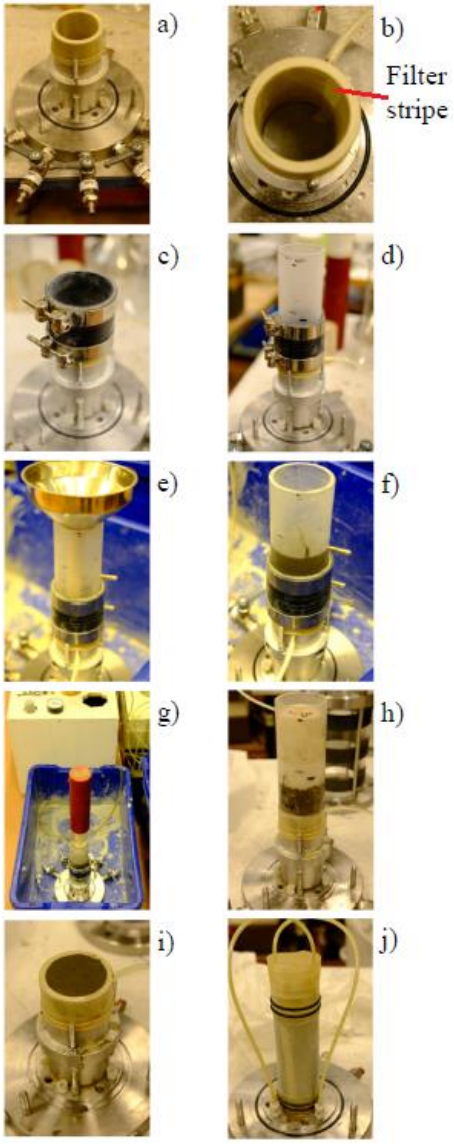

Figure 1. Steps for reconstitution of a sample by slurry deposition.

3 RESULTS

The presented results serve as an initial assessment to validate the suitability of the slurry deposition method for sulphide-rich soil. Four consolidated drained triaxial tests were carried out on reconstituted samples, with confining pressures of 30, 60, 100 and 200 kPa, respectively. The density, water content and void ratio of the four samples are shown in Figure 2. The samples exhibit a satisfactory level of homogeneity. The range of results from the reconstituted samples is in fact narrower than the relatively broad range in results obtained from testing undisturbed samples of this soil type.

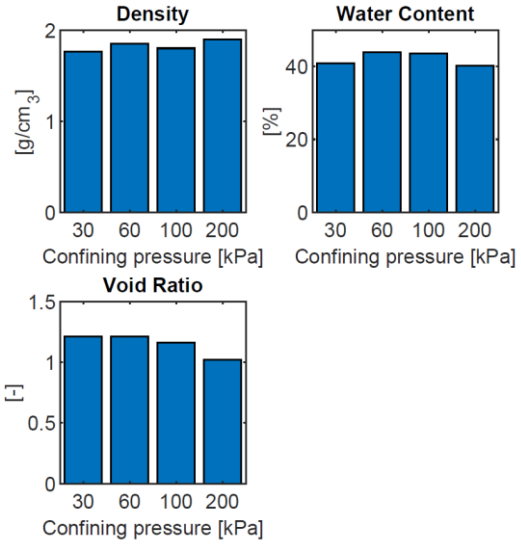

Figure 2. Measured density, water content and void ratio from the reconstituted samples for triaxial testing.

The triaxial test results are plotted in Figure 3 and 4. As the confining pressure increases, the samples exhibit failure at higher deviatoric loads, accompanied by a more distinct peak strength (Figure Figure 3a). Moreover, it is noteworthy that the failure of these samples takes place at high strains, undergoing significant consolidation while shearing, denoted by the large volumetric strains (Figure 3b), which is common for undisturbed samples (Yu, 1993). An indication of comparable behaviour between samples is the assymptotic tendency of the volumetric strains at failure around the same value (Lade, 2016). Also, the critical points utilized in deriving the critical state line (Figure 4) align well.

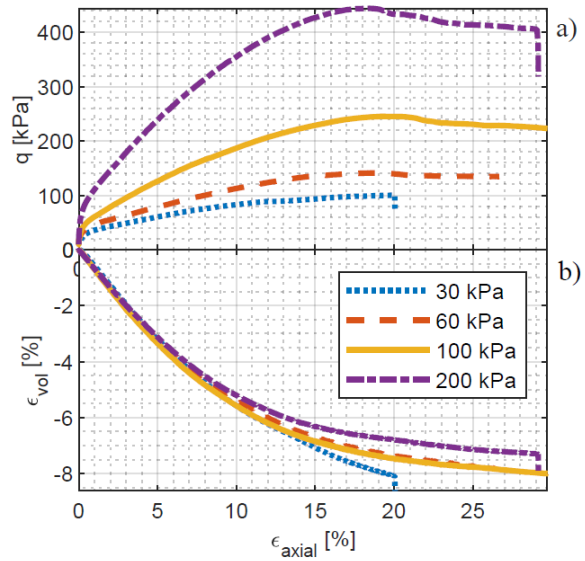

Figure 3. Results from the static triaxial tests: a) axial strain ϵ_{axial} vs deviatoric stress q, and b) axial strain ϵ_{axial} vs volumetric strain ϵ_{vol}.

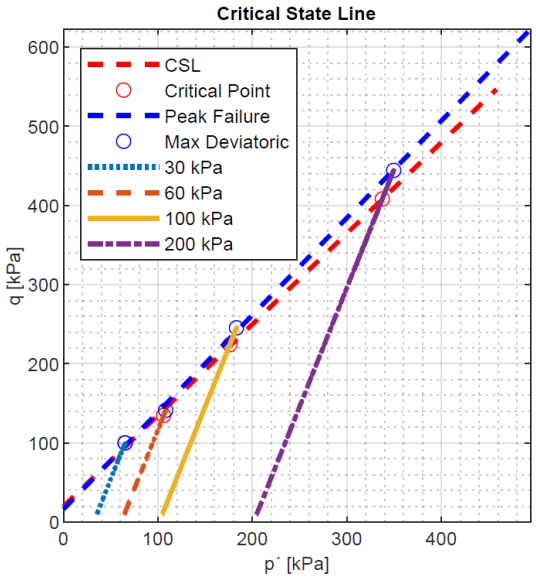

Figure 4. Derived critical state line (CSL) and peak failure line on the plane of deviatoric stress (q) and mean effective stress (p′).

4 CONCLUSION

The slurry deposition method was evaluated for generating reconstituted samples of sulphide-rich soil. Index property tests and consolidated drained triaxial tests were performed on reconstituted samples. The results show that the slurry deposition method not only yielded samples with remarkable homogeneity, both within and across multiple samples, but also provided the flexibility to influence sample density, allowing for a closer match to in-situ conditions. Triaxial testing of the reconstituted samples displayed the main typical characteristics of undisturbed samples, i.e. failure at large deformations and significant volumetric strain change. However, it is essential to acknowledge that the natural soil exhibits an array of anisotropies that cannot be replicated using this method.

Sulphide-rich soils are frequently observed to be overconsolidated, particularly in the uppermost strata of the deposit. Samples obtained through the slurry deposition method and isotropically consolidated in the triaxial are normally consolidated, as shown by the contractant behaviour of the tested samples. This condition does not pose a significant concern, as the targeted overconsolidation ratio can be reached by adding a second consolidation step in the triaxial test.

Based on the results of this paper, the slurry deposition method is a valuable tool for the reconstitution of sulphide-rich soil samples in geotechnical studies. To have a final verdict about the method, reconstituted sulphide-rich soil samples will be compared with undisturbed samples of the same source material.

A case study on energy-based evaluation of deep vibro compaction method

Une étude de cas sur l'évaluation basée sur l'énergie de la méthode de compactage par vibration profonde

ABSTRACT: This case history describes a well-documented and recently completed project in the Caribbean consisting of densification of hydraulic fills by vibro compaction method. The results of compaction are discussed based on energy criteria. The project site covers approximately 13,500 m^2 with an average depth of 9.5 m are densified to a minimum relative density of 65% against liquefaction. Soil classification for initial state of the hydraulic fills is investigated based on CPTU tests. Before the commencement of the works, vibro compaction parameter tests were carried out in 3 different test areas. The physical properties of the hydraulic fill and the details of the densification applications are presented. A comprehensive quality control program was pursued in the project. The successful execution of works illustrates the effectiveness of the selected method. In this study, the total amount of compaction energy transferred per unit volume of loose hydraulic fill, corresponding increase in cone resistance (Δq_c), the grid spacing, the vibro compaction production time are presented for each type of soil and results are presented.

RÉSUMÉ: Cette étude de cas décrit un projet bien documenté et récemment achevé dans les Caraïbes, qui consiste à densifier des remblais hydrauliques par la méthode du vibrocompactage. Les résultats du compactage sont discutés sur la base de critères énergétiques. Le site du projet couvre une superficie d'environ 13,500 m^2 et le sol y est densifié jusqu'à une profondeur moyenne de 9.5 m et une densité relative minimale de 65% contre la liquéfaction. La classification du sol pour l'état initial des remblais hydrauliques est étudiée sur la base des résultats de l'essai de pénétration au piézocône (Piezocone Penetration Test CPTu). Avant le début des travaux, des essais sur les paramètres de vibrocompactage ont été effectués dans 3 différentes zones d'essai. Les propriétés physiques des remblais hydrauliques et les détails des travaux de densification sont présentés. Un programme compréhensif de contrôle de la qualité a été mis en place dans le cadre du projet. L'exécution satisfaisante des travaux illustre l'efficacité de la méthode choisie. Dans cette étude, la quantité totale d'énergie de compactage transférée par unité de volume de remblai hydraulique meuble, l'augmentation correspondante de la résistance du cône, (Δq_c), l'espacement des grilles, le temps de production du vibrocompactage sont présentés pour chaque type de sol et les résultats pertinents sont indiqués.

Keywords: Hydraulic fill; compaction energy; vibro compaction; liquefaction; cone Penetration Test (CPT).

1 INTRODUCTION

The proposed port in the Caribbean has been under operation since 1929. Due to the development of the maritime transport methods and port facilities in the recent years, a development plan was implemented for future port layout design to meet traffic demand through 2020.

The project involves the redevelopment of the existing port. The project will enhance the passenger experience and provide additional business opportunities for the local population. The project will also include the construction of a new terminal building; the creation of an event and entertainment area; investments in retail facilities; and the design and construction of new food and beverage facilities. The project consists of expansion of the existing cruise pier, combi-wall driving works on existing wharf, construction of two new marinas for tour boats, dredging, densification of dredged hydraulic fill by vibro compaction method, expanding the port area by reclaiming and renovating & refurbishing of existing piers, arrival building, museum, signature restaurant, amphitheatre, 3 pier buildings, canopies, town square, market place, landscape works and all relevant construction, mechanical, electrical and architectural activities.

With the completion of all construction activities, the renovated port is expected to welcome over 4 million passengers annually. The location and general layout of the project site are shown in Figure 1.

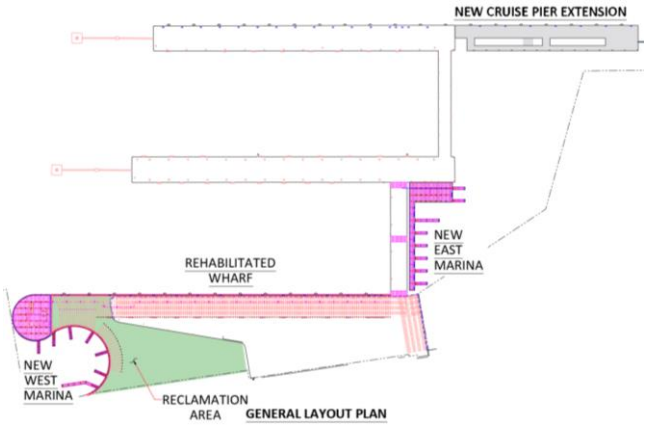

Figure 1. General layout of project site.

2 SUBSOIL CONDITION AND DREDGING WORKS

A total of five boreholes were carried out within the scope of preliminary soil investigations in the project area. Among these boreholes, B-5 and B-7 were carried out on the land side, and B-4, B-6, and B-9 boreholes were carried out on the sea side. Samples from soil and rock layers were taken by the Standard Penetration Test (SPT) and NQ rock coring. Borehole layout plan given in Figure 2.

Figure 2. Borehole layout plan.

The idealized soil profile of the proposed project site and BIM model of seabed are shown in Figure 3. For onshore boreholes, the groundwater elevations are typically the same as the sea level in the adjacent port area.

The project consists of a construction of a 250-meter-long pier extension to the east of the northernmost existing cruise ship pier and the reclamation of the quay area at the south end of the port, between the pier structure and the coastline, by filling with hydraulic fill sand. A new combi-wall consisting of steel pipe piles and sheet piles was constructed in front of the existing combi-wall system to renovate the existing system. Behind the combi-wall, dredged loose granular hydraulic fill material covering an area of approximately 13,500 m^2 with an average depth of 9.5 m was placed. Then the hydraulic fill was compacted by vibroflotation method to achieve a minimum relative density of 65%.

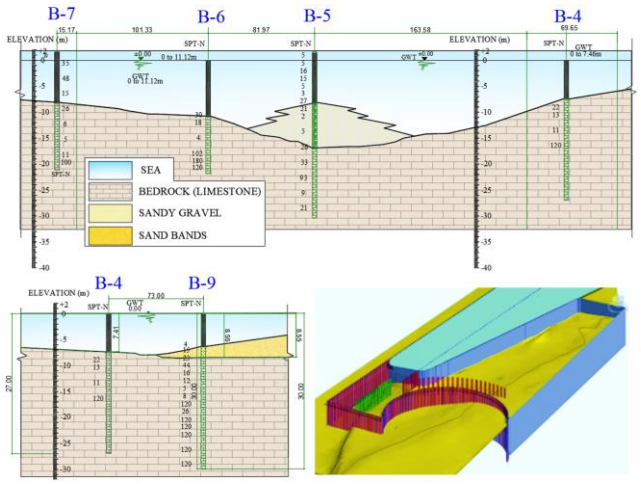

Figure 3. Idealized soil profile and BIM model of seabed.

In total, approximately 127,530 m^3 of loose granular fill material was dredged from the seabed and transported to the reclamation area by pipelines. Double rows of silt curtains are installed on the outside of the combi-wall to reduce and limit turbidity.

2.1 Evaluation of Fill Material Quality

Two methods were used to evaluate the quality of fill material. In the first evaluation method, with the help of the relation developed by Brown (1977), the suitability of the fill material for vibro compaction method was determined according to the soil grain size:

$$SN = 1.7\sqrt{\frac{3}{D_{50}{}^2} + \frac{1}{D_{20}{}^2} + \frac{1}{D_{10}{}^2}} \qquad (1)$$

where D50 is the diameter of the grain through which 50% of the soil passes, D20: It is the diameter of the grain through which 20% of the soil passes. D10: It is the diameter of the grain through which 10% of the soil passes. The suitability numbers method is an accepted and widely used method used to decide on the improvement of the fill material by the vibro compaction method. It is stated that vibro compaction is suitable for fill materials where the suitability numbers are in the range of 1 to 30.

The preliminary evaluation of the samples taken from the hydraulic fill from the project site area shows that suitability of the hydraulic fill is good to excellent. The results of the sieve analysis and suitability numbers (SN) performed on 13 samples taken from the filling area are summarized in Figure 5.

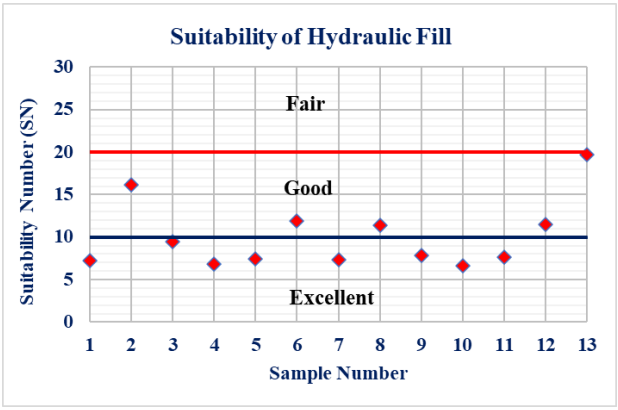

Figure 4. Suitability number of hydraulic fills.

In the second method, the results of the two pre-CPT tests performed in the center of the reclamation area were evaluated for compactability of the hydraulic fill by using the method proposed by Massarsch (1991). The results show that the hydraulic fill is marginally compactible to compactible as shown in the Figure 5.

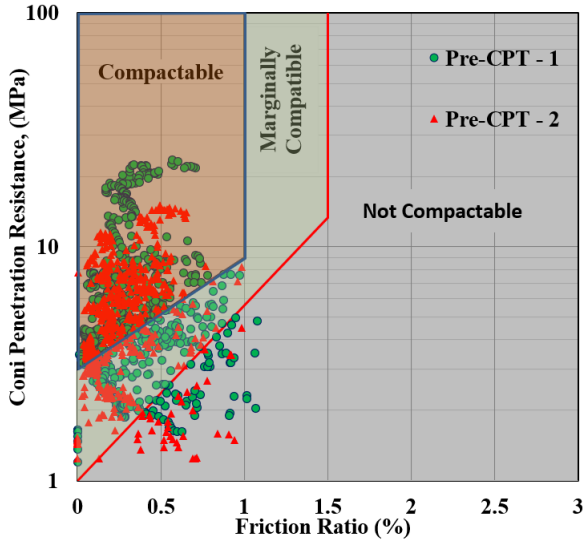

Figure 5. Compatibility assessment of hydraulic fill.

3 FULL-SCALE FIELD TESTS

To verify the installation parameters of vibro compaction works, preliminary tests were performed at a designated test area before the commencement of the works. In the test area, different grids of vibro compaction were tested with an equilateral triangular grid of 3.25x3.25m, 3.50x3.50m and 3.75x3.75m. These grid configurations were chosen to assess the performance of the vibro compaction method under different grid spacing. Before the tests, pre-CPT (Cone Penetration Test) were performed at the center of the test area for evaluating the initial state of the hydraulic fill.

Post CPT tests were performed ten days after the completion of the vibro compaction application. The layout plan for full scale preliminary tests is shown in Figure 6.

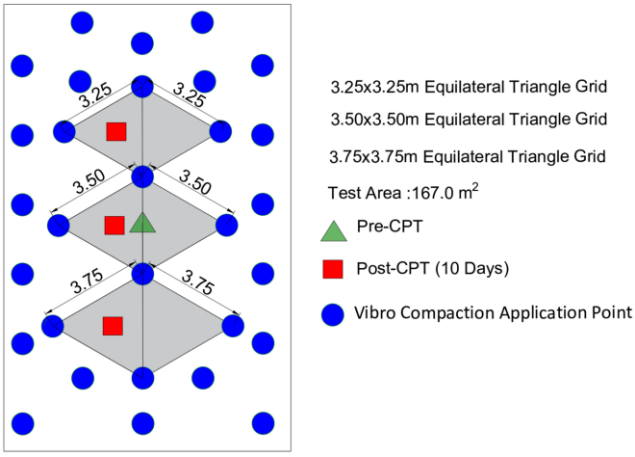

Figure 6. Layout plan for full scale preliminary tests.

Since the hydraulic fill is marginally compactible a double pass application method was introduced and tested. The double pass method consists of two passes over the same location by using vibroflot as shown in Figure 7. This approach is commonly employed to achieve a higher degree of compaction compared with single pass method.

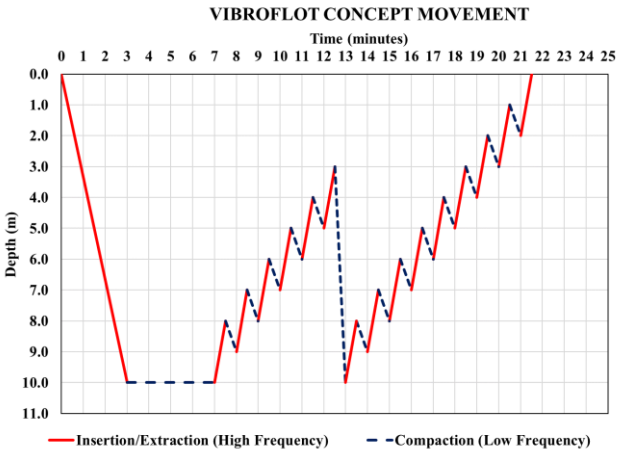

Figure 7. Vibro compaction with double pass method.

CPTs performed before and after the densification by vibroflotation method and the energy applied to the soil in the vicinity of CPT test location (TA-7) are shown in Figure 8.

In order to measure and evaluate the effectiveness of vibro compaction application, production parameters were recorded with the help of a full-time electronic data collection unit. Using the obtained data, compaction energy was calculated precisely along the depth. The correlation developed by Baldi et al. (1986) was used to convert the targeted relative density value

into the equivalent cone end resistance with overburden pressure correction.

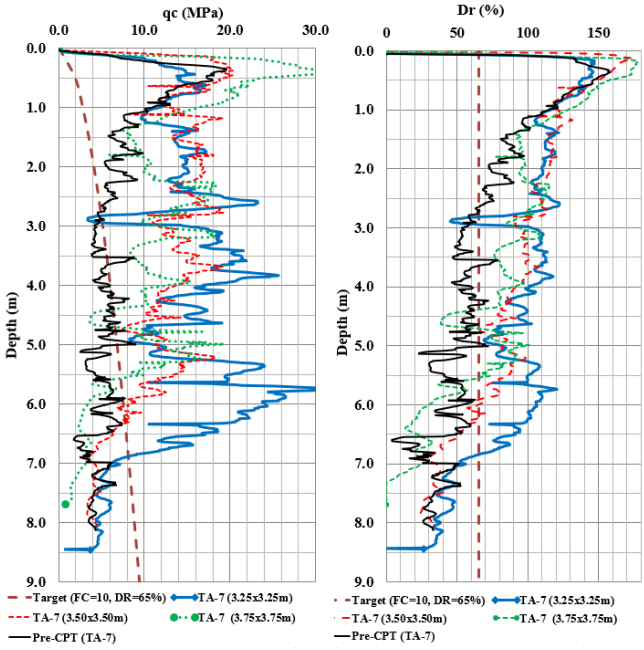

Figure 8. Cone penetration test results of TA-7.

Vibro compaction application with double passes and CPTs were performed using different grid spacing. According to the post-CPT results, all applications using the double pass method fulfils the target cone tip resistance and average relative density criteria (65%), and an average increase in cone tip resistance was obtained between 65% and 124%. The results of the full-scale field experiment using different grid spacings are summarized in Table 1.

Table 1. Full-scale field tests results.

Grid Spacing (m)	Avg. Depth (m)	Average Compaction Energy (kJ/m^3)	Δqc (Mpa)	Δqc (%)
3.25	8.80	2201.85	7.67	**124%**
3.50	8.50	1843.09	5.67	**91%**
3.75	8.00	1737.38	4.01	**65%**

In vibro compaction works, an optimization is required for production parameters in order to optimize production time and grid spacing. After determining the targeted improvement rate, the compaction energy that needs to be transferred to the fill material can be calculated with the help of the relationship given below. Since compaction energy is calculated using vibro compaction application parameters, this relationship can be used to evaluate whether the parameters are chosen correctly. As a result of the preliminary tests carried out in three different areas within the proposed site, a 93.8% linear correlation was obtained between the increase in cone tip resistance (Δqc) and compaction energy. The relationship between compaction energy and increase in cone tip resistance (Δqc) is given in Figure 9 and equation 2.

$$\Delta qc = 0.0073xE_c - 8.27 \qquad (2)$$

where Δqc is the increase in tip resistance (Mpa) and Ec is the vibro compaction energy (kJ/m^3).

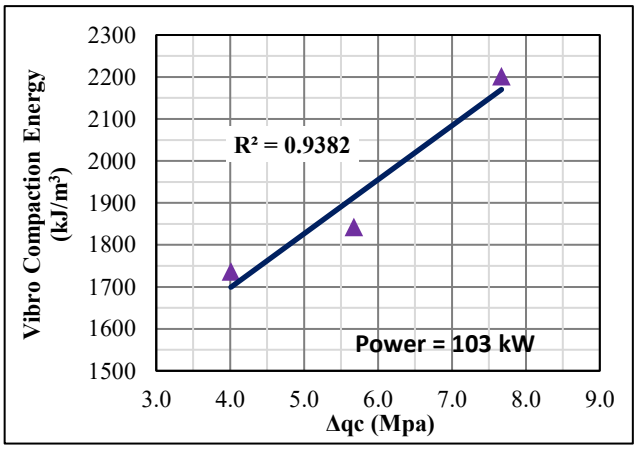

Figure 9. Relationship between vibro compaction energy and Δqc.

3.1 Evaluation of time-dependent improvement rate

An additional in-situ preliminary field test was conducted in Test Area-4 to evaulate time-dependent improvement behaviour after completion of vibro compaction works. The general layout plan of the test area is shown in Figure 10.

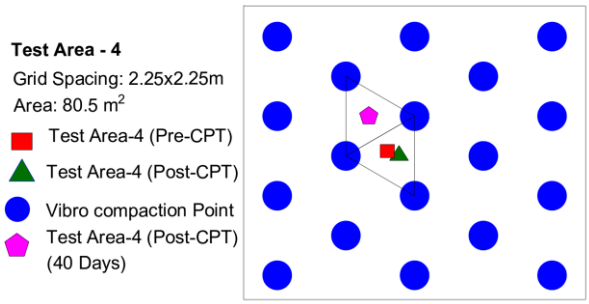

Figure 10. Layout of test area-4.

The time dependent behaviour is shown in Figure 11 by comparing pre-CPT, 2-day, 10-day, and 40-day Post-CPT cone tip resistance with depth.

According to the 40-day post Cone Penetration Test (CPT) results, in vibro compaction applications using a high-pressure water jet, the water jet initially increases the pore water pressure in the soil. After the completion of the compaction process, the pore water

pressure starts to decrease over time, and soil particles come closer together. As the excess pore water pressure in the soil diminishes over time, the cone tip resistance is observed to increase gradually because the soil particles transit to a denser arrangement pattern. The rate and magnitude of time-dependent improvement varies depending on various factors, such as the soil permeability, coefficient and drainage conditions.

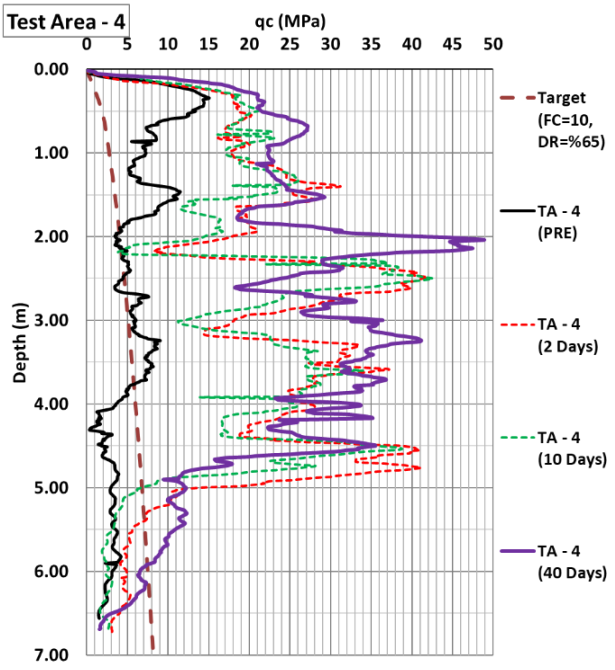

Figure 11. Cone penetration test results of TA-4.

It was determined that there was an increase in average cone tip resistance along the depth in the Cone Penetration Test conducted 40 days after the vibro compaction application. Thus, results support and confirm other studies conducted in this context in the literature.

4 CONCLUSION

This study emphasized the importance of selecting correct relationship between improvement rate and energy consumption per unit soil volume in vibro compaction applications. This would enhance the efficiency of quality control and design processes, while also offering advantages in terms of cost, quality control and work schedule in large-scale soil improvement projects.

Within the scope of this study, the initial engineering properties of the filling material acquired by dredging from the seabed and placed hydraulically in the reclamation area, the details of the seabed dredging application, the details of the vibro compaction application, the details of the full-scale field experiment carried out from the reclamation area, and the results obtained are explained.

In the double-pass vibro compaction application, in which three different grid spacings are realized with equilateral triangle grid spacing, it has been observed that the cone tip resistance decreases with the increase in the grid spacing.

The study investigated the correlation between the energy applied during vibro compaction, the resulting CPT tip resistance values, and the actual improvement rate of the soil. This analysis aimed to assess the effectiveness of the vibro compaction method in achieving the desired improvement rate in soil engineering properties.

The correct handling of the relationship between the improvement rate and the energy consumed per unit soil volume in vibro compaction applications is believed to enhance the efficiency of the quality control and design processes. By optimizing this relationship, it is possible to achieve desired improvements in soil properties.

The results obtained from the study are expected to significantly contribute to the design and quality control processes in large-scale soil improvement projects. These findings likely provide insights into the relationship between energy consumption, improvement rates, and soil performance, allowing for more efficient and effective planning and execution of vibro compaction projects.

Overall, the study emphasizes the importance of proper handling of energy consumption and improvement rates in vibro compaction applications. By ensuring the correct balance and understanding of this relationship, advantages can be gained in terms of cost-effectiveness, quality control, and adherence to work schedules in large-scale soil improvement projects.

Performance evaluation of CDC compaction for warehouses: a case study of European projects

Évaluation des performances de CDC compaction pour les entrepôts: une étude de cas des projets européens

C. Guglielmelli*, J.W. Dijkstra
Cofra B.V., Amsterdam, The Netherlands
**claudio.guglielmelli@boskalis.com*

ABSTRACT: In recent years, Cofra Dynamic Compaction (CDC), a heavy Rapid Impact Compaction (RIC) technique, has been increasingly used worldwide to compact granular subsoils prior to the construction of, for example, warehouses, reclamations, hotels, wind turbines, and infrastructures. This paper provides an overview of the test results and final work methods with a focus on the compaction design for two projects. The discussed case studies include a touristic complex project located in Portugal and a terminal project in the Netherlands. Each project required, due to their own particularities, a specific work method and monitoring of the compaction activities. In all cases, the improvement of the subsoil conditions beneath the surface and foundation elements was necessary to ensure either sufficient bearing capacity while reducing total and differential settlement of shallow foundations and floor slabs or to ensure homogenization of the areas for future use. Ad hoc detailed designs were prepared to ensure that different structural elements were treated individually to meet the project requirements. Compaction efforts were constantly monitored using a GPS-based crane monitoring system to assess the effectiveness of the compaction method and adapt compaction energy where necessary. The observational method used during the compaction operations proved to be a valuable tool to optimize production but also to improve the result of the compaction works. Verification of the compaction effort was achieved by means of pre- and post-compaction CPTs, and the requirements were checked in accordance with Eurocode 7.

RÉSUMÉ: Au cours des dernières années, la technique de Cofra Dynamic Compaction (CDC), une technique lourde de Rapid Impact Compaction (RIC), a été de plus en plus utilisée dans le monde entier pour compacter les sols granulaires avant la construction, par exemple, d'entrepôts, de réclamations, d'hôtels, d'éoliennes et d'infrastructures. Cet article présente un aperçu des résultats des tests et des méthodes de travail finales, en mettant l'accent sur la conception du compactage pour deux projets. Les études de cas discutées concernent un projet de complexe touristique et un projet de terminal situés aux Portugal et au Pays-Bas. Chaque projet nécessitait, en raison de leurs particularités propres, une méthode de travail spécifique et un suivi du compactage. Dans tous les cas, l'amélioration des conditions du sous-sol sous les éléments de surface et de fondation était nécessaire pour garantir soit une capacité portante suffisante tout en réduisant les tassements total et différentiel des fondations peu profondes et des dalles de sol, soit pour assurer l'homogénéisation des zones en vue d'une utilisation future. Des conceptions détaillées ad hoc ont été préparées pour garantir que différents éléments structuraux soient traités individuellement afin de répondre aux exigences du projet. Les efforts de compactage étaient constamment surveillés à l'aide d'un système de suivi de grue basé sur le GPS pour évaluer l'efficacité de la méthode de compactage et adapter l'énergie de compactage si nécessaire. La méthode d'observation utilisée pendant les opérations de compactage s'est avérée être un outil précieux pour optimiser la production, mais aussi pour améliorer le résultat des travaux de compactage. La vérification de l'effort de compactage a été réalisée à l'aide de CPTs (essais de pénétration statique) avant et après le compactage, et les exigences ont été vérifiées conformément à l'Eurocode 7.

Keywords: Rapid impact compaction, RIC; cofra dynamic compaction, CDC; warehouse; granular soil; densification; cone penetration test, CPT; GPS-based crane monitoring system.

1 INTRODUCTION

As part of the design of warehouses and infrastructure projects on loose granular soils, the method of deep compaction is often overlooked in favour of deep foundations or ground improvement techniques such as stone columns and rigid inclusions.

However, the alternative approach using Heavy Rapid Impact Compaction (RIC) has proven to be highly effective and cost-efficient compared to commonly chosen solutions. Compaction with RIC ensures that the compacted materials easily meet the necessary support requirements for the loads imposed by the superstructure.

Cofra Dynamic Compaction (CDC), a heavy Rapid Impact Compaction technique, is often employed to effectively densify the uppermost soil layers, typically 6 to 10 meters deep, depending on the local soil conditions. Within the compaction process, the drop weight (9-ton to 20-ton), drop height (from 0.2 m to 1.5 m), grid spacing, and effort (number of blows given at a frequency of 0.7-1.2 Hz) are optimized to allow for the application of various tailored work sequences to meet the specific requirements of different foundation elements.

The high production and efficiency of the technique can be attributed to the constant contact between the foot (with a diameter ranging from 1.5 m to 2.6 m) and the ground surface, which transfers kinetic energy into compression and shear waves. The shear waves, combined with the dense compaction grid used during the operations, ensure uniform and highly effective compaction.

The process is schematically illustrated in Figure 1.

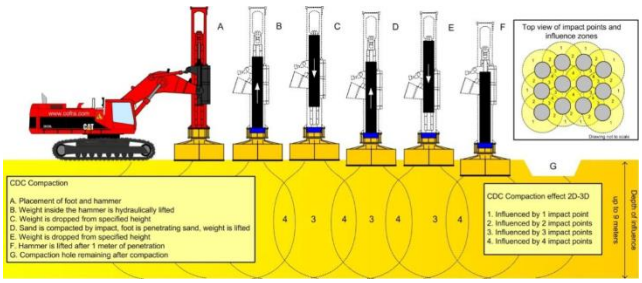

Figure 1. Illustration of the CDC work method and overlap of influence zones.

During compaction operations, several parameters are logged and displayed alongside the AutoCAD design drawing on the operator's screen. Compaction is stopped once the anticipated number of blows, maximum vertical displacement of the foot, or target settlement per blow is reached. To ensure the compaction process is both homogeneous and effective, real-time measurements of the field performance are sent back to the operator's screen and to the geotechnical engineer by uploading these into the data cloud. This enables adjustments to be made during the compaction process, such as change in foot size, grid spacing, drop height, and number of blows. Additionally, updated drawings can be immediately transferred back to the machine. Such an approach results in an optimal work process and outcomes.

This paper provides two case studies out of numerous projects executed worldwide. The examples were chosen to highlight the effect on relatively small-scale application areas where the observational method used during compaction played an important role to the projects' success. Moreover, case study 1 was selected to describe the use of RIC with challenging soil conditions, being the material to be compacted rounded dune sand.

2 CASE STUDY 1: ALDEAMENTO COLOMEIAS I PROJECT, TRÓIA, PORTUGAL

The Aldeamento Colmeias I project is located in the dune area on the Tróia Peninsula, in Portugal (Figure 2). The dune sand underneath several future buildings (logistics, restaurant, spa, hotel, luxury villas and reception facilities) required compaction over a thickness of 6 m to 7.5 m. This was needed in order to use shallow foundations with different sizes and loading configurations. The total surface area to be compacted was around 31,000 m^2.

Figure 2. Overview of the project scope (Aldeamento Colmeias I, Tróia) with an indication of the compaction points in light blue.

The compaction design focused on achieving the required bearing capacity with a minimal settlement for the different prefabricated footing configurations of the various buildings. With the main aim to reach the required depth of influence and sufficient densification, a design was prepared to perform RIC compaction using a 16-ton hammer (Figure 3) with 1.2 m drop height and a range of compaction efforts to consistently meet the requirements.

Figure 3. CDC equipment deployed on the project.

During the field trials, four combinations of compaction energy were tested, and based on their performance, two configurations were selected for the project. These two configurations were deployed on the basis of the pre-compaction CPTs, as well as the required bearing capacity and settlement behaviour following the treatment.

2.1 Results

After a single pass of CDC hammer, the functional requirements were successfully met at all tested locations up to a depth of 7.5 m. The result of the homogeneous compaction is shown in Figure 4, which illustrates the pre- and post-compaction CPT cone resistances (qc) of the trial area. During the trial, two passes were executed. To investigate its effect, CPTs were carried out on and in-between the compaction locations to show the lateral difference. Figure 4 clearly indicates that the second pass resulted in an increased qc over a greater depth of influence. Moreover, the qc values measured within one compaction location and between four compaction locations showed minimal variation, suggesting a satisfactory overlap of the compaction influence zones. This effect was also shown in Vink et al. (2016).

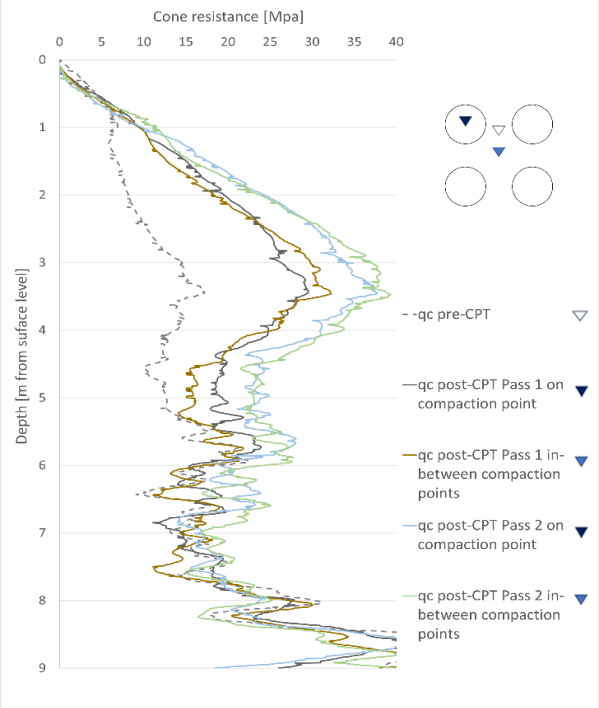

Figure 4. Cone resistance before compaction (pre-CPT), cone resistance after first pass compaction (post-CPT Pass 1) and cone resistance after second pass compaction (post-CPT Pass 2).

The effect of CDC compaction in terms of settlement is shown in Table 1. This is calculated using the Schmertmann's method (Schmertmann, 1978) for square footings, in line with Eurocode 7 (BS EN 1997-1, 2004).

Table 1. Part of the compliance check based on CPTs using Schmertmann's method from Eurocode 7.

Project area	Bearing capacity [kPa]	Settlement before CDC [mm]	Settlement after CDC [mm]

Colmeia 7	200	10.4	1.2
Colmeia 31	200	8.2	1.3
Colmeia 69	200	9.9	1.3
SPA	200	12.6	1.2
Hotel	200	6.3	1.2

3 CASE STUDY 2: TERMINAL AREA, MOERDIJK, THE NETHERLANDS

The following case study is a compaction project for a brownfield development of a new terminal located in Moerdijk, southeast of Rotterdam, The Netherlands. The project required compaction of the subsoil within loosely backfilled zones right underneath a number of demolished warehouses. The main purpose of the ground improvement (over a maximum depth of maximum 3 m) was to obtain a homogeneously densified sand fill with the surrounding existing soil, to accommodate for the heavy loads that the future terminal will need to support. The total surface area to be compacted was around 37,000 m^2.

Figure 5. CDC equipment deployed on the project.

3.1 Stop criterion: settlement per blow

For this project, a specific work method was developed to carry out RIC with a 9-ton hammer (Figure 5) and reduced drop height of only 0.9 m, using a settlement per blow stop criterion. The compaction process was monitored using the advanced GPS-based crane monitoring system, which measures the settlement of the compaction foot for each blow. During the field trial, a fixed grid was tested on both the backfilled area and the existing soil, with a baseline of 40 blows. The collected settlement data was analysed to establish a

correlation between qc and settlement per blow. As a result, a specific settlement per blow target was chosen for the project. This was generally reached after the first few blows in the non-excavated area and at the end of the compaction sequence in the backfilled area. This target settlement was implemented in real-time during the operations, and the measurements were visible to the operator of the rig, facilitating and optimizing the compaction process.

The outcome of the homogeneous compaction achieved in this project can be observed in Figure 6 and Figure 7. Whilst Figure 8 displays the number of blows given at each compaction point to reach the target settlement per blow.

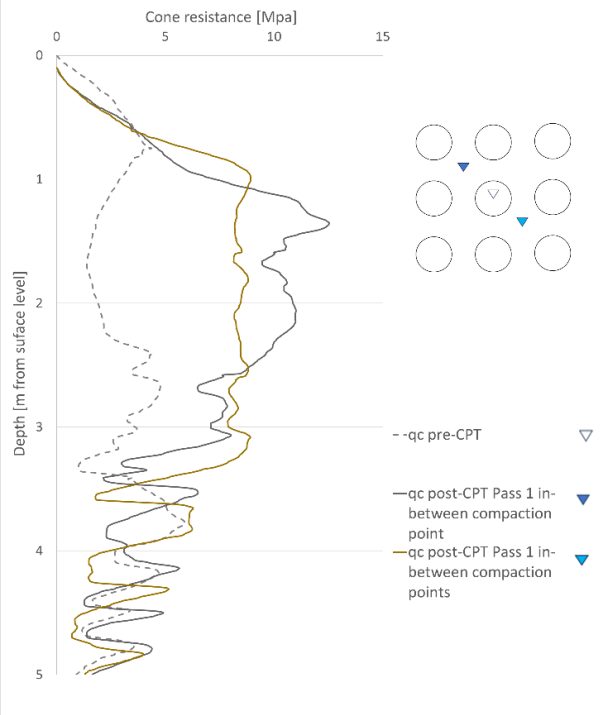

Figure 6. Cone resistance before compaction (pre-CPT) and cone resistance after first pass compaction (post-CPT Pass 1) using the settlement per blow stop criterion.

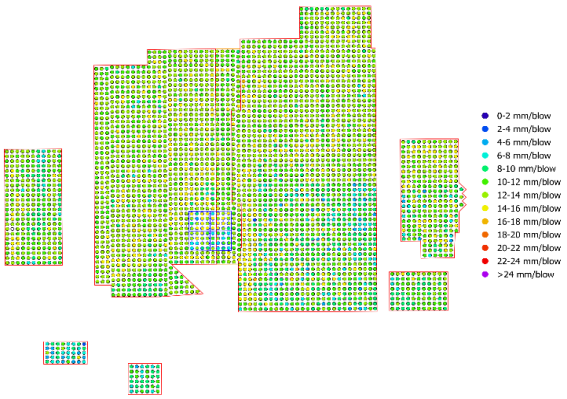

Figure 7. As-built settlement per blow after CDC compaction.

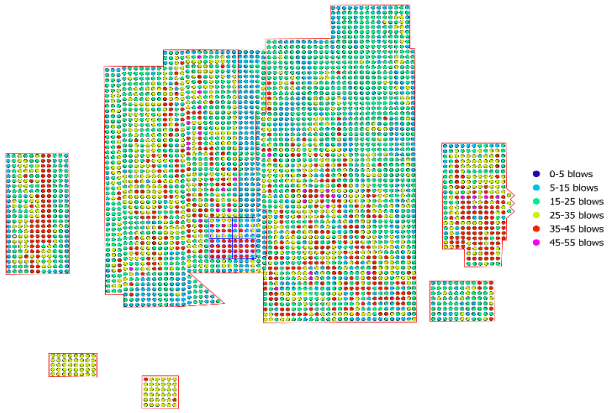

Figure 8. As-built number of blows from CDC compaction.

4 CONCLUSION

This article highlights the effectiveness of project-specific RIC design methods through two project examples. These methods enabled the treatment of loose granular subsoils up to a depth of 7.5 meters in compliance with the project requirements, leading to cheaper soil improvement solutions, as less compaction energy was used during the execution.

Over the past decade, numerous projects worldwide have been executed using this observational method, thanks to the development of a tailored ad hoc design that addresses the specific needs of each project. This approach relies on a GPS-based crane monitoring system and fully automated processing of real-time data. The evaluation of the field performance during the implementation of the Cofra Dynamic Compaction technique has consistently demonstrated its high effectiveness not only in mitigating the risks of liquefaction, differential settlement, and ensuring sufficient bearing capacity for prefabricated footings of varying sizes, but also in optimising the production and the quality of the compaction works.

ABSTRACT: This study develops a numerical thermo-hydraulic model to simulate the Artificial Ground Freezing (AGF) intervention as a ground improvement. Frozen soil is modelled based on the partially saturated framework, considering a three-phase material composed of solid grains with liquid water and ice filling the voids. A physically based criterion is proposed to estimate the freezing temperature at which the soil attains the impermeable conditions and thus is completely frozen. According to this criterion, coarse-grained soils freeze around a temperature of -1°C, and fined-grained soils freeze progressively for lower temperatures, down to -9°C. The modelling approach is applied to the AGF case study of the Isarco River Underpass in the Brenner Base Tunnels project. The incoherent and heterogeneous coarse-grained soils under a water seepage regime that characterise the site, within the few-meters thin covering separating the tunnel from the riverbed, make using the AGF necessary to furnish the proper safety conditions for the excavation works. The accessible geotechnical investigation surveys and the monitored soil temperature data aimed to validate the proposed numerical model. The model predictions regarding temperatures reveal a strong dependence of the freezing process on the soil's hydraulic and thermal properties and the seepage flow regime. An optimised freezing temperature aims to improve the process of artificial freezing by reducing the time of freezing activation and designing an efficient configuration of probes, maintaining equal levels of safety against the waterproofing of the excavation area.

RÉSUMÉ: Cette étude développe un modèle thermohydraulique numérique pour simuler l'intervention Artificial Ground Freezing (AGF) en tant qu'amélioration du sol. Le sol gelé est modélisé sur la base du cadre partiellement saturé, en considérant un matériau triphasé composé de grains solides avec de l'eau liquide et de la glace remplissant les vides. Un critère physique est proposé pour estimer la température de congélation à laquelle le sol atteint les conditions imperméables et est donc complètement gelé. Selon ce critère, les sols à gros grains gèlent autour d'une température de -1 °C et les sols à grains fins gèlent progressivement pour des températures plus basses, jusqu'à -9 °C. L'approche de modélisation est appliquée à l'étude de cas AGF du passage inférieur de la rivière Isarco dans le projet de tunnels de base du Brenner. Les sols incohérents et hétérogènes à gros grains sous un régime d'infiltration d'eau qui caractérisent le site, à l'intérieur de la mince couche séparant le tunnel du lit de la rivière, rendent l'utilisation de l'AGF nécessaire pour fournir les conditions de sécurité appropriées pour les travaux d'excavation. Les enquêtes géotechniques accessibles et les données de température du sol surveillées visaient à valider le modèle numérique proposé. Les prédictions du modèle concernant les températures révèlent une forte dépendance du processus de congélation sur les propriétés hydrauliques et thermiques du sol et le régime d'écoulement d'infiltration. Une température de congélation optimisée vise à optimiser le processus de congélation artificielle en réduisant le temps d'activation de la congélation et en concevant une configuration efficace des sondes, en maintenant des niveaux de sécurité égaux contre l'étanchéité de la zone d'excavation.

Keywords: Frozen soils; excavations; numerical modelling; unsaturated soils.

1 INTRODUCTION

Artificial ground freezing (AGF) is a temporary excavation support technique adopted in various engineering applications (*e.g.*, Harris, 1995; Viggiani & Casini, 2015). Its basic principle is to reduce soil temperature below 0°C by circulating cooled fluid through freezing pipes installed in the ground around the future excavation section, creating a close and stable waterproof shell. The AGF design should be performed by thermal and structural analyses (Chang & Lacy, 2008). The thermal analysis will provide shape and temperature profiles of the frozen body. The

structural analysis will use the resulting frozen ground structure to evaluate whether it is stable during the excavation. Modelling the freezing process is challenging since it has a strongly coupled thermo-hydro-mechanical nature that should include phase changes. This article proposes a new method to optimise the thermal analysis design of AGF based on the theoretical framework of unsaturated soils extended to frozen conditions (Casini *et al*., 2023). This novel approach was applied to the case study of AGF intervention adopted for the Isarco River underpass tunnels within the Brenner Base Tunnel*s* project, performing numerical simulations with a coupled *thermo*-hydraulic model implemented in a finite element code.

2 THE METHOD

During the AGF operation, the soil temperatures must be continuously recorded to check the thickness and tightness of the frozen shell. The soil can be considered frozen when the temperature falls below a target value, conservatively assumed to be T^*= - 10°C, regardless of the soil type. However, the volume of liquid water that changes phase into ice depends highly on the temperature applied, the type of soil, and its hydraulic properties.

Figure 1 reports literature experimental data from Williams (1964) relating the temperature *vs* the degree of liquid water saturation (Soil Freezing Curve) for sand, silt and clay, interpolated by Clausius-Clapeyron joined with the van Genuchten laws (Casini, 2021; Nishimura *et al*., 2009):

$$S_{ew} = \left\{ 1 + \left[\frac{-\left(1-\frac{\rho_i}{\rho_w}\right)P_w - \rho_i L \ln\left(\frac{T}{273.15}\right)}{P} \right]^{\frac{1}{1-m}} \right\}^{m} \qquad (1)$$

where S_{ew}=(S_w-S_{res})/(1-S_{res}) is the effective degree of liquid water saturation, ρ_i e ρ_w are the density of ice and water, respectively, P_w is the pore water pressure, L is the latent heat of water fusion, and P and m are the parameters of the van Genuchten retention curve. According to the Soil Freezing Curve, frozen conditions are achieved when the liquid phase is discontinuous, and the effective degree of liquid water saturation is close to the residual values: S_{ew}≈0.05÷0.10. It occurs for different temperatures depending on soil type, generally greater as grain size increases. In Figure 1, the soil frozen condition corresponds to a temperature range of: -0.6 to -2.0°C, for sand; -1.3 to -2.6°C for silt; -5.9 to -10.5°C for clay. Thus, based on the water retention properties of the soil, the target freezing temperature can be estimated as T_{sand}*=-1°C, T_{silt}*=- 2°C and T_{clay}*=-9°C, respectively.

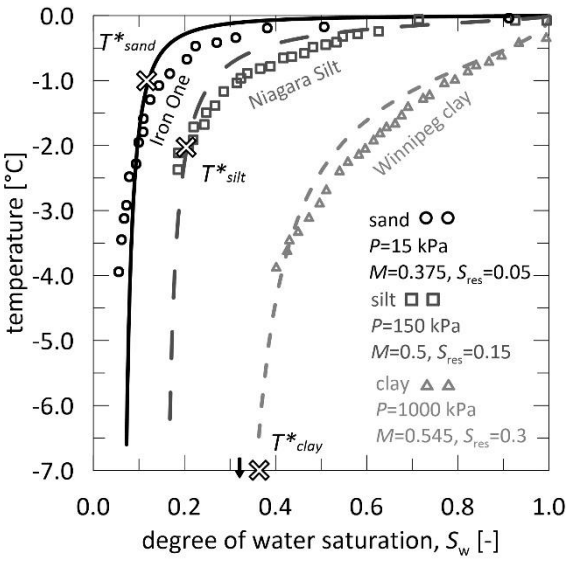

Figure 1. Relation between the degree of liquid water saturation and the temperature. Experimental data after Williams (1964).

3 THE CASE STUDY

AGF is typically adopted in contexts such as excavations in heterogeneous soils below the water table, characterised by issues related to instability and significant seepage flows. The case study under examination is the Isarco River underpass tunnel, whose critical conditions due to the low coverage (about 5 m) and the need to excavate through loose, coarse-grained soils below the water table made AGF the unique safe intervention possible. The area is located 1 km north of Fortezza in the Isarco Valley (Bolzano), at an elevation of about 750-850 m above sea level. A plan view of the underground structures is shown in Figure 2(a): four shafts, named POBDN, POBDS, POBPN, and POBPS, were constructed to allow the excavation of the four underpass tunnels of about 50-55 m in length. This work simulates the freezing operations in the first tunnel to be completed, highlighted in red in Figure 2(a) between the POBPN and POBPS shafts. The reference excavation cross-section is 12 m distant (S12m in Fig.2a) from the POBPN shaft. The AGF was carried out by driving the freezing pipes around the excavation section parallel to the development of the tunnel, as shown in Figure 2(b). Freezing was activated with liquid nitrogen, entering at about - 196°C (open circuit) and maintained using brine (calcium chloride) at approximately -35°C, which recirculates through a refrigeration plant. The excavation operations start when the frozen body becomes 1 m thick. Optic fibres

installed in 42 thermometric rods parallel to the tunnel development monitored every 25 cm the temperature of the soil and the growth of the frozen body.

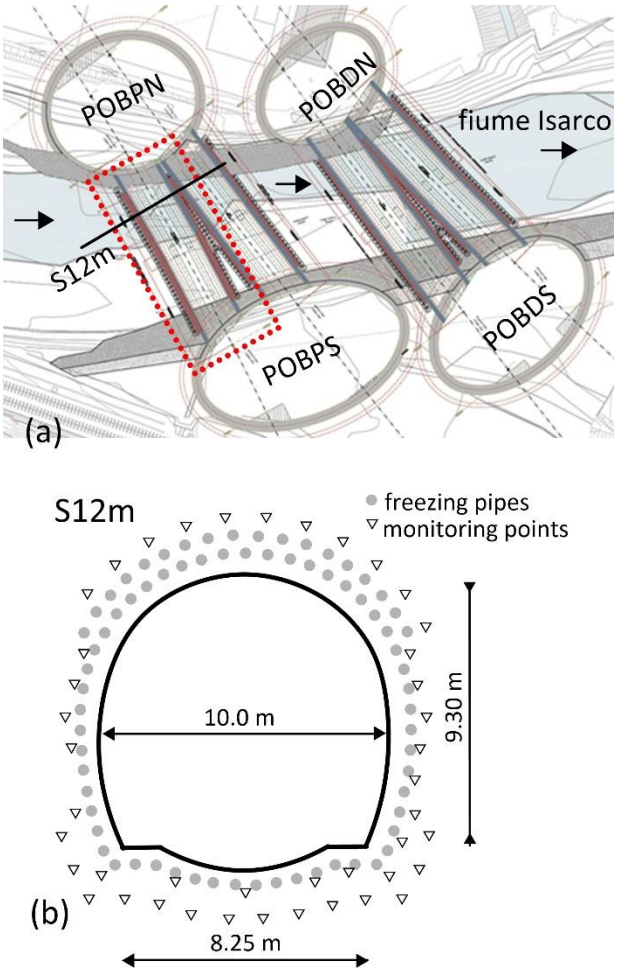

Figure 2. (a) Plan view of the underground structures; (b) enlarged view of the tunnel cross-section under examination specifying the position of the freezing pipes and the monitoring points.

Figure 3(a) shows the evolution over time of the temperatures in the monitoring points M1 and M2 arranged at two different points of the tunnel cross-section (Fig. 3b). The lowest temperatures were recorded at the end of the activation phase (~day 9), which are approximate -10°C and -28°C, in M2 and M1, respectively. In the following maintenance phase with brine, the monitored temperatures increase and reach a thermal equilibrium around day 12. The differences between trends can be attributed to the relative distance between the freezing pipes and the thermocouples, the seepage effect, and the soil heterogeneity.

4 NUMERICAL SIMULATIONS

The AGF process was numerically reproduced using a coupled thermo-hydraulic model capable of accounting for the phase change from liquid water to ice induced by temperature below 0°C, Soil Freezing Curve, and seepage. For details of the implementation and parameters adopted, see Casini *et al*. (2023). Figure 3(a) compares the model predictions and monitoring data at the two monitoring points, M1 and M2. The simulations were conducted considering uncertainty about the position of the freezing probes of ± 10 cm in the horizontal and vertical directions due to possible deviations of the perforations. The envelope of model predictions qualitatively reflects the monitoring data trends in the liquid nitrogen activation and brine phases. However, the model predictions overestimate the monitoring data, especially in the activation phase (up to day 9). The discrepancy is possibly due to the faster achievement of the subzero temperature at the freezing pipes boundary conditions. Figure 3(b) shows the contour lines of temperatures evaluated at the end of the liquid nitrogen activation phase (9th day). The formation of a closed, frozen wall with temperature values below -10°C is observed around the entire tunnel excavation area. The imposed seepage regime from left to right (0.7 m water gradient in 60 m) determines the non-symmetry of the contour lines. Figure 4 reports the evolution with time of the equivalent thickness th_{eq} of the frozen wall, quantitatively evaluated from the images of the numerical temperature contours considering as target value T*=-10°C and T_{sand}*=-1°C. The curves have the same monotonous increasing trend with time. The proposed method allows an optimised design of the frozen wall thickness and the duration of the nitrogen activation phase, while maintaining the same level of safety against waterproofing (see Casini *et al.,* 2023).

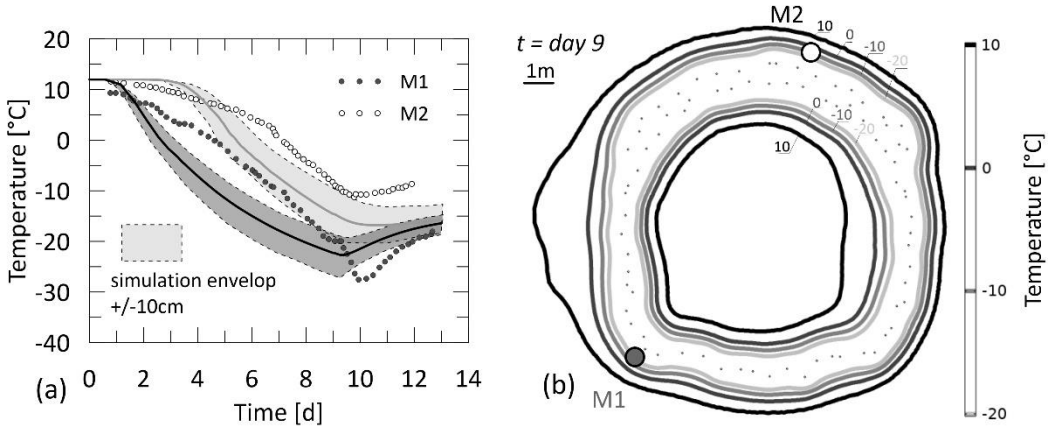

Figure 3. (a) comparisons of temperature evolution over time at measurement points M1 and M2; (b) Contour plots of temperatures obtained from simulations on day 9 between monitoring data and model predictions.

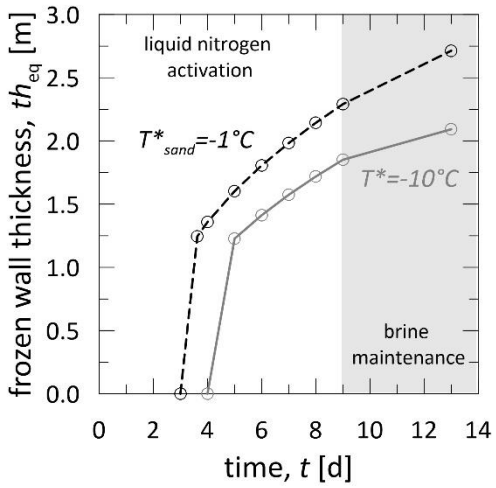

Figure 4. Equivalent frozen wall thickness evolution with time adopting two different target temperatures T.*

5 CONCLUSIONS

This work proposed a new design criterion to optimise the design and monitoring of the artificial ground freezing intervention. It consists of defining the target temperature value to identify the frozen state of the soil based on the Soil Freezing Curve. The new approach is then applied to the artificial ground freezing case study of the Isarco River underpass tunnel, showing a potential reduction of the activation phase duration without compromising safety against waterproofing.

ACKNOWLEDGEMENTS

Dr Giulia Guida obtained Regione Lazio's financial support through her position as a fixed-term researcher (POR-FSE 2014/20 Contributions for the permanence of excellence in the academic world, No. 65629/2020). We would like to thank the WEBUILD SPA Company and its technicians for the contribution offered in the drafting of this article and for the opportunity given to us to visit the construction site during the various phases of artificial ground freezing and Marco Carosi for his collaboration during his master thesis work.

Innovative and sustainable geosynthetic solutions in the field of bridge abutment construction

Solutions géosynthétiques innovantes et durables dans le domaine de la construction de culées de ponts

H. Hangen*, O. Detert
HUESKER Synthetic GmbH, Gescher, Germany

**Hangen@HUESKER.de*

ABSTRACT: The constant increase in traffic volume and the dilapidated condition of many existing infrastructure requires constant maintenance, modernisation, and reconstruction. Bridge structures play a particularly important role in this context. The use of geosynthetics can help to overcome this challenge in a more cost-effective and sustainable way compared to established technologies. Geosynthetic-reinforced soil structures can be used, for example, to relief the foundation or the abutment structure from earth-pressure. In many cases it can even be used to form the abutment as such. In any case these solutions impress with their simplicity in construction, robustness, and their quick implementation. This is demonstrated by means of completed projects.

RÉSUMÉ: L'augmentation continue du volume du trafic et l'état de délabrement de nombreuses ouvrages d'infrastructure existants nécessitent un entretien, une modernisation et une reconstruction constants. Les ponts jouent un rôle particulièrement important dans ce contexte. L'utilisation de géosynthétiques peut aider à relever ce défi d'une manière plus rentable et plus durable que les technologies traditionnelles. Les structures de sol renforcées par des géosynthétiques peuvent être utilisées, par exemple, pour soulager la fondation ou la structure de la culée de la pression du sol. Dans de nombreux cas, elles peuvent même être utilisées pour former la culée en tant que telle. Dans tous les cas, ces solutions séduisent par leur simplicité de construction, leur robustesse et leur rapidité de mise en œuvre. Des projets réalisés le démontrent.

Keywords: Bridge abutment; geogrid reinforced soil; sustainability; earth pressure relief; geosynthetic encased columns.

1 INTRODUCTION

1.1 Geosynthetic reinforced retaining structures

Due to their ecological and economic advantages over traditional construction materials the use of geosynthetic reinforcement products is common practice today. Geosynthetic-reinforced retaining structures (GRS) occupy a special position here and represent one of the oldest and most common application of geosynthetics. A comprehensive overview about the beginnings of GRS can be found, for example, in (Allen et al., 2002); a systematic survey and evaluation of the structural behaviour of representative GRS can be found, for example, in (Crouse and Wu, 1996). Bathurst (Bathurst, 2014) provides an overview of the current state of the art and current developments in design concepts and modelling. Overall, GRS can be characterized by the following main advantages over conventional construction methods:

1. ductile load-bearing behaviour enables reduced requirements for subsoil and backfill materials
2. fast and therefore cost-effective construction or disposal (for temporary structures) using conventional earthworks equipment
3. low global warming potential (GWP)
4. wide range of architectural design options.

1.2 Geosynthetic reinforced bridge abutments

Many investigations and reference projects have shown that GRS structures can also withstand extremely high loads without failing or exhibiting excessive deformations. This was demonstrated very impressively, for example, in real-scale load tests at the Landesgewerbeanstalt Nürnberg (LGA) (Alexiew, 2007) and (Alexiew and Detert, 2008) or (Bräu and Bauer, 2001). Figures 1 and 2 show the test arrangement as well as the horizontal and vertical deformations of the 4.5 m high GRS for vertical loading with a 1.0 m wide and 3.0 m long concrete beam. The horizontal deformation which was measured for a vertical stresses of 200 to 250 kN/m²,

reached a value of about 4 mm. The corresponding settlement was approx. 6 mm. The structure started to show signs of imminent failure only when the load was increased to about 500 kN/m² following two unloading and reloading cycles with only marginal elastic deformation. Clear failure, however, could not be achieved even under the maximum applicable load of 650 kN/m². Such behaviour is described also from other researchers such as or (Bräu and Bauer, 2001). The maximum bearing capacity is even given as up to 1200 kN/m².

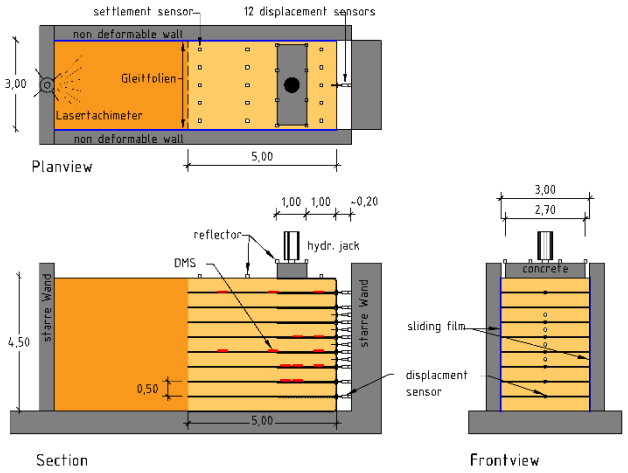

Figure 1. Testing arrangement at LGA-Nuremberg (Hangen and Jaramillo, 2016, translated from German).

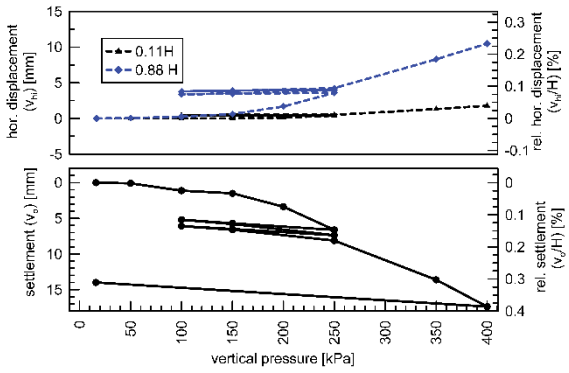

Figure 2. Monitoring of horizontal and vertical deformations for increasing vertical stress (Hangen and Jaramillo, 2016, translated from German).

Based on this experience it is reasonable to use GRS even for the construction of highly loaded bridge abutments and several reference structures show that this is feasible. However, in many countries GRS-bridge abutments have only rarely been used to date.

2 TYPICAL APPLICATIONS OF GRS-BRIDGE ABUTMENTS

2.1 GRS for wing walls and raised abutments

As shown in Figure 3 GRS can be used focusing several differing objectives. The simplest application of GRS bridge abutments is the formation of raised abutments and wing walls (Figure 3 upper left). In this application, dead weight of the bridge and traffic loads are usually transferred conventionally via piles into stable ground. This option is appropriate in case of very high abutments loads or bridges with continuous girders and if the subsoil conditions are extremely unfavourable.

Beside cost savings for GRS compared to reinforced concrete (RCC) it is basically construction time and logistics which makes GRS attractive in this case. Drilling rigs could be acting from the top of the GRS when all abutment and backfilling of the ramp have been finished. Access and construction would not interfere with traffic at the base of structure in this case. This can be a huge advantage in case reconstruction needs to be done in tight spaces. Furthermore, this construction sequence would allow to reduce or exclude negative skin friction and horizontal earth-pressure acting on the foundation piles.

2.2 GRS to relief earth-pressure

Another possible application of GRS is the formation of so-called earth pressure absorbers, ref. Figure 3 upper right. In this case, the GRS is used to absorb the horizontal earth pressure of the abutment backfill. Depending on the bridge designer's structural concept, this can be done over the entire height of the abutment or only in the upper area of the structure. This can be temporary, to secure certain construction stages or permanent. In most cases GRS is designed to eliminate the entire earth pressure acting on a neighbouring structure. Theoretically, however, it would be possible to design for a reduced earth pressure only. In practice, unfortunately, there is not yet a method available as to reliably quantify the stress-reduction.

The construction of an earth pressure relief opens possibilities for significant changes or optimization in the structural design of the bridge structures, particular regarding torsional loading and bending. This is of particular interest wherever crossings are skewed. Earth-pressure relief with GRS can also be combined to optimise the design of integral bridges, eliminating complex bearings and transition structures but reducing maintenance costs in particular. The advantages of GRS for the construction of integral bridges, have been reported by (Pötzl and Naumann,

2005). One of the largest reference structures using this construction method in Germany is the so-called taxiway bridges at Frankfurt Airport (Steiger et al., 2012).

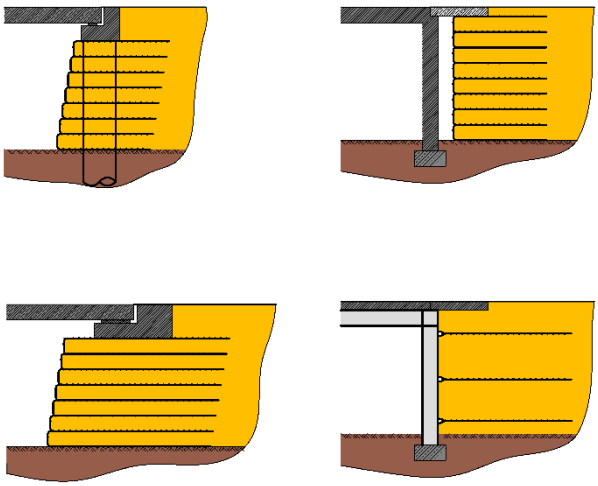

Figure 3. Configuration of GRS in bridge abutments (Hangen and Jaramillo, 2016).

2.3 GRS directly supporting the superstructure

The design of a bridge abutment, in which GRS is used to transfer the entire structural loads (ref. Figure 3 lower left), offers by far the greatest opportunities for optimization and benefit in sustainability. However, as the external forces acting on the structure increase, so do the requirements for the design and input parameters such as reinforcement products and fill-material. Increased attention also needs to be given for the quality of execution. In addition to the verification of the ultimate limit state (ULS), proof of the serviceability limit state (SLS) needs to be addressed more in detail. Latter is still challenging from an academic point of view since adequate analytical models allowing for a realistic estimation of the deformation behaviour of GRS are still lacking. Therefore, finite element modelling (FEM) is recommended to enable a safe prediction of the SLS. When using FEM however, one needs to consider that most deformations of a GRS are generated during the construction. Proper modelling should therefore address especially those deformations which are generated under service loads. Deformations encountered during construction usually could be balanced before the structure goes into operation.

Figure 4. Preloading of bridge abutment at Motorway A 74, Venlo, Netherlands (HUESKER).

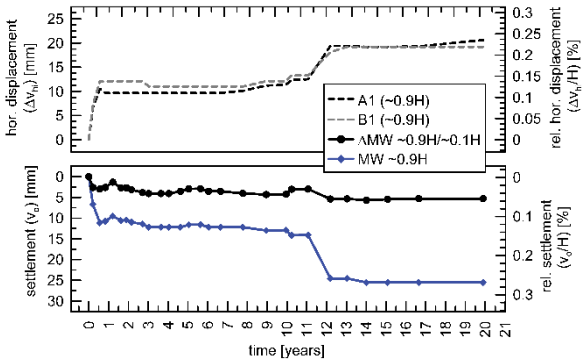

Figure 5. Average settlement and horizontal displacement at monitoring points A1 and B1 (~0,9 x H), Motorway A 74, Venlo, Netherlands (Hangen and Jaramillo, 2016 and Duijnen van, 2012).

Figures 4 and 5 show a GRS-bridge abutment under the motorway A74 close to Venlo in the Netherlands. In this project a preloading with concrete blocks was applied for about two weeks as to induce deformation of the GRS and the subsoil prior to the installation of the bridge superstructure. Total vertical deformation generated during this short preloading time was about 10 mm. After removal of the preloading the settlement increased to 15 mm due to consolidation of the subsoil.

Additional settlement of about 10 mm was monitored when the bridge deck was installed. The differential vertical displacement between the crest and the base of the GRS (ΔMW in Figure 5), however, did not exceed the initial value of about 5 mm, indicating that most deformation of the structure can be allocated to deformations of the subsoil. This observation matches perfectly with the findings of the real scale test at LGA, Figures 1 and 2: once the GRS is "sufficiently activated" additional loading will result in marginal deformation only. Settlement of the subsoil of course needs to be considered carefully and ground improvement may be required prior to the erection of the GRS. Differential settlement, however, is not critical if the superstructure would be resting on

a GRS. Abutment and embankment would be deforming at the same amount and rate. This is in contrast with typical designs, where the bridge is built on piles, the approach embankment however, built without any ground improvement.

Consequently, if properly designed and constructed, it is obvious that GRS is not only strong enough to resist the loading of a bridge superstructure but also stiff enough to fulfil the requirements of the serviceability limit state (SLS).

Further details about the design, materials and monitoring of the project in Venlo are presented in (Duijnen van et al., 2012).

2.4 GRS as anchor element for conventional retaining structure

Geosynthetic reinforcement can be used to anchor conventional retaining structures like sheet pile walls or soldier pile walls. This technology requires special care with regard to its design and installation and hence only been used in a few cases. It will not be discussed here, but interesting information about a small-scale experiment and FE-modelling of an geogrid anchored sheet pile wall has been published from Wittekoek et al. (2022).

3 LATERAL EARTH PRESSURE RELIEF USING GEOSYNTHETIC ENCASED COLUMNS (GEC)

Advantages of earth pressure relief using GRS have already been discussed in section 2.2. The application of geotextile encased sand columns (GEC), however, is another possibility to optimise the design of bridge foundations. This concept can be used to reduce horizontal pressure acting on foundation piles: vertical load generated by the backfill material of the abutment is mainly transferred by GECs down to a competent foundation level. Therefore, the embankment load is generating only marginal horizontal pressures. GECs are non-cohesive soil columns encased by a seamless, tubular geosynthetic reinforcement sleeve. GECs are typically uniformly arranged in a triangular pattern and the axial spacing varies between 1.7 m and 2.4 m. The diameter typically ranges between 600…800 mm. The remarkable reduction of lateral loads on bridge piles using CFP has been demonstrated in successfully executed projects (Alexiew et Thompson, 2016).

Figure 6 shows the typical section of the abutment of a single-span bridge of a motorway in the north of Germany (span w = 23 m) and its approach embankment. The abutment is built on in-situ-concrete piles with a diameter of D ~ 0.50 m and a pile inclination of 4:1.

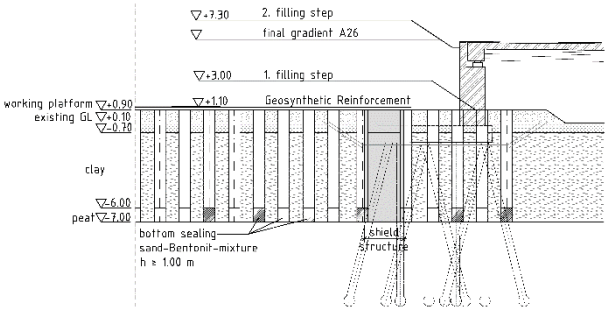

Figure 6. Typical longitudinal section of a piled bridge abutment with GEC-foundation and in-situ soil replacement as shield-structure (Hortmann et. al., 2019).

Due to logistic reasons the bridge foundation, however, had to be built prior to the approach embankment. As the concrete piles had not been designed to withstand lateral loads which would be generated by the embankment filling, a shield structure incorporating GEC was erected in the initial construction phase. The shield structure is a local soil replacement built like a secant wall and has a width of b = 3.5 m. This replacement zone, is entirely encircled by GECs and covered with horizontal reinforcement, ref. Figure 7.

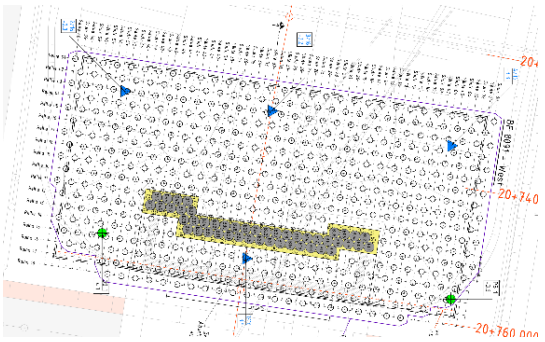

Figure 7. Site plan of GEC columns and shield structure, Bridge BW 8091-West, (Hortmann et. al., 2019).

Design verification of the shielding structure was carried out using a simplified approach as described in EA-Pfähle (2007): consideration of lateral stresses can be omitted if the estimation of the overall slope stability results in a utilization factor $\mu \leq 0.75$, where μ is defined as the degree of utilization ($\mu = 1/FOS$) acc. to DIN 1054 (2021) and DIN 4084 (2021). The improving effect of the GECs was taken into account using the concept of an equivalent cohesion. Thus, the GECs are transformed into discrete soil layers with enhanced shear strength parameters estimated in accordance with Raithel (1999). Additionally, a horizontal basal reinforcement is considered in the calculation.

In other projects it could be demonstrated that a "conventional ground improvement" using GEC was sufficient to fulfil the $\mu \leq 0.75$ requirement. In those

cases, the in-situ soil replacement (shield) structure was not required and consequently not installed on-site.

4 SUSTAINABILITY OF GRS BRIDGE ABUTMENTS

The environmental benefits of using geosynthetics have already been demonstrated in various studies such as EAGM (2011) or WRAP (2010). A reduction of up to 85..90 % cumulative greenhouse gas emissions could be demonstrated depending on the application and the particular design situation. More recent studies have focused on the environmental of bridge construction. Görtz and Pham (2023) have analysed that the bridge abutments contribute significantly to the overall impact of a bridge construction, where the impact of construction materials showed to be most relevant. Figure 8 shows an exemplary comparison of the CO_2 emissions for the construction of a conventional abutment and a corresponding GRS structure (with and without the use of lime-cement stabilizers) for an abutment height of 4.8 m: the reduction in CO_2 emissions is maximum for small bridges and strongly depending on the fill-material that is used. The use of lime-cement stabilizers has a remarkable negative impact. Hence, hydraulic binders should only be used to enable construction with (local) fill-material of marginal quality (if this leads to positive result of the LCA) or in limited amount if technically unavoidable e.g. to increase the stiffness of the GRS. If lime-cement stabilizers are used one should not forget to prove that the reinforcement material is durable in high alkaline conditions. Otherwise, the durability of the structure would be endangered. Recent research (Detert and Koroliuk, 2018) has shown that products from polyethylene terephthalate (PET), for example, would not fulfil this requirement due to the strong impact of external hydrolysis. Reinforcement from polyvinyl alcohol (PVA), however, is durable even in high-alkaline conditions and would provide a proven alternative in such case.

An additional benefit of GRS which has not been considered in the studies of Görtz is the effect of construction speed. GRS can immediately be loaded once they are erected, deshuttering times as would be required for in-situ reinforced concrete are not required.

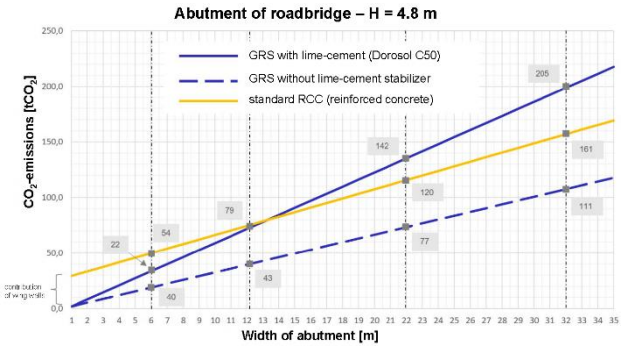

Figure 8. Estimation of CO_2-emission for the construction of a bridge abutment, comparison of different construction techniques (Görtz and Pham., 2023).

Combining modular bridge systems and GRS can therefore contribute to significantly decrease construction time of a bridge and all related impact from traffic-jams or total closures of traffic connections (roads and railroads).

5 CONCLUSIONS

Practical experience as well as academic knowledge about geosynthetic reinforced soil retaining structures (GRS) has significantly increased over the last decades. Overall, the performance of GRS which have carefully been designed and properly erected has shown to be good. More recently even highly loaded bridge abutments have been built with GRS. Using GRS in bridge construction can contribute to limit the impact of differential settlement between abutment and backfill, to reduce horizontal stresses and additional loads generated by negative skin friction in foundation piles or to cut off completely horizontal stresses in form of an earth pressure relief. Various reference projects have shown that GRS is even able to fully replace structural reinforced concrete in the abutment.

Comparative LCA has shown that the quantity of CO_2 emitted for the abutment construction can be reduced significantly using GRS. Additional benefits can be observed as GRS can be erected much faster than in-situ reinforced concrete. A combination of modular bridge systems and GRS would generate the biggest advantage in that regard.

Despite of the advantages of GRS its application is still limited in many countries. The mindset of designers as well as limitations prescribed by design codes and local regulations would be the reason for that. However, continued development and enthusiasm in the construction industry as well as updates of international standards such as EC7 (Eurocode 7) or specific local regulations will help to overcome this problem.

ABSTRACT: Few studies have analysed the deep excavation retaining wall system response when passive-sided panels of load-bearing deep dry mixing columns are installed with geometrical imperfections. This study applies parametric 3D modelling to generate DDM panel geometries with random geometric imperfections for individual columns drawn from a probability distribution. Simulations are performed with FEA to investigate the retaining wall response from imperfect panels. Comparisons are made to both idealized rectangular panels and panels consisting of octagonal columns without imperfections. Four column imperfections are considered - XY offset, azimuth, length and inclination. Results indicate that geometric panel imperfections contribute to overall greater horizontal displacement, shear force, bending moment and strut forces in the retaining wall system. This study considered 101 simulations with imperfect panels. Although the number of simulations performed in this study is modest, initial results indicate that the moving average of the response is converging as the simulation count is increased.

RÉSUMÉ: Peu d'études ont analysé la réponse d'un mur de soutènement dans une excavation profonde lorsque des panneaux de contreforts en colonnes traitées à la chaux à sec contiennent des imperfections géométriques. Dans cette étude, une modélisation paramétrique 3D est utilisée afin de générer des panneaux DDM avec des imperfections géométriques aléatoires pour des colonnes individuelles tirées d'une distribution de probabilité. Des simulations numériques sont effectuées pour étudier la réponse du mur de soutènement à partir de panneaux imparfaits. Des comparaisons sont faites avec des panneaux rectangulaires idéalisés et des panneaux constitués de colonnes octogonales sans imperfections. Quatre imperfections de colonne sont prises en compte: décalage XY, azimut, longueur et inclinaison. Les résultats indiquent que les imperfections géométriques des panneaux contribuent à un déplacement horizontal, une force de cisaillement, un moment de flexion et des forces d'appui globalement plus importants dans le système de mur de soutènement. Cette étude a considéré 101 simulations avec des panneaux imparfaits. Bien que le nombre de simulations effectuées dans cette étude soit modeste, les premiers résultats indiquent que la moyenne glissante de la réponse converge à mesure que le nombre de simulations augmente.

Keywords: Deep mixing panels; parametric modelling; geometric imperfections; installation error.

1 INTRODUCTION

Ground improvement with deep dry mixing columns is often used in geotechnical engineering to reduce deformation of retaining walls, and to enhance the stability and safety in a deep excavation pit. Column installation is complicated, and several imperfections could evolve during the installation (Larsson, 2005, Pan et al., 2019). Imperfections may introduce non-stabilized soil to occur within the DDM-panels lowering the panel capacity to resist and transfer loads. Installation errors include XY offset, azimuth, length deviation and inclination, depicted in Figure 1.

During engineering design, deep mixing panels are often simplified as an idealized panel geometry (rectangular) in plain strain, neglecting the potential for imperfections.

In this study, DDM installation data from a construction project is used to simulate probability

distributions for the actual offset and length deviation imperfections.

The main purpose of the study is to investigate if and how installation errors for DDM columns affect the retaining wall system response considering deformation, bending moment and shear force in the retaining wall, in addition to strut and beam forces, when the DDM panels act as load-bearing stiffeners on the passive side.

A parametric script is developed to generate the DDM panel geometry, with or without imperfections. The DDM panels are then imported into the FEA software, in this case Plaxis, with the excavation pit. Calculations with defined phases are performed, and the simulations are then compared.

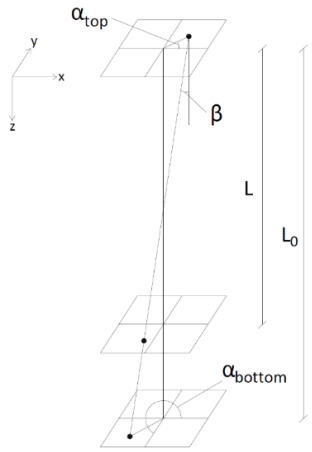

Figure 1. Illustration of main installation errors. XY offset at top, azimuth top and bottom (α), inclination (β) and deviation between design and installed length (L_0-L).

2 CASE STUDY

The case study use data from a cut-and-cover tunnel in Drammen, Norway. The excavation pit consists of sheet pile walls and two strut levels with DDM-panels in one part of the excavation pit. The geometry is shown in Figure 2.

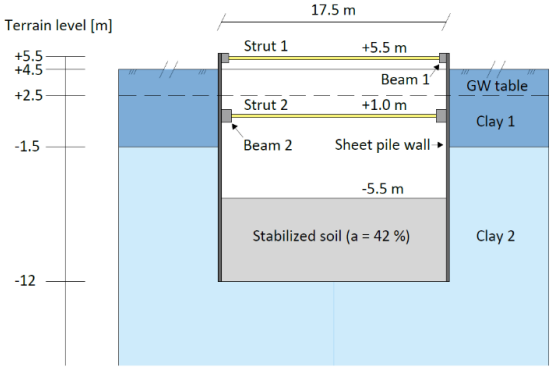

Figure 2. Plain-strain view of the case study excavation pit. The figure illustrates the situation after the final excavation phase.

The DDM panels have two rows of columns with a column diameter of 800 mm and a column overlap of 20 % of the diameter. The spacing between each panel is 3.05 m and strut spacing is 5.00 m.

3 PROBABILITY DISTRIBUTIONS OF GEOMETRIC IMPERFECTIONS

During the case study project, GPS coordinates and total length for the columns were recorded. Azimuth top, offset and length deviation are calculated from these measurements. The data package consisted of 3365 columns in total, and there was generated a boxplot with outliers. The outliers were excluded from the final data package.

3.1 Offset

The recorded offset has been adapted with a Weibull distribution, illustrated by Figure 3, along with generated random variables from the same Weibull distribution.

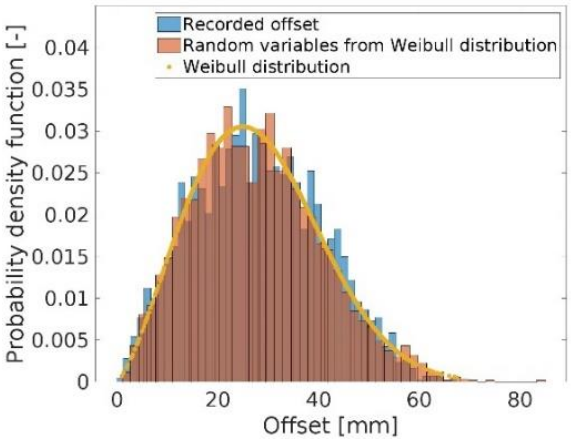

Figure 3. Recorded offset, and random offset variables from Weibull distribution fit in a probability density function.

3.2 Azimuth

The calculated azimuth angle is simplified to be uniformly distributed based on recorded XY offset.

3.3 Length deviation

A Cauchy distribution has been adapted to the recorded length deviation to generate random variables. The average value has been assigned as the location factor, and a scaling factor γ of 4.5 has been utilized. A similar plot as Figure 3 have been made.

3.4 Inclination

Inclination for the DDM columns is not measured during installation. In this study, the inclination is

assumed to follow a uniformly distributed function with maximum inclination of 1.15 degrees, which is based on the inclination demand from Eggen et al. (2012) considering installation data from Norway.

The inclinations reported by Eramo et.al. (2011) and Croce & Modoni (2007) were reviewed but not considered in this study. By including these one may get different outcome which could be interesting for future work.

4 PARAMETRIC MODELLING

Parametric 3D modelling is utilized in this study to generate the DDM columns geometries. The columns are generated as octagonal columns to reduce the number of mesh elements, and therefore decreasing the computing capacity and computing time.

Chosen parameters versus original parameters are illustrated in Figure 4. The chosen geometry parameters are different from the original parameters to ensure that the degree of coverage is approximately the same for both situations.

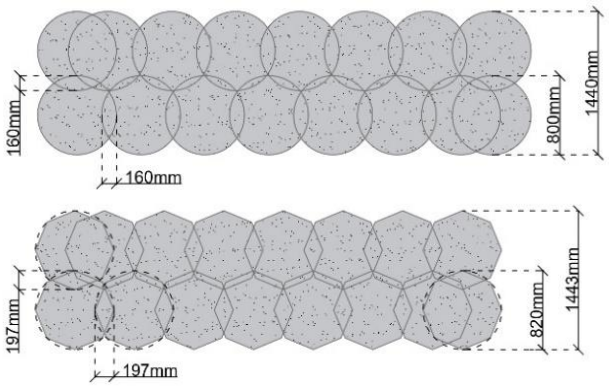

Figure 4. DDM column geometry in case study versus chosen DDM column geometry for this study.

5 FEM-MODEL

The FEM model in Plaxis 3D is a symmetric model of the excavation pit, as depicted in Figure 5 during calculation after the last excavation phase. A refined mesh is applied around the excavation pit. As illustrated, there is only one DDM panel modelled, this to reduce the computing time by reducing the number of mesh elements. The extent of the model in y-direction is set to 3.05 m, and the DDM panel is in the centre. An equivalent axial-stiffness is applied for the two struts. Total stress analysis is considered.

The deformation in y-direction is set to zero, equalling a plain strain situation. The boundary conditions are fixed at the bottom, while no deformation in x-direction is allowed along the symmetric line.

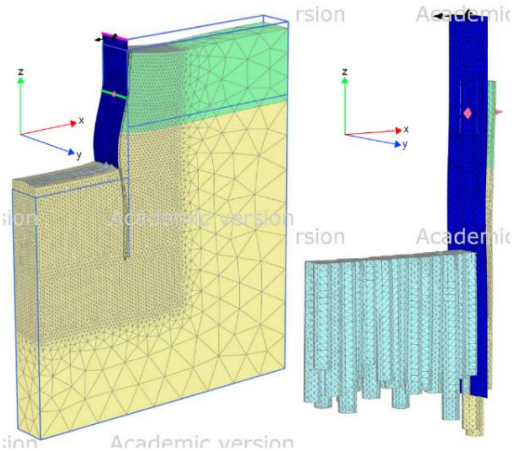

Figure 5. FEM model shown during calculation after the last excavation phase. Deformations are scaled up to the left. The surrounding unstabilized soil is hidden to the right.

6 RESULTS AND DISCUSSION

101 simulations with random imperfections were calculated using Plaxis 3D. Strut forces, shear force, bending moment and horizontal displacement of the retaining wall, along with safety factor F were inspected as the result parameters. Figure 6 shows the resulting maximum bending moment for the retaining wall after the final excavation stage. The result for a situation with octagonal columns without imperfections, along with an idealized, rectangular panel are also shown. Similar graphs are made for the other result parameters.

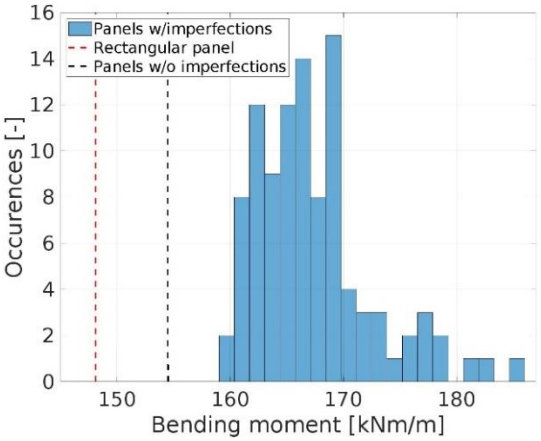

Figure 6. Maximum bending moment for the retaining wall after the last excavation phase.

Table 1 presents results for shear force, bending moment and horizontal displacement for the retaining wall, with average values for imperfect panels. The results expose that installation deviations will generally increase both loads and displacement for the retaining wall, due to occurrence of non-stabilized soil in between the DDM-panels.

Table 1. Results from the simulations with shear force, bending moment and horizontal displacement for the retaining wall.

Model type	Shear force [kN/m]	Bending moment [kNm/m]	Displac-ement [mm]
Rectangular panel	175.2	148.1	92.4
Panel w/o imperfections	198.7	154.5	95.8
Panels w/imperfections	217.9	167.4	105.4

Because of limited simulation capacity, a plot in Figure 7 depicts the continuous floating average and moving average to gauge result reliability. It can be observed that the floating average, moving average and percentile values of the resultant bending moment each have notable similarity between 80 simulations and 100 simulations, indicating a convergence of results.

When considering total horizontal stresses in the DDM panels, the results expose greater stresses in the imperfected panels versus the panels without imperfections, as shown in Figure 8.

The presented results manifest that geometric imperfections in DDM panels will decrease the panels characteristics as load-bearing stiffeners on the passive side in an excavation pit.

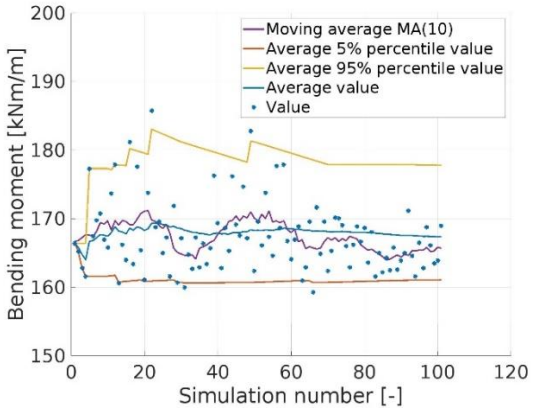

Figure 7. Continuous floating average and moving average for the bending moment.

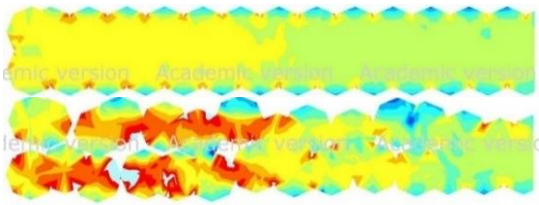

Figure 8. Total horizontal stresses in x-direction in DDM panel without imperfections and with imperfections. Increasing compression stresses from blue to red. The sheet pile wall is located to the right.

7 CONCLUSION

Simulations using 101 different DDM panel geometries drawn from probability distributions show that geometric imperfections decrease the panels characteristics to resist and transfer earth pressure. Geometric imperfections for DDM panels should be accounted for during geotechnical design to avoid unwanted displacement and possible system failure.

Initial results with 101 simulations show that the continuous average and moving average appear to converge.

Future work should focus on the following: (1) increase the number of calculations, (2) include more case studies, (3) investigate more retaining wall system parameters, e.g. excavation depth and (4) modify material parameters for soil and DDM panels.

ABSTRACT: This paper aims to describe the deep excavation solutions adopted for the construction of a logistics park with an implantation area of approximately 107 000 m^2, located in the municipality of Loures in Lisbon. The use of this site for the construction of a large-scale building with demanding future performance criteria proved to be extremely challenging, particularly because the original place had previously been used as a limestone quarry and subsequently as a landfill for various materials associated with the construction of the nearest main road network. Given the existing constraints, particularly the desired implantation area, the geological-geotechnical study and the neighboring conditions, a deep excavation solution was defined for a maximum height of 20 m, consisting of a bored pile wall with 800 mm diameter and with shotcrete between the piles, braced by permanent anchors and complemented with a concrete Berlin-type wall solution in areas where the limestone rock, with low degrees of alteration and fracturing, emerged above the excavation bottom. In addition to the adopted design criteria, the proposed instrumentation and monitoring plan for the retaining solution and neighboring infrastructure are also presented.

RÉSUMÉ: Cet article vise à décrire les solutions de excavation profonde adoptées pour la construction d'un parc logistique d'une superficie d'environ 107 000 m^2, situé dans la municipalité de Loures à Lisbonne. L'utilisation de ce site pour la construction d'un bâtiment à grande échelle répondant à des critères de performance futurs exigeants s'est avérée extrêmement difficile, en particulier parce que l'endroit d'origine avait été précédemment utilisé comme carrière de calcaire, puis comme décharge pour divers matériaux associés à la construction du réseau routier principal le plus proche. Compte tenu des contraintes existantes, en particulier de la superficie d'implantation souhaitée, de l'étude géologique-géotechnique et des conditions environnantes, une solution de excavation profonde a été définie pour une hauteur maximale de 20 m, comprenant un mur de pieux forés de 600 mm de diamètre avec du béton projeté entre les pieux, renforcé par des ancres permanentes et complété par des solutions de mur "Berlin" dans les zones où la roche calcaire, avec des degrés d'altération et de fracturation faibles, émergeait au-dessus du fond de excavation. En plus des critères de conception adoptés, le plan d'instrumentation et de surveillance proposé pour la solution de soutènement et les infrastructures avoisinantes sont également présentés.

Keywords: Deep excavation; bored pile wall; concrete Berlin-type wall.

1 INTRODUCTION

The deep excavation solutions presented in the present article are located in the municipality of Loures (Figure 1) and were developed and designed to enable the construction of a logistic park with an approximately 55,000 m^2 footprint.

Figure 1. Site identification (Google Earth image).

The use of this site for the implementation of a large-scale building with demanding future performance criteria proved to be extremely challenging due to the fact that the original land had previously been used as a limestone quarry and subsequently as a dumping for various materials. These two situations determined, during excavation, the occurrence of very abrupt geological transitions and completely distinct geotechnical behaviors over very short distances.

After an extensive geological-geotechnical characterization, substantiated by various prospecting campaigns, the best deep excavation and earth support solutions were adapted for both excavation and embankment areas; the latter, however, are not covered in the present article.

For the excavation areas located in the southern elevation, adjacent to the national road EN250, a bored pile wall was adopted, with a maximum height of 20 m, permanently anchored and complemented with a concrete Berlin-type wall in areas where the limestone mass, with low degrees of alteration and fracturing, emerged above the excavation bottom.

On the other side, for the embankment areas, on the western, northern and eastern elevations, considering the existing levels, available space, and the need to ensure the maximum possible storage capacity for surplus soils from the embankment platform, a gabion wall and a reinforced earth wall with facing panels of precast reinforced concrete were constructed.

2 MAIN EXISTING CONDITIONS

2.1 Geological-geotechnical conditions

Four prospecting campaigns were conducted in the area of the logistics park from 2019 to 2021, that involved the execution of around fifty hollow stem auger borings, accompanied by dynamic penetration tests of the SPT type at every 1.5 m, reaching depths of 34 m, twenty-four exploratory pits, using an excavator, with depths ranging from 0.70 to 4.90 m and ten seismic refraction profiles.

The borings from the second and fourth phases were considered particularly representative for the design of the bored pile wall solution due to their location, almost coinciding with the boundary perimeter of the existing quarry. The analysis of these campaigns confirmed the variability of encountered terrains and abrupt geological variations (Figure 2).

During the excavation process, it was also observed that within a few meters, there was a transition from a rocky mass near the surface to a rocky mass below the excavation bottom (Figure 3).

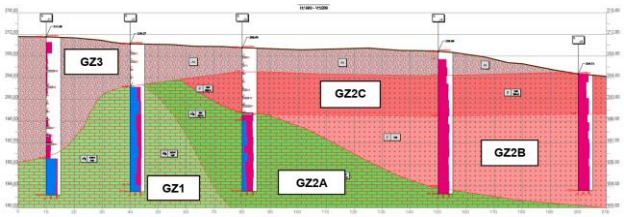

Figure 2. Geotechnical interpretative profile along the alignment of the bored pile wall.

Figure 3. View of abrupt transitions between landfill zones and vertical faces of the limestone quarry.

The analysis of the geological-geotechnical campaign allowed the individualization of the 5 geotechnical zones identified below:

GZ3 - Corresponds to landfill deposits;

GZ2C – Soils corresponding to volcanic breccias and decomposed volcano-sedimentary formations from the Lisbon Volcanic Complex;

GZ2B – Soils corresponding to volcanic breccias and decomposed volcano-sedimentary formations from the Lisbon Volcanic Complex;

GZ2A - Massif corresponding to basalts, volcanic breccias, and decomposed volcano-sedimentary formations or rock ranging from highly altered to moderately altered from the Lisbon Volcanic Complex;

GZ1 - Massif corresponding to whitish crystalline limestones to grayish marly limestones ranging from little to moderately altered.

2.2 Pre-existing conditions

The intervention area is located, in part, over former limestone quarries that were subsequently used as a landfill. In this context, there was a high level of uncertainty about the composition of the fill materials but also about the configuration/inclination of the cut slopes, which were created during the quarrying activities.

2.3 Topographic constrains

The land used for the construction of the logistics park had a slope towards the north, with the area adjacent to national road EN250 being the highest and the area adjacent to a watercourse on the opposite elevation

having lower elevations. To achieve a level platform, as previously mentioned, it was necessary to develop a retaining structure through excavation along the northern elevation and part of the western elevation (Figure 4). Additionally, gabion retaining walls and reinforced earth walls were designed on the southern elevation, part of the western elevation, and part of the eastern elevation. As mentioned above, this article will exclusively address the deep excavation solutions in the northern and western elevations.

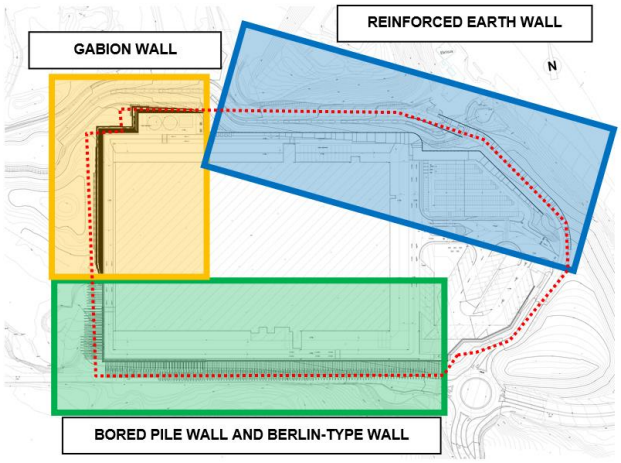

Figure 4. Identification of the retaining and embankment solutions and lot boundary (highlighted in red).

3 PROPOSED SOLUTIONS

3.1 Bored pile wall

Based on the existing constraints, particularly topographical, geological-geotechnical, neighboring occupancy, and the need for rapid execution, it was adopted a bored pile wall, with a 800 mm diameter and spaced at a center-to-center distance of 1.5 m (Figure 5). This arrangement enabled an excavation of about 20 m in maximum height.

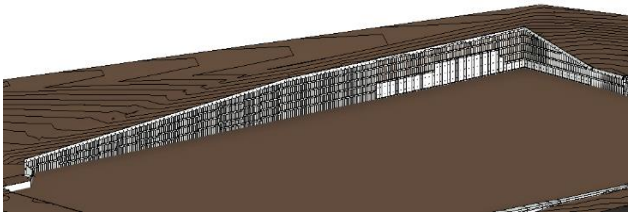

Figure 5. 3D perspective oof the bored pile wall solution.

Given the geological conditions of the site and the length of the piles, they were entirely executed using a telescopic Kelly bar, occasionally with temporary casing at the borehole entrance. When encountering larger blocks or to ensure anchoring in the rock mass, a tricone bit, rock auger, and coring tool were used.

To enhance efficiency in excavation, the wall was braced using 2 to 5 levels of permanent anchors with planar spacings of 3.0 m, aiming to provide temporary and definitive horizontal balance of the containment against ground impulses, both in static and seismic conditions.

To ensure a more even distribution of forces on the wall and prevent excessive load concentration, reinforced concrete distribution beams were implemented and properly anchored to the piles (Figure 6).

The anchors were installed at different inclinations to the horizontal (between 15º and 30º) and with variable free lengths (between 9 m and 17 m), with a minimum sealing length of 8 m (Bustamante and Doix., 1985) and a maximum long-term traction of 900 kN.

Considering the permanent nature of the anchors, the provisions of NP EN 1537 were followed regarding the characteristics of the tendons, injection grout, anchor head protection components, and anti-corrosion protection.

The exposed soil between piles was protected with a sprayed concrete coating applied in two layers and reinforced with metal fibers. The area was properly drained using geodrains between piles.

Figure 6. Excavation works near the bored pile wall.

3.2 Concrete Berlin-type retaining wall

As indicated in the geological-geotechnical study, an intersection of the piles with slightly altered limestone occurred near the corner of the wall. In this area, the pile wall was underpinned using micro-piles. The remaining excavation was carried out with advances under a concrete Berlin-type retaining wall with rock bolts (Figure 7).

In this type of solution, the retaining wall is constructed in levels, from top to bottom. Each level is created by constructing reinforced concrete panels (first the primary panels and then the secondary ones), supported by spaced micro-piles, on average 3 m apart. These micro-piles are installed before the start of

excavation work and function to support the vertical loads to which the retaining wall is subjected. The panels, with a theoretical minimum thickness of 30 cm, are cast against the open vertical face of the limestone mass and connected at the top through a reinforced concrete beam with pre-stressed anchors. This beam simultaneously ensures the underpinning of the base of the bored pile wall and the partial transfer of vertical loads to the micro-piles.

Regarding the horizontal bracing of this wall, the execution of high-strength steel tie rods with a diameter of 32 mm was anticipated.

Figure 7. Excavation works near the concrete berlin-type retaining wall.

4 DESIGN METHODS

To analyze the behavior of the retaining wall solutions with respect to forces and deformations, finite element models were employed using the PLAXIS 2D software.

The analyses conducted generally involved studying various cross-sections deemed representative of the diverse geometries along the lengths of each of the construction solutions used.

The geomechanical behavior of soils was simulated using Hardening-Soil constitutive models, while for more rocky materials, their behavior was simulated using elasto-plastic Mohr-Coulomb constitutive models, and thus, without hardening.

Structural elements, such as the bored pile wall, concrete Berlin-type retaining wall, and anchors, were modeled based on their elastic properties. The modeling limited their maximum strength to ultimate limit states, allowing for the assessment of the maximum global safety factor.

5 MONITORING PLAN

The implemented monitoring plan aimed to ensure the safe and cost-effective execution of activities related to excavation process and during the lifespan of the logistics park. Additionally, it involved analyzing the surrounding behavior during this phase of construction, leading to adaptations based on the obtained results.

Installed devices allowed for the measurement of the following parameters on a weekly basis:

- Horizontal and vertical displacements of the retaining structures using topographic targets;
- Horizontal displacements of the soil behind the retaining solutions using inclinometers;
- Measurement of tension load in the anchors using load cells.

As of the current date, no significant deviations from the project estimates have been recorded based on the available readings. The maximum horizontal movements on the targets and inclinometers are approximately 15 mm, associated with a maximum excavation height of about 15 m and anchor load increments of less than 10%.

6 CONCLUSIONS

Considering the positive outcomes of the established instrumentation and observation plan, along with the accomplishments during the excavation works, it is concluded that the alternative solutions developed in the context of the design and construction process carried out in collaboration between the designer (JET_{SJ}) and the contractor (Norton EI), have proven to be extremely versatile and well-suited to local constraints.

ACKNOWLEDGEMENTS

The authors express their gratitude to the Client (LIDL) for granting permission for the drafting and publication of this article. It is also important to emphasize that the implemented solutions were the result of a team effort developed in collaboration with the contractor (Norton EI), subcontractors (Ancorpor, MaccaferriI, VSL, among others), and supervision (Duplano).

ABSTRACT: The interaction of a high-speed train with the track system, and the response of the supporting ground can result in amplification of quasi-static track deflections as the train speed approaches a critical velocity. Numerous factors govern the development of this phenomenon, but of particular importance is the propagation of surface waves (Rayleigh waves) in the supporting ground. To avoid dynamic amplification, criteria for the design of earthwork structures are commonly specified as a minimum Rayleigh wave velocity as a function of train speed. Whilst this geo-dynamic phenomenon is recognised within the industry, there are no well-established guidelines or standards for assessing and mitigating this risk. This paper presents the approach used for contract C23 on Phase 1 of the HS2 project to assess and manage this risk, including the design of foundation treatment to improve the dynamic response of the earthwork structure.

RÉSUMÉ: L'interaction d'un train à grande vitesse avec le réseau de voies ferrées et la réponse du sol d'appui peuvent entraîner une amplification des déformations quasi statiques de la voie lorsque la vitesse du train s'approche d'une vitesse critique. De nombreux facteurs régissent le développement de ce phénomène, mais la propagation des ondes de surface (ondes de Rayleigh) dans le sol de support revêt une importance particulière. Pour éviter l'amplification dynamique, les critères de conception des ouvrages de terrassement sont généralement spécifiés comme une vitesse minimale de l'onde de Rayleigh en fonction de la vitesse du train. Bien que ce phénomène géodynamique soit reconnu au sein de l'industrie, il n'existe pas de lignes directrices ou de normes bien établies pour évaluer et atténuer ce risque. Cet article présente l'approche utilisée pour le contrat C23 de la phase 1 du projet HS2 afin d'évaluer et de gérer ce risque, y compris la conception du traitement des fondations afin d'améliorer la réponse dynamique de la structure de terrassement.

1 INTRODUCTION

1.1 Background

The HS2 project is a High-Speed railway line currently under construction in the UK. Phase 1 of HS2 runs between London and Birmingham and this paper focuses on an 80 km long open route section between Wendover in Buckinghamshire and Southam in Warwickshire (Contract C23).

High Speed 2 Ltd are the delivery authority for the project with Eiffage, Kier, Ferrovial Bam Joint Venture (EKFB) the appointed Contractor for C23 supported by an Arcadis, Setec, COWI Joint Venture (ASC) providing design services for the main civil engineering assets.

This section of the route will be constructed using track slab with a design speed of 360 km/hr which is significantly higher than traditional railways. At higher train speeds, there are additional engineering

issues to consider, of particular importance is a form of resonance between the train and the supporting track-bed, termed Critical Velocity Effect, which is heavily influenced by the dynamic response of the underlying earthworks. Critical velocity effects have been recorded at various rail sites around the world (Woldringh et al 1999), with the phenomenon being linked to the proximity of the train speed to the site critical velocity (Madshus et al 2000).

There are no well-established design basis, guidelines and/or standards for assessing and mitigating the risks in routine design. This paper describes a simplified design approach developed for the design of HS2 earthworks to meet the dynamic performance criteria defined in HS2 Technical Standards for Earthworks (TS-E) (HS2, 2019a). The approach provides a robust and repeatable methodology for carrying out the design of earthworks and managing the associated uncertainty and risk.

The HS2 earthworks dynamic performance criteria were established based on precedent from past projects and the back analysis of problematic sections of existing track on other railways. The approach adopted by the TS-E does not establish wave amplitudes or particle velocities for the dynamic performance serviceability limit state of the track bed, but rather sets a minimum dynamic stiffness requirement for the earthwork, based on the design speed of the train, with the objective of ensuring that resonance is avoided.

1.2 Critical Velocity Effects

As a train travels over the ground, it creates a downward, deflection of the track bed due to the load of the wheels and bogies. In doing so, it generates surface waves that propagate through the track bed and supporting ground. At low train speeds, the surface waves travel faster than the train. As the train speed increases towards the speed of the propogating wave a critical velocity is reached at which resonance can occur, resulting in the dynamic amplification of the deflections.

The wave sources that are applicable for design of the earthwork structures are based on where there is likely to be significant variations in the magnitude of repetitive load applications. This is limited to the vertical load applied through the bogies and individual wheel axles of the train. (Arup, 2017). Each bogie and wheel axle act as a moving load that creates a downward deflection of the track along the railway line (Arup, 2017 & HS2, 2019b). As such, the loading at any given point is applied over a very short period (instantaneous) and at a frequency that is dependent upon the train speed.

The design of the earthwork structure needs to consider how the waves propagate longitudinally within the track bed-earthworks system and continue to interact with the moving train. It has been shown that the site critical velocity is governed by the minimum phase velocity of the fundamental Rayleigh wave mode of the foundation and embankment profile at the site (Madshus et al, 2000).

According to studies on the soil structure interaction between slab track and supporting earthwork (Arup, 2017), there are two wave velocities that may affect the overall performance of a track-earthworks systems:

- Track slab ‘Winkler Beam’ bending wave speed; and
- Rayleigh wave velocity of the earthworks structure.

One conclusion of the study is that the bending stiffness of the track slab does not affect the critical Rayleigh wave velocity of the earthworks but may reduce the displacements with stiffer track bed elements. This enables the stiffness requirement of the earthworks structure to be decoupled and designed for separately to the rail system (i.e. track bed) once the overall system performance and earthworks design criteria have been established.

Figure 1 summarises the terminology that defines and groups the track bed and earthworks components. This paper covers the earthwork structure and foundation located below the Protection Layer.

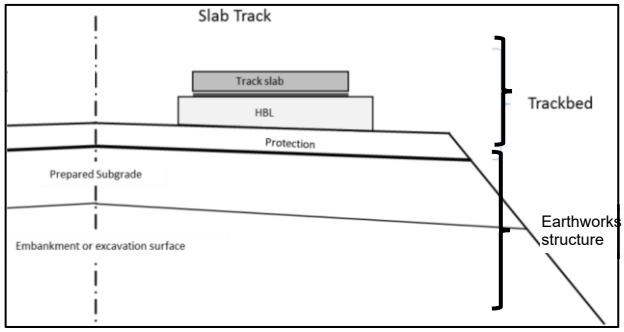

Figure 1. Schematic section illustrating track-earthworks system terminologies (adapted from HS2, 2019a).

2 FUNDAMENTALS OF RAYLEIGH WAVE PROPOGATION

The theoretical Rayleigh wave velocity for an elastic half space can be estimated using Poisson‘s ratio (ν), Youngs Modulus (E) and density (ρ), as the governing parameters:

$$V_R = \left(\frac{0.87 + 1.12\nu}{1+\nu}\right)\sqrt{\frac{E}{2\rho(1+\nu)}} \quad (1)$$

The waves are characterised by an anti-clockwise particle motion relative to the direction of travel as shown in Figure 2 below.

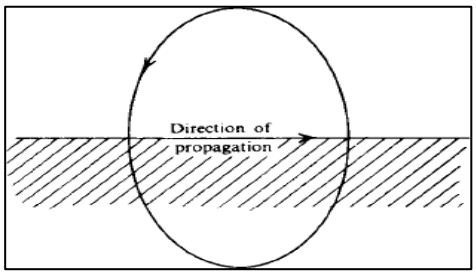

Figure 2. Particle motion on the surface during the passage of Rayleigh wave in an elastic homogenous half space (from Richard et al., 1970).

The frequency or wavelength affects the depth of influence beneath the surface. Lower frequencies with a longer wavelength excite particles to a deeper depth. This geometrical zone of influence normalised to wavelength is illustrated in Figure 3 below.

Reflecting on this zone of influence, a common ground profile with increasing stiffness with depth will have a higher Rayleigh wave velocity at lower wave frequencies (longer wavelength) and lower wave velocities at high frequencies.

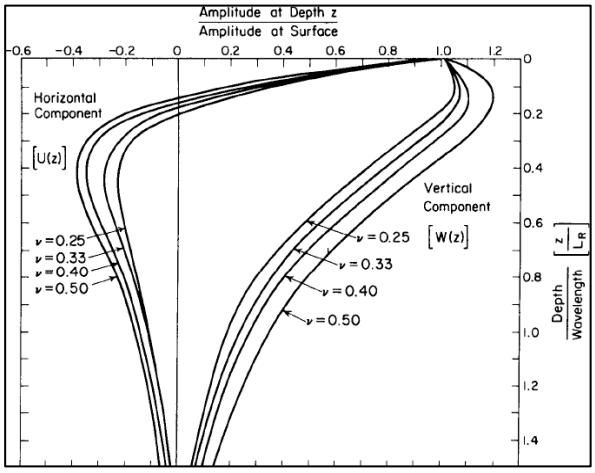

Figure 3. Amplitude ratio vs dimensionless depth for Rayleigh waves in a homogenous half space (from Richard et al., 1970).

This type of profile is known as normally dispersive. A profile that has decreasing stiffness with depth is known as inversely dispersive and will result in lower Rayleigh wave velocities for lower wave frequencies. This concept is graphically presented in Figure 4 below.

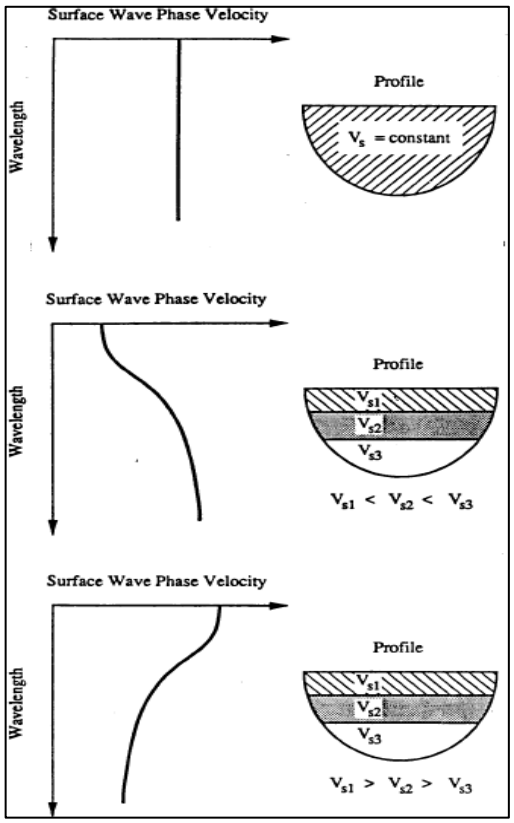

Figure 4. Example of non-dispersive (homogenous half space), normally dispersive and inversely dispersive profile (from Rix, 1988).

Surface waves will decay as the distance from the source increases. This decay is partly caused by the geometrical attenuation as the wave front spreads. This phenomenon is illustrated in Figure 5.

There is also hysteretic damping within the soil that dissipates energy due to straining of the soil, referred to as material damping. While geometric and material damping rapidly attenuates the wave energy, they do not affect the fundamental Rayleigh wave velocity of the system and the potential for amplification to occur.

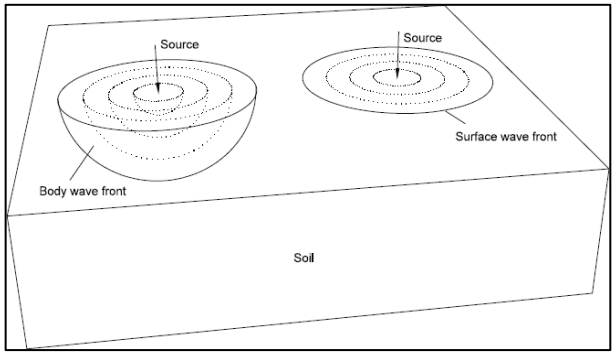

Figure 5. Geometrical attenuation of vibrations.

3 DYNAMIC PERFORMANCE CRITERIA AND REQUIREMENTS

The TS-E (HS2, 2019a) defines the earthworks dynamic stiffness as the *"transient stiffness of the earthwork at any defined level in response to dynamic loading"*. The same TS-E (Table 4.2/1) specifies the performance criteria to be satisfied by the earthworks design and construction verification testing as a limiting Rayleigh wave velocity (V_R), measured at Formation Level:

$$V_R \geq 1.6 \times DS \quad (2)$$

where DS is the design speed which for HS2 Contract C23 has been set at 360 km/hr (100 m/s). The standard requires that the dynamic performance is demonstrated by design and validated by construction verification testing. This has been achieved through verification by calculation in design, supported by the undertaking of demonstration field trials, and by end product testing of the completed earthworks.

4 DYNAMIC PERFORMANCE DESIGN APPROACH

4.1 Risk assessment method

Initially, a qualitative screening was used to determine sections of subgrade of potentially low stiffness that were at risk of requiring foundation treatment to achieve the specified minimum Rayleigh wave velocity criteria. A risk rating process was followed to focus risk mitigation activities at the different stages of the design and construction.

The first step was to identify areas along the route where the in-situ ground may have low stiffness. The risk levels were derived from assessment of predicted shear wave velocity profiles based on the geological model and published data. The risk categories applied in the early stages of design development are summarised in Table 1. The shear wave velocity for individual layers within a layered deposit is more familiar to design engineers and is a useful indicator of the expected Rayleigh wave response. This was therefore used as part of the screening exercise. Based on the initial mapping, various areas along the route were categorised as being at high risk of requiring foundation treatment to achieve the HS2 dynamic performance criteria, notably:

- Shallow/at grade embankments and shallow cuttings;
- Faulted zones and dissolution features (soft infill/voids);
- Transitions between cuttings and embankments.

Table 1. Risk Categories relative to HS2 Rayleigh Wave Performance criteria and equivalent shear wave velocity.

Parameter	Low Risk (1)	Medium Risk (1)	High Risk
Rayleigh Wave Velocity V_R (m/s)	>200	160<V_R<200 and where there are local heterogeneities (<50m)	<160
Shear Wave Velocity V_S (m/s)	>210	170<V_S≤210 and where there are local heterogeneities (<50m)	<170

(1) – For V_R, the boundary between Medium and Low Risk is defined as (1.6×DS)×1.25

In the initial categorisation of risks and development of the scheme design, a partial factor of 1.25 was adopted to reflect uncertainty in the ground investigation data that was available and the potential effectivness of proposed mitigation measures. In addition, field trials were initiated to better define the dynamic properties of the proposed fill material and investigate the improvement in dynamic response achieved by the proposed foundationt treatment methods.

4.2 Design methodology

The HS2 project involved developing a Scheme Design followed by a Detailed Design for the earthworks. At each stage, the risk assessment was updated based on the latest information. Two methods for predicting the dynamic performance of the completed earthworks by calculation were developed, starting from the simplest form:

- Direct comparison of shear wave velocity profiles for each layer in the earth structure to ensure that all layers are greater than 1.7 x the design speed using a simplified relationship between shear wave velocity and Rayleigh wave velocity (Richart et al 1970)
- Forward modelling, 1D analysis method to establish the anticipated performance of the entire layered Earth Structure.

To forward predict the performance of the earthwork using a 1D analysis method, a weighted average velocity forward modelling approach has been used to estimate the Rayleigh wave dispersion curve for a layered deposit (Leong *et al*., 2012 & 2013). The method enables the rapid assessment of multi-layered systems, including; in situ strata and the engineered earthwork structure, and provides the resulting estimated Rayleigh Wave velocity (V_R) dispersion curve at formation level. The modelling requires the Shear wave velocity (V_S) and the Poisson's ratio (ν) of each layer for the ground profile representing an

earthwork asset. The analysis can be rerun to establish the depth of treatment needed to improve the stiffness of the layered system to ensure that the dynamic performance criteria are achieved.

This method allows individual, low stiffness layers to be assessed as being acceptable due to the compensating response of stiffer layers within the profile. The 1D analysis method was used to develop standard look up charts for the design of foundation treatment which were used as an intermediate step in the design process. The design process followed for the design of the earthworks is given in Figure 6.

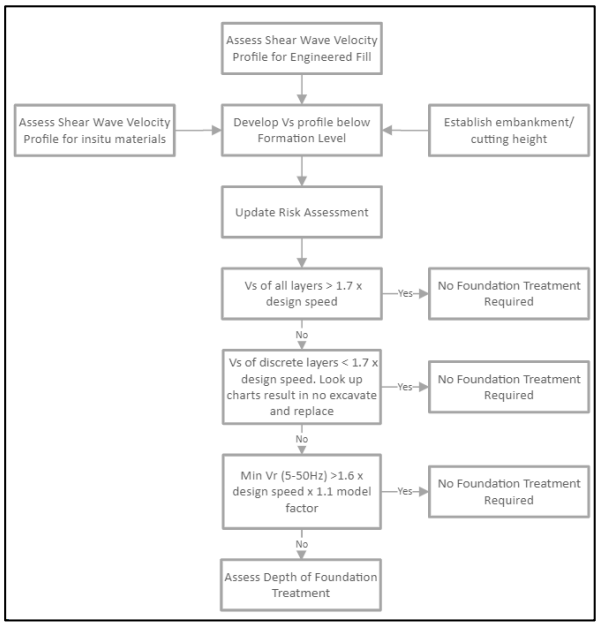

Figure 6. Design process for dynamic performance risk assessment and foundation treatment design.

For engineered fill forming the earthworks, the Shear wave velocity (V_S) was conservatively assumed as 250 m/s through Scheme Design with the same shear wave velocity value being assigned to the foundation replacement fill. This value was investigated as part of Detailed Design field trials which subsequently allowed an increase in the design value to 300 m/s to reflect increased confidence in the performance of the specified fill materials to be placed within the high-speed rail earthworks.

4.3 Foundation Treatment Design

4.3.1 Treatment options

The foundation treatment options focussed on achieving a homogenous improvement in the foundation to the high-speed rail earthworks. This was necessary due to the need to verify the minimum Rayleigh wave velocity of the completed earthwork using in-situ testing of end-product performance. Solutions that consist of locally stiffened elements such as rigid inclusions would not enable these construction stage verifications to be readily completed. The excavate and replace solution using a combination of imported engineered and stabilised site won fill was selected as the preferred solution. This in effect, modifies the 1D layered model by replacing a low velocity layer with a higher velocity layer to provide an increase in the overall dynamic performance of the earthwork.

The performance of the layered soil system was verified by a series of field trials carried out on earthworks constructed with replacement fill material to confirm the overall Rayleigh wave velocity as detailed in Section 5.

4.3.2 Target design criteria and construction verification testing

Following the results of the earthworks field trials the additional safety factor of 1.25 applied in Scheme Design was subsequently removed, but a model factor of 1.1 was adopted in the 1D analysis to recognise the uncertainty inherent in the forward modelling method and its relationship to field measurements.

To reflect the discrete extent of ground investigations and the variable nature of the natural materials, additional construction risk management controls are specified in the design to ensure that the completed earthworks meet the end product testing requirements. To account for potential variability of each fill material type demonstration areas are required during the works for each unique source of fill, construction team (workmanship), and/or unique subgrade strata.

Measurement of compacted fill density and E_{V2} stiffness will be used for earthworks quality control to ensure the engineered fill achieves the minimum shear wave velocity required to improve the overall Rayleigh Wave performance. Surface geophysical testing in advance of foundation treatment will also be used to manage potential variability in natural ground conditions for higher risk areas.

Ultimately, the completed earthwork structure is required to be verified using an end product test in accordance with the Technical Standard. Continuous Surface Wave (CSW) geophysical testing is proposed to be utilised at final earthworks formation level for this field verification. This is following the sucessful demonstration during the Detailed Design field trials and calbration during cosntruction stage demonstration areas for each fill type.

5 DETAILED DESIGN FIELD TRIALS

Six earthworks field trials have been undertaken on site to date to assess the static and dynamic performance of different fill types as well as their suitability for use in earthworks' construction including as replacement fill for foundation treatment. Material types used in the trials comprised granular fill (imported and site won), stabilised glacial tills, and both stabilised and unstabilised Chalk. Embankments up to 3.6m high were constructed and tested before construction, during fill placement and after construction to validate key design assumptions.

For the dynamic performance, geophysical testing was performed at various stages during construction and after completion of the earthworks. The results obtained demonstrated the improved dynamic performance of the earthwork due to increased stiffness of the replacement fill adopted for foundation treatment.

In addition to the improvement with increasing depth of replacement fill material, the results also validated the suitability of the 1D weighted velocity forward modelling method and Figure 7 shows a comparative example of Rayleigh wave velocity dispersion curves predicted from the 1D analysis and those obtained from the field specific trial for that tested location. A good agreement between the two sets is observed.

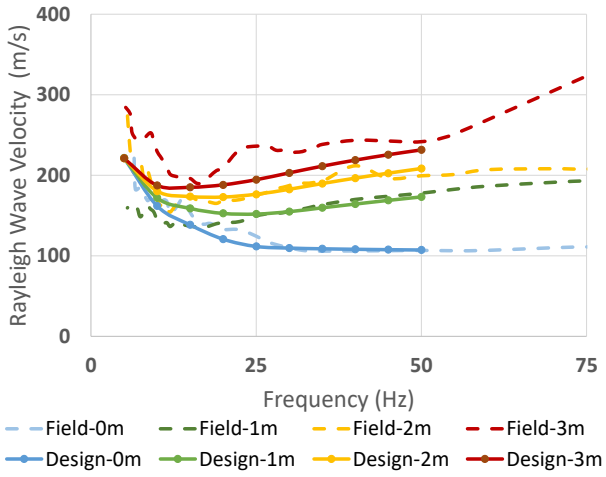

Figure 7. Typical Example of comparative Rayleigh Wave velocities dispersion curves obtained from the design forward analytical tool and from field trials.

6 CONCLUSIONS

The risk management-based design approach adopted for assessing the dynamic performance of the earthwork structures, and the design of foundations treatment has been found to be reliable in demonstrating compliance with dynamic performance criteria and requirements specified for the HS2 earthworks structures.

The use of a relatively simple, 1D wave propagation forward modelling method has enabled a more efficient design to be developed that considers the improvements obtained from stiffer layers of earthworks constructed over less stiff in-situ foundation materials.

ACKNOWLEDGEMENTS

The Authors acknowledge the support of the Integrated Project Team (IPT) and the corresponding design, construction, and assurance teams from ASC, EKFB and HS2. Input from HS2 Expert Panel members William Powrie and Nick O'Riordan and HS2 Head of Geotechnics Nick Sartain to a HS2 specific dynamic performance workshop in December 2021 is specifically recognised.

Enhanced ductility and energy absorption of coal wash-rubber crumb mixtures for track substructure

Amélioration de la ductilité et de l'absorption d'énergie des mélanges de lavage au charbon et de mie de caoutchouc pour la sous-structure de la voie

H. Hunt, B. Indraratna*, Y. Qi

ABSTRACT: Particularly within developed countries, landfill and stockpile volumes of industrial waste materials are reaching alarming levels. Two examples of these wastes are coal wash (CW), a by-product of the coal washing process; and scrap rubber tyres, which can be shredded to produce granulated rubber crumbs (RC). Moreover, high-quality natural aggregates are growing in scarcity, leading to increased procurement difficulties and associated costs. Consequently, reusing CW and RC in large-scale civil engineering applications is both a financially and environmentally attractive alternative to traditional granular materials. This study evaluates the ductility and strain energy density of CW-RC mixtures, at varying RC contents and compacted at the same void ratio, under static triaxial shearing. Expectedly, including rubber enhances the ductility and energy absorption of these waste mixtures. Improving these characteristics makes CW-RC mixtures a promising energy-absorbing alternative to traditional track substructure design as rail loads are expected to increase in the future. Additionally, this study proposes an empirical model for strain energy density as a function of RC content and shear strength.

RÉSUMÉ: En particulier dans les pays développés, les volumes d'enfouissement et de stockage de déchets industriels atteignent des niveaux alarmants. Deux exemples de ces déchets sont le charbon de lavage (CW), un sous-produit du processus de lavage du charbon; et les pneus en caoutchouc usagés, qui peuvent être déchiquetés pour produire des miettes de caoutchouc granulé (RC). De plus, les granulats naturels de haute qualité se font de plus en plus rares, ce qui entraîne une augmentation des difficultés d'approvisionnement et des coûts associés. Par conséquent, la réutilisation de CW et RC dans des applications de génie civil à grande échelle est une alternative financièrement et écologiquement attrayante aux matériaux granulaires traditionnels. Cette étude évalue la ductilité et la densité d'énergie de déformation des mélanges CW-RC, à différentes teneurs en RC et compactés au même taux de vide, sous cisaillement triaxial statique. Comme on pouvait s'y attendre, l'inclusion de caoutchouc améliore la ductilité et l'absorption d'énergie de ces mélanges de déchets. L'amélioration de ces caractéristiques fait des mélanges CW-RC une alternative prometteuse d'absorption d'énergie à la conception traditionnelle des sous-structures de voie, car les charges sur les rails devraient augmenter à l'avenir. De plus, cette étude propose un modèle empirique pour la densité d'énergie de déformation en fonction de la teneur en RC et de la résistance au cisaillement.

Keywords: Coal wash; rubber crumbs; ductility; energy absorbing capacity.

1 INTRODUCTION

Coal wash (CW) is a coarse-grained by-product derived from the coal washing process, with annual productions exceeding a hundred million tonnes in Australia alone (Leventhal and De Ambrosis, 1985). Prior research has been undertaken into the application of this waste material as an alternative to traditional granular geomaterials (e.g. Rujikiatkamjorn et al., 2013), although its high susceptibility to particle breakage limits is viability for use in dynamic loading environments (Qi et al., 2018).

Moreover, Australia's annual production of waste rubber tyres is expected to reach 488,000 tonnes in the year 2024-25, with about 30% being disposed on site, stockpiled, illegally dumped, or sent to landfill (O'Farrell, 2019). This can create environments that attract harmful wildlife, as well as increase the risk of fires and the release of toxic gases. Reusing waste tyres for geotechnical applications has been standardised by ASTM (2012), although less than 10% are currently used (Tasalloti et al. 2021). Rubber is an attractive material due to its low weight, high ductility, and high energy absorbing capacity, although it has a low shear strength. For important structures like railways where failure can be catastrophic, prolonged ductile failure is preferred to brittle behaviour. Rubber has been previously shown to improve the ductility of sand (Sheikh et al., 2013) and other waste material

mixtures (Indraratna et al., 2018). It has also been reported to improve energy absorption and particle breakage characteristics (Indraratna et al., 2018). Therefore, adding granulated rubber crumbs (RC), produced by shredding rubber tyres, may improve the ductility and reduce CW breakage, rendering the mixture suitable for use as an energy absorbing track substructure layer. However, it should be noted that European countries have recently proposed to tighten controls on, and possibly cease, the use of rubber due to the potential release of microplastics into the environment as a result of the recovery and recycling process (Coopland and Winter 2021).

Using the consolidated drained static triaxial tests conducted by Indraratna et al. (2019), this study aims to investigate how RC content influences the ductility and strain energy absorption of a compacted CW-RC mixture. These mixtures were blended at RC:CW ratios of 0%, 5%, 10%, and 15% based on weight. To simulate the typically low confinement conditions for subballast, these tests were conducted at effective confining pressures (σ_3') of 10, 25, 50, and 75 kPa. Additionally, to align with Australian Rail Track Corporation (ARTC, 2010) compaction requirements for a capping layer, the test specimens were all compacted at the same initial void ratio of about 0.3 using a modified energy level. The particle size distributions (PSD) of each mixture are portrayed in Figure 1, while Indraratna et al. (2019) should be referred to for further detail on specimen preparation and testing methodology.

2 DUCTILITY

The stress-strain response of the CW-RC mixtures with varying RC content at $\sigma_3' = 25$ kPa is shown in Figure 2. Understandably, increasing the RC content

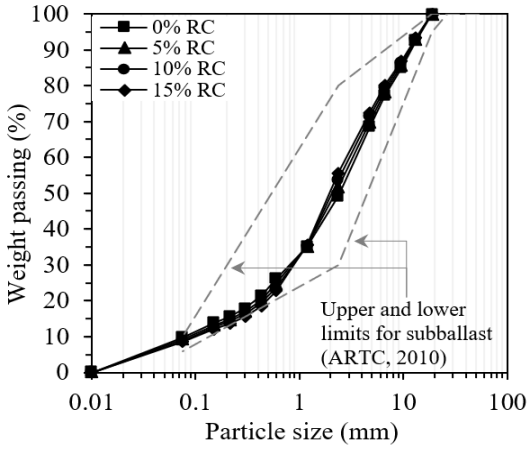

Figure 1. PSD of CW-RC mixtures with varying rubber content (modified after Hunt et al., 2023).

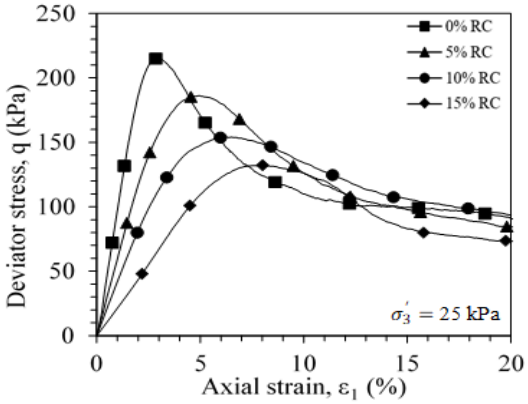

Figure 2. Stress-strain response of CW-RC mixtures under $\sigma_3' = 25$ kPa (modified after Hunt et al., 2023).

corresponds to a reduction in the peak deviatoric stress (q_{peak}) due to the inferior shear strength of rubber in comparison to the CW particles. As RC content increases, the curvature around q_{peak} is broadened as the post-peak state of the mixture transitions from being predominately brittle to more ductile, which can be attributed to the increasing rubber-to-rubber particle contacts and interactions within the soil skeleton (Sheikh et al., 2013; Qi et al., 2018). Although a larger settlement is experienced, this increase in ductility translates to a substructure material that is capable of sustaining larger post-peak loads, thus lowering the risk of catastrophic train derailments due to failure. The CW-RC mixture ductility can be quantified by calculating its brittleness index (I_B), as proposed by Consoli et al. (1998) and defined by Equation (1):

$$I_B = \frac{q_{peak}}{q_{residual}} - 1 \qquad (1)$$

where $q_{residual}$ is the residual deviatoric stress, and a lower brittleness index equates to a higher ductility. Figure 3 presents the variation in brittleness index of the CW-RC mixtures at different RC contents and

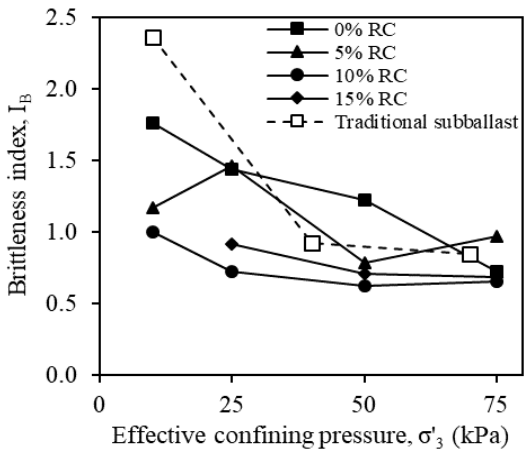

Figure 3. I_B values of CW-RC mixtures compared to traditional subballast (modified after Hunt et al., 2023).

confining pressures. Generally, I_B decreases as σ_3' increases, although this does fluctuate for the 5% RC mixture. Compared to traditional subballast material, all four mixtures have a greater ductility at the lower confining pressures ($\sigma_3' \leq 25$ kPa), while those comprised of ≥10% RC maintained a lower I_B for the entire set of confining pressures tested. These results indicate ductility is maximised for the mixture with 10% RC since this content yielded the smallest I_B for each confining pressure, after which brittleness increased as the reduction in particle breakage becomes less significant at higher RC contents.

3 STRAIN ENERGY ABSORPTION

3.1 Strain energy density

The strain energy absorption can be quantified by calculating the area enveloped by the shear stress-strain curve up to the point of failure (Equation (2) and Figure 4), which is termed strain energy density (E):

$$E = \int_0^{\gamma_f} \tau d\gamma \qquad (2)$$

where τ_f is the shear strength, γ is the shear strain, and γ_f is the shear strain at failure. The results in Figure 4 emphasises how influential even a small amount of RC is on improving the energy absorption of the CW-RC mixture. Without rubber, CW has a much lower energy absorbing capacity compared to traditional subballast and a steel furnace slag-coal wash (SFS-CW) mixture tested by Qi et al. (2018). However, at 5% RC, the mixture is superior at the lower confining pressures ($\sigma_3' \leq 25$ kPa) in terms of energy absorption, although further improvement is less significant with larger RC proportions. These low confining pressures are typical for Australian railways and therefore selecting a preferred RC content (e.g. 5% or 15%) to enhance the CW-RC mixture's strain energy absorption under lighter axle loads makes little difference. Although, at the higher confining pressures, they do not perform as well, where only the 15% RC mixture is more energy absorbing at $\sigma_3' = 50$ kPa. This can be attributed to the increased particle breakage of CW at higher confinement reported by Indraratna et al. (2019). Therefore, in terms of strain energy absorption, these CW-RC mixtures are more suitable for use within lower confining pressure ranges when compared with traditional subballast.

3.2 Strain energy density relationship

Referring to Figure 5, the strain energy density of the mixtures can be represented as a function of the shear strength and rubber content by Equations (3a,b):

$$E = \psi \tau_f \qquad (3a)$$

$$\psi = a_1 X_{RC} + a_2 \qquad (3b)$$

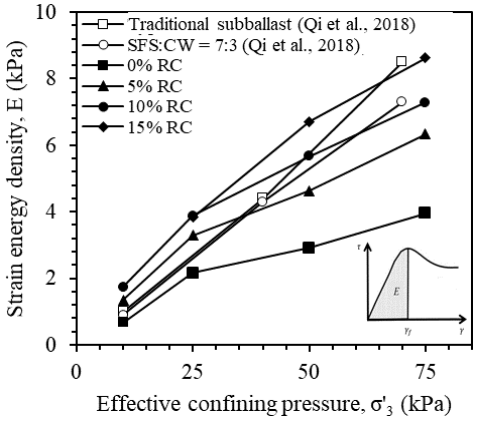

Figure 4. E values of CW-RC mixtures compared with subballast and SFS-CW (modified after Hunt et al., 2023).

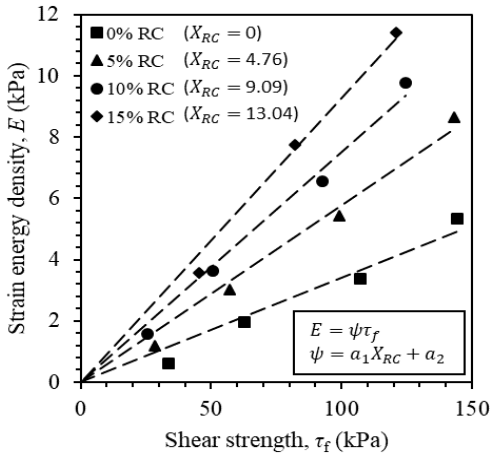

Figure 5. Increase in E with respect to shear strength of CW-RC mixtures (modified after Hunt et al., 2023).

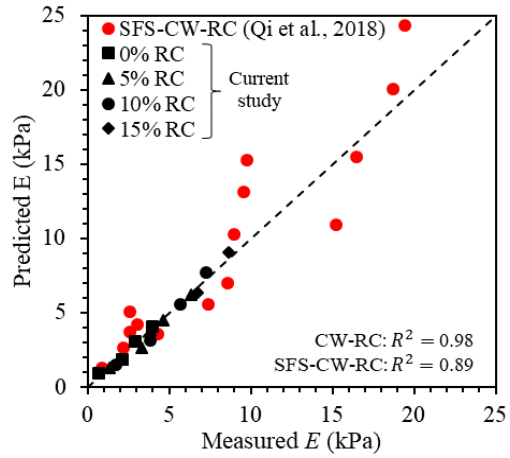

Figure 6. Predicted vs. measured E for CW-RC and SFS-CW-RC mixtures (modified after Hunt et al., 2023).

where ψ is an empirical parameter accounting for the shape of the stress-strain curve as a function of RC content, a_1 and a_2 are calibration parameters ($a_1 = 0.0036$, $a_2 = 0.0282$), and X_{RC} is the RC percentage relative to the total mixture. For further detail on these equations, see Hunt et al. (2023). The strain energy density of the CW-RC mixtures is approximated well with an R^2 value of 0.98 (Figure 6). Extending this to SFS-CW-RC mixtures (0–30% RC) tested by Qi et al. (2018), the model still performs well with an R^2 value of 0.89, although the authors recommend recalibrating the parameters a_1 and a_2 for different mixtures.

4 CONCLUSIONS

The ductility and strain energy absorption of coal wash when blended with rubber crumbs subjected to triaxial shearing was investigated in this study. Expectedly, adding rubber to coal wash significantly enhances its ductility and strain energy absorbing capabilities, particularly when 10% RC is added where ductility is at a maximum. An empirical relationship to estimate the strain energy density based on shear strength and rubber content was also proposed in this study. The model performed well on both the experimental and validation data, although the empirical constants should be recalibrated for different mixtures. When compared to typical subballast material and confining pressures, the CW-RC mixture with 10% RC is more ductile and energy-absorbing, making it suitable for use as an energy absorbing track substructure layer.

Exploring the use of fine surplus silica sand in low CO_2 emission earth construction

Exploration de l'utilisation de sable de silice excédentaire fin dans la construction terrestre à faible émission de CO_2

anoosheh.iravanian@aalto.fi

ABSTRACT: The usage of industries' by-products and recycled materials in construction has become crucial for a sustainable future, as it reduces waste, has economic benefits, and helps to preserve natural resources while lowering CO_2 emissions. This research explored the possibility of utilizing fine silica sand, a by-product of quarrying, as a construction material aligned with circular economy strategies. Investigating various by-products alongside surplus fine silica sand from Nilsiä district, Finland, the study aimed to identify optimal recipes for stabilized silica sand blocks. The main focus was on experimentally assessing the technical properties of these blocks and evaluating the suitability of silica sand for sustainable rammed earth construction techniques. The filler and aggregates used were silica sand as well as quarry fines, while the binders included bio-based fly ash, bottom ash, green liquor dreg, lime kiln dust and cement. The material's index properties were measured, and the binders were tested for the flexural and compressive strength. Selected binders, exhibiting strength properties, were incorporated with sand and quarry fines to prepare cylindrical blocks, subsequently subjected to uniaxial compression tests. The comparison of 28 days cured compressive strength of different recipes revealed that samples containing bio-based fly ash with ratios of 1:5 and 1:6 binder to aggregate demonstrated superior results, with the best recipe containing a 50%-50% ratio of quarry fines to sand and a binder to aggregate ratio of 1:6, containing fly ash sourced from paper and pulp industry.

RÉSUMÉ: L'utilisation des sous-produits industriels et des matériaux recyclés dans la construction est devenue cruciale pour un avenir durable, car elle réduit les déchets, offre des avantages économiques et aide à préserver les ressources naturelles tout en réduisant les émissions de CO2. Cette recherche a exploré la possibilité d'utiliser du sable de silice fine, un sous-produit de l'exploitation de carrières, comme matériau de construction aligné sur les stratégies d'économie circulaire. En étudiant divers sous-produits aux côtés du surplus de sable de silice fine du district de Nilsiä, en Finlande, l'étude visait à identifier des recettes optimales pour des blocs de sable de silice stabilisés. L'accent principal a été mis sur l'évaluation expérimentale des propriétés techniques de ces blocs et sur l'évaluation de la pertinence du sable de silice pour les techniques de construction en terre battue durables. Les charges et agrégats utilisés étaient du sable de silice ainsi que des résidus de carrière, tandis que les liants comprenaient des cendres volantes biologiques, des cendres de fond, des résidus de liqueur verte, de la poussière de four à chaux et du ciment. Les propriétés index du matériau ont été mesurées et les liants ont été testés pour leur résistance à la flexion et à la compression. Des liants sélectionnés, présentant des propriétés de résistance, ont été incorporés avec du sable et des résidus de carrière pour préparer des blocs cylindriques, ensuite soumis à des tests de compression uniaxiale. La comparaison de la résistance à la compression des différentes recettes durant une période de 28 jours de durcissement a révélé que les échantillons contenant des cendres volantes biologiques avec des ratios de liant à agrégat de 1:5 et 1:6 ont montré des résultats supérieurs, avec la meilleure recette contenant un ratio de 50%-50% de résidus de carrière à du sable et un ratio de liant à agrégat de 1:6, contenant des cendres volantes provenant de l'industrie du papier et de la pâte.

Keywords: Sustainable construction; low CO_2 binders; circular economy; silica sand; quarry fine.

1 INTRODUCTION

Within the last decade, due to the increased environmental and economic benefit, re-use of recycled glass as the source material in glass and China production is adapted in many European countries. Due to this, the demand for fine-grained (< 1 mm) silica sand has decreased, and it is resulted in a problem in mass balance and surplus of the material on many quartzite quarry sites. Additionally, transporting large quantities of this material to regions with higher demand is deemed unsustainable.

In addition, with the rise of awareness about circular economy, it is essential to acquire by-

products from mining, forestry, and energy industries in a manner that is consistent with the trend.

This study tries to evaluate the usage possibility of fine sand together with other secondary materials in non-load-bearing structure construction. This may provide a sustainable solution for the surplus of the material, assist with the waste management, and foster a more environmentally responsible approach to building practices.

One of the methods of construction that employs the use of secondary materials is rammed earth technology. In this method of construction, a damp material composed of soil, sand, silt or clay is rammed into a formwork. After the material has achieved the desired height the formwork is removed revealing a monolithic wall structure. In modern construction, besides the artistic reasons, the primary objective of utilizing rammed earth is to enhance its strength properties to meet the standards' requirements. To achieve this, stabilized rammed earth compositions typically integrate a small proportion of cement, typically ranging from 5% to 10% (Avila et al., 2022). In the stabilized rammed earth technique, the binder interacts with the available water, initiating a hydraulic binding process that contributes to the structural cohesion of the material (Jaquin, 2012). Numerous studies on the rammed earth technique highlight the influence of water content on the final strength of the structure. Unconfined compressive strength (UCS) achieved through the rammed earth technique typically span from 0,5 to 4 MPa, while the stabilized rammed earth technique can attain strengths exceeding 10 MPa after 7 days of curing. The strength ranges can vary depending on the type of aggregates and binders and the amount of water used. Nevertheless, the process of hydration and strength gain is gradual in these types of structures, therefore, the immediately post-construction strength measurements may not provide a realistic result (Jaquin et al., 2009; Walker et al., 2005).

In an experimental study, Holopainen (2022) investigated the possibility of using the recycled materials generated in Helsinki metropolitan area in rammed earth technology by constructing a testing-scale wall. In their work they studied the compressive strength of blocks made of different recipes of fly ash, crushed concrete, slag, and excavated desulphurization products with small amounts of cement. The compressive strength of his laboratory samples varied between 0,43-11,85 MPa, and it was concluded that the variation of the test results was an indicator of the susceptibility of the method to errors in the construction work. The main factors affecting the final results were named as: thoroughness of material mixing, initial moisture content of the mixture, and the compaction method.

Limited research exists on the properties of quarry fines in relation to rammed earth technology. However, Zhang et al. (2019) investigated the mechanical properties of stabilized quarry fines to be used in base and subbase layers in pavement construction. The quarry fines size ranging 0 to 4 mm were stabilized with cement, Ecolan Infra 80 (composed of coal ash, wood biomass, lime, and 20% cement) and fly ash from 100 % coal combustion residuals. Their cement stabilized samples showed acceptable performance for base layer applications when compacted to at least 93% of its maximum dry density.

The use of clean, fine quarried silica sand, characterized by angular-shaped grains, in conjunction with recycled material has not yet been explored in existing literature. However, the use of foundry sand, primarily consisting of uniformly sized, round-grained silica sand, has been studied in a few previous works. Zhang et al. (2021) have studied the use of stabilized waste foundry sand, (WFS) for applications in pavement structures. After monitoring the strength and durability properties of the proposed mixtures, they concluded that stabilized waste foundry sand (WFS) in combination with crushed rock exhibits promising potential for utilization in pavement structural layers. Malathy et al., (2022) tried to address the depletion of natural aggregates, by investigating the use of industrial silica sand as a substitute for natural fine aggregates in concrete. In their study it was concluded that all silica sand samples perform lower strength when compared to reference river sand and manufactured sand, and that the workability of concrete substituted with silica sand is superior to the concrete samples containing river sand.

In the current research, the silica sand from Nilsiä district of Finland was tested together with quarry fines as the main frame of the mixtures for the testing program. The by-products of a close-by forestry (paper and pulp) industry, namely bio-based fly ash, bottom ash, lime kiln dust and green liquor dreg together with by-products of a local energy company, namely: bio-based fly ash and bottom ash, was used as possible binders together with small amounts of cement as activator, to prepare samples. The aim of the research is to explore the potential application of different low carbon embedded recipes within the construction industry, in alignment with circular economy principles, as well as to determine the suitable ratios for the silica sand-containing mixtures adapted for different construction needs including non-load-bearing structures and noise barrier walls.

2 MATERIALS AND METHODS

The sand sample used in the study was a uniform poorly graded silica sand obtained from SIBELCO company's quarrying operation in Nilsiä located in Northern Savonia region of Finland. The fine fraction of silica sand (0.1 to 0.6 mm) is of less demand in the industry and is recently considered as a side stream product in quartzite quarrying activities.

As the coarser portion of the mixtures, quarry fines were used. The quarry fines (QF) are secondary product of the rock crushing process, characterized by a high fine grain size content. The quarry fines used in this study had a grain size distribution of 0 to 8 mm and the geological composition of the source rock was identified as Quartz syenite.

The material used for main frame of the mixtures, sand and QF, was dried for 24 hours at at the oven of 110 ± 5 °C. Subsequently, quartering was performed to prepare the samples for their index properties testing. Specific gravity and sieve analysis tests were performed according to SFS-EN ISO 17892-3 and SFS-EN 933-1, respectively. The maximum dry density (MDD) and optimum moisture content (OMC) of the material were then determined according to SFS-EN 13286-2 standard by using modified Proctor test. The Index properties of the material can be found in Table 1.

Table 1. Index properties.

Property	Silica sand	Quarry fine
Specific gravity	2,65	2,72
Percent fine <0,063 mm, (%)	0,1	6,15
C_u	2,5	0,9
D_{50}, (mm)	0.6	0,9
OMC, (%)	10	10,5
MDD, (g/cm^3)	1,57	2,15

To explore potential sustainable binder materials, an initial investigation was undertaken to identify locally sourced by-products. The aim was to minimize the requirement for long-distance transportation, thereby lowering CO_2 emissions. Stora Enso Oy, a provider in the renewable bio-products industry operating within the same region, supplied this work with five types of by-products: bio-based fly ash (1), two variants of bottom ash (1 & 2), lime kiln dust (LKD), and green liquor dreg. Additionally, Savon Voima, a local energy company, provided two of their own by-products: bio-based fly ash (2) and bottom ash (3). To assess the binding properties of these products in the presence of an activator, the flexural and compressive strengths of the hardened mortars, were tested after curing for 28 days, following the European standard SFS-EN 196-1:2016. Following the methodology outlined by Holopainen (2022), the proportion of activating agent, CEM I, was set up at 20%, while the remaining 80% was allocated to various binders. The test results of the strength properties of activator added binders are provided in table 2. The green liquor dreg did not exhibit any hardening properties, attributable to its high initial water content. Consequently, it was excluded from the designed recipes.

Table 2. Strength of activated binders.

Specimen	Flexural strength (MPa)	Compressive strength (MPa)
Fly ash 1 + CEM I	2,5	7,5
Bottom ash 1 + CEM I	1,5	4,5
Lime kiln dust + CEM I	0,4	0,9
Fly ash 2 + CEM I	1,6	5,8
Bottom ash 2 + CEM I	4,4	23,1
Green liquor dreg+ CEM I	NA	NA
Bottom ash 3 + CEM I	3,2	10,1

3 RESULTS AND DISCUSSIONS

The initial combination utilized in this study, referred to as Recipe-1, contain 75% quarry fines and 25% silica sand serving as the frame material together with binders. The binders were added at ratios of 1:5 and 1:6 binder to aggregate, respectively, to develop potential working recipes.

For evaluating the compressive strength following a 7-day curing period, a total of twelve specimens were prepared using an intensive compactor tester (ICT) machine. As shown in Figure 1, the stabilized mixture containing Fly ash 1, from Stora Enso, showed the highest recorded strength of 6,85 MPa. This fly ash was collected from a bed boiler that has a 150 MW thermal output and operates at an efficiency of 88%, with the annual production output of 5000 metric tons fly ash. Wood-based fuels such as bark, wood chips, forest chips and wood residue classes A and B, which are obtained from the factory and external sawmills are used as the main fuel type for this boiler. In addition, peat and sewage treatment plant sludge can be burned and coal is used as back-up fuel. The elevated chloride content present in this fly ash could be attributed to its higher strength, as chlorides are recognized accelerators of compressive strength in mortars and concrete. Fly ash 1, in particular, contains chloride, different oxides, and sulphate ions. The presence of chloride ions within the hydrated cement pore water stimulates the activator's hydration, thereby enhancing the strength

gain (Galan and Glasser, 2015). Similarly, at a ratio of 1:5, the mixture containing fly ash 2 exhibited promising results, likely due to the same mechanism. Conversely, to the fly ash bearing samples, the remaining four binders exhibited less favourable outcome for the 1:5 and 1:6 binder-aggregate ratios. Consequently, a higher binder content was deemed necessary for these recipes, prompting an adjustment to binder-aggregate ratio to 1:3.

The percentage increase in strength, comparing the 1:5 to 1:3 ratios of binder to aggregates, were 25%, 77%, 132%, and 4% for samples containing bottom ash 1, lime kiln dust, bottom ash 2, and bottom ash 3, respectively as visible in Figure 1.

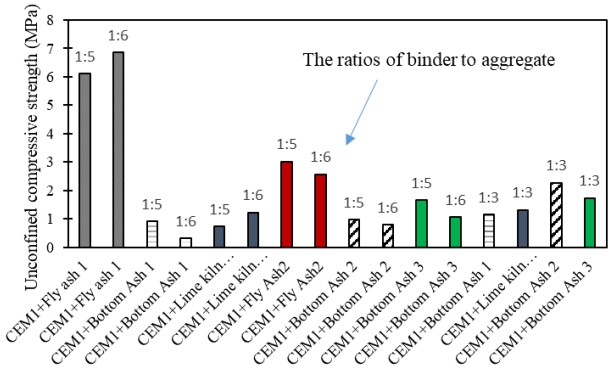

Figure 1. Unconfined compressive strength of 7-day.

Based on the revised recipes, the four best-performing binders exhibiting strengths were selected along with their corresponding ratios. Three specimens were prepared for each recipe to undergo testing for 28-day cured compressive strength. On the other hand, in order to maximize the utilization of the fine side stream sand, Recipe-2 was introduced, which involved a reduction in the amount of quarry fines by 25%, while maintaining the same ratios of binders. Following changing the ratio of quarry fines to sands to 50-50% the 7 days strength of samples were measured, and the comparison of result can be seen in figure 2. It is evident that the impact of this change varies across different recipes. For samples containing lime kiln dust, the frame material ratio change led to a notable 65% enhancement in strength compared to Recipe-1. However, in the remaining samples, it resulted in a strength reduction ranging from 26% to 117%.

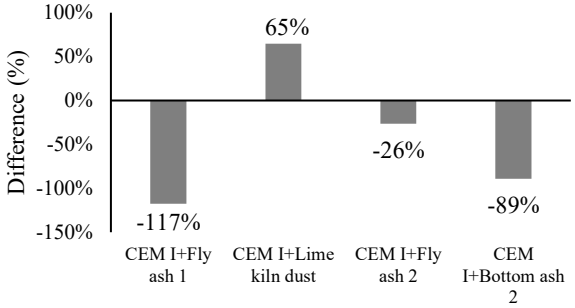

Figure 2. Comparison of 7-day strength difference from 75-25% (recipe 1) to 50-50% quarry fine-sand (recipe 2).

Among the recipes yielding better results in Recipe-2, those containing fly ash 1 and lime kiln dust (LKD) demonstrated strengths of 3.15 MPa and 3.17 MPa, respectively. These two samples were selected for comparison of their 28-day compressive strengths. Table 3 displays the results for both 7-day and 28-day compressive strengths of the selected samples of Recipe-1 and Recipe-2. These samples were prepared by ramming technique in five layers with a 4 kg hammer dropped 20 times from 0.45meter height. It can be observed that all samples, except those containing lime kiln dust, demonstrated strength gain with the extension of curing time.

Previously, it has been noted that incorporating lime kiln dust (LKD) into ash-bearing concrete mixtures and mortars leads to an increase in their water demand (Dvorkin and Zhitkovsky, 2023). This phenomenon suggests that LKD retains a higher water absorption capacity compared to CEM I, potentially attributed to its porous and larger particle size (Latif et al., 2015). In stabilized samples prepared using the rammed earth technique, compaction occurs at a relatively low water content. Consequently, the rapid absorption of available water by LKD can impede the hydration process of the remaining calcite (both from the activator and binder) in the mixture. This can lead to a cessation or even reversal of the strength gain process.

Table 3. Compressive strength of the final recipes.>

Quarry fine to sand ratio	Binder	Binder to aggregate	7 days strength (Mpa)	28 days strength (Mpa)
75%-25%	CEM I+Fly ash 1	1:6	3,15	4,83
75%-25%	CEM I+Fly ash 2	1:5	2,39	4,89
75%-25%	CEM I +Bottom ash 2	1:3	1,2	3,17
75%-25%	CEM I+Lime kiln dust	1:3	3,73	3,67
50%-50%	CEM I+Fly ash 1	1:6	3,15	6,61
50%-50%	CEM I+Lime kiln dust	1:3	3,73	2,56

4 CONCLUSIONS

The suitability of utilizing by-products of fine silica sand and quarry fines as construction materials was evaluated through a comparative study, with a particular focus on the compressive strength properties. Six different types of low CO_2 binders were employed to produce stabilized mixtures. Two ratios of 25% to 75 % and 50% to 50% of quarry fines to sand were kept as the base for frame material, while the proposed binders were added at 1:6, 1:5 and 1:3 ratios of binder to aggregate. Overall, samples containing bio-based fly ash in different mixtures and recipes demonstrated superior results, with the best recipe containing 50%-50% quarry fines to sand ratio, containing the bio-based fly ash from paper and pulp industry. It can be concluded that the higher concentration of fine silica sand particles in the mixture resulted in a wider range of gradation distribution of material within the standard upper and lower limits of aggregates. This, in turn, leads to a tighter packing of materials, particularly when combined with quarry sand and fly ash. Consequently, the reduction in void space within the material contributes to an increase in compressive strength. Additionally, it was observed that the effect of curing time on lime kiln dust containing samples was slightly detrimental. Further research is still required to assess the durability of utilized recipes over the long term and to enhance their strength properties.

ACKNOWLEDGEMENTS

The authors are grateful for the financial support provided by SIBELCO NORDIC mineral company. We thank Stora Enso and Savon Voima for providing the by-products, as well as Kiertomaa Oy for providing the quarry fines. All the experiments were done at the Aalto university laboratories.

Framework for evaluating scour risk and optimising scour mitigation

Cadre d'évaluation du risque d'affouillement et d'optimisation de son atténuation

J. Irvine*, I. Torres, M. Divilly
Cathie, Newcastle, UK

**Jamie.Irvine@cathiegroup.com*

ABSTRACT: Scour poses a significant risk to seabed foundations. Common practice is to design scour protection to ensure protection against extreme metocean events such as 50-year storms. This may have been acceptable for oil and gas projects but, with the increasing size of offshore wind projects, this could result in excessive costs associated with the transportation and installation of scour protection. This paper aims to provide a framework to evaluate the main factors influencing scour risk such as; soil conditions including surface soils and the depth to potentially scour resistant soils, the metocean conditions which could result in scour, the potential rate of scour, as well as understanding the potential consequences of scour on foundation performance. This understanding will allow the specification of appropriate scour mitigation.

RÉSUMÉ: L'affouillement se produisant autour des structures sous-marines peut engendrer un risque important pour la stabilité des fondations. La pratique courante consiste à concevoir une protection contre l'affouillement visant à assurer une protection contre les évènements météo-océaniques extrêmes tels que les tempêtes de période de retour 50 ans. Cette approche était acceptable pour les projets pétroliers et gaziers. Mais, du fait de la taille croissante des projets de développement éoliens offshore, implémenter cette même approche pourrait engendrer des coûts excessifs associés au transport et à l'installation de protection anti-affouillement. Cet article vise à fournir un cadre pour évaluer les principaux facteurs influençant le risque d'affouillement, tels que: les conditions du sol, y compris les sols de surface et la profondeur des sols potentiellement résistants à l'affouillement, les conditions météo-océaniques qui pourraient générer l'affouillement, le taux potentiel d'avancement d'affouillement avec le temps, ainsi qu'une compréhension des conséquences potentielles de cet affouillement sur les performances des fondations. Une telle compréhension permettra de définir des mesures d'atténuation appropriées.

Keywords: Offshore foundations; scour protection; scour risk; scour mitigation.

1 INTRODUCTION

The installation of structures such as offshore wind turbine foundations is likely to cause a local increase in seabed stresses due to wave and current motions. This increase can result in local erosion of seabed soils around the structure. This process is generally known as scour whereas widespread sediment mobility away from structures is known as 'global sediment mobility'.

Scour can result in reduced foundation capacity and/or a 'softer' foundation response, potentially resulting in natural frequency or fatigue issues. The risk of scour is usually mitigated by using rock berms placed around the foundations to 'shield' the seabed, however, alternatives such as filter units and fronded mattresses can also be used.

Scour assessment and subsequent scour protection design usually consider extreme metocean events such as 50-year storms and assume any significant scour is unacceptable. This may have been acceptable for oil and gas projects but, with the increasing size of offshore wind projects, this could result in excessive costs associated with the transportation and installation of scour protection around hundreds of offshore structures.

The aim of this paper is to propose a framework to better understand the risk of scour and potential consequences, to then determine the most appropriate scour mitigation measures. It should be noted that global seabed mobility is not considered as part of this paper.

2 SCOUR PRINCIPLES

Scour processes are commonly triggered as a result of the presence of a structure which disturbs pre-existing

flow patterns, increasing the fluid velocity / current speed as it flows around the structure. At the seawater-seabed interface, this increased velocity is translated into a bed shear stress. This can subsequently lead to higher local erosion occurring around a foundation structure, reducing with distance from the structure.

The evolution of the scour mainly depends on several parameters such as soil characteristics, the prevailing metocean conditions, and structure geometry, as discussed below.

2.1 Soil characteristics for scour resistance

The characteristics of the shallow seabed soils can significantly influence scour potential. For example, in cohesionless soils: smaller, lighter soil particles are more prone to scour than larger heavy particles. Effective soil cohesion also increases soil scour resistance.

As a minimum, the following soil parameters are required:

- Sediment specific gravity (density of soil grains);
- Sediment size (particle size distribution);
- Cohesion.

Other factors such as grain shape or clay plasticity may also be a factor but are considered less critical.

2.2 Metocean parameters for scour propagation

The prevalent metocean conditions, such as tidal current and waves, can have a significant influence on scour potential. The collection of site-specific metocean data is considered an invaluable asset to aid in the development of the risk-based approach for initial categorising of the site. The following parameters are required as a minimum:

- Maximum current velocity and direction at seabed level (or just above);
- Metocean parameters for anticipated design conditions i.e., 1 year storm, 5-year storm, etc would also add significant value.
- Wave parameters including wave direction, maximum wave height and period.
- Low-water and high-water levels.

Metocean criteria and input for design should be contemplated as part of a site specific metocean assessment. In order to select realistic conditions for a 50-year event, consideration should be given to the realities of climate change. What were previously considered extreme events may become more frequent and therefore expectations of what constitutes an extreme event should be updated as part of the metocean assessment.

2.3 Structure size

The classical representation of flow modification around a vertical pile is shown in Figure 1. Local scour is often induced by the generation of the horseshoe vortex (rotation of the incoming flow), vortex shedding (generation of lee-wake vortex behind the pile) and the contraction of the streamlines around the structure (Sumer and Fredsoe, 2002).

The larger the structure, the larger the flow disturbance.

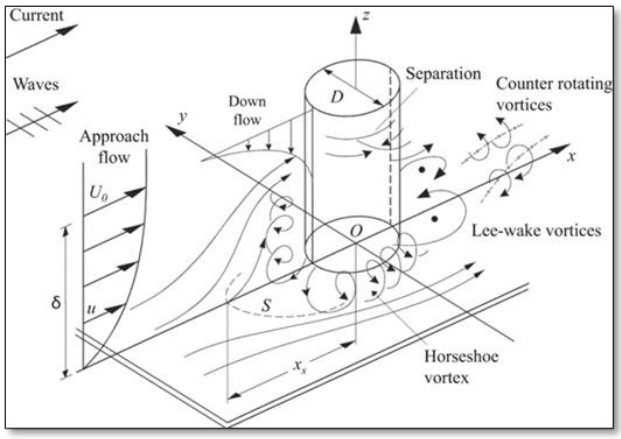

Figure 1. Flow around a vertical pile – extract Sumer and Fredsoe (2002).

3 SCOUR RISK ASSESSMENT PROCESS

The risk of scour should be considered throughout the development cycle to ensure sufficient information is collected and evaluated to allow for informed decisions without unnecessary or abortive work. The following process is hence recommended:

1. Initial site characterisation (basic soil and metocean parameters);
2. Initial scour risk evaluation and sensitivity analysis;
3. Detailed site characterisation;
4. Detailed scour assessment;
5. Evaluation of scour consequences;
6. Cost benefit analysis of scour mitigation options / measures.

4 INITIAL SITE CHARACTERISATION

At early project stages, limited information is likely to be available. Therefore, there should be a detailed desk study including a review of all public domain information and likely conditions across the planned development area including water depth, anticipated seabed sediments, potential bedforms, shallow geology and indicative metocean parameters.

Ideally, the desk study information should also provide an initial qualitative scour risk assessment. Identification of seabed features such as sand waves, megaripples, etc. are meaningful indicators that scour should be considered a risk. Whilst a relatively flat featureless seabed with high strength clay or rock at seabed would be considered lower risk.

Even if the available data are not of sufficient resolution to identify potential bedform features, the indication of water depth and metocean parameters should also be somewhat informative.

The outcome of the initial risk assessment should inform the scope of future survey campaigns. For example; a geophysical survey undertaken in order to accurately identify bedforms, potentially with multiple phases to monitor bedform migration speed. The planned surveys should be scoped to provide the information required for the scour analysis.

Key outputs:

- Qualitative risk assessment across site;
- Input into future survey scopes.

5 INITIAL RISK EVALUATION

Once site specific data are available in the form of seabed soils and metocean data, then initial numerical analysis can be undertaken to better understand scour potential. At this stage, a relatively simple numerical analysis is likely to offer reasonable understanding of the risk.

5.1 Metocean seabed stresses

The seabed stresses developed by the current are dependent upon the current velocity, water density and the turbulent flow regime. Specific formulation can be used to estimate current induced seabed stresses.

5.2 Shields stability method

Shields (1936) proposed a detailed, rational approach to the problem of hydrodynamic stability by defining the erosion limit in terms of the particle Reynolds number (a dimensionless parameter detailing the ratio of inertial to viscous forces) and the critical Shields parameter (normalised critical seabed stresses). Shields‘ theory can then be extended to the combined action of currents and waves.

It is noted that based on the randomness of the packing of the particles at the seabed, McEwan and Heald (2001) observed that, for a given bed stress or shear velocity, some particles are more vulnerable to erosion than others. The physical significance of this phenomenon was better described by Sato (1966), who studied erosion under wave action. Sato defined two levels of seabed mobility, called “surface layer movement” and “completely active movement”, respectively. Surface layer movement corresponds to the state where the first layer of particles of the seabed moves in the direction of the wave propagation. Completely active movement corresponds to such movement of bed material as to produce a notable variation in the seabed profile and Sato classifies “completely active” behaviour as more than 8% of sediment by volume.

5.3 Initial risk evaluation outputs

The initial risk assessment shall assess the conditions across the planned site for a number of potential metocean conditions to better understand scour risk.

The site could be split into zones of similar seabed sediments and water depth (and metocean conditions) and then an assessment undertaken to understand scour risk for the different conditions. For example:

- Zone A (deep water, high strength clays) – low risk;
- Zone B (medium water and coarse sands) – potential surface movement (medium risk);
- Zone C (shallow water, fine sands) – potential for ‘completely active’ movement (high risk).

6 DETAILED SITE CHARACTERISATION

The initial scour risk assessment should provide an indication of scour risk across the potential development area. The planned surveys including sediment sampling and potentially in-situ testing should be tailored based on these results. The site characterisation should aim to identify the main soil units anticipated across the development area, map the lateral and vertical distribution of these units, and provide sufficient information to allow scour potential to be accurately determined for each of the soil units.

In zones where a high risk of scouring is indicated, it may be necessary to plan additional tests potentially including benthic flume testing.

6.1 Sediment sampling

Representative seabed sediment core samples should be collected from across the site. The planned campaigns should obtain sediment samples of the main shallow soil units anticipated across the development area.

These soils can be targeted based on the scour risk assessment previously undertaken. Engineering judgement should be applied in order to obtain and preserve as many intact samples as necessary, particularly in higher risk zones to potentially perform

erosion tests as discussed in section 6.1.2. Additionally, it is important to perform sufficient index testing of the surface sediments in order to properly characterise the soils.

Samples shall generally be obtained using vibro-cores or boxcores (and potentially even boreholes) in order to obtain a better understanding of the most surficial soils and allow for a number of subsamples for testing (and for example, to verify cohesion).

6.1.1 Onshore laboratory testing - classification

As outlined above, soil characteristics which have the largest effect on scour occurrence and severity are:

- Soil type. Clay soils are most resistant to scouring whereas sands are often prone to scour.
- Particle size and specific gravity. Larger heavier soils tend to be more scour resistant.
- Cohesion. Experience indicates that sands which possess some levels of cohesion are far more scour resistant than those without.

As part of the geotechnical testing campaigns, it is vital to identify the main soil units present across the development area, and characterise each unit with sufficient index and other laboratory tests such as:

- Particle density (specific gravity);
- Particle size distribution (PSDs) for d50 and fines content;
- Shear box testing for cohesion.

6.1.2 Onshore laboratory testing – erosion

The initial numerical assessment detailed in section 5 is considered a useful indicator, but physical erosion testing should be considered to validate and/or optimise these results, particularly in high-risk areas.

Erosion testing generally comprises placing a soil sample in a flume and increasing the flow speed to investigate the sediment erosion with current speed.

It is important to use test conditions that are representative of the site and preferably based on measured metocean data.

The soil samples should undergo detailed assessment prior to onshore flume testing to ensure that they are representative of the anticipated soil units to the base of the potential scour depth.

The flow speeds should be carefully specified to represent anticipated field conditions and provide an accurate indication of the flow velocity to initiate erosion.

The main aim of erosion testing is to identify:

- Flow velocity at which mobility begins;
- Erosion rate at various current speeds.

Examples of results from indicative soils including sand, silt and clay are shown in Figure 2 below. These results indicate clays are generally highly resistant to scour with limited erosion even at significant current speeds (>1m/s), sands can erode at relatively low current speeds and even relatively limited cohesion can provide significant additional resistance against scour.

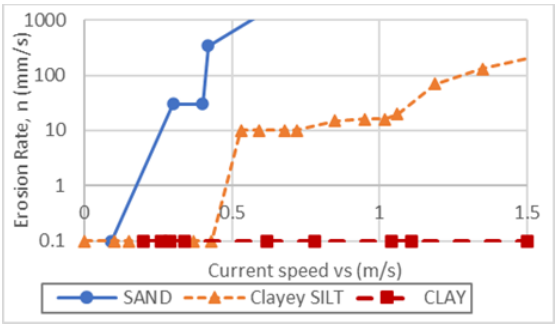

Figure 2. Erosion test results example.

It should be noted that testing a reasonable sample size can provide indications of the bulk behaviour of the soils. For example, there may be preferential erosion of smaller particles which leaves a layer of coarse sediments, shells and gravel at surface which is more resistant to scour. If this occurs, then it is recommended to carefully observe the test to understand the potential for sediment winnowing and the point at which the 'shield' layer becomes unstable. Consideration could also be given to testing the 'shield' layer at reduced velocities to better understand the benefits of this shielding.

Key outputs:

- Current velocity to initiate scour for each soil unit;
- Scour rate for each soil unit;
- Understand potential for formation of 'shield' layers and the potential benefits.

6.1.3 In-situ benthic flume testing

The Seaflume (KC Denmark, 2023) is a device which can provide an understanding of the in-situ erodibility of seabed sediments, particularly sands, fine gravels, and silts.

In-situ testing like this should be considered in zones which are high risk as it can provide a rapid insight to the reality and severity of erosion at an expected "worst-case" location. However, it should be noted that seabed flume testing is likely to incur additional offshore time and costs, and should be carefully planned as part of the survey campaigns.

Key outputs:

- Current velocity to initiate scour at representative locations;
- Scour rate for representative locations at anticipated flow velocities.

6.1.4 Near-bed flow monitoring

Collection of flow data (current speed and direction) very close to the seabed (within 2m) and through the water column at relatively small vertical intervals (0.25 m or 0.5 m maximum) is recommended. This requires specific instrumentation; it aims to provide valuable site-specific data on those flows which are most relevant to scour assessment and within the scour protection zones.

A current measuring system within a configuration which permits very near-bed flow measurement, detailed water column resolution and which preferably can also measure waves is suggested. Data should be collected for a period which includes more quiescent tidally dominated conditions (e.g., summertime) and more energetic wave dominated conditions.

7 SCOUR PROPAGATION ANALYSIS

In order to undertake a detailed evaluation of the risk of scour to the installation, it is necessary to undertake detailed modelling, utilising the results of site-specific testing and site specific metocean data and their analyses.

7.1 Sub-structure influence

The presence of the substructure is likely to result in acceleration and/or disturbance of the flow which would increase the seabed stresses. The magnitude of the stress increase could be determined using Computational Flow Dynamics (CFD) and/or scale model testing.

Key output:

- Relevant flow acceleration factors for the structures.

7.2 Numerical model

Numerical model using the time domain metocean data, scour test results, and sub-structure flow modification to estimate scour propagation with time can be valuable to understand anticipated scour depth and propagation timescales for various events i.e., 1-year, 5-year and 50-year storms.

The numerical study should also consider the potential for ‘natural’ backfill with time after the significant design events.

8 SCOUR CONSEQUENCES

The consequences of scour can vary significantly depending upon the substructure and foundation types as outlined below:

- Monopiles – Significant scour could result in a reduced lateral capacity and a shift in the natural frequency which may have implications for the structure fatigue life;
- Jacket pin-piles - The axial capacity of jacket piles is generally the design driver. Scour may not have a significant influence on the design capacity, however, stiffnesses and frequency response should be checked;
- Suction caissons -The axial capacity of suction caissons is usually the design driver for jacket structures. Scour could result in a significant reduction in design capacity;
- Gravity Base Structures - GBS structures rely on full base contact. Scour could result in uneven settlement and/or foundation ‘rocking’. Therefore, any scour risk is likely to be unacceptable.

The sensitivity of the structure type to scour should be carefully considered. It should also be noted that the overall foundation ‘stiffness’ can change with time; i.e., thixotropy effects increasing stiffness of piles / caissons. Cyclic loading potentially ‘softening’ stiffness after a significant storm.

Sensitivity checks could be undertaken to determine allowable stiffnesses and associated scour depths in conjunction with other considerations such as thixotropy. This could be used to develop an understanding of ‘acceptable’ scour depth and timescales as well as understanding timescales for remediation, for instance:

- 2.5m scour during 5-year storm – acceptable;
- 4.5m scour due to 50-year storm – soft response increases fatigue – must be remediated within 3 months.

9 SCOUR MITIGATION OPTIONS

9.1 Scour allowance design and observation

The main suggestion of the proposed framework is to understand storm risk and incorporate a suitable scour allowance into the scour protection design. This option would require regular monitoring of the scour evolution and resultant effects on the foundation dynamic response.

Highly specified monitoring of the offshore environment is recommended as the usual means of de-risking the engineering work into the future and for

providing the project development team with a suitable level of reassurance that an accurate understanding of marine conditions as they relate to recent scour issues is available (as far as it can be in practice).

Implementation of some form of monitoring is considered to be crucial to de-risking the issues related to scour and to improving asset integrity over the timeframes of an offshore windfarm (typically 25-30 years).

9.2 Full scour protection (Rock Berm)

Rock berms are one of the most common scour protection solutions. The thickness and lateral extent of the rock berm, and resultant required rock volume, will depend on multiple factors including the berm design approach, water depth, metocean input, ground conditions, and stone gradings, amongst others.

The rock berms are generally designed to be stable under 50-year design conditions. Additionally, the rock berms are usually surveyed regularly to ensure they remain stable. Measurement errors and tolerances must also be considered. Monitoring and inspection are generally undertaken every six months for the first 2 years, covering the seabed level, local scour at the unprotected areas around the foundations, and the condition of the scour protection at each location, using appropriate methods.

The cost of rock berms and post construction survey is usually significant. However, rock berms are considered highly effective as long as they are properly designed to account for design metocean events, winnowing, and edge scour.

9.3 Alternatives (anti-scour frond mattresses)

The market offers other alternative and proven solutions for preventing scour that could potentially be economically advantageous. An example of this is the anti-scour frond mattress constructed of aerated polyethylene fronds that when installed on the seabed will naturally float to resemble natural seaweed. As the sediments are transported through the frond mattresses with the current, the soils amass onto the mattress forming a natural fibre reinforced sand bank protecting the area of interest.

Installation methods for this type of solution may include; weight ballast bags attached around the perimeter mattresses, the use of frond mattresses pre-fitted to a concrete mattress offering instant scour protection and easier installation in a high subsea current environment, or the use of divers with anchors driven into the seabed.

The cost of fronded mats is lower than rock berms; however, they may be less effective, resulting in higher residual risk.

10 CONCLUSIONS

The paper provides a framework to understand and make an informed decision on the optimal risk mitigate strategy for scour.

Field tests on vertical and horizontal resistance of steel sheet piles installed by the Press-in with Auger

Essais sur le terrain de résistance verticale et horizontale des palplanches en acier installées par Enfonçage avec Tarière

ABSTRACT: The steel sheet piles, which have long been used for temporary retaining structures, are recently being applied to non-temporary structures such as coastal levees, railway bridge foundations and others. However, the number of load tests on the sheet piles conducted so far is limited, and their design methods seem to have room for sophistication. In addition, the installation methods have some influence on their performance. This paper focuses on the installation method of the "Press-in with Auger" (PA) which can be applied to hard ground conditions with SPT *N* being greater than 50. In PA, a sheet pile is penetrated into the ground together with an auger device, and then the auger device alone is extracted while the soil is refilled. In this research, the full-scale installation tests and the static load tests were conducted at two filed testing sites having different ground conditions, to investigate the vertical and horizontal resistance of PA sheet piles. The results showed that the vertical and horizontal capacity were dependent on the refilling condition. Tin addition, the axial jacking force in the termination was suggested to correlate with the vertical and horizontal capacity, reflecting the inhomogeneity of the ground.

RÉSUMÉ: Les palplanches en acier, qui ont longtemps été utilisées pour des structures de retenue temporaires, sont récemment appliquées à des structures non temporaires telles que les digues côtières, les fondations de ponts ferroviaires et autres. Cependant, le nombre d'essais de charge sur les palplanches effectués jusqu'à présent est limité, et leurs méthodes de conception semblent pouvoir être perfectionnées. En outre, les méthodes d'installation ont une certaine influence sur leurs performances. Cet article se concentre sur la méthode d'installation de "l'enfoncement à la tarière" (PA) qui peut être appliquée à des sols durs dont le SPT N est supérieur à 50. Dans la méthode PA, une palplanche est enfoncée dans le sol en même temps qu'une tarière, puis la tarière seule est extraite tandis que le sol est rechargé. Dans le cadre de cette étude, des essais d'installation en grandeur réelle et des essais de charge statique ont été menés sur deux sites d'essai déposés présentant des conditions de sol différentes, afin d'étudier la résistance verticale et horizontale des palplanches PA. Les résultats ont montré que la capacité verticale et horizontale dépendait des conditions de remplissage. En outre, il a été suggéré que la force de poussée axiale dans la terminaison était en corrélation avec la capacité verticale et horizontale, reflétant l'inhomogénéité du sol.

Keywords: Static vertical load test; static horizontal load test; steel sheet pile; Press-in with Auger.

1 INTRODUCTION

The steel sheet piles have long been used for the construction of temporary retaining structures. In recent years, they are increasingly applied to non-temporary structures such as coastal levees (Ishihara et al., 2020), railway bridge foundations (Kasahara et al., 2018), architectural buildings (GIKEN, 2016; Kondo et al., 2023) and so on. For the reliable use of the sheet piles for the non-temporary structures, the performance of the sheet piles has to be adequately considered in design.

The performance of the sheet pile is influenced by its installation method. The press-in method (IPA, 2016) is a static pile installation method and has been preferred in the construction in dense cities or with difficult conditions. One of the four branch installation techniques in the press-in method is the "Press-in with Auger" (PA), which is applicable to hard grounds with the SPT *N* values being greater than 50. In PA, the auger device (Figure 1) is attached to the sheet pile in its narrow side. The sheet pile and the auger device are penetrated into the ground together while the soil around the auger head is temporarily lifted up to the ground surface. After the termination of the penetration, the auger device alone is extracted while the lifted soil or other material is refilled.

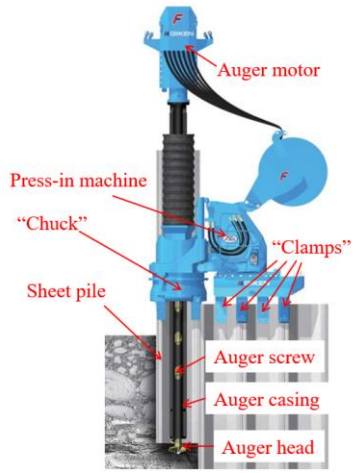

Figure 1. Example of auger device used in PA.

The installation process of PA, especially the conditions of termination and refilling, will be influential to the performance of the sheet pile. However, there has been no load test databases on the PA piles so far. This paper investigates into the vertical and horizontal resistance of the PA sheet piles, by conducting field tests. In addition, the test results will be compared with the design calculation results.

2 METHODS OF FIELD TESTS

Two sets of field tests, J2001 test series in a soft cohesive ground (Figure 2a) and J2101 test series in a dense non-cohesive ground (Figure 2b), were conducted. The test used sheet piles with the width of 600 mm (SP-IIIw). The test layout is shown in Figure 3. The test conditions and the press-in conditions are summarized in Tables 1 & 2, where v_d, v_u and v_r are the downward, upward and peripheral velocity of the sheet pile or the auger head, Q'_{UL} and T'_{UL} are the upper limits for the axial jacking force and rotational torque, and f_a is the flowrate of the air injected in the auger head.

2.1 J2001 test series

The test procedures were as follows. (1) The reaction sheet piles were installed by PA. (2) The installation test was conducted, where the test pile was installed by SP or PA down to the depth of 6.45 m. (3) The vertical static load test was conducted on each test pile. (4) The horizontal static load test was conducted on each test pile that previously experienced the vertical load test.

In the installation test, the press-in machine (F201) grasped the reaction sheet piles at its Clamps and installed the test pile. The interlocks of the test pile and the reaction sheet pile were not connected with each other. The jacking force (Q') and the penetration depth

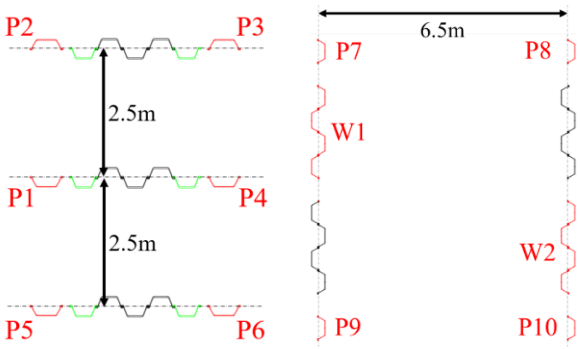
Figure 2. Site profiles.



(a) J2001 test series *(b) J2101 test series*

Figure 3. Test layout (black: reaction piles, green: dummy piles without embedment).

were obtained by the measurement system equipped in the press-in machine. The sheet pile was installed monotonically or with the displacement-controlled "surging" (repeated penetration and extraction) when the jacking force (Q') or torque (T') was smaller than Q'_{UL} or T'_{UL}, and was installed with the load-controlled surging when Q' or T' exceeded Q'_{UL} or T'_{UL}.

In the termination condition [A] for the SP sheet pile, the sheet pile was installed by l_T with the upper-limit (Q'_{UL}) being removed, at the velocity of smaller than 10 mm/s. In the termination condition [B] (in Figure 4) for the PA sheet piles using the normal auger head, (1) when the penetration depth of the auger became $z_T - l_T$ (where z_T is the final penetration depth), the auger device was extracted to above the sheet pile base, (2) the sheet pile and the auger device were installed together while the auger was rotated, until the penetration depth of the sheet pile became $z_T - l_T$, (3) the sheet pile and the auger device were installed together to z_T without the auger being rotated. In the termination condition [C], (1) when the penetration

depth of the auger became $z_T - l_T$, the auger device was extracted so that the penetration depth of the auger became shallower than that of the sheet pile, (2) the sheet pile and the auger device were installed together to z_T, without the auger being rotated.

It should be noted that the actual termination condition in P6 was irregular. A greater value of l_T was adopted, expecting a greater pile capacity. In the procedure (3), when the penetration depth of the sheet pile became z_T – 0.07 m, the further installation became difficult because Q' reached Q'_{UL}. To cope with this, the auger device was extracted by 0.07 m before completing the procedure.

In the refilling condition [A] (in Figure 5), (1) the temporarily lifted soil was returned by the reverse rotation and compacted by the repeated extraction (500 mm) and penetration (250 mm), until the penetration depth of the auger became z_{a1}, (2) the auger device was extracted completely, and newly prepared sands (mean diameter D_{50} = 1.37 mm, uniformity coefficient U_c = 1.78, fine fraction content F_c = 0.4 %) were filled into

the void up to the depth of z_{s1}, (3) the filled sands were compacted by the penetration of the auger by l_{a1}, (4) additional sands were filled into the void up to the ground surface, (5) the filled sands were again compacted by the penetration of the auger by l_{a2}, (6) additional sands were filled into the void up to the ground

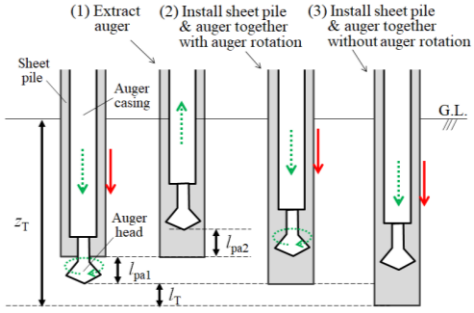

Figure 4. Termination condition (B).

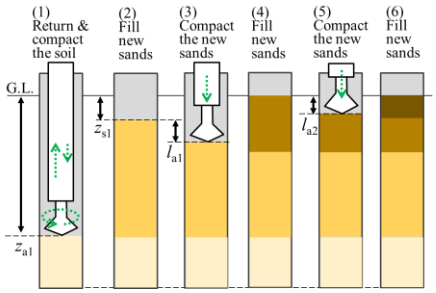

Figure 5. Refilling condition (A).

surface. In the refilling condition [B], the procedures of (4) and (5) in [A] were omitted, and the compaction in the procedure (3) in [A] was conducted in a load-controlled manner until Q' reached Q'_{a1}. In the refilling condition [C], (1) the temporarily lifted soil was returned by the reverse rotation, until the penetration depth of the auger head became z_{a1}, (2) the auger device was extracted completely, and the remaining of the temporarily lifted soil was returned manually into the void.

The static vertical load test was conducted, basically based on the JGS Standard (JGS 1811-2002) (JGS, 2002). The elapsed time from the end of installation to the start of the vertical load test (t_{VLT}) was 14 days or longer. The press-in machine (F201) was used for securing the reaction force from the reaction sheet piles. The head load (Q) was applied by a hydraulic jack which was sandwiched between the steel plate placed on the pile head and the steel jig grasped by the Chuck of the press-in machine, as shown in Figure 6, and was measured by a load cell placed on the pile head. The pile head displacement was obtained by displacement transducers. The loading condition was one-cycle continuous loading.

The static horizontal load test was conducted, basically based on the JGS Standard (JGS 1831-2010) (JGS, 2010). The elapsed time from the end of installation to the start of the horizontal load test (t_{HLT}) was 16 days or longer. The horizontal load (P) was applied to two test piles at the same time, by connecting the two test piles by a steel chain and shortening the steel chain gradually, and was measured by a load cell. The loading height was 0.2 m above the ground surface. The loading direction was towards the narrow side of the sheet pile. The horizontal displacement was measured by displacement transducers. The loading condition was one-cycle continuous loading.

2.2 J2101 test series

The test procedures were as follows. (1) Reaction sheet piles were installed by PA. (2) The installation test was conducted, to form the single PA sheet pile or the PA sheet pile wall down to the depth of 6.5 m. (3) The horizontal static load test was conducted.

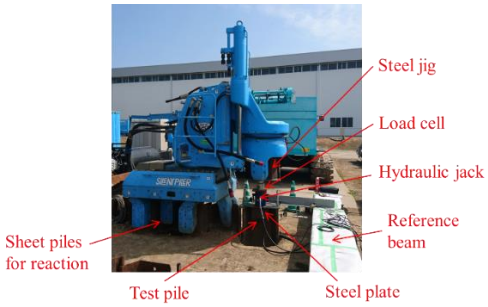

Figure 6. Situation of static vertical load test in J2001.

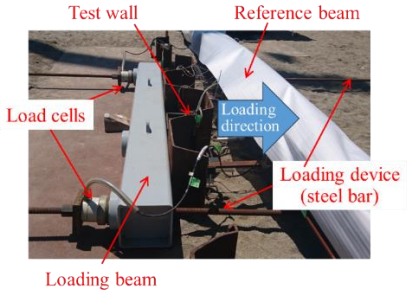

Figure 7. Situation of static horizontal load test in J2101 test series.

The installation test was conducted in the same way as in J2001 test series. The termination condition was [B], and the refiling condition was either [A] or [C].

The static horizontal load test was conducted, basically based on the JGS Standard (JGS 1831-2010). t_{HLT} was 16 days or longer. As shown in Figure 7, a beam was placed behind each sheet pile or sheet pile wall, and a pair of the beams were connected with steel bars. The horizontal load (P) was applied by shortening the steel bars using a hydraulic jack. The

loading height was 0.2 m above the ground surface. Load cells were used to measure *P*. The horizontal displacement was measured by displacement transducers. The loading condition was one-cycle continuous loading.

3 RESULTS AND DISCUSSIONS

3.1 Vertical capacity in soft cohesive ground

Figure 8 shows the load displacement curves obtained in the static vertical load tests in J2001 test series, as well as the lines representing the results of design calculation based on JARA (1999). The resistance was higher in the tests with complex refilling condition (P3, P6) than in the tests with simple refilling condition (P1, P2). The resistance of PA sheet piles in the weakest cases (P1, P2) were about half of that of the SP sheet pile (P4). This ratio is consistent with the description in JARA (1999).

The greater value in P3 than in P4 and the smaller value in P5 than in P1 or P2 are believed to be due to the ground condition. The site is sandwiched with a hill in the side of P3 and a river in the side of P5, and the soil layers may be tilting towards the direction from P3 to P5. The soil layer beneath the sheet pile base may have been harder in P3 and weaker in P5.

If the vertical capacity is defined as the head load recorded at the pile head displacement of 0.1 $D_{o,eff}$, where $D_{o,eff}$ represents the outer diameter of the equivalent tubular pile having the same sectional area as the sheet pile (= 36 mm for SP-IIIw), the measured vertical capacity of the single PA sheet pile was comparable with or greater than that estimated based on JARA (1999).

3.2 Horizontal capacity

Figure 9 shows the results of the load tests and the design calculation in J2001 test series (in the soft cohesive ground). The horizontal resistance was found to vary in accordance with the complexity of the refilling condition, being the greatest in P3 and P6 and the smallest in P1 and P2. It was also influenced by the type of the auger head (expandable or normal). It ranged from 40 % to 85 % of that of the SP sheet pile.

Figure 10 shows the results of the load tests and the design calculation in J2101 test series (in the dense non-cohesive ground). As for the single PA sheet pile, the horizontal resistance was 1.5 times or 2 times larger in the tests with complex refilling condition (P9, P10), and was larger in the tests with the loading direction being towards the wide side of the sheet pile (P7, P9). The effect of the loading direction was smaller in the tests with complex refilling condition.

As for the PA sheet pile wall in J2101 test series, the horizontal resistance was 1.25 times larger in the test with complex refilling condition. The smaller effect of the refilling condition in the sheet pile wall than in the single sheet pile is thought to be partly because the refilled sands in the installation of one sheet pile was disturbed in the PA installation of the next sheet pile.

(a) Vertical capacity in J2001 *(b) Horizontal capacity in J2001* *(c) Horizontal capacity in J2101*

Figure 11. Effect of maximum axial jacking force in termination on pile capacity.

In JARA (2012), the allowable horizontal displacement for the foundation of a highway bridge is taken as 15 mm at the ground surface. If the horizontal capacity is taken as the horizontal load recorded at this displacement, it was comparable with or greater than the design calculation results based on JARA (1999).

3.3 Effect of axial jacking force in termination

Figure 11 shows the correlation between the maximum axial jacking force recorded in the termination (Q_T) and the vertical or horizontal capacity. In J2001, both the vertical and horizontal capacity showed a positive correlation with Q_T. On the other hand, the correlation between the horizontal capacity and Q_T was very weak.

From these facts, the following are hypothesized. If the ground is homogeneous, the horizontal capacity is little influenced by Q_T and depends more on the refilling condition. If the ground is not homogeneous, the vertical and the horizontal capacity depend both on Q_T and the refilling condition.

4 CONCLUSIONS

By conducting the field tests and the design calculation based on JARA (1999) on the sheet piles installed by the Press-in with Auger (PA), the following findings were obtained. (1) The vertical and horizontal capacity of the single PA sheet pile in the soft cohesive ground were dependent on the refilling condition, and were comparable with or greater than the design calculation results. (2) The horizontal resistance of the single PA sheet pile in the non-cohesive ground was influenced by the refilling condition and the loading direction, and was comparable with or greater than the design calculation results. The effect of loading direction was smaller for the sheet piles with more complex refilling condition. (3) The horizontal resistance of the PA sheet pile wall in the non-cohesive ground was influenced by the refilling condition, and was comparable with or greater than the design calculation results. The effect of refilling condition was smaller on the sheet pile walls than on the single sheet piles, presumably because the refilled sands were disturbed in the installation of the next sheet pile. (4) The axial force in termination was influential on the vertical and the horizontal capacity in the soft cohesive ground. This was thought to be reflecting the ground inhomogeneity.

ABSTRACT: The press-in method is a piling method using a hydraulic jacking force to install a prefabricated pile. Its applicability in hard ground has been enhanced by the relatively recent development of its branch techniques such as the press-in with auger and the rotary cutting press-in (RCP). In RCP, a tubular pile equipped with several cutting teeth on its base is pushed and rotated, so that even concrete or rock can be penetrated through by the pile. The RCP piles are usually used for retaining walls, but are also used for structures where their axial stiffness and capacity are of concern. In this paper, three sets of subsurface information (CPT cone resistance), the piling data of the RCP and the static vertical load test results on the RCP piles with an outer diameter of 508 mm are reported, which were obtained in preparation for the project of updating the quay walls in the World Heritage-listed Canal Ring Area of Amsterdam. In addition, the cone resistance and the vertical capacity are estimated from the piling data obtained during the RCP, and are compared with the results of the CPT and of the load tests.

RÉSUMÉ: La méthode d'enfoncement est une méthode de battage utilisant une force de vérinage hydraulique pour installer un pieu préfabriqué. Son applicabilité aux sols durs a été améliorée par le développement relativement récent de ses techniques dérivées, telles que l'enfoncement à l'aide d'une vis sans fin et l'enfoncement par découpe rotative (RCP). Dans le RCP, un pieu tubulaire équipé de plusieurs dents de coupe à sa base est poussé et tourné, de sorte que même les bétons ou les rochers peuvent être pénétrés par le pieu. Les pieux RCP sont généralement utilisés pour les murs de soutènement, mais également pour les structures dont la rigidité et la capacité axiale sont importantes. Dans cet article, trois ensembles d'informations sur la subsurface (résistance du cône CPT), les données sur les pieux en RCP et les résultats des essais de charge verticale statique sur les pieux RCP avec un diamètre extérieur de 508 mm sont rapportés, qui ont été obtenus en préparation du projet de mise à jour des murs de quai dans la zone de la ceinture du canal d'Amsterdam classée au patrimoine mondial. En outre, la résistance du cône et la capacité verticale sont estimées à partir des données sur les pieux obtenues en RCP, et sont comparées aux résultats du CPT et des essais de charge.

Keywords: Steel tubular pile; rotary cutting press-in; static vertical load test; piling data.

1 INTRODUCTION

The press-in method is one of the static piling methods to install a prefabricated pile using a hydraulic jacking force (IPA, 2016; Bolton et al., 2021). Based on its principle to achieve a reaction force from previously installed piles, it saves temporary works and is applicable to the piling projects with severe restrictions of space and headroom. It has also been applicable to hard ground conditions since the development of its branch installation techniques such as the press-in with auger and the rotary cutting press-in (RCP). In RCP, a tubular pile equipped with several cutting teeth on its base is pushed and rotated, so that the hard ground or materials including concretes or rocks can be penetrated though. The RCP piles are usually used for cantilever type retaining walls, but are also used for structures where their axial stiffness and capacity are of concern. However, since RCP is a relatively new installation technique, its design methods have not been well established. To improve the situation, accumulation of piling data and of vertical load test results in different soil conditions are essential.

On the other hand, in the press-in method, piling data such as the jacking force, torque and penetration depth are obtained for every single pile. Methods to utilize the piling data for autonomous operation of the press-in machine, for the estimation of subsurface information (Ishihara & Kusakabe, 2021) and for the estimation of the pile capacity (Ishihara, 2023) have been developed. To put these methods into practice reliably, further validation is necessary.

Based on these backgrounds, this paper reports three sets of subsurface information (obtained by Cone Penetration Testing, CPT), the piling data of the RCP and the static vertical load test results on the RCP piles, which were obtained in preparation for the project of updating the quay walls in the World Heritage-listed Canal Ring Area of Amsterdam, as shown in Figure 1. In addition, the cone resistance and the vertical capacity are estimated from the piling data obtained during the RCP, and are compared with the results of the CPT and of the load tests.

2 PILE INSTALLATION AND STATIC LOAD TESTS

2.1 Test methods

The cone resistance (q_c) obtained by the CPT and the soil type estimated from the CPT results are shown in Figure 2, where the reference level was taken as the NAP (Normal Amsterdam Peil). The shallow layers consist of relatively soft clays and sands, while the deeper layers dominantly contain sands with q_c being around 20 MPa.

The test conditions and the test layout are shown in Table 1 and Figure 3, respectively. A total of three tests were conducted. In each test, three reaction piles were installed in advance to the installation of the test pile. The embedment length of the reaction piles was in between 1/2 and 1/3 of that of the test pile.

Figure 1. Project of updating the quay walls in the World Heritage-listed Canal Ring Area of Amsterdam.

The specification of the test pile is shown in Figure 4. It was a steel tubular pile with an outer diameter of 508 mm and a thickness of 22.2 mm. It was equipped with a base ring having 8 cutting teeth, and the outer diameter and the thickness of the base ring were 518 mm and 32 mm, respectively. It was also equipped with 2 small-diameter pipes to allow water injection in the pile base. It was instrumented with 2 optical fibers to measure the axial strains at 14 sections.

Table. 1. Specification of piles and press-in conditions.

Test No. (Am2022-) CPT No.	A CPT-A	B CPT-B	C CPT-C
Outer diameter of pile [mm]	508	508	508
Thickness of pile [mm]	22.2	22.2	22.2
Outer diameter of base ring [mm]	518	518	518
Thickness of base ring [mm]	32	32	32
Number of cutting teeth	8	8	8
Embedment depth [m]	26.5	26.5	26.5
Flow rate of water [l/min.]	80	80	80
Downward displacement [mm]	250	250	250
Upward displacement [mm]	79	79	70
Downward velocity [mm/s]	22, 33	33	22, 33
Upward velocity [mm/s]	41	41	41
Rotational velocity [rpm]	15, 23	20, 23	15, 23
Upper limit of jacking force [kN]	200	200	200
Upper limit of torque [kNm]	130	130	130
Curing period [day]	72	70	67

The test procedures were as follows; (1) the reaction piles were installed by the vibro-hammering method, (2) the test pile was installed by the RCP and (3) the static load test was conducted on the test pile. The elapsed time from the end of installation to the start of load test (curing period, t_{LT}) was about 70 days.

The test pile was installed by the RCP using the press-in machine GRV0611e, as shown in Figure 5, while gaining the reaction force from the three reaction piles. The press-in conditions are summarized in Table 2. The installation was conducted using the semi-automatic operation system. The jacking force (Q'), torque (T') and the penetration depth were obtained by an automatic measurement system equipped in the press-in machine. In the end of installation, the inner soil column length (h_{sc}) was obtained by manually measuring the distance from the pile head to the surface of the inner soil column using a tape measure. When the penetration depth reached one D_o above the final depth, the flowrate of water injection in the pile base was minimized to around 10 *l*/min. At the end of installation, the test pile was axially loaded without rotation and water injection, with the jacking force (Q'_T) of 600 kN. Exceptionally in Am2022-A, after the axial loading, the test pile was installed by 50 mm, by the RCP with water injection by 40 mm and by the RCP without water injection by 10 mm.

The static axial load test was conducted based on the guideline of the Class A1 test in NPR 7201+A1. The reaction force was secured by using weights. The load and displacement at the pile head were measured by a load cell and displacement transducers. The readings of the optical fibers were offset to be zero just before the start of the load test. The residual load acting on the pile at the start of the load test, which will result from the installation of the pile, is unknown. As shown in Figure 6, the load was increased in a multi-cycle way, and was maintained for 30 minutes or longer in each cycle. If the displacement rate under the maintained load was higher than 0.1 mm per 20 minutes, the constant load stage was increased up to 4 hours.

2.2 Test results

Figure 7 shows the variation of Q', T' and h_{sc} with depth during installation. Both Q' and T' were small at shallow de pth and increased in deeper sandy layers, with Q' reaching its upper limit in several depth ranges. As a result, the pile was installed with load-controlled surging in these depth ranges. According to the plot of h_{sc} obtained in the end of installation in each test, the value of h_{sc} was about one-third of the penetration depth. This indicates that the installation process was "partially plugged" on average. In Am2022-C, T' became too large when the penetration depth was about one D_o above the pile base, and the pile was largely extracted (by around 3 m) and installed again.

Table 2. Press-in conditions in the end of installation.

	Am2022-A	Am2022-B	Am2022-C
Last 1 D_o	Water injection was minimized to 10 *l*/min.	Water injection was minimized to 10 *l*/min.	Water injection was minimized to 10 *l*/min.
Axial loading at the end of installation	Started at 50 mm above the planned final depth. Axial load of 600 kN was applied for 1 min. without water injection. Pile head displacement was zero. After this, pile was installed by RCP to the planned final depth by 40 mm with water injection and 10 mm without water injection.	Started at the planned final depth. Axial load of 600 kN was applied for 5 min. without water injection. The maximum and the residual pile head displacement were 5 mm and 2 mm respectively.	Started at the planned final depth. Axial load of 600 kN was applied for 5 min. without water injection. The maximum and the residual pile head displacement were 20 mm and 13 mm respectively.

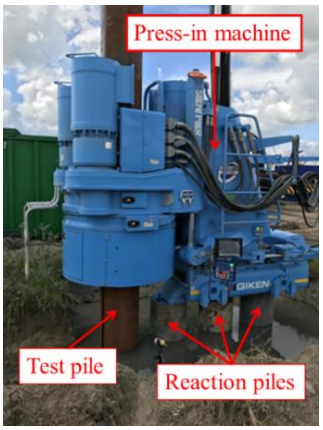

Figure 5. Installation of test pile.

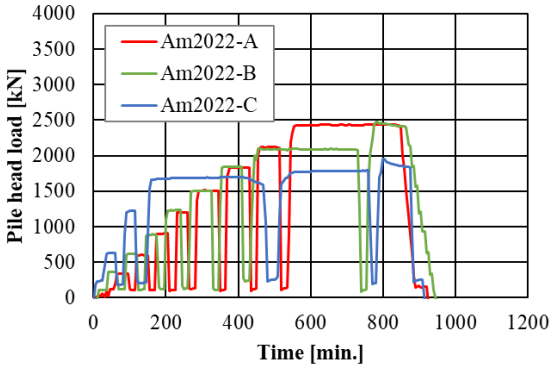

Figure 6. Loading record in static vertical load tests.

Figure 8 shows the variation of Q'_T with time, which was recorded during the axial loading at the end of installation. Q'_T was maintained at 600 kN intermittently with time, by setting Q'_{UL} to be 600 kN and applying a downward motion to the pile repeatedly. The duration of loading was shorter in Am2022-A. The pile head displacement recorded during this loading and unloading is summarized in Table 2.

The load-displacement curves obtained in the static load tests are shown in Figure 9. If the yielding load (Q_y) is taken as the "first-limit-resistance" in the JGS Standard (JGS 1811-2002), the Q_y values in the three tests are determined as shown in Table 3. The same table shows the ultimate capacity at the pile head, base and shaft (Q_f, Q_{bf} and Q_{sf}) as well, which were defined as the values recorded when the pile head displacement reached 0.1 D_o. The values of Q_y and Q_f were similar in each test. This trend was different from the four load test results conducted in Japan (JSCE, 2021) where Q_y / Q_f was around 0.45.

Base capacity	662	508	427
Shaft capacity	1552	1572	1165

3 VERIFICATION OF CONE RESISTANCE AND VERTICAL CAPACITY ESTIMATED FROM PILING DATA

3.1 Methods of estimation

The estimation methods were basically based on those proposed by Ishihara (2023). They are composed of the following four steps.

The first step is to decompose the head load (Q) and the head torque (T) during the installation into the base and shaft components (Q_b, Q_s, T_b and T_s). To avoid the instrumentation on the pile, four equations are introduced: the base stress (q_b) is used to link Q_b and T_b, and the frictional stress on the pile shaft is assumed to be shared by Q_s and T_s in proportion to the ratio of vertical to rotational velocity.

The second step is to use the estimated Q_b and T_b for calculating the Specific Energy (SE, the energy required for installing something into the ground by a unit volume) consumed in the pile base. The effect of surging (repetitive downward and upward motion of the pile) is incorporated by taking into account the energy consumed in all the downward motions.

The third step is to convert the calculated SE into the subsurface information (CPT q_t or SPT N). For this, the SE in the RCP, in the CPT and in the SPT are assumed to linearly correlate with each other. More precisely, the knowledge that the SE in rock drilling and the unconfined compressive strength of the rock are linearly correlated (Hughes, 1972; Li & Itakura, 2012) is assumed to apply to the penetration of any material into the ground. In other words, the SE in the RCP, in the CPT and in the SPT are assumed to linearly correlate with the strength of the ground.

The fourth step is to input the estimated subsurface information into the bearing capacity formulae. The formula for the base capacity is derived from the CPT-based UWA-05 method. A parameter representing the plugging condition (IFR) is calculated by considering the estimated base stress during the installation. On the other hand, the formula for the shaft capacity is based on the SPT-based method, with the parameter being adjusted using the load test databases on RCP piles in Japan.

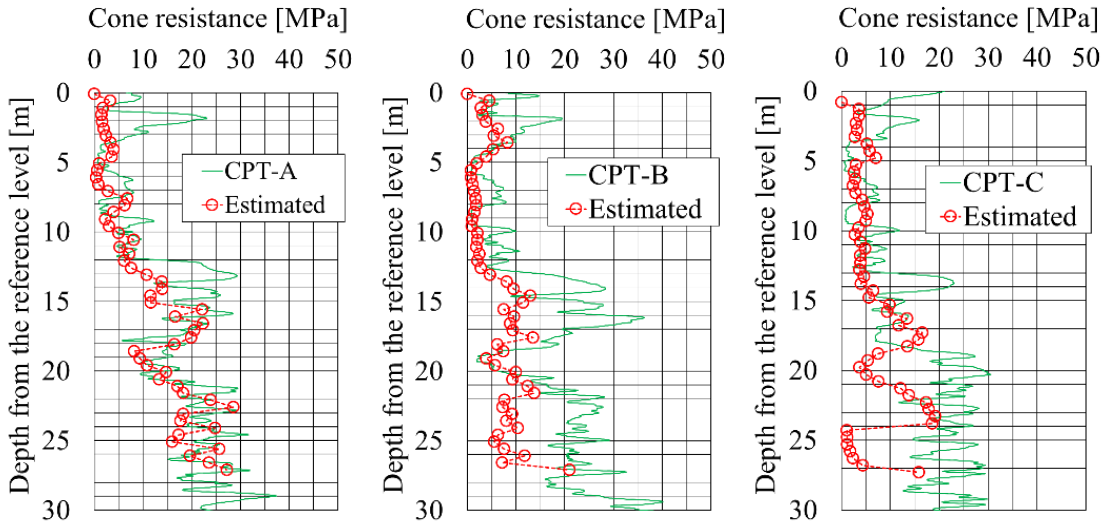
The above methods were applied to the piling data obtained in the installation tests. As for Am2022-C, the data recorded in the depth range where the large extraction was conducted (from 24 m to 27 m) was only partially used: the data prior to the extraction was omitted.

3.2 Comparison between the test results and estimated results

Figure 10 shows the comparison of the cone resistance obtained by the CPT and that estimated from the piling data. As a whole, the estimated values were comparable with or smaller than the measured values. The best agreement was found in Am2022-A. The underestimating tendency in Am2022-B might suggest that the ground around the position of this test was relatively soft. The underestimation in the depth range from 24 m to 27 m in Am2022-C was mainly due to the large extraction in this depth range. The time and resistance required for the installation after the large extraction were smaller than those required in the corresponding depth range in the other two tests.

Figure 11 shows the comparison of the total vertical capacity measured in the load tests and that estimated from the piling data. Generally, the estimated values were comparable with or greater than the measured values. This trend is different from the one using the datasets (piling data and load test data) obtained in Japan, where the estimated values were comparable with or smaller than the measured values (Ishihara, 2023).

To mitigate the extent of overestimation, the upper limit for the unit shaft resistance ($q_{sf,UL}$) was introduced. In Figure 11, the hollow and the solid dots correspond to the estimation with $q_{sf,UL}$ being 90 kPa and 50 kPa, respectively. If $q_{sf,UL}$ was taken as 90 kPa, which roughly corresponds to the values adopted in Ishihara (2023), the extent of overestimation was significant in two of the three tests (31% and 37%).



(a) Am2022-A *(b) Am2022-B* *(c) Am2022-C*

Figure 10. Comparison of cone resistance obtained by CPT and that estimated from piling data.

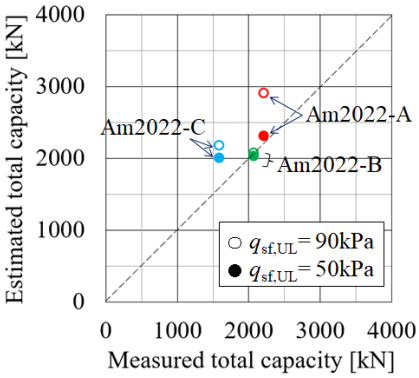


Figure 11. Comparison of pile capacity obtained by load test and that estimated from piling data.

If $q_{sf,UL}$ was reduced to 50 kPa, which corresponds to the recommended value in JSCE (2021), the overestimating trend was seen only in one test, by 25%.

4 CONCLUSIONS

Three sets of CPT cone resistance (q_c), the piling data and the static vertical load test results on the RCP piles, which were obtained in preparation for the actual project in Amsterdam, were reported. The obtained piling data were then processed to estimate the cone resistance and the pile capacity, and the estimation results were compared with the measured values. As a result, the estimated q_c was comparable with or smaller than the measured values, while the estimated capacity was comparable with or larger than the measured values. Further study is necessary to work out the causes for these inconsistent trends.

ACKNOWLEDGEMENTS

The authors appreciate the members of G-Kracht for the information of the three static load tests.

ABSTRACT: The Santa Maria Dam on the Baluarte River is a concrete face rockfill dam with a total height of 152 m from the rock stratum, located 32 m depth. Cofferdams will be constructed upstream and downstream. At the foundation of the upstream cofferdam, a cut-off wall has been constructed. Alluvial soils with rocky blocks generate difficulties on the verticality control of the cut-off walls. A combination of construction methods and instrumentation of the excavation avoids deviations of the bentonite cement diaphragm wall. A pre-excavation and fill with fine sand prevent deviations and improves the production yields in the construction of the diaphragm wall. A methodology for the optimization of panel overlap is defined based on the instrumentation of the panel verticality, during excavation works. The adoption of a conservative overlap is usual if there isn't a detailed analysis of the site conditions. By the overlap optimization, it is improved the efficiency of the project, saving time and resources. The excavation of the adjacent primary panels and their deviations are independent events, their analysis allows defining a statistical distribution and the confidence interval for the overlap value.

RÉSUMÉ: Le barrage de Santa Maria sur la rivière Baluarte est un barrage en enrochement avec un parament en béton, avec une hauteur totale de rideau de 152 m à partir de la strate rocheuse, située à 32 m de profondeur. Des batardeaux seront construits en amont et en aval. Un mur de séparation a été construit à la base du batardeau en amont. Les sols alluviaux avec des blocs rocheux génèrent des difficultés sur le contrôle de la verticalité des murs de séparation. Une combinaison de méthodes de construction et d'instrumentation de l'excavation permet d'éviter les déviations de la paroi moulée en ciment bentonite. Une pré-excavation et un remplissage avec du sable fin évitent les déviations et améliorent les rendements de production dans la construction de la paroi moulée. Une méthodologie pour l'optimisation du chevauchement des panneaux est définie sur la base de l'instrumentation de la verticalité des panneaux, pendant les travaux d'excavation. L'adoption d'un chevauchement conservateur est habituelle en l'absence d'une analyse détaillée des conditions du site. L'optimisation du chevauchement permet d'améliorer l'efficacité du projet et d'économiser du temps et des ressources. L'excavation des panneaux primaires adjacents et leurs déviations sont des événements indépendants, leur analyse permet de définir une distribution statistique et un intervalle de confiance pour la valeur du chevauchement.

Keywords: Construction; optimization; monitoring; statistical analysis.

1 SANTA MARIA DAM COFFERDANS

The Santa María dam is part of the Baluarte-Presidio System, in Sinaloa, Mexico, and regulates the Baluarte River and its tributaries through the construction of a dam. The materials on which the Santa Maria dam is located consist of a rocky substrate of extrusive andesitic and intrusive rocks of the dioritic porphyry type. Quaternary alluvium is located on the bedrock, corresponding to the current deposits of the Baluarte river. The thickness of alluvium is about 33 m below the riverbed.

Figure 1. Diaphragm wall excavation with hydraulic grabs (Baya TEC Systems) on mobil crane Liebherr.

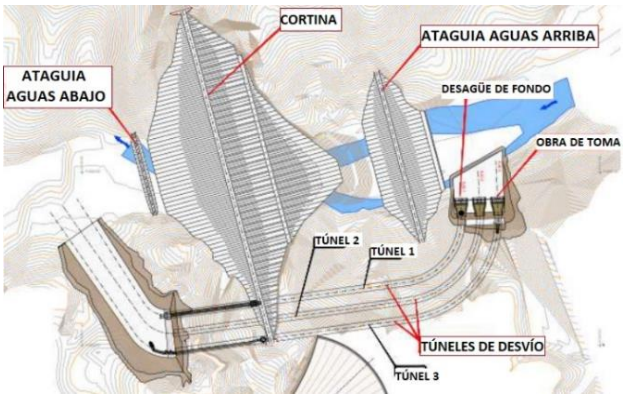

Figure 2. Layout Santa Maria Dam project.

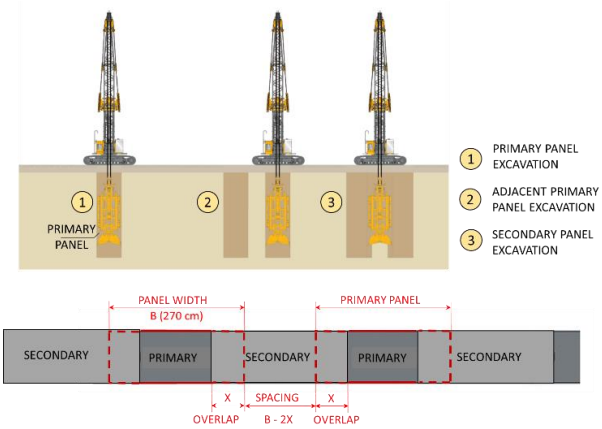

Figure 3. Diagram of primary and secondary panels.

The upstream cofferdam is a homogeneous embankment dam made of rockfill. The waterproofing above the riverbed level is made with a geomembrane layed on the upstream slope, achored on a lower plinth. The waterproofing below the level of the riverbed is made with a bentonite-cement cut-off wall, which crosses the alluvium until it reaches the underlying rock. The downstream cofferdam is placed on a regularization platform on the riverbed.

The purpose of this paper is to expose the construction procedure and present a methodology that allows us to define the optimum overlap between panels based on the control and statistical analysis of verticality deviations during excavation, in order to ensure the continuity of the cut-off wall.

1.1 Diaphragm wall construction procedure

First, the primary panels (PP) are executed with a spacing between them equivalent to the width of the grab minus an overlapping margin to ensure that there are no gaps between panels. In the space between each two primary panels, the secondary panels (PS) are executed. The trajectory of the secondary panels is guided by the inclination trend that was generated during the primary panel excavation process. The deviation in the construction of the primary panels depends on the equipment used, the material excavated and the operator's expertise.

The type of alluvial deposit has a key influence on the verticality of the excavations, since the presence of very coarse materials in the riverbed can force a deviation tendency, by causing greater opposition to the excavation in one of the directions. This is why the greatest deviations occur in the vicinity of the bedrock, where there is a greater presence of blocks.

The following factors have been incorporated in the construction procedure in order to control the deviations:

- Pre-drill. A pre-excavation in the alluvium deposit and fill with fine sand improves the production yields in the construction of the diaphragm wall, and prevent deviations.
- Equipment. Hydraulic grab Baya (TEC System) with semi kelly, and automatic half turn and verticality control.
- Geotechnical monitoring with Jean Lutz instrumentation system, with real time recording of depth, deviation in the vertical plane (parallel to the axis of the wall), deviation in the vertical plane (perpendicular to the axis of the wall), and deviation due to the rotation.

This construction procedure with monitoring instrumentation system, hydraulica grabs with semi kelly has been used in projects such as the Misicuni Dam (Tecnosuelo, 2018), or the cut-off wall in Xochimilco (Jimenez, 2023).

1.2 Recording deviations on the cut-off wall

Once the deviation data were obtained from the primary panels, they were classified into left deviation, data with a negative sign, and right deviation, with a positive sign. The following aspects are observed:

- Most of the data obtained are in values less than 4 cm and in percentage values less than 0.30%.
- Diaphragm wall deviation is cumulative with depth, for the definition of the overlap it will be necessary to make the analysis for the maximum expected depth.
- There are a limited number of panels with high deviation values, which increase in the final depth of each panel, due to the presence of blocks or bedrock.

2 STATISTICAL ANALYSIS OF DEVIATIONS IN PRIMARY PANELS

Probability theory is used in modelling the behaviour of a variable if a sufficient set of measurements is available. Quantitative evaluation of soil variability

modelling requires the use of descriptive and inferential statistical techniques, as well as probabilistic modelling to process the data from the measurements made.

The stages leading to the probabilistic modelling of a random variable are shown schematically in Figure 4. Descriptive analysis includes the calculation of the sample moments of the recorded measurements, mainly mean and variance and the skewness and kurtosis coefficients, as well as the inspection of data and histograms. The inferential analysis includes the selection of the distribution function, estimation of its parameters and the goodness-of-fit test to the source data. The result is the obtaining of a probability model for the analysed variable, which, in this case study, will allow us to evaluate the probability of occurrence of a certain deviation in the verticality of the primary panels and from these results establish an overlap value, with a sufficient level of confidence that no discontinuities are generated on the diaphragm wall.

Table 1. Sample descriptive parameters.

Diaphragm wall Deviation (%)	
Mean	0,055%
Median	0,035%
Mode	0,000%
Variance	0,188%
Kurtosis coefficient	1,131183368
Skewness coefficient	0,195754426
Range	1,209%
Maximum (right deviation)	0,67%
Minimum (left deviation)	-0,54%
Data	7124

For the selection of statistical distributions, the concept of "entropy maximization" is usually adopted, which states that the least biased model that encodes the available information is the one that maximizes entropy while remaining consistent (Uzielli et al. 2007). From the physical sense of the measurements and the expected values, the most appropriate distribution can be chosen, as shown in Table 2. From this analysis the distribution that maximizes entropy and, therefore, would best fit the data is the normal probability distribution.

A normal distribution has been adopted with mean values 0.0553% and standard deviation 0.188%. To check the goodness of fit, the quantile-quantile diagram was obtained, with similar conclusions. It is observed that the central part of the diagram fits very accurately to the normality hypothesis, and that in the tails of the distribution there are some slight mismatches, influenced by the outliers. Considering the inherent heterogeneity of an alluvial stratum, the goodness of fit is acceptable.

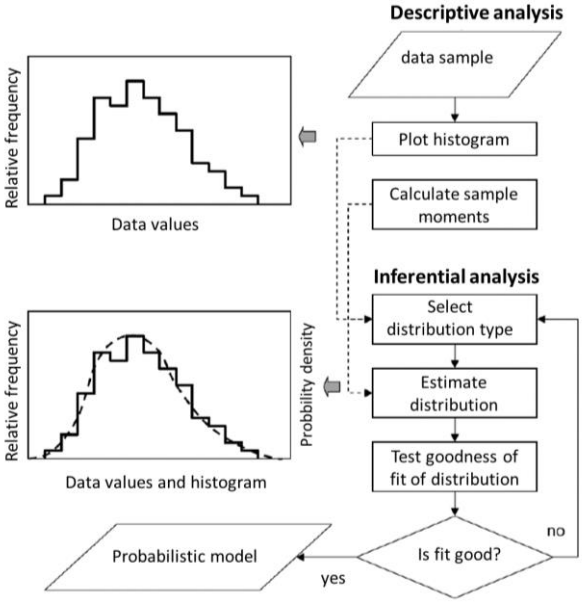

Figure 4. Integrated descriptive and inferential analysis for probabilistic modelling of a random variable (Uzielli 2006).

Table 2. Maximum-entropy criteria and constraints for the selection of a probability distribution (Uzielli et al. 2007).

Known	Known	Unacceptable	Unknown	***Lognormal***
Known	Known	Acceptable	Known	***Type- I Beta***

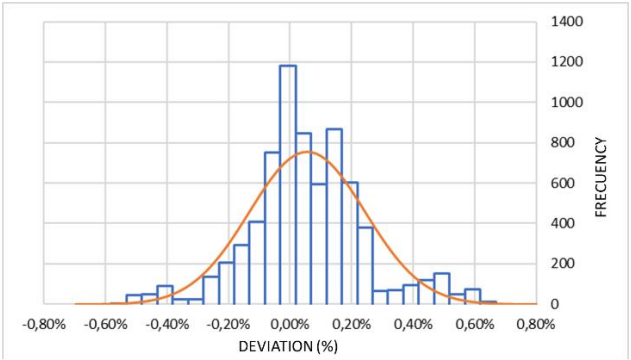

Figure 5. Normal probability distribution fit to histogram of diaphragm wall deviations data.

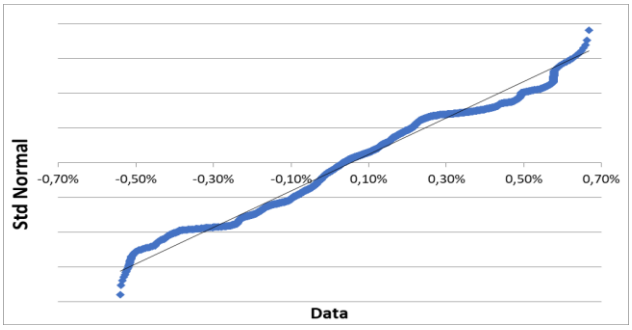

Figure 6. Goodness-of-fit in quantile-quantile plot.

3 OVERLAP BETWEEN PRIMARY AND SECONDARY PANELS. PROBABILITY OF DEVIATION

From the probability model obtained, it is possible to obtain the probability of the occurrence of a right or left deflection greater than that allowed by the overlap.

The probability that the deviation of subsequent primary panels is in opposite directions is governed by the criterion of dependent probability which establishes that, for any independent number of events, the probability that these events occur simultaneously is the product of the individual events occurring.

The probability that the overlap is less than a given value is obtained by calculating the simultaneous probability of the different combinations of deflections that produce the indicated overlap. It has been estimated for different values of overlapping (table 3).

Table 3. Combination of left and right deviations that maximize the probability of exceeding the overlap.

Overlap (cm)	Σ Overlap (cm)	Deviation. Rigth/ Left. (cm)	Dev. Rigth Probability (%)	Dev. Left Probab. (%)	Deviation > Overlap Probability (%)
40,00	80,00	(40.0,-40.0)	0,0000056%	1.9E-7%	1.1E-14%
30,00	60,00	(30.0,-30.0)	0,0047%	0,00035%	1.6E-8%
20,00	40,00	(22.0,-18.0)	0,27%	0,24%	0,000654%
15,00	30,00	(17,5,-12.5)	1,56%	2,05%	0,032%
12,50	25,00	(15.0,-10.0)	3,55%	4,51%	0,16%
10,00	20,00	(12,5, -7.5)	7,28%	8,95%	0,65%
7,50	15,00	(10.0, -5.0)	13,46%	16,02%	2,16%
5,00	10,00	(7.0, -3.0)	24,65%	23,76%	5,86%
2,50	5,00	(5.0, 0.0)	34,29%	38,43%	13,18%

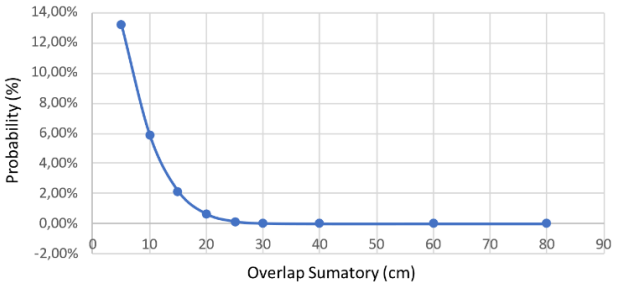

Figure 7. Probability that the deviation exceeds the overlap.

4 CONCLUSIONS

The impermeabilization of the upstream and downstream cofferdams of the Santa María Dam, in Sinaloa, has been achieved below the level of the riverbed through the execution of a bentonite - cement diaphragm wall. The instrumentation of the excavation process and the use of equipment with hydraulic grabs makes it possible to control the risks of vertical deviation and its correction during excavation by measuring the deviations in real time.

This makes it possible to establish a methodology to optimize the separation between primary panels by reducing overlapping. In the cofferdams of the Santa Maria dam, this optimization allowed a primary panel spacing of 2.30 m, with grabs of 2.70 m excavation width, compared to the 1.90 m that were initially considered, achieving a saving of 20%. The required volume of slurry is reduced, waste is reduced and execution timeschedule is improved.

As a relevant conclusion, the use of semi-guided and instrumented excavation equipment provides important economic and time advantages compared to other types of equipment in which the excavation process is not controlled, with more uncertainties. Introducing imaginative measures such as pre-drilling and backfilling with fine sand in a first stage, ensures verticality and continuity of the cut-off wall in difficult soils.

An overlap of 20 cm on each side of the panel has been considered, with a confidence margin of 99.9993% that the deviations in the verticality do not cause defects. The process has a control greater than 4.5 σ, where only every 152,833 measurements could find a point with out-of-range values.

ABSTRACT: The project involves the construction of the railbed for a section of high-speed line, in the Pulpí – Vera stretch with 25.7 km, in the Murcia – Almería section. It is part of the Mediterranean railway corridor and will improve the connectivity of Almería. A variable geology is observed with a predominance of Miocene and Pleistocene materials. The lithology is composed of Miocene marls with gypsum lenses and a cover of alteration soils and fills. The railway runs through areas with a significant thickness of soft soils in the embankments R-15, R-17, R-21 and R-33 (glacis deposits with sandy silts, valley deposits with clayey silts) and a zone with anthropic landfill from agricultural activities in the embankment R-14. From this background, high deformability and low strength of soils are mitigated by a wide range of soil improvement techniques. Rigid inclusions are installed with objective to support concrete structures and culverts to prevent structural damages due to excessive settlements. Transitions with non-treated areas are solved by increasing the inclusions spacing, by a soil improvement with surcharge and wick drains or by combining the inclusions with stone columns to match the settlements between the embankment and the treated area (R-14).

RÉSUMÉ: Le projet porte sur la construction de la voie ferrée d'un tronçon de la ligne à grande vitesse, sur le tronçon Pulpí - Vera, d'une longueur de 25,7 km, dans la section Murcie - Almería. Il fait partie du corridor ferroviaire méditerranéen et améliorera la connectivité d'Almería. On observe une géologie variable avec une prédominance de matériaux du Miocène et du Pléistocène. La lithologie est composée de marnes du Miocène avec des lentilles de gypse et une couverture de sols d'altération et de remblais. La voie ferrée traverse des zones présentant une épaisseur importante de sols meubles dans les remblais R-15, R-17, R-21 et R-33 (dépôts de glacis avec des limons sableux, dépôts de vallée avec des limons argileux) et une zone de décharge anthropique dans le remblai R-14. La grande déformabilité et la faible résistance des sols sont atténuées par un large éventail de techniques d'amélioration des sols. Des inclusions rigides sont installées dans les structures en béton et les ponceaux pour prévenir les dommages structurels dus à des tassements excessifs. Les transitions avec les zones non traitées sont résolues en augmentant l'espacement des inclusions, en améliorant le sol avec une surcharge et des drains à mèche ou en combinant les inclusions avec des colonnes de pierre pour faire correspondre les tassements entre le remblai et la zone traitée (R-14).

Keywords: Soil improvement techniques; stone columns; rigid inclusions; staged construction.

1 SOIL IMPROVEMENT METHODS IN THE MEDITERRANEAN CORRIDOR

The Pulpi Vera stretch of the Mediterranean corridor runs over a variable geology with a predominance of Miocene and Pleistocene materials, covered by colluvial and alluvial alteration soils or anthropic fillings from agricultural activities. These alteration soils and uncontrolled fills constitute a variable thickness of soft soils exceeding 10 m in the case studies, which would cause settlement between 50 and 80 cm, as well as stability problems, which are not compatible in times and magnitude with the structures and embankments of the project.

1.1 Initial project limitations

A problem of the initial project is the execution of embankments with underpasses or large drainage

structures above soft soils. The initial approach of the project was the treatment of soft soils with some techniques that accelerate the consolidation times or make it compatible with the construction schedule. This approach had the disadvantage of not taking into account the lower allowable deformability of the concrete structures compared to the embankments.

The project's initial solution was to carry out the improvement to consolidate initially the embankment and, once the settlements were reached, excavate the areas where the concrete structures are located, and excecute them in a second stage. (Adif, 2018) This construction system has the following disadvantages:

- Cost: use of temporary embankments and subsequent removal for construction of concrete structures.
- Time: Execution by stages and increasing of construction times.
- Necessity of temporary drainage culverts, although with a lower return period than the definitive elements.

1.2 Soil improvement solutions

Use of rigid inclusion that makes deformations compatible with allowable settlements of concrete structures. This solution is combined with other consolidation and treatment techniques in enbankments.

The project includes the following solutions:

- Stone columns and rigid inclusions below the underpass 509+900, at the embankment R-14
- Rigid inclusions below concrete structures and surcharge and wick drains in transitions, at the embankments R-17, R-21.
- Rigid inclusions with a gradation in the spacing of inclusions at embankments R-22 and R-33.
- Soil improvement with surcharge and wick drains, embankment staged construction, R-15.

2 SOIL IMPROVEMENT WITH RIGID INCLUSIONS AND STONE COLUMNS

The treatment area in the R-14 embankment is located between the km 509+825 and km 509+960, with the presence of the 509+900 underpass (Figures 1 and 2). The embankment runs over a lithology with a thickness of soft soils exceeding 10 m in some areas.

The geology is composed by the M_m formation of Miocen marls with a lithology of clayey silts and marls with intercalations of sandstones, siltstones and gypsum lenses. Above M_m unit are the Qg unit of glacis deposits of silt and fine sands with scattered gravels, and the Rv unit of uncontrolled fills (Table 1).

Figure 1. Improvement treatment with stone columns and rigid inclusions at the embankment R-14.

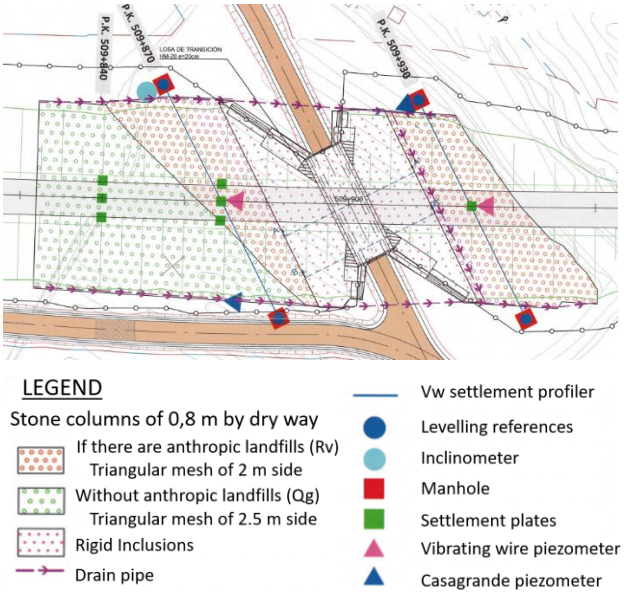

Figure 2. Layout of soil improvement treatment and geotechnical monitoring at the embankment R-14.

Table 1. Geotechnical parameters at Embankment R-14.

Unit	Depth (m)	γ_{ap} (t/m^3)	c (t/m^2)	Φ (º)
Rv	0,00 - 6,00	1,80	1,0	12
Qg	6,00 - 12,00	1,90	8,2	13
Mm	> 12,00	2,00	2,0	28
Embankment		2,00	1,0	30

The untreated solution presents stability problems, with safety coefficients lower than 1.5 and 1.1 required in static and seismic situations. Bishop method has been used in stability analysis. Settlements of up to 0.80 m are obtained, which would occur in more than 10 months, with a consolidation degree of 90% in 5 months, which is considered unacceptable. Results has been obtained with a stress method basis in Boussinesq and Westergaard theory with the software Settle 3D.

2.1 Stone columns improvement

Soil improvement is proposed with a treatment using stone columns of 0.80 m diameter and 6 m long, executed by dry method, with pre-drilling. The improvement is considered by substitution and improvement of the drainage, without densification. The treatment with stone columns has been executed with a 2 x 2 m triangular mesh in the area of anthropic fills, between Km 509+863 and Km 509+941, and with a 2.5 x 2.5 m mesh in the area without fills. A 0.5 m thick layer of granular material is placed above the columns. (Hernández, 2020) (Martínez, 2022)

With the 2 x 2 m spacing in the backfill area, and a 10.04 m embankment height, settlement is reduced to 48.8 cm, reaching more than 90% of the total settlement a month after completion. In the area without landfills, with a 2.5 x 2.5 m spacing, and a 9m height, the expected settlement is 47.5 m. Stone columns has been calculated with Priebe method, obtaining a settlement ratio of 0.55. (Adif, 2018)

The geotechnical monitoring plan includes control sections with settlement plates, control lines with vibrating wire settlement profiler, vibrating wire piezometer, inclinometer and Casagrande piezometer. Geotechnical monitoring will be a key factor in the evaluation of the achievement of the improvement objectives. (Hernández, 2020)

2.2 Rigid inclusions

The initial project considered a soil improvement using stone columns, however settlements under the structure exceeded the admissible values (5 cm for concrete structures). The solution under the structure of the underpass was a soil improvement through rigid inclusions (Figure 3). The spacing between inclusions has been designed to achieve a transition of stiffness with the improvement with stone columns. One of the problems to avoid with this type of soil improvement is an abrupt change in soil stiffness that can lead to differences in settlement between the area treated with stone columns and rigid inclusions. It is relevant to mention the time effects, since settlements with stone columns are usually produced during construction and rigid inclusion need some time for consolidation.

The treatment below the concrete frame of the 509+900 underpass is a 2 x 2 m mesh of inclusions of 36 cm diameter and 12 m depth, with 20 MPa concrete. According to the geotechnical survey, the stratigraphic profile is as follows, the columns will be embedded 3 meters in the Mm unit. The estimated maximum settlement was 4.54 cm, obtained with a FEM model with Plaxis 2D (Figure 4). For an adequate transition, the rigid inclusions will be extended outside the structure with a gradation in the treatment.

Figure 3. Rigid inclusions construction.

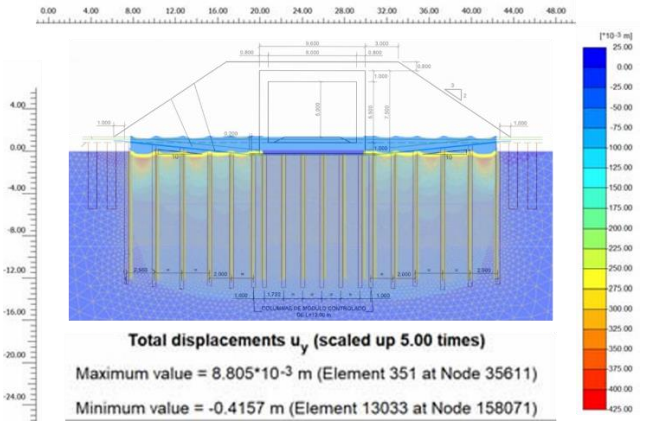

Figure 4. Geotechnical model with Plaxis 2D and section of the treatment with rigid inclusions (Hernández, 2020).

The distribution outside in transitions is defined as 1 row of columns at 1 meter from the frame columns and 2 additional rows separated by 2 meters, always keeping the transverse spacing at 2 meters. The gap between the transition zone of the wing walls and the frame will be filled with a inclusions grid of 2.5x2.0 meters. (Hernández, 2020) (Martínez, 2020)

A FEM model with Plaxis 2D shows a maximum settlement of 14.8 cm between the frame and the first row outside the structure, 30.7 cm between the second and third rows (separated by 2 meters) and 37.8 cm between the rows with 2.5 m spacing and 42.5 cm in the contact with stone columns. (Hernández, 2020)

3 SOIL IMPROVEMENT WITH RIGID INCLUSIONS, SURCHARGE AND WICK DRAINS

Soil improvement has been carried out combining rigid inclusions and embankment staged construction, with wick drains in embankments R-17 and R-21.

The case study in the R-21 embankment runs through km 515+521 to 515+740, with the 515+600 and 515+700 drainage structures with a section 8 x 5.5 m. The lithology of this area consists of uncontrolled anthropic fills (Rv), with a thickness of 3 m. (Figure 5)

Figure 5. Soil improvement with rigid inclusions below concrete structures and surcharge and wick drains in R-21 embankment and in Burjulu bridge abutments location.

The Qfv unit is formed by alluvial deposits of valley bottom, with a thickness of up to 13 m, consisting of silty clays and muddy clayey silts. The Miocene materials (Unit Mm) are found as substratum, formed by clayey marly silts and loams.

The maximum settlements obtained without improvement are estimated at 49.4 cm for more than one year, being unacceptable. The stability of the untreated solution is below the admissible safety coefficients. (Adif, 2018)

A solution of rigid inclusions is adopted in the area of the concrete structures, with 6 rows of columns of 36 cm diameter, 2 m spacing and 14 m length for the 515+60 frame and 12 m for the 515+70 frame. The treatment is extended outside the structure with another 6 rows with increased spacing to achieve a transition of deformations and stiffnesses with the area improved with preloading. Expected settlement with the treatment varies between 4.58 cm under the structure, gradually increasing up to 40.4 cm, with an increment of spacing until 2.5x2 m. (Hernández, 2020) (Villegas, 2021)

Soil improvement with preloading and wick drains, arranged in 2 m triangular mesh, with a length between 6 and 11 m depending on the area (Figure 6). The improvement technique was the embankment staged construction with an initial stage of 6.5 m for 3 months and other stage between 1 and 4 months up to 11.23 m.

4 RIGID INCLUSIONS COMBINED WITH REMOTION OF SOFT SOILS

A solution with rigid inclusions combined in the adjacent areas with replacement of soft soils in a thickness of about 1 - 1.5 m, and embankment staged construction at the locations R-33, R-22 and R-21 between km 515+740 and 516+480. (Martínez, 2022)

Figure 6. Wick drains installation in R-21 embankment.

5 CONCLUSIONS

The initial project proposed soil improvement through consolidation processes, with subsequent removal of the embankment at the location of drainage structures or underpasses. The advantage of the proposed methods is the combination of different soil improvement techniques to make the allowable deformations between concrete structures and embankments compatible. Rigid inclusions have been used in combination with other techniques, in conjunction with wick drains, stone columns, soft soil removal or embankment staged construction.

ABSTRACT: This paper refers to the excavation and retaining wall solutions for a residential development located in Lisbon, where part of the basement structure is located 4m above the Lisbon Metro (ML) tunnel crest. The constraints related to the execution of peripheral earth retaining walls are discussed, using the technology of Munich Walls, Berlin Walls, and Mixed Walls, duly adapted to the existing constraints. Finally, the results of the Monitoring and Survey Plan are pointed out, confirming its importance as risk management tool in a work of high geotechnical complexity and located very close to very sensitive structures, as it was ML tunnel.

RÉSUMÉ: Cet article fait référence aux solutions d'excavation et de mur de soutènement pour un développement résidentiel situé à Lisbonne, où une partie de la structure du sous-sol est située à 4 m au-dessus de la crête du tunnel du métro de Lisbonne (ML). Les contraintes liées à l'exécution des murs de soutènement périphériques sont discutées, en utilisant la technologie des murs de Munich, des murs de Berlin et des murs mixtes, dûment adaptée aux contraintes existantes. Enfin, les résultats du plan de surveillance et d'arpentage sont soulignés, confirmant son importance en tant qu'outil de gestion des risques dans un ouvrage de grande complexité géotechnique et situé très près d'ouvrages très sensibles, comme il s'agissait d'un tunnel ML.

Keywords: Munich walls, Berlin walls, mixed walls, deep excavations.

1 INTRODUCTION

This paper describes the excavation and peripheral retaining walls solutions, designed and executed in a residential development, in Lisbon, whose excavation bottom level was about 4m from the vault of the Lisbon Metro (ML) tunnel, corresponding to the section of the Red Line, located between the stations of Moscavide and Encarnação, executed using NATM technology. The work studied includes two buildings (Plot 1 and Plot 2), with Plot 1 consisting of 8 upper floors and 2 underground basements and Plot 2 consisting of 8 upper floors and 3 buried basements. Figure 1 shows an aerial view of the location of the site.

This article aims to address in more detail the solutions of Mixed Berlin (peripheric wall where the upper side is as munich walls (concrete) and lower side is as Berlin walls (timber lagging), with soldiers piles connecting both type of wall), and Suspended Munich walls (supported by adjacent peripheric walls), conditioned by the proximity of sensitive structures, such as the ML gallery.

Figure 1. Site Plan and ML path.

There was a need to resort to studies of non-conventional solutions considering the regulations and standards of the ML, which does not allow the execution of structural and foundation elements within 3m of the ML.

2 CONSTRAINTS

Given the location of the ML tunnel, about 4m below the entire North peripheral retaining wall of Plot 1, it was not possible to execute the traditional Munich Walls (as Figure 2). Likewise, in Plot 2, in an extension of about 20m, it was not possible to execute piles or micropiles, due to the need to respect the precautionary distance of 3m to the ML tunnel.

According to ML documents (Metropolitano de Lisboa 2010a), in addition to the need to respect the precautionary distance of 3m, during the excavation and peripheral containment works, the following criteria of maximum deformation were also imposed, to be proven by the instrumentation:

- The structure of the ML tunnel could not suffer displacements greater than 7 mm vertically and/or horizontally;
- On the ML rails, it was not possible to verify a variation of relative displacement, between sections of 8m distance, greater than 3mm.

These rules are applied to any excavation that takes place within 25m of the ML tunnel, which was the case (Metropolitano de Lisboa 2010b).

3 CONCEPTUAL SOLUTIONS

3.1 PLOT 1

The conceptual solution for Plot 1 North area was with the execution of a Mixed Berlin Wall (Figure 2 and 3). In this solution, a Munich wall was executed in the top area of the retaining wall and a Berlin wall was executed in the bottom area, because the space between the mixed berlin walls and the definitive wall of the building was to be fille (as Figure 3).

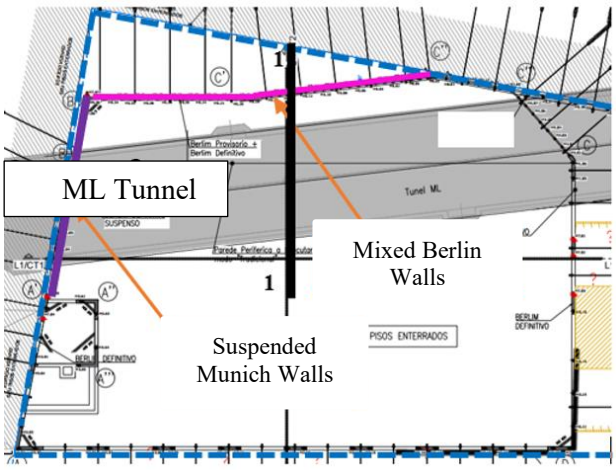

Figure 2. Plot 1 – Conceptual solution.

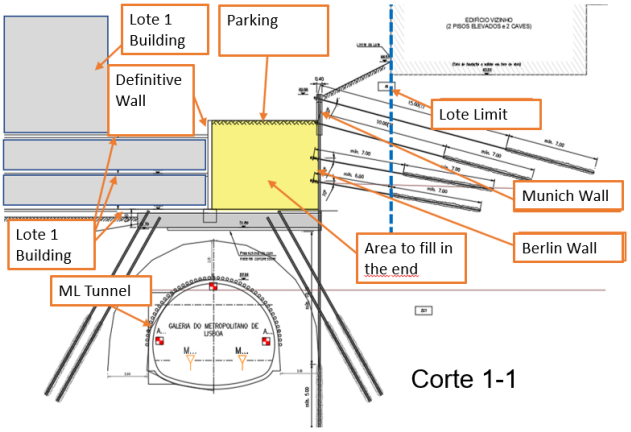

Figure 3. Plot 1 – section 1.

3.2 PLOT 2

The conceptual solution for Plot 2 North area was with the execution of a Suspended Munich Wall (Figures 4 and 5). In this solution, the micropiles in the suspended Munich wall are in tension, to transmit the vertical load from the wall to the top beam (with 2m height). Due to the suspended load, reinforcement of the micropiles in the end of Munich wall is required, to hold all vertical load from the suspended Munich wall.

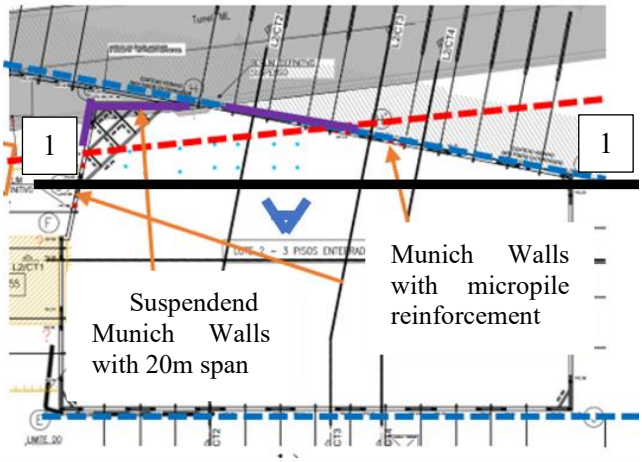

Figure 4. Plot 2 – Conceptual solution.

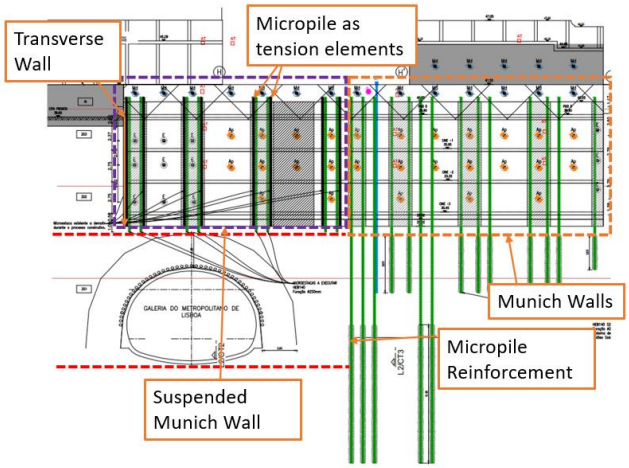

Figure 5. Plot 2 – section 1.

4 EXECUTION

4.1 PLOT 1

Figures 6 and 7 show the site at completion of the excavation. Figure 7 shows the beginning of execution of the permanent wall of the building and the space (min 3m) to the Mixed Berlin Wall.

Figure 6. Plot 1 – Mixed Berlin Wall.

Figure 7. Plot 1 – Suspended Munich Walls.

4.2 PLOT 2

Figure 8 show the suspended Munich wall solution at bottom excavation. To reduce vertical load, 3 levels of props were adopted.

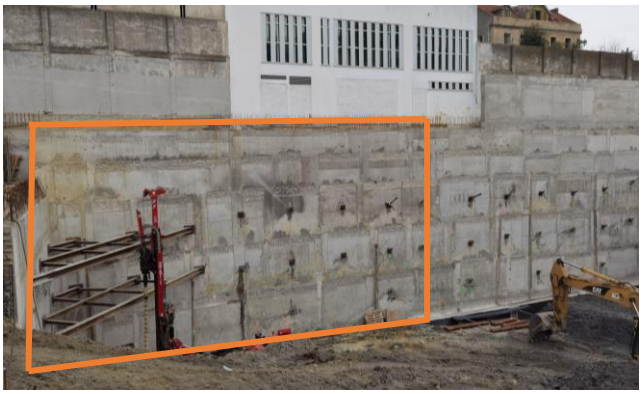

Figure 8. Plot 2 – Suspended Munich Walls.

5 MONITORING AND SURVEY PLAN

The instrumentation adopted in situ, consisted of a wide range of devices, as the following:

- Topographic targets in the peripheral retaining structures, placed during their execution;
- Topographic targets in the surrounding structures, installed before the start of excavation work;
- Piezometers, installed to control the position of the water table;
- Inclinometers, installed to control the evolution of horizontal displacements of the ground;
- Load cells, used to evaluate loads on temporary anchors;

Topographic targets and topographic marks installed inside the ML gallery to control the relative (convergences) and absolute deformations of the vault and rails, respectively. Figures 9 to 13 show the results.

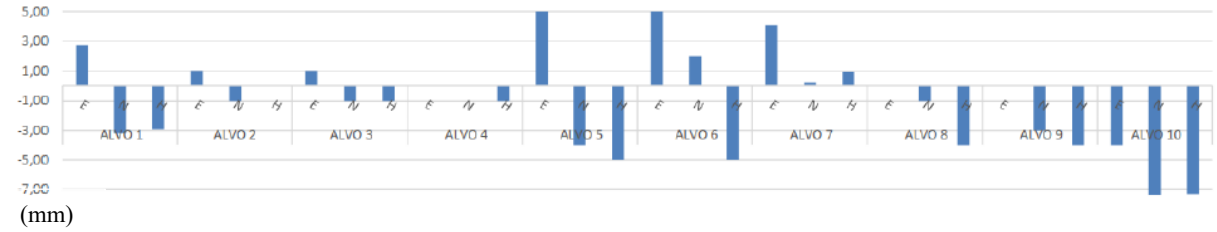

Figure 9. Surrounding Structures settlements (mm).

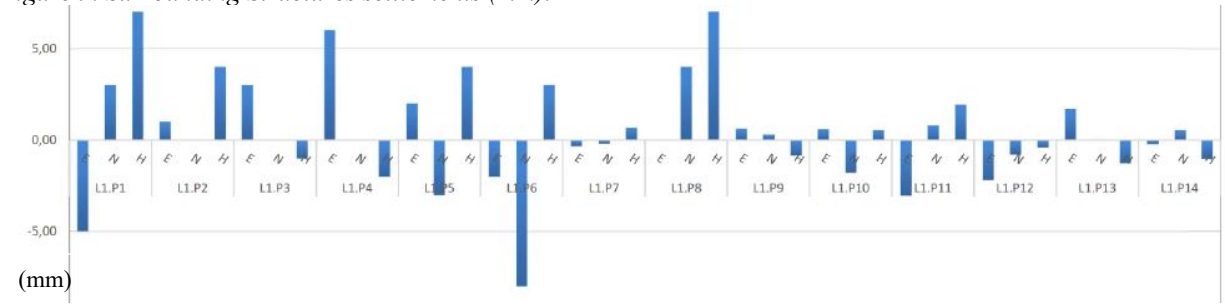

Figure 10. Plot 1 Peripheric wall settlements (mm).

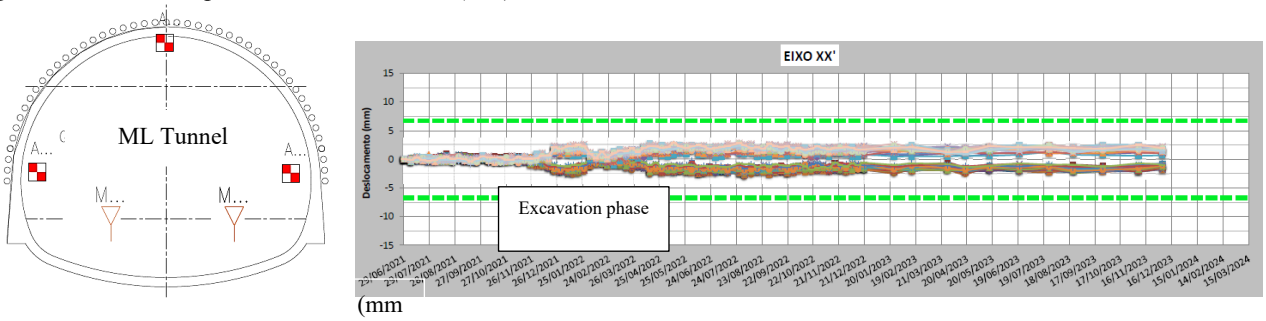
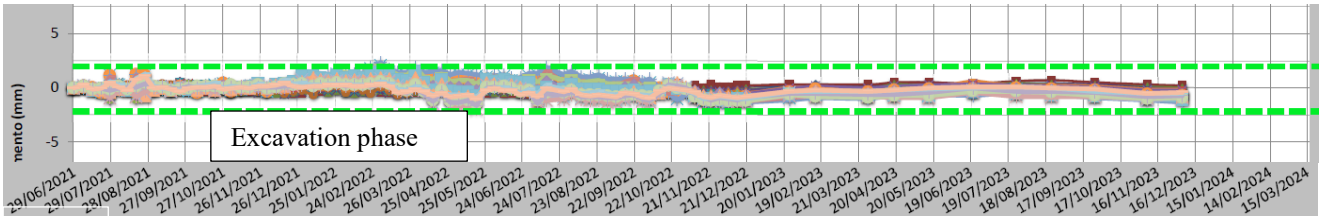
Figure 11. Plot 2 Peripheric wall settlements (mm).



(mm

Figure 12 - ML Tunnel – Topographic longitudinal settlements of the vault (mm).



(mm)

Figure 13. ML Tunnel – Rails vertical settlements (mm).

Settlement result of the peripheric retaining wall suggest good correlation with the model considered in the design. Settlement result of surrounding structures were compatible with the profile of those structures. ML tunnel settlement was lower than max acceptable value. Rails settlements were at the max acceptable value (3mm) during excavation phase.

6 CONCLUSIONS

This article highlights the main solutions of peripheric earth retaining walls in a sensitive geotechnical area, due the vicinity of the ML Tunnel. Risk management, soil behaviour with good correlation with design models and assessment of good behavior of the structures were only possible with the execution of a Monitoring and Survey Plan.

Deep and complex excavation in an urban environment in Miraflores, Oeiras

Excavation profondes et complexes en milieu urbain à Miraflores, Oeiras

JETsj Geotecnia, Lisbon, Portugal

**rjustiniano@jetsj.com*

ABSTRACT: This paper addresses the design and building solutions for the peripheral earth retaining structures, required for the construction of a development, which is a building complex of two building each 14 storeys high. The excavation footprint has approximately 6000 m2 with the deepest excavation depth of 9 m. The majority of the excavation intersected on heterogenous landfills, resting on top of Lisbon's Vulcanic Complex. The site is located in Miraflores, near Monsanto Forest Park. Surrounding the site there are public roads and other building constructions taking place. To minimize settlements around the excavation a secant pile wall was built, and braced either by a concrete strip slab or temporary ground anchors, the north elevation has an open filed, which was used to create a slope, to access to the final excavation level allowing an easy way to remove the soil.

RÉSUMÉ: Cet article traite des solutions de conception et de construction pour les structures périphériques de soutènement en terre, nécessaires à la construction d'un lotissement, qui est un complexe immobilier de deux bâtiments de 14 étages chacun. L'empreinte d'excavation est d'environ 6000 m2 avec une profondeur d'excavation maximale de 9 m. La majorité des fouilles ont été recoupées sur des décharges hétérogènes, reposant sur le complexe vulcanique de Lisbonne. Le site est situé à Miraflores, près du parc forestier de Monsanto, autour du site, il y a des routes publiques et d'autres constructions en cours. Pour minimiser les tassements autour de l'excavation, un mur de pieux sécants a été construit et contreventé soit par une dalle de béton ou des ancrages au sol temporaires, l'élévation nord a un dépôt ouvert, qui a été utilisé pour créer une pente, pour accéder au niveau d'excavation final permettant un moyen facile d'enlever le sol.

Keywords: Munich walls; Berlin walls; mixed walls; deep excavations.

1 INTRODUCTION

This paper addresses the peripheral earth retaining walls solution for the construction of a private condominium with two buildings of 14 storeys high on a plot with over 6000m^2, and three levels below ground, with a maximum excavation over 9 m.
The main constraints of earthwork were the tight deadline to execute the excavation work, the geological and geotechnical environment, and the proximity to nearby constructions. Figure 1 presents the locations of the constructions site.

Figure 1. Site Plan plus ML path.

This article aims to address in more detail the solutions of peripheric retaining walls taking account than in west side is not possible to execute provisory anchors and that 60 000 m3 needed to be excavated in less than 6 months.

2 MAIN CONSTRAINTS

From the site geological and geotechnical investigation, it was possible to confirm that the site was located on the Lisbon's Vulcanic Complex, covered by a heterogeneous landfill deposit layer. In Figure 2 is presented the geological chart of Portugal, 34-D Lisbon.

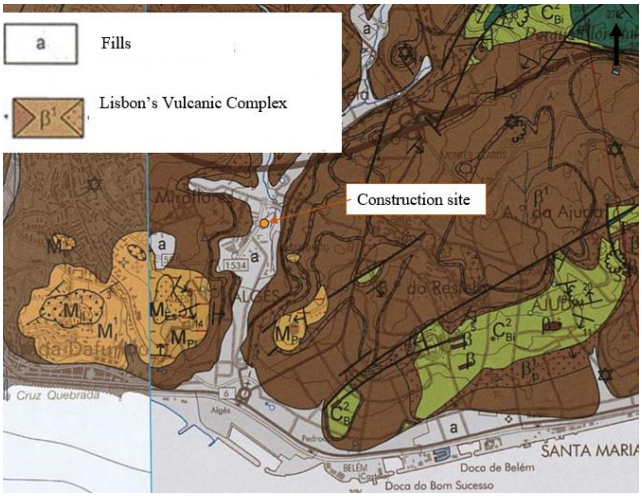

Figure 2. Geological Chart of Portugal.

The laboratory testing on the basalt rock mass shows a high modulus of elasticity and compressive resistance, in line with historical results in excavations in the area.

The existence of two PT (Transformation Post) constraints the solution, as electric cables with median tension were active in the area with no possible deactivation.

At last, the main constraint was the time schedule for the execution of the peripheric retaining walls and the excavation, in less than 6 months.

3 CONCEPTUAL SOLUTIONS

The conceptual solution for the excavation was developed considering time restrictions, space limitation and the type of geotechnical field. The design solution was an overlapped pile wall consisting on 500mm diameter piles spaced 400mm. The primary piles consist of unreinforced piles, which reach the basalt rock mass. As for the secondary piles, which are reinforced, they have an embedment length of 2,5 m on the rock mass underneath the maximum excavation depth, ranging from 7 to 12 m. Figure 3 and 4 show pile wall section.

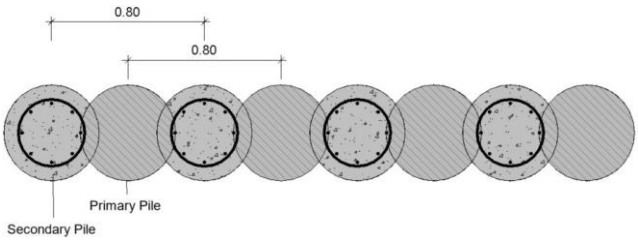

Figure 3. Overlap pile wall.

Figure 4. Overlap pile wall preparation in situ with marks.

The overlapped pile wall was horizontally supported by two types of solution. In South, North and East side, provisory anchor levels were considered with pretension. Figure 5 shows the section solution.

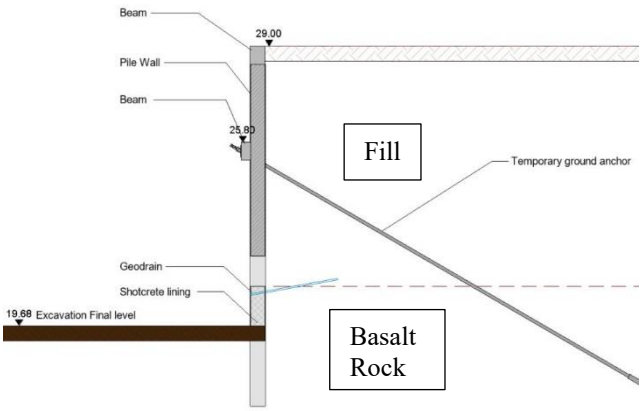

Figure 5. Section solution for North, South and East side.

On the West side, provisory anchors were not possible due to the proximity to adjacent lot excavation.

Due to time restrictions, the solution for horizontal support was slab bed solution. In this solution, the slab is partially executed before the full excavation. The pile wall has enough stiffness to allow 3m excavation with no support, followed by the execution of the slab bed that is fixed in the extremities by the pile wall showed in Figure 5 and or by sub vertical micropile elements, as Figure 6.

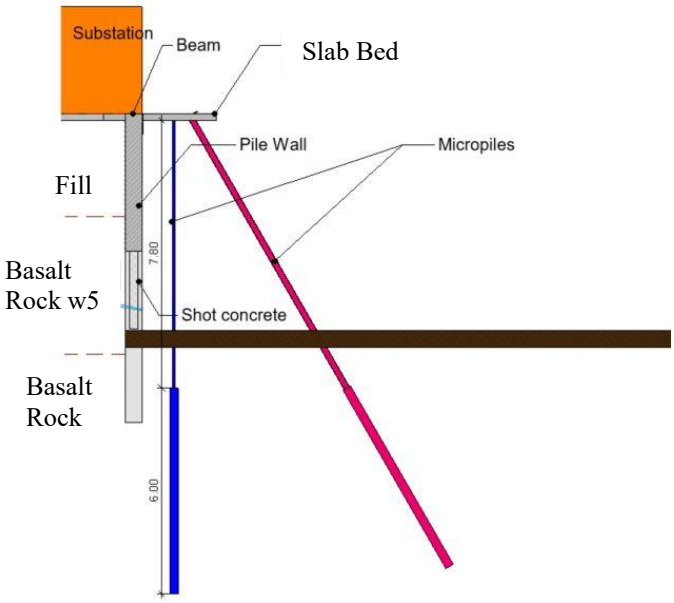

Figure 6. Section solution for West side.

Due to length of the slab bed, vertical support was needed to control the deformation of the slab bed in excavation phase.

Taking in consideration the overall force in the slab bed in excavation phase, additional reinforcement bars were considered, in addition to the reinforcement bars predicted in the stability project. Figure 7 show BIM model for the excavation.

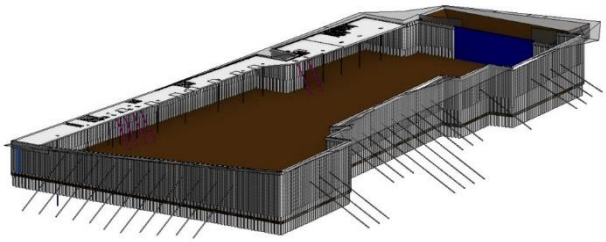

Figure 7. BIM model.

The design of the peripheric retaining wall was developed with Plaxis 2D models and Autodesk Robot models for the strip slab (figure 8 and 9).

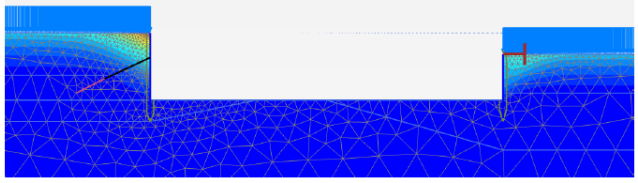

Figure 8. Plaxis 2D model.

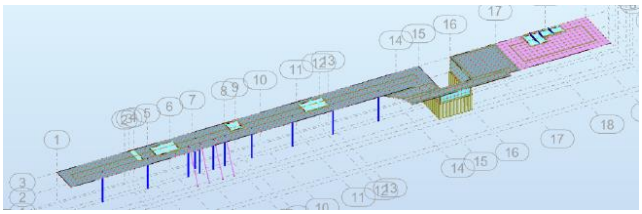

Figure 9. Autodesk Robot Model.

Due to the complexity of the geotechnical field, it was executed a survey and observation plan in situ, to confirm the design criteria and evaluate the behaviour of peripherical retaining wall structure.

4 EXECUTION

The solution of pile wall allows the execution of the peripheric retaining wall with multiple site fronts, with 5 pile machines at the same time.

Intended to support the high intensity work of 5 pile machines, 2 auto concrete mixers were in site to support the piles machines.

Figure 10. East Side with 2 pile machines.

Figures 11, 12, 13 and 14 show the retaining pile wall solution at bottom excavation or during excavation.

Figure 11. West Side solution with slab bed.

Figure 12. East Side solution with provisory anchors.

Figure 13. South Side solution with provisory anchors. (definitive structure already in place).

Figure 14. West Side (Left) and East Side (Right) solution at bottom excavation. (definitive structure already in place).

5 MONITORING AND SURVEY PLAN

The instrumentation adopted in situ consisted of a wide range of devices, of which the following stand out:

- Topographic targets in the peripheral retaining structures, placed during their execution.
- Topographic targets in the surrounding tower cranes, installed before the start of excavation work.
- Piezometers, installed to control the position of the water table.
- Inclinometers, installed to control the evolution of horizontal displacements of the terrain at depth;
- Load cells, used to evaluate loads on temporary anchors;

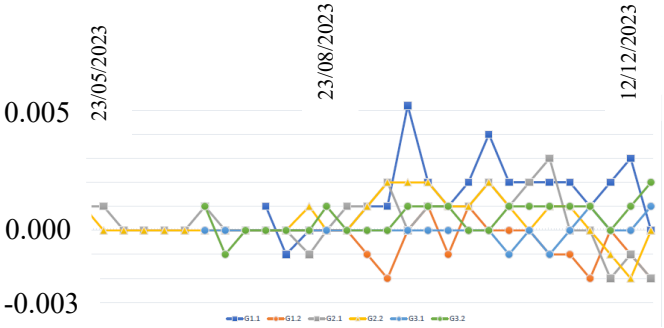

Figure 15. Towers Cranes vertical deformation (m).

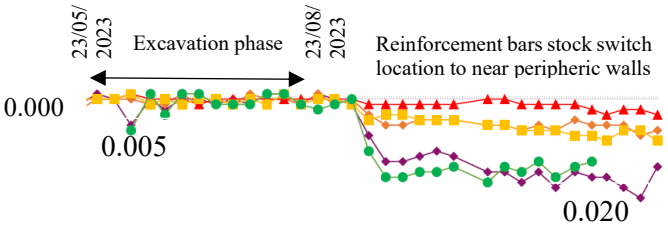

Figure 16. Horizontal deformation pile wall (m).

The survey and observation plan confirmed the design criteria of the project. Nevertheless, during the construction of the structure from the bottom of the excavation, the reinforcement bars stock switch to a very close area near the peripheric retaining wall, which results in a significant horizontal deformation, yet, under accepted values.

6 CONCLUSIONS

This article highlights the mains solutions of peripheric earth retaining walls with time constrains and nearby excavations constrains. Risk management, conceptual confirmation, assessment of good behaviour of the structures were only possible with the execution of a Monitoring and Survey Plan.

Performance investigation of a newly proposed drainable pipe fitting

Enquête sur les performances d'un nouveau raccord proposé de tuyau d'évacuation

ABSTRACT: We propose a versatile drainage system that incorporates drainage inlets for pipe fittings that can connect to standard steel and PVC pipes. In existing drainage pipe systems, soil entering from small openings clogs the drainage path and is a cause for concern. With the proposed pipe fittings, however, it is possible to freely design the drainage inlet shape, position and inflow path, thereby reducing the amount of soil entering the drainage route. In this study, drainage performance and sediment control capabilities of the newly proposed drainable pipe fittings were investigated through laboratory and full-scale model experiments. Consequently, it was found that the drainable pipe fittings ultimately possessed equivalent drainage performance to conventional drainage pipes with better control of sediment discharge. Further inlet shape improvements can provide effective drainage systems for geotechnical engineering sites.

RÉSUMÉ: Nous proposons un système d'écoulement polyvalent qui intègre des entrées d'évacuation grâce à un raccord de tuyauterie pouvant se connecter à des tuyaux standard en acier ou en PVC. Dans les systèmes de canalisations d'écoulement existants, la terre pénètre par de petites ouvertures et bouche l'entrée des conduites d'écoulement et constitue un problème. Néanmoins, avec le raccord de tuyauterie proposé, il est possible d'établir librement la forme, l'emplacement et l'afflux des ouvertures d'écoulement, réduisant ainsi la quantité de terre entrant dans les voies d'écoulement. Dans cette étude, les performances des écoulements et les capacités de contrôle des sédiments du nouveau raccord de tuyauterie a écoulement proposé ont été étudiées en laboratoire et sur modèles à grande échelle. Par conséquent, il a été constaté que les raccords de tuyau d'écoulement possèdent finalement des performances d'écoulement équivalentes à celles des tuyaux d'écoulement conventionnels et peuvent mieux contrôler l'écoulement des dépôts de sédiments. D'autres améliorations de la forme peuvent fournir un système d'écoulement efficace pour les sites d'ingénierie géotechnique.

Keywords: Drainage system; underground pipe; permeability test.

1 INTRODUCTION

Limited methods exist for draining excessive water from natural slopes or existing earth structures. Drainage pipe systems, which drive a perforated steel pipe into ground with high phreatic surfaces offers not only the advantage of requiring a relatively small construction space and small workforce, but also the ability to increase the rigidity of the penetration area owing to a nailing effect (Saito et al., 1968). However, challenges arise when soil material intrudes into the pipe and clogs the drainage holes, leading to a rapid decline in drainage efficiency. Additionally, the loosening of the ground along the drainage route due to the induction of soil also causes concern. In this study, a new pipe fitting is proposed with a drainage function and mechanism to reduce soil leakage into the drainage route by directing the flow against gravity. Here, the performance of the newly developed pipe fitting was investigated through laboratory and full-scale model tests.

2 DRAINABLE PIPE FITTING

The pipe fitting proposed in this study is designed to have drainage functionality at the joint connecting the prefabricated PVC or steel pipes. This drainable pipe fitting, as shown in Figure 1, features a bulge on the side that serves as the drainage inlet. Generally, drainage pipes are installed with a 5-degree upward slope. The drainable fitting is used with the drainage

Figure 5. Alignment of drainage pipe.

inlets at the lower slope position, as illustrated in Figure 1. This configuration allows groundwater to flow upward through the drainage inlet into the drainage route and then to drain from the end of the non-perforated pipe. As a result, less soil particles are expected to enter the drainage route, because they would have to defy gravity to flow upward. Furthermore, the use of prefabricated pipes garners the advantage of applying existing drilling and pipe installation methods without modification. Incorporating multiple fittings increases the number of drainage inlets, and as drainage positions are specified, it is also possible to strategically lower the phreatic surface using this system.

3 EXPERIMENTAL PROCEDURES

3.1 Laboratory model test

Figure 2 illustrates an overview of the model test. The model box has internal dimensions of 300mm width, 300mm height, and 200mm depth, allowing the installation of the drainage pipe at a 5-degree upward angle from the central part of one side of the model box with a water inlet at the lower part of the upstream side. Drainage from the outlet of the pipe was collected in an attached tank through filter paper and recirculated by a pump. During the test, volumes of drainage water and soil were measured periodically. To simulate materials prone to enter the drainage path, silica sand No. 5 ($G_s = 2.67$) was used. Figure 3 shows the particle size distribution of the soil test material. Through maximum and minimum density tests, a maximum void ratio of 1.050 and a minimum void ratio of 0.708 were obtained. When making the soil model, dry samples were compacted in 10 layers to a height of 240mm to achieve a void ratio of 0.70 (as determined from a separately conducted permeability test ($k = 3.4 \times 10^{-3}$ m/sec). To prevent drainage during the experiment, the soil model was first saturated up to lower part of the drainage pipe. Then, the flow control valve was adjusted to establish a constant hydraulic gradient while monitoring the manometers at the inflow section to confirm a steady state. The water level was raised every 1cm until soil leakage became significant and the drainage pipe was completely clogged.

3.2 Full-scale model test

The performance of the proposed drainage systems was investigated on a full-scale embankment model (Figure 4) constructed at Kobe Airport. The drainage systems tested consist of four types, as shown in Figures 5 and described as follows: DF4 and DF2 are the drainable fittings proposed in this study, with 4 and 2 drainage inlets, respectively; ST is a steel drainable fitting that incorporates drainage functionality into existing anchor rods, maintaining the same shape with two drainage inlets; and DP is a perforated PVC pipe installed for comparison purposes. All the drainage systems were inserted at an upward angle of 5-degrees from the slope surface to a depth of 2 meters. Drainable fittings were connected to pipes at every 50 cm, including at the tip (DF4, DF2, ST). ST, a self-

drilling type of pipe made of rust-resistant steel, had high rigidity and allowed for being driven into position using impact. Placements for DP, DF2, and DF4 were pre-augured before insertion to ensure that the auger holes had stable walls. The pipes were then inserted and installed. Drainage from the drainage pipes was collected in acrylic containers, and the drainage water and soil were measured periodically. Additionally, during the measurement period, the drainage process was recorded with a time-lapse camera, and days with drainage were recorded.

4 EXPERIMENTAL RESULTS AND DISCUSSIONS

First, we discuss the results of the laboratory model tests. Before testing the drainage fittings, model tests were conducted using PVC pipe with small hole perforations and an inner diameter of 31mm. Soil entered from the upper holes of the perforated pipe regardless of the drainage process for the soil sample. To compare the drainable pipe fitting systems, all the holes on the upper surface of the perforated pipe without the drainable pipe fittings and those upstream of the drainable pipe fitting were sealed with waterproof tape. Figure 6 shows the results of the perforated pipe model test. During the test, due to sensitivity issues with the manometers, hydraulic gradient was calculated by dividing the difference between the water level in the inflow section manometer and the height of the lowermost hole by the horizontal distance. As the hydraulic gradient increased, the drainage volume also increased linearly. In the case of the perforated pipe, there was a constant amount of soil leakage even at low hydraulic gradients; however, a significant amount of soil leakage was observed once the hydraulic gradient exceeded 0.2.

Next, we conducted experiments using a drainable pipe fitting. The experimental results are shown in Figure 7. Although it is difficult to directly compare the absolute values of the hydraulic gradient, the trend of increasing drainage volume with increasing hydraulic gradient is the same. At low hydraulic gradients, soil leakage was not observed; however, once soil began to leak, it increased exponentially, and clogging due to soil leakage made it impossible to continue the experiment above a hydraulic gradient of 0.2. The drainable pipe fittings had a drainage design with a 5-degree upward angle at the inflow section, which resulted in a greater flow velocity than gravity acting on soil particles. This design could not sufficiently prevent soil from leaking.

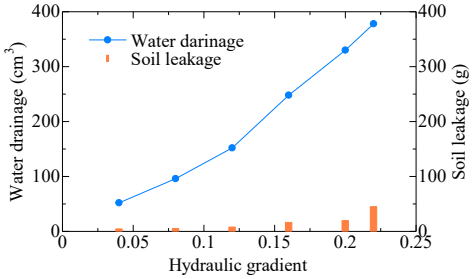

Figure 6. Test results for perforated pipe.

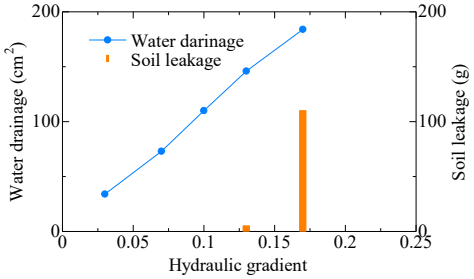

Figure 7. Test results for drainable pipe fitting.

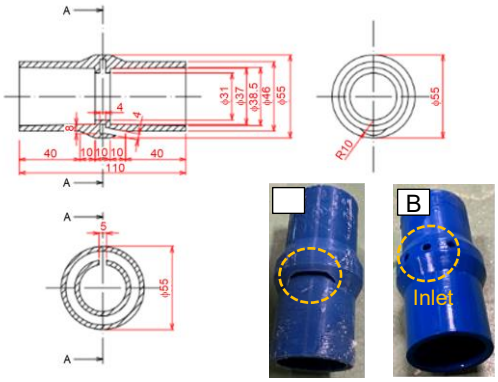
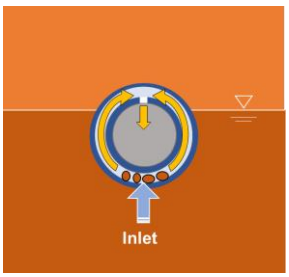


(a) Shape and photos



(b) Drainage mechanism

Figure 8. Modified drainable pipe fiting.

Therefore, as shown in Figure 8, we improved the fitting design. The modified drainable pipe fitting utilized an inlet at the bottom of the drainage pipe and a drainage route confluence point at a higher position inside the drainage pipe, creating a structure with greater height differences. We prepared two different inlet shapes, denoted as A and B. Figure 9 shows the test results using the modified drainable pipe fittings. There was no significant difference in the results between fittings A and B. The results showed that the inlet shape had little impact on the drainage and sediment control functions on the same internal structure. Compared to before the improvement, soil

leakage was reduced; however, once the hydraulic gradient exceeded a certain threshold, soil leakage became excessive, making it difficult to continue the experiment. As mentioned earlier, direct comparison of the absolute values of the hydraulic gradient was not appropriate, so we compared the drainage components based on the relationship between drainage volume and soil leakage, as shown in Figure 10. In the case of the perforated pipe, soil leakage was observable even at low drainage volumes, whereas the proposed drainable pipe fittings hardly had any soil leakage. Nevertheless, it was evident that significant soil leakage occurred once the drainage volume exceeded a certain threshold, which appeared to be strongly dependent on the rate of water level rise.

Drainage and soil leakage in the full-scale embankment test were measured over six separate periods. Figure 11 shows the precipitation during each measurement period. There was little to no substantial rain between autumn and winter, while precipitation increased significantly from early spring to the rainy season, resulting in variations during the measurement period. Figures 12 and 13 show the measured drainage and soil leakage, respectively. It is difficult to compare the type of drainage pipe since the installation locations and soil conditions were different. However, it is evident that there is not a significant difference in drainage volume between perforated pipes and drainable pipe fittings. This suggests that drainable pipe fittings provide a comparable drainage performance to perforated pipes. On the other hand, soil leakage was rarely observed during periods of low precipitation and was most pronounced with perforated pipes. Observation from time-lapse cameras revealed that drainage occurred only on days with substantial rainfall exceeding 30mm. Tensiometers indicated that the conditions for perched water to accumulate in this embankment occurred with daily rainfall of around 25mm. Below this threshold, water dissipated through surface runoff or evaporation without generating perched water, indicating that the drainage system is effective during times when free water, such as perched water, is generated.

5 CONCLUSIONS

In this study, we conducted model experiments to investigate the drainage function and soil leakage control function of drainable pipe fittings with a new drainage mechanism. As a result, we found that the new drainable pipe has sufficient drainage capacity and offers soil leakage control under low hydraulic gradients.

ABSTRACT: We studied the precipitation of carbonate minerals used as cements for ground improvement. The carbonate minerals were prepared by combining divalent ions (Mg^{2+}, Ca^{2+}, and Fe^{2+}) with carbonate ions (CO_3^{2-}) induced by microbial activity. Scanning electron microscopy (SEM) and X-Ray Diffraction (XRD) analyses observed the shapes and sizes of the minerals and attested the formation of dolomite ($CaMg(CO_3)_2$) and siderite ($FeCO_3$). Consolidated drained triaxial tests (CD) were performed on treated specimens of silica sand with the CO_2-induced siderite and dolomite cements with and without the addition of nanoclay. Specimens treated with siderite had higher strengths than dolomite-treated specimens. The addition of nanoclay further increased the shear strength of the specimens and reduced their brittleness. Moreover, it was found that the shearing resistance of fully saturated specimens was not considerably reduced compared to that of dry specimens, as it only decreased by 5–15% compared to that of dry specimens.

RÉSUMÉ: Nous étudions la précipitation de carbonates que nous utilisons comme ciments pour l'amélioration de sols. Les minéraux carbonatés ont été préparés en combinant des ions divalents (Mg^{2+}, Ca^{2+}, et Fe^{2+}) avec des ions carbonate (CO_3^{2-}) formés à partir de l'activité métabolique microbienne. La forme et la taille des minéraux ont été observées par analyses microscopiques (microscope électronique à balayage). L' analyse minéralogique des minéraux (par diffraction des rayons X) a confirmé la formation de dolomite ($CaMg(CO_3)_2$) et de sidérite ($FeCO_3$). Ces minéraux ont ensuite été utilisés pour l'amélioration des propriétés d'un sol granulaire. Des essais triaxiaux consolidés drainés (CD) ont été effectués sur des échantillons de sable siliceux traités par la sidérite et dolomite ainsi produites, avec ou sans nanoargile. Les échantillons traités à la sidérite avaient une résistance au cisaillement plus élevée que ceux traités à la dolomite. L'ajout de nanoargile a augmenté la résistance des échantillons au cisaillement ainsi que leur ductilité. De plus, la résistance des échantillons saturés n'était pas considérablement inférieure à celle des échantillons secs, n'ayant diminué que de 5 à 15% par rapport à celle des échantillons secs.

Keywords: MICP; siderite; dolomite; soil improvement.

1 INTRODUCTION

Sustainable precipitation of carbonate minerals has the potential to offer environmentally friendly ways of improving soils of poor engineering characteristics preventing soil erosion, slope instability, or low bearing capacity. Microbially-induced carbonate precipitation (MICP) has emerged as one such potentially more sustainable process, as it uses natural mechanisms to induce mineral precipitation in the soil pore space leading to soil cementation (Keykha et al., 2017, 2019; Wang et al. 2021, Romiani et al. 2023).

The precipitation of minerals by microbial activity, which may be extracellular precipitation, is known as biologically induced mineralization. In various types of living organisms, the extracellular mineralization-related carbonate precipitation is a well-known phenomenon (Lowenstam, 1989). By altering the surrounding environmental conditions and acting as nucleation sites, bacteria can promote mineral precipitation in microenvironments in some challenging natural conditions in terms of pH and temperature (Sánchez-Román et al. 2011).

MICP works have mostly studied $CaCO_3$ precipitation biotechnology using ureolytic bacteria to hydrolyse urea to carbonate by producing urease enzyme release as shown in equations 1-2 (Ivanov & Chu, 2008; Tang et al. 2020):

$$CO(NH_2)_2+2H_2O \xrightarrow{urease\ enzyme} CO_3^{2-} + 2NH_4^+ \quad (1)$$

$$CaCl_{2\,(aq)} + CO_3^{2-}{}_{(aq)} \rightarrow CaCO_3\,(s) \quad (2)$$

MICP can produce different polymorphs of $CaCO_3$ such as aragonite, calcite, and vaterite, as well as $CaCO_3$ monohydrate, $CaCO_3$ hexahydrate, and amorphous $CaCO_3$ (Mortensen et al. 2011).

This study aims to evaluate the use of various types of precipitated carbonate minerals other than only $CaCO_3$ to improve mechanical properties of soils. The minerals were obtained using carbonate ions (CO_3^{2-}) produced by the metabolic action of microbes as an *ex situ* process, to overcome complications of bacteria activity and survival in different soil environments. The carbonate minerals thus produced were then combined with nanoclay additive, to further enhance the mechanical properties of the treated soil.

2 MATERIAL AND METHODS

2.1 Bacteria type strain and culture media

The present study used urease-producing bacteria *Sporosarcina pasteurii* (PTCC 1645), grown in NH_4-YE, a medium made up of 800 mL of Tris-buffer 0.13 mol/L (pH = 9.0), 20.0 g of yeast extract, 10.0 g of $(NH_4)_2SO_4$, and 100 ml of distilled water. Before autoclaving, the pH of the growth medium solution was measured to be adjusted in 9.0. After that, the components were individually autoclaved (at 121 °C for 15 min) before being cooled and combined in an Erlenmeyer flask. Bacteria were cultivated at pH=9.0, which was the optimal pH for *S. pasteurii* growth. The bacteria were transferred to the medium broth in an incubator (30 °C) and shaken aerobically for 3 days at 200 rpm. A previously established optical density of 1.6 at 600 nm (about 108 cells/mL), was obtained. The bacteria were recovered from an overnight culture by centrifugation at 8000 g for 10 min. Next, 100 mL of urea (1M) was mixed with 100 mL of the bacteria culture to produce a free carbonate ion solution. The carbonate ions thus produced were combined with Fe^{2+}, Mg^{2+}, or Ca^{2+} ions (using $FeSO_4$, $MgCl_2$, and $CaCl_2$ solutions respectively) to induce $FeCO_3$, $CaCO_3$ and $CaMg(CO_3)_2$ mineral precipitation according to equations 3-4:

$$FeSO_{4\,(aq)} + CO_3^{2-}{}_{(aq)} \rightarrow FeCO_3\,(s) \quad (3)$$

$$CaCl_2/MgCl_{2\,(aq)} + CO_3^{2-}{}_{(aq)} \rightarrow CaMg(CO_3)_2(s) \quad (4)$$

The characteristics of the reagents used are listed in Table 1.

Table 1. Chemical reagents used.

Reagents	Molarity	Cation:Carbonate Ratios
$FeSO_4{\cdot}7H_2O$	1M	Fe^{2+}: CO_3^{2-} 1:1
$CaCl_2$/ $MgCl_2$	1M	Mg^{2+}/Ca^{2+}: CO_3^{2-} 1:1

2.2 SEM and XRD Analysis

Selected carbonate samples were analysed using various techniques including scanning electron microscopy (SEM) and X-ray diffraction analysis (XRD). SEM was used to examine the size, shape, and arrangement of mineral crystals. To ensure good conductivity, the dry powder specimens were coated with gold before SEM testing. During these tests, we applied accelerating voltages between 2 and 10 kV. Additionally, XRD was employed at 30 kV and a 30 mA current to identify the mineral type.

2.3 Soil treatment and triaxial testing

The soil used in this study was clean silica sand of a particle size distribution shown in Figure 1, a uniformity coefficient of 2.74, a specific gravity of 2.65, and maximum and minimum void ratios of 0.90 and 0.57, respectively.

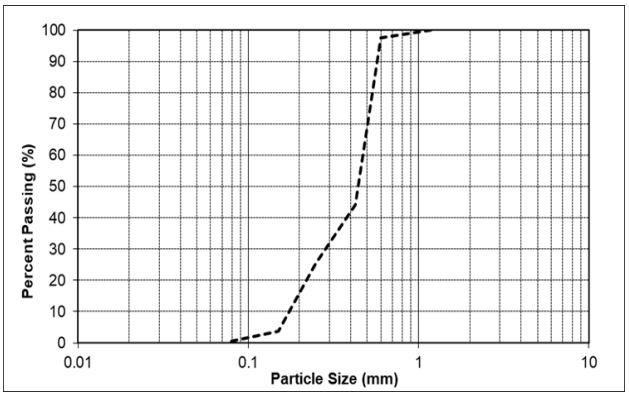

Figure 1. Particle size distribution of silica sand.

To conduct triaxial tests, cylindrical specimens of 10cm length and 5cm diameter were prepared by combining sand with a 15% content of carbonate minerals (specifically, $FeCO_3$ and $CaMg(CO_3)_2$) in accordance with ASTM D2166 standards. In some specimens 2% nanoclay was also introduced into the carbonate mixture. The specimen preparation procedure is presented in Table 2. After allowing the specimens to cure for 7 days, consolidated drained triaxial tests (CD) were performed on the treated samples following ASTM D7181 guidelines with a triaxial cell pressure of 100 kPa. All experiments

were carried out in triplicate under both dry and fully saturated conditions respectively.

Table 2. Properties of sample preparation.

Sample NO.	Carbonate mineral (15%)	Nano -clay (%)	W (%)	γ (g/cm^3)
D15	Dolomite	0	10	1.98
D15+nano2	Dolomite	2	10	2
S15	Siderite	0	10	1.98

3 RESULTS AND DISCUSSION

3.1 Carbonate mineral production

Figure 2 shows the formed carbonate minerals. $FeCO_3$ particles exhibit a polycrystalline, spherical shape with sizes ranging from 0.5-2 µm (Figure 2 (a)). Conversely, Ca-$Mg(CO_3)_2$ crystals have a botryoidal shape, with sizes ranging from 5-16 µm (Figure 2(b)). The XRD analysis confirms the presence of $FeCO_3$ as siderite and $CaMg(CO_3)_2$ as dolomite (Figure 3).

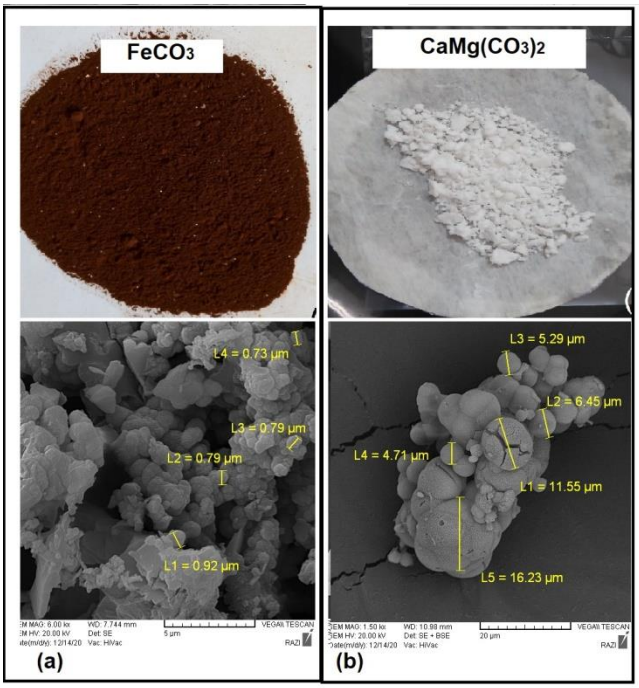

Figure 2. Macro and microstructure of carbonates.

3.2 Triaxial Compressive Strength (CD)

Figure 4 presents the stress-strain behaviour of samples treated with carbonates in a triaxial test conducted under dry conditions (CD). As illustrated, the samples treated with siderite exhibited greater strength compared to those treated with dolomite. Furthermore, samples treated with a combination of carbonate minerals and nanoclay displayed even higher strength when compared to the other treatments, with the highest strength recorded at 525 kPa observed in the sample treated with siderite and nanoclay. Additionally, the specimens treated with siderite and nanoclay were more ductile than specimens treated solely with siderite.

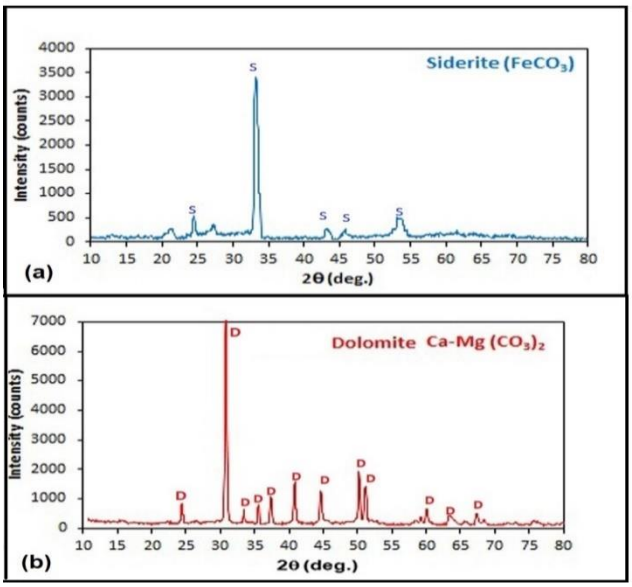

Figure 3. XRD analysis of carbonate minerals (a) Siderite, and (b) Dolomite.

The results of the triaxial test conducted under saturated conditions closely resembled those obtained under dry conditions (Figure 5). Strengths de-creased by 5% to 15% for all saturated specimens, compared to those of dry specimens; the highest strength recorded under saturated conditions was approximately 464 kPa, in the specimens treated with siderite and nanoclay. The secant modulus E_{50} of specimens decreased with the addition of nanoclay (Figure 6).

4 CONCLUSION

In this study, microbially induced carbonate precipitation was used to generate free carbonate ions (CO_3^{2-}). Different carbonate minerals were formed by introducing Fe^{2+}, Mg^{2+}, and Ca^{2+} ions into CO_3^{2-} solutions, resulting in the precipitation of siderite ($FeCO_3$) and dolomite ($CaMg(CO_3)_2$). Scanning electron microscopy (SEM) analysis revealed that siderite had a polycrystalline, spherical morphology ranging from 0.5 to 2 µm, while dolomite displayed a botryoidal shape ranging from 5 to 16 µm.

Consolidated drained triaxial tests (CD) were conducted on treated silica sand samples with siderite and dolomite carbonate cements (15%) as well as

nanoclay (2%), under both dry and saturated conditions. The findings indicated that specimens treated with siderite had higher strengths compared to those treated with dolomite in both dry and saturated conditions. The addition of nanoclay resulted in further strength increase, with the highest recorded strength at 525 kPa observed in specimens treated with siderite and nanoclay. Nanoclay-treated samples had a reduced brittleness and can be advantageous for soil improvement.

ABSTRACT: The paper describes innovative geotechnical methods to implement staged construction of surcharged embankments up to 5.5 m high on very soft blanket peat soils in north west Ireland. Shear wave velocities, CPT ball tests and direct simple shear tests were used to assess the undrained strength of the peat. Intermediate hold periods and consolidation benefits were exploited to optimise the filling schedule. Changes to instrumentation, basal reinforcement, anchorage detailing and filling rates were implemented to assure stability. Detailed interpretation of settlement and pore pressure responses during loading and unloading at instrument clusters is presented, including back-calculated field coefficients of consolidation and observed deformation ratios.

RÉSUMÉ: L'article décrit des méthodes géotechniques innovantes pour mettre en œuvre la construction par étapes de remblais surchargés jusqu'à 5,5 m de haut sur des sols tourbeux très mous dans le nord-ouest de l'Irlande. Les vitesses des ondes de cisaillement, les essais à la bille CPT et les essais de cisaillement simple direct ont été utilisés pour évaluer la résistance non drainée de la tourbe. Les périodes de détention intermédiaires et les avantages de la consolidation ont été exploités pour optimiser le calendrier de remplissage. Des modifications apportées à l'instrumentation, au renforcement basal, aux détails d'ancrage et aux taux de remplissage ont été mises en œuvre pour garantir la stabilité. Une interprétation détaillée des réponses au tassement et à la pression interstitielle pendant le chargement et le déchargement au niveau des groupes d'instruments est présentée, y compris les coefficients de consolidation sur le terrain rétro-calculés et les taux de déformation observés.

Keywords: Peat soils; observational approach; multistage construction; surcharge.

1 INTRODUCTION

The N56 national road forms the major transportation corridor along the remote, north-west coast of Co. Donegal, Ireland. Route upgrades require maintenance of existing 'lifeline' traffic and provision of new alignments. Much of the route is underlain by Atlantic Blanket Bog peat and shallow Caledonian Granite bedrock. The paper describes works on a 4.1 km two-lane road located just north of Glenties, the southern half of which falls within the Owenea River Freshwater Pearl Mussel catchment. Concerns about potential impacts of mass excavation of peat on this protected aquatic species led to a solution involving crushed rock fill and surcharge (Figure 1).

Figure 1. Looking south towards Glenties: temporary diversion on left and main embankment at surcharge level.

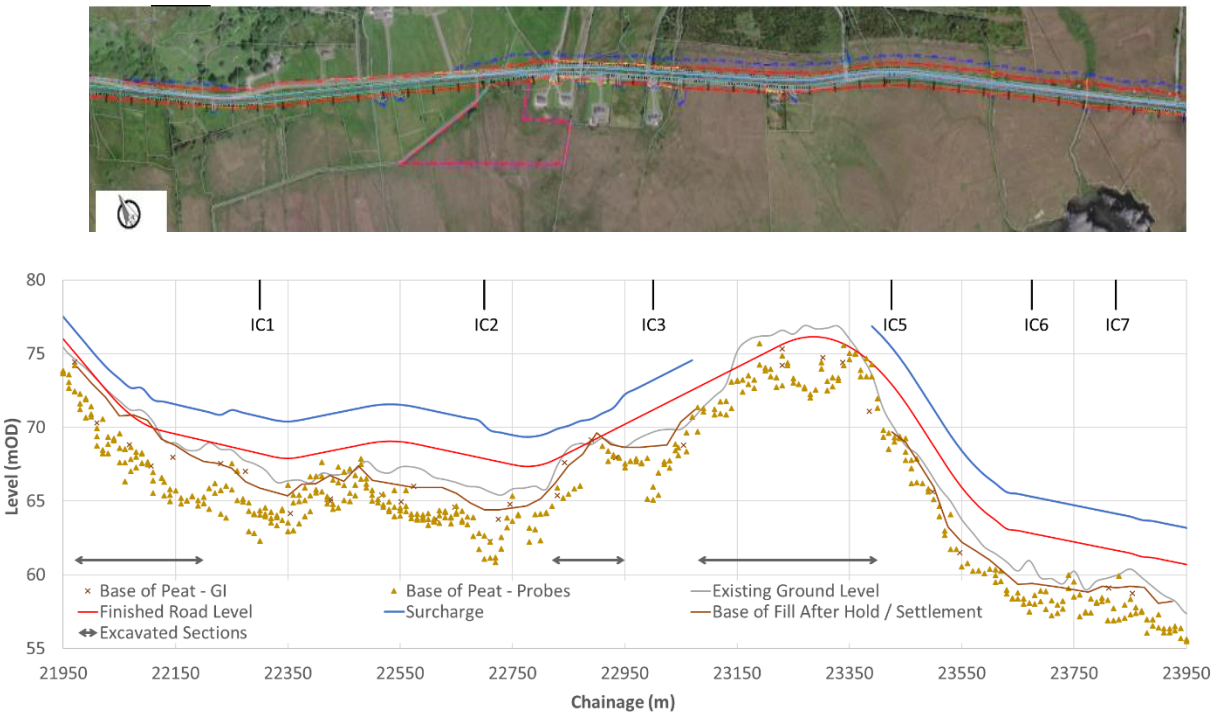

Figure 2. Aerial map of alignment and profile of peat and fill levels (surcharge and final settlements).

A 1.25 km long section was constructed directly onto extremely low-strength soils, using geosynthetic basal reinforcement, multi-stage construction and 1.5–2.5 m high temporary surcharge (Figure 2), informed by extensive instrumentation. The full surcharge height was achieved in all of this section with the exception of Chainage 23080 to 23400.

Construction commenced in early 2021, diverting traffic onto a 1.5 km single-lane temporary road (Figure 1), with supplemental investigations and refinements to the proposals prior to multi-stage embankment construction. Just under 50% of the surcharge material brought to site was used efficiently after completion of the hold period, filling excavations where peat removal was necessary (where at-grade or in cutting into peat). Geosynthetic reinforcement of the pavement foundations was also provided to mitigate differential creep movements. The completed works were opened to traffic in late 2022.

2 INVESTIGATING PEAT PROPERTIES

2.1 Peat probing

The construction contract required confirmation of peat thicknesses at 10 m intervals upon possession of the site. The contractor, Wills Bros. Ltd., provided the peat probes, noting depths in the range 0.3 m to 5.2 m, as shown in Figure 2. This probing provided more useful information in several areas than previous investigations, which were confined to locations close to the existing road embankments, typically 1.0 m in height above surrounding peat and prone to long-term deformation. Upwelling of pore pressures from the base of some probes was also observed, which was consistent with high ground water levels and low (hand) shear vane strengths at these locations.

2.2 Temporary road hand vane data

Construction of the temporary road (Figure 1) provided an opportunity to review some design assumptions from the perspective of risk avoidance, as disastrous peat slides had been initiated elsewhere in the county in the months prior to commencement.

Hand vane tests performed at shallow depths of 0.3 m to 0.6 m gave undrained strengths (c_u) typically in the range 5–50 kPa along the subgrade of the temporary road prior to its construction. Failure by extrusion at the edges of the temporary road was observed in the softest deposits, coincident with saturated conditions due to a shallow rock profile. It is likely that the filling rate was greater for the temporary road than for the mainline, with approximately 1.0m placed directly onto 30 kN grade geogrids.

2.3 Peat moisture contents and humification

Peat moisture contents (w) range from 600-1500% across the site, averaging ≈1000%. The degree of humification, according to the Von Post (1922) classification, generally increases with depth from H3 to H6/H7. Most of the peat incorporates fine and

coarse fibres, with a significant timber content observed at the northern end of the site.

2.4 Shear wave velocities & direct simple shear laboratory testing

In-situ shear wave velocities (V_s) in the range 14-40 m/s were measured at critical locations on site. An innovation on this project was the use of V_s profiles to infer c_u values, using the following established correlation: $c_u = 55.8(V_s/w)^{0.683}$ (Trafford and Long 2020). This confirmed extremely low strengths of the order of 4-6 kPa. These values fall slightly below Direct Simple Shear (DSS) test results conducted at normal stresses of between 6 and 7 kPa. Peat samples used for the DSS tests were retrieved from block samples at 0.6m depth. Both sets of strength data are shown in Figure 3.

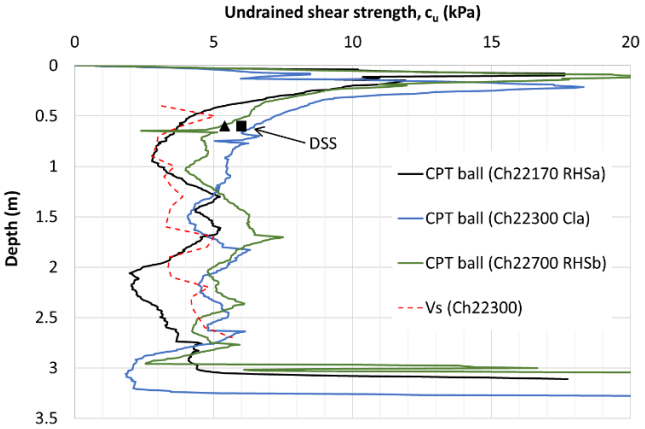

Figure 3. Undrained shear strengths derived from DSS tests, CPT ball tests and shear wave velocities.

2.5 CPTu / ball cone penetration testing

In-situ cone penetration testing (using a lightweight rig, Figure 4) was undertaken with standard piezocone and ball-cone apparatuses suited to lower strength organic peat soils at critical locations between the temporary road and the previous N56. Profiles of c_u values inferred from the CPT ball data (adopting $N_{t\,ball}$ = 15) are also shown in Figure 3 and are in keeping with those derived from shear wave velocities and DSS data.

2.6 Laboratory oedometer testing

A total of six maintained load oedometer tests were performed on 80 mm diameter, 19 mm high peat specimens obtained from serrated edge, thin-walled tubes. Sample depths ranged from 0.5 m to 2.4 m and natural moisture contents from 520% to 1136%. Load stages, each 24 h in duration, were 2.5, 5, 7.5, 10, 20, 40, 80, 120 and 80 kPa. The unloading generated an effective surcharge overload ratio (also known as Adjusted Amount of Surcharge or AAOS; Ladd 1971) of (120-80)/80, i.e. 50%, for the final stage. Two tests showed evidence of a yield pressure in the peat of between 5 and 10 kPa. Coefficients of consolidation c_v typically varied between 2 and 5 m^2/yr at initial load stages, reducing to 0.2 to 0.6 m^2/yr above 40 kPa. These values are at the lower end of those reported by Long & Boylan (2013) for Irish peats.

Figure 4. Lightweight CPT rig using ball-cone apparatus.

An extended (7-month duration) oedometer test with a maximum load of 100 kPa and AAOS of 69% was carried out on a block sample with natural moisture content 1030%. At maximum load, the normally consolidated creep strain rate was C_{sec}=0.017 with corresponding C_α=0.26 (assuming specific gravity G_s=1.5; initial void ratio e_0=15.5). This value is consistent with values quoted by Long & Boylan (2013). After reloading, a much-reduced secondary creep coefficient C_{sec}=0.001 was observed. However, this improvement was short-lived; the normally consolidated creep rate was re-established after a period of 2 months. This post-surcharge creep strain behaviour was also observed in research on Norwegian peats (Keary, 2020).

3 CONSTRUCTION DETAILING & INSTRUMENTATION

3.1 Stability analysis and design changes

Originally, a 200 kN geogrid was envisaged across the embankment base without any anchorage detail at the toes and a second 400kN layer to be wrapped back fully over and overlapping in the middle of the

embankment as part of the next fill stage. Given the lower than anticipated peat strengths, refinements were made by swapping the order of the geosynthetics and providing an anchorage length in Class 6I/6J fill on the basal layer. Side-slopes were reduced from 1:1 (vertical:horizontal) to 1:2, compromising the original goal of maximising the surcharge treatment on the underlying peat for a more stable arrangement. The embankment cross section at IC1 is shown in Figure 5.

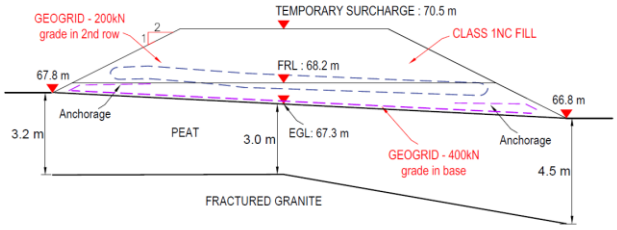

Figure 5. Embankment cross section at IC1, showing levels and geosynthethic reinforcement.

3.2 Detailed instrumentation clusters

Six instrument clusters (IC1, IC2, IC3, IC5, IC6, IC7), were incorporated along the surcharged embankment (locations shown in Figure 2), each comprising:

(i) a single settlement plate, installed at or close to the centre of the embankment cross section and at the original peat surface,
(ii) a single vibrating wire piezometer, installed at or close to the centre of the embankment cross section, intended for mid-depth within the peat,
(iii) a sub-surface profile gauge (SSPG) spanning transversely underneath the embankment, immediately beneath the original peat surface,
(iv) a pair of inclinometers, located within 1 m on either side of the embankment toes.

The purpose of these clusters was to inform the timing of surcharge release and monitor embankment stability throughout construction, in areas of weakest peat (as observed in geophysics, CPTu ball cone and probing) and considering local maxima in peat depths and fill heights. Regular instruments including settlement plates and Toe Survey Monuments (TSM) were placed at intervals of 25 m to 50 m along the alignment for continuity of measurement between IC locations. Additional peat testing and sampling was undertaken at these instrument cluster locations.

3.3 Staged filling & consolidation

Embankment filling stages above peat soils were limited in the contract specification to 0.5 m following a 2-week minimum hold period, equating to a maximum filling rate of 0.25 m/week. In practice, this global filling rate was never exceeded by the contractor, who achieved the maximum temporary surcharge height within 90 to 215 days, with average fill rates from 0.1 to 0.2 m/week. A target of 90% consolidation was specified by the designers for the final surcharge load stage with a minimum hold duration of 90 days at maximum height. Values of AAOS varied from ≈23% to ≈77% from across the six ICs, partly due to local alignment issues and avoiding variability in surcharge heights.

4 ANALYSIS OF MONITORING DATA

4.1 Practicalities for observational control

Processing of twice-weekly instrument readings assisted in directing the contractor away from areas with higher deformation ratios or pore pressures in order to control filling in areas of highest risk. This did not result in delays to the contract overall, due to ease of access across the site enabled by the proximity of the new alignment to both the existing alignment and the temporary road.

4.2 Settlements and consolidation

An example of the vertical settlement response (from the SP and central SSPG measurements) to eight stages of embankment loading at IC1 is presented in Figure 6, at which the peat thickness was ≈3 m. The embankment loading is presented as a total stress increase, corrected for submergence, as the lower portion of the embankment settled beneath the groundwater table (≈0.6 m deep at this location). The early stress increments (Stages 1–3) involved an initially fast becoming slower settlement rate, with a steadier rate from Stage 4 onwards. This is probably due to the cumulative effects of consolidation carried over from previous increments, while also reflecting the dramatic reduction in the coefficient of consolidation (c_v) characteristic of peat at higher effective stress levels (e.g. Carlsten, 1988). There is broad agreement between the SP and (central) SSPG settlements at IC1, with primary consolidation strains of ≈46% and ≈41% respectively at the time of surcharge release.

The corresponding degree of consolidation (U_v) at this time, estimated by applying the Asaoka (1978) method to the settlement plate data, was 96–100% at all ICs. An overall c_v was computed for the entire construction process, assuming that the full embankment height was attained instantaneously at the midpoint of the staged loading period. Double drainage was assumed based on ground investigation data, and a reducing peat layer thickness as a result of settlement was modelled. The values of c_v ranged

between 2 to 8.5 m^2/yr across all ICs, corresponding to effective stress ranges from 38 to 97 kPa.

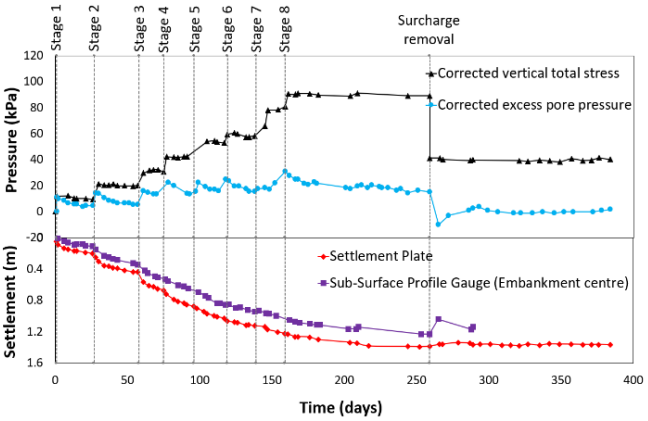

Figure 6. Excess pore pressure and settlement response to embankment loading at IC1.

Values of the compression index (C_c) were back-figured from the SP data, using settlements from Stage 3 onwards, at which stage the yield stress will have been exceeded. The average water at each IC location was used to calculate e_0. C_c was typically found to fall in the range 4 to 15.8, broadly in keeping with values for other Irish peats (Long and Boylan 2013).

4.3 Pore pressures

The large strains in Figure 6 also had implications for the pore pressure interpretation, with the piezometric datum changing as a consequence of piezometer settlement. For example, at IC1, it was assumed that the piezometer settled by 42% of the surface settlement, given (i) its initial depth of ≈1.75 m within the peat, (ii) that the stress increase within the central peat imposed by the embankment decayed little over the peat depth, and (iii) the uniformity of the peat itself, evidenced from water contents and shear wave velocity profiles. Excess pore pressures, corrected on this basis, are also shown in Figure 6. Temporary negative excess pore pressures were measured for a period of ≈3 weeks after surcharge removal, in tandem with minor swelling, before reverting to ≈0 kPa.

The increments in corrected total stress and excess pore pressure at the start of each of the stages were examined; the sums of each over the entire eight stages were found to be approximately equal (when allowance was made for the time lag between filling and the first piezometer reading). Therefore, the maximum excess pore pressure corresponding to instantaneous embankment construction was assumed to be equal to the corrected total stress reached by Stage 8. U_v values were corrected to relate to the mean of the entire peat layer, rather than at just the piezometer level; these ranged from 64–88% across all ICs with corresponding values of c_v ranging from 0.5–2.1 m^2/yr, lower in general than the Asaoka-derived values and requiring more assumptions. Possible reasons for discrepancies between c_v values derived from laboratory, pore pressures and settlements will be explored in a later publication.

4.4 Deformation and stability

The concomitant interrogation of inclinometer and SSPG data at the IC locations on this scheme was considered a novel means of monitoring embankment stability on peat. The ratio of the lateral deformation at the toe of the embankment on both sides of the mainline (ΔY), inferred from the inclinometer pair to the maximum settlement of the embankment (ΔS) at any time deduced from the SSPGs was computed. For single-stage embankments constructed on deep, soft mineral soils, a global trend of $\Delta Y/\Delta S < 0.3$ is considered acceptable (Jardine, 2002), but it is recognised that this might vary for shallow peat soils. In Figure 7, it can be seen that the deformation ratio history falls within this limit for IC1. The 'jagged' nature of the ratio observed in the early load stages may be because the lateral position at which the maximum SSPG settlement occurred varied.

Considering the broader dataset, the range of lateral movements per 0.5 m incremental loading stage were in the range of 50-70 mm on average, but extrema of the order of 100-200 mm were observed on the first and second fill stages. Higher ΔY/ΔS ratios arose where instruments were sited close to the previous load alignment (pre-compressed ground), in which case low central SSPG readings were compared with modest lateral displacements in softer ground along the margins. This was unrepresentative of the material behaviour overall.

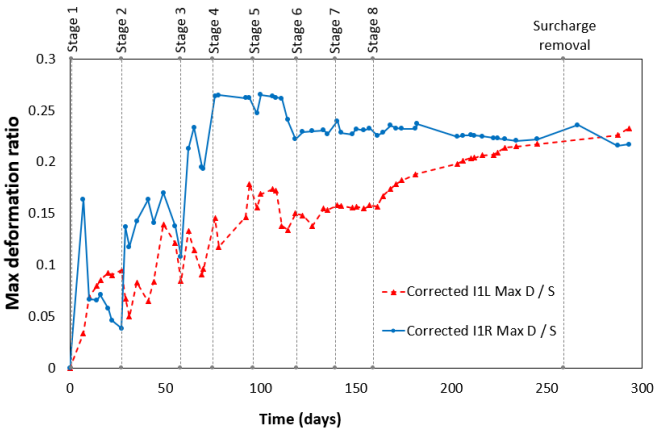

Figure 7. Maximum deformation ratio for IC1.

4.5 Lessons learned on monitoring equipment and informing stage/surcharge releases

Continuous pore pressure monitoring would have been preferable to capture more reliable baseline pore pressures and for greater resolution on the response to each fill increment. A companion extensometer would have been useful to establish the exact position of each piezometer as consolidation of the peat progressed.

Movement trends in TSMs and settlement plates were effective in informing the range of deformations along the embankments in addition to the detailed ICs. The TSM readings were more useful for detecting lateral movements in the early stages, predominantly because of the closer spacings (25 m) and size of dataset. The settlement plates were reliable but did not give as good a picture of overall deformations across each section and tended to be influenced by previous road embankment/field accesses in some locations. Hence the collective view afforded by concentrated (IC) and longitudinal (TSM/SP) data was vital.

Also, when fill becomes buoyant upon settling below the water table, there is effectively a very modest unloading phase during each intermediate hold if sufficient time is allowed. Observations of slight recovery in lateral movements close to release points were noted. These helped to signal a suitable point to recommence filling, if also confirmed using the other instruments, particularly the piezometers. This behaviour requires further research.

Consolidation targets were difficult to validate at two ICs; excess pore pressures upon surcharge release were ≈10 kPa higher than baseline levels. This topic will be explored in a future publication.

5 CONCLUSIONS & FUTURE RESEARCH

Innovative investigation techniques and sampling methods were utilised to establish extremely low peat strengths and refine the proposed embankment design configurations to be implemented at the N56 site. Building embankments up to 5.5 m high on very soft peat up to 5 m deep was challenging but was successfully executed without failures, primarily due to adoption of slow, controlled filling rates, geosynthetic basal reinforcement and substantial specialised ground information and instrumentation monitoring.

A total duration of 8–10 months was required to perform the earthworks related to embankment plus surcharge construction, hold and removal. This is approximately 6–8 months longer than standard excavate and replace methods in peat of similar depths. Some further optimization of geosynthetic reinforcement and construction filling rates could potentially reduce costs and construction durations by 1–2 months. It should be noted that the surcharge strategy boasts significantly better carbon credentials than an excavate-and-replace approach.

Analysis of settlement data interpreted by the Asaoka (1978) method showed that consolidation was achieved generally between 80 and 100 days. These field rates of consolidation are significantly faster than implied by laboratory oedometer tests.

In a novel research project led by the University of Galway, long term settlements are being monitoring at the N56 site with a view to quantifying by how much (and for how long) the surcharging process reduces the secondary settlement rate in the peat.

New concept of drilling auger for displacement pile installation

Nouveau concept de tarière pour la mis en œuvre de pieux déplacés

A. Krasiński*
Gdansk University of Technology, Gdansk, Poland
**adam.krasinski@pg.edu.pl*

ABSTRACT: In 2020, a new version of the screw displacement auger for pile installation in soil was developed and patented in Poland. It was named DPDT (Displacement Pile Drilling Tool). The general aim of its development was to reduce the soil resistances to the auger during screwing into the ground while maintaning a good load-bearing capacity for the screw displacement piles. The "DPDT-Auger" prototype was tested as a scaled-down model in the laboratory as well as in full-scale in the field. Its efficiency was compared with an ordinary SDP auger in two ways: by assessing soil resistances during screwing into the ground and by assessing the bearing capacity of completed piles. This paper presents the field tests and their results. Over 80 piles were tested in six test sites. Among them, 24 piles were instrumented and subjected to static load tests. The test results were generally positive and showed that the DPDT auger generates less torque than the SDP auger but requires more rotations and a slightly longer pile installation time. When it comes to the bearing capacity of the compression load, both DPDT and SDP piles showed similar characteristics.

RÉSUMÉ: En 2020, une nouvelle version de la tarière à vis pour l'installation de pieux dans le sol a été développée et brevetée en Pologne. Il a été nommé DPDT (Displacement Pile Drilling Tool). L'objectif général de son développement était de réduire les résistances du sol à la tarière lors du vissage dans le sol tout en conservant une bonne capacité portante aux pieux vissés. Le prototype "DPDT-Auger" a été testé en modèle réduit en laboratoire ainsi qu'en vraie grandeur sur le terrain. Son efficacité a été comparée à celle d'une tarière SDP ordinaire de deux manières: en évaluant les résistances du sol lors du vissage dans le sol et en évaluant la capacité portante des pieux terminés. Cet article présente les tests sur le terrain et leurs résultats. Plus de 80 pieux ont été testés sur six sites d'essai. Parmi eux, 24 pieux ont été instrumentés et soumis à des essais de chargement statique. Les résultats des tests ont été globalement positifs et ont montré que la tarière DPDT génère moins de couple que la tarière SDP mais nécessite plus de rotations et un temps d'installation des pieux légèrement plus long. En ce qui concerne la capacité portante de la charge de compression, les pieux DPDT et SDP présentent des caractéristiques similaires.

Keywords: Screw displacement pile; pile drilling tool; pile installation; bearing capacity of pile.

1 INTRODUCTION

Screw displacement piles and columns are currently one of the most popular technologies for piling and subsoils improvement. They are characterized by several technical and economic advantages, such as: quick construction, no excavation, no shocks and noise, and relatively good load-bearing capacity and stiffness in the ground (Bottiau, 2006; Basu & Prezzi, 2009). However, the disadvantage of this technology is the high resistance during the screwing of pile augers (drills, tools), especially in non-cohesive soils. These resistances require the use of piling machines (drilling rigs) with high rotational power and make it difficult to pass through dense intermediate layers and to create longer piles in the bearing layers.

The high screwing resistance was primarily the reason for the development of various varieties and shapes of displacement drills (SDP, "Omega", FDP, CMC, "DeWaal", APGD and others). Also, the author of this article, who has been dealing with the subject of screw displacement piles at the Gdansk University of Technology for years (habilitation thesis - Krasiński, 2013), has developed his own prototype version of the DPDT (Displacement Pile Drilling Tool) pile auger. It was patented in Poland (Krasiński, 2020, patent No PL 235442 B1). The scheme of the DPDT auger is shown in Figure 1.

In the DPDT auger, the disc helix, which is in the lower part of the typical SDP or CMC augers, has been replaced with a less prominent bar helix (round or square). The main reason for this was to reduce the torque M_T value when screwing the augur into the soil

and to reduce or eliminate the loosening of non-cohesive soil around the pile base. A side effect of the change is the slightly conical shape of the pile base which, however, according to research (Krasiński et al., 2022a,b), does not significantly reduce soil resistance under the pile base. An additional advantage of the DPDT drill is its simple design, which reduces the costs of its production and regeneration.

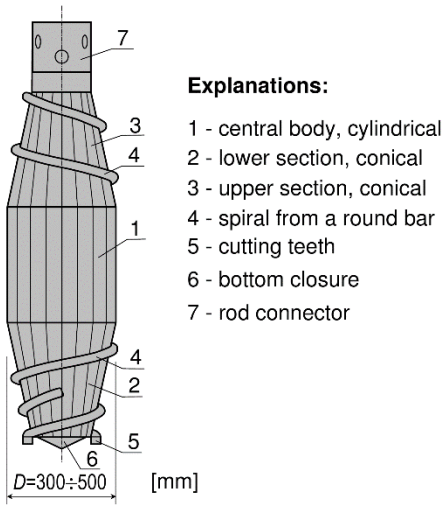

Figure 1. Scheme of new DPDT pile auger (Krasiński, 2020).

2 RESEARCH PROJECT

The development of the DPDT auger became an inspiration to launch the 2019-2022 "DPDT-Auger" research project by the consortium of Gdansk University of Technology and the Polish geotechnical contracting company Budokop Geotechnika Sp. z o. o. (Consortium Leader).

The research project examined the effectiveness of the DPDT auger by comparing it with other drills, first in the laboratory and then in situ in full-scale. Model-scale studies gave generally positive results as described, e.g., in Krasiński et al. (2022b).

The results of the entire research project, which, in addition to comparative research, also included several other issues regarding the execution, calculation and design of screw displacement piles and columns, were included in the Report (Krasiński et al. 2022a) and briefly characterized in the works of Krasiński et al. (2022b, 2023) and Krasiński (2023).

In a field study of the research project, a prototype DPDT auger was tested against an SDP auger. Figure 2 presents photographs of the tested drill bits, which also shows a modified version of the new DPDT-S auger, with the central cylindrical section (soil displacement body) shortened by half. Field tests were carried out on prepared experimental plots, where drill and pile tests were combined with in-situ and laboratory tests of the subsoil.

Figure 2. View of pile augers to be tested.

3 FIELD INVESTIGATIONS OF AUGERS AND PILES

As part of the research project, 6 field experimental plots were organized in several places in northern Poland. A total of over 80 screw displacement piles were made and tested by consortium member - Budokop Geotechnika. The given number included 24 research piles, and the rest were anchor piles for test loading stands. The geotechnical structure of the subsoil in the plots was determined using boreholes, CPTU and DMT soundings, and laboratory tests of soil samples. During the field study, first the augers from Figure 2 were tested for resistance and parameters of their drilling into the ground during the installation of research and anchor piles. Then, in each plot, static load tests were performed on 4 test piles, instrumented by a chain of vibrating wire extensometers.

4 TEST RESULTS

The complete results of field tests of the augers and piles are included in the Report (Krasiński et al., 2022a). This article presents only sample results regarding auger screwing resistance and pile settlement characteristics (Q-s) from load tests. All the results are characterized only qualitatively. A detailed quantitative and statistical analysis of the discussed results has been omitted in this article due to space limitations.

4.1 Test results of auger screw-in resistances

The resistance of the augers when screwing into the ground was defined by three basic parameters: torque M_T, specific number of rotations per unit of penetration

n_R and total time of pile hole drilling t_D. Other parameters were omitted as less important derivatives of the three above parameters (Krasiński, 2014). The SDP, DPDT and DPDT-S augers are compared in terms of M_T, n_R and t_D in Figure 3, 5, 7 and 9. They concern three selected research plots (No. II, IIIab and IV). In order to connect screwing resistances with the soil conditions, the auger resistance graphs appear alongside geotechnical profiles and q_c cone resistance charts from CPTu soundings. The research plots were specially selected due to their non-cohesive soils in load-bearing layers.

The aim of the pile tests and measurements was to determine the load-bearing capacity and Q-s characteristics of the piles, divided into the shaft (Q_s) resistances and the base (Q_b) resistances in the lower load-bearing soil layers. Comparative charts from static tests of piles in selected experimental plots No. II, III and IV are presented in Figure 4, 6 and 8. Both these results and those from the remaining experimental plots showed that piles made with the tested DPDT and DPDT-S augers and SDP auger are characterized by similar parameters of interaction with the soil (bearing capacity and Q-s characteristics for compression loads).

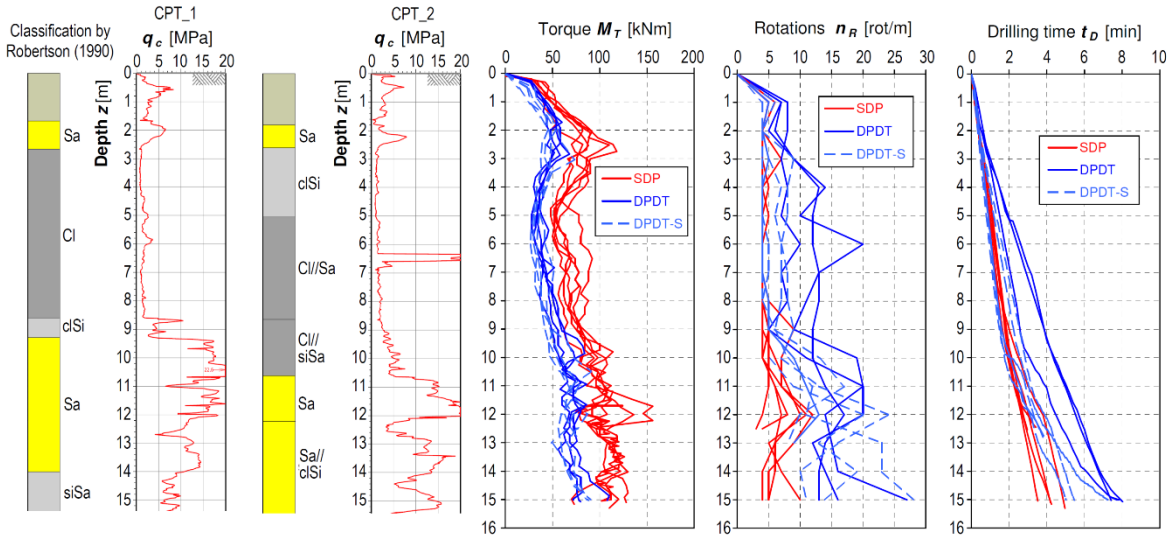

Figure 3. Drilling resistances of pile augers with CPTu diagrams on the experimental plot No. II.

The presented results confirmed observations previously made in the model studies described in Krasiński et al. (2022), and should generally be assessed positively. As expected, the prototype DPDT and DPDT-S augers generated lower values of M_T torques than the SDP auger. However, it was obtained at the expense of a larger number of rotations n_R and a longer pile hole drilling time t_D. The quantitative differences between individual plots are not the same and depend on the geotechnical structure of the subsoil. However, the general patterns in these differences were consistent or similar in all cases.

4.2 Pile load test results

Static pile load tests (SPLT) in field plots were carried out with additional instrumentation of pile shafts using a chain of vibrating wire extensometers Geokon - model 1300 (A9) (Geokon, 2023).

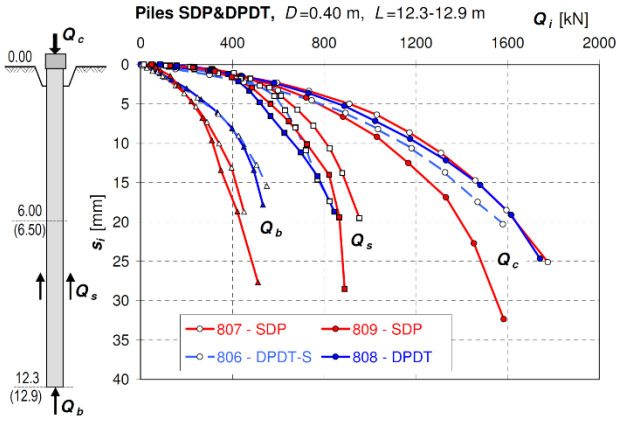

Figure 4. SPLT results of piles on the field experimental plot No. II.

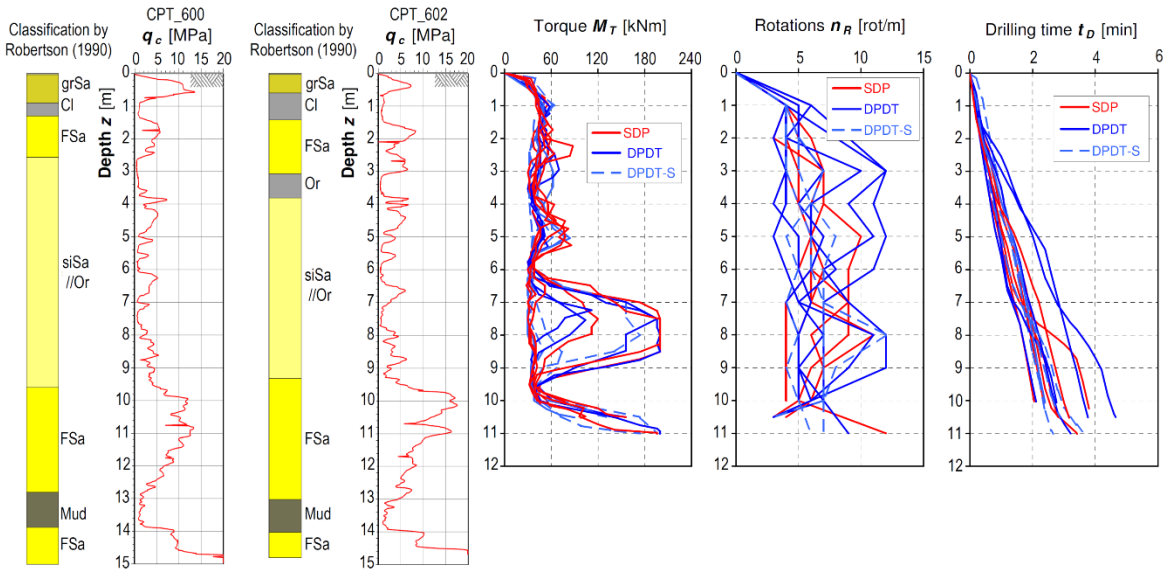

Figure 5. Drilling resistances of pile augers with CPTu diagrams on the field experimental plot No. IIIa.

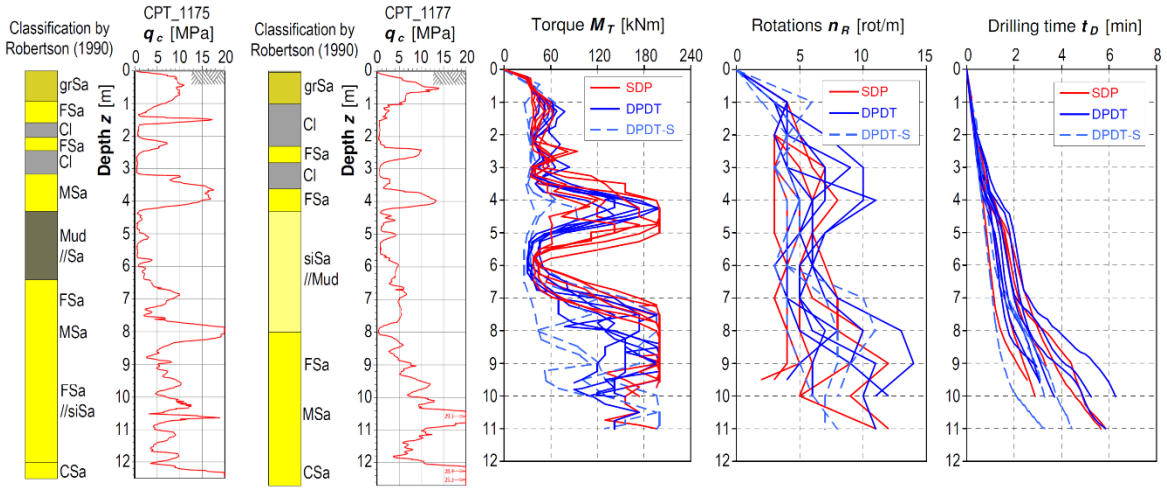

Figure 6. Drilling resistances of pile augers with CPTu diagrams on the field experimental plot No. IIIb.

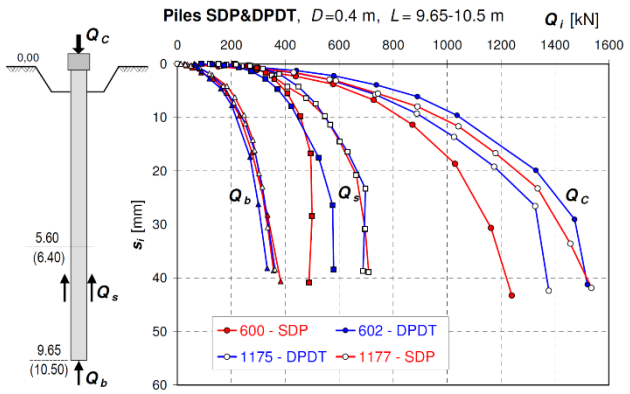

Figure 7. SPLT results of piles on the field experimental plot No. III.

To sum up, the performance of the prototype DPDT and DPDT-S drill bits should once again be positively assessed, mainly due to the fact that they generate a lower M_T torque value than the SDP drill bit. This advantage is crucial and outweighs the disadvantage of increased n_R and t_D parameter values. A lower value of M_T makes it possible to achieve greater auger penetration depths, and thus create longer piles with greater load-bearing capacities. It also provides a greater guarantee of successfully overcoming stronger interlayers in the subsoil and creating piles of desired lengths. At the same time, the shapes of the DPDT and DPDT-S drill bits do not deteriorate the load-bearing capacity or *Q-s* characteristics of the thus constructed piles.

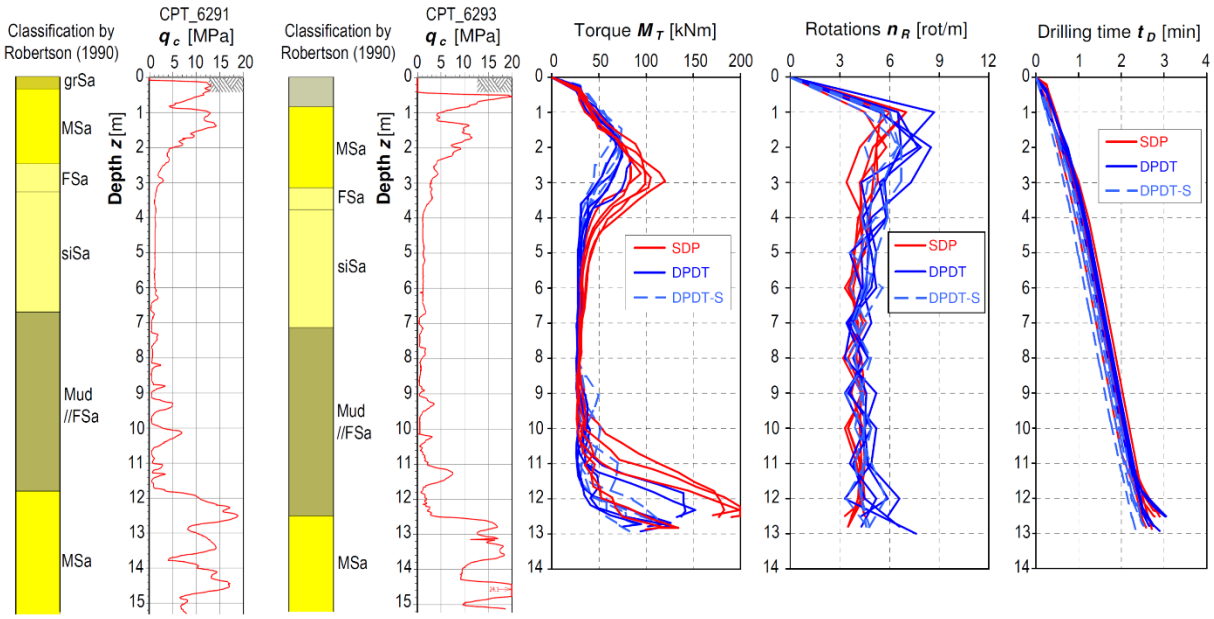

Figure 8. Drilling resistances of pile augers with CPTu diagrams on the experimental plot No. IV.

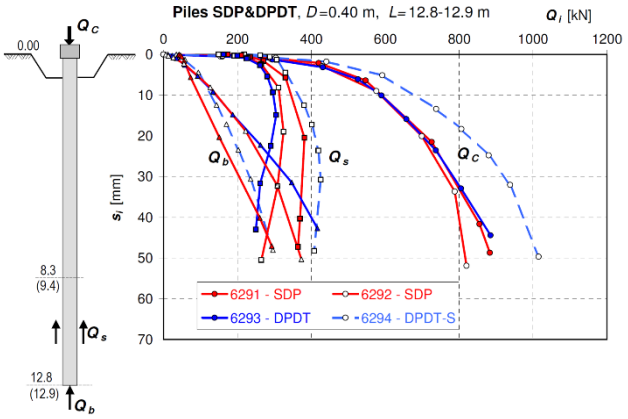

Figure 9. SPLT results of piles on the experimental plot No. IV.

5 CONCLUSIONS

i) Comparative analyses showed that the DPDT and DPDT-S auger indeed required lower torque M_T values but a higher number of rotations per depth unit n_R and longer drilling time t_D in comparison with the SDP auger. The middle section of the DPDT-S auger is shortened by half in relation to the DPDT auger. Thanks to this, the value of the torque M_T is additionally reduced. The overall balance of screwing resistance should be considered favorable for the DPDT and DPDT-S augers, because the generation of a lower torque value allows for the achievement of greater drilling depths and pile lengths, and more effectively overcomes stronger soil layers.

ii) Piles made with SDP and DPDT (DPDT-S) augers are characterized by very similar interaction with subsoils of various geotechnical configurations. Statistically, the load-bearing capacity and stiffness of both types of piles are similar.

iii) In practice, the use of DPDT and DPDT-S drills may be of technical and economic benefit without any significant risk of lowering the quality and load-bearing capacity of the piles in comparison to those made by traditional augers, e.g. SDP. On the contrary, piles and columns made with DPDT drills can achieve more favorable shaft shapes with smaller deformations, neckings and soil inclusions, which are observed when using classic drills with disc helix spirals. They are also more advantageous when making piles in contaminated soils and landfill areas.

ACKNOWLEDGEMENTS

The described test and analyses results of augers and piles were obtained from research works conducted in the "DPDT Auger" research project, financially supported by the Polish National Centre for Research and Development (project No. POIR 4.1.4. 0124/18, “Development of a method and tools for the installation of screw displacement columns/piles in various ground conditions in Poland, together with the preparation of a methodology for the design and acceptance of works”). The project was carried out by the consortium of Gdansk University of Technology and the Polish geotechnical company Budokop Geotechnika Sp. z o.o.

Comparative trials of geosynthetic materials in the base of road pavement on the section of the Central Ring Road in the Moscow Region

Essais comparatifs de matériaux géosynthétiques dans la base du revêtement routier sur le tronçon du Périphérique Central de la région de Moscou

ABSTRACT: During the period from 2016 to 2019, a complex comparative trial was conducted by "Russian Highways" State Company on the Central Ring Road in Moscow region. Under extremely high traffic volume of 10161 vehicles per day, 22 trial section, with various geosynthetic materials below the aggregate base layer were constructed and monitored in order to demonstrate the improvement in pavement performance. This paper describes a series of static plate loading and falling weight deflectometer tests together with rut depth measurement. On the basis field tests and monitoring, polypropylene geogrids appeared to be the most effective materials for aggregate layers stabilisation. The greatest effect from the use of polypropylene geogrids was achieved by reducing the rut depth. As a result, there is an increase in the residual life of pavement, which for polypropylene geogrids ranges from 22 to 105%, depending on the manufacturer.

RÉSUMÉ: Entre 2016 et 2019, un essai comparatif complexe a été mené par la société d'État « Autoroutes russes » sur le périphérique central de la région de Moscou. Sous un volume de trafic extrêmement élevé de 10161 véhicules par jour, 22 sections d'essai avec divers matériaux géosynthétiques sous la couche de base de granulats ont été construites et surveillées afin de démontrer l'amélioration des performances de la chaussée. Cet article décrit une série d'essais de chargement statique de plaques et de déflectomètre à poids tombant ainsi que la mesure de la profondeur de l'ornière. Sur la base des tests terrain et du suivi, les géogrilles de confinement en polypropylène sont apparues comme les matériaux les plus efficaces pour la stabilisation des couches de granulats. Le plus grand effet de l'utilisation de géogrilles en polypropylène a été obtenu en réduisant la profondeur de l'ornière. Il en résulte une augmentation de la durée de vie résiduelle du revêtement qui, pour les géogrilles en polypropylène, varie de 22 à 105 %, selon le fabricant.

Keywords: Geosynthetic materials; pavement optimization; stabilization.

1 INTRODUCTION

The current trend towards increasing axle loads and driving speeds on highways has clearly identified the problem of rapid wear of road pavement materials. The use of geosynthetic materials in the asphalt and base layers can increase the strength and stiffness of the structure, improving its service life. In 2008 Russian Federal Highway Agency approved a manual for flexible pavements with reinforced aggregate layers design. Original concept and design method for mechanically stabilized granular layers was developed in Saint Petersburg Military Engineering-Technical University (VITU) on the basis of laboratory and field tests in 1999-2002. The effect of aggregate modulus increasing using geogrid is presented by enhancement factors, incorporated into traditional pavement design procedure. Enhancement factors are calculated depending on the thicknesses and modules of the structural layers, the diameter of the wheel footprint and the brand of geogrid. Only polypropylene punched and drawn (P&D) geogrids were tested by VITU and therefore included into the design manual.

Later, in 2015, a national standard GOST R 56338 “Geosynthetic materials for reinforcing the lower layers of road pavement bases” was issued approving the minimum tensile strength required as 30kN/m.

Since then, pavement optimisation via geogrid installation has become widely spread. At the same time, construction industry explored various types of geosynthetic materials with reinforcing/stabilising functions, like hexagonal, welded and glued geogrids, woven geotextiles and geocells. The mechanism of their interaction with aggregate and the effect they produce differs significantly. Haliburton et al. identified a few mechanisms of enhancement, the main

ones being lateral restrain and tensioned membrane. The first is realized due to the interlock of crushed stone particles in the rigid cells of the geogrid, and the second due to frictional contact with subsequent tension of the geosynthetic material.

State Company "Russian Highways" (an operator for toll roads in Russia) decided to run comparative research on this subject and validate the performance of different geosynthetic materials on the federal level.

2 TEST SITE

A perfect opportunity arose during the construction of a temporary bypass for the section of Central Ring Road in Moscow region in 2016. Expected traffic volume of 10161 vehicles with 22% heavies per day provided an accelerated testing with about 4 million ESALs in a two-year period. Typical road cross-section is shown on the Figure 1.

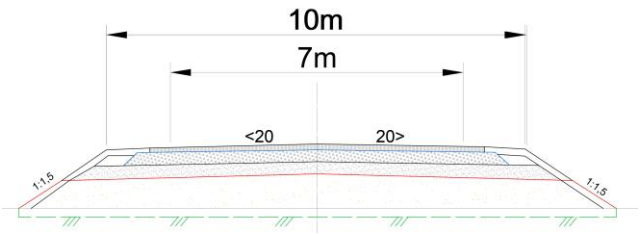

Figure 1. Road cross-section.

2.1 Pavement structure and geosynthetic materials

Pavement structure is shown, Figure 2. It consisted of two asphalt concrete layers (AC), aggregate mix type C-4 with maximum particle size of 80 mm and medium sized sand. Geosynthetic materials were placed between base and sand layers.

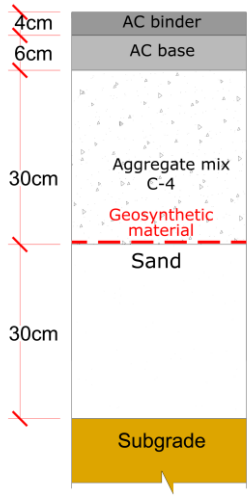

Figure 2. Pavement section.

Along 720m of test section 22 types of geosynthetic materials together with control site with no reinforcement were installed. Each reinforced section was 20m long. The following material were presented:

- 6 types of 40kN/m punched and drawn (P&D) polypropylene (PP) biaxial geogrids;
- 2 types of hexagonal (TX) geogrid 17 and 20kN/m;
- 4 woven geotextiles from 40 to 100kN/m;
- 6 types of woven polyester (PE) geogrids/composites 50kN/m;
- 2 types of basalt geogrid;
- 2 types of geocells.

The full list of geosynthetic materials is presented in the Table 1.

Table 1. List of geosynthetic materials.

Materials on site are shown, Figures 3-5.

Figure 3. Geocell.

Figure 4. Geocomposite.

Figure 5. Hexagonal P&D geogrid.

Geosynthetic materials samples were taken in order to perform quality control tests on tensile strength and strain at maximum load in accordance to GOST R 55030 (equivalent to ISO 10319).

2.2 Testing

Static plate loading tests were carried out in accordance with standard STO AUTODOR 10.3-2014 (close equivalent to DIN 18134, plate diameter 300mm, maximum pressure 0.5MPa). Under this standard, E_{v1} and E_{v2} modulus are measured together with "resilient modulus", obtained from the recovered resilient part of settlement during the uploading stage. The ratio of E_{v2} to E_{v1} characterizes the quality of the layer compaction and should be less than 2.5.

First series of static plate tests was conducted on the sand subbase layer surface. Average resilient modulus appeared to be 75.15MPa and was lower than designed 108MPa value.

The second series of plate tests was conducted on the surface or aggregate base. Results for modulus are shown in the section 3.

For the further analysis, the effect of geosynthetic materials on the total resilient modulus on the surface of the asphalt concrete layers had to be evaluated. These tests were carried out with the falling weight deflectometer (FWD). The tests had been being carried out during two years, twice a year in mid-August and the third ten days of April. Typical results are shown in Section 3.

After two years in-service a rut depth measurement was performed using a mobile road diagnostic laboratory equipped with a system based on planar lasers and video cameras as shown on the Figure 6.

Figure 6. Mobile road laboratory.

At that moment, the site had passed about 4 million ESALs.

3 TEST RESULTS

3.1 Static plate tests and FWD

Test results for resilient modulus on the base surface, E_{v2} to E_{v1} ratio, and results for asphalt are shown on the Table 2. Control section modulus on the base level was 114MPa.

Table 2. Plate test results.

N	Material	Base surf. MPa	Comp. indicator	Asphalt surf. MPa
1	PPBXGG1	134	2.24	288
2	PPBXGG2	139.5	2.26	301
3	PEGG1	119.5	2.74	322
4	PEGG2	115	3.65	315
5	PPGT1	150	1.74	293
6	PPGT2	124	2.70	249
7	PPGT3	132	2.56	266
8	PEGG3	161	3.48	261
9	PEGC1	128.5	1.25	243
10	PPBXGG3	117.6	4.37	305
11	PEGT1	131.5	2.50	244
12	PPBXGG4	137	1.28	310
13	PPTXGG1	136.7	1.27	323
14	PPTXGG2	131.5	1.13	316
15	GCell1	112	2.27	288
16	PEGG4	126.5	1.04	250
17	PPBXGG5	169	1.02	265
18	BGG1	139	3.72	295
19	PEGG5	154.5	1.16	282
20	GCell2	152	1.22	149
21	BGG2	175	1.07	273
22	PPBXGG6	131	3.05	283

Due to the compatitive ethics material names were hidden from the participants. In gerenal, all section with geosynthetics had shown higher resilient modulus (up to 1.5 times higher) compared to the control before asphalt layers installation.

The average resilient modulus on the base surfest for 8 sections with punched and drawn (P&D) polypropylene (PP) geogrids appeared to be the highest one, followed by polyester geogrids and textiles. Modulus over geocell sections was not consistent, but on average the lowest one.

3.2 Falling weight deflectometer tests

Typical results of summer measurements (2019) are shown, Figure 7.

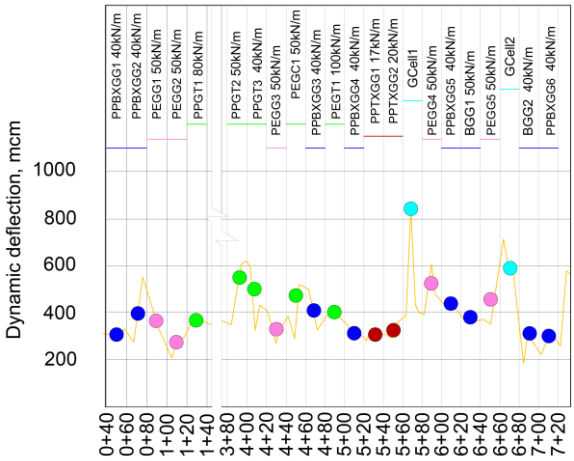

Figure 7. Typical results of FWD measurements.

In general, it was obresved that geocell materials had shown the lowest modulus, followed by geotextiles. Almost all geogrids performed better with polipropylen punched and drawn leading.

3.3 Rut depth control

Control section showed the rut depth of 17mm. Measurements for other sections are shown on the Figure 8.

The majority of sections with geosynthetic materials accumulated less rut depth that control section. This fact is related to the better base layer performance and its resistance to the structural deformation when reinforced or stabilised.

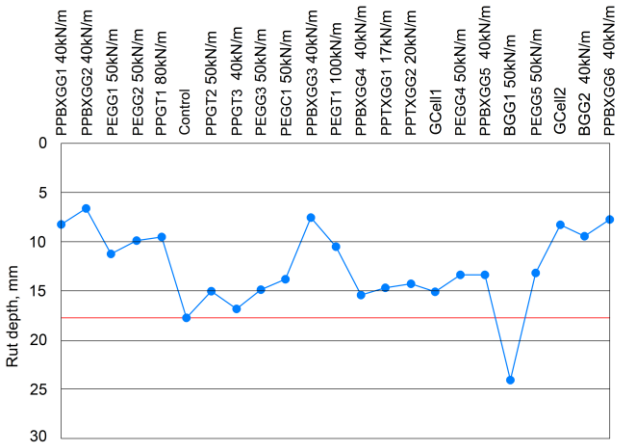

Figure 8. Rut depth measurements.

The best results had been observed along sections with punched and drawn (P&D) polypropylene (PP) biaxial geogrids.

Woven geotextiles with strength approximately equal to that of geogrids showed lower modulus values on the base and asphalt concrete, as well as deeper ruts. 80 and 100 kN geotextiles showed a high modulus at the base level, but after two years of service the modulus at the asphalt concrete surface was lower than in areas with geogrids

4 CONCLUSIONS

Whitin the described research, the most effective materials for reinforcing/stabilising discrete layers are polypropylene geogrids. The greatest effect from the use of polypropylene geogrids is achieved by reducing the rut depth. As a result, there is an increase in the residual life of road pavement, ranging from 22 to 105% depending on the manufacturer. Modulus measurements for the best performing group of geogrids are presented on the Figure 9.

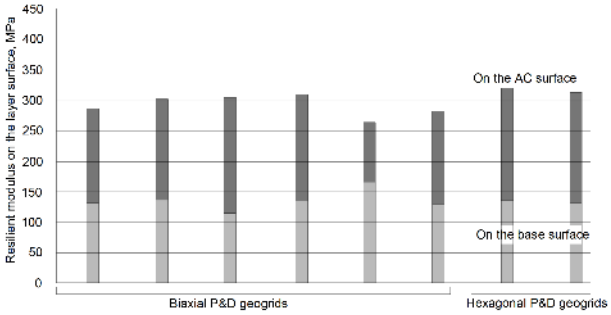

Figure 9. Resilient modulus on the top of AC and base layers.

Hexagonal geogrids having two times lower tensile strength comparing to biaxial one had shown sufficient efficiency and were included into national standard GOST R 56338 in 2023.

Geotextiles and woven geogrids, operating on the principle of a tensioned membrane, on average showed lower modules on the base surface and after two years of service, the deflection of asphalt concrete above them was greater.

Rigid geogrids, operating on the principle of limiting the lateral movement of aggregate particles, ensured high performance during construction and subsequently maintained the rigidity of the base and the entire structure as a whole.

At the moment, "Russian Highways" State Company promotes stiff stabilising geogrid installation as competitive alternative to cement or bitumen treatment.

Degradation of expanded clay strength after creep tests

Dégradation de la résistance de l'argile expansée après des essais de fluage

ABSTRACT: After subjecting a material to a constant load maintained over time (creep), it is expected that internal crack growth will occur, resulting in a degradation (decrease) of its strength. This paper analyses the strength of single expanded clay grains after being subjected to constant loads for a period of 40 days. These tests, which, from now on, will be, referred to as creep tests, were performed using three different load magnitudes. To determine whether there is a degradation of the grain strength or not, the results are compared with those obtained in grains tested in simple compression without performing a creep test previously. Expanded clays are a lightweight expanded ceramic aggregate also known as LECA, obtained from heating clay soils in two phases (drying and expanding phases) to high temperatures (above 800ºC and 1100ºC, respectively) in a rotary kiln. The expanded clay obtained is characterized for presenting a very porous and low-density core, and a densely vitrified outer shell, notably more resistant.

RÉSUMÉ: Après avoir soumis un matériau à une charge constante maintenue dans le temps (fluage), on s'attend à ce que des fissures internes se développent, entraînant une dégradation (diminution) de sa résistance. Cet article analyse la résistance de grains d'argile expansée après avoir été soumis à des charges constantes pendant une période de 40 jours. Ces essais, qui seront dorénavant appelés essais de fluage, ont été réalisés en utilisant trois magnitudes de charge différentes. Pour déterminer s'il y a ou non dégradation de la résistance des grains, les résultats sont comparés à ceux obtenus avec des grains testés en compression simple sans essai de fluage préalable. Les argiles expansées sont des agrégats céramiques, également connus sous le nom de LECA, obtenus en chauffant des sols argileux en deux phases (séchage et expansion) à des températures élevées (supérieures à 800ºC et 1100ºC , respectivement) dans un four rotatif. L'argile expansée obtenue se caractérise par un noyau très poreux et de faible densité, et une enveloppe extérieure densément vitrifiée, notablement plus résistante.

Keywords: LECA; strength degradation; creep; breakage.

1 INTRODUCTION

Lightweight expanded clay aggregate (LECA) is an artificial ceramic aggregate that has numerous uses in construction, such as the manufacture of lightweight concrete, lightweight geotechnical backfill on structures, fills over compressible soils, and the manufacture of concrete for the construction of new buildings (Prisco, 2007).

LECA grains have a rather spherical shape and a size that usually varies between 10 and 20 mm, although there are other commercial diameters (Figure 1).

The LECA strength, as for other ceramic materials, presents values with certain variation that can be adjusted by means of a statistical Weibull function. This type of distributions were used for simple compressive strength of different ceramic materials, (Roces-Alonso et al., 2021, Anaya et al., 2022) and for other breakage modes (Lei et al., 2020, Lei et al., 2021).

Figure 1. Intact lightwight expanded clay grains.

Considering that the breakage of a grain is associated with the presence of defects in its interior,

it is more likely that a larger volume element will have more and larger defects, so it is common that the strength of the different grains decreases with increasing element size. Thus, it is reasonable to introduce the grain volume, in the Weibull strength distributions of the grain (McDowell et al., 2013).

When a material is subjected to previous stresses or aggressive atmospheres, its strength characteristics degrade significantly. Numerous examples of this phenomenon can be found in literature, for different materials and after different situations, such as: freeze–thaw cycles for rock (Jia et al., 2015), granite (Tan et al., 2011) or concrete (Qu et al., 2023), freeze–thaw and fatigue for marble (Song et al., 2021), sandstone in carbon dioxine atmosphere (Laskowski et al., 2023) or after fatigue for various materials, such as composites (Philippidis et al., 2007) or sandstone (Chu et al., 2022).

In this article, the degradation of the compressive strength of LECA grains after being subjected to a 40-day creep test is analyzed.

2 MATERIAL AND METHODS

2.1 Materials

The expanded clay used for the tests was manufactured by LECA at its plant in Avelar (Portugal). The main components of the expanded clay are silicon oxide (SiO_2) and aluminium oxide (Al_2O_3), which account for more than 75% of the total grain composition (Roces, Muñiz-Menéndez et al. 2021)

The grains tested had an average diameter (obtained as the mean of three perpendicular diameters measured with callipers) between 14 and 18 mm, as it can be seen in Fig 1.

Each of the grains consisted of a vitrified outer shell and a porous core that gives it its characteristic lightness. The specific dry weight of the grains tested is 5.7 kN/m^3.

2.2 Methods

For the performance of this research, 340 individual grains of expanded clay were tested (121 grains tested under creep loads and 219 tested applying instantaneous loads), according to the following procedure:

- Determination of the weight of each of the grains using a balance with an accuracy of 0.001 g.
- Measurement three of perpendicular diameters (the largest, the smallest and a third perpendicular to the two previous ones) using a calliper of precision 1/50 mm. Grains with an average diameter of less than 14 mm or more than 18 mm were discarded.
- Mechanical test on the grains. These tests were of two types:
  - Simple compression breakage, using a Point Load type equipment, according to ASTM D5731-16 standard. The maximum breaking load of the grain is recorded.
  - To perform the creep tests, each grain was mounted on an oedometer-type equipment. This equipment allows a load to be applied by means of weights and maintained over time. In this paper, the testing period chosen was 40 days. The grains that survived this test were further subjected to a uniaxial compressive stress, to determine their residual strength, performing a Point Load Test.

A scheme of these tests is shown in Figure 2. All these tests were carried out at the Laboratorio de Geotecnia-CEDEX in Madrid (Spain).

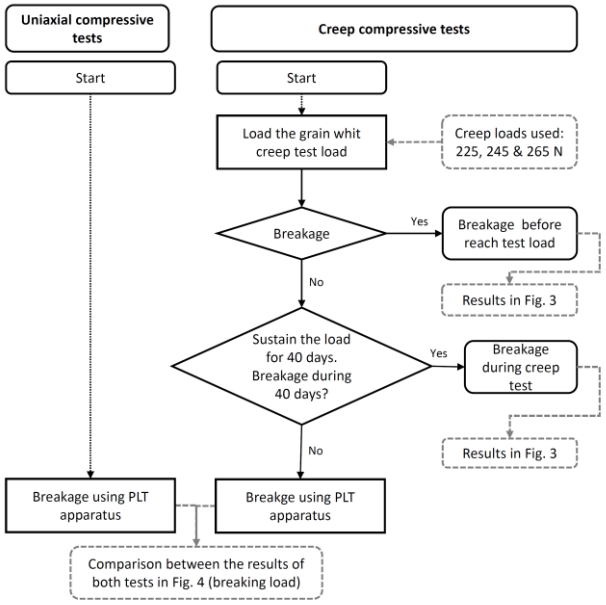

Figure 2. Flowchart of the work carried out.

The stress in a grain subjected to uniaxial compression can be estimated from the following Equation:

$$\sigma = \alpha \cdot \frac{F}{d^2} \quad (1)$$

Being σ the grain stress, F the force applied to the grain, d the grain diameter (calculated as the arithmetic mean of the three measured diameters) and α a constant. In this study, a value of $\alpha = 1$ will be used as recommended by (McDowell et al., 2000).

3 RESULTS

In Figure 3, the results obtained from performing creep tests over 121 LECA grains are presented. In this plot, the breakage time of each of the grains tested is shown in terms of its average diameter and the constant load to which it was subjected during the 40-day testing period. Those grains that broke before reaching the creep load are indicated as BB. Grains that did not break during the entire duration of the test are indicated as NB. These last were furtherly tested under an instantaneous uniaxial compressive stress, being these results plotted in Figure 4. Finally, the grains that broke during the 40-day period are represented between BB and NB.

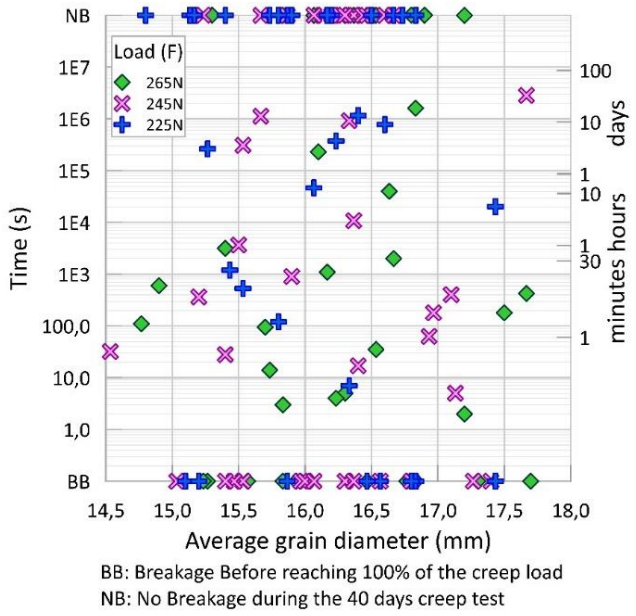

Figure 3. Time required for the breakage of creep-tested grains, depending on their diameter and the load tested.

Since the value of the breaking stress obtained according to Eq. 1 for LECA grains is not a deterministic function, but a stochastic value, in order to estimate the influence of the creep loads and time on the breaking stress of the grains, distribution functions must be compared. For this purpose, the strengths obtained are sorted and, depending on the number of tests available, the cumulative distribution function (CFD) is performed.

Figure 4 shows the comparison between grains previously creep tested (depending on the creep load used) and the tests carried out on grains without previous creep test.

In order to be able to make this comparison, the following aspects must be taken into account: the weakest grains of those tested at creep have already broken before reaching the creep load (BB in Fig 3) or have broken during the creep test for a time of less than 40 days (Figure 3 shows the grains that have broken during creep). Therefore, it seems logical to shift the CFD of the failure stress of these grains by a value equal to the percentage of grains broken during the creep test. This percentage is determined by summing up both the grains that failed while the creep load was being applied, as well as the ones that failed during the 40-day proposed application period of the constant testing load. Bearing this in mind, as it is indicated in Figure 4, the CFD curve corresponding to the grains tested under an instantaneous uniaxial compressive load after being subjected to a 225 N constant load during 40 days was shifted 57%, while the curves representing the grains that resisted 245 N and 265 N creep loads were shifted 70% and 74%, respectively. In Figure 4, both the CFD curves corresponding to the grains previously tested under constant loads and the ones only tested under an instantaneous uniaxial compressive stress are plotted.

In order to minimize the influence of grain size on grain strength, the results were taken for similar mean diameter values. The mean values for each of the series are shown in Figure 4.

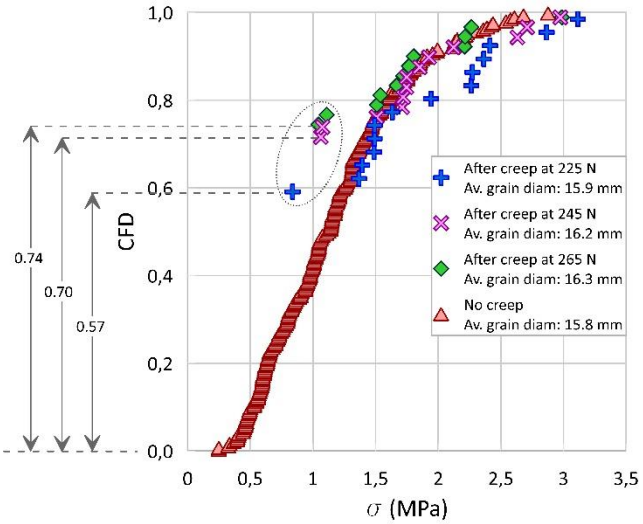

Figure 4. Comparison of breakage stresses of broken grains after creep tests of grains without previous creep test.

Figure 4 shows that there is a great coincidence between the results obtained from performing a point load test on grains previously and not previously tested under creep loads. It can also be seen that the coincidence is not exact, as there are 5 grains from the previously creep-tested group, that don't seem to have the same behavior. These LECA grains, marked in the graph with an ellipse, have a residual strength of approximately 0.5 MPa lower than the expected one. This value is determined by comparing the strength values of the CFD curves obtained for each of the previously creep-tested grains and the CFD curve obtained for the not previously tested grains.

4 CONCLUSIONS

An experimental study was carried out on the failure of expanded clay grains at room temperature, under simple compression, both under sustained and instantaneous loads. The study includes the results obtained from testing 340 grains (121 grains subjected to creep loads and 219 tested under instantaneous loads).

For grains that did not fail after a 40-day period of load application during creep tests and were tested under uniaxial instantaneous compression loading, there was no significant variation between the remaining strength and the original strength. Only in 5 grains marked with an ellipse in Figure 4. a lower strength than that obtained for grains without prior creep test is observed. This decrease in strength could be due to internal crack growth during creep or to statistical variation in the results.

On the ground settlements observed during execution of jet grouting columns in urban area adjacent to a historic building

Tassements au sol observés lors de l'exécution de colonnes de jet grouting en zone urbaine adjacente à un bâtiment historique

ABSTRACT: During the execution of jet grouting columns for the stability of deep excavation of the construction pit for new residential building, the adjacent historical building settled for 15 to 35 mm causing cracks in its masonry walls. The historical building is 132 m long and 18 m wide having shallow foundation 2 m below ground surface. The cracks of the building during the execution of JG columns were noticed up to 90 m away from the construction activities. In the paper, we present the tentative explanation of the reasons for the observed behaviour and the activities that brought us to the conclusions. The ground profile consists of three characteristic soil layers resting on a weak bedrock. The foundation layer for the historic building is a very dense clean alluvium gravel with a thickness of 10 m. Next 10 m consist of saturated very loose to loose silty gravel with sand. Following some hints from the literature, we believe that the drilling and jet-grouting procedures affected the loose structure of the layer between 10 and 20 m depth resulting in far reaching settlements of entire upper stiff gravel layer and structures resting on it.

RÉSUMÉ: Lors de l'exécution des colonnes de jet grouting pour la stabilité de l'excavation profonde de la fosse de construction d'un nouveau bâtiment résidentiel, le bâtiment historique adjacent s'est affaissé de 15 à 35 mm, provoquant des fissures dans ses murs en maçonnerie. Le bâtiment historique mesure 132 m de long et 18 m de large et possède des fondations peu profondes à 2 m sous la surface du sol. Les fissures du bâtiment lors de l'exécution des colonnes JG ont été constatées jusqu'à 90 m des travaux de construction. Dans cet article, nous présentons une explication provisoire des raisons du comportement observé et des activités qui nous ont amenés aux conclusions. Le profil du sol est constitué de trois couches caractéristiques reposant sur un substrat rocheux fragile. La couche de fondation du bâtiment historique est un gravier alluvionnaire propre et très dense d'une épaisseur de 10 m. Les 10 m suivants sont constitués de gravier limoneux saturé, très meuble à meuble, avec du sable. Suite à quelques indications tirées de la littérature, nous pensons que les procédures de forage et de jet grouting ont affecté la structure lâche de la couche entre 10 et 20 m de profondeur, entraînant des tassements étendus de toute la couche supérieure de gravier rigide et des structures reposant sur elle.

Keywords: Jet grouting; settlements; deep excavation.

1 INTRODUCTION

The stability of 13.2 m deep construction pit was provided by total 127 jet grouting (JG) columns, subsequently anchored by pre-stressed ground anchors in three levels. 25 m deep JG columns 2 m in diameter at 1.8 m spacing were used in order to reach impervious bedrock and make the construction pit watertight.

After one month of execution, 85 JG columns were installed. The last 5 JG columns were made in the immediate vicinity of adjacent historic building. The subsequent inspection of this building showed that cracks occurred not only in the vicinity of construction works but up to 90 m away from the location of executed JG columns. The historic building is 132.3 m long, 18.4 m wide and 19 m high having 3 storeys and the attic.

Geodetic measurements showed that the maximum settlement of the historic building from the beginning of the works were 31 mm at the most exposed SE corner of the building. 30 m farther away, the settlement of the building was still 15 mm.

Before the complete stop of the installation of JG columns, additional 21 columns were made at minimum distance of 15 m from the historic building. These JG columns caused additional 5 mm of settlements of the SE corner of the building.

At this stage, investigations started in order to understand the ground behaviour during installation of JG columns, to assess the state of the historic building, to design the rehabilitation measures for it and to adjust the procedure for installation of final 20 JG columns.

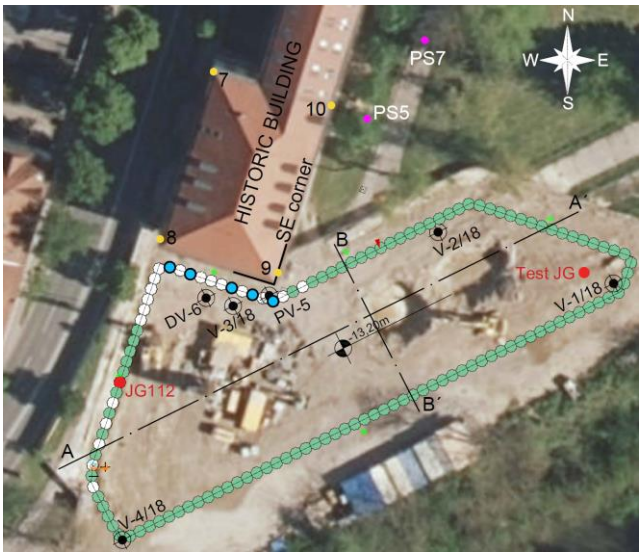

Figure 1. Layout of the construction pit and adjacent historical building, location of boreholes (black), benchmark points (yellow), test JG columns (red) and persistent scatterers (magenta). Ground profile along section A-A' is shown in Figure 2.

2 GROUND CONDITIONS

Four boreholes were made in the design phase. The geotechnical cross-section A-A' is presented in Figure 2. Below 1-2 m thick fill layer, a layer of very dense sandy gravel appears down to the depths between 9 to 13 m. Between this stiff gravely layer and the weak bedrock at a depth of 24 m, proluvial loose gravels with 15 to 25 % of fines were found. A significant difference in stiffness was observed with depth. The upper dense sandy gravel and the lower loose silty gravel were characterized by elastic moduli of 95 MPa and 5 MPa, respectively.

Groundwater level is generally 14 m below the ground surface but can rise up to 10 m below the ground surface.

From Figure 2 one can observe that the loose ground layers vanish at the western side of the construction pit.

3 CONSTRUCTION

3.1 Jet grouting columns

JG columns of 2 m diameter at a spacing of 1.8 m were made using two phase technology with 7 mm nozzle, grout pressure of 420 bar with flow rate 525 l/min and air pressure of 8 bar. Other parameters varied according to the soil profile and are given in Table 1.

Table 1. JG execution parameters.

Depth (m)	w/c ratio	Lift (cm/min)	Rotations/ minute
0.0 – 9.5	1.0	50	9
9.5 – 14.8	1.0	40	8
14.8 – 24.0	1.4	36	6
> 24.0	1.4	30	10

3.2 Monitoring

Observation of settlements/heave of historic building and nearby road had been foreseen during construction works. Zero reading of all benchmark points was made before the works started. However, further readings were not made until cracks were observed in the historic building 1 month after the start of construction work. At that time, 2 mm to 31 mm settlements were recorded on the adjacent building.

Detailed inspection of the historic building showed that cracks extended up to 90 m away from the construction activities.

3.3 Temporary suspension of construction

Due to the observed harmful influences of the execution of JG columns on the historic building next to the construction site, construction activities were temporarily suspended.

Structural engineers were employed to inspect and reinforce the historic building and geotechnical experts were asked to find the reasons for the observed ground response and give guidance for the execution of remaining 20 JG columns.

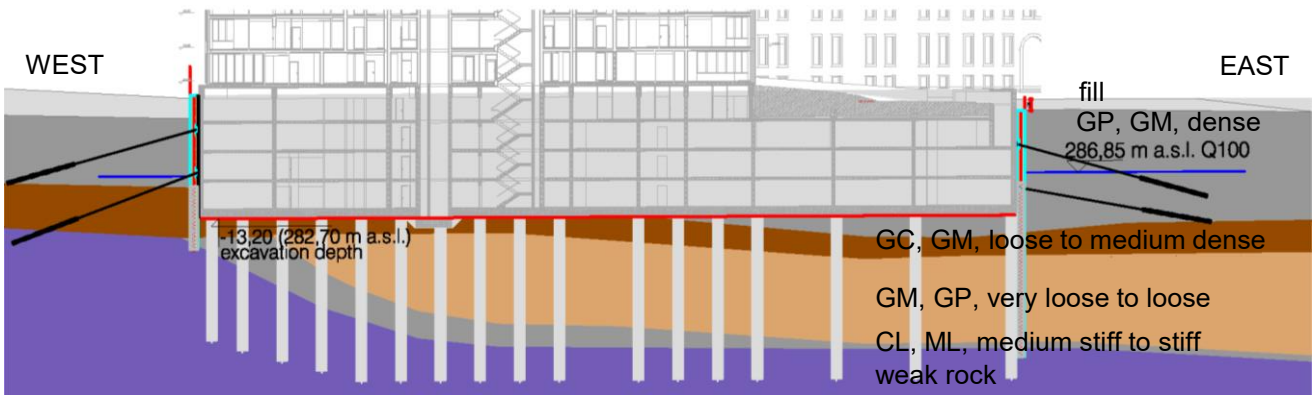

Figure 2. Cross section

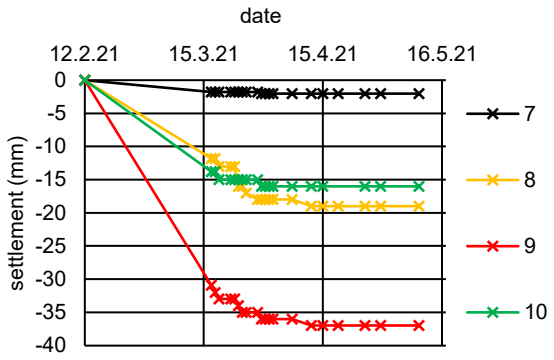

Figure 3. Settlements of the historic building measured at benchmark points.

4 ADDITIONAL INVESTIGATIONS

Initially, it was believed that the damage of the existing building was due to the execution of the last 5 JG columns exactly on the day when cracks were noticed by the users of the historic building (5 JG columns coloured in blue at the southern side of the historic building in Figure 1).

Although this explanation seemed reasonable, it could not explain the appearance of cracks of the building up to 90 m away from its southern wall. Alternative assumption was made that the settlements of the building occurred gradually throughout the execution of all JG columns. In order to test this assumption, satellite radar interferometry (InSAR) was used for displacement observation in the absence of geodetic measurements of installed benchmarks. Furthermore, additional boreholes were drilled (PV-5 and DV-6), two test JG columns were made ("Test JG" and "JG 112") and FEM analyses were performed.

4.1 Satellite InSAR

We have performed Persistent Scatterer Interferometric Synthetic Aperture Radar (PS InSAR) processing on Sentinel-1 satellite radar images. Sentinel-1 acquires an image every 6 days; in total, 41 images from September 2020 to May 2021 were used. PS InSAR is a technique used to estimate local ground deformation with millimetric accuracy. It focuses on the phase-stable scatterers and identifies pixels in which a single persistent scatterer (PS) represents the dominant backscattering signal in a series of interferograms. In built areas, permanent scatterers can be detected on man-made structures (roofs, fences, roads, etc.); many PS were detected within the construction period in the area.

Several PS were found on the historic building and enabled the interpretation of displacements during the entire construction period. The absolute accuracy of interpreted individual displacements (in the period of 6 days) is 2 to 3 mm, while relative accuracy is ~1 mm/year (for the time series). Figure 4 presents the movements of two scatterers, PS5 and PS7, located close to the SE corner of the historic building (see Figure 1). It can be clearly observed that movements started immediately after the start of the execution of JG columns and continued at a nearly constant rate throughout the grouting works.

4.2 Literature review

From the reported case histories on the influence of execution of JG columns on ground movements it can be learned that heave is more often a problem than ground settlements. Nevertheless, few papers report settlements during the execution of JG columns (Eramo et al, 2011; Guan and Yang, 2019) without giving any explanations for such ground behaviour.

Byle (2017) reports that loose gravels with high percentage of fines are prone to inner instability and represent challenging conditions for drilling and grouting operations in terms of ground movements.

4.3 Execution of test JG columns

Two JG columns were made with continuous measurements of settlements at 2, 4, 6, 8 and 10 m distance from the JG column centre (Figure 5). Test JG columns are marked as "Test JG" and "JG 112" in Figure 1.

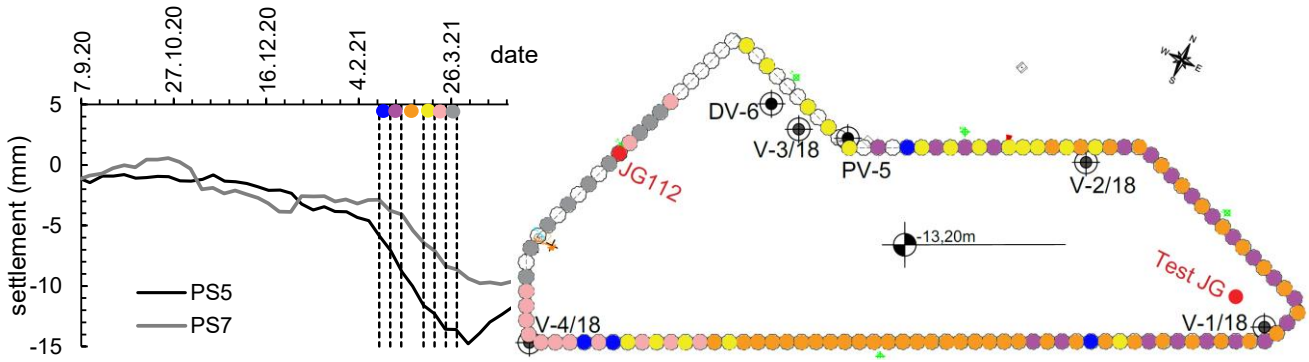

Figure 4. Left: Ground settlements from InSAR data for PS 5 and PS 7 (locations are shown in Figure 1); Right: Time sequence of execution of JG columns is shown by respective colours shown on left graph.

During the execution of "Test JG", from 0.6 mm to 0.4 mm settlements were observed at 2 m and 10 m distance respectively. Surprisingly, 0.6 mm settlement was observed also at the SE corner of the historic building, which is located 40 m away from the "Test JG".

The execution of "JG 112" which is located within the JG wall had much less effect on its surroundings. Maximum settlement at 2 m distance was 0.2 mm, at 4 m 0.1 mm and no settlements were measured at larger distances including benchmarks on historic building. This is partly due to the fact that it is located between two adjacent already executed and hardened JG columns and partly to the fact that the layer of loose silty gravel is thinner at this location.

Figure 5. Settlement monitoring during execution of TestJG.

4.4 Numerical analyses

Based on the suggestion by Byle (2017), volume reduction of loose ground may occur during drilling and grouting operations. Hence, a simple 2D FEM analysis was performed along the section B-B' (see Figure 1) of the construction pit. Measured difference in stiffness of two dominating soil layers was considered. Volume change within JG body was imposed on the model (i) along the entire height of the JG column, (ii) only in the upper layer and (iii) only in the loose lower layer.

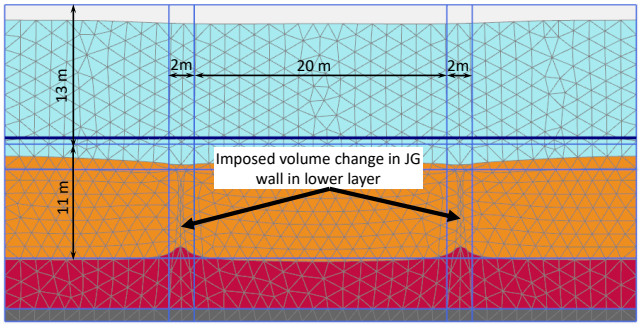

Figure 6. Displacements from 2D FEM analysis considering volume change within JG column body in lower layer.

The first two models resulted in surface settlements concentrated in the vicinity of JG column walls. Only the third model gave the behaviour, similar to the observations on site (Figure 6) where settlements extended far beyond the extent of the construction pit.

5 CONCLUSIONS

Based on the analyses of all the collected data, we have concluded that the most likely cause of the deformation of the ground and the adjacent historic building is a lower layer of very loose to loose silty gravel with sand. Drilling and grouting procedures cause the change in loose structure of the soil, which leads to a volume reduction of this soil layer in the vicinity of each individual JG column and consequently settlements of the ground surface. Due to the presence of stiff 10 m thick upper layer of clean gravel above the layer of loose silty to clayey gravel, the deformations are detected even at very large distances from the executed JG columns. That is why the ground outside the construction pit gradually settled during the entire period of construction of JG columns. Cracking of the historic building was therefore not only the consequence of the execution of the 5 JG columns next to the southern wall of the historic building.

The installation of remaining 19 JG columns started 2 months after the first damage on historic building had been observed. These works had hardly any effect on the nearby structure. The reasons for this are (i) a large number of JG columns had been already in place for over 2 months and represented a significant reinforcement of the soil, (ii) only one JG column per day was executed near the historic building with reduced w/c ratio of the grout and (iii) the observation during execution of test JG column "JG 112" showed that by a proper order of execution, most of the remaining JG columns can be executed in-between previously executed JG columns thus reducing ground settlements.

Precision measurements constrain the implementation of more accurate testing in earthworks quality assurance

Les mesures de précision limitent la mise en œuvre de tests plus précis dans l'assurance qualité des travaux de terrassement

B.G. Look*
AGTRE, Brisbane, Australia
**lookburt@agtre.au*

ABSTRACT: Density was selected as the key Quality control (QC) parameter as its high precision was recognized in the early days. Precision in QC was chosen in favour of more relevant but difficult to measure parameters at the time. Precision is not the same as accuracy. As dry density ratio (DDR) index is now fully embedded in QC, one may mistakenly think that the factors measured are the key factors. DDR was intended to be just part of the decision-making process of quality and verification of the design requirements. On projects which use end product specifications, a DDR value then becomes THE de facto decision on pass / fail. This simplifies the site decision in having assessment metronomically stated. Because traditionally industry did not or cannot measure something should not diminish its importance. Several in-situ devices have been available for the past two decades and various research has shown the benefits. Data was acquired as part of field trials over multiple "live" projects. Conventional QC testing was supplemented with other field strength and modulus tests. Correlating to established DDR tests is blind to the influences of other factors influencing strength and modulus. Such tests measure a combination of underlying material, material quality, moisture content and density. A 95% DDR does not have a singular strength or modulus value as measured with one-to-one correlated testing as this is governed by material type.

RÉSUMÉ: La densité a été choisie comme paramètre clé du contrôle de la qualité (CQ), car sa haute précision a été reconnue dès les premiers jours. La précision en CQ a été choisie au profit de paramètres plus pertinents mais difficiles à mesurer à l'époque. La précision n'est pas la même chose que l'exactitude. Comme l'indice de rapport de densité sèche (DDR) est maintenant entièrement intégré dans le contrôle qualité, on peut penser à tort que les facteurs mesurés sont les facteurs clés. Le DDR devait n'être qu'une partie du processus décisionnel de qualité et de vérification de la conception. Sur les projets qui utilisent des spécifications de produit final, une valeur DDR devient alors LA décision de facto sur la réussite / l'échec. Cela simplifie la décision du site en ayant l'évaluation métronomiquement énoncée. Le fait que, traditionnellement, l'industrie ne mesurait pas ou ne pouvait pas mesurer quelque chose ne devrait pas en diminuer l'importance. Plusieurs dispositifs in situ ont été disponibles au cours des deux dernières décennies et diverses recherches ont montré les avantages. Les données ont été acquises dans le cadre d'essais sur le terrain dans le cadre de plusieurs projets « en direct ». Les essais de contrôle qualité conventionnels ont été complétés par d'autres essais d'intensité de champ et de module. La corrélation avec les tests DDR établis est aveugle à l'influence d'autres facteurs influençant la résistance et le module. Ces tests mesurent une combinaison du matériau sous-jacent, de la qualité du matériau, de la teneur en humidité et de la densité. Un DDR à 95% n'a pas de valeur de résistance ou de module unique, telle que mesurée par des tests corrélés un à un, car elle est régie par le type de matériau.

1 INTRODUCTION

The aim of compaction is to reduce the air voids, and with many associated gains such as strength, reduction of permeability, reduced settlement, etc. The use of maximum dry density (MDD), optimum moisture content (OMC), dry density ratio (DDR) and California Bearing Ratio (CBR) originated from studies completed in the 1930s and standardised by the 1960s. The DDR compares the field dry density to the laboratory MDD.

The standard density test has revolutionized construction testing, enabling engineers to assess and control soil compaction in a consistent manner. DDR has been used successfully as density tests are very precise. Precision is not the same as accuracy, which is closeness to a "true" value, while precision is the closeness of the measurement to each other.

Look (2018) showed that DDR is very precise but is not very accurate. Conversely, the plate load is (PLT) is accurate, but not very precise. Such findings

were also apparent when adopting DDR as the defacto standard as a quality QC measurement. The decision on pass / fail can then be simply applied to the site decision making process in having your daily assessment activities metronomically stated. This may create a false confidence in the design and construction process when precision is not the same as accuracy.

Engineers assume a direct relation between density and strength or modulus (i.e., the greater the density achieved, the higher the strength or modulus of the compacted material). However, the peak CBR does not necessarily occur at the MDD. Seed and Chan (1959) had shown the peak strength is lower at the MDD due to the lower moisture content even when the density is lower (Figure 1 from Leroueil and Hight, 2013).

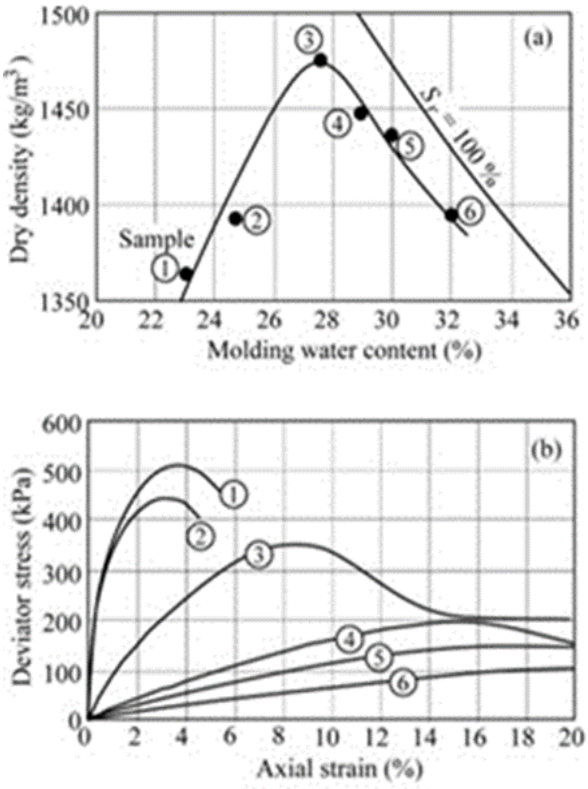

Figure 1. (a) Influence of moulding water content on the dry density and (b) stress-strain relationships.

Several in-situ devices have been available to industry for the past two decades with many benefits being constrained by correlations to DDR. Nazarian and Correia (2009) show the field modulus is highly dependent on the moisture content (Figure 2). Drying or wetting after compaction can significantly influence the modulus result. A minor change in moisture content results in 6% change in density, but 300% change in modulus. Most of these modulus values still satisfy a 95% MDD criteria – but at a different moisture content.

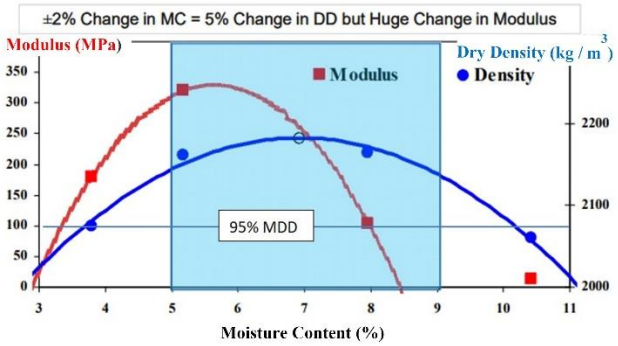

Figure 2. Impact of moisture on density and modulus.

2 HISTORICAL DDR AND CBR IN QC

2.1 Past decisions with present considerations

Figure 3 shows a retrospective decision process using a force field analysis to arrive at accepting DDR in QC testing. This approach is used as a decision-making tool. It compares the forces that are either driving the movement toward a decision or goal (helping forces) as compared to the factors blocking the movement towards that goal or decision (hindering forces).

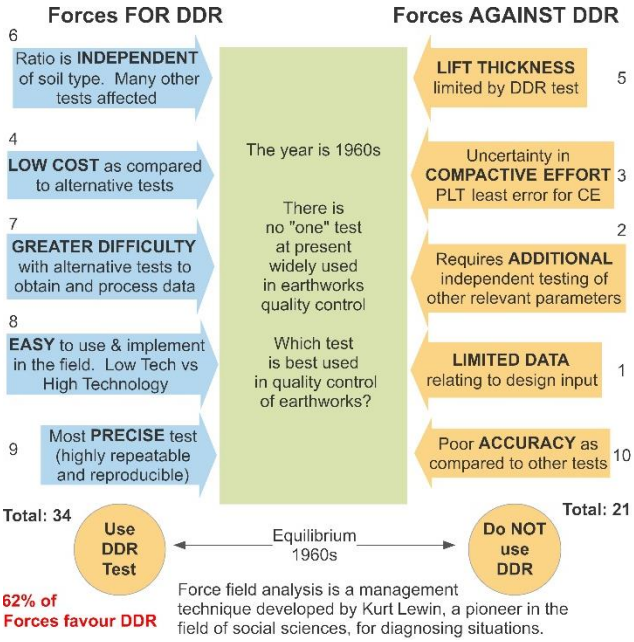

Figure 3. Force field analysis decision to use DDR as the main QC parameter in the 1960s. 10 is most desirable.

Adopting DDR as the main QC parameter far outweighs the negative considerations. High precision, ease of use, and greater difficult of technology of the tine outweigh negative considerations of accuracy. Thus, using DDR was logical choice in the 1960s based on the technology of the time.

Figure 4 uses the similar considerations in the decision to use DDR as the main QC parameter in the

2020s but updated for current technology. The decision is now weighted against using DDR given current technology in current times.

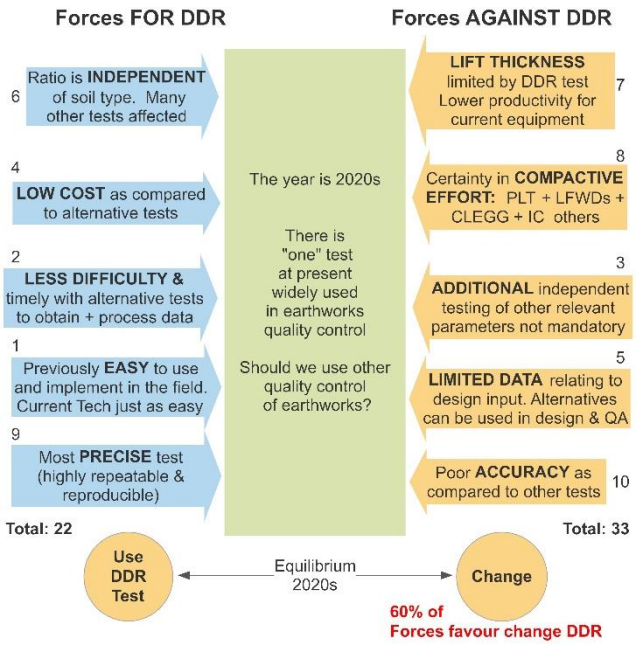

Figure 4. Force field analysis decision to NOT use DDR in the 2020s using similar considerations as the 1960s.

2.2 Historical testing and compaction history

The CBR test was developed to assess the load-bearing capacity of soils. In modern times it is used to correlate with resilient modulus.

A heavier compaction roller can achieve greater compaction energy and soil density. Early machines prior to 1900 were 6 tons but increased to 10 to 12 tons by the time the compaction test in the 1930s, and 15–20 tons in the 1940s by the time the modified compaction test was introduced.

During the early standardisation of tests (1950s) the development of smooth drum vibratory compaction rollers further improved compaction efficiency, with machine around 20-25 tons. By the 1990s, advances in engineering and construction materials allowed for larger compaction rollers with typical weights of 30-35 tons. High-frequency vibratory compaction rollers from 2000, and sophisticated control systems has led to larger and heavier models weighing over 40 tons.

Vehicles weights also changed over the years. However, it is truck axle loads that governs road performance. The average truck axle load was around 2.5t in the 1920s and increased to approximately 8.5t by the 1980s with technological in truck design.

3 COMPARSION OF TESTS

3.1 Early days to assess benefits of tests

In the symposium on compaction of earthworks and granular bases, Selig and Truesdale (1967) examined various testing devices for various factors affecting compaction. They found density has a low variability compared to other tests. Thus, precision took preference over the more useful but wider variability of other measurements of the time.

3.2 Current tests and benefits

A survey of engineers ranking what attributes are desirable in a test equipment showed that accuracy is the preferred attribute (Look, 2018). The ranking order for the 8 attributes of a test equipment was:

1. Accuracy; 2. Precision
3. Time to conduct test / Ease of use
4. Time to process results / Ease to process & report
5. Amount of data obtained / Cost of equipment

Field trials were used to benchmark the various alternative equipment and compared with traditional DDR measurements for various sites (Table 1).

Table 1. COV for various tests considered over 5 sites.

Test	**Coefficient of Variation (%)**		
	Median	Low	High
Density Ratio	2.0	1.8	2.9
Geogauge	26.5	19.1	34.5
Prima LFWD	33.5	15.0	35.7
CBR	40	17.0	58
Zorn LFWD	34.1	21.6	51
Clegg	36.0	26.0	54
PANDA			
(50 – 100mm)	53	34	74
(150 – 200mm)	50	48	92
DCP			
(50 – 100mm)	38.0	28	97
(150 – 200mm)	53	34	74
Plate Load Test	77	14	142

The lot coefficient of variation (COV = standard deviation / mean) at each site was used to judge the precision, and the DDR test is the standout leader (COV < 3.0%), with the Plate Load test (PLT), the most variable as compared to other tests.

However, precision is the 2nd preference attribute as compared to accuracy. Accuracy was assessed in terms of how well the results compared with each other for similar order of the high to the low values for the various test sites. The PLT was the most accurate, but is the least precise test (Look, 2018).

4 DISCUSSION

Density has historically satisfied a 1 parameter need in QC assessment. Other quality parameters are assessed independently. A 95% DDR does not have a singular strength or modulus value – although this is an implicit assumption (Table 2). This is not rock fill testing as all materials conform to "soil" after compaction.

Table 2. Modulus and strength at 95% DDR (Look, 2021).

Fill Material Origin	PLT E_{V2} (MPa)	In situ angle of friction φ (°)	
		Smooth	Padfoot
Sandstone	70	45	45
Interbedded Siltstone/Sandstone	40	41	39
Basalt	65	39	43

When field supervisors ask for a correlation of modulus to provide a linkage with DDR as the de facto standard, a poor correlation often results. This is due to different zones of influence, modulus being affected by several factors (not just DDR), and the DDR having a normal probability density function (PDF) and other tests having a non-normal PDF. Look (2021) show a methodology to avoid such correction inconsistencies

LFWD results (Figure 5) show that both Type I and Type II errors are occurring when DDR is compared with LFWD data. A Type I error is the incorrect rejection of a true null hypothesis. Type II error is the failure to reject a false null hypothesis. A direct paired correlation had 20% "errors" in its assessment.

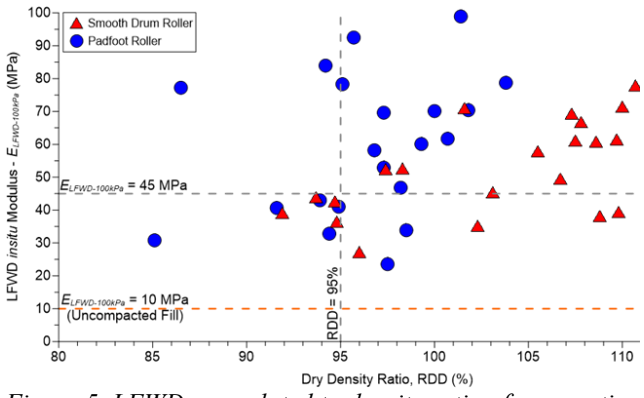

Figure 5. LFWDs correlated to density ratio of compaction for sandstone material.

Riad et al. (2023) review various testing equipment in compaction QC in the U.S. Curently, 93.5% of state agencies use density specifications rather than modulus based compaction controls. Similarly, in Australia, modulus based compaction levels are curently the exception. A requirement on parallel testing with DDR leads to additional cost and time.

5 CONCLUSIONS

Modern pavement designs are based on modulus and strength values. When such measurements are correlated to QC density testing, a poor correlation often results as this is a multivariate relationship.

Traditional QC testing density has focused on its key benefit of precision and simplicity without appreciating the poor accuracy associated with this measurement. The decision is between the past comforts and success of using density measurements vs the technical benefits of modern testing equipment. The early benefits of using DDR now seem to impede what should be possible given current technologies.

ABSTRACT: The present work addresses the ground improvement solutions adopted for the soft soils as foundation of the future industrial warehouse, to be built at the plot 14 of the Northern Lisbon Logistic Platform, at Castanheira do Ribatejo, Vila Franca de Xira, Portugal, comprising an area of 49 813 m^2. A description of the existing conditions is made, particularly of the geological-geotechnical scenario, highlighting the existence of an alluvial layer, with clayed soft soils, with low characteristics of strength and stiffness as well as very low average permeability. The solution adopted consists in the execution of preload embankments associated with (i) stone columns, executed at the area of the warehouse indoor pavements, and (ii) vertical prefabricated geodrains, at the area of the outdoor pavements, in the places designed for car parking and circulation of light and heavy vehicles. This article describes the criteria and methods used at the design of the preload fills, seeking to reduce the hydrodynamic consolidation schedule. The Monitoring and Survey Plan and respective results are also presented.

RÉSUMÉ: Le présent travail traite des solutions d'amélioration du sol adoptées pour les sols meubles comme fondation du futur entrepôt industriel qui sera construit sur le lot 14 de la plate-forme logistique du nord de Lisbonne, à Castanheira do Ribatejo, Vila Franca de Xira, Portugal et qui comprend une superficie de 49 813 m^2. Une description des conditions existantes est faite, en particulier du scénario géologique-géotechnique mettant en évidence l'existence d'une couche alluviale et de sols meubles et argileux, aux faibles caractéristiques de résistance et de rigidité, ainsi qu'une très faible perméabilité moyenne. La solution adoptée consiste à l'exécution de remblais de pré chargement associés à (i) des colonnes ballastées exécutées dans la zone d'entrepôt des trottoirs intérieurs et (ii) des geodrains préfabriqués verticaux au niveau des trottoirs extérieurs aux endroits prévus pour le stationnement et la circulation des véhicules légers et lourds. Cet article décrit les critères et méthodes utilisés lors de la conception des remblais de pré chargement cherchant à réduire le temps de consolidation hydrodynamique. Le plan d'observation et de surveillance et les résultats respectifs sont également présentés.

Keywords: Ground improvement; soft soils; preloading embankments.

1 INTRODUCTION

The Northern Lisbon Logistic Platform (NLLP) is located at Vila Franca de Xira, Portugal, in an area of approximately 1 000 000 m^2. This platform was built with the intend of creating an interconnection point for international, national, and regional logistical flows within the Lisbon and Tagus Valley region.

On plot 14 of the stated platform, the construction of a new industrial building is expected, with an area of approximately 32 968 m^2. In the aerial view in Figure 1, it is possible to identify the target area for intervention, as well as the limits of the NLLP.

2 GEOLOGICAL AND GEOTECHNICAL CONDITIONS

The area is located on the right bank of the Tagus River, dominated by the alluvial soils of the Lower Tagus, ancient deposits of river terraces and, in depth, by soils dating from the Miocene.

Figure 1. Aerial view of the construction site (image taken from Google Earth).

According to the information obtained during the geotechnical investigations, it is confirmed that the local geological-geotechnical scenario is characterized, superficially, by a layer of landfills, developing to a depth variable between 1.1 m and 3.4 m. According to the available sampling, it is a heterogeneous layer made up of silts with calcareous gravel.

Immediately below the layer of landfills, to a maximum depth of 20,0 m, there are alluvial deposits, essentially made up of soft silts and very soft high plasticity clays, with a high content of organic matter and shell fragments.

Underlying the alluvial layer, colluvial formations can be identified, composed of sandy clays of medium consistency with rounded heterometric gravel of an essentially quartzite nature.

The position of the water table is dependent on the water level in the Tagus River, being influenced not only by seasonal variations, but also by the daily tidal cycles felt in the estuary. During the prospecting geotechnical works, the presence of the water table was detected at a depth varying between 1.3 m and 3.4 m, generally occurring at the level of the interface between the natural terrain and the overlying landfills.

3 GROUND IMPROVENT SOLUTIONS

Given the presence of soft clayey soils, with low strength and stiffness, as well as reduced support capacity, and considering the extended period available for the execution of the works, it was decided to implement ground improvement solutions with the aim of increasing the geomechanical characteristics of the foundation soils, thus providing favourable conditions to obtaining total and differentials settlements compatible with the good performance of the pavements during the service lifetime of the new industrial building.

In this context, a consolidation ground improvement solution was adopted using preload embankments.

To accelerate the process of hydrodynamic consolidation of the compressible materials (soft clayey soils), the introduction of drainage elements was considered, namely, stone columns, at the area of the warehouse indoor pavements, and prefabricated vertical drains (PVD), at the area of the outdoor pavements, in the places designed for car parking and circulation of light and heavy vehicles. It should be noted that the stone columns were installed in a previous work in 2010, while the PVD were installed more recently in 2022.

Considering the magnitude of the predicted service load in the indoor and outdoor pavements (50 kN/m^2 and 20 kN/m^2, respectively), it was proposed to build 8.0 m and 4.0 m high embankments, with slopes H=1.5; V=1.0.

The stone columns were arranged in a square array with 3.0 m centre-to-centre spacing. The PVD were installed in a triangular arrangement with 1.2 m spacing. Both these elements were executed up to an estimated average depth of 20.0 m, in relation to the work platform elevation.

In Figure 2 the typical cross section of the consolidation ground improvement solution is presented.

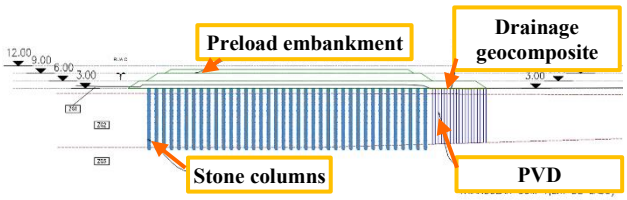

Figure 2. Typical cross section of the consolidation ground improvement solution (not to scale).

Given the presence of a surface layer of landfills, the execution of the PVD required pre-drilling works (Figure 3).

Figure 3. Installation of the prefabricated vertical drains.

After the installation of the PVD, and prior to the execution of the pre-load embankments, a drainage geocomposite responsible for directing the inflowing water to the vertical geodrains was applied (Figure 4).

Figure 4. Aerial photograph of the drainage geocomposite installation.

Figure 5 shows an aerial photograph of the preload embankments.

Figure 5. Aerial photograph of the preload embankments.

4 DESIGN

4.1 Settlements

The total settlement of the compressible soil as a result of the increase in vertical stresses can be calculated by adding the portions corresponding to (i) the immediate settlement, produced during construction in undrained conditions, therefore without volume variation; (ii) primary settlement, resulting from the expulsion of water due to the dissipation of excess pore pressure, during the development of the primary consolidation process; (iii) and secondary settlement, corresponding to the continuation of soil deformation after conclusion of primary consolidation, corresponding to secondary consolidation or creep.

For the problem under study, immediate and primary consolidation settlements were considered.

The value of immediate settlement was estimated, adopting, for the foundation soil, an isotropic linear elastic behaviour at constant volume and carefully choosing the deformability modulus in undrained conditions.

The methodology for calculating settlements by primary consolidation included the application of Terzaghi's theory of one-dimensional consolidation, associated with a two-dimensional distribution of loads transmitted to the ground.

For this purpose, the settlement by primary consolidation was estimated based on the parameters obtained in the oedometer laboratory tests, discretizing the compressible stratum into layers, and estimating the total settlement considering the variation in effective stresses in depth.

The stress increments for the stated calculation and, as such, for definition of the height of the preload embankments, were determined, considering the self-weight of the embankments (temporary and permanent), the self-weight of the pavement slab and the different service loads. It should be noted that in this estimate second-order effects associated with the expected settlement of landfills were considered.

The estimate of the duration of the primary consolidation process involved calculating the estimated vertical and horizontal consolidation times and subsequently the total value resulting from these two mechanisms.

Having knowledge of the total settlement value associated with a given embankment height, as well as the law that governs its evolution over time, it was possible to estimate the settlement evolution curves over time shown in Figure 6.

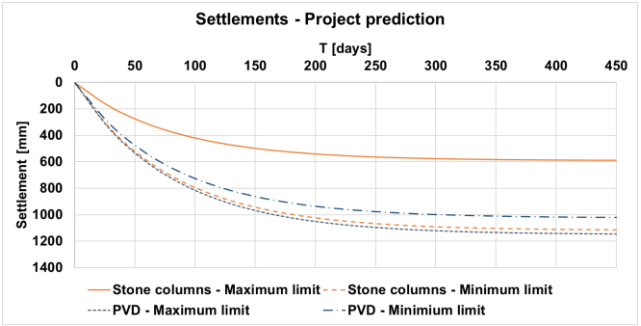

Figure 6. Primary consolidation settlements prediction at design stage.

4.2 Slope stability

As part of the verification of the global stability of the pre-load embankment slopes and the bearing capacity of the foundation, including the quantification of safety factors, an automatic calculation program designed for this purpose was used: SLIDE (V6.0) which allows carrying out analyses in a limit equilibrium regime. This software made it possible to carry out a stability analysis, using circular failure surfaces based on the Bishop-Simplified Method. Two-dimensional finite element analysis was also carried out in parallel using the PLAXIS 2D software.

5 MONITORING AND SURVEY PLAN

To guarantee the carrying out, in safe conditions, of the ground improvement works, mainly the stability of the embankments/foundation and the evolution of settlements/degree of consolidation, a Monitoring and Survey Plan was employed.

In this context, it was considered essential to monitor the following quantities:

a) Water levels installed on the ground, through the installation of 72 vibrating wire piezometers, arranged in a total of 18 locations, at 4 different depths.

b) Horizontal movements of the ground measured using 6 inclinometers, arranged on the periphery of the embankments.

c) Surface settlements of the natural terrain and embankments/platforms, through the measurement of topographic marks supported on 52 settlement plates.

Figures 7 and 8 show, respectively, the vertical displacements measured in the settlement plates, recorded until March 9, 2023, in the area where the stone columns and PVD were built.

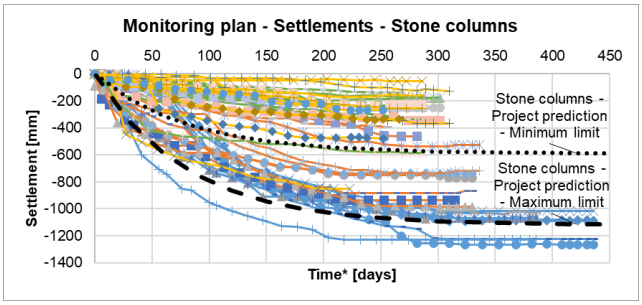

Figure 7. Observed settlements – stone columns.

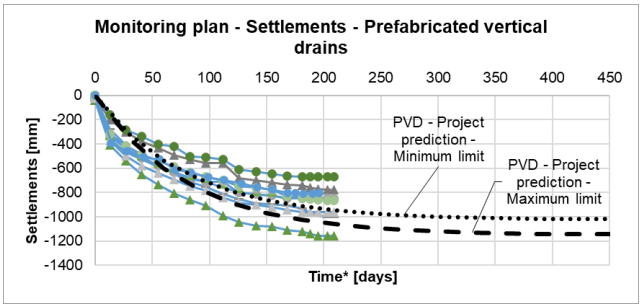

Figure 8. Observed settlements – prefabricated vertical drains.

Regarding measurements of water levels and horizontal displacements, it is important to note that the late installation of piezometers and inclinometers did not allow for a complete record of these quantities to be obtained from the beginning of the construction of the pre-load embankments. Nevertheless, the evolution recorded is in accordance with the project prediction, particularly regarding the reduction, over time, of pore water pressures tending towards values that are close to the hydrostatic distribution. Regarding the recording of horizontal displacements, the mobilization of displacements of greater magnitude was observed at the depths corresponding to the existence of the soft clayey stratum, with a higher rate of evolution during the construction period, which stabilized after the end of the construction of the embankments.

6 FINAL REMARKS

The framework of the work described, including the available time, determined the need to develop innovative ground improvement solutions aiming to provide favourable conditions for the future employment of economic foundation solutions, compatible with the structure serviceability, not only on plot 14, but also on adjacent plots, taking profit of both soil behaviour knowledge (from monitoring results) and existent preloading embankment.

In this context, it should be noted that the adopted solutions make it possible to mitigate, during the life of the future industrial structure, high magnitude settlements, resulting from the primary consolidation process, developed at the level of soft clayey alluvial layers.

The importance of the Monitoring and Survey Plan in managing the behaviour of the work is highlighted, allowing the interpretation of the observed settlements and the establishment, with greater accuracy, of the time necessary to obtain the specified degree of consolidation. As such, it is an indispensable tool in a geotechnical work, with the characteristics of this one.

It is noted that the magnitude of settlements estimated at the project stage, in general, was in line with the values measured on site. The exception to this statement were the settlements recorded in the NW area of the plot, where the stone columns were installed, and where settlements of a magnitude considerably lower than the values recorded and estimated for the SE area were observed. This difference is attributed to the effect of the prolonged presence of previously constructed pre-load embankments, as well as the effect of reinforcing the ground provided by the stone columns.

ACKNOWLEDGEMENTS

The authors would like to thank the site owner for the permission to present this paper. It is also worth highlighting the fact that the earthworks were carried out by the company “Iranzo Excavaciones” and the work related to the execution of the geodrains by the company “Terratest”.

The foundations of the Rhine bridge Hard-Fussach (Austria)

Les fondations du pont Hard – Fussach sur le Rhin (Autriche)

F. Lopez*, E. Steinlechner
Tiroler Rohre GmbH, Hall in Tirol, Austria

**freddy.lopez@trm.at*

ABSTRACT: Due to the high damage potential that a possible flood event has for the densely populated areas along the 26 km-long International Stream of the alpine Rhine, the discharge capacity needs to be expanded from the current 3100 m³/s (100-year flood) to 4300 m³/s (300-year flood), in line with the requirements of the Swiss-Austrian project RHESI Flood Control for the Rhine Valley. In this context, a new Rhine Bridge connecting the Austrian towns of Hard and Fussach was designed to replace the old structure, which is no longer able to ensure the primary framework conditions for neither flood protection nor the increasing volume of traffic. The extremely unfavourable subsoil conditions, consisting of shallow, very soft to soft plastic lacustrine clay deposits, required a deep foundation solution for the substructure (abutments and piers). Due to the high flood risk, the construction of the substructure could only be carried out during a period of low water discharge (winter), resulting in a very tight construction schedule (winter half-year 2020/2021). For the deep foundation of the substructure, several options were evaluated. Finally, a solution consisting of pile grillages, executed with ductile cast-iron driven piles (320 mm of diameter), was adopted for the project. The fast, safe and simple execution of the piles allowed for the successful erection of the substructure within the limited available time frame. The completion of this construction stage was critical for the further phases. After a construction time of only 28 months, the Rhine Bridge Hard- Fussach was officially opened for traffic on November 18, 2022. The following technical paper presents an overview of the adopted deep foundation solution, covering the design and execution of the piled foundation.

RÉSUMÉ: En raison du potentiel élevé de dommages qu'une éventuelle inondation pourrait avoir pour les zones densément peuplées situées le long du cours d'eau international du Rhin alpin, long de 26 km, la capacité d'écoulement du cours d'eau d'une valeur actuelle de 3100 m³/s (crue centennale) doit être augmentée à 4300 m3/s (crue tricentennale), conformément aux exigences du projet austro-suisse RHESI de protection contre les crues dans la vallée du Rhin. Dans ce contexte, un nouveau pont sur le Rhin reliant les villes autrichiennes de Hard et Fussach a été conçu pour remplacer l'ancien ouvrage qui ne répondait plus aux exigences modernes des infrastructures vis-à-vis de la protection contre les crues et de l'augmentation du trafic. Les conditions géotechniques extrêmement médiocres du sol, constitué de dépôts alluvionnaires d'argile lacustre plastique, molle à très molle, ont nécessité une solution de fondations profondes pour les appuis (culées et piles de pont). En raison du risque élevé d'inondation, la construction des appuis n'a pu être réalisée que pendant une période de faible débit d'eau (hiver), ce qui a entraîné un calendrier des travaux très serré (semestre hivernal 2020/2021). Pour les fondations profondes des appuis, plusieurs options ont été évaluées. Finalement, une solution constituée d'un maillage de pieux, réalisés avec des pieux battus enrobés en fonte ductile (diamètre 320 mm), a été retenue pour le projet. La mise en œuvre rapide, sûre et simple des pieux a permis avec succès l'élévation des appuis dans les délais limités disponibles. L'achèvement de cette étape de construction était crucial pour les phases suivantes. Après une durée de construction de seulement 28 mois, le pont sur le Rhin reliant Hard à Fussach a été officiellement ouvert à la circulation le 18 novembre 2022. Cet article technique présente une description de la solution de fondations profondes adoptée, couvrant la conception et la mise en œuvre des fondations sur pieux.

Keywords: Bridge foundation; ductile cast-iron piles; sustainability.

1 FLOOD CONTROL OF THE ALPINE RHINE

The alpine Rhine is the section between Reichenau in the Swiss Canton of Graubünden and the confluence with Lake Constance. The Swiss-Austrian flood control project RHESI aims to protect the habitat of about 300'000 people living in the valley along the "international stream" of the alpine Rhein, where the river flows today towards Lake Constance, in a canal-type bed with fortified embankments (Figure 1a).

With the implementation of the RHESI project, the middle channel of the Rhine will be significantly widened and the foreland consequently reduced, creating more space for the river (Figure 1b), with the correspondent increment of the current discharge capacity of 3100 m³/s (100-year flood) to 4300 m³/s (300-year flood).

Figure 1. Current (a) and future (b) layout of the alpine Rhine (mod. after Int. Rheinregulierung, 2022).

2 THE RHINE BRIDGE HARD-FUSSACH

The existing 255m-long Rhine Bridge connecting the Austrian towns of Hard and Fussach is the last Rhine crossing before reaching the Lake of Constance. It was built in 1971 and its substructure is founded on wooden piles. The bridge is no longer able to ensure the primary requirements for flood protection acc. to the RHESI project. In addition, the standard cross-section of the supporting structure no longer meets today's traffic engineering requirements and therefore the bridge needed to be replaced by a new structure.

The new Rhine Bridge Hard-Fussach, a state-of-the-art steel composite bridge with a separated cable (rope) construction (Figure 2), was designed to meet the new requirements for flood protection as well as to satisfy the increasing volume of traffic.

With a self-weight of approx. 12000 metric tons, the new bridge has three new piers, two of which support the pylons that carry the cable structure. The new structure (4-span girder) has a total length of 255.60 m and a width of approx. 24 m, ensuring enough space for two traffic lanes (one in each direction), one exclusive bus lane, a sidewalk and a bicycle path.

Figure 2. New and old Rhine Bridge Hard-Fussach in November 2022 (ORF, 2022).

3 THE FOUNDATIONS OF THE NEW RHINE BRIDGE HARD-FUSSACH

3.1 Subsoil conditions

The subsoil conditions in the project area are characterized by the presence of loose to medium dense floodplain sands with rather favourable mechanical properties, underlain by highly compressible cohesive soils (silts and clays with high organic content), fine to medium grained silty sands with moderate load-bearing capacity and very soft to soft lacustrine clay deposits (alluvium) with unfavourable geotechnical properties (Figure 3).

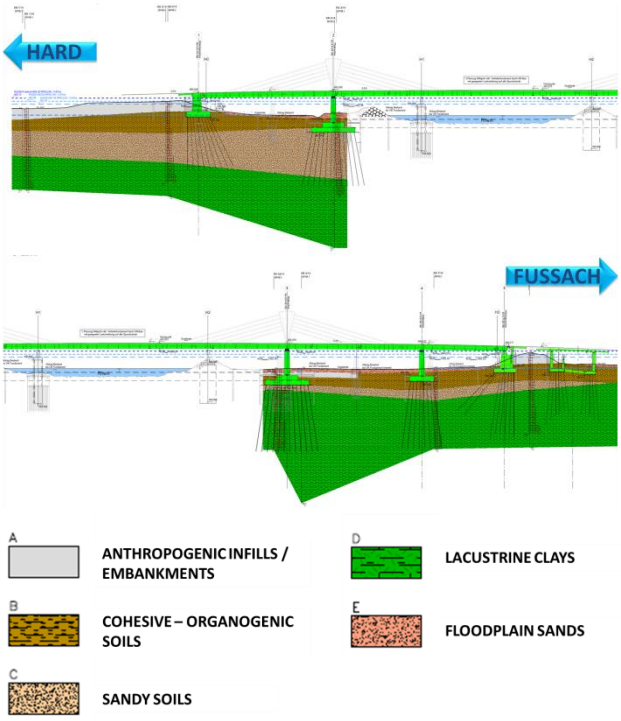

Figure 3. Subsoil profile along the new Rhine Bridge Hard-Fussach (mod. after BGG Consult, 2016).

The geotechnical properties of the identified soil units are summarized in Table 1.

3.2 Deep foundations

On account of the aforementioned unfavourable subsoil conditions, a shallow foundation was not feasible and a deep foundation solution for the substructure (abutments and piers) was unavoidable, nevertheless, due to the presence of high compressible lacustrine clays, encountered up to the investigation depth of 50 m below natural ground level, a classical solution based on end-bearing piles (i.e. cast-in-place bored piles or drilled shafts) with reasonable lengths was unsuitable for the foundation of the substructure. As an alternative to end-bearing piles, downwards fanned out pile grillages (a combination of vertical and racked floating piles) were proposed to support the substructure (Figure 4) with the goal to obtain the largest possible foundation area to achieve an optimum load distribution in order to maintain the deformations (settlements) within acceptable ranges.

Table 1. Geotechnical parameters of the soil units (after BGG Consult, 2016).

Layer	Description	Thicknes (m)	φ' (°)	c' (kN/m²)	γ/ γ' (kN/m³)	UCS (kN/m²)	E_s (MN/m²)
E	Floodplain sands, loose to medium dense	1.2 – 2.0	30	-	18 / 10	-	-
B	Cohesive/organogenic soils, very soft to soft	2.0 – 10.0	17 - 22	5 - 10	15 / 16	15 – 55	0.8 – 3.6

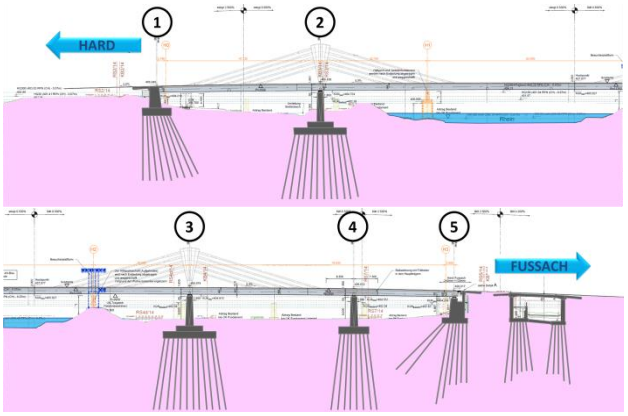

Figure 4. Longitudinal view of the pile grillages (mod. after Schimetta Consult, 2020).

3.3 Adopted piling system

An extensive analysis of different piling systems was conducted for the project. The most suitable and cost-effective solution was provided by ductile iron piles (DIP), due to the flexibility and large adaptability of the equipment, as well as the high installation speed.

DIP are low vibration, driven, full-displacement piles, installed using a medium-sized excavator and a hydraulic breaker hammer with a modified shank that seats into the pile socket (bell) for driving, using the hammer's percussive energy. The hydraulic hammers typically range from 1200 kg to 2500 kg and operate at frequencies between 250 and 500 blows per minute, delivering much higher frequency than traditional high-impact, low-frequency driven piling systems (Lopez and Steinlechner, 2023). The hammer size (energy) is matched with the size of the pile and the subgrade driving conditions to develop the most efficient installation while not overstressing the pile material (Plaskett et al., 2022).

DIP are used to transfer loads from the superstructure into the lower soil layers and/or to limit deformations and have the flexibility to be installed to transfer the loads developing skin friction and/or end-bearing capacity (Lopez and Steinlechner, 2023). A central reinforcing bar can be inserted in the wet concrete if required for tension or additional compression capacity. For the project, frictional (grouted) DIP were adopted (Figure 5) and their execution is schematically presented in Figure 6.

Figure 5. Frictional (grouted) ductile iron piles.

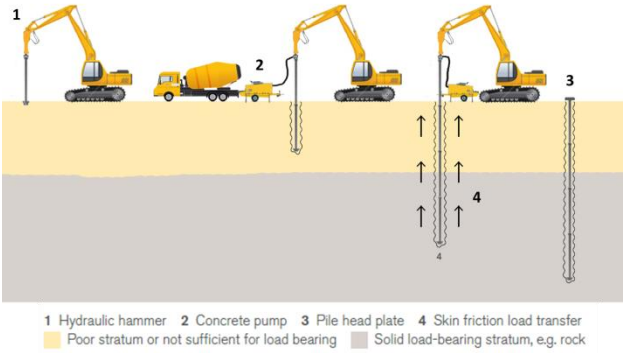

Figure 6. Execution of frictional (grouted) ductile iron piles (Lopez and Steinlechner, 2023).

3.4 Design

The relevant parameters for the estimation of the load-displacement behaviour of the piles were obtained from the results of a load test, carried out on a test pile group, comprised of 4 grouted DIP (25 m long), connected by a rigid pile cap.

The results of the load test are presented in Figure 7.

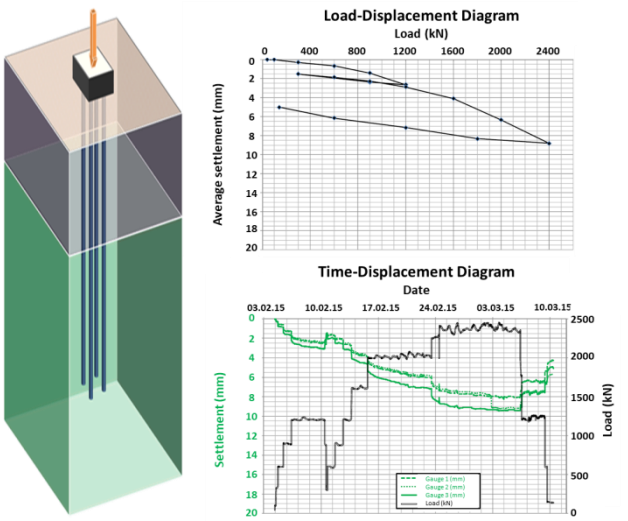

Figure 7. Load test results (mod. after BGG Consult, 2016).

An average group settlement of about 25 mm was limited for the verification of the serviceability limit state (SLS). For the aforementioned settlement, an allowable service load of about 1200 kN (300 kN per pile) could be derived. For the ultimate limit state (ULS), a characteristic external load-bearing capacity of 750 kN (both in compression and in tension) for a single 25 m-long pile could be defined. The results of the load test and the available local experience were also used to predict the time dependent load-displacement behaviour of the piles, based on their interaction with the local lacustrine clays.

The lacustrine clays showed a slight creep behaviour in the load transfer area, where almost 80% of the registered settlement for each load stage occurred over a time period between 2 and 3 days after applying the load increments.

Taking into account the above mentioned considerations, the required pile reinforcement could be defined for the project. A summary of the pile reinforcement is presented in Table 2. The racked piles were designed to counter act the large horizontal forces acting on the piers and abutments. Taking into consideration the provisions and requirements for the corrosion protection (BMK, 2020), the permanent piles were designed for a service life of 100 years.

3.5 Execution

Due to the high flood risk, the construction of the substructure could only be carried out during a period of low water discharge (winter), resulting in a very tight construction schedule (winter half-year 2020/2021).

The piling works for the bridge were carried out between late September 2020 and early March 2021. Figure 8 presents some pictures of the installation:

Figure 8. Execution of the piling works.

Table 2. Pile requirements (after Schimetta Consult, 2020).

[1)] Measured from the vertical

The use of adequate equipment (hydraulic manipulator) offered the required flexibility and precision for the execution of piles with different inclinations (Table 2), enabling to carry out interventions in areas with restricted space (i.e. excavation pits), causing only small affection to the surrounding work environment.

With the completion of the last pier on the Hard side at the beginning of April 2021 and final re-cultivation works in the Rhine floodplains, the construction of the substructure (abutments and piers) was successfully completed as planned at the end of April 2021. With this critical construction phase (substructure) finalized, the further construction works covering the longitudinal shifting of the steel box girders, the concrete carriageway slab, the stiffening of the supporting form of a harp-shaped span with the pylons and tensioning cables, the construction of the edge beams, the installation of the bridge railing and the paving works were completed in November 2022 (Baumanagement, 2022).

4 SUMMARY AND FINAL REMARKS

The new Rhine Bridge Hard-Fussach, a state-of-the-art steel composite bridge with a separated rope construction, was designed to meet the new requirements for flood protection as well as to satisfy the increasing volume of traffic. With an estimated investment of 70 million €, the construction of the new bridge began on June 29, 2020 and was entirely opened to traffic just 28 months later, on November 25, 2022.

The extremely unfavourable subsoil conditions (shallow, very soft to soft plastic lacustrine clay deposits) required a deep foundation solution for the substructure (abutments and piers). The proposed solution consisting of frictional (grouted) ductile iron piles (DIP) was proven to be the most suitable and cost-effective for the project, due to the flexibility, large adaptability and installation speed.

A very professional work preparation together with a high level of commitment of all the people involved in the project made possible to complete the project on time and to the required quality standards, overcoming additional challenges such as the construction in the hazardous area of the alpine Rhine under unfavourable weather conditions and the supply difficulties associated with the corona pandemic.

Role of tunnel ground loss on the mitigating effect of pile-wall barriers

Rôle de la perte de volume au tunnel sur l'effet atténuant des murs à pieux

N. Losacco*
Politecnico di Bari, Bari, Italia
**nunzio.losacco@poliba.it*

ABSTRACT: Pile wall barriers are an effective mitigation measure to protect heritage or infrastructure from tunnelling-induced ground movements. This paper presents the results of parametric finite element analyses aimed at studying the effect of tunnel volume loss on the efficiency of end-bearing pile wall barriers, accounting for shearing at the soil-pile interface. The considered scenario is the field trial of a pile wall barrier installed at an experimental site during the construction of the Line C of Rome underground railway. Results indicate that, at small volume loss, the excavation induced movements can propagate across the barrier. Contrarily, at larger applied tunnel volume loss, shearing at the pile interface, enhanced due to the barrier embedment in the stiff bottom layer, results in the progressive formation of a slip plane that prevents the transmission of soil displacements behind the wall, thus acting as a smooth continuous diaphragm wall. The transition from perfect compatibility to slipping between the soil and the barrier affects the propagation of the ground loss, and hence surface settlements, on both sides of the wall.

RÉSUMÉ: Les barrières à parois de pieux constituent une mesure d'atténuation efficace pour protéger le patrimoine bâti, ou les infrastructures, du mouvements de sol induits par la construction des tunnels. Cet article présente les résultats d'analyses paramétriques par éléments finis visant à étudier l'effet de la perte de volume au tunnel sur l'efficacité des barrières de pieux portantes aux extrémités, en tenant compte du cisaillement à l'interface sol-pieu. Le scénario considéré est l'essai sur le terrain d'une barrière à murs de pieux installée sur un site expérimental lors de la construction de la ligne C du métro de Rome. Les résultats indiquent que, avec une faible perte de volume, les mouvements induits par l'excavation peuvent se propager à travers la barrière. Au contraire, lorsque la perte de volume du tunnel est plus importante, le cisaillement à l'interface des pieux, accru en raison de l'encastrement de la barrière dans la couche inférieure rigide, entraîne la formation progressive d'un plan de glissement qui empêche la transmission des déplacements du sol derrière le mur, agissant ainsi comme une paroi moulée continue lisse. Le passage d'une compatibilité parfaite au glissement entre le sol et la barrière affecte la propagation des pertes de terrain, et donc des tassements de surface, de part et d'autre du mur.

Keywords: Tunnelling; ground movements mitigation; pile wall barrier; numerical analyses.

1 INTRODUCTION

The construction of tunnels can affect existing building heritage and infrastructures in urban areas. Numerous case studies (e.g. Bai et al., 2014) have shown that embedded bored pile walls are an effective protective measure to minimise ground movements induced by tunnelling. Furthermore, the installation of pile wall barriers induces less soil disturbance with respect to continuous diaphragm walls, whose construction, instead, may cause displacements as large as those induced by tunnelling (L'Amante et al., 2012).

The mechanical behaviour of diaphragm walls for various geometries and wall-soil interface roughness has been extensively characterised by means of centrifuge experiments and numerical analyses (Bilotta 2008; Rampello et al., 2019; Song et al., 2023). Results of those studies show that a smooth diaphragm deeper than the tunnel invert represents a slip plane causing a strong discontinuity in the displacement field induced by tunnel excavation, such that no soil ground loss is transferred to the rear of the wall. A rough interface, instead, results in non-negligible settlements behind the wall. Recent research on the efficiency of protective barriers consisting of bored piles focused on relatively low volume losses (Ledesma and Alonso, 2017; Masini and Rampello, 2021; Franza et al. 2021) with numerical results somewhat indicating that the pile wall efficiency might increase with tunnel ground loss (Bilotta and Russo 2011).

This paper presents the results of FE parametric analyses of a tunnel interacting with a pile-wall barrier, focusing on the role of volume loss on the

efficiency of the barrier in mitigating ground movements. The problem geometry and the employed geotechnical model (soil stratigraphy, mechanical properties, groundwater conditions), as well as the 3D reference numerical solution for model validation, obtained with a detailed simulation of the physical processes occurring around the TBM, are the same already published for the class-A predictions of the excavation of the Metro C running tunnels through the AMA site in Rome (Losacco et al. 2019; Losacco and Viggiani, 2020).

2 CASE STUDY

The geotechnical model of the field trial used for the parametric study presented in this paper was thoroughly discussed in Losacco et al. (2019) and Losacco and Viggiani (2020). The barrier is approximately 43 m long and is composed of 48 bored piles with length L_p = 34.5 m, diameter d_p = 0.6 m, spacing $s_p = 1.5\ d_p$.

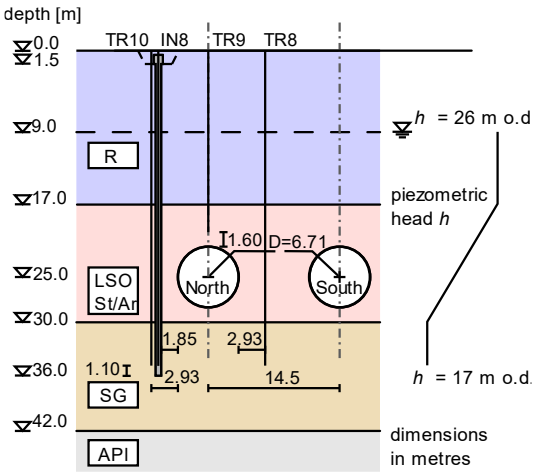

Figure 1. Geotechnical model and problem layout.

The monitoring cross-section, at midspan of the barrier, is drawn in Figure 1, also showing the soil stratigraphy and piezometric head distribution. Soil strata, starting from the ground surface, are:

- R: 17 m thick madeground layer, made of gravelly sand in pyroclastic matrix;
- LSO – St/Ar: 13 m thick recent or Pleistocene alluvial silty sands, sandy silts and silty clays;
- SG: 12 m thick Plio-Pleistocene Paleotevere fluvial deposits consisting of sand and gravel;
- APl: very thick Pliocene stiff silty clays "Argille Vaticane", the impervious bedrock of the whole city.

The groundwater table is found at 9 m depth b.g.l. in the R layer. The inferred piezometric head distribution shown in Figure 1 implies downward seepage in the LSO layer.

The base of the piles is embedded into the stiff, coarse-grained SG layer, hence beneficially influencing the performance of the barrier in minimising tunnel-induced settlements. Twin tunnels with diameter D = 6.7 m are excavated at z_0 = 25 m axis depth in the LSO-St/Ar layer, with s = 14.5 m spacing between their axes. The study presented here only considers excavation of the first tunnel (North Tunnel), that is carried out at quite a short distance from the barrier (1.85 m springline to pile shaft).

3 NUMERICAL MODEL

The parametric analyses were carried out using the FEA software Abaqus. The calculations were performed in terms of effective stress and assuming drained conditions; this is a reasonable assumption given the relatively large permeability obtained from field tests for the fine-grained soil layer (LSO – St/Ar), and the results of hydromechanically coupled class A analyses of the same site (Losacco and Viggiani, 2020) due to the relatively low advance rate of the excavation (average 8.5 m/day). The FE mesh employed for the analyses is shown in Figure 2.

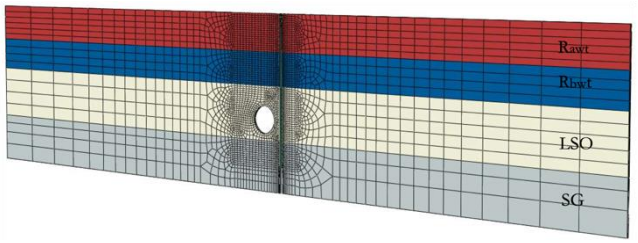

Figure 2. FE mesh.

Two hypoplastic constitutive models were chosen to simulate the mechanical behaviour of the R and the LSO layers: the von Wolffersdorff (1996) model for coarse-grained materials for the former and a critical-state based model for clays (Mašín, 2005) for the latter. The values of the material constants are provided in Losacco and Viggiani (2020). A simple linear elastic-perfectly plastic material model was employed for the deep SG layer. The top of the Apl layer represents the base of the numerical model.

The barrier was modelled with solid elements as a separate body from the soil, assuming linear elastic behaviour, with elasticity coefficients and unit weight of concrete. A no-penetration/no-tension behaviour was employed for the contact between the barrier and the soil in the normal direction, whereas a Coulomb frictional law was adopted in the tangential direction, assuming a rough interface (i.e. $\delta = \varphi'$), with φ' the effective soil friction angle and δ the friction angle at the pile-wall interface.

Assuming an infinitely long barrier and the tunnel excavation carried out simultaneously throughout its length (i.e. neglecting the excavation advance), an $s_p/2$ long domain only was modelled, containing half pile, resulting in a quasi-2D simulation. Standard mechanical constraints were prescribed at the sides of the mesh and hydraulic boundary conditions were applied to reproduce the piezometric head distribution depicted in Figure 1. After an initial stage of geostatic equilibrium, the barrier was activated. Then, tunnel excavation was simulated by applying a homothetic contraction of the tunnel boundary, focused on the tunnel axis (Boldini et al., 2016; Masini and Rampello, 2021). This simulation technique was chosen as the results exhibited the best agreement with those obtained through the detailed 3D simulation of the mechanised excavation process in the same site. The minimum tunnel radius after homothetic contraction (i.e. the tunnel volume loss $V_{L,T}$) was calibrated separately for the analysis with the barrier and for the greenfield case, by matching the reference 3D solutions.

4 RESULTS

In this study, the adopted 2D simulation technique is aimed at performing parametric analyses to assess the effect of tunnel volume loss on the settlement field behind a barrier of end-bearing piles, which would be unfeasible using the detailed—computationally expensive—3D simulation method. Hence, the simplified technique is validated with respect to the predictions provided by the detailed simulation, taken as a reference solution here, rather than to field measurements.

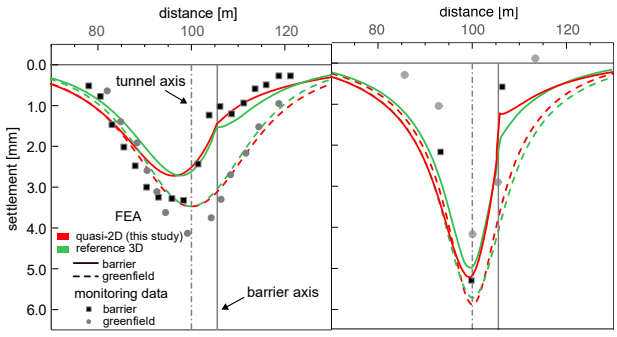

Figure 3. Settlements in greenfield and with the barrier: at ground surface (left) and at 17 m b.g.l. (right).

In this respect, Figure 3 shows the comparison between the surface settlements predicted with the adopted approach, the reference 3D solution, and monitoring data, obtained through precise levelling. Field measurements were carried out , both for the greenfield and the barrier monitoring section. The same comparison is shown at 17 m b.g.l. (1.2 D above tunnel axis), where field data are obtained from Trivecs measurements. The results of the 2D analyses, calibrated as explained in the previous section, show a good agreement with the reference solution, somewhat improving the quality of the predictions behind the barrier and at depth.

Hence, the proposed simulation technique is employed to carry out parametric analyses varying the tunnel ground loss from 1.7% (value used in Figure 3) to 4.5%. Figure 4 shows the predicted settlement troughs in greenfield conditions and when the barrier is present, at the ground surface and at 17 m depth. The embedded end-bearing barrier is seen to significantly reduce soil settlements and volume loss, both behind and in front of the barrier, for all values of imposed tunnel volume loss. Clearly the most significant reduction occurs right behind the wall. More interestingly, the settlements behind the barrier seem to achieve a limit value, as negligible settlement increase occurs for $V_{L,T} > 3.0\%$, in particular at depth. This confirms the efficiency increase of the barrier with $V_{L,T}$, as already suggested by Bilotta and Russo (2011). Conversely, the relative reduction of maximum settlement w_{max} with respect to the greenfield case diminishes with increasing $V_{L,T}$.

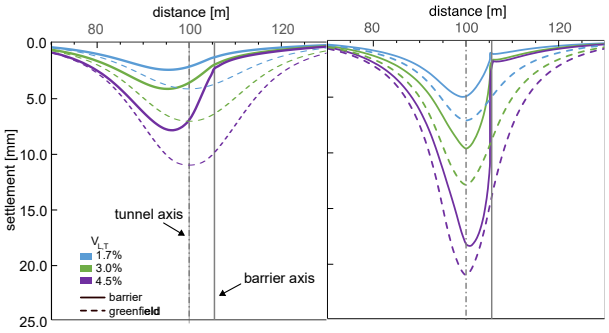

Figure 4. Predicted settlements in greenfield and with the barrier: at ground surface (left) and 17 m b.g.l (right).

To explain the observed behaviour, Figure 5 displays the sliding occurring along the vertical of the pile shaft facing the tunnel, and the mobilised tangential stress at the same location, compared to the maximum available shear strength of the interface. Positive sliding and shear stress imply downward movement of the soil with respect to the wall. The plots show that little sliding occurs along the pile for $V_{L,T} = 1.7$ % and $V_{L,T} = 3\%$, both above and below the tunnel, with different sign, whereas no sliding occurs right at tunnel depth, where soil movements are predominantly horizontal. The maximum sliding takes place in the LSO – ST/Ar layer, due to the significant compliance of the soil. For the same $V_{L,T}$, sliding is not observed on the top 1/3 – 1/4 of the pile,

as the downward tangential stresses have not reached the limit value. Conversely, above tunnel crown depth, for the largest $V_{L,T}$ = 4.5% the shear strength at the soil-pile interface is fully mobilised up to the pile head, resulting in large sliding.

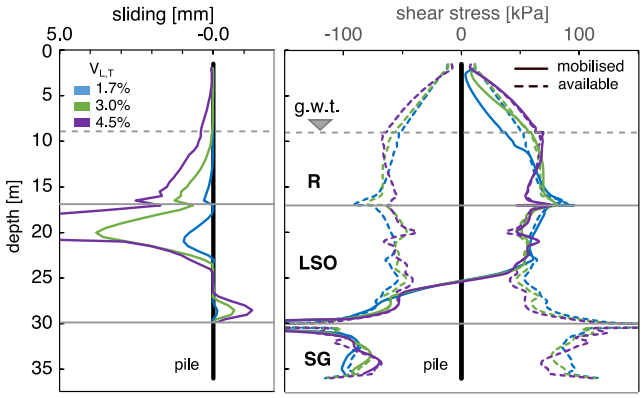

Figure 5. Interface behaviour along the pile shaft vertical facing the tunnel: sliding (left) and shear stress (right).

5 CONCLUSIONS

The results presented in this paper highlighted the relative influence of the volume loss applied at the tunnel boundary on the performance of an embedded barrier of end-bearing bored piles. The analyses have been performed with reference to a specific representative case study. The proposed quasi-2D simulation technique, if properly calibrated, can reproduce correctly the predictions provided by quite more complex 3D simulations.

The parametric analyses show that the efficiency of an end-bearing pile wall barrier increases significantly with increasing prescribed tunnel volume loss. This is due to sliding at the pile-soil interface facing the tunnel, occurring when, for large $V_{L,T}$, the shear strength along the pile shaft is fully mobilised. Shearing causes the soil behind the pile wall to disconnect from the soil ahead of the barrier, so that no further settlements are generated for increasing volume loss, as the incremental response of the barrier approaches that of a smooth diaphragm.

Sand-rubber mixtures as vibration dampening foundation materials: scaled physical model studies

Mélanges de sable et de caoutchouc comme matériaux de fondation amortissant les vibrations: études sur modèles physiques à l'échelle

B.R. Madhusudhan*
A'Sharqiyah University, Ibra, Oman
**madhusudhan.ramu@asu.edu.om*

ABSTRACT: The accumulation of scrap rubber tires is a serious environmental issue. Rubber is a good damping material. In view of these, it is prudent to use rubber along with soil for engineering applications in general and possibly as foundation materials in particular. In this regard, some past studies have discretely evaluated the physical and mechanical properties of soil-rubber mixtures. However, there is a lack of comprehensive experimental studies highlighting the significance of the use of sand-rubber mixtures as vibration dampening foundation materials. The present study deals with the instrumented laboratory scaled physical models subjected to a series of impact hammer tests. Different base conditions for the physical models consisting of fixed base, and structure founded on sand-rubber mixture layer in a tank filled with sand are considered. The impact force and the acceleration responses of the structure are recorded using an HBM made amplifier with the data acquisition system. The damping ratio values are estimated from the frequency response function plots of the measured signals. The results of the present study show that the sand-rubber mixtures possess an adequate potential for their application as vibration dampening foundation materials for low-rise buildings.

RÉSUMÉ: L'accumulation de pneus usés en caoutchouc constitue un grave problème environnemental. Le caoutchouc est un bon matériau amortisseur. Compte tenu de cela, il est prudent d'utiliser le caoutchouc avec la terre pour des applications techniques en général et éventuellement comme matériaux de fondation en particulier. À cet égard, certaines études antérieures ont évalué discrètement les propriétés physiques et mécaniques des mélanges sol-caoutchouc. Cependant, il manque des études expérimentales complètes mettant en évidence l'importance de l'utilisation de mélanges sable-caoutchouc comme matériaux de fondation amortisseurs de vibrations. La présente étude porte sur des modèles physiques instrumentés à l'échelle d'un laboratoire soumis à une série d'essais au marteau. Différentes conditions de base pour les modèles physiques constitués d'une base fixe et d'une structure fondée sur une couche de mélange sable-caoutchouc dans un réservoir rempli de sable sont prises en compte. La force d'impact et les réponses d'accélération de la structure sont enregistrées à l'aide d'un amplificateur fabriqué par HBM avec le système d'acquisition de données. Les valeurs du rapport d'amortissement sont estimées à partir des tracés de fonction de réponse en fréquence des signaux mesurés. Les résultats de la présente étude montrent que les mélanges sable-caoutchouc possèdent un potentiel adéquat pour leur application comme matériaux de fondation amortisseurs de vibrations pour les bâtiments de faible hauteur.

Keywords: Sand rubber mixtures; damping; foundation; scaled physical models.

1 INTRODUCTION

The accumulation of scrap rubber tires is an environmental issue which requires immediate attention. The accumulation of rubber causes serious environmental imbalances. It is known as 'black pollutant' (Xiong and Li, 2013). In the past, few studies have been conducted on scrap rubber tire-sand mixtures (Madhusudhan et al., 2017, 2020, 2021). These laboratory studies investigated the properties of scrap rubber tire-sand mixtures under various testing conditions, such as monotonic and cyclic triaxial, cyclic simple shear tests, etc. These studies show the favourable response required for their applications as seismic base isolation materials of buildings. Few recent numerical studies (Boominathan et al, 2019) also investigate the same and concur on the merits of using these mixtures for a similar purpose. Hence, the potential of sand rubber mixtures needs to be further investigated for the stated application. This paper presents the experimental results related to the evaluation of the damping response of scaled physical models founded on scrap rubber tire-sand mixtures by carrying out 1g model tests. The present study further strengthens the benefits of using scrap rubber tire-sand mixtures as vibration dampening foundation materials for buildings.

2 MATERIALS USED FOR TESTING

The sand used for testing was locally available sand (Figure 1) used for the building construction. The rubber tire shreds (devoid of embedded steel wires) were obtained by shredding the tires in a tire shredding machine. The fine size rubber particles of desired size (less than 2mm) were obtained by (Figure 1). The grain size distribution of sand and rubber materials are shown in Figure 2. Table 1 presents the properties of sand and rubber tire shreds.

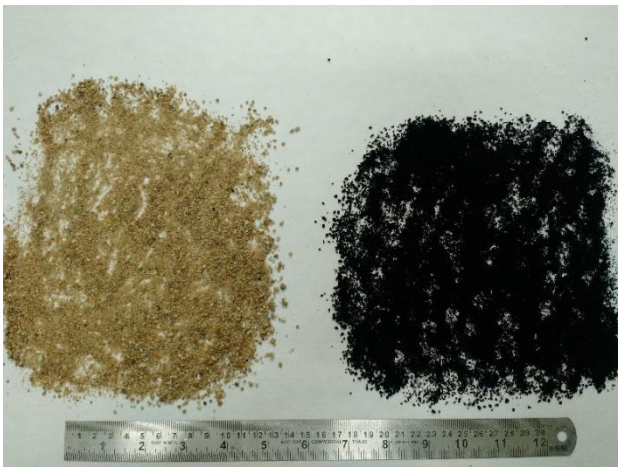

Figure 1. Materials used - sand and rubber tire shreds.

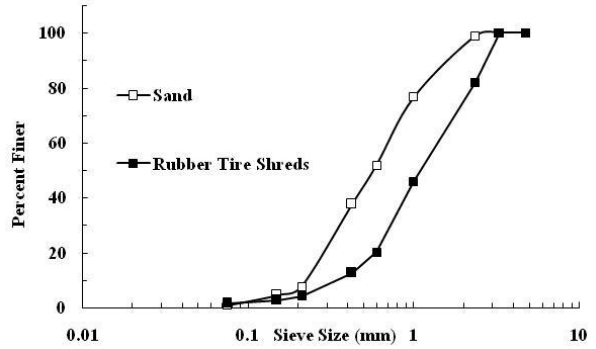

Figure 2. Grain size distribution of materials used.

Table 1. Properties of the materials used for testing.

Item	G_s	D_{10} (mm)	C_u	C_c	γ_{dmax} (kN/ m^3)	γ_{dmin} (kN/ m^3)
Sand	2.68	0.22	3.18	0.8	17.6	15.3
Rubber	1.14	0.35	3.57	1.12	5.2	2.8

3 EXPERIMENTAL SETUP, PROCEDURE AND ANALYSIS

The prototype structure considered has a plan area of 6 sq.m and consists of ground floor + up to 2 storeys (each storey 3m height). The steel model was made of square steel rods (beam size 10mm, column size 12mm) with each storey height 30cm. The footing size of the model was 10cm x 10cm x 1cm. The scaling laws as proposed by Iai (1989) were adopted.

Foundation conditions consisted of 4 cases as shown in Table 2. Rigid connections were made between model footings and heavy steel sections in the fixed base case (Figure 3a). Other base conditions had the model structure founded on pure sand, 10% sand-rubber tire mixture (gravimetric) and pure rubber. In latter cases, the model was setup within a 1.5m diameter and 0.85m height steel tank internally covered with EPS strips. These strips were provided to prevent reflection of the vibrations from the boundaries. The procedure reported in Madhusudhan et al. (2017, 2020) was adopted to create a sand bed inside the tank. The dense sand bed was made in various layers with each layer given an adequate number of tamping.

Careful placement of the model structure footing was ensured in the foundation block to maintain the desired footing depth from the sand surface level. The test setup is shown in Figure 3(b).

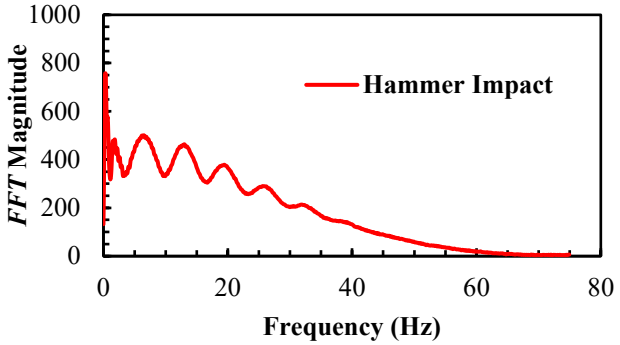
(a) *(b)*

Figure 3. Test setup (a) Scaled model with fixed base (b) Scaled model structure placed on sand-rubber mixture.

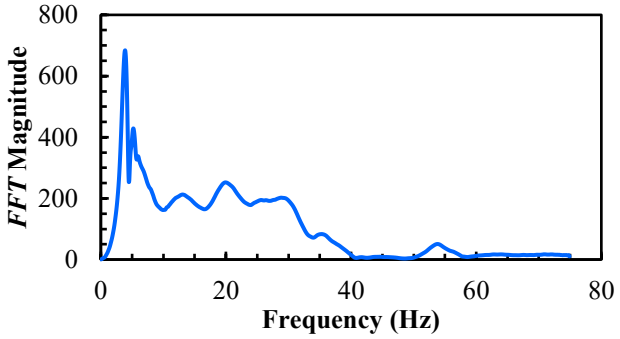
The impact was applied to the model structure using a PCB Piezotronics made impact hammer (086D20 model, 22.2kN capacity). The response of the structure was measured using PCB Piezotronics made accelerometers (393B04 model, cylindrical shape, dia 25mm, height 31mm, screw mounted). These sensors were attached to the model at various locations (floor levels, footing, and tank boundary). The hammer and the sensors were connected to the HBM made digital carrier frequency amplifier system. Notations *A1*, *A2*, and *A3* were used for the sensors mounted on the ground, first-floor, and second-floor beam levels respectively.

The impact locations were at storey beam levels (middle of the beam). The resulting acceleration time

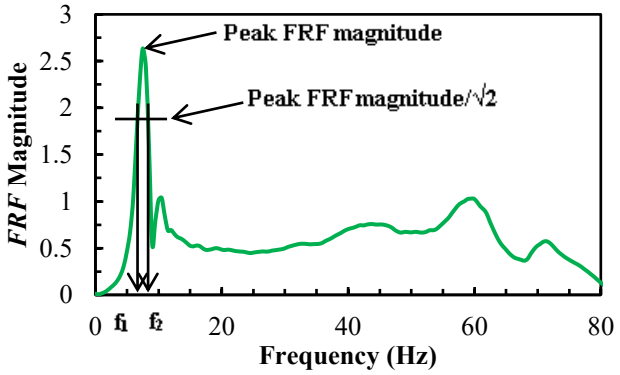
histories were recorded by the mounted sensors. They were further converted to the frequency domain using Fast Fourier Transforms (*FTT*). Further, the Frequency Response Function (*FRF*) is the ratio of the output response of the system and the input excitation given to the system. Both the output and input signals in the frequency domain i.e., the Fourier amplitudes were used to obtain the *FRF* plot as a complex spectrum of the system. Figure 4 shows the typical frequency response of a hammer impact, the corresponding acceleration response of the structure, and the resulting *FRF* magnitude plot calculated using the *FFT*s of hammer input and the acceleration response.



(a) FFT of hammer impact



(b) FFT of an accelerometer signal



(c) FRF magnitude plot

Figure 4. Estimation of the damping ratio from the FRF magnitude plot using half-power bandwidth method.

The damping ratios were estimated from the FRF plots using the Half-Power Bandwidth method (Chopra, 2023) as given by Equation 1.

$$D = \frac{f_2 - f_1}{2 * f_n} \quad (1)$$

where f_1 and f_2 are the frequencies corresponding to the peak *FRF* magnitude/√2, and, f_n is the fundamental frequency of the system. The frequency corresponding to the peak of the *FRF* magnitude plot represents the fundamental frequency of the system

4 RESULTS AND DISCUSSION

Tables 2 to 4 present the damping ratio of the structure with different floors and hammer impact locations. (Note: Ground Floor is abbreviated as *GF*).

Table 2. Damping ratio of GF structure (GF hammer hit location).

Base condition	Load factor	Damping Ratio (%)	
		At *A1*	At *A4*

	1	7.6	8.6	5.7
	1.5	-	-	-
10% Mixture	*NL*	13.9	13.6	10.8
	1	11.6	11.6	13.3
	1.5	5	12.3	14.3
Pure Rubber	*NL*	11.8	11.8	10
	1	15.7	-	16.7
	1.5	31.2	18.7	20

Table 4. Damping ratio of GF+2 structure (GF hammer hit location).

Base condition	Load Factor	Damping Ratio (%)			
		At *A1*	At *A2*	At *A3*	At *A4*
Fixed Base	NL	13.2	11.0	9.3	-
	1	8.2	16.7	11.3	-
	1.5	8.9	20.0	10.2	-
Pure Sand	NL	-	11.4	-	-
	1	18.2	-	-	-
	1.5	-	18.5	17.0	-
10% Mixture	NL	14.6	12.5	12.8	-
	1	17.8	14.3	14.3	13.5
	1.5	15.0	11.6	10.8	-
Pure Rubber	NL	16.5	15.8	-	12.0
	1	22.5	21.0	7.83	23.7
	1.5	12.5	16.2	14.6	36.7

At the outset, the damping ratio was found to be lowest for the structure whose base was fixed. This is because the displacements developed upon impact were the least in the case of a structure with a fixed base. This is in line with the known fact that at low strains, the damping ratio is minimal.

When the base condition of the structure was changed from fixed to pure sand, an increase in the damping ratio was observed. Further, for the structure with sand-rubber tire shred mixture foundation (10% mix), the damping ratio remained more or less the same as observed in the case of pure sand. However, in many cases, the damping values of the system were observed to increase. Interestingly, for the structures on the pure rubber tire shred block, the overall damping ratio was found to be comparatively less than that of the cases where the structure was founded on pure sand and the 10% sand rubber tire shred mixture. This observation is also supported by the experimental results from the laboratory element tests where the pure rubber tire shreds were found to show the least damping ratio in comparison with the damping ratio observed for pure sand and the 10% sand-rubber tire shred mixture (Madhusudhan et al., 2017, 2019, 2020).

5 CONCLUSION

The dynamic responses of scaled physical models were studied using impact hammer testing. The base conditions of the foundation and the loading on the models were varied. The results are higlighted in terms of the damping ratios.

The damping evaluated for the case of a model structure founded on a 10% sand-rubber mixture foundation block is higher than the cases where other materials are used in the foundation.

The present experimental study shows that the 10% sand-rubber mixture can be a promising material. The results of the present study show that this mixture has a potential to act as a vibration dampening foundation material for low-rise buildings. However, future research is essential for more rigorous analysis under more realistic conditions.

Performance assessment of a combined foundation system of end-bearing and floating piles in a challenging soil profile

Évaluation des performances d'un système de fondation combiné de pieux porteurs et de pieux flottants dans un profil de sol complexe

A. Magdy*, M. Shahien, M. El Sawwaf, A. Nasr

ABSTRACT: This study evaluates the performance of a combined foundation system of end-bearing and floating piles in a challenging soil profile consisting of a sand layer of thickness of 12 m overlying a substantial deposit of soft to medium stiff clay in Egypt Nile Delta deposits. The objective is to assess the effectiveness of this foundation system in providing stability highlighting the load-sharing ratios. This system offers a time-efficient alternative to conventional soil improvement techniques such as wick drains or vacuum consolidation. These methods often require considerable time and may have limited effectiveness on deep clay soil, especially beyond a depth of 10 - 15 meters below ground level, hence the challenge arises. By incorporating piles of varying lengths, this system provides a rapid solution for achieving the desired stress distribution by capitalizing on the high end-bearing capacity in sand and the skin friction provided by long piles in clay. 3D numerical simulations were conducted to assess the performance of three systems, using only end-bearing piles, only friction piles, and the combined foundation system. The insights gained assured that this system has a superior performance on decreasing settlement and benefiting from all factors, piles end bearing in sand, high friction from piles rested in clay, and bearing capacity of soil beneath the raft.

RÉSUMÉ: Cette étude évalue les performances d'un système de fondation combiné de pieux en bout et flottants dans un profil de sol difficile, composé d'une couche de sable d'une épaisseur de 12 m recouvrant un dépôt substantiel d'argile molle à moyennement raide dans les dépôts du delta du Nil en Égypte. L'objectif est d'évaluer l'efficacité de ce système de fondation dans la fourniture de stabilité, en mettant en évidence les ratios de partage de charge. Ce système offre une alternative efficace en termes de temps aux techniques conventionnelles d'amélioration des sols telles que les drains de mèche ou la consolidation sous vide. Ces méthodes nécessitent souvent un temps considérable et peuvent avoir une efficacité limitée sur les sols argileux profonds, en particulier au-delà d'une profondeur de 10 à 15 mètres sous le niveau du sol, d'où le défi. En incorporant des pieux de longueurs variables, ce système fournit une solution rapide pour atteindre la distribution de contraintes souhaitée en capitalisant sur la capacité portante élevée en bout dans le sable et la friction de la peau fournie par les pieux longs dans l'argile. Des simulations numériques 3D ont été réalisées pour évaluer les performances de trois systèmes, en utilisant uniquement des pieux en bout, uniquement des pieux de friction et le système de fondation combiné. Les informations obtenues ont confirmé que ce système offre des performances supérieures en termes de réduction des tassements et bénéficie de tous les facteurs, la capacité portante des pieux en bout dans le sable, la friction élevée des pieux reposant dans l'argile et la capacité portante du sol sous la dalle.

1 INTRODUCTION

The utilization of piled rafts (PRs) for the construction of high-rise buildings and offshore structures has proven to be an effective and cost-efficient solution for controlling total and differential settlements and increasing bearing capacities. Traditional design approaches often adopt the assumption that all structural loads are supported by piles, neglecting the significant load-sharing potential of soil beneath the raft, depending on the pile group concept. However, remarkable research, e.g., by Cooke (1986) has emphasized that about 30% of the total load can be effectively supported by the soil. Furthermore, Katzenbach, et al. (1998) pointed out the importance of taking the soil-structure interactions between raft, soil, and piles while designing a PR. Hence, the design approaches for PRs, which consider this load-sharing effect, are more rational and economical. Over the past decades, researchers have studied the behavior of PRs using various techniques for different soil types. Experimental studies have been conducted to understand the PRs behavior in sandy soils, for instance, by Elwakil

and Azzam (2016) and in saturated clay such as Hoang et al. (2024), and Hoang and Matsumoto (2020). Numerical methods have been employed to investigate PR behavior in stiff clay, e.g., Mali and Singh (2018). It is worth noting that the suitability of PRs can differ depending on geological soil profiles. Poulos (2001) pointed out that in situations with end-bearing piles and a layer of loose sand or soft clay near the foundation surface, PRs may not be the best choice because of the limited contribution of the soil after losing contact due to several factors. Reul and Randolph (2003) analyzed PRs in over-consolidated clay. Furthermore, the application of PRs extends to various soil types, as evidenced by studies in Frankfurt stiff clay (Sommer, et al. 1985) and Berlin Sand (El-Mossallamy, et al. 2006). Researchers have explored the behavior of PRs in soft clay as well, such as studies conducted by El Sawwaf et al. (2022a, 2022b) who proved the applicability of PRs in soft clay, under reasonable stress, emphasizing the ability of soil to carry a substantial portion of the load conditional on the shaft resistance of the piles.

1.1 Research objectives and methodology

In areas of the Egypt Nile Delta with a soil profile featuring a sand layer overlying soft to medium stiff clay, traditional ground improvement techniques like vertical drains and vacuum consolidation may not be effective due to the limited efficacy of the upper fill on the clay and the time required for these methods. Therefore, this study proposes a piled raft (PR) solution. End-bearing piles, where all tips are in sand, may not be optimal due to limited friction from short lengths and the decreased end bearing because of soft layers beneath while using long piles, where all tips are in soft to medium stiff clay, sacrifices end-bearing. To address these challenges, numerical simulations will be conducted to evaluate three scenarios: Short piles with all tips in sand (end-bearing piles), long piles with all tips in clay (friction piles), and mixed configurations combining end-bearing and friction piles. Through these simulations, the research aims to provide insights into cost-effective foundation solutions for structures in challenging soil profiles like those found in the Egypt Nile Delta.

2 SOIL PROFILE DESCRIPTION

This study was carried out on an actual soil profile situated within the Nile Delta deposits of Egypt. The soil profile consists of a 12-meter layer of medium to dense sand, which is underlain by an extensive 48-meter layer of soft to medium stiff clay. Beneath this clay layer, a further layer of dense sand extends to the end of the boreholes. The groundwater level is situated at a depth of approximately 3.0 meters below the ground level. The site investigation was conducted by Hamza Associates, a reputable organization in Egypt, with expertise in geotechnical studies.

3 FINITE ELEMENT MODELING

The foundation was subjected to a uniform load (q) of 150 kPa (the raft own weight and additional stress). The constitutive model, mesh, boundary conditions and piles and raft modelling are presented in the following subsections.

3.1 Constitutive model

In this study, the Hardening Soil (HS) model was adopted for all soils, as the (HS) model can simulate the behavior of both stiff and soft clays (Schanz, 1998). In addition, Brinkgreve et al. (2010) reported that the HS model covers the behavior of a wide range of sands. A distinctive attribute of the HS model is its ability to account for stress path and their consequent impact on soil behavior. It considers three stiffnesses, the secant stiffness (E_{50}^{ref}), Oedometer loading stiffness, (E_{oed}^{ref}), and unloading/reloading stiffness, (E_{ur}^{ref}). Furthermore, this model considers the stress-dependency of stiffness.

3.2 Finite element mesh and boundary conditions

The parametric investigation was executed on a quarter-section of the PR, chosen for its symmetry. The lateral limits of the soil domain were restricted to prevent horizontal translation while permitting vertical soil displacement. The horizontal boundary was 4 times of raft width from the raft edge. The vertical soil boundary was set to exceed three times the width of the raft below the equivalent raft depth, as per the equivalent raft concept proposed by Tomlinson (2001) for the case with the longest piles. The model employed a medium-mesh size, although a finer mesh was utilized within the active zone.

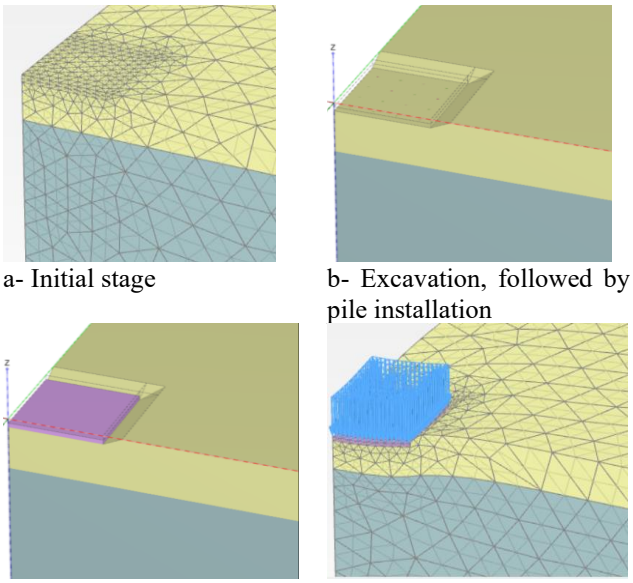
3.3 Modelling of raft and piles

The raft was modeled using a 10-node tetrahedral element, while the piles were modeled as 3-noded embedded beam elements with fixed head conditions. The study also considered the interaction between the soil and the structural elements, incorporating an interface strength value of 0.7 for the concrete-soil interface, Elwakil and Azzam (2016). Bored piles were utilized

in the study, with layer-dependent pile friction activated. The end-bearing value of the piles was not limited, allowing it to be obtained from the program solution.

3.4 Construction stages

The analysis included 5 stages, shown in Figure 1, the initial stage, excavation up to the depth of 2.0m, pile installation, raft construction, and loading. The excavation was carried out with appropriate slopes to prevent side falling. The displacement was set to be zero after the pile installation stage, where the raft settlement was the summation of the raft construction and loading stages. Tables (1-3) show the input parameters.



a- Initial stage b- Excavation, followed by pile installation

3.5 Parametric study

The vertical settlement and load sharing ratio (LSR), load carried by piles, were obtained for all cases where the raft was (40 × 40 × 1) m, and pile number (n), pile diameter (d), and pile spacing (s) were 64, 0.80 m, 6d, respectively. To study the effect of increasing pile length for the case of end-bearing piles, simulations were carried out on a PR with piles of 5, 6, 7, 8, and 9m. These lengths were changed to 20, 25, 30, and 35m in case of friction piles. Appropriate lengths of end-bearing piles, and friction piles would be selected to create the combined foundation system of end-bearing and friction piles. Figure 2 presents the different configurations studied of the combined foundation system.

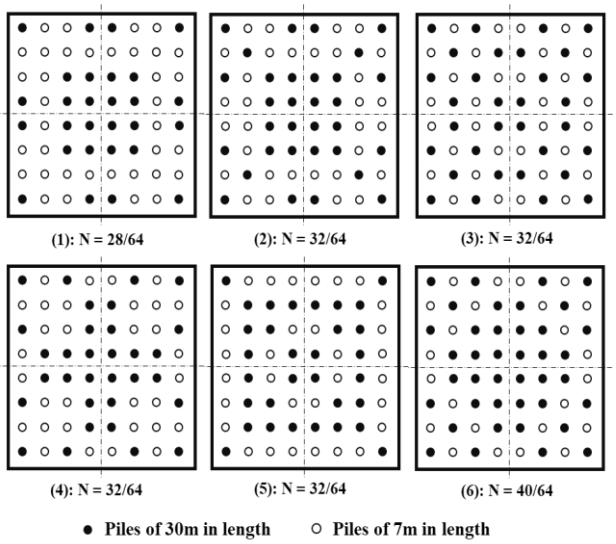

Figure 2. Different configurations of the combined foundation system of end-bearing and friction piles.

4 RESULTS AND DISCUSSIONS

A detailed analysis of findings, organized into three distinct categories is presented as follows:

1- using only end-bearing piles, 2- using only friction piles, and 3- using the combined foundation of end-bearing and friction piles.

4.1 Using only end bearing piles

As depicted in Figure 3, the various lengths of end-bearing piles consistently exhibited similar behavior even with increasing pile length. This may be explained as the longer pile length could affect the soft to medium stiff clay layer, as it brought the pile tips closer to this layer, resulting in higher load transmission through the end bearing. Regarding load sharing, it was observed that the total pile loads exhibited a gradual increase as the pile length increased up to 7.0 meters, (see Figure 4). Beyond this point, the rate of increase became limited. This can be attributed to the following: given that the skin friction of the piles increased marginally, the primary factor influencing load sharing was the end bearing; it was determined that pile lengths exceeding 7.0 meters were impacted by the presence of a weaker layer, soft to medium clay, as the depth beneath the pile tips was insufficient to achieve a higher end bearing capacity.

4.2 Using only friction piles

The primary aim was to evaluate how floating piles could effectively mitigate settlement in such a challenging soil profile. As illustrated in Figure 5, there was a notable reduction in vertical settlement as the length of the floating piles increased. This superior performance of floating piles compared to end-bearing piles could be the result of the substantial lengths, which provided a greater capacity for generating frictional resistance against movement. Additionally, under the same applied stress, the pressure bulb resulting in the case of long piles (friction piles) had a greater depth compared to that resulting in the case of short piles (end-bearing piles), (see Figure 6). Therefore, the settlement was smaller, as the stress was distributed over a larger volume of soil, causing less compression of soil particles. Regarding load sharing, Figure 7 illustrates the relationship between pile length and load sharing ratio. It was observed that the total pile loads exhibited a gradual increase with increasing pile length because of increasing pile friction. This increase was expected with increasing lengths; however, it can be linked to the increased vertical stress resulting from the own weight and external loads, leading to heightened horizontal stresses and consequently, an enhancement in frictional resistance.

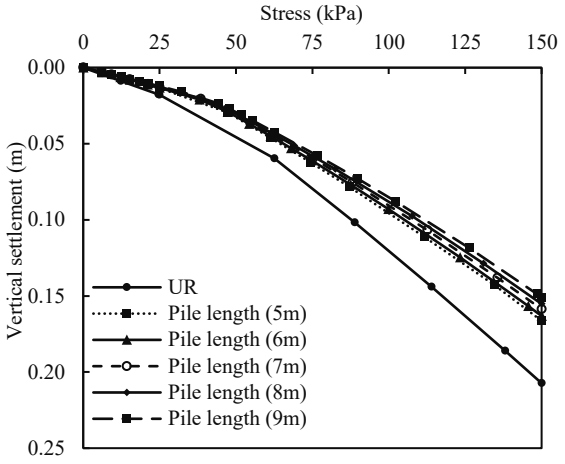

Figure 3. Relationship between stress and vertical settlement for UR and PR with all tips in sand.

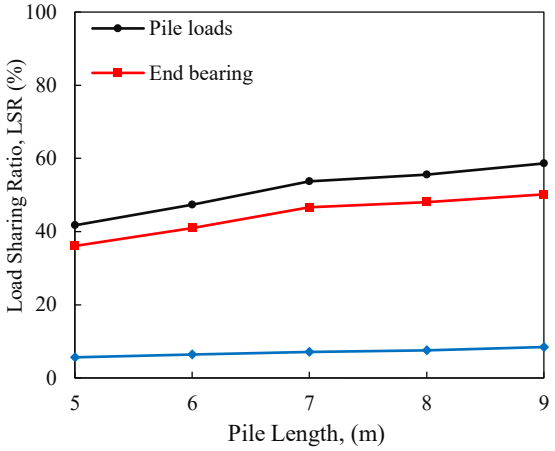

Figure 4. Relationship between pile length and load sharing ratio (LSR) for piled rafts with all tips in sand.

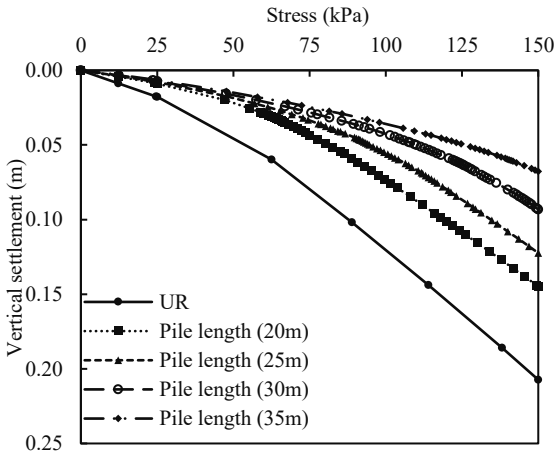

Figure 5. Relationship between stress and vertical settlement for UR and PR with all tips in clay.

4.3 Using a combined system of end bearing and friction piles

For this system, the lengths of 7.0m, and 30m were chosen for end-bearing piles, and friction piles,

respectively. The length of 7.0 m for end-bearing piles was proven to be the most appropriate one, whereas the length of 30m for friction piles was chosen from an economic perspective. The relation between the applied stress and vertical settlement for the different configurations is presented in Figure 8. Mainly, the combined foundation system could achieve a decrease in the vertical settlement more than the chosen case from cases of end-bearing piles only. However, this system couldn't achieve the same decrease in settlement of the case of only friction piles, it may be adoptable based on the project criteria and requirements. The decrease in settlement was a result of benefiting from the frictional resistance of long piles and high-end bearing from short piles. Moreover, this system expanded the pressure bulb more than in all cases of end-bearing piles only (not presented due to space limitations), so the settlement of individual particles was reduced. To go deeper among the mixed systems, system 3 exhibited comparatively lower efficiency due to the random configuration of long piles, particularly away from the raft center. Conversely, system 6 was the most efficient choice, due to the higher number of piles. The performance of this system in decreasing settlement was nearly 90% of the friction piles system with 40 long piles and 24 short piles. The economic benefit was not using 552 m of concrete (around 278 m^3 of concrete). Therefore, employing this system can be a safe and economical solution. For the mixed systems 1, 2, 4, and 5, their stress-settlement behavior displayed similarities. This superiority of system 1 even with less number of piles was attributed to its strategically concentrated pile positioning around the center of the raft, coinciding with the location of maximum vertical settlement. For the load sharing, Table 4 shows that the piles carried around half of the total load in all cases, which was around 30% carried by frictional resistance. This assured the importance of growing friction in deeper soil that was influenced by the increase in horizontal stresses.

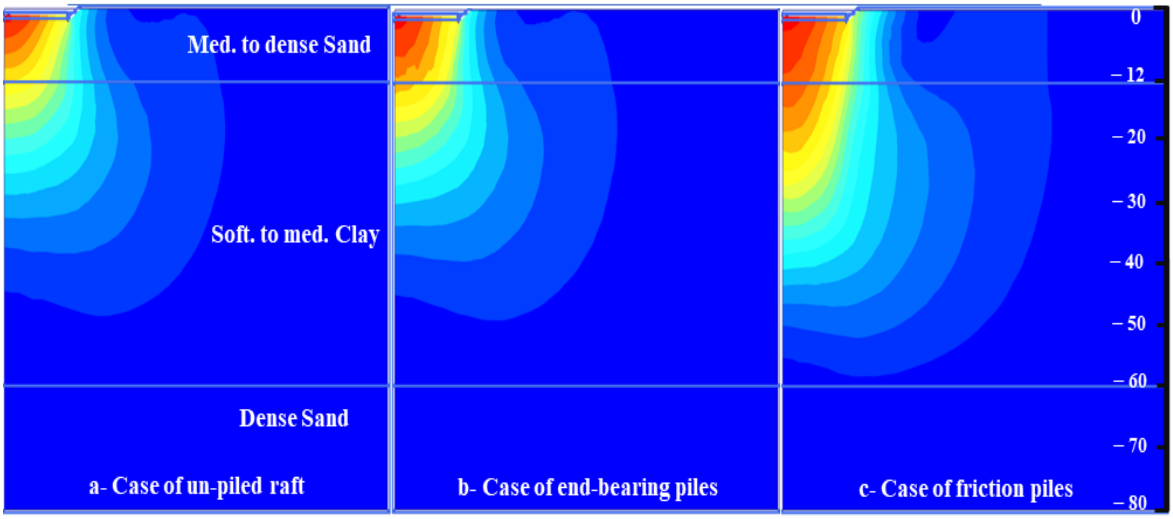

Figure 6. Stress distribution for different cases (a- un-piled raft; b- case of end-bearing piles; case of friction piles).

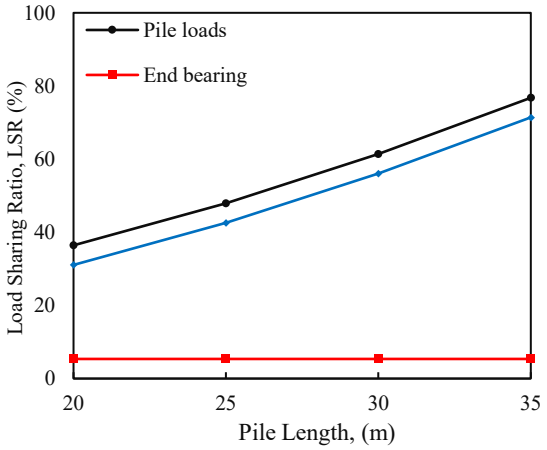

Figure 7. Relationship between pile length and load sharing ratio (LSR) for piled rafts with all tips in clay.

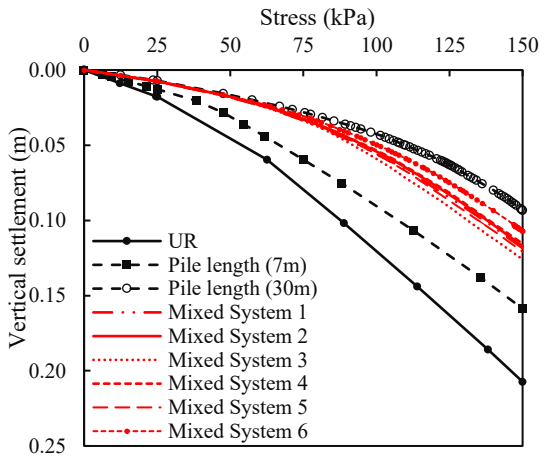

Figure 8. Relationship between stress and vertical settlement for UR, PR, and the combined foundation systems.

Table 4. Load sharing ratios as a ratio of total applied load.

	Pile loads (%)	End bearing (%)	Skin Friction (%)
1	51.79	23.31	28.48
2	52.44	20.08	32.37
3	50.64	21.72	28.92
4	52.10	20.05	32.05
5	52.37	20.46	31.92
6	53.33	14.97	38.35

5 CONCLUSIONS

Due to the potential for unacceptable settlements resulting from the utilization of un-piled rafts, this research compares three solutions of piled rafts: those with all pile tips in sand, those with all pile tips in clay, and a mixed system with some pile tips in sand and some in clay. Based on the study, the following remarks can be drawn:

- Friction piles were highly effective in decreasing settlement in such a challenging soil profile due to increased frictional resistance and bigger pressure bulbs.
- The combined system reduced settlement remarkably compared to using end-bearing piles alone. The system of higher pile numbers was the most efficient choice, offering nearly 90% of the friction piles system benefits while being economically advantageous.

ABSTRACT: Rigid inclusion is a ground improvement method that has been significantly developed in recent years. Granular load transfer platforms (LTP) are commonly used in this technique leading to an increase in the use of natural resources. In this context, soil treatment can be considered as an alternative solution to use the in-situ soil, improve its characteristics, and limit the pressure on the granular material resources. As part of the national ASIRI+ project, two full-scale tests have been carried out to test the efficiency of treated LTP. An experimental program has been conducted to fully characterize the soil and find the best treatment for the LTP with consideration for the environmental and the economic effects. Then, both tests have been carried out in an 8m x 8m pit with 16 rigid inclusions of 30cm diameter and 1m height. Settlement and stress sensors were installed to monitor the mechanism of load transfer within the platform. Numerical simulation tests have also been performed to better understand the behaviour of the treated LTP.

RÉSUMÉ: Le renforcement du sol par inclusions rigides est une méthode d'amélioration du sol qui a été développée de manière significative ces dernières années. Les plateformes de transfert de charge (PTC) granulaires sont couramment utilisées dans cette technique, ce qui entraîne une augmentation de l'utilisation des ressources naturelles. Dans ce contexte, le traitement du sol peut être considéré comme une solution alternative pour utiliser le sol in situ, améliorer ses caractéristiques et limiter la pression sur les ressources granulaires. Dans le cadre du PN ASIRI+, deux essais en vraie grandeur ont été programmés pour tester l'efficacité des PTC traitées. Un programme expérimental a été mené pour caractériser le sol et trouver le meilleur traitement en tenant compte des effets environnementaux et économiques. Les essais ont été réalisés dans une fosse expérimentale de 8m x 8m avec 16 inclusions rigides de 30cm de diamètre et de 1m de hauteur. Des capteurs de tassement et de contrainte ont été installés pour observer les mécanismes de transfert de charge. Des modélisations numériques ont également été réalisées pour mieux comprendre le comportement de la PTC traitée.

Keywords: Soil treatment; rigid inclusions, load transfer platform, full-scale test.

1 INTRODUCTION

Rigid inclusion is a soil reinforcement technique that has been widely spread during the last 50 years (Briancon *et al.*, 2020). It consists of installing rigid columns known as rigid inclusions (RI) in soft soils and a load-transfer platform (LTP) that transfers the loads applied on the surface to the RI through the arching effects. The difference of settlement between the RI and the soft soil creates negative friction along the RI leading to a better load transfer. The field of application for this technique has been widely extended given its many advantages: rapid implementation, increase of the bearing capacity and the soil resistance and decrease of the settlements of the surface structure (ASIRI, 2012).

Granular LTP formed of sand or gravel are quite common in this technique (Girout *et al.*, 2013) leading to an increase in the exploitation of natural resources, hence the need to find an alternative solution to use the in-situ soil, improve its characteristics and limit the pressure on granular material resources has led to consider treated LTP. This article presents a full-scale experiment to test the efficiency of treated LTP on rigid inclusions.

2 EXPERIMENTAL STUDY

An experimental campaign was held to characterize the soil used for the LTP and find the best treatment with regards to the economic and the environmental effects. Mechanical soil tests were conducted to determine the efficiency of the treatment.

2.1 Soil treatment

The soil used for the treated LTP is silt, extracted from Dieppe in the north of France of type F1 (low plasticity silt) according to the new French guide for earthworks, embankments, and subgrades (GTR, 2023). It has a water content between 17 and 23%.

Three different formulas were adopted for the test:

- SLC: soil + 1% lime + 4% cement
- SLCO: soil + 1% lime + 4% COmpaxem
- SA: soil + 5% Argiliant+

The 1st treatment "SLC" and the percentages of lime and cement were chosen based on the state of art, the French technical guide for soil treatment (GTS, 2000), and for the fact that it is widely used for treating working platforms on construction sites. It has a workability time of 1 hour. The lime is supplied by the Lhoist group (quicklime CL90-Q), and the cement is CEM II 32.5.

The 2nd and the 3rd treatments "SLCO" and "SA" were considered to take into effect the environmental effects. Argiliant+ and COmpaxem are binders that comply with the French norm NF P15-108 and are perfectly suited to soil treatment, with a workability time of 1h30 and 6h respectively. They are composed of different metakaolin/cement ratios. Table 1 shows the different studied formulations.

Table 1. Treatment formulations

Treatment	Lime (%)	Cement (%)	Metakaolin
SLC	1	4	-
SLCO	1	2.4	1.6
SA	1	1.5	2.5

2.2 Mechanical properties

Mechanical soil tests were conducted at different curing periods by laboratory standardized tests according to the French norms to explore the effect of the treatment on the mechanical resistance. Samples were prepared and kept for curing with reference to the French norms.

The shear strength was determined by triaxial tests. The natural soil has a friction angle of 29° and a cohesion of 34 kPa. The friction angle does not vary with treatment and remains around 29°. The treated soils show an increase in cohesion. The results are presented in figure 1 with SLC presenting the best long-term cohesion at 550 kPa.

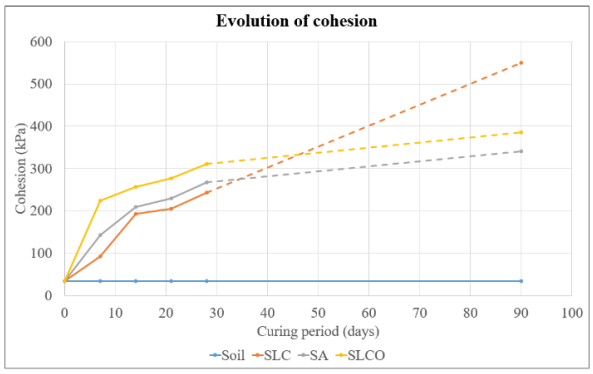

Figure 1. Evolution of cohesion.

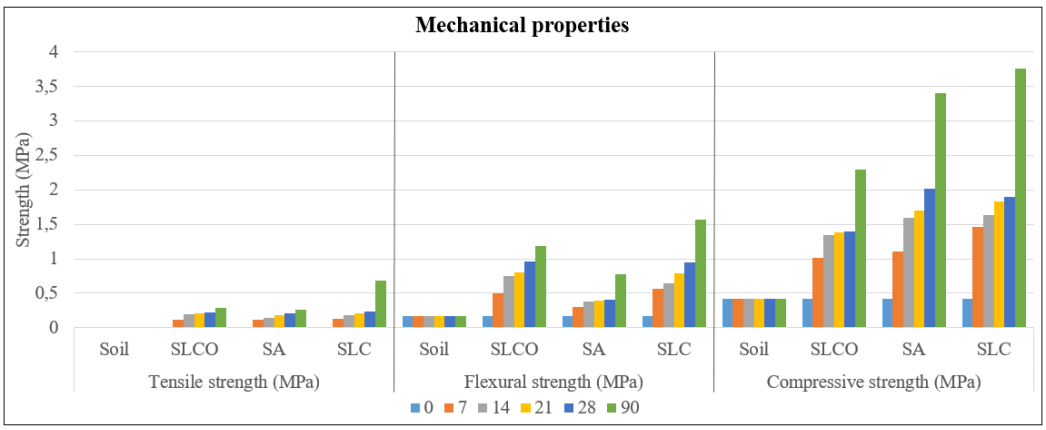

Figure 2. Mechanical properties of treated soil.

The evolution of other mechanical properties is presented in figure 2 through tensile, flexural, and compressive strengths with SLC presenting the best results compared to SLCO and SA.

2.3 Experimental study

The full-scale test in Cerema's experimental pit is representative of the real-life case of a soil reinforced with rigid inclusions. This 64 m^2 pit features 16 rigid inclusions of 30 cm diameter and 1 m height, set in a 2 m square mesh (Figure 3).

Figure 3. Experimental pit – Cerema.

The system, designed to test the effectiveness of treated LTP, consists of several layers of soil, a treated LTP and different types of loading.

A first layer of 2.5 cm thick of wooden grating is installed, followed by a 10 cm layer of biocofra (honeycomb cardboard planks). Biocofra is very rigid when dry but biodegrades uniformly throughout its thickness in the presence of water, hence the need for the grating layer to facilitate water supply.

Dissolving the biocofra will be used only if necessary to achieve failure of the treated LTP, as this may help us to better understand the failure mechanism and behaviour of the treated platform.

A third 40 cm layer of Deltagom (tire aggregate) is installed. Due to its compressibility, this material can help us to obtain a representative settlement of what happens in the real case. Above the Deltagom, a 37.5 cm layer of sand is installed to reach the level of the heads of the rigid inclusions (Height = 1m).

Compaction of the sand is possible on the Deltagom and the combination of these 2 soil layers represents the soft soil found in the real case of a site reinforced with rigid inclusions.

For the load transfer platform, the “SLC” treatment was chosen, based on the mechanical strength tests and for being widely used for treating working platform on construction sites. The soil cannot be treated directly in the pit, as there is a risk of consuming all the Deltagom settlement and damaging the sensors on the heads of the RI. Therefore, the soil was prepared aside, homogenized, treated with lime, and followed by cement one hour later. This procedure reduces the water content of the soil, facilitates particle flocculation, and brings the soil to an optimal state, ideal for effective cement treatment.

After cement treatment, the mixture is transported to the pit by tractors and the LTP is installed in 2 layers of 20 cm to ensure good compaction of the mix and good soil density.

Finally, a 1.5 m embankment is placed on top of the treated platform. The LTP is loaded after 14 days of compaction. This curing time has been chosen to ensure that the platform reaches the required mechanical strength to withstand the different loadings. The embankment was kept for 1 month to monitor the load transfer mechanisms, then, surcharges were added and left for 14 days before the final phase: dissolving the biocofra.

Figure 4 shows a cross-section of the entire experimental setup. Instrumentation is carried out using stress and settlement sensors installed in the different layers of the setup to monitor the load transfer mechanisms, measure the soil settlement, and test the efficiency of the treated platform.

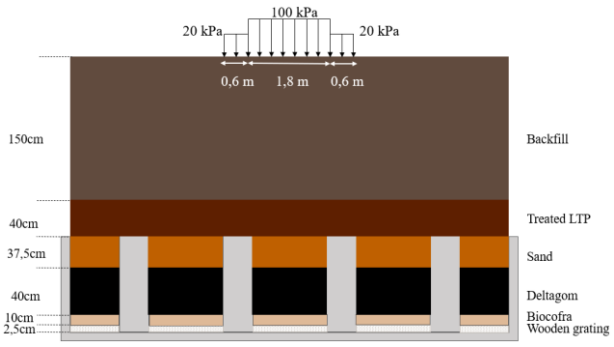

Figure 4. Cross section of the experimental setup.

3 RESULTS

In order to understand the load transfer mechanisms and the behaviour of the treated platform, the evolution of stresses and settlements was studied as well as the LTP’s behaviour and the failure mechanisms.

3.1 Stress evolution

Stress sensors were installed within the differents layers of the setup presented in figure 4. Instrumentation was performed on the central mesh to eliminate the edge effects. Figure 5 presents the stress at the base and the head of the RI as well as the soil (sand) during the different phases of construction.

Based on the stress evolution we noticed:

- The good functioning of the system where a load transfer towards the rigid inclusions in relation to the soil was observed.
- A proper load transfer where the stress is higher at the base than it is at the heads due to the negative friction along the entire length of the RI.
- The load transfer is immediate for the treated platform. When the embankment is placed the stress goes up directly to 742 kPa at the head of the RI. During the 1 month's wait, it increases only by 9.9% (816 kPa) indicating that the load transfer started the minute the embankment was placed for the treated LTP. This was not the case for the granular LTP where the same test was carried out by (Terqueux *et al.*, 2022) using the same experimental setup and instrumentation. The results for the granular LTP showed that load transfer mechanisms were more gradual and during the 1 month's wait, the stress increased by 79.4% at the head of the RI.

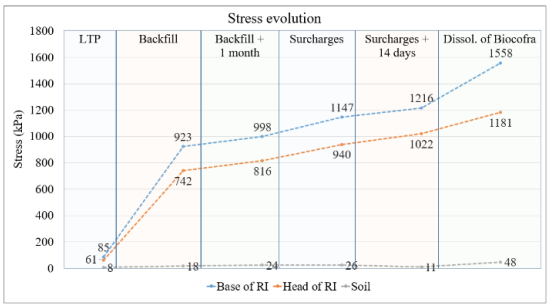

Figure 5. Stress evolution.

3.2 Settlement evolution

Same as for the stress sensors, settlement sensors were installed on the different layers to monitor the settlement of the system (Figure 6).

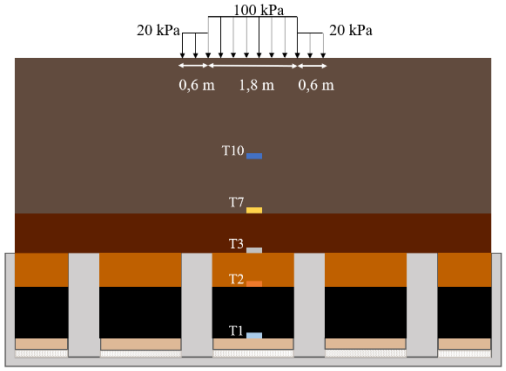

Figure 6. Settlement sensors.

Based on the settlement evolution presented in Figure 7, we noticed:

- The experimental protocol has been validated in terms of the dissolution of the biocofra that is very rigid when dry (0 cm of settlement during all the stages of loading) but biodegrades uniformly throughout its thickness in the presence of water (9.2 cm of settlement was observed for the sensor T1 placed on the biocofra once it was dissolved).
- The settlement was evolving in a homogeneous way across the different layers of soil, indicating that a punching shear was taking place at the RI. After the dissolution of the biocofra, the final settlement was around 20 cm.

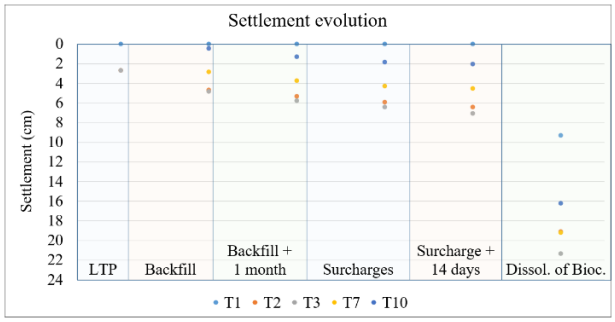

Figure 7. Settlement evolution.

3.3 LTP behaviour

To study the behaviour of the treated platform, the stress measured on the LTP is presented in function of the settlement in Figure 8.

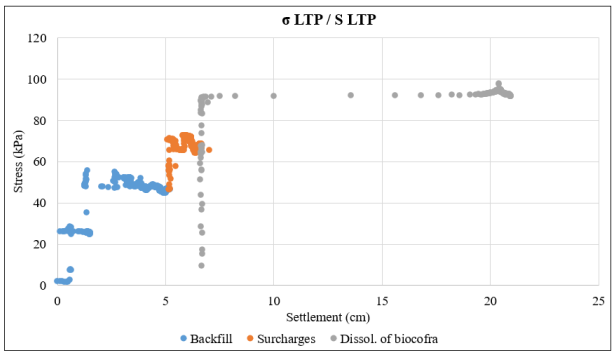

Figure 8. LTP behaviour.

We can clearly see that when the embankment was laid, the stress increases on the treated platform and then, during the 1 month's wait, it is the settlement that increases for a constant stress. This indicates that a punching shear is taking place at the LTP, and the platform is behaving like a slab that settles uniformly and homogeneously. This phenomenon was repeated when the loads were added and during the dissolution of the biocofra. However, we noticed that when the biocofra was dissolved, the stress drops suddenly to 0 due to the rupture within the treated platform, before going back up due to the fact that the embankment and the loads are now resting entirely on the LTP. After the failure of the LTP, we have a total settlement of 20 cm.

3.4 Failure mechanisms

Based on the stress and the settlement evolutions and the behaviour of the treated LTP, we concluded that the failure of the platform was caused by a punching shear that took place at the RI, with a total settlement of 20 cm.

Figure 9 shows the initial and the final state of the LTP. There was a 10 cm crush at the heads of the RI, with the surrounding soil settling by 20 cm as already measured.

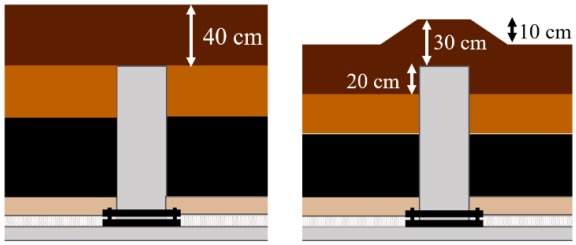

Figure 9. Initial and final state of the treated LTP.

The failure mechanisms were visually validated after disassembling the setup. The punching shear and the settlement are presented in the figure 10 below.

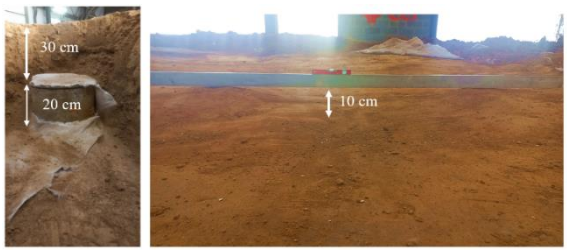

Figure 10. Failure of the platform.

4 CONCLUSIONS

As part of the national ASIRI+ project, a study of the behaviour of treated load transfer platform has been planned. This study aims to improve the understanding of load transfer mechanisms in treated platforms. A full-scale test was carried out to test the efficiency of treated LTP and the following conclusions were formed:

- Treated LTP was properly installed and controlled during the test.
- Experimental protocol was validated (good functioning of sensors, load transfer, dissolution of biocofra …)
- Load transfer was immediate for the treated LTP.
- Treated platform behaved like a slab.
- Punching shear failure has occurred in the treated platform.

Numerical modelling is underway to better understand the load transfer mechanisms in the treated LTP. A second test will also be carried out with some modifications:

- A 10cm treated working platform will be added under the LTP to homogenize the compaction and reduce the punching shear effects.
- A gammadensimeter will be used to control the density of the treated platform throughout the test.

ACKNOWLEDGMENTS

This work was carried out as part of the national ASIRI+ project. The authors would like to thank all the members of this project for their support.

Comparison of the effects of different additives on the improvement of physical and mechanical properties of clayey soil

Comparaison des effets de différents additifs sur l'amélioration des propriétés physiques et mécaniques des sols argileux

ABSTRACT: Bearing in mind that fine-grained clayey soils are the most sensitive to changes in moisture content, the paper presents the results of testing the effects of chemical stabilisation of clayey soils by considering a variety of chemical additives. In addition to the previously known chemical stabilisers, such as calcium carbonate and magnesium carbonate, less frequently used materials such as sodium silicate and potassium hydroxide were also considered. For each of the considered chemical stabilisers mixing was performed with three different percentages of a share of a stabiliser in the mixture with clay, in order to determine the optimal amount of a stabiliser in the mixture. Furthermore, with an aim to evaluate the durability and permanence of the effect of clay stabilisation, which is of crucial importance in geotechnical engineering, changes in the physical and mechanical properties of the treated clay were also determined in four different time intervals after the chemical treatment. Based on the results of this research, it can be concluded that different chemical stabilisers have different effects on the physical and mechanical properties of clayey soil, such as Atterberg limits and uniaxial compressive strength. The general conclusion is that the physical and mechanical properties of clayey soil can be significantly improved by applying chemical stabilisers, which opens up the possibility of applying the technique of chemical soil stabilisation in solving numerous geotechnical problems.

RÉSUMÉ: Considérant que les sols argileux fins sont les plus sensibles aux changements de teneur en eau, l'article présente les résultats des essais sur les effets de la stabilisation chimique des sols argileux en considérant divers additifs chimiques. En plus des stabilisateurs chimiques déjà connus, tels que le carbonate de calcium et le carbonate de magnésium, des matériaux moins fréquemment utilisés ont également été pris en compte, tels que le silicate de sodium et l'hydroxyde de potassium. Pour chacun des stabilisateurs chimiques considérés, le mélange a été réalisé avec trois pourcentages différents de la part du stabilisateur dans le mélange avec l'argile, afin de déterminer la quantité optimale de stabilisateur dans le mélange. De plus, dans le but d'évaluer la durabilité et la permanence de l'effet de la stabilisation de l'argile, ce qui est d'une importance cruciale en génie géotechnique, les changements dans les propriétés physiques et mécaniques de l'argile traitée ont également été déterminés à quatre intervalles de temps différents après le traitement chimique. Sur la base des résultats de cette recherche, on peut conclure que différents stabilisateurs chimiques ont des effets différents sur les propriétés physiques et mécaniques du sol argileux, tels que les limites d'Atterberg et la résistance à la compression uniaxiale. La conclusion générale est que les propriétés physiques et mécaniques du sol argileux peuvent être significativement améliorées en appliquant des stabilisateurs chimiques, ce qui ouvre la possibilité d'appliquer la technique de stabilisation chimique des sols pour résoudre de nombreux problèmes géotechniques.

Keywords: Chemical stabilisation; clayey soil; additives; uniaxial compressive strength; Atterberg limits.

1 INTRODUCTION

Clayey soils are a challenge in the construction industry due to their characteristics, caused by the mineral composition of clay and its water content, which make them prone to cracking or swelling. They are characterised by low bearing capacity, high compressibility, and high sensitivity to moisture content. Due to these facts, these soils in their natural state are not suitable for direct application in construction projects. In such cases, it is necessary to apply soil stabilisation and improvement procedures in order to meet the minimum requirements regarding the bearing capacity and quality of the soil. In an effort to make clayey soils more suitable for construction purposes, a number of techniques have been developed and numerous materials (stabilisers, reagents, additives) have been used for their

stabilisation. One of the most common techniques is chemical soil stabilisation, which is in the focus of this research.

Chemical soil stabilisation is an engineering technique that has evolved throughout history to enable the construction of safe and durable structures on a variety of soil types. The development of this technique dates back thousands of years, from early attempts to use materials such as lime and ash to improve soil characteristics. The ancient Greeks and Romans used lime to stabilise the soil, which was the forerunner of contemporary methods (Han, 2015).

Nowadays, researchers and engineers continue to improve methods of chemical soil stabilisation. Advanced research in the field of analysis and testing enables a more precise approach to soil stabilisation problems. In addition, environmental-friendly additives and materials are being examined in order to reduce the impact on the environment. Chemical stabilisation is an approach that seeks to improve the engineering and physical properties of weak soil by adding soil stabilisers or other binding additives. The effect of an additive can vary depending on the type of soil to which it is applied. Chemical treatment is predominantly used to improve the properties of fine-grained clayey soils, since these types of soils are highly susceptible to high water content (Marinkovic et al., 2021).

Soil stabilisers can be categorised into two groups. The first group includes materials that are commonly used in construction industry, such as cement, lime, fly ash, and bituminous products. In practice, in over 80% of cases, these materials are most often used for soil stabilisation (Onyelowe and Okafor, 2012). These additives have a long history of application and they are proven to be effective in improving soil properties. The second group includes chemical reagents that do not have a commercial use in geotechnics, and studies on their effects on the soil properties are current all over the world. These stabilisers provide flexibility and customisation, allowing engineers to adjust their approach to specific project needs and local soil characteristics. The application of new chemical stabilisers has opened up new possibilities for solving the challenges posed by clayey soils, offering more sustainable and cost-effective solutions for construction industry projects.

Reactions between the stabiliser and the clay occur through two distinct processes: the process of rapid ion exchange reactions, known as soil modification, and the process of slower pozzolanic reactions, known as soil stabilisation or hardening (Maaitah, 2012).

In the present research, in addition to the previously known chemical stabilisers, such as lime (calcium carbonate) and magnesium carbonate, less commonly used materials such as sodium silicate and potassium hydroxide were also considered. Soil modification was evaluated by monitoring changes in Atterberg limits and uniaxial compressive strength (UCS) during chemical stabilisation. With an aim of determining the optimal amount of a chemical stabiliser in the mixture, for each of the considered stabilisers clay samples were treated with 3%, 5%, and 7% of a share of a stabiliser in the mixture with clay (in relation to the dry weight of the soil sample). After the chemical treatment, for each of the considered stabilisers samples were tested at time intervals of 3, 7, 14, and 28 days.

2 MATERIALS AND METHODS

Clayey soil from the Crvena Reka borrow pit, along the route of the E-80 Niš–Dimitrovgrad Highway in the south-eastern part of the Republic of Serbia, was used for the tests. During the construction of the Highway, a landslide was triggered at this location. The designed remediation measures included a support structure in the form of a curtain of piles. Samples of clayey soil for the laboratory tests were taken during the construction of bored piles, from the depth at which the sliding surface was registered.

2.1 Properties of soil

The basic characteristics of the natural soil material are shown in Table 1.

In order to evaluate the effects of chemical stabilisation of the clayey soil by considering a variety of additives, changes in Atterberg limits (Liquid Limit - LL and Plastic Limit - PL) and the associated Plasticity Index - PI, as well as uniaxial compressive strength (UCS), were monitored. The tests were carried out in the Laboratory for Geotechnics at the Faculty of Civil Engineering and Architecture of University of Niš (Serbia).

2.2 Properties of additives

One of the most widely used materials for soil stabilisation is *lime (calcium carbonate) - $Ca(OH)_2$*. This naturally occurring mineral, often found in the form of limestone, has been used for decades in various construction industry projects. Lime is a versatile and cost-effective solution, primarily due to its neutralising effect on soil acidity. When added to acidic soils, lime reacts with the acidic compounds, increasing the soil pH value and improving its engineering properties.

Table 1. Properties of the clayey soil used in the research.

Property	Symbol (unit)	Value
Particle Density	Gs (1)	2.705
Liquid Limit	LL (%)	49
Plastic Limit	PL (%)	23
Plasticity Index	PI (%)	26
Grain Size Distribution	Gravel (%)	1.2
	Sand (%)	4.9
	Silt (%)	40.6
	Clay (%)	53.3
Coefficient of Uniformity	Cu (1)	8.0
Coefficient of Curvature	Cc (1)	2.0
Soil Classification	USCS Symbol	CI
Maximum Dry Density	MDD (g/cm^3)	1.903
Optimum Moisture Content	OMC (%)	18.5
Uniaxial Compressive Strength	UCS (kPa)	2.05

This stabiliser also stimulates the flocculation of soil particles, thus reducing the soil swelling potential and enhancing the soil shear strength. According to Bell (1996), all types of clay minerals react with lime. In addition, the most suitable for stabilisation with lime is clayey soil of medium to high plasticity, where PI > 15%.

While lime remains a standard choice for soil stabilisation, several less common materials have demonstrated soil stabilising potential in specific applications.

Magnesium carbonate ($MgCO_3$) represents a viable option for improving the physical and mechanical soil properties, particularly for soils with a high clay or silt content. This additive has been shown to be effective in increasing the cohesion, reducing the plasticity, and enhancing the load-bearing capacity of the treated soil (Yi et al., 2013).

Sodium silicate (Na_2SiO_3), also known as *water glass*, has been used for soil stabilisation in specific conditions. It contributes to reducing the permeability and improving the cohesion of fine-grained soils. Sodium silicate forms chemical bonds with soil particles, reducing their susceptibility to moisture-induced expansion and contraction. A research of Pakir et al. (2015) indicated the successful application of this additive for improving the properties of marine clay.

Potassium hydroxide (KOH) is a highly alkaline substance that can be utilised for soil stabilisation in certain conditions. It is particularly effective for improving the bearing capacity and compactness of clayey soils. The addition of potassium hydroxide initiates reactions that enhance the soil strength and reduce its sensitivity to changes in moisture content.

2.3 Methods

The *uniaxial compressive strength (UCS*) *test* was applied to all specimens according to the standard SRPS EN 13286-41:2022 (ISS, 2022). Each sample had been compressed until peak load was achieved, where the applied load was recorded by a data acquisition system. The UCS test was used to determine the compressive strength of soil in natural conditions and chemically treated soil for each of the four considered stabilisers. The result represents the average value of three tested samples.

The *testing of Atterberg limits* was performed according to the standard SRPS EN ISO 14688-2:2018 (ISS, 2018). The samples were dried, crushed, and sieved through a 425 μm sieve and mixed with different reagent contents to determine the effect of each on the change in values of LL, PL, and PI.

3 RESULTS AND DISCUSSION

The aforementioned tests were performed on clayey soil samples, taking into account different amounts of each of the considered stabilisers (3%, 5%, and 7%), as well as different curing periods, specifically at 3, 7, 14, and 28 days after the chemical treatment.

3.1 Uniaxial Compressive Strength (UCS)

Figure 1 provides an overview of the UCS test results of the treated soil, for each of the used chemical stabilisers: lime, magnesium carbonate, sodium silicate, and potassium hydroxide. Each result represents the mean value of three tested samples for each of the used stabilisers, for each of the considered contents of stabilisers, and for each of the considered time intervals after the chemical treatment.

In general, it is evident that each stabiliser has a beneficial effect on the UCS of the treated soil. It can be observed that the UCS values increased significantly over time as the soil was treated with lime and magnesium carbonate. On the other hand, there was a slight improvement of the UCS values when the soil was treated with sodium silicate and potassium hydroxide.

The highest values of UCS after the treatment were obtained in samples treated with ***lime***. The improvement of UCS with regard to these samples is clearly noticeable with the increase in the percentage of a share of a stabiliser in the mixture with clay. The results showed a particularly significant improvement when the lime content was increased from 3% to 5%, whereas an increase to 7% gave approximately the same results as for the 5% lime content. Regardless of the amount of the added reagent, it was clearly

observed that a remarkable improvement occurred over time. For example, after a curing period of 3 days, the UCS value increased from 2.05 kPa (for natural clay) to 4.35 kPa after the clay treatment with the addition of 3% lime, whereas with the addition of 7% lime an increase to 6.22 kPa was registered. After 28 days, an increase to 8.96 kPa and 11.78 kPa was detected for the addition of 3% and 7% lime, respectively.

The addition of ***magnesium carbonate*** gave similar results as for the lime when the content was 5% and 7%, but only in the first 14 days. After 28 days, however, samples with the addition of magnesium carbonate resulted in approximately 30% lower UCS values when compared to the lime. When the magnesium carbonate content was of 3%, a significant difference was noticed already after 7 days in comparison with the case of lime. Furthermore, as it was the case with the addition of lime, a higher increase in UCS values was observed when the content of magnesium carbonate was increased from 3% to 5%, compared to the increasing the content from 5% to 7%. Thus, after 3 days, the value of UCS was 4.04 kPa with the stabiliser content of 3%, 5.21 kPa with the content of 5%, and 5.91 kPa with the content of 7%. After 28 days, the value of UCS with the addition 3% of the stabiliser was 4.55 kPa, 7.44 kPa with the addition of 5%, whereas the value of UCS with the addition of 7% was 8.03 kPa.

The measured UCS values with the addition of sodium silicate and potassium hydroxide were significantly lower than the values obtained with the addition of lime and magnesium carbonate; however, their application certainly resulted in an increase in soil uniaxial compressive strength.

The maximum UCS value with added ***sodium silicate*** was 3.79 kPa at 5% content after 28 days. The results also indicated that with the addition of 5% sodium silicate slightly higher values of UCS were obtained than with the addition of 7% in the corresponding time intervals.

The samples treated with ***potassium hydroxide*** resulted with the maximum UCS value of 4.83 kPa at 7% content after 14 days. It can also be observed that similar UCS values were obtained after 14 days and after 28 days, regardless of the percentage of added reagent. In contrast to the three previously mentioned stabilisers, a trend of steady increase in UCS values with increasing content of potassium hydroxide was observed for all the considered time intervals. Therefore, further research could focus on the effects of using a higher percentage of potassium hydroxide to determine the optimal reagent content in the clay mixture.

The observed soil strength enhancement during the curing process can be attributed to the formation of a gel-like material with highly binding properties. This material is being formed as a result of the interaction between the soil and the stabilising reagent.

Furthermore, extended duration of curing plays a vital role in enhancing the rate of reaction among the soil particles and the stabiliser. This is primarily due to the amplified positive charge within the mixture, which leads to the repulsion of soil particles and facilitates more effective stabilisation (Latifi et al., 2013).

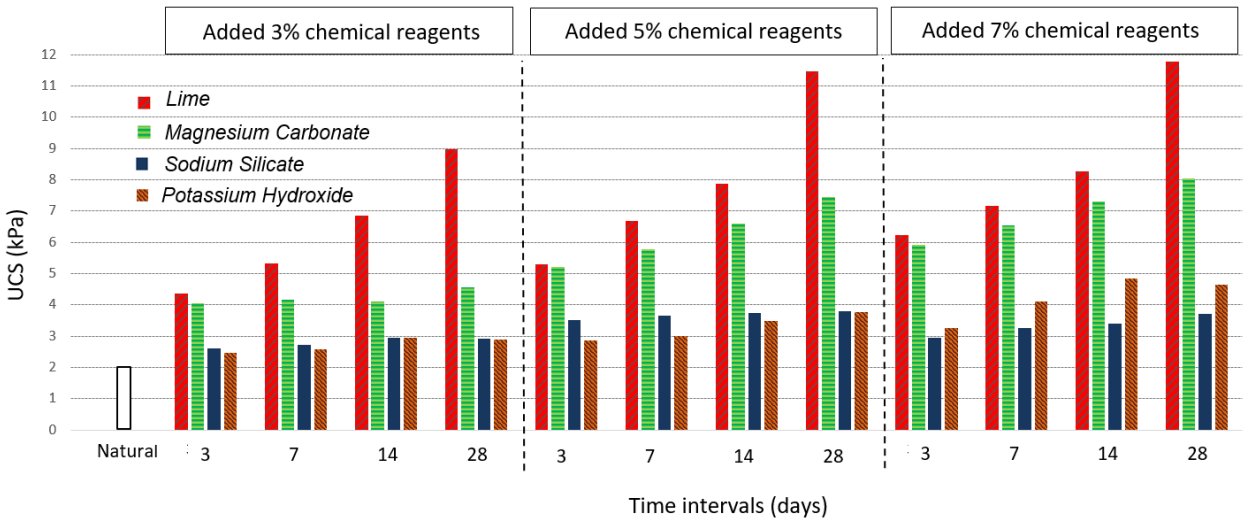

Figure 1. Change in the UCS values of the clayey soil after the chemical stabilisation with different additives.

3.2 Atterberg limits

Table 2 shows the obtained values of consistency limits for clayey soil mixtures with three different percentages of share and at four time intervals after the treatment for each of the four considered stabilisers. For the sake of comparison, it should be noted that the measured values of LL, PL, and PI of the untreated clay (soil in natural conditions) were 49%, 23%, and 26%, respectively (Table 1).

For all the considered stabilisers, the ***LL value*** did not change significantly, either with increasing stabiliser content or over time. Three days after the chemical treatment, a more pronounced increase in LL values was detected only in the samples with the addition of sodium silicate. After 7 days, all tested samples had similar LL values and this trend was also observed in testing after 14 days and 28 days. The highest increase was registered for the case of the addition of 5% magnesium carbonate after 28 days, when the registered LL value was of 54%.

A change in ***PL*** and ***PI values*** was observed in the case of all tested samples over time. A trend of increasing PL values and decreasing PI values over time may be considered positive, since there are no major changes in LL values as stated previously. Such changes indicate the possibility that clay can remain in a semi-solid state of consistency even with a higher water content. The greatest change in PL and PI values occurred after 28 days. The maximum value of PL after 28 days was 37% and was determined for the soil sample with the addition of 5% sodium silicate. The same sample also had the lowest PI value of 12%. All other samples had PI value after 28 days in the range of 17% to 20%, which indicates that the results did not significantly differ from each other regardless of the type of chemical stabiliser.

4 CONCLUSIONS

In this research, a clayey soil of unfavourable physical and mechanical properties in its natural state was examined in laboratory before and after chemical stabilisation, considering a variety of stabilisers, different percentages of stabilisers in the mixture with clay, as well as different time intervals after stabilisation.

The results presented in this paper confirmed that the improvement of soil properties can be successfully achieved by applying lime, magnesium carbonate, sodium silicate, and potassium hydroxide as stabilisers of clayey materials. All the considered stabilisers added to the natural clayey material contributed to a significant increase in the load-bearing capacity of the clay and thus enabled its application for various practical construction purposes.

Modification of the values of Atterberg limits and UCS were tested. From the aspect of these two parameters, the addition of all the considered stabilisers resulted in a significant improvement of the soil properties. The most important findings are:

- It has been proven that lime and magnesium carbonate are the most effective stabilisers, in particular from the aspect of increasing the UCS values of the treated clayey soil.
- After a period of 14 days, the UCS values obtained with regard to both reagents are quite similar, whereas after 28 days, the addition of lime contributes to a significantly better soil improvement.
- Considering both stabilisers, the increase of UCS values is more pronounced with the content increase from 3% to 5% than the increase from 5% to 7%, which indicates that the optimal content in terms of these stabilisers could be considered around 7%.

Table 2. Change in the consistency limits of the clayey soil after the chemical stabilisation with different additives.

Sample	After 3 days			After 7 days			After 14 days			After 28 days		
	LL	PL	PI	LL	PL	PI	LL	PL	PI	LL	PL	PI

Soil + 5% sod. silic.	51	28	23	50	32	18	52	36	16	49	37	12
Soil + 7% sod. silic.	53	27	26	53	34	19	51	33	18	53	36	17
Soil + 3% pot. hydrox.	49	24	25	48	28	20	51	30	21	52	32	20
Soil + 5% pot. hydrox.	50	26	24	48	27	21	51	33	18	52	33	19
Soil + 7% pot. hydrox.	51	24	27	51	29	22	50	32	18	51	34	17

- Sodium silicate and potassium hydroxide have a smaller effect on soil strength in comparison with lime and magnesium carbonate; however, they certainly contribute to the improvement in relation to the natural soil properties.
- With the addition of 5% sodium silicate slightly higher UCS values were obtained than with the addition of 7% in the corresponding time intervals. This indicates that the optimal content considering this stabiliser is 5%.
- With the addition of potassium hydroxide, the maximum UCS values were reached after 14 days for all the considered stabiliser contents.
- A trend of constant increase in UCS values with increasing content of potassium hydroxide was observed for all the considered time intervals. Therefore, further research could focus on the effects of using a higher percentage of potassium hydroxide, in order to determine the optimal reagent content in the clay mixture.
- Significant improvement of LL values compared to a natural soil was not achieved with any of the considered stabilising materials, either with increasing stabiliser content or over time.
- On the other hand, each of the considered stabilisers resulted in an increase in PL value, in particular over time, which ultimately contributed to a decrease in PI values over time. Such changes indicate the ability of clay to remain in a semi-solid state of consistency even with a higher water content.

In addition to the significant improvement of soil material properties, lime is also the most cost-effective stabiliser. In comparison with sodium silicate and potassium hydroxide, the cost of using lime as chemical stabiliser is several times lower, whereas compared to magnesium carbonate it is even several tens of times lower.

It should be noted that the results presented in this paper refer to local soil materials. Therefore, there is a necessity for more comprehensive further research, which will include soil samples from a wider area, as a larger number of tests on a greater variety of clayey soil materials will give more reliable results. In addition, in order to meet the requirements of a specific project, site-specific soil testing with the selected stabiliser should be a mandatory part. Current practice shows that in most cases 3% stabiliser content would be quite sufficient; however, a large number of studies in this area, including the one presented, indicate that the optimal amount of additives still depends both on the stabiliser itself and on the composition of the particular type of soil.

ABSTRACT: The new Lisbon metro line will cross a densely urbanized part of the city, connecting Rato station located at one of the hills of the city and Cais do Sodré station at Tagus River right bank. The interconnection between the new line and the existing terminus is located close to the Tagus River bank where the landfill and clayed soft soils rasting over the Miocene bedrock have more than 20m thickness. Given this geotechnical scenario and the constrains related to the densely urbanized area, the cut and cover excavation solutions have been designed to minimize the surrounding ground perturbance and surface settlements. Diaphragm walls braced by steel struts were used to hold a 20m depth excavation. The connection was materialized by the existing wall demolition and the simultaneous construction of a new structural system inside the terminus structure. This intervention included the construction of new reinforced concrete beams and columns with a meticulous construction phasing aligned with the demolition works using as well temporary support systems. The complexity of those works was increased by the constrains inside the terminus where the impact on Metro circulation should be minimized. This paper presents an overall description of the adopted solutions, how they were implemented as well as the monitoring plan that allowed the risk management of those complex works.

RÉSUMÉ: La nouvelle ligne de métro de Lisbonne traversera une partie densément urbanisée de la ville, reliant la station Rato située sur l'une des collines de la ville et la station Cais do Sodré sur la rive droite du Tage. L'interconnexion entre la nouvelle ligne et le terminus existant est située à proximité de la rive du Tage, où la décharge et les sols meubles argileux reposant sur le substratum rocheux du Miocène ont une épaisseur de plus de 20 mètres. Compte tenu de ce scénario géotechnique et des contraintes liées à la zone densément urbanisée, les solutions d'excavation en tranchée couverte ont été conçues pour minimiser les perturbations du sol environnant et les tassements de surface. Des parois diaphragmes contreventées par des étais en acier ont été utilisées pour maintenir une excavation de 20 m de profondeur. La connexion a été matérialisée par la démolition du mur existant et la construction simultanée d'un nouveau système structurel à l'intérieur de la structure du terminus. Cette intervention comprenait la construction de nouvelles poutres et colonnes en béton armé avec un phasage de construction méticuleux aligné sur les travaux de démolition en utilisant également des systèmes de support temporaires. La complexité de ces travaux a été accrue par les contraintes à l'intérieur du terminus où l'impact sur la circulation du métro devait être minimisé. Cet article présente une description générale des solutions adoptées, la manière dont elles ont été mises en œuvre ainsi que le plan de surveillance qui a permis la gestion des risques de ces travaux complexes.

Keywords: Metro; terminus; diaphragm walls; deep excavation.

1 INTRODUCTION

The new Lisbon circular metro line will cross a densely urbanized part of the city, connecting Rato Station, located at one of the hills of the city, and Cais do Sodré Station at the Tagus River right bank. Where the construction of the tunnel section is closer to the river a Cut&Cover method is used.

In the Cais Sodré area, the new metro line intersects the terminus of the existing metro line, and this is one of the points of intersection between the existing and new construction of the new Lisbon metro circular line. This type of connection, associated with geological and geotechnical constraints, existing infrastructures, a dense urban environment, the need for demolition and new construction, required the construction of a diaphragm wall, reinforced concrete framing structure, metal elements, micropile foundations and the use of hydraulic jacks and specific monitoring.

2 AFFECTED BUILDINGS

In the area intercepted by the connection of the new metro line to the existing terminus, the intervention essentially intersects one of Lisbon's busiest streets, Avenida 24 de Julho. Road and rail traffic will be affected, forcing the temporary and phased diversion of these infrastructures (see Figure 1).

Inevitably, this intervention, as already mentioned, intersects the structure at the terminus of the existing metro line. The structure of the existing terminus appeared to be in good condition, and parts of it could continue to be used in the new structural solution.

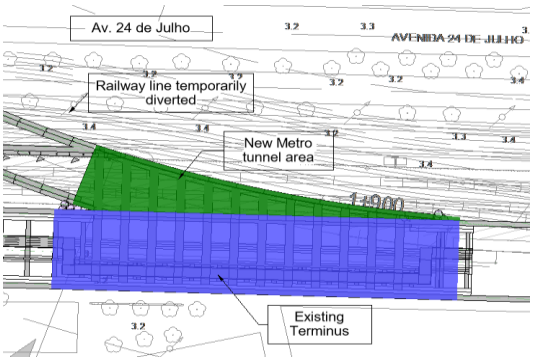

Figure 1. Plan: Layout of the new tunnel and the existing terminus.

3 MAIN CONSTRAINS

3.1 Geological and geotechnical constrains

The geological investigation campaign included the execution of multiple boreholes that allowed the characterization of the ground units along the extension of the Cut&Cover trench on which the intervention is based (see Figure 2). As the line progressed approaching the Tagus River, based on prospecting and geotechnical and geological surveys, it was possible to confirm a progressive increase in the thickness of the materials of recent genesis (landfill and alluvium - essentially sandy type), reaching a thickness of around 17.0m, in parallel with the decrease of the Miocene layer depth overlying the units of the Lisbon Volcanic Complex.

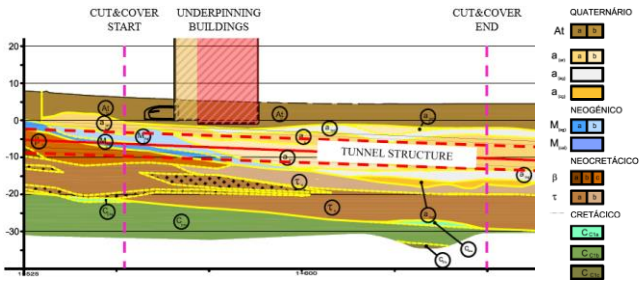

Figure 2. Longitudinal geological section.

It is also worth mentioning that, given the proximity of the Tagus River, the groundwater level was considered to be 1,0m below the surface.

3.2 Constructive technologies constrains

The solutions had to respect the local constraints regarding the accessibility of equipment and material, guarantee the partial operational continuity of the terminus throughout the intervention as well as its opening hours and the deadline for completion of the construction work. It should also be mentioned that the intervention ensured that the embankment over the existing terminus cover slab remained in place throughout the intervention, so as not to further restrict transport infrastructure in the area. Considering the need to work inside the existing terminus, the solutions had to be compatible with equipment and material that could initially be transported in an opening with a width of 2.0m and solutions that could be carried out in a short period of time.

3.3 Demolitions and load transfer procedure

The solution had to guarantee the safe partial demolition of elements of the existing terminus, while preserving the existing conditions above the terminus' roof slab. In this way, it was necessary to implement reinforcement solutions that would allow the demolition of one of the side walls of the terminus, duly reconciled with the other constraints described. Since the embankment over the roof slab of the existing structure and its partial functioning were preserved, to minimize the occurrence of pathologies on the roof and surface, due to differential settlements, the solutions and construction phases had to be compatible with a procedure of controlled load transfer from the existing structural solution to the new structural solution, which was carried out using hydraulic jacks accompanied by monitoring equipment to interpret the behaviour of the systems.

4 SOLUTION DESCRIPTION

The solution adopted consists of executing a diaphragm wall to carry out the excavation in the Cut&Cover trench, provisionally restrained by horizontal metal struts. This excavation solution allowed the demolition work to begin and equipment and materials to enter through the side wall of the existing terminus. Inside the terminus for the demolition phase, porticoed structures made of metal elements were defined, using hydraulic jacks and prestressed bars for provisional stability.

For the final phase of the terminus structure, the work generally consisted of building a new porticoed reinforced concrete structure. Locally, metal columns were used to support the concrete beams and the existing foundations were reinforced with micro-piles. The Figure 3 shows the Cut&Cover excavation solution adopted.

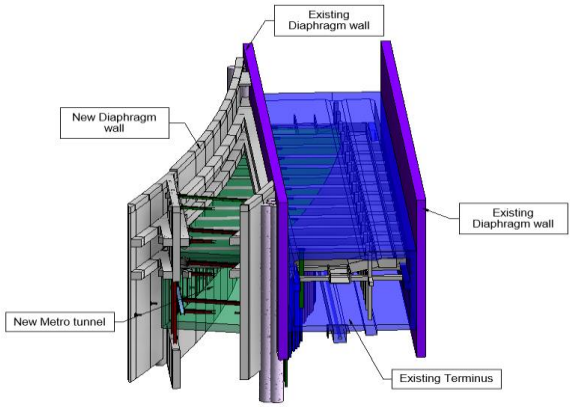

Figure 3. 3D View: Cut&Cover excavation and final structure of the terminus.

4.1 Cut&Cover excavation solution

The Cut&Cover solution was generally composed of an 800mm thick diaphragm wall that was horizontally braced by distribution beams and metal struts, materialised by HEB 400 to 600 profiles. It should also be noted that in this connection area, the existing diaphragm wall was used as a containment for excavation. This existing diaphragm wall had been used 25 years ago to build the structure of the terminus (see Figure 4).

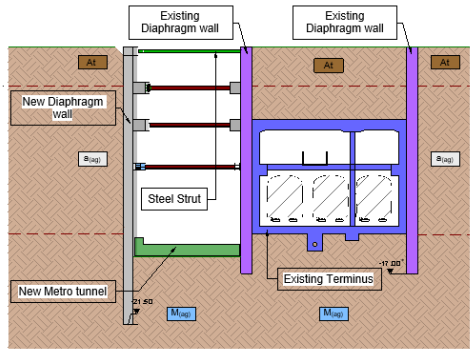

Figure 4. Section: Cut&Cover excavation solution.

4.2 Demolitions and load transfer procedure

For the demolition phase, it was initially decided to make an opening in the side wall of the existing terminus to bring in the equipment and materials needed to carry out the temporary reinforcement. Initially, the connection between the side wall of the existing terminus and the existing diaphragm wall was guaranteed by means of prestressed bars, and then a metal portal with hydraulic jacks at the top was installed along the entire length of the north side wall of the terminus to be demolished (see Figure 5).

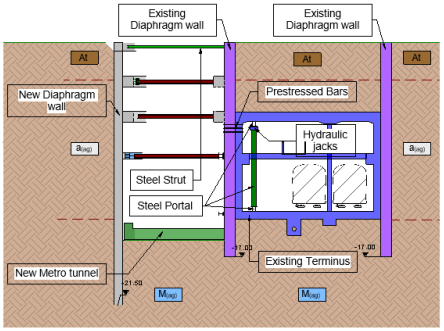

Figure 5. Section: Cut&Cover excavation, demolitions, and load transfer procedure solution.

After some secondary demolition, the existing diaphragm wall and the north side wall of the existing termination were demolished in 4.0 metre strips (see Figure 6).

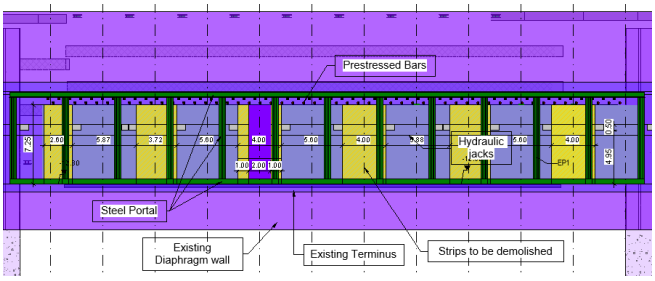

Figure 6. Elevated: Cut&Cover excavation, demolitions, and load transfer procedure solution.

The metal portal was materialised by HEB 500 vertical profiles and two HEB 500 horizontal beams.

Hydraulic jacks were used to ensure a smoother transfer of loads between the existing structure and the new structural solution.

4.3 Final structural solution for terminus

The final structural solution for the terminus consisted of making foundation micropiles on top of the existing floor slab to accommodate the localised load increase of the new solution. A wall beam (VPA) was built over these micropiles to distribute the loads from the new reinforced concrete columns (PB) (see Figure 7 and Figure 8).

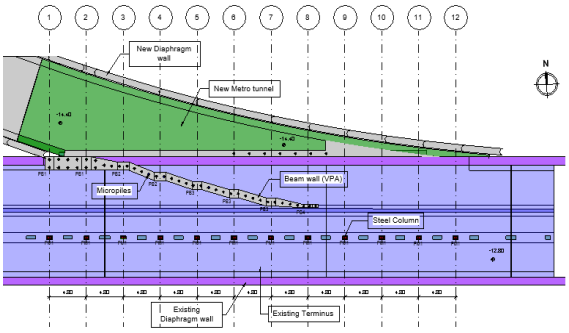

Figure 7. Plan: Foundation of the final solution to the terminus.

Beams (VB1) were built on top of the new columns, running between the south side wall of the existing terminus and the new north side wall of the new line's tunnel. Once the entire new structure was built, demolition of the remaining existing north side wall was completed along the length of the connection between the structures, in order to guarantee the track areas and widths defined in the project.

The structural system described has the capacity to replace the demolished north side wall of the terminus, leaving it with the capacity to support the roof slab and guarantee the correct connection between the new tunnel structure and the existing structure (see Figure 7 and Figure 8).

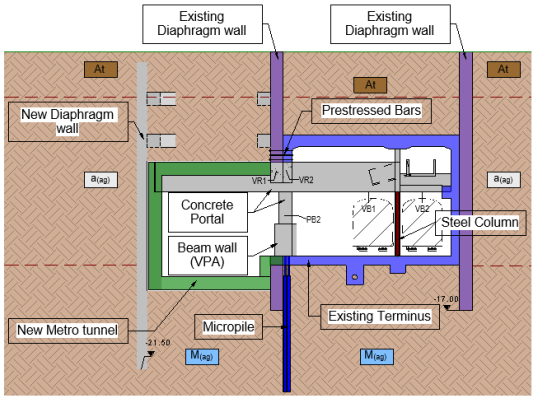

Figure 8. Section: final structural solution for terminus.

5 SOLUTION DESIGN

The temporary diaphragm wall containment was dimensioned using a two-dimensional model in *Plaxis 2D* software. In this model, the diaphragm wall elements were modelled with plates, and the metal struts by anchor elements.

The final structure of the terminus was designed using a three-dimensional model in SAP2000 software. All the walls and slabs were modelled using shell elements, and the beams and columns were modelled using frames. The structural model was vertically braced using compression springs to simulate the foundation soil of the floor slab, and horizontal compression springs to simulate the resistance of the ground (see Figure 9).

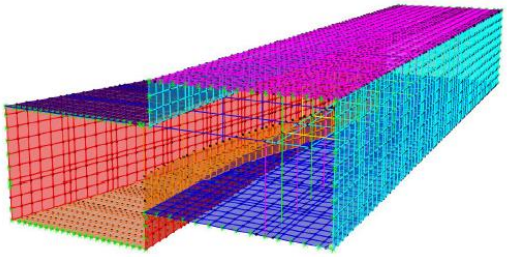

Figure 9. 3D View: Structural model developed in SAP 2000.

This model made it possible to estimate the design forces in the new and existing structural elements.

The model also made it possible to estimate the deformations in the various structural elements of the terminus, considering the new structural solution.

6 MONITORING PLAN

For monitoring the Cut&Cover excavation, traditional elements such as topographic targets, inclinometers and piezometers were used.

In addition to the instruments used in the Cut&Cover excavation, a monitoring plan was installed using liquid level sensors and strain gauges to measure the settlement behaviour of the existing terminus cover slab during the demolition phase.

The monitoring plan establishes alert and alarm values for the limits of each device. With the aim of guaranteeing safety and compliance with the values estimated in the project.

7 FINAL REMARKS

The definition and implementation of a new metro line in a densely urbanised area, on recent soil, with a high water level, with a circular shape and using the structures of the existing metro, leads to areas of connection between new and existing structures, requiring demolition and construction work. For scenarios such as the one presented in this work, based on experience in this type of construction work with these geological-geotechnical conditions and the other constraints mentioned, the solution for carrying out the excavation using a diaphragm wall restrained by metal struts seemed to be the most appropriate for maintaining the integrity of the existing structures and infrastructures. The remaining solution adopted for connecting the new structure to the existing one also

proved to be adequate, guaranteeing all the regulatory safety criteria.

An adequate monitoring and survey plan was essential to confirm the suitability of the solution during excavation work, and also to manage the transfer of loads between the new structural system and the new structural system. the shoring system during excavation work.

ABSTRACT: Modern machinery for executing deep foundations and soil treatments is equipped with sensors that allow the measurement of execution parameters such as torque, thrust, and speed (Measurement While Drilling, MWD). These parameters are related to soil characteristics and, by using machine learning (ML) algorithms, it is possible to translate them into a penetrometric soil profile. Therefore, each perforation can provide analogous information of that obtained from a penetrometer. However, in order to apply these algorithms in the specific case of pile drilling and soil treatment, several factors must be considered in both ML techniques and specific to geotechnics. These factors include the presence of anomalous values in the data, the distance between the penetrometers and the drilling points or the selection of the most appropriate algorithms, among others. This paper proposes a specific methodology that outlines the various steps required in order to apply ML algorithms to drilling data for deep foundations and ground treatments.

RÉSUMÉ: Les machines modernes pour l'exécution de fondations profondes et de traitements du sol sont équipées de capteurs qui permettent de mesurer les paramètres d'exécution tels que le couple, la poussée et la vitesse (Measurement While Drilling, MWD). Ces paramètres sont liés aux caractéristiques du sol et, en utilisant des algorithmes d'apprentissage automatique (ML), il est possible de les traduire en un profil penétrométrique du sol. Ainsi, chaque perforation peut fournir une information équivalente à celle d'un pénétromètre. Cependant, afin d'appliquer ces algorithmes dans le cas particulier du forage de pieux et du traitement des sols, plusieurs facteurs doivent être considérés à la fois généraux à ML et spécifiques à la géotechnique. Ces facteurs incluent la présence de valeurs anormales dans les données, la distance entre les pénétromètres et les points de forage, les algorithmes les plus appropriés, entre autres. Cet article propose une méthodologie spécifique qui décrit les différentes étapes nécessaires pour appliquer les algorithmes ML aux données de forage pour les fondations profondes et les traitements de sol.

Keywords: Machine learning; measurement while drilling; penetrometer; rigid inclusions.

1 INTRODUCTION

Machine Learning (ML) can be defined as the extraction of information from large data sets by using mathematical algorithms applied by computers. One of the advantages of this approach is its ability to reveal hidden relationships between variables that are difficult to observe otherwise.

Geotechnical engineering is a field characterized by complex and often empirical relationships between variables, making it an ideal domain for the application of ML. Consequently, ML has gained increasing attention in recent years, leading to the establishment of a dedicated Technical Committee, TC309, by the International Society for Soil Mechanics and Geotechnical Engineering (ISSMGE, 2022).

There are numerous applications of ML in geoscience, including soil and rock classification, soil stratification, settlement analysis, bearing capacity

estimation, slope stability assessment, dam monitoring, and more (Liu and Lacasse, 2022).

The objective of this paper is to show how to apply ML to correlate drilling data from deep foundations and soil treatments with the values of penetrometers.

2 PENETROMETERS

The penetrometer is a soil investigation technique that measures the resistance to perforation by using a standardized cone. There are two main types of penetrometers: static and dynamic (CEN, 2008; ISO/TC 182 Geotechnics, 2012). An example of the output of a penetrometer can be seen in Figure 1.

One advantage of penetrometers is their ability to provide continuous information along their length. As a result, they are well-suited for correlation with drilling parameters.

3 MEASUREMENT WHILE DRILLING

Measurement While Drilling (MWD) refers to the continuous collection of data during the drilling process. Modern geotechnical machinery and equipment are equipped with ample instrumentation that enables the measurement of various drilling parameters, including drilling speed, rotary torque, rotary speed, and applied crowd.

These parameters should be correlated with the characteristics of the soil being traversed, and several authors have developed compound parameters to establish these relationships (Laudanski et al, 2012). There is a standard specific to MWD (CEN, 2016) that primarily focuses on boreholes but can also be applied to geotechnical equipment.

Instead of relying on compound parameters, an alternative approach is to utilize ML to correlate the drilling feedback at a certain depth with the previous penetrometer value at the same level.

4 DATA FORMAT

The information obtained from penetrometers and drilling can be provided in various formats or, in some cases, without any specific format. Therefore, to effectively utilize ML, it is recommended to standardize all the information into a consistent format.

For geotechnical data, a suitable option is to employ the AGS format (Association of Geotechnical & Geoenvironmental Specialists, 2023a). This format can be easily converted and utilized with a dedicated library (Association of Geotechnical & Geoenvironmental Specialists, 2023b).

5 DATA PREPROCESSING

Data preparation and cleaning are crucial steps when using ML algorithms, which include handling missing values. Additionally, it is essential to detect outliers, as this is a common task in all ML problems. However, the criteria for identifying outliers can vary depending on the specific case.

5.1 Penetrometers outlier detection

An approach to identify outliers could be the distance from the mean value. But this is not possible due to the difference in nature of soil layers. A value of 15 blows could be an outlier at depth 4 m, but no at a depth of 10 m (Figure 1).

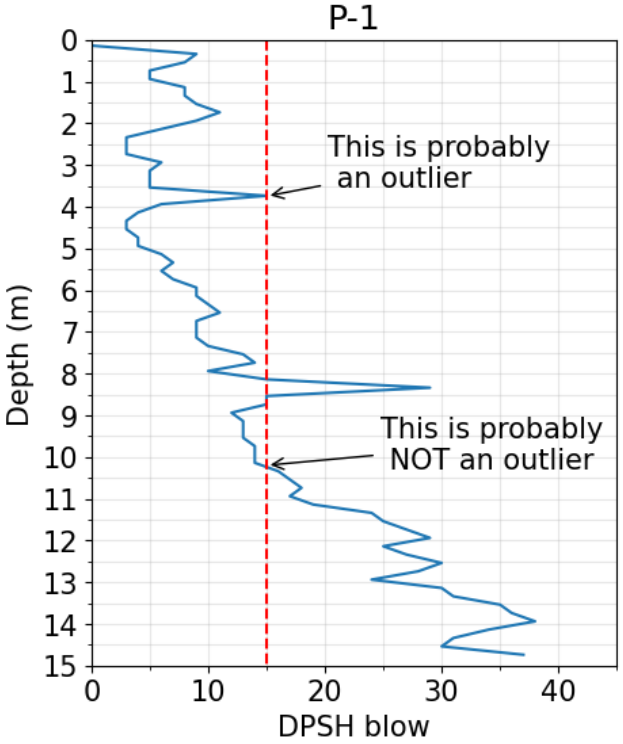

Figure 1. Example of a DPSH penetrometer output.

To assess this issue, a moving average of the penetrometer can be used, with a window that depends on the desired level of smoothness. It is very difficult to know if a strange value in the penetrometers is an outlier (i.e. the presence of some gravels) or a true soil condition. Using a moving average allow to keep the value while softening the profile.

5.2 Drilling data outlier detection

In the case of the drilling data, the detection of outlier becomes more complicated as is a multivariate

problem. A high value of one parameter can be normal or not depending on the values of the other parameters.

For this problem, a specific outlier detection, such as isolation forest (Liu et al, 2008), can be used. Isolation forest classifies outliers by how difficult the sample is to isolate, with easier to isolate meaning more probability to be an outlier.

5.3 Data labelling

To correlate the drilling data to the penetrometric profile, a value of it should be assigned to each sample of the data. This could seem easy enough: assign the value from the closer penetrometer as the proper level.

But the closer penetrometer could be quite far. In fact, these correlations are interesting because the geotechnical data are usually scarce. In Figure 2, inclusions 1 and 2 are closer to the penetrometer P1. At inclusion 1 there is a small error, but at inclusion 2 the error is much greater due to distance and changes in the soil.

To address this problem, Bunieski (2022) proposed two different methods. The variability method establishes a maximum distance where the error is considered acceptable. The continuous method uses the mean value of close penetrometers but establishing and information level depending on distance. Points with low information are discarded. Both methods consider how the soil profile changes in the available penetrometers.

6 CHOOSE ML ALGORITHM

The selection of the algorithm to be used is very case dependent. Some of them need some preprocessing of the data for being used (for example a normalization of the values). Others can avoid preprocessing but would benefit from previously applied algorithms. On top on that, the hyperparameters that control the process should be tuned for each problem, greatly affecting the performance.

As can be seen, finding the most adequate approach is no easy task.

One possible solution is to use an auto-ML library, such as TPOT (Olson et al., 2016), which will suggest the best possible pipelines after a series of iterations.

A disadvantage for this approach is that it can be very computationally demanding and time consuming, depending on the data. The number of iterations can be limited, but that will decrease the possibility of reaching the best pipeline.

7 PROPOSED PIPELINE

The proposed pipeline for the use of ML with MWD data is as follows:

- Transform the available information to a consistent data format.
- Data preprocessing.
  - Outlier detection
  - Data labelling (special care to distance)
- Auto-ML and selection of algorithms.
- Evaluation of the obtained results (correlation coefficient, root of mean squared error, etc.)
- Auto-ML and selection of algorithms.
- Evaluation of obtained results (correlation coefficient, root of mean squared error, etc.)

Figure 3 shows the scheme of this process.

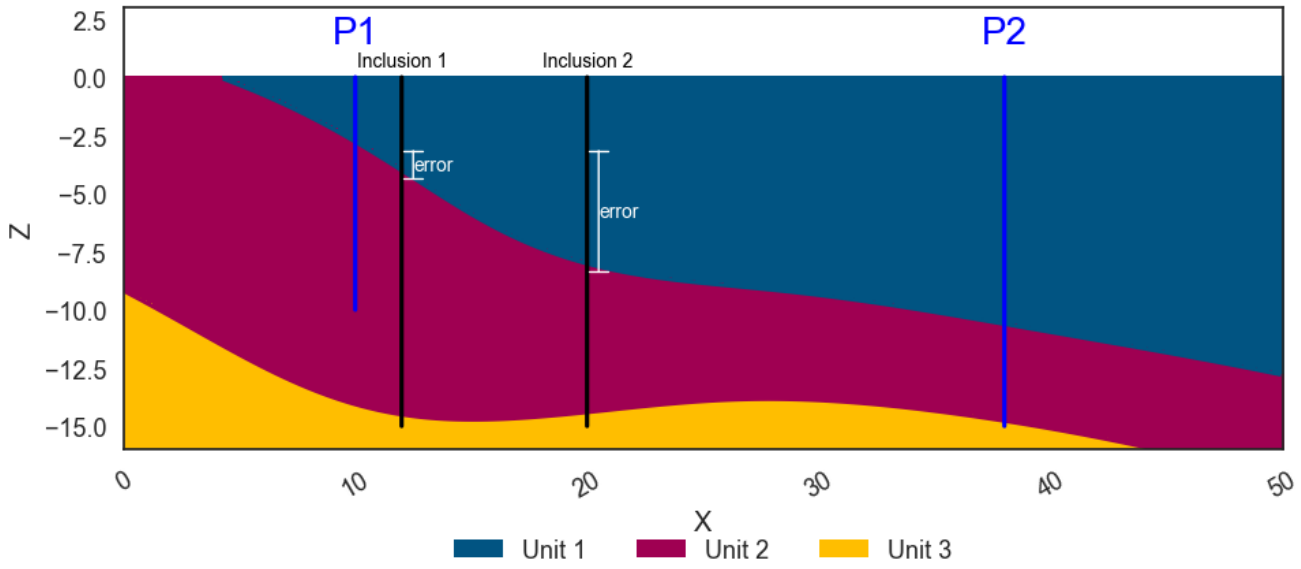

Figure 2. Soil cross section. Error introduced by distance between inclusion and penetrometer.

8 CONCLUSIONS

This paper has highlighted the specific challenges associated with using ML for MWD data, particularly emphasizing the significance of considering the distance between the perforation and penetrometer, as well as the detection of outliers. It is evident that expert knowledge plays a critical role in addressing ML problems, especially in the geotechnical field where it is difficult to account for every variable that may affect the process. But, with the proper pipeline, ML is a very interesting tool to extract information from perforations.

cmartins@jetsj.com

ABSTRACT: The new Lisbon circular metro line will crosses a densely urbanized part of the city, connecting Rato Station located at one of the hills of the city and Cais do Sodré Station, at the Tagus River right bank. The underground excavation intersects a wide range of materials, from rock mass to soft soils. Where the construction of the tunnel section is closer to the river, with about 10 m of cover, a Cut&Cover method is used. In this metro the tunnel intersected a pile foundation of two reinforced concrete buildings with 9 upper floors and 1 basement, determining the need to underpin the structures and change permanently its foundation system. The geotechnical and geological conditions present in this metro, associated to highly limited access and working conditions, led to the execution of the retaining walls using jet-grouting technology. Those elements were also used as the building deep foundations, which consists of a reinforced concrete slab (length=50m, width=13m and thicknesses=1.4m and 1.8m), being also responsible for the structure underpinning. In this complex process is defined a controlled load transfer between the structure and the new slab, which was executed using hydraulic jacks, limiting the building differential settlements thought gradual jacks opening and according with monitoring. This paper presents an overall description of the solutions, how they were implemented and the buildings' behaviour during the underground works.

RÉSUMÉ: La nouvelle ligne de métro circulaire de Lisbonne traversera une zone densément urbanisée de la ville, reliant la Station Rato, située sur l'une des collines de la ville, et la Station Cais do Sodré, sur la rive droite du Tage. L'excavation souterraine couvre une large gamme de matériaux, depuis les masses rocheuses jusqu'aux sols meubles. Lorsque la construction du tronçon de tunnel est plus proche de la rivière, avec une profondeur de couverture d'environ 10 m, la méthode de tranchée couverte est utilisée. Dans cette section, la ligne a traversé une fondation sur pieux de deux bâtiments en béton armé de 9 étages supérieurs, ce qui a déterminé la nécessité de soutenir la structure et de modifier de manière permanente son système de fondation. Les conditions géotechniques et géologiques présentes dans ce section, associées à des conditions d'accès et de travail très limitées, ont conduit à la matérialisation de murs de soutènement grâce à la technologie du jet-grouting. Ces éléments ont également servi de nouveau fondations profondes des bâtiments, constitué d'une dalle en béton armé (longueur = 50 m, largeur = 13 m et épaisseurs = 1,4 m et 1,8 m), qui est également chargée de soutenir la structure. Dans ce solution complexe, un transfert de charge contrôlé est défini entre la structure et la nouvelle dalle, qui a été réalisé à l'aide de vérins hydrauliques, limitant les tassements différentiels du bâtiment grâce à l'ouverture progressive des vérins et au contrôle concomitant. Cet article présente une description générale des solutions, de la manière dont elles ont été mises en œuvre et du comportement des bâtiments lors des travaux souterrains.

Keywords: Metro; underpinning; reinforced concrete building; jet-grouting; excavation cut&cover.

1 INTRODUCTION

The new Lisbon circular metro line will cross a densely urbanized part of the city, connecting Rato Station, located at one of the hills of the city, and Cais do Sodré Station at the Tagus River right bank.

Where the construction of the tunnel section is closer to the river a Cut&Cover method is used. In this section the line path intersected a pile foundation of reinforced concrete buildings with 9 upper floors and 1 basement, determining the need to underpin these structures.

The geotechnical and geological conditions in this section, associated to highly limited access and working conditions, led to the execution of retaining walls using jet-grouting technology. Those elements were also used as deep foundations of an reinforced concrete slab with 1.4m and 1.8m tick, built for the structure underpinning.

In this complex process was defined a controlled load transfer between the structure and the new slab, which was executed using hydraulic jacks and specific monitoring to control the buildings differential settlements.

2 AFFECTED BUILDINGS

The metro line tunnel intersets buildings nº 42 and nº 44 at Avenida D. Carlos I. Both buildings were built in the XX century, presenting a reinforced concrete structure and pile foundations. The buildings have 9 elevated floors and 1 basement (see Figure 1).

Figure 1. Reinforced concrete buildings above de tunnel.

Building nº42 was recently subject to rehabilitation works for conversion into residential use. As a result of the changes needed, was designed a reinforcement of both the structure and foundations, the latter with micropiles. Building nº44, on the other hand, is in its original conditions, used for offices, and showing a good state of conservation. In Figure 2 is presented the buildings plan superimposed with the tunnel structure layout, showing the need to underpin several columns over intervention area.

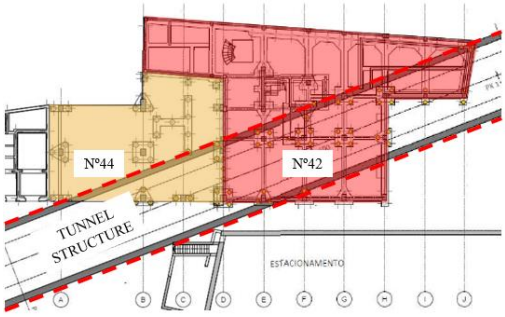

Figure 2. Buildings plan view and tunnel structure projection.

3 MAIN CONSTRAINS

3.1 Geological and geotechnical constrains

The geological investigation campaign included the execution of multiple boreholes that allowed the characterization of the ground units along the extension of the Cut&Cover trench over which the buildings to be underpinned are located (see Figure 3). It was possible to confirm that in the increasing direction of the mileage of the trench, there is a progressive increase in the thickness of recent materials (landfill and alluvium - essentially sandy type) in parallel with the decrease of the Miocene layer depth overlying the units of the Lisbon Volcanic Complex.

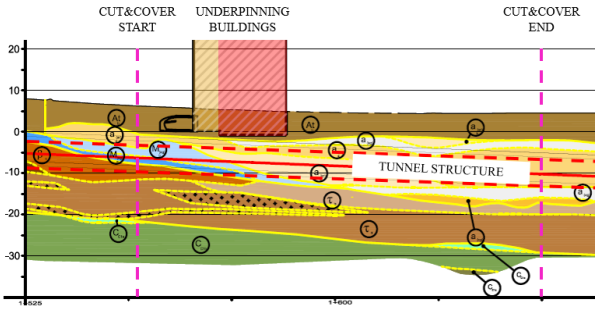

Figure 3. Geological and geotechnical scenario.

3.2 Constructive technologies constrains

The solutions had to respect the local constraints regarding the accessibility of equipment. Considering the need to work inside the building's basements, the solutions had to be compatible with equipment that can operate with a minimal ceiling height of about 3,0m.

3.3 Load transfer procedure

To minimize the occurrence of pathologies in the underpinning buildings, due to differential settlements, the solutions and construction phases had to be compatible with a procedure of controlled load transfer from the buildings to the new foundation system, which was carried out using hydraulic jacks accompanied by monitoring equipment to interpret the behaviour of the buildings and new foundation system.

4 SOLUTION DESCRIPTION

The solution consists of an underpinning system of the buildings columns and pile caps located above the tunnel alignment, which will allow the deactivation of the existing piles and the maintenance of the building's structure functionality and, simultaneously the construction and operation of the new metro tunnel.

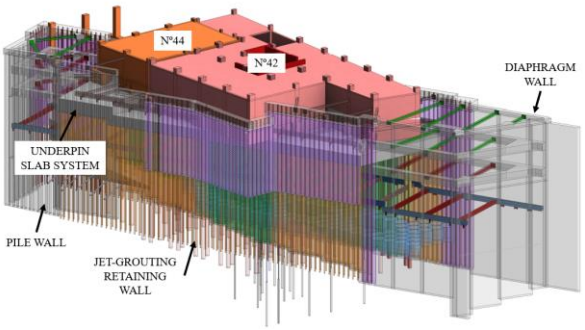

Figure 4. 3D view: Cut&Cover excavation and underpinning solution.

Once the underpinning system had been placed, which is composed of a reinforced concrete slab laterally supported by a double jet-grouting columns curtain wall, the excavation works done inside this curtain and below of the underpinned slab.

4.1 Cut&Cover excavation solution

Since the underpinning solution is connected with the Cut&Cover solution, a brief description is given of, although this is not the focus of this paper.

The Cut&Cover solution was generally composed of a double jet-grouting columns retaining wall with 1000mm diameter columns, spaced 700mm apart, and reinforced with tubular steel profiles, which have a dual function as a foundation of the underpinned slab, as well as retaining the soil and water to allow the excavation required to build the tunnel. In addition to this, and to reach the underpinned slab level, it was executed a third row of jet-grouting columns, also reinforced with steel profiles (Figure 5).

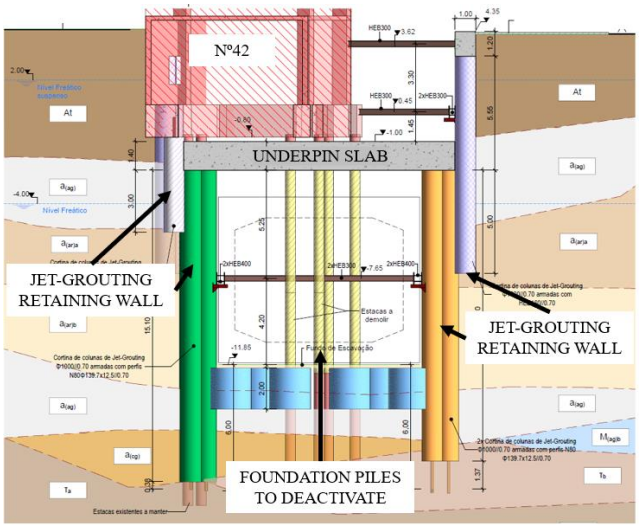

Figure 5. Section: Cut&Cover excavation and underpinning solution.

Finally, the retaining walls were temporary propped each other using four levels of steel struts, 5m apart, resting over steel and reinforced concrete distribution beams. However, in the underpinning area, reinforced concrete slab was used as the third strut level.

4.2 Underpinning solution

The underpinning solution consists of a reinforced concrete slab, not prestressed, supported indirectly on jet-grouting columns, reinforced with steel profiles in order to increase their ductility and stiffness, placed outside the tunnel. The underpinned slab was positioned below the existing pile caps and above the tunnel alignment, with geometry of approximately 50,0m by 13,0m and a variable thickness between 1.40m and 1.80m (see Figure 6).

Taken together, these elements make it possible to change the foundation system of the buildings, transferring the loads from the structural columns to the slab which, basically by cylindrical bending, transmits them to the two rows of jet-grouting columns, which finally transmit the reactions to the competent ground layers located below the bottom slab of the tunnel.

This solution makes it possible to deactivate the piles foundation of the buildings existing over the tunnel area, as well as to proceed with the excavation works to build the new tunnel.

4.3 Load transfer procedure

Hydraulic jacks were used in order to ensure a smoother transfer of loads between the buildings columns and the underpinned reinforced concrete slab, and thus allow for greater control of the settlements occurring in this process. Hydraulic jacks positioned between the underpinned slab and the pile caps, will be responsible for relieving the loads of the foundation piles, using the reaction provided by the slab.

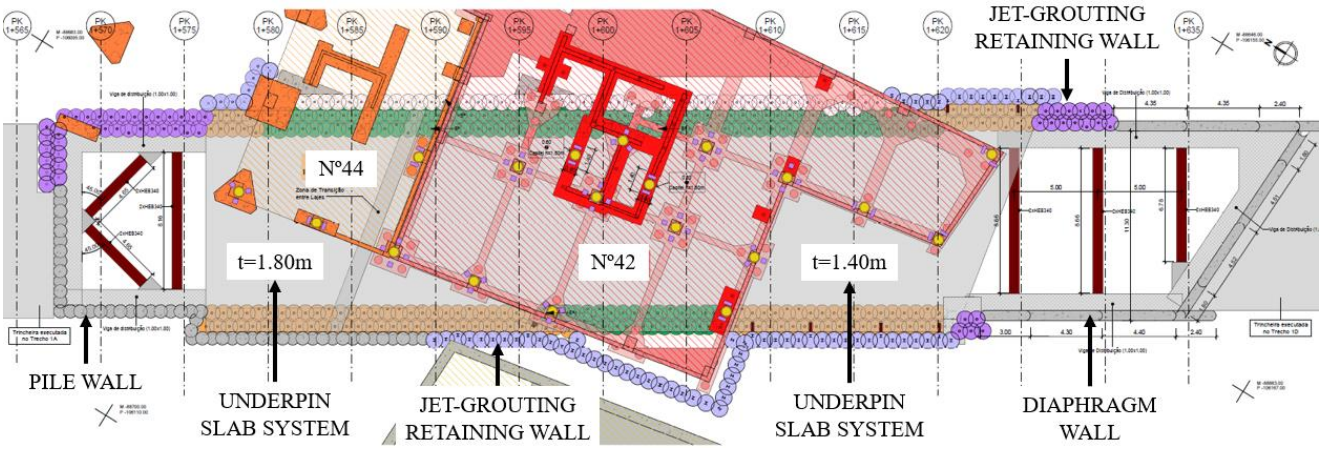

Figure 6. Plan view: Cut&Cover excavation and underpinning solution.

The phases related to the load transfer are summarized below and illustrated in Figure 7:

1. Installation of the instrumentation system at the columns;
2. Excavation to the bottom level of the slab;
3. Sheathing of the piles followed by slab construction and hydraulic jacks installation;
4. Excavation under the slab, followed by hydraulic jacks activation and subsequent existing piles demolition, managed by monitoring data analysis.

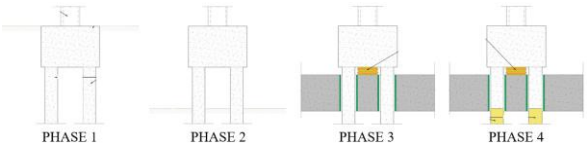

Figure 7. Underpinning solution – Load transfer beams.

5 SOLUTION DESIGN

The underpinning concrete slab was designed using structural models within the *SAP2000* software.

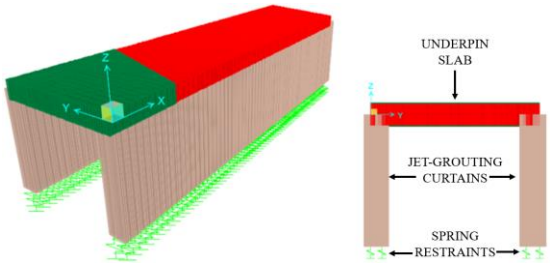

Figure 8. SAP2000 analysis model for underpin slab.

The underpinned slab, as well as the supporting jet-grouting columns, were modelled using shell type elements, and in the case of the latter, these were supported on springs type restraint. This model made it possible to estimate slab structural efforts (see, for example, bending moments in Figure 9) as well as its elastic deformation (see Figure 10).

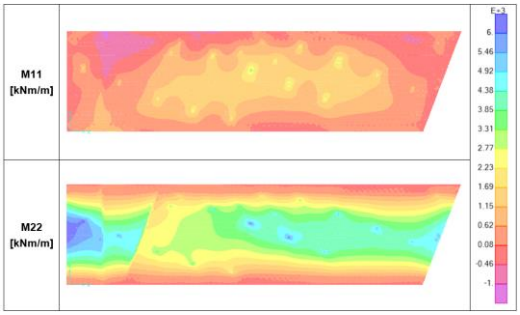

Figure 9. SAP2000 – Underpin slab bending moments.

Considering the support springs on the structural model, was estimated the maximum design axial load on each jet-grouting column, allowing, in parallel analysis with the geotechnical model for Cut&Cover solution, the safety validation of those elements.

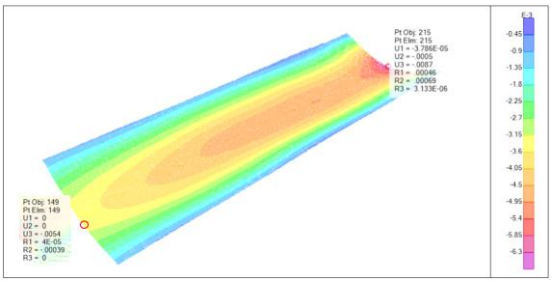

Figure 10. SAP2000 – Underpin slab displacements.

6 MONITORING PLAN

Complementarity, fort the Cut&Cover excavation, a monitoring plan using liquid level sensors and strain gages was installed to measure the settlement behaviour of the slab and columns, as well as the interaction between them (see Figure 11).

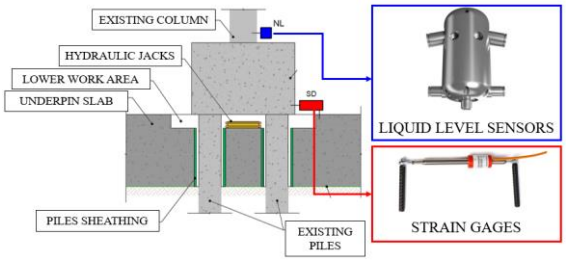

Figure 11. Monitoring devices: liquid level sensors and strain gages

The monitoring plan establishes threshold values for each device. The numerical analyses results were used to determine reference values for measured parameters that were used to set warning values, for 80% of the reference values, and alarm ones, for 120%.

7 FINAL REMARKS

The definition and implementation of a new metro line in a densely urbanized area may lead to interference with existing structures. For scenarios such as the one presented in this paper, an underpinning solution was the most appropriate way to maintain the integrity of the existing structures, although this type of solution often presents multiple restrictions regarding equipment access and operation.

An adequate monitoring and survey plan is essential to manage the load transfer to the underpinning system during the excavation works.

Effect of the binder content in a soft stabilized soil unreinforced and reinforced subjected to cyclic loading – energy evaluation

Effet de la teneur en liant dans un sol stabilisé mou non renforcé et renforcé soumis à une charge cyclique - évaluation énergétique

L.A. Martins*, A.A.S. Correia, P.J. Venda Oliveira, L.J. Lemos
University of Coimbra, Coimbra, Portugal

**uc2020142548@student.uc.pt*

ABSTRACT: When a soil is subjected to cyclic loading, there are changes in the behaviour of the material that need to be characterized for a safe design. To this end, a series of unconfined compressive strength (UCS) tests were performed, with and without the application of cyclic loading, to study the effect of the binder content on the behaviour of a soft soil stabilized under cyclic loading, unreinforced and reinforced with polypropylene fibres. The results were analysed in terms of the evolution of plastic deformation, and of the elastic and plastic energy. It was observed that plastic energy prevails in the first cycles but decreases with the increase in the number of loading cycles, and the increase of the binder content is associated with the decrease of the initial plastic energy. The accumulated plastic deformation occurring during the cyclic loading induces a strain hardening effect that is responsible for the increase in the undrained resilient modulus. The addition of polypropylene fibres prevents the development of some cementitious bonds and promotes an increase in the plastic deformation energy, leading to an increase in the accumulated plastic strains and to a reduction in the undrained resilient modulus during the cyclic loading stage.

RÉSUMÉ: Lorsqu'un sol est soumis à une charge cyclique, il y a des changements dans le comportement du matériau qui doivent être caractérisés pour une conception sûre. À cette fin, une série d'essais de résistance à la compression non confinée (UCS) a été réalisée, avec et sans application d'une charge cyclique, pour étudier l'effet de la teneur en liant sur le comportement d'un sol mou stabilisé sous charge cyclique, non renforcé et renforcé avec des fibres de polypropylène. Les résultats ont été analysés en termes d'évolution de la déformation plastique et de l'énergie élastique et plastique. Il a été observé que l'énergie plastique prédomine dans les premiers cycles mais diminue avec l'augmentation du nombre de cycles de chargement, et l'augmentation de la teneur en liant est associée à la diminution de l'énergie plastique initiale. La déformation plastique accumulée pendant le chargement cyclique induit un effet d'écrouissage qui est responsable de l'augmentation du module de résilience non drainé. L'ajout de fibres de polypropylène empêche le développement de certaines liaisons cimentaires et favorise une augmentation de l'énergie de déformation plastique, ce qui entraîne une augmentation des déformations plastiques accumulées et une réduction du module de résilience non drainé pendant la phase de chargement cyclique.

Keywords: Stabilized soil; reinforced soil; cyclic loading; energy.

1 INTRODUCTION

One of the techniques that has been applied to improve the geomechanically behaviour of soils is chemical stabilization, in which the natural soil is mixed in situ with chemical stabilizers such as Portland cement (Horpibulsuk et al. 2003; Lemos et al. 2021; Venda Oliveira et al. 2013). However, the composite material is in general characterized by brittle behaviour and poor tensile strength. In this context, the inclusion of randomly distributed fibres to the stabilized soil promotes the increase in the tensile strength as well as increases the ductility (Consoli et al. 2009; Correia et al. 2015; Tang et al. 2007).

When a cycling loading is applied to a fibre-reinforced stabilized soil there are changes in the material's behaviour that need to be characterized. So far, the knowledge acquired about such behaviour is still limited and sometimes inconsistent. Dall'Aqua et al. (2010); Venda Oliveira et al. (2017) presented an increase in the plastic deformations induced by cyclic loading, with the most significance during the first loading cycles. Instead, Chauhan et al. (2008)

observed an increase in the plastic deformations for a high number of loading cycles.

The application of the energy concept in geotechnical studies has focus on elucidating the behaviour of cohesionless soils subjected to dynamic loads in which the deformation of a material under cycling loading corresponds to the dissipation of energy (Lenart 2008; Sas et al. 2017). In cases of cyclic loading, stress-strain hysteresis loops provide a means to analyse the plastic energy, equivalent to the area enclosed by the hysteresis loop. Simultaneously, the elastic energy is determined by the area beneath the unloading curve (Sas et al. 2017). The energy concept has been applied to a limited number of fibre-reinforced stabilized soils subjected to cyclic loading. Narani et al. (2021) observed that the plastic energy is higher in initial cycles but decreases rapidly with the increase in the number of cycles and increases with cement content. Additionally, the addition of fibres induces a reduction in plastic energy, due to the absorption of deformation by the fibres, resulting in less energy transfer to the soil matrix.

Despite the existing research, the impact of the number of the loading cycle on the behaviour of a fibre-reinforced stabilized soft soil has not been adequately explored. So, this study aims to improve the knowledge regarding the cyclic loading behaviour of fibre-reinforced stabilized soft soil.

2 MATERIALS AND PROCEDURES

2.1 Characteristics of the materials

It was used a soft soil from Coimbra, Portugal. The geotechnical characterization revealed a grain size composition of 77% of silt, 12% of clay and 11% of sand, a liquid limit of 72%, a plastic limit of 45%, organic matter content of 9.5%, and a natural moisture content of 81%. The soil was classified as a high plasticity organic silt (OH) (ASTM-D2487, 1998) and presents a pH of 4.6 (Martins et al. 2023).

The binder chosen was Portland cement Type I 42.5 R (EN-197-1, 2000) characterized by a high composition of calcium oxide (CaO) 63% and silica oxide (SiO_2) 19%. It was used a binder content of 12, 21, 30 and 39% (dry weight ratio of binder to soil).

In the case of reinforced samples, polypropylene fibres were used as reinforcing elements. The fibres have a length of 12 mm and a diameter of 32 µm. The content of fibres added to the chemically stabilized soil was 1.2% (weight ratio of dry fibre to dry soil).

2.2 Experimental procedures

The samples used for this research were prepared based on the laboratory procedure described in Correia (2011); EuroSoilStab (2002); Martins et al. (2023): (i) the soil, in its natural water content, the cement and the fibres were mixed in a mechanical mixer at a speed of 142 rpm for four minutes; (ii) the paste was introduced into PVC moulds (37 mm diameter, 85 mm high) and compacted in three layers each (tapping the moulds against a wooden table twenty times by hand); (iii) the samples were cured under water in a room with temperature and humidity control (20±2°C and 95±5%, respectively) for 28 days; (iv) at the end of the curing period, the samples were removed from the moulds and the surfaces were cut to obtain 76 mm high samples.

A monotonic UCS test was carried out to define the mechanical characteristics under monotonic loading conditions, with a constant axial strain rate of 1% min (BSI-1377-7 (1990). The UCS cyclic loading tests were carried out for a deviatoric stress level of 50%; an amplitude of ±10% of the maximum unconfined compressive strength (defined in the monotonic UCS test), a frequency of 0.5 Hz and during 5,000 loading cycles.

3 RESULTS

3.1 Plastic deformation

The evolution of the accumulated plastic axial strain with the numbers of loading cycles is shown in Figure 1 for the different binder content in both unreinforced and fibre-reinforced stabilized soil.

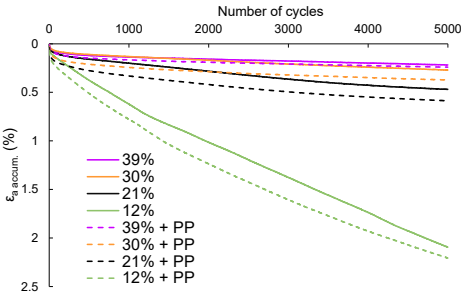

Figure 1. Evolution of the accumulated plastic axial strain with the number of loading cycles.

The analysis of the results reveals that the samples with binder content between 21 and 39% show a rapid increase in axial strain within the first 100 loading cycles, followed by a gradual, asymptotic approach to a constant value over subsequent cycles. Distinct behaviour is noted for samples stabilized with the lowest binder quantity, 12%, exhibiting a continuous

increase in accumulated permanent axial strain during all the cyclic stage. It is possible to observe a decreasing of accumulated plastic axial strain as the binder quantity increases. This trend aligns with the understanding that a higher binder quantity promotes the formation of cementitious bounds, resulting in a stronger and stiffer stabilized matrix, as seen in previous studies (Kaniraj and Havanagi 2001).

Furthermore, the results suggest that the addition of fibres may reduce the development of certain cementitious bonds within the stabilized matrix, leading to a composite material with lower strength and stiffness. Consequently, fibre-reinforced stabilized material experiences higher plastic axial strains during cyclic loading. The reduction of the impact of the fibre addition as the binder content increases is attributed to the constant amount of fibres added across all fibre-reinforced stabilized samples, resulting in a decrease in relative fibre importance.

3.2 Plastic and Elastic Energy

The plastic energy corresponds to the area enclosed by the hysteresis loop, while the elastic energy is calculated as the area beneath the unloading curve (Martins et al. 2023; Narani et al. 2021; Ostadan et al. 1996). These calculi were carried out utilizing the trapezoidal rule integration method in Matlab software, employing an in-house algorithm. The results are illustrated in Figures 2 and 3.

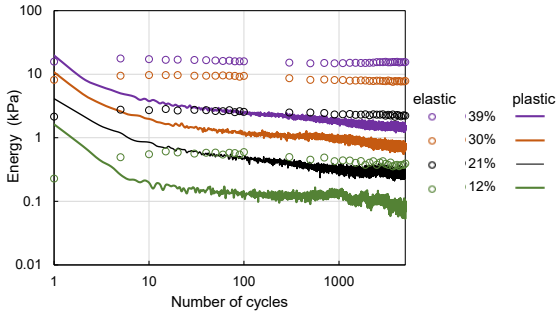

Figure 2. Evolution of plastic and elastic energy with the number of loading cycles – without fibres.

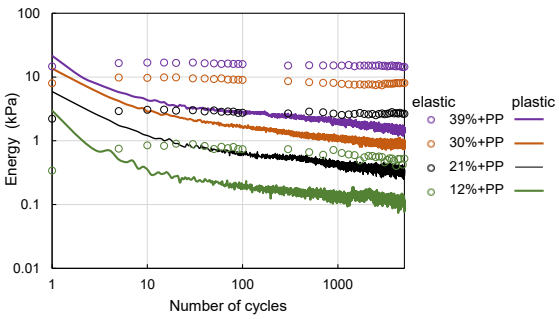

Figure 3. Evolution of plastic and elastic energy with the number of loading cycles – with fibres.

For both unreinforced and fibre-reinforced stabilized materials, the initial cycles reveal a dominance of plastic energy, which gradually reduce as the number of loading cycles increases. In contrary, elastic energy exhibits a progressive increase, particularly evident in the first 10 cycles. During the early loading cycles, the external cyclic load primarily dissipates energy as plastic, with some residual energy absorbed elastically by the composite material. However, this dynamic shifts rapidly as cycles progress, leading to a quasi-steady hysteretic response of the stabilized material, as observed from Figures 2 and 3.

Analysing the addition of fibres, it is possible to observe that the introduction of fibres amplifies the plastic energy and diminishes the elastic energy. This behaviour seems to be induced by the combined effects of the polypropylene fibres' high compressibility (Narani et al. 2020) and the presence of fibers potentially impeding the development of specific cementitious bonds.

For both unreinforced and fibre-reinforced stabilized materials, there is a noticeable transition of energy from plastic to elastic, particularly pronounced in the initial cycles.

4 CONCLUSIONS

The outcomes from the unconfined compressive strength tests conducted on both unreinforced and fibre-reinforced stabilized samples subjected to a cyclic loading stage. lead to the following conclusions:

i) The accumulated plastic axial strain decreases with the increase in binder content, attributed to a larger amount of cementitious bonds leading to a stronger and stiffer stabilized matrix.

ii) In the initial loading cycles, most of the energy applied by the external cyclic load is dissipated as plastic energy, with the remaining energy absorbed elastically by the composite material. This trend changes with the increase in the number of cycles. After a limited number of cycles (10 to 100). The results suggest the predominant dissipation mechanism involves the breakage of cementitious bonds, inducing plastic deformations in the solid skeleton, particularly intensified with lower binder content.

iii) The addition of fibres amplifies plastic energy, especially noticeable in the initial cycles. These results are coherent with a high accumulation of plastic axial strains in the first steps of cycling loading.

ACKNOWLEDGEMENTS

The authors would like thanks to CIMPOR and Biu International for supplying the binders and the fibres, and to the institutions that financially supported the research: individual research grant 2021.05748.BD, project research grant FCT (POCI-01-0145-FEDER-028382) and ACIV. This work was partly financed by FCT/MCTES through national funds (PIDDAC) under the R&D Units CIEPQPF (UIDB/00102/2020), ISISE (UIDB/04029/2020), and ARISE (LA/P/0112/2020).

Underpinning and strengthening of an existing port infrastructure to allow 8m depth dredging for the installation of a high-capacity vessel synchrolift

Soutènement et renforcement d'une infrastructure portuaire existante pour un dragage à une profondeur de 8 mètres pour l'installation d'un synchrolift pour navires de haute capacité

P. Matias Ramos*, L. Esteves
Teixeira Duarte EC, Oeiras, Portugal

**pmr@teixeiraduarte.com*

ABSTRACT: This article describes the structural and geotechnical solutions devised to the underpinning and reinforcement of an existing gravity-type block retaining wall quay. These enhancements were essential to allow an 8-meter seabed dredging, extending from -10.00ZH to -18.00ZH, to enable the installation and operation of a high-capacity vessel *synchrolift*, in a region characterized by high seismic activity. In addition to the extensive dredging, the project included the construction of high-capacity complementary strengthening structures, designed to work in perfect interaction with both the soil and the existing quay infrastructure, ensuring their capacity to support the significant load increase resulting from the lifting, onshore transfer, and dry-docking operation of vessels weighing up to 9000 tonnes on reinforced concrete platform slabs, supported on bored cast-in-situ foundation piles. Focusing on the design principles, the seismic design methodologies and the sensitivity analysis procedures towards safety factor maximisation, this article spotlights key local constraints and their influence on the cost-benefit analysis process that ultimately dictated the adopted technical solutions. The article also addresses a summary of the construction sequence, highlighting the critical role of a meticulous project timeline planning. The knowledge acquired from past experience and a thorough analysis of all process variables, from conception and design to construction, proved to be indispensable to successfully achieve an unconventional underpinning and strengthening solution in a complex geotechnical environment, by means of technical systems that permitted a substantial dredging under the foundation level of an existing infrastructure, significantly enhancing its resistance in compliance with current regulations.

RÉSUMÉ: Article décrivant les solutions structurelles/géotechniques développées pour le renforcement et le soutènement d'un quai existant, afin de permettre le dragage du fond marin jusqu'à une profondeur de 8 mètres, du niveau -10,00ZH au niveau -18,00ZH, pour l'installation d'un *synchrolift* d'haute capacité dans une région à haute sismicité. En plus du dragage significatif, cette intervention a imposé la construction de structures de renforcement complémentaires, conçues pour fonctionner en parfaite interaction et interconnexion avec le sol et avec l'infrastructure du quai existante, afin de permettre une augmentation massive de charge résultant de l'élévation, transfert à terre et du stationnement (à sec) de navires jusqu'à 9000 tonnes de déplacement sur des dalles de plateforme en béton armé, construites sur des pieux de fondation. L'article se concentre sur les approches de conception, les méthodologies de calcul sismique adoptées et les procédures d'analyse de sensibilité, réalisées pour maximiser les coefficients de sécurité, en soulignant les principales contraintes existantes et leurs effets sur le processus d'analyse coût-bénéfice qui a déterminé les solutions techniques adoptées. Il résume également la séquence de construction et l'importance d'une planification minutieuse lors de la conception du processus chronologique. L'expérience et l'analyse méticuleuse de toutes les variables du processus, de la conception à la construction, sont éléments essentiels pour mettre en œuvre une solution de soutènement/renforcement non conventionnelle dans un environnement géotechnique complexe, en adoptant des systèmes qui ont permis un dragage considérable sous le niveau de fondation d'une infrastructure existante, lui conférant une résistance significative, en conformité avec la réglementation en vigueur.

Keywords: Dredging; underpinning; strengthening.

1 GUIDELINES

The naval base of the Project described in this article houses a naval repair sector occupying approximately 16 hectares within its premises (Figure 1). To support the maintenance and repair of the operating vessels, the base was equipped with a lifting platform capable of handling ships up to 3000 tons, enabling their transitions between the sea and the port platform.

Figure 1. Naval Base location.

As time passed, the detection of deformations in the quay wall structures and signs of corrosion in the steel and electromechanical elements of the lifting platform prompted the responsible entities to initiate an international tender for the development and implementation of a rehabilitation and reinforcement solution.

The objective was to facilitate the installation of a new synchrolift with a 9000-ton capacity, aligning with the size and capacity demands of the existing operational vessels. In general terms, the requirements expressed in the tender specifications determined:

- The design of onshore and offshore reaction structures, to support a vessel lifting platform measuring 25m x 145m and a 9000-ton capacity.
- Reinforcement of the current quay walls, enabling the dredging procedures ranging from 3 to 8m in depth within the new berthing quay and the new lifting platform zones.
- Development of a 145m length transference zone, for ship transfer operations between the lifting platform and five parking areas for the construction, repair, and maintenance of vessels, with lengths ranging from 100 to 150m.
- Design of a 623m length circulation path for two overhead cranes with lifting capacity of 40 tons, at a 50m distance.
- Construction of support and control buildings, along with extensive network grid systems and operational equipment.

These requirements resulted in the occupational layout shown in Figure 2.

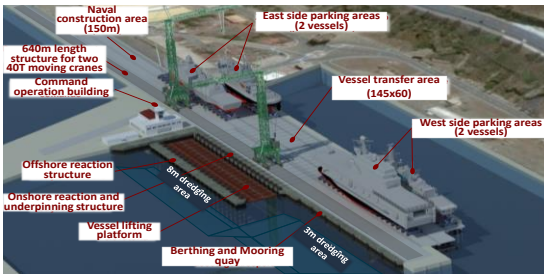

Figure 2. 3D image of the conceived intervention layout.

2 EVALUATION OF EXISTING SOIL AND INFRASTRUCTURES

Figure 3 shows the stability design assessment of the existing quay walls, which have their base at the seabed level (-10.00ZH). This assessment implied an extensive geotechnical survey involving multiple activities which included 25 boreholes along with various characterization procedures and laboratory tests. The data collected was summarized in geotechnical reports, which provided the basis for the interpretation and assignment of geomechanical parameters used in subsequent calculations.

- C2 - Heterogeneous port backfills: Ø'=25º; c'=5kN/m2; γ=19kN/m3;
- C3A - Clay with sand intercalations ($15<N_{SPT}<30$): Ø'=25º; c'=3kN/m2; γ=20kN/m3;
- C3B - Silty clays ($30 < N_{SPT} < 60$): Ø'=25º; c'=50kN/m2; γ = 20kN/m3;
- C4 - Compact marls ($N_{SPT} >60$): Ø'=30º; c'=50kN/m2; γ = 20kN/m3.

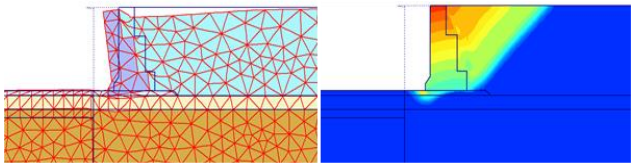

Figure 3. Numerical simulation of the existing quay structures (SF ≅ 1.1 => very low).

3 PROJECT DESIGN

The assessment of the existing quay confirmed the complexity of the tender demands. In addition to rehabilitating, retrofitting and strengthening a highly sensitive infrastructure, to comply with current regulation standards, this project involved the reinforcement of the port's backfill and of the pre-existing quay to cope with the substantial load increase resulting from the vessel suspension, transfer and parking operations.

Furthermore, the ship's draft specifications, the thickness of the new lifting platform and the characteristics of the new transfer system (including supporting trestles and bogies) dictated the necessity to deepen the seabed by 8 meters. This operation extended from -10.00ZH to -18.00ZH, requiring the underpinning of the existing quay walls.

Even though the singularities of the *synchrolift* operations impose a wide range of load actions whose description is beyond the scope of this article, Figure 4 provides a visual representation of the maximum loads managed by all 38 suspension winches (19

onshore and 19 offshore) during the new vessel lifting operations.

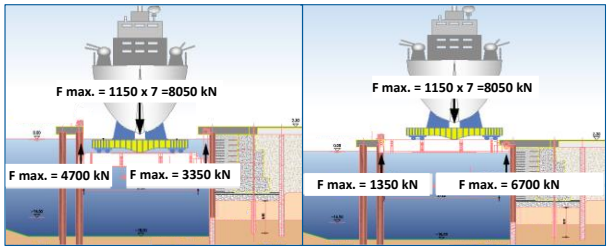

Figure 4. Maximum loads on onshore / offshore structures.

Alongside the load increment due to vessel lifting and transfer procedures, the solution needed to address the substantial ≈21meter earth pressure differential arising from the differential between the level of the elevation of the new port platform (+3.20ZH) and the post-dredging seabed level (-18.00ZH).

Furthermore, it's essential to emphasize the significance of seismic activity, a decisive factor in the design for Ultimate Limit States. Considering all the specified criteria and following extensive research, evaluating numerous technical solutions and construction scenarios, the outcomes led to the implementation of an integrated structural approach, where the new transfer and parking areas shall function as integral load-bearing components, in conjunction with the existing quay walls and their innovative underpinning solution.

The designed underpinning structure consists of a retaining wall curtain formed by Φ1200mm cast-in-place bored piles with a 1.35m spacing, acting with the complementary stabilizing resistance of the existing quay walls and by a plain concrete fill placed in the 6m gap between these two structures.

The massive loadings resulting from ship transfer and parking led to the use of a transfer system carried out by bogies, circulating on rail tracks positioned over a grid of reinforced concrete beams (2.0mx1.8m). Along with the reinforced concrete platform slabs, this grid of high-capacity beams forms a horizontal diaphragm element which is supported by Φ1500mm bored piles, reaching depths compatible with suitable penetration into the marl substrate, occurring from a depth of 16m. This diaphragm allows for the joint mobilization of the passive soil earth pressure along the pile foundation shafts that, functioning together with the underpinning structure, proved to be capable to counteract the ≅21m active earth pressures actions resulting from dredging procedures.

The joint interaction between existing and strengthening structures imposes a suitable interconnection between all interface areas, capable of ensuring their monolithic behaviour. This interconnection proved to be essential for the overall solution stability, where the bond between structural elements was achieved by suitable dowel steel bars, attached to the existing quay walls through epoxy resins and to the new reinforced concrete structural elements by means of embedded anchoring lengths.

Over the existing quay, the impossibility of large diameter deep foundation drilling across the existing concrete structures led to the adoption of micropiles, suitably spaced according with their resistance and the applied load values. These micropiles (N80-Ø177.8×15mm) were grouted into the marl substrate through a repetitive and selective injection system.

The described solution is generically shown in Figure 5, by the schematic illustration of the lifting platform suspension operations over the offshore and onshore reaction structures, allowing the vessel ascent that precedes its transfer to the parking areas.

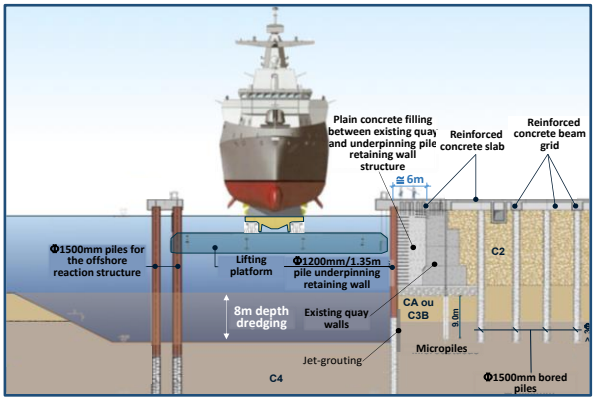

Figure 5. Typical section cut of the described solution.

The design of the adopted solution was performed with 2D and 3D nonlinear numerical simulations, using different software and conducting sensitivity analyses by judicious comparison of the obtained results. The 2D models were developed using the software PLAXIS, where the soil is simulated through finite elements governed by Mohr-Coulomb failure criteria, and the remaining elements (micropiles, quay walls, backfill, piles, beams, and slabs) through linear/elastic behaviour elements. In these models, it was possible to simulate the construction phasing and determine the combined design stresses, forces, deformations, and safety factors for each intervention stage (Figure 6).

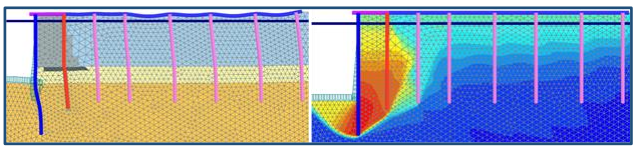

Figure 6. Calculation deformations ($\delta_{max\ horiz.}$=1.7cm) and failure surfaces of the adopted solution (SF ≈ 2.6).

As sown in Figure 7, the 3D design models, using SAP2000, simulated the soil/structure interaction through nonlinear spring elements, with stiffness corresponding to the soil's Winkler modulus and plastic behaviour corresponding to the value of the passive earth pressure in depth. The steel, plain concrete and reinforced concrete elements were simulated by linear/elastic finite elements.

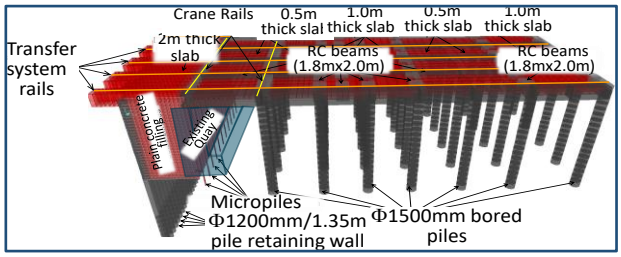

Figure 7. 3D model for the transfer zone structural body.

With the developed numerical calculation models, properly adapted to the characteristics/particularities of the various structures and intervention areas, it was possible to determine the maximum values of forces, stresses and displacements for all Ultimate Limit State and Service Limit State combinations, by numerical simulation of all structural elements and interconnections considering all construction phases.

In addition to the global numerical simulations, the calculations also involved numerous additional lower scale models, performed to address more specific situations. Figure 8 presents two images of one of these supplementary models.

In this case, the calculations were performed to simulate the solution's stability immediately after the dredging procedures. In this construction phase it was mandatory to have the micropiles for existing quay foundation strengthening, the pile retaining wall curtain and the plain concrete stabilization filling fully concluded. However, the connection to the platform slab, that establishes the stabilization diaphragm of the solution in its final stage, was yet to be completed, which imposed additional verifications.

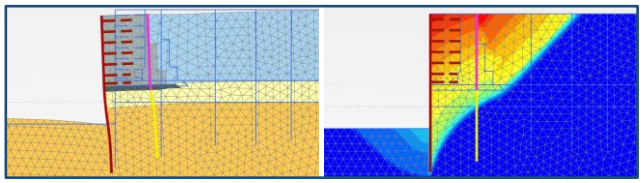

Figure 8. Evaluation of temporary dredging effects.

4 CONSTRUCTION METHODS AND PHASES ADOPTED

The underpinning of the existing quay walls, whose main operations are represented in Figure 9, began with the execution of micropiles foundation strengthening elements, followed by sequential vibro-driving of a curtain of permanent steel casing tubes, with an internal diameter of Φ1200mm and a thickness of 12mm, ensuring a 6m distance between its axis and the existing quay wall elements. With lengths of approximately 16m (5m driven into the ground => casing toe approximately at -15.00ZH), these steel casing elements were positioned with a 1.35m spacing between axes, establishing a retaining wall curtain parallel to the existing quay, covering the entire length of the dredging area.

The "hook" connection that assembles these casing tubes, establishing a continuous joint element, allowed for subsequent underwater concrete placing between the curtain and the existing quay, preventing material leakage into the sea.

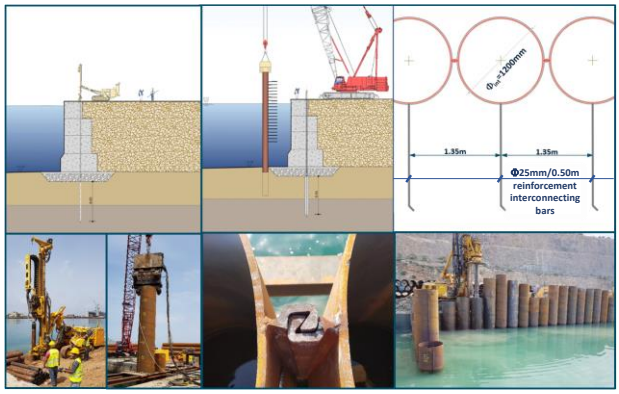

Figure 9. Schemes and images of micro-pile execution and steel casing driving.

The drilling, reinforcement positioning and concrete pouring operations for the execution of the underpinning curtain piles, presented in the schemes and images of Figure 10, were carried out with machinery operating from the port backfill, through the steel casing, using drilling equipment attached to powerful cranes or a suspended fly-drill equipment, reaching depths compatible with the -26.00ZH level.

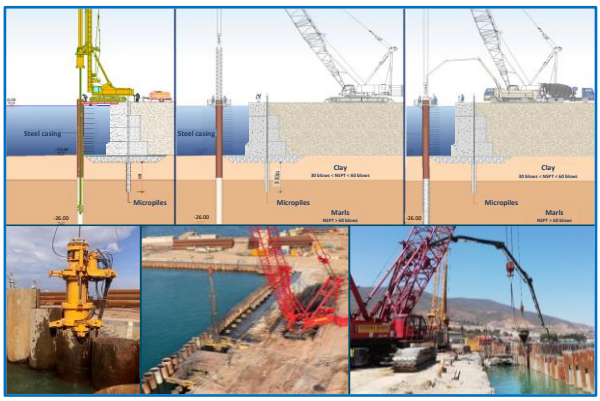

Figure 10. Schemes and images of the construction operations of the bored piles of the underpinning curtain.

Following the defined phasing sequence, the construction works proceeded with the filling of the gap between the underpinning pile curtain and the existing quay walls through submerged pouring of plain concrete, followed by the execution of jet-grouting columns that filled the 15cm gap between adjacent piles, located below the base of the tubes (and their connecting elements), exposed after dredging procedures of the seabed (from -10.00ZH to -18.00ZH).

These operations were executed along with the installation of interconnection dowel bars, which were sealed with epoxy resins or incorporated into the new structural elements, designed to ensure a monolithic behaviour between the piles, the existing quay, the plain concrete filling, and the reinforced concrete structural slab/beam grid (Figure 11).

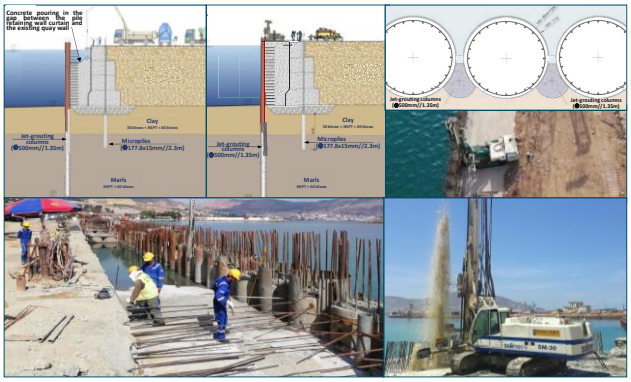

Figure 11. Concrete pouring in the gap between the pile retaining wall curtain and the existing quay wall and execution of the jet-grouting columns.

Following the previously described design established phasing procedures, the conclusion of the primary underpinning reinforcement curtain, including the plain concrete filling, allowed to begin the dredging operations (Figure 12), to deepen the seabed in 8m, achieving the required clearance for the Project vessel draft, including the height of the synchrolift system's platform structure and the ship supporting berth beams (trestles).

Figure 12. Dredging reaching maximum depths of 8.0m, up to the -18.00 ZH level.

These dredging operations involved the removal of marl material from the C3A, C3B, and C4 geotechnical layers, occurring under approximately 1.0m of sedimentary material.

The construction of the 411 foundation piles (72 Ø1200mm and 339 Ø1500mm) for the reinforced concrete beam foundation for the crane runway and the ship transfer/parking platforms was executed simultaneously with the previously described quay underpinning and foundation strengthening operations.

As illustrated in the schematic drawings and images of Figure 13, these structural elements are located on the port backfill areas. Ensuring a minimal penetration of 3Ø into the marl formations, the piles have variable lengths between 21m and 25m, and were designed to support vertical loads and to provide a supplementary horizontal stability solution through the mobilization of passive earth pressure along their shafts.

Figure 13. Execution of foundation piles for the ship transfer and parking platform.

The conclusion of all dredging operations allowed the beginning of the construction of the offshore reaction structure, located approximately 28m from the alignment of the quay's underpinning pile curtain.

This structure consists of a reinforced concrete 1.6m thickness slab, placed over 42 bored Φ1500mm piles, executed by drilling through steel casing previously introduced into the ground (Figure 14).

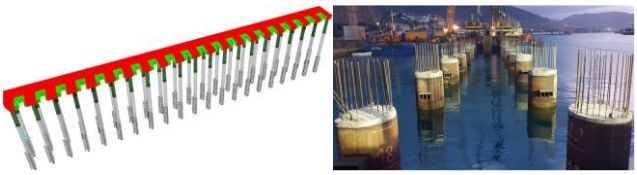

Figure 14. Design model and pile execution of the offshore structure, using floating platforms.

The vibro-driving of the permanent casing, the drilling, reinforcement placement, and concrete pouring for the execution of the offshore piles followed similar procedures to those described earlier, with the particularity of being carried out by equipment operating on floating platforms.

5 CONCLUSIONS

The imposition of new exploitation requirements on old maritime structures generally implies the execution of complex and expensive structural interventions. In this context, the execution of reinforcement and underpinning interventions requires the adoption of multidisciplinary solutions and suitable construction methodologies, capable of overcoming existing constraints and achieving the structural behaviour required by the new operating conditions.

Whenever the geomechanical characteristics of the soils don't allow element driving, such as sheet piles, until the required depths for underpinning structures, the option for bored cast-in-place piles may be advantageous. This methodology, which uses drilling with soil extraction, overcomes many of the constraints imposed by driving limitations, enabling the achievement of the design depths through the use of suitable drilling tools.

The extreme constraints of this intervention required the design of an integrated solution where the overall equilibrium is achieved throughout the joint functioning of both existing and reinforcing structural elements. It's imperative to highlight that this global integrated system required a thorough analysis of all material rheological properties, evaluating the structural behaviour of both existing and strengthening elements, considering the geomechanical characteristics of the soil and of the structural interaction between all components. This option, which proved to be crucial in the success achieved in this complex Project, is shown in Figures 15 and 16.

Figure 15. Project site after conclusion of the control building and installation of the synchrolift.

The combined structural behaviour between the underpinning pile curtain, the existing quay walls, the plain concrete filling, jet grouting columns, micropiles, and foundation piles, all interconnected by a top diaphragm consisting of reinforced concrete beams and slabs, made it possible to obtain a resistance capacity compatible with a significant load increase and a significant dredging, enabling the Project vessel lifting and transfer operations, such as shown in Figure 16, meeting the current regulation requirements and achieving significant safety factors.

Effects of sheet pile driving on soil density within soil exchange drillings

Effets du battage de palplanches sur la densité du sol dans les forages d'échange de sol

U.Matthiesen*, M.Pohl
Federal Waterways Engineering and Research Institute, Hamburg, Germany
**ulf.matthiesen@baw.de*

ABSTRACT: For the overhaul of a major port construction soil exchange drillings using large diameter cased boreholes were carried out along the wall alignment to support the installation process of the subsequent pile driving. In order to minimise the environmental impact, the exchange drillings were backfilled using the excavated drilling material. If the material was deemed unsuitable, sand from an offshore depot was used instead. During the pile driving several of the king piles sank up to 9 m into the ground with minimal application of driving energy. An extensive investigation was launched to identify the cause of these failures. Different fill materials as well as backfilling methods of the exchange drillings were investigated using before and after cone penetration tests (CPT). In order to assess the structural integrity of the driven king piles, CPTs were carried along the wall alignment, adjacent to and within the double beam piles. This paper presents the findings of the above-mentioned investigation focussing on the installation effects of the pile driving on the soil density within the exchange drillings. The CPT results suggest a sufficient compaction of the fill material due to the pile driving process even in areas where the piles initially sank into the ground.

RÉSUMÉ: Dans le cadre de la remise en état d'une construction portuaire majeure, des forages d'échange de sol ont été réalisés à l'aide de trous tubés de grand diamètre le long de l'alignement du mur afin de soutenir le processus d'installation du battage de pieux ultérieur. Afin de minimiser l'impact sur l'environnement, les forages d'échange ont été remblayés à l'aide des matériaux excavés. Si le matériau n'était pas approprié, du sable provenant d'un dépôt offshore a été utilisé à la place. Pendant le battage des pieux, plusieurs des pieux centraux se sont enfoncés jusqu'à 9 m dans le sol avec une application minimale de l'énergie de battage. Une enquête approfondie a été lancée pour identifier la cause de ces défaillances. Différents matériaux de remplissage ainsi que des méthodes de remblayage des forages d'échange ont été étudiés à l'aide d'essais de pénétration au cône (CPT) avant et après. Afin d'évaluer l'intégrité structurelle des pieux battus, des CPT ont été effectués le long de l'alignement du mur, à côté et à l'intérieur des pieux à double poutre. Cet article présente les résultats de l'étude susmentionnée, en mettant l'accent sur les effets de l'enfoncement des pieux sur la densité du sol dans les forages d'échange. Les résultats du CPT suggèrent un compactage suffisant du matériau de remblai dû au processus de battage des pieux, même dans les zones où les pieux se sont initialement enfoncés dans le sol.

Keywords: Soil exchange drillings; soil structure interaction; combined sheet pile wall; installation effects.

1 INTRODUCTION

The overhaul of a major tidal port construction in Germany entails a new, approximately 2.2 km long and 15 m high, quay wall in front of the existing wall at a distance of 5 m. The new combined sheet pile wall consists of over 30 m long double beam HZM 1080 king piles as structural supports, and AZ sheet piles as intermediate infill elements. The wall is tied back using pressure grouted steel displacement piles (Figure 1).

Due to the predominating very dense sands, locally occurring soft marine clay as well as debris from WW2 bombings, soil exchange drillings using large diameter cased boreholes were carried out along the wall alignment to support the installation process of the pile driving. The exchange drillings were backfilled using, if suitable, the excavated drilling material as well as sand from a nearby depot. During installation, several king piles sank over several metres (up to 9 m) into the ground with minimal application of driving energy.

The works were stopped in order to investigate the cause of this phenomenon. This paper contains a description of the investigations carried out as well as an assessment of the installation effects of the pile driving on the surrounding soil and the possible causes of the observed sinking of the piles.

2 GROUND CONDITIONS

The local geology is composed of superficial quaternary soils, consisting of soft cohesive soils and sand. Onshore, along the quay wall, the upper layer consists of made ground underlain by soft marine clay followed by medium dense to dense sands. The upper layer of the harbour basin consists of mud of up to 5 m thickness underlain mostly by sand and in parts by marine clay or silty sands (Figure 1).

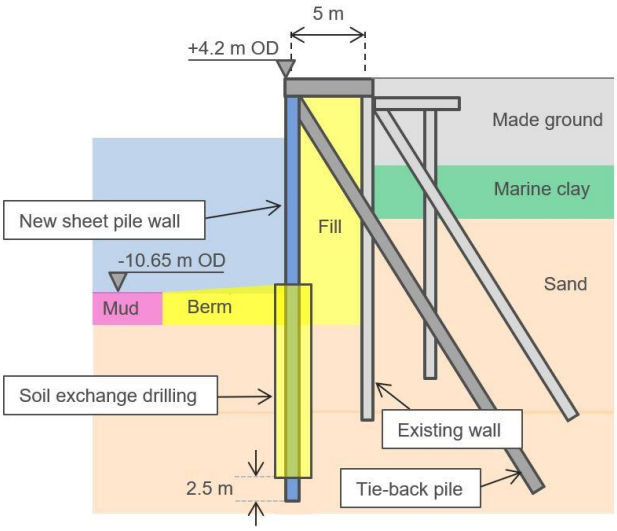

Figure 1. Cross section of the old and new quay wall including ground conditions.

3 CONSTRUCTION & ANOMALIES

3.1 Construction sequence

The first step of construction was to remove the fluid mud layer in front of the existing wall and replace it with a sand berm in order to stabilize the structurally inadequate quay wall and to avoid settlement of the future backfill. This was achieved by dredging the material using water injection while simultaneously backfilling with sand (Matthiesen et al., 2015). Prior to the driving of the new combined sheet pile wall, the soil exchange drillings using large diameter cased boreholes were carried out along the wall alignment. The installation of the wall was followed by the driving and connecting of the tie-back piles. Finally, the space between old and existing wall was incrementally backfilled and the new platform was constructed.

3.2 Soil exchange drillings and sheet pile driving

The soil exchange drillings were carried out from a jack-up barge along the alignment of the new sheet pile wall using large diameter cased boreholes. The soil was extracted using the Kelly drilling method. The boreholes were drilled to a depth of 2.5 m above the bottom of the king piles (Figure 1) to ensure sufficient toe resistance of the piles. After completion of the borehole the excavated material was reinstalled as backfill material. Before its reuse the soil was checked for obstacles and its suitability as filling soil. If necessary it was replaced by sand from a nearby offshore depot. Figure 2 shows an example of the alignment and the sequence of the soil exchange drillings.

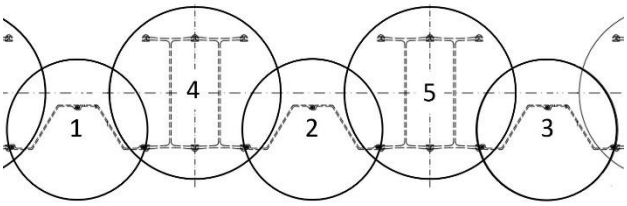

Figure 2. Soil exchange drillings - alignment and construction sequence.

In order to ensure that the king piles were installed within the specified tolerance, the piles were fixed into position within a pile-driving template using welded bracket guides as well as leader rig guidance (Figure 3). The piles were installed using the large driving sequence (back-step method) which ensured that the pile toe encountered soil uniformly on its total circumference and not just on one side.

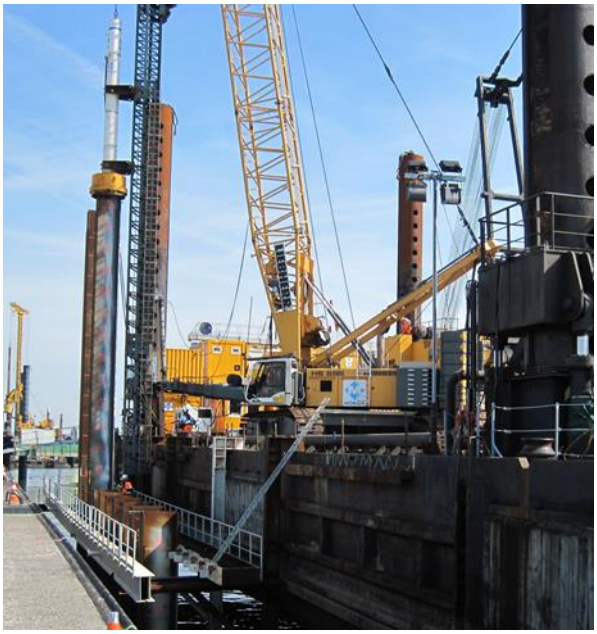

Figure 3. Installation of the king piles.

3.3 Anomalies

In the course of the works, a large number of the soil exchange drillings required a considerable additional amount of backfilling material of up to twice the

arithmetic volume of the borehole (Matthiesen & Pohl 2021).

During the subsequent pile installation, several king piles sank over several metres (up to 9 m) into the ground with minimal application of driving energy. This occurred in the upper metres of the piles and affected 16 of the 53 king piles installed until the works were stopped in order to investigate the cause.

4 INVESTIGATION

In order to identify the cause of the aforementioned sinking of the piles as well as the additional filling material required an extensive investigation was launched. Different fill materials as well as backfilling methods of the exchange drillings were investigated using before and after cone penetration tests (CPT). The findings of these investigations are presented in (Matthiesen and Pohl, 2021).

In order to assess the structural integrity of the driven king piles, CPTs were carried out along the wall alignment, adjacent to and between two neighbouring king piles. The position of the CPTs is shown as an example in Figure 4. The CPTs were used to determine the relative density D_r of the sand surrounding the piles as well as for the detection of potential embedded cohesive layers within the fill. As a baseline reading additional CPTs were carried out in the adjacent natural ground at a distance of 5 m to the piles, which showed no effect of the pile driving.

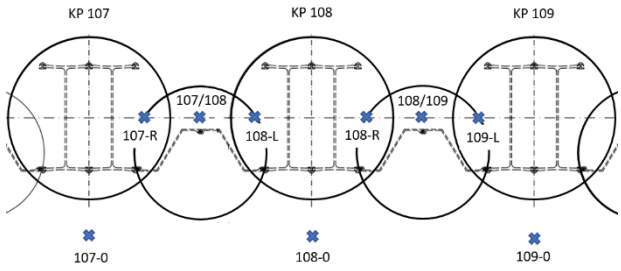

Figure 4. Locations of CPTs at king pile locations KP 107 / 108 / 109.

It was noticeable that the phenomenon of the sinking of the piles occurred in groups of consecutive king piles. The CPTs were therefore carried out at several locations of 3 king piles each. The selected locations included both well driven piles, showing a steadily increasing driving energy with depth, and locations where the sinking of the piles occurred.

5 ANALYSIS

For the purpose of this evaluation, two representative pile groups are compared below. These are king piles 81-83, showing a normal or good driving progress with depth and king piles 107-109, which sank over several meters into the ground during driving. To this end, the soil conditions and the pile driving data are being analysed.

Table 1 gives a summary of the driving data of the aforementioned piles, showing the number of blows and total energy required for the driving of the piles. On average, the number of blows and total driving energy is twice as high for the first pile group, the biggest difference being between king piles 81 and 107 showing a factor of 4.6 in the number of blows and a factor of 6 in the required total driving energy.

Table 1. Summary of pile driving data.

King Pile	No. of blows	Total Energy [kN]
81	2441	203.910
82	1771	133.770
83	2103	176.513
107	528	34.096
108	1438	112.330
109	1187	98.724

Additionally, Figure 5 depicts the driving progress with depth for each of these piles. While the first pile group (KP 81-83) shows a steady increase in the number of blows with depth due to a compaction of the fill material as a result of the driving and an increase in skin friction, the second pile group clearly shows the aforementioned sinking of the piles into the ground within the first 9 m with minimal application of driving energy.

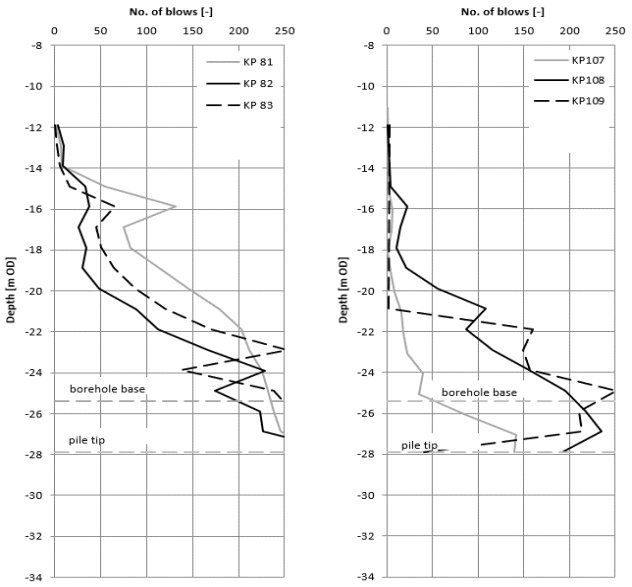

Figure 5. Number of blows with depth for king piles 81/82/83 (left) and 107/108/109 (right).

The relative density D_r within the exchange drillings prior to driving for these pile locations is unknown. Investigations have shown, however, that

the execution of the exchange drillings result in a decrease in cone resistance q_c of up to 76 % irrespective of the fill material used (Matthiesen and Pohl, 2021). Therefore, a loose to very loose relative density D_r can be assumed within the exchange drillings prior toe driving.

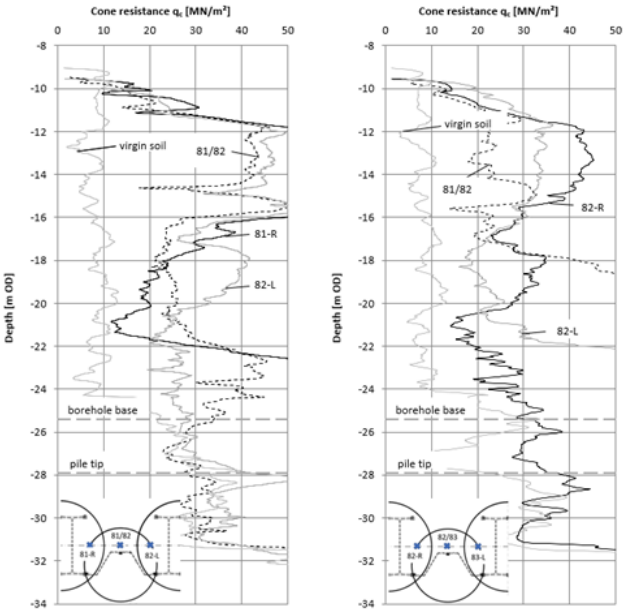

Figure 6. Cone resistance q_c between king piles KP 81/82 and KP 82/83.

Figures 6 and 7 show the cone resistance q_c of the CPTs carried out within the fill material of the exchange drillings for the respective pile groups. The first pile group (Figure 6) shows an average q_c of 33.6 MPa within the exchange drillings, corresponding to a dense to very dense relative density D_r after pile driving. The CPT results show a significantly higher cone resistance than the virgin (natural) soil outwith the borehole over the entire length of the pile. The CPTs in between the piles (CPTs 81/82, 82/83) also depict a similar – in some places higher - increase in soil strength than the ones directly adjacent to the piles showing that pile driving also leads to significant compaction in the neighbouring exchange drillings.

The CPTs carried out within the area of the second pile group (Figure 7) show, in parts, lower cone resistances q_c, especially in the upper parts of the pile (i.e. CPT 107-R, 107/108, 108-L). This was to be expected as this is the area where the sinking of the piles occurred. However, the cone resistances q_c are still consistently higher than those of the virgin (natural) soil, which formed the basis of the structural design. Some CPTs within this pile group also show cone resistances q_c similar to the previously discussed group. The average cone resistance q_c in this pile group is 25.1 MPa, also confirming a dense to very dense relative density D_r.

Surprisingly, no significant increase in cone resistance q_c can be observed between the base of the exchange drilling and the pile toe in either of the pile groups. In fact, the cone resistances q_c are of similar magnitude than the virgin soil conditions suggesting no or little compaction of the soil in this area.

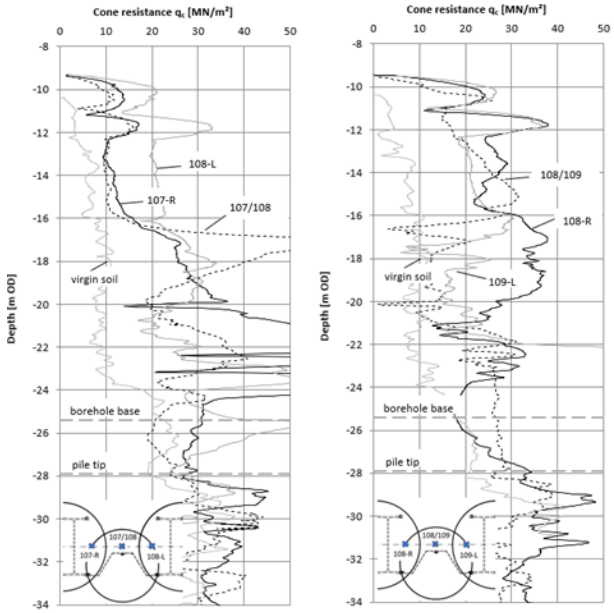

Figure 7. Cone resistance q_c between king piles KP 107/108 and KP 108/109.

6 CONCLUSIONS

Although some piles sank into the ground over several metres at the start of the pile driving due to the very loose soil conditions within the exchange drilling, the CPTs suggest a sufficient compaction of the fill material due to the pile driving process, when compared to the natural ground conditions, which formed the basis of the original structural design. The driving energy which is transferred into the surrounding soil leads to a compaction not only of the fill material within the exchange drilling but also the neighbouring regions, leading to soil densities higher than the natural ground before drilling, therefore confirming the validity of the original structural design.

Use of xanthan gum produced by a bacteria to reduce the soil permeability

Utilisation de la gomme xanthane produite par une bactérie pour réduire la perméabilité du sol

ABSTRACT: The construction of Civil Engineering structures on some soils requires their stabilization. Portland cement as a stabilizing agent presents many environmental concerns, so it is fundamental to find sustainable alternatives for soil stabilization in the construction field. Thus, this work analyzes the ability of the xanthan gum-like biopolymer, produced by the Stenotrophomonas maltophilia strain Faro439 (LabXG), to reduce the permeability of a sandy soil. In addition, the effectiveness of this LabXG is compared with the use of a commercial xanthan gum (XG) and Portland cement for different hydraulic gradients and curing times. The results of permeability tests show that the treatment with any type of XG can be used to replace cement in the short term (cure time of less than 14 days), although a higher level of effectiveness is obtained with the use of commercial XG due to its higher level of purity. SEM images show that treating the soil with LabXG creates a mesh of fibers that bind the soil particles together, while commercial XG fills the voids with a homogeneous paste.

RÉSUMÉ: La construction d'ouvrages du génie civil sur certains sols nécessite leur stabilisation. Le ciment Portland en tant qu'agent stabilisant présente de nombreux problèmes environnementaux, il est donc fondamental de trouver des alternatives durables pour la stabilisation des sols dans le domaine de la construction. Ainsi, ce travail analyse la capacité du biopolymère de type gomme xanthane, produit per la souche Faro439 de Stenotrophomonas maltophilia (LabXG), à réduire la perméabilité d'un sol sablonneux. En outre, l'efficacité de ce LabXG est comparée à l'utilisation d'une gomme xanthane commerciale (XG) et du ciment Portland pour différents gradients hydrauliques et temps de durcissement. Les résultats des tests de perméabilité montrent que le traitement avec n'importe quel type de XG peut être utilisé pour remplacer le ciment à court terme (temps de cure de moins de 14 jours), bien qu'un niveau d'efficacité plus élevé soit obtenu avec l'utilisation de XG commerciale en raison de son niveau de pureté plus élevé. Les images MEB montrent que le traitement du sol avec le LabXG crée un maillage de fibres qui lient les particules du sol entre elles, tandis que le XG commercial remplit les vides avec une pâte homogène.

Keywords: Biopolymer; soil stabilisation; xanthan gum; sandy soil.

1 GUIDELINES

The rising demand for urban infrastructure requires construction on challenging soil types. Traditional enhancement of these soils has predominantly involved the use of conventional cement. However, environmental concerns have catalyzed the exploration of biomaterial alternatives. Xanthan gum (XG) has emerged as a promising candidate for soil stabilization, inducing significant reduction in permeability and improvement in mechanical properties, particularly in sandy soils (Ayeldeen et al., 2017). However, the environmental footprint of industrial-scale production of commercial XG remains a significant concern. This study proposes the use of xanthan gum derived from a specific bacterial strain (LabXG) as a sustainable alternative. The primary aim is to evaluate the effectiveness of LabXG with commercial XG and traditional cement to soil stabilization, with a specific focus on the coefficient of permeability in sandy soil. The research also explores the impact of other parameters, including curing time (7 and 28 days), hydraulic gradient, XG content and content of cement. The characterization of treated soil involves the use of scanning electron microscopy (SEM) along with energy dispersive X-ray (EDX) analysis to examine the microstructure and chemical composition of soil samples treated with LabXG and commercial XG.

1.1 Soil characterization

The particle size distribution and the main characteristics of the soil used are shown in Table 1. It is a non-organic, non-plastic silty sand, composed of

72.7% sand and 27.3% silt, classified as SM (ASTM D2487, 2017). The soil compaction characteristics achieved using the standard Proctor test (ASTM D698, 2012) show an optimum water content (w_{opt}) of 14.3% and a maximum dry weight (γ_{dmax}) of 16.2 kN/m^3. The pH value of the untreated soil is approximately 7.1.

Table 1. Main characteristics of the soil.

Properties	Values
Particle size distribution	
Sand (%)	72.7
Silt (%)	27.3
Clay (%)	0
Specific density, G	2.66 g/m^3
Consistency limits	NP(**)
Proctor test [ASTM D698]:	
Maximum dry weight, $_{dmax}$	16.2 kN/m^3
Optimum water content, w_{opt} (%)	14.3
Organic matter content, OM (%)	0.19
pH	7.1

1.2 Production of Xanthan Gum-based biopolymer compound

The production of the biopolymer compound involves a systematic process, as outlined by Ayeldeen et al. (2017): (i) Cultivation of Stenotrophomonas maltophilia strain Faro439 on R2A agar plates for 3 days at 25 °C; (ii) Inoculation of cultured cells into xanthan medium in a batch system, followed by a 24-hour incubation on a shaker at 150 rpm. The resultant cells are employed as inoculum in a subsequent batch system with xanthan medium, incubated for 3 days on a shaker at 150 rpm, and then subjected to centrifugation to recover the biomass containing the biopolymer; (iii) Draining the biomass for 24 hours to eliminate excess water, followed by a 24-hour freeze-drying process to obtain a powdered form for convenient mixing with soil.

The use of this xanthan-enriched compost is justified by its uncomplicated production process, which skips purification phases, solvents or equipment that may pose ecological consequences. With a pH of 7.1, the production of xanthan gum is considered environmentally friendly compared to commercial XG. Its cost-effectiveness, together with its ecological attributes compared to other biopolymers and its proven ability to reduce soil permeability, further enhance its attractiveness as a sustainable solution.

1.3 Commercial Xanthan gum

Commercial XG is available in powder form and is produced by the bacterium *Xanthomonas campestris* through the fermentation of glucose/sucrose. It is a heteropolysaccharide made up of glucose, mannose and glucuronic acid units. It is a non-toxic hydrophilic colloid with pseudoplastic rheological properties (Chang et al., 2019) and is stable over a wide range of temperatures (10ºC-80ºC) and pH values (1-13).

1.4 Portland cement

Part of the mixtures in this research (Table 2) were chemically stabilised with Portland cement type I 42.5 R, which is made up of 45% particles of less than 45 mm. The cement is mainly composed of calcium oxide (CaO = 63%), which induces a spontaneous reaction with water, i.e. hydraulic properties.

1.5 Test procedure

The permeability tests utilized samples prepared in six distinct configurations: natural soil, a blend of soil with the biopolymer compound xanthan gum-based produced by bacteria (Lab XG) at 0.33%, a mixture of soil with commercial biopolymer xanthan gum at concentrations of 0.33% and 0.16%, and a mixture of soil with cement at concentrations of 0.33% and 1.0%. Each mixture type underwent testing across various hydraulic gradients (6.9, 8.2, 9.4, and 10.6) and two distinct curing times (7 and 28 days). The comprehensive test program details are presented in Table 2. While all samples were uniformly prepared, the permeability tests were conducted three times for each condition to ensure the quality and reproducibility of the obtained results.

2 RESULTS AND DISCUSSION

The Figures 1 and 2 show the permeability coefficients obtained experimentally for different mixtures and hydraulic gradients, considering the different curing times. The natural soil serves as a reference to evaluate the impact of each material on the permeability coefficient of the treated soil; the chemically stabilised samples with cement were included to compare the effectiveness of two types of xanthan gum (commercial and produced by bacteria) with the use of cement in reducing soil permeability.

The detailed analysis reveals a significant dispersion in the results, attributed to the heterogeneity of the natural soil and the challenges in producing homogeneous samples with low xanthan gum content. Remarkably, an increase in the commercial xanthan

gum content from 0.16% to 0.33% results in a substantial reduction in the dispersion of the results.

Table 2. Programme of tests.

Materials added			Hydraulic gradient (m/m)	Curing time (days)
Lab XG (%)	Commercial XG (%)	Cement (%)		
--	--	--	6.9 8.2 9.4 10.6	--
--	0.16	--	6.9 8.2 9.4 10.6	7 / 28
--	0.33	--	6.9 8.2 9.4 10.6	7 / 28
0.33	--	--	6.9 8.2 9.4 10.6	7 / 28
--	--	0.33	6.9 8.2 9.4 10.6	7 / 28
..	--	1.0	6.9 8.2 9.4 10.6	7 / 28

2.1 Effect of the hydraulic gradient

Most results indicate a slight decrease in the permeability coefficient with an increase in hydraulic gradient, especially for soil treated with 0.16% commercial XG. Some exceptions were noted, such as in the mixture of soil with Lab XG during a 14-day curing time. Although this trend is not in line with most of the results showed by Cabalar et al. (2017) for a hydraulic gradient range of 5 to 100, in some cases, increasing the hydraulic gradient from 5 to 10 (similar to the range considered in this study) also results in a decrease in soil permeability. This trend contrasts with previous studies and can be attributed to the specific methodology of measuring water flow. The results suggest that an increase in hydraulic gradient raises effective vertical stress (flow from top to bottom), reducing soil void ratio, and consequently, permeability. Samples with a high degree of stabilization, especially with 0.33% commercial XG and cement, exhibited lower sensitivity to variations in hydraulic gradient due to the stronger solid skeleton promoted by stabilization.

2.2 Effect of the curing time

Independent of the XG production process, a substantial decrease in soil permeability is observed in the first 3 days of curing, followed by a gradual decline until reaching a minimum coefficient at 14 days of curing. Although this indicates that the hydrogel's hydration occurs mainly in the short term (< 3 days), there is also evidence of continuous hydration during the initial 14 days. After this period, there is a slight increase in soil permeability, attributed to the potential biodegradation of XG and/or dehydration of the hydrogel. These factors increase the pore spaces in the soil, facilitating the flow of water and resulting in an increase in the permeability coefficient.

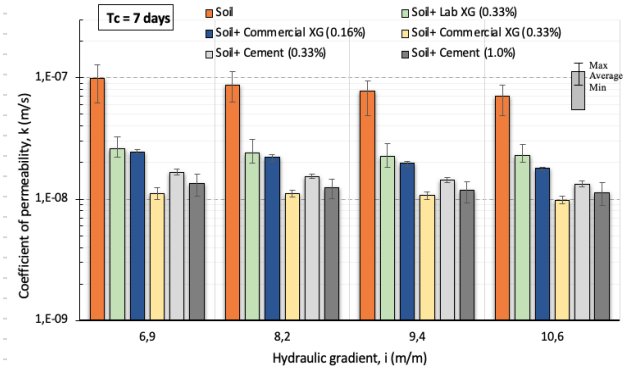

Figure 1. Permeability coefficient of natural and stabilised soil at 7-day curing time (Mendonça et al., 2021).

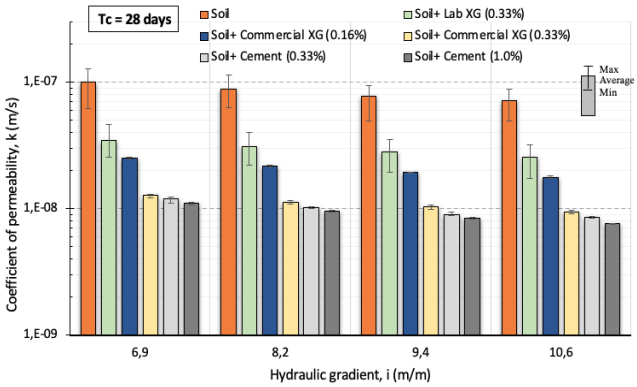

Figure 2. Permeability coefficient of natural and stabilised soil at 28-day curing time (Mendonça et al., 2021).

The literature (Venda et al., 2019) supports the observed short-term decrease in permeability. As expected, cement-stabilised specimens show a reduction in permeability over time due to pozzolanic reactions.

2.3 Analysis of the structures formed in the biopolymer-soil mixture

The Figures 3 and 4 illustrate the SEM images of soil treated with Lab XG and commercial XG. Lab XG creates fibre-like structures connecting soil particles, reducing voids, and decreasing permeability. In contrast, commercial XG forms a homogeneous paste, likely due to hydrogel hydration, resulting in reduced permeability. Both effects are compared to the natural soil and the distinct structure types correspond to

variations in their effectiveness. Lab XG's open structure is linked to higher permeability, while commercial XG's homogeneous paste restricts water flow.

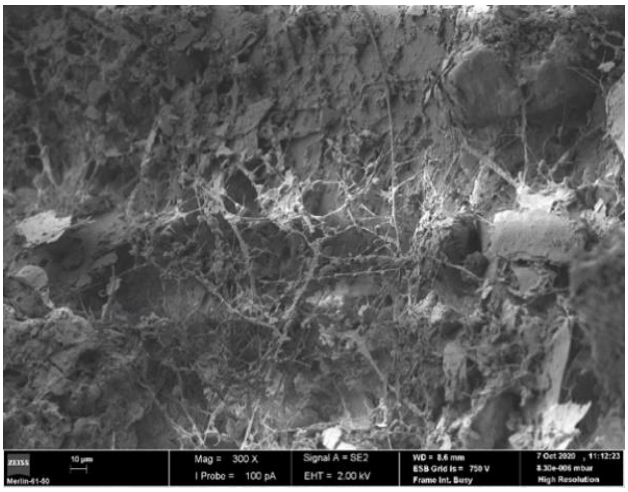

Figure 3. SEM image of the stabilized soil with Lab XG (Mendonça et al., 2021).

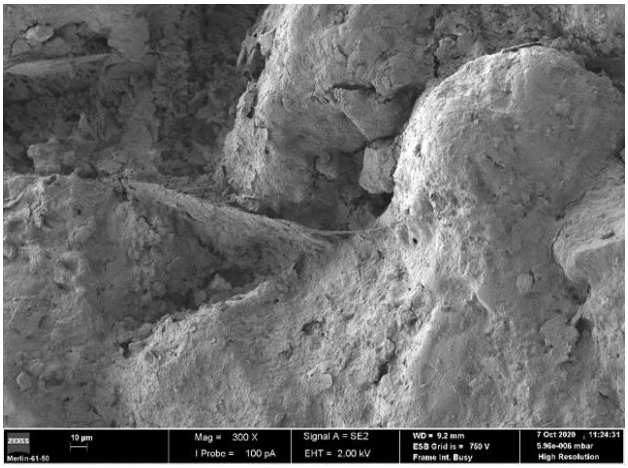

Figure 4. SEM image of the stabilized soil with Commercial XG (Mendonça et al., 2021).

3 CONCLUSIONS

This study compares the effectiveness of xanthan gum obtained directly from the *S. maltophilia Faro439* strain (LabXG) with commercial xanthan gum (XG) and Portland cement in reducing the permeability coefficient of a sandy soil. Both types of XG significantly reduced the permeability coefficient compared to untreated soil, with commercial XG been more effective. The use of 0.33% commercial XG was more effective than 1% of cement, suggesting its potential temporary replacement. Increasing the hydraulic gradient resulted in a slight reduction in permeability. The microstructure of the treated soil modified, with LabXG associated with a fibre-like network and commercial XG with a homogeneous paste. LabXG emerges as an interesting alternative, but future studies are needed to ensure its safety, as S. maltophilia falls under BSL-2 without specific regulations for environmental release.

ACKNOWLEDGEMENTS

The authors would like to express their sincere gratitude to the institutions that financially supported the research: individual research grant FCT 2021. 07819.BD, project research grant FCT (POCI-01-0145-FEDER-028382) and ACIV. This work was partly financed by FCT/MCTES through national funds (PIDDAC) under the R&D Units ISISE (UIDB/04029/2020) and ARISE (LA/P/0112/2020).

ABSTRACT: This paper presents an experimental study to evaluate the influence of adding 5% of cement, by dry mass of soil, on the strength and deformability of two different clays. Oedometer tests were performed on specimens of two different clayey soils, low plasticity Portugal clay and high plasticity Pljevlja clay, compacted according to standard Proctor test. Adding cement to the specimens resulted in reduction of instantaneous and time-dependent deformations under oedometric conditions. The increase in the preconsolidation stress, as determined by the oedometer test, along with the foregoing, indicates that adding cement has the similar effect as to pre-consolidate the clay. Conventional triaxial compression tests (CU) were performed on specimens of Portugal clay. The results of these tests showed that, with added cement, the compressive strength and secant Young's modulus E50 increases. Results of the CU tests indicated also that, once the cement is added, the soil behaviour changes from plastic to brittle plastic along with the pore pressure dropping during the shear stage.

RÉSUMÉ: Cet article présente une étude expérimentale pour évaluer l'influence de l'addition de 5% de ciment, par poids sec de sol, sur la résistance et la déformabilité de deux argiles différentes. Des éssais œdométriques ont été effectués sur des échantillons des deux sols argileux différents, l'argile du Portugal à faible plasticité et l'argile de Pljevlja à haute plasticité, compactés avec le même poids volumique sec déterminé par les éssais Proctor. L'ajout de ciment aux échantillons a entraîné une réduction des déformations instantanées et dépendantes du temps dans des conditions œdométriques. L'augmentation de la contrainte de préconsolidation, telle que déterminée par le test œdométrique, ainsi que ce qui précède, indique que l'ajout de ciment a le même effet que la pré-consolidation de l'argile. Des essais de compression triaxiale (CU) conventionnels ont été réalisés sur des échantillons d'argile du Portugal. Les résultats de ces éssais ont montré qu'avec l'ajout de ciment, la résistance à la compression et le module d'Young sécant E50 augmentent. Les résultats des tests CU ont également indiqué qu'une fois le ciment ajouté, le comportement du sol passe de plastique à plastique cassant et la pression interstitielle diminnue pendant l'étape de cisaillement.

Keywords: Cement-stabilized soil; clay soil; triaxial compression test; oedometer.

1 INTRODUCTION

Numerous reviews of soil stabilization using cement (Jawad, 2023) emphasize the efficiency of this old soil improvement method. Most of the researchers are focused on the strength parameters of the cemented soil, with fewer researchers oriented to the deformation properties (Rios et al, 2019). Moreover, in the field of improved soil strength, the unconfined compressive strength (UCS) has received much attention in comparison to the triaxial shear behaviour of cement improved soil (Azneb et al, 2021;Rios et al, 2019), due to the simplicity of determining this parameter. This paper presents an experimental study to evaluate the influence of the amount of cement on the strength and deformability of two different clayey soils.

2 EXPERIMENTAL INVESTIGATION

For the purpose of testing the characteristics of the cement-stabilized clay soil, the laboratory testing was

performed including oedometer tests and conventional triaxial compression tests.

2.1 Materials

A sample of a clay soil was obtained along the local road in the place Capuchos of the Almada County, south of Lisbon, Portugal (Miocene "Xabregas blue clays"), hereinafter referred to as the Portugal clay. The samples of the Miocene lacustrine clay, referred as the Pljevlja clay were collected from the construction site of the transformer station 400/220/110Kv Pljevlja 2, K.O. Ilino Brdo Municipality of Pljevlja in Montenegro (Figure 1). The basic physical properties of these two soils are summarized in Table 1. X-ray diffraction (XRD) was performed on Portugal clay. According to XRD, Portugal clay is mainly composed of quartz (52.9%), albite (18.3%), muscovite (10.8%), microcline (10.3%), calcite (3.0%), donbasite (3.2%).

Figure 1. Sampling locations of of the tested clays.

Table 1. Tested soil physical properties.

Soil	Portugal clay	Pljevlja clay
Unit weight (kN/m^3)	19.5	20.7
Liquid limit (%)	39	62
Plasticity limit (%)	25	24
Plasticity index (%)	14	38
D_{50} (mm)	0.20	0.0035
Unified Soil Classification	CL	CH
Optimal moisture content OMC (%)	13.5	-

The cement used for the purposes of this work was PC 35M (V-L) 32,5R, which represents a Portland-composite cement containing 64-79% clinker and 21-35% mixed silica fume and fly ash and lime. The water used was from public water system (potable water).

2.2 Specimen preparation and test procedure

Conventional triaxial tests were performed at the geotechnical laboratory of the Department of Civil Engineering, NOVA University of Lisbon. The testing involved the consolidated undrained triaxial tests (CU) on specimens of Portugal clay compacted at energy level of the standard Proctor's. Six specimens were tested, out of which three cemented-soil specimens with 5% of added cement. Oedometric tests were performed at the geotechnical laboratory of the Faculty of Civil Engineering, University of Montenegro in Podgorica. One non-cemented and one cemented specimens (5% of added cement) per each clay type were tested. A review of the specimens properties before testing is given in Table 2.

Table 2. Review specimen's properties before testing.

Soil	Test	w(%)	γ_d (kN/m^3)
Portugal clay	Triaxial	12.6	18.7
	Oedometer	13.5	16.1
Pljevlja clay	Oedometer	13.5	16.5

2.2.1 Oedometer test

Cement in quantity of 5% of the total dry weight was added to the clay, after which water was added. For specimens of both clays, a water content of 13.5% was achieved. The specimens for the oedometer test were compacted in oedometer cell by a 2.5 kg hammer dropped from the height of 30.5 cm, with 6 blows per one layer. This way, the compaction energy of 572 kJ/m^3, similar to the one specified by Standard Proctor test (624 kJ/m^3), was achieved. Immediately upon preparation, the non-cemented specimen was placed in the oedometer cell and then subjected to testing. Two cemented-soil specimens were cured for 7 days. The initial load applied was 100 kPa, with each subsequent load increment doubling the previous value, i.e. 200, 400 and 800 kPa respectively. Each loading step lasted for 24 hours and exceptionally for 48 hours.

2.2.2 Triaxial compression test

Cement in quantity of 5% of the total dry weight was added to clay that was in a relatively loose condition with the moisture content varying around 0.79%.

Upon achieving the moisture content, on dry side of optimal, of 12.6% (OMC – 0.9%), the specimens were compacted. The two-part cylindrical mould was used. Specimen diameter was D = 70 mm and the specimen height was H = 140 mm. The soil was compacted in four layers of 3.5 cm in thickness, using the 2.5 kg hammer dropped from the height of 30.5 cm.

This way, the equivalent compaction energy of 566 kJ/m^3 was achieved. The specimens were kept in plastic bags for 8 days to preserve moisture content of the specimen to the highest extent possible. Triaxial automated system (GDS Instruments) was used for the purposes of conducting CU test. The test was performed in three phases - saturation, consolidation and shear under undrained conditions with pore pressure readings. The specimen was sheared at rate of 0.05 mm/min.

3 RESULTS AND DISCUSSION

3.1 Oedometer test

Comparative diagrams of the total settlement to time and vertical load σ_z to vertical strain ε_z for the two clay specimens are shown in Figure 2 and Figure 3, respectively. Adding cement to soil specimens results in reduction of vertical settlement and vertical strains ε_z in vertical load σ_z range from 100 to 800 kPa, for specimens cured for 7 days.

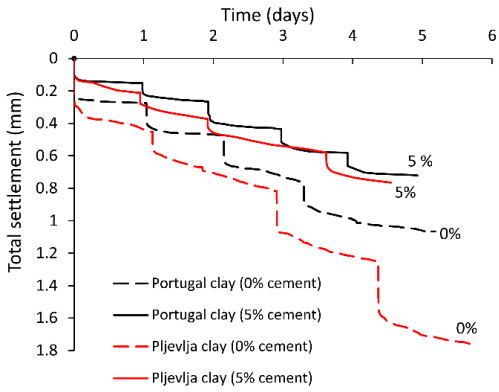

Figure 2. Comparative diagram of total settlement in relation to time for the clay specimens.

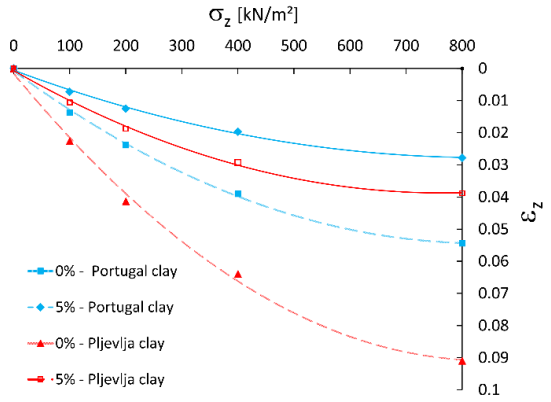

Figure 3. Comparative σz–εz diagram for the two clays.

Adding of cement affects the reduction in the instantaneous and time-dependent deformations (primary consolidation and/or creep), i.e. increases in the oedometric modulus E_{oed}. Calculated values of E_{oed} for cemented specimens are from 2.1 to 2.8 times higher compared to untreated specimens. The increase in the E_{oed}, can be partly attributed to the hardening, i.e. hydration of cement over the course of time.

The pre-consolidation stress can be defined by means of the Casagrande's method (1936), provided that the values of void ratio are known. For the cement-treated specimen of Portugal clay with the 5% added cement, the pre-consolidation stress p‘ is approximately 300 kPa, which is by 2.3 times higher than the p‘ for the same clay without added cement (p‘=130 kPa). The obtained result is compliant with the conclusion reached by Tugba (2015), indicating that the pre-consolidation stress changes with adding of cement, meaning, that increases with the percentage of cement.

3.2 Triaxial test

Figure 4 presents the deviator stress relation with axial strain of the non-cemented and cement-treated clay specimens of Portugal clay. The diagram indicates that for each value of the consolidation pressure of 100, 200 and 400 kPa, the maximum deviator stress of the cement-treated specimens is approximately 1.5 times higher than the deviator stress of the non-cemented specimens. It is also characteristic that at all levels of the all-around stress of 100, 200 and 400 kPa the cement-treated specimens underwent brittle failure at relatively low values of axial strain of about 5-7%. The non-cemented specimens underwent ductile failure, while in case of the cement-treated specimens a failure plane (shear bands) can be easily observed (Figure 4).

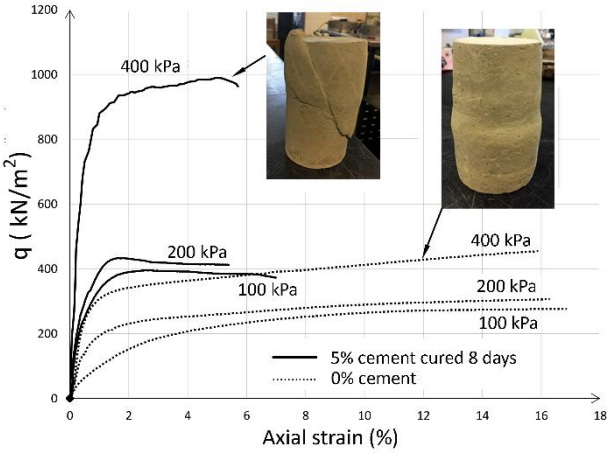

Figure 4. Diagram of ratio between the axial strain and deviator stress.

The effective stress paths for all specimens are illustrated in Figure 5. Reducing pore pressures during shearing of the non-cemented clay specimens (negative pore pressures for σ_c’=100 kPa) suggests

that the tested Portugal clay has the properties of the overconsolidated clay.

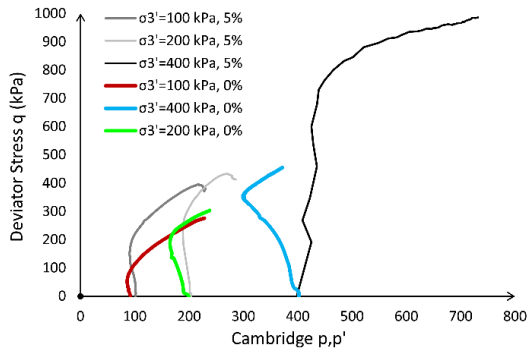

Figure 5. Effective stress paths for all specimens.

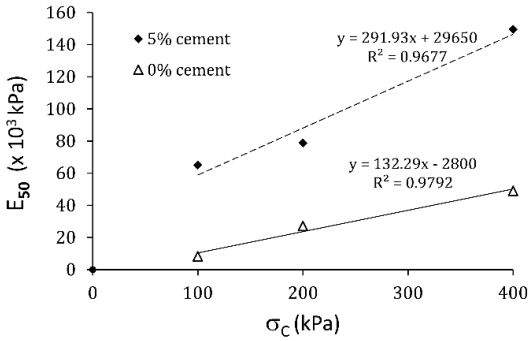

Figure 6. Diagram of the Young's modulus of elasticity E_{50} and lateral stress σ'c.

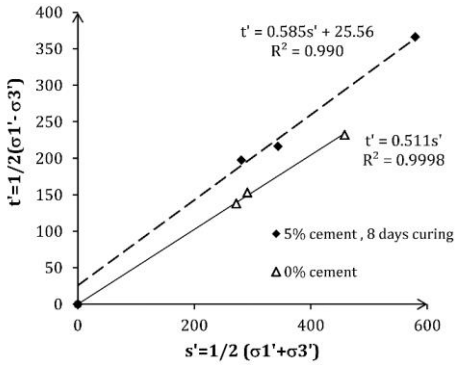

Figure 7. Mohr-Coulomb failure envelope for effective stresses for cement-treated and non-cemented specimen.

Secant elastic moduli of clay E_{50} have been obtained as a value of ratio of 50% of total deviator stress to the corresponding axial strain. E_{50} of the cement-treated specimens 3 to 7 times higher compared to the results of the non-cemented specimens under a lateral stress range from 100 to 400 kPa (Figure 6). Figure 7 shows Mohr-Coulomb failure envelopes for the cement-treated and non-cemented test specimens. It can be observed from the diagram, that for the non-cemented specimen the effective cohesion c' is 0 kPa as expected, and the angle of internal friction ø' is 30.7°. These values for the cement-treated specimen are cohesion c'=25.5 kPa and ø'=35.8°. Observed cohesion intercept indicates existence of true cohesion which results from chemical bonds between particles.

4 CONCLUSIONS

According to the results of oedometer test, adding of cement by 5% affects the reduction in the deformations of both clay specimens. Calculated values of E_{oed} for cemented specimens are from 2.1 to 2.8 times higher compared to untreated specimens. Results of CU triaxial tests on specimens of Portugal clay indicate an increase in value of the cohesion from zero value to 25.5 kPa, angle of internal friction from 30.7° to 35.8° and elastic moduli E_{50} by 3 to 7 times, compared to relevant values of parameters of nontreated soil. For Portugal clay, the increase in the preconsolidation stress by 2.3 times compared to the non-cemented clay and transition from ductile to brittle failure mode indicates that adding cement has the similar effect as the overconsolidation of the clay. Bearing in mind the limited scope of experimental testing, the verification of the above conclusions is foreseen through the directions of further research that may include other percentages of cement and longer times of curing, conducting similar tests at higher compaction energy (Modified Proctor test) conducting in-situ tests on the selected trial location of the cement-stabilized soil.

ABSTRACT: This study aimed to evaluate the accuracy of various semi-empirical methods for estimating the bearing capacity of bored piles with the innovative Expander Body technology in lateritic soils. The study analyzed the precision and accuracy of different methods based on PMT tests using the Ranking Distance Index (RD). Results showed that methods based on PMT tests were adequate for estimating the load capacity of piles equipped with the Expander Body technology in lateritic soils.

RÉSUMÉ: Cette étude visait à évaluer la précision de diverses méthodes semi-empiriques pour estimer la capacité portante des pieux forés avec la technologie innovante Expander Body dans les sols latéritiques. L'étude a analysé la précision et l'exactitude de différentes méthodes basées sur des tests PMT utilisant le Ranking Distance Index (RD). Les résultats ont montré que les méthodes basées sur les essais PMT étaient adéquates pour estimer la capacité de charge des pieux équipés de la technologie Expander Body dans les sols latéritiques.

Keywords: Expander body; pile load test; pile bearing capacity; pressuremeter; bored piles.

1 INTRODUCTION

The development in the civil construction sector results in increasingly complex buildings, necessitating progressively greater loads in foundations. In order to meet this demand, techniques are developed and refined to enable such constructions. A notable example is the Expander Body (EB) technology, a device installed at the tip of the pile, providing an increase in its bearing capacity. As indicated by Terceros Herrera and Terceros Arce (2016), this technique was conceived in the 1980s by the Swedish engineer Bo Skoberg and subsequently perfected in Bolivia, aiming to enhance the installation process and monitor the soil adjacent to the pile base (Fellenius and Terceros Herrera, 2014; Terceros Herrera and Massarsch, 2014; Fellenius et al. 2018).

The selection of an appropriate foundation type requires carrying out tests to obtain preliminary information into the characteristics of the soil under investigation, with an emphasis on its resistance. These tests include the pressuremeter tests (PMT) and many other in-situ testing procedures.

To estimate the bearing capacity of the pile-soil system, many semi-empirical approaches are used, including those proposed by Ménard (1963), Baguelin *et al*. (1978), and NFP 94-262 (2012). However, the results of these approaches are frequently variable. As a result, it is up to the practitioner to select the best

method for calculating the load-bearing capability of the evaluated pile-soil system. Compared to data obtained through pile load testing, acceptability criteria such as the Ranking Distance Index (RD) improve decision-making regarding the most accurate methodology. Orr and Cherubini (2003) proposed the use of a statistical index (RD - Ranking Distance), which assesses both accuracy through the mean and precision through the standard deviation of the ratio Q_p/Q_m (predicted/measured values) of any quantities, as described in the following equation:

$$RD = \sqrt{\left\{1 - \left[\mu\left(\frac{Q_p}{Q_m}\right)\right]\right\}^2 + \left[s\left(\frac{Q_p}{Q_m}\right)\right]^2} \qquad (1)$$

Where $\mu(Q_p/Q_m)$ and $s(Q_p/Q_m)$ represent the mean and standard deviation of the values (Q_p/Q_m), respectively. The optimum point occurs when $(Q_p/Q_m) = 1$ and $s = 0$.

Based on PMT test results from the Federal District of Brazil, this study assesses the accuracy and precision of three methods used to estimate the load-bearing capacity of mechanically bored piles equipped with Expander Body (EB) technology. The precision of the pile bearing capacity estimation methods is evaluated by comparing them to the results from pile load tests conducted on mechanically bored piles equipped with EB at the University of Brasilia's experimental field of foundations and in-situ tests.

2 EXPANDER BODY

The Expander Body System (EB) is a 0.12 m wide (initial diameter) by 1 to 2 m long bent steel tube that is inflated (expanded) during the first pressure-grouting stage and discharged over a grouting tube inside the rebar, as depicted in Figure 1. Distinct EB models enable expansion to a diameter of 400 to 800 mm. During the EB expansion process, grout pressure and volume are continuously recorded. The EB bottom tip rises as a result of the lateral expansion of the EB, which causes the EB tube length to shorten by approximately 0.1 m. As a result of this expansion, the soil beneath the EB decompresses, which is compensated by a second grouting stage of the soil at the pile tip (Figure 2).

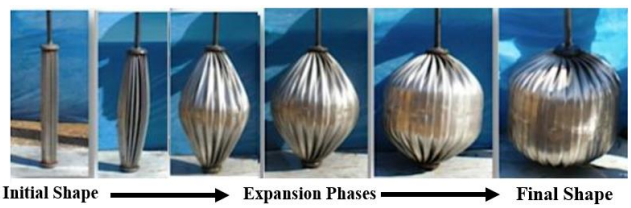

Figure 1. Expander Body expansion in-air.

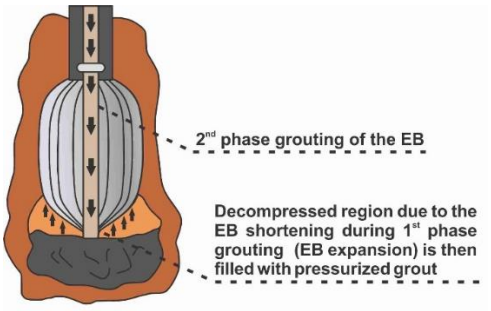

Figure 2. Post-grouting stage after Expander Body expansion.

Bored cast-in-situ piles can be constructed using a variety of techniques. Although each approach has some variation, the overall concept is the same. Drilling mud with permanent or temporary casing are typically combined with a rotary or percussive approach for pile drilling. Drilling ceases as soon as the design depth is achieved. Concrete is subsequently poured into the borehole after the reinforcement cage has been installed. Bored cast-in-situ piles that have EB technology installed use a similar installation process. The installation process of a bored cast-in-situ pile equipped with an EB system is shown in Figure 3.

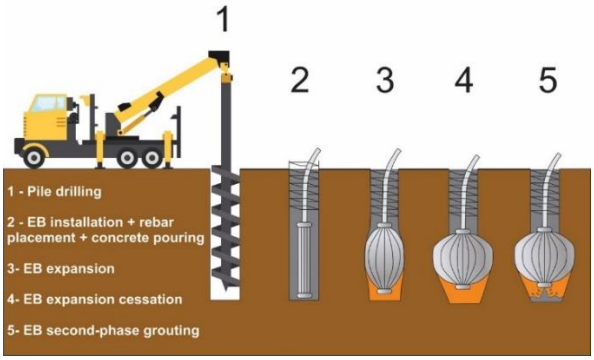

Figure 3. Bored cast-in-situ piles equipped with EB system installation technique.

The installation procedure of bored piles equipped with EB technology can be divided into five steps (Figure 3). Initially, pile drilling is carried out. Secondly, the EB is placed at design depth along with the reinforcement bar, and then, concrete is poured into the borehole. The next step consists of an initial grouting phase, delivered through a hollow schedule tube (EB expansion). After EB expansion ceases, the second-phase grouting step is carried out so that the decompressed region (pile tip) is filled with pressurized grout. Both injection pressure and volume are continuously monitored using a mortar pump and pressure gauge. This equipment not only provides adequate monitoring of the EB expansion but also provides pressure *versus* volume charts. The Expander Body effective diameter (D_{EB}) is determined from calibration curves for each EB model.

3 CASE STUDY

The Federal District is enclosed on the south by the 16°03' parallel and on the north by the 15°30' parallel, with a total area of 5814 km^2. The research location of the UnB geotechnical group has already been thoroughly explored and described in the literature (Cunha, 2011). This research location used various piling techniques, and the piles were horizontally and vertically loaded. Furthermore, several laboratory and in-situ tests have been conducted at this location. Block samples were collected and transferred to the laboratory, where triaxial, direct shear, oedometer, and routine characterization tests were performed. In the upper portion of this region, the soil strata change between clay, silt, and silty sand.

Two bored cast-in-situ piles equipped with EB technology with 8.8 and 10 m length were excavated with a rotating auger at the University of Brasilia experimental site, displayed in Figure 4. More details regarding the pile's geometric characteristics are shown in Table 1.

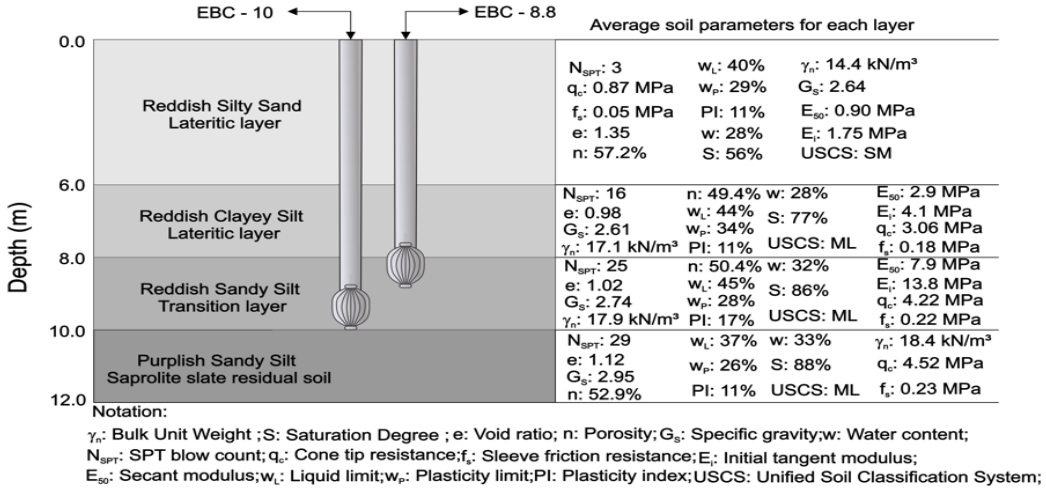

Figure 4. Typical soil profile at the UnB research site.

Figure 5 depicts the pressuremeter curves acquired during PMT tests in the experimental field. It is possible to determine relevant parameters such as limit pressure (p_L) and the coefficient of earth pressure at rest (K_0) from pressuremeter curves to use methods for assessing load-bearing capacity based on pressuremeter tests. The value obtained at a depth of 1 m was discarded due to issues with the test measurement. An increase in effective pressure with depth and a significant development in effective pressure in the saprolitic horizon are noticed.

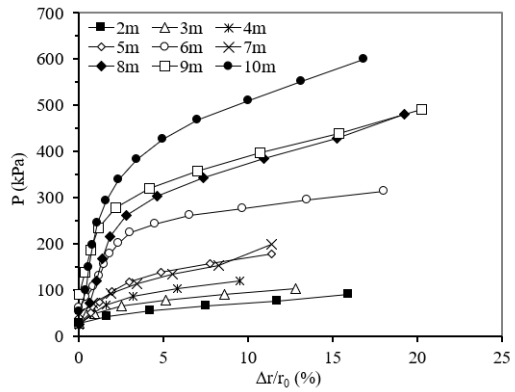

Figure 5. Pressuremeter test (PMT) curves.

A reaction beam, reaction piles, hydraulic jack, loading platform, and calibrated load cell were used to apply load. The spacing between reaction piles was at least three pile diameters. Mechanically bored, cast-in-place piles with the EB System were subjected to compression (Figure 6). The Brazilian Standard ABNT NBR 12131 (2006) specifies four pile load test conditions: slow maintained load, rapid maintained load, combined load, and cyclic load test.

All piles in this study were submitted to slow-maintained load tests, as shown in Table 1.

Table 1. Pile geometric characteristics, load type and velocity.

Test Pile	D (m)	D_{EB} (m)	Load condition	Load increment (kN)
EBC - 8.8	0.30	0.6	Slow maintained	100
EBC - 10	0.30	0.6	Slow maintained	120

The load increments were conducted in ten corresponding load stages, each representing 20% of the working load of the piles analyzed in the study. In the load tests performed, it was observed that the

displacement of the piles varied between 52.21 and 66.51 mm, reaching settlements close to the limit of the deflectometer (70 mm), thus noting displacements exceeding 10% of the diameter of the pile shaft. In this work, semi-empirical methods for predicting the load bearing capacity based on the limit pressure (p_L) measurements from the PMT test conducted in Brazil were studied. The methods used were Ménard (1963), Baguelin *et al*. (1978), and NFP 94-262 (2012).

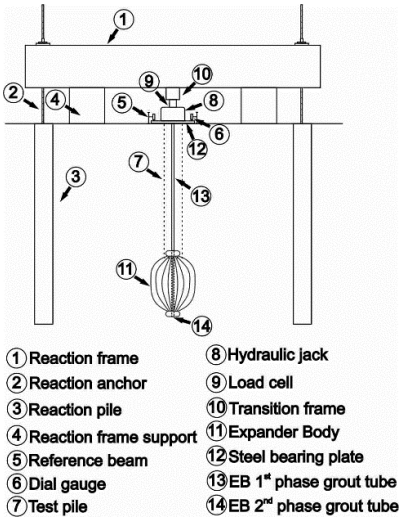

Figure 6. End view of compression pile load test set-up.

4 RESULTS

The load-displacement curves for the analyzed piles are presented in Figure 6. The pile with a length of 10 m, equipped with EB technology, sustained a load of up to 1200 kN, while the pile with a length of 8.8 m, also equipped with EB technology, reached a maximum load of approximately 1000 kN. Based on the displacement levels observed in the load tests, the conventional failure load of each pile can be determined using the 10% criterion of the pile shaft diameter. This criterion, widely adopted in European countries in accordance with Eurocode 7 (ECS, 2004) recommendations, results in interpreted conventional failure loads of 1140 and 823 kN for the bored piles equipped with the EB system, respectively.

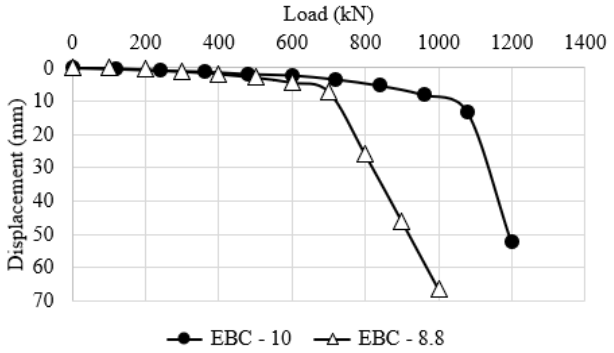

Figure 7. Load-displacement curves of analyzed piles.

Figures 8 and 9 present ratios between predicted and measured load capacities (Q_p/Q_m). Comparing the load capacity estimates from semi-empirical methods with the failure load interpreted from the conventionally determined load for a settlement equivalent to 10% of the pile diameter, it is observed that the methods proposed by Ménard (1963) and NFP 94-262 (2012) showed ratio values (Q_p/Q_m) below the range of ±20% for both piles equipped with the EB technology. While the Baguelin *et al*. (1978) method overestimates the reference values obtained from the interpretation of the pile load test results.

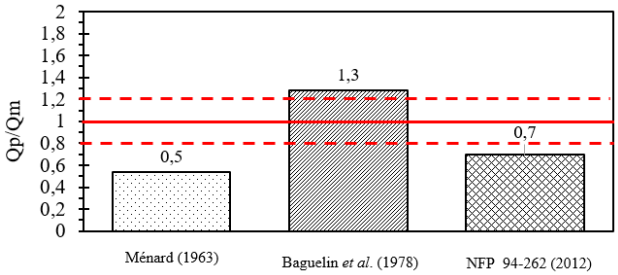

Figure 8. The ratio between predicted and measured load capacities for the EBC – 8.8 pile.

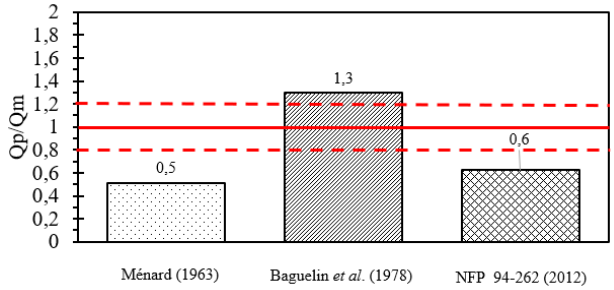

Figure 9. The ratio between predicted and measured load capacities for the EBC – 10 pile.

The semi-empirical methods for bearing capacity, based on pressuremeter tests, often use charts or tables to determine the tip resistance and side friction of piles. These methods require input parameters such as the limit pressure measured during the test, soil type, pile installation process, pile slenderness ratio (L/D),

and a load capacity factor (K_p) according to the soil type. The determination of the pile tip load capacity unit requires the use of the load capacity factor (K_p), while the unit side friction resistance is intrinsically linked to the values of the effective limit pressure of the soil layers through which the pile is installed. The determination of the effective limit pressure of the soil layers is influenced by various factors, including soil type, soil density, stress history, degree of saturation, anisotropy, variation of horizontal stress (directly related to the determination of K_0 values), and test depth. The pressuremeter tests in pre-drilled holes (MPM) carried out at the UnB Experimental Field presented effective limit pressure values between 77 and 466 kPa. According to the results obtained from the pre-drilled hole pressuremeter tests (MPM), using curve-fitting techniques, it was found that the K_0 values for the porous clay of Brasília varied between 0.34 and 0.72 along the depth, with an average value of 0.5. The K_p values range from 1.2 to 9.2 for different pile installation methods in the Baguelin *et al*. (1978) method. In the estimate presented in Figures 8 and 9, a load capacity factor (K_p) equivalent to 7.5 was adopted, explaining the likely overestimation of the load capacity of the piles equipped with EB. On the other hand, for other methodologies, the estimates are conservative due to the use of lower load capacity factor (K_p) values (between 1.2 and 2.1).

Table 2 presents the average values and standard deviations for the ratios between predicted and measured load capacity values (Q_p/Q_m) of the analyzed piles in this study. From these values, the Ranking Distance Index (RD) is determined. Low RD values represent an estimation method with high accuracy and precision. As RD values increase, this statistical index characterizes the estimation methodology as less accurate and less precise.

Table 2. Statistical analysis of the Q_p/Q_m ratios for the evaluated methods.

Method	Average (Q_p/Q_m)	Standard deviation (Q_p/Q_m)	RD
Ménard (1963)	0.50	0.0	0.50
Baguelin et al. (1978)	1.30	0.0	0.29
NFP 94-262 (2012)	0.30	0.1	0.35

Among the load capacity estimation methodologies based on PMT tests analyzed in this study, it is observed that the Baguelin et al. (1978) method presents the lowest RD value, making it the most accurate and precise methodology despite the estimated values being overestimated. On the other hand, the method proposed by Ménard (1963) shows the highest RD value, making it the least accurate and precise technique in relation to the data analyzed in this study. However, it was verified that using a load capacity factor (K_p) of magnitude 4 for the three methods results in Q_p/Q_m ratios between 0.8 and 1.0. This suggests, preliminarily, that the bearing capacity estimation using semi-empirical methodologies based on PMT test results for bored piles equipped with Expander Body technology in lateritic soils is satisfactory at the design level.

5 CONCLUSIONS

This work emphasized results obtained from load tests on mechanically bored piles equipped with the Expander Body technology, conducted at the Geotechnical Experimental Field of the University of Brasília. The analyzed foundations were axially loaded under compression, producing load-displacement curves that were interpreted to assess the precision and accuracy of load capacity prediction methodologies for bored piles equipped with the Expander Body system in the tropical soil of the Federal District, based on PMT test results.

Experimental data acquired from load tests and load capacity estimates using the methodologies of Ménard (1963), Baguelin et al. (1978), and NFP 94- 262 (2012) were compared for bored piles equipped with the EB technology, and these were presented and discussed. Although the results are confined to the conditions of the analyses, based on a limited dataset, they allow for preliminary generalizations of the overall behavior. Furthermore, they highlight the fact that the phenomena involved in such processes are considerably complex. In this regard, this research provided a better understanding of some characteristics involved in the loading mechanisms of single piles equipped with EB technology in lateritic soils. It should be noted, however, that some analyses were formulated as hypotheses to explain the results and need further research for a more informed appreciation in the future. Therefore, based on the observed trends in the data and analyses, some general conclusions can be drawn:

- The Baguelin *et al*. (1978) method shows the lowest RD value, making it the most accurate and precise methodology analyzed in this study;
- The method proposed by Ménard (1963) indicates the highest RD value, making it the least accurate and precise method in relation to the data analyzed in this study;

- Based on the experimental results and bearing capacity calculations, it is observed that the bearing capacity estimates, using methodologies reliant on PMT tests and considering a bearing capacity factor (K_p) of magnitude 4, prove to be suitable tools for estimating the load capacity of bored piles equipped with the Expander Body technology in lateritic soils.

It should be emphasized that the described conclusions need to be considered of limited scope and applicability. However, these results, along with the experience gained during the research, can be of great interest to foundation researchers and designers in this region and beyond.

ACKNOWLEDGEMENTS

This research was conducted with the participation of the Foundation and Field Testing Research Group (GPFees) from the Graduate Program in Geotechnics at the University of Brasília and the Special Foundations and Geotechnics Research Group (GPFEG) from the Undergraduate Program in Civil Engineering at Unichristus. The authors would like to express gratitude for the field assistance provided by the engineering company EMBRE and for the scholarship granted for this first author during his Ph.D.(GM/GD-140423/2017-6) by the governmental sponsorship organization CNPq (National Council for Scientific and Technological Development).

Influence of temperature on strut loads in braced excavations

Influence de la température sur les charges des butons dans les excavations contreventées

P.-A. Mortensen*, T. Sandane
Norwegian Geotechnical Institute (NGI), Oslo, Norway

*per.anders.mortensen@ngi.no

ABSTRACT: For deep excavations a significant portion of the total load on steel struts originates from temperature variations. Ignoring the temperature induced load can lead to failure of the support system as the temperature induced load has been recorded as high as 65 % of the total load. The paper presents measurements of strut temperature load variations from 4 different deep strutted excavations in central Norway. The site conditions vary between the projects, from soft, normally consolidated quick clays to stiff, overconsolidated clays, and glacial moraine deposits. A total of 29 instrumented struts have been evaluated. The measured strut load and air temperature variations are analysed and used to define the degree of end restraint for each of the instrumented struts. Measured temperature loading is compared with estimates based on empirical relations proposed in the literature and with finite element analysis. The difference in soil conditions, excavation depth and number of strut levels are further used to evaluate the differences in the measured and estimated results.

RÉSUMÉ: Dans le cas des fondations profondes, une part significative de la charge totale sur les entretoises en acier provient des variations de températures. Ne pas prendre en compte la charge induite par la température peut mener à la rupture du système de support étant donné que des charges induites pouvant atteindre 65% de la charge totale ont été enregistrées. Cet article présente des mesures de charges induites par la température sur des entretoise profondes installées sur 4 excavations profondes différentes dans le centre de la Norvège. Les conditions de terrain sur chaque site sont différentes, allant d'argiles molles sensibles normalement consolidées à des argiles raides surconsolidées ou des dépôts morainiques (dépôts glaciaires). Au total, 29 entretoises instrumentées ont été évaluées. La charge mesurée et les variations de températures sont analysées et utilisées pour définir le degré d'encastrement de chaque entretoise instrumentée. Les charges induites par la température mesurées sont comparées aux estimations basées sur des relations empiriques proposées dans la littérature et sur des analyses par éléments finis. Les différences entre le type de sols, la profondeur d'excavation et le nombre de niveaux d'entretoise sont ensuite utilisés pour évaluer les différences entre résultats mesurés et estimés.

Keywords: Deep excavation; strut loads; retaining wall; temperature effects; load cells.

1 INTRODUCTION

When designing deep excavations, the estimation of forces acting on the retaining structure and bracing is of the outmost importance. There is a wide range of methods proposed in the literature for estimating the strut loads. Most common in design is apparent earth pressure (AEP) diagrams and numerical models such as finite element method (FEM) analysis. The AEP envelopes are derived from measurements of actual maximum strut loads (Peck, 1969). This means that the AEP diagrams implicitly include some effect of temperature on strut load (Twine and Roscoe, 1999; Hashash et al., 2003). 29 instrumented struts from four case studies in Norway are presented in this paper showing that the temperature induced strut load can become as high as 65% of the total load. If numerical models are used in the design process, additional temperature load must therefore be properly included in the final design load (Blackburn et al., 2005). Two of the cases presented, UDK02 and Wergelandstunnelen, are railway projects located in Drammen and Eidsvoll respectively. At UDK02 the ground conditions are normally consolidated quick clay of decreasing thickness over moraine. At Wergelandstunnelen the soils are dominated by low sensitive, stiff overconsolidated silty clays. The Havnelageret highway tunnel excavation in Oslo was performed in a refilled harbour basin. The top mases consisted of sand, gravel and brick remains, above a soft normally consolidated silty clay (Johansen and Woldsengen, 2014). Schweigaardsgate 33 was a commercial development project in Oslo where a ten-storey building with two basements was constructed. The ground conditions were about 4 m of fill material over clayey silt and sand, over soft normally consolidated clay.

2 MEASURED STRUT LOADS

Boone and Crawford (2000) plotted incremental changes in load against incremental changes in temperature with a best-fit line through the origin with slope m. The coefficient m, named thermal load coefficient, assumes a linear-elastic response in the soil and retaining wall system. Hashash et al. (2003) show with numerical analysis that thermal load coefficient is stage-dependent, meaning that it varies with the excavation depth and number of struts installed. Blackburn et al. (2005) suggested that the thermal load coefficient should be calculated for expansion and contraction separately and the study finds that the coefficient is larger for expansion. This would however suggest that the temperature fluctuations give rise to a steady increase in load for each temperature fluctuation, and this is not observed in the data presented here in this study. The method of analysing the data proposed by Boone and Crawford (2000) is therefore implemented, with the results of Hashash et al. (2003) in mind. For each load cell, a period during which little or no construction work took place is identified. The measured strut force is plotted against measured air temperature, and the thermal load coefficient is estimated as shown in Figure 1.Twine and Roscoe (1999) defines the degree of end restraint as the ratio between the occurring temperature load (P_T) over the theoretically induced temperature load in a fully restrained strut in which no expansion occurs, given by:

$$DR = \frac{\mathrm{P}_T}{\alpha_S E_S A_S \Delta T} = \frac{m}{\alpha_S E_S A_S} \qquad (1)$$

where DR is the degree of end restraint, α_S is the coefficient of thermal expansion of the steel, E_S is the elastic modulus of the steel and A_S is the cross sectional area of the strut. Table 1 summarizes the excavation geometry, site conditions and resulting measurements.

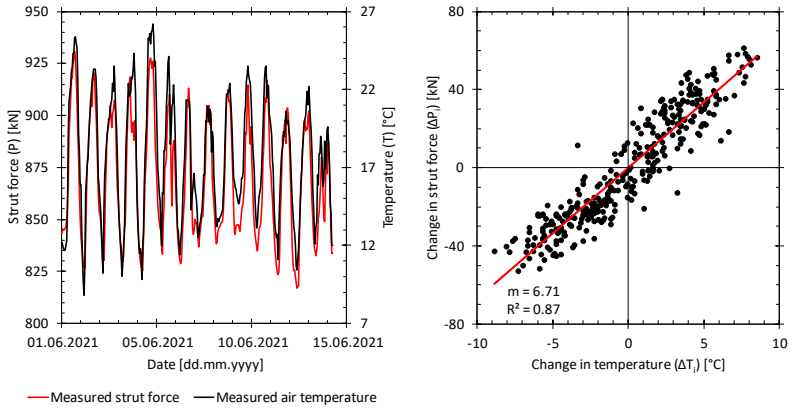

Figure 1. Example plots of measured strut force and air temperature and the determination of the thermal load coefficient (m).

3 ESTIMATED STRUT LOADS

Four methods of estimating DR have been employed. The first method, referred to as E1, was proposed by Chapman et al. (1972) and is based on a combination of the equations of deformation of an elastic half-space under a uniform rectangular foundation and the equation of thermal expansion of the strut. The second method, referred to as E2 was proposed by Boone and Crawford (2000) and is also based on Boussinesq solution, but for a smaller foundation given by the horizontal strut spacing (c/c) and the vertical equidistant (s) from subject strut to the strut above and below. The third method, referred to as E3, was proposed by Wu et al. (2019) and is an approximation utilizing Mindlin solution i.e. beam-on-elastic-foundation (BEF). The fourth and final method, referred to as E4, is based on FEM analysis using Plaxis 2D and the model established in the design of each case. The temperature loading from the FEM analysis is determined using the method proposed by NGF (2019), in which the strut is replaced by point loads with the same magnitude as the calculated load. The point loads are increased according to the assumed temperature load and the displacements are evaluated. This is repeated until the applied temperature load and resulting displacements matches a specific degree of end restraint. The estimated DR is shown in Table 1 for each case. The in-situ soil stiffness is the undrained soil stiffness achieved by triaxial testing or plate loading tests. When results are lacking, empirical relationships, such as Duncan and Buchignani (1976) have been employed. The residual standard deviation of E1, E2, E3 and E4 is 14.9%, 12.4%, 27.8% and 13.2%, and the measured value is on average 2.9, 0.78, 0.41 and 1.6 times the estimate, respectively.

Table 1. Summary of site conditions, construction details, measured and estimated degree of end restraint (DR).

Based on the given dataset E2 and E4, yields the best estimate. E2 and E3 overestimates, while E1 and E4 underestimates the temperature loading on average. Chapman et al. (1972) and Boone and Crawford (2000) both commented that the soil stiffness needed to achieve the measured DR seems to be systematically higher for E1 and lower for E2. As done by Boone and Crawford (2000), the soil stiffness is back-calculated and a linear best fit is proposed. The linear fit, shown in Figure 2, relates the measured in-situ soil stiffness with the stiffness which should be used in the empirical relationship to achieve the best possible DR estimation. Using the proposed best fit line in E2 lowers the standard deviation from 12.4% to 9.1%.

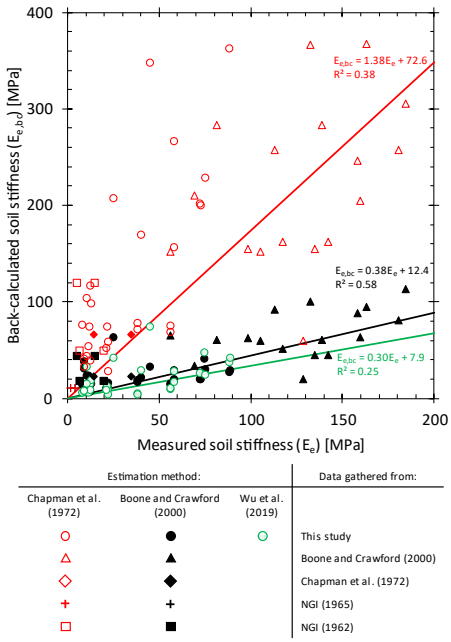

Figure 2. Back-calculated soil stiffness as a function of the measured soil stiffness.

Looking at the outliers we see that strut 3-1 and 3-2 of UDK02 are underestimated by all methods. These measurements are the only ones performed on a secant pile wall, and we see that the stiffness of the wall is much larger than for the other cases. Twine and Roscoe (1999) found that both wall and soil stiffness correlated with DF. However, none of the empirical methods include wall stiffness. The measurements from Schweigaardsgate 33 are also underestimated by all methods except E3. The strut length is the main deviation compared to the other cases, suggesting that longer struts lead to greater risk of underestimating the temperature load.

4 CONCLUSIONS

Estimating the temperature loading with the method proposed by Boone and Crawford (2000) gives the best fit to the case studies presented. This fit is further improved by using an empirical relationship between the measured soil stiffness and the stiffness utilized in the calculation. FEM gives just slightly higher residual standard deviation. However, FEM underestimates the temperature load on average, which could imply that the soil stiffness in the calculations is on average too low. The temperature load is underestimated when the supporting wall is very stiff, and in the case with long struts.

Development of a pioneering foundation system for a 225 000 m^3 LNG storage tank in Canada by using driven closed-ended steel piles non-connected to the concrete slab (rigid inclusions)

Optimisation du système de fondation d'un réservoir GNL de 225 000 m^3 au Canada avec l'utilisation de pieux battus en acier à pointe fermée déconnectés de la dalle en béton (inclusions rigides)

ABSTRACT: This paper presents the optimisation of the foundation system of a LNG storage tank of 225 000 m^3 volume, built in Kitimat, Canada. Site geology consists of a 160 m thick alluvial deposit, composed by alternating layers of clayey silts and gravelly sands. Surficial deposits are prone to liquefaction due to their low density and the high seismic activity in the area. To mitigate this risk, the design was optimised to a system of rigid inclusions, instead of the initial system proposed in the FEED, consisting of a piled foundation with a system of stone columns. This system was innovative in the LNG industry as it was the first time it was used for a LNG tank of such dimensions.
The robustness of the design has been confirmed by the performance of: CPTs after pile installation, confirming the increase of soil density; static and dynamic pile tests, validating the pile bearing capacity; and, monitoring of tank settlement, verifying that settlements are within the criteria defined in the project specifications.

RÉSUMÉ: Cet article présente l'optimisation du système de fondation d'un réservoir de Gaz Naturel Liquéfié (GNL) de 225 000 m^3, construit à Kitimat, Canada. Le site est caractérisé par un dépôt alluvial de 160 m d'épaisseur, composé par une alternance de limons argileux et sables graveleux. Les sols de surface sont potentiellement liquéfiables à cause de leur faible densité et du niveau de sismicité fort. Afin de réduire ce risque, la fondation a été optimisée avec un système d'inclusions rigides, au lieu de la conception FEED initiale, composé par une fondation sur pieux accompagnée par de colonnes ballastées. Ce système est novateur dans l'industrie du GNL car il est utilisé pour la première fois dans un réservoir GNL de ces dimensions.
Le système a été confirmé par différents types d'essais: des CPTs après l'installation des pieux qui ont confirmé la densification du sol; des essais de chargement statique et dynamique des pieux qui ont validé leur capacité portante; et, le suivi des tassements qui a prouvé que la fondation est dans les critères de tassement exigés par les spécifications du projet.

Keywords: Liquefied Natural Gas (LNG); foundation; rigid inclusions; design.

1 INTRODUCTION

Particular attention should be given to the foundation design of large diameter LNG tanks. The choice of foundation is governed by the natural heterogeneity of the soils, seismic hazard, nature of soils and behaviour, among other natural risks. The cost and feasibility of a LNG project is thus impacted by the soil condition.

This paper presents the optimization of the foundation system for a LNG tank located within the LNG Canada Site, close to Kitimat in British Columbia, Canada. The project includes the design and construction of an onshore 225 000 m^3 LNG tank; Figure 1 shows a generalized cross section of the tank, which is approximately 100 m diameter.

A risk of liquefaction has been detected in the area, which is driven by the following site conditions: the site soils are mostly sandy, the groundwater table is close to the ground surface, and the area is of high seismicity. A soil improvement method using driven closed-ended steel piles as rigid inclusions under the tank slab, was chosen to mitigate the risk of liquefaction. The system allows also to keep the settlement and differential settlement of the tank within the criteria and to improve the ground bearing capacity.

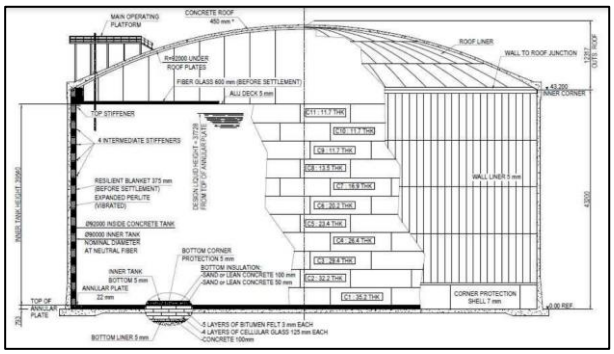

Figure 1. Cross section of the LNG tank.

2 CONTEXT

2.1 Geology, stratigraphy, geotechnical parameters

The whole plant area is located in the floodplain of Kitimat River, composed by a deposit of more than 120 m of interbedded and highly variable alluvial/deltaic Holocene sediments, overlying late Pleistocene marine clays. Bedrock is deeper than 260 m.

These sediments consist of predominantly fine sand and non-plastic to low plasticity silts. A gravellier layer is often encountered at depths ranging between 5 m and 10 m, and some gravel lenses can be found at greater depths. Cobbles and boulders are known to be present within some layers including the noted gravelly layer. Apart from this gravelly layer, which appears stronger that the surrounding sandy and silty layers, the average strength of the soils is low but slightly increases with depth. The silty layers are noticeably weaker than the sandy layers.

Deltaic progradation of the Kitimat River in the period since the last ice age has resulted in deposition of interbedded fine and coarse sediments that are relatively steeply dipping towards the south. The high horizontal variability of the sediments is worth to notice as boreholes closely spaced may show very different soil conditions at equivalent depths.

Based on geotechnical data, the soil layers encountered are presented, from top to bottom, in Table 1. The geotechnical parameters, presented in Table 2 and Table 3, have been defined from CPT data and some boreholes with sample extraction.

Table 1. Soil stratigraphy.

Unit	Description
S0	Very silty loose SAND with some layers of firm silt, 3 m to 6 m thick.
S1	Medium dense SAND and GRAVEL, 4 m to 32 m thick, with large lenses of firm sandy SILT within (LC1).
C1	Very sandy, very low plasticity, very stiff to hard SILT, 4 m to 18 m thick.
S2	Very silty and very gravelly medium dense to dense SAND and GRAVEL, 13 m to 26 m thick.
C2	Sandy, low plasticity, very stiff to hard SILT, 6 m to 15 m thick.
SC	Silty SAND composed by a mix of dense to very dense SAND and hard, low plasticity, SILT, approximately 60 m to 66 m thick.
C3	Predominantly hard, low plasticity to medium plasticity LEAN CLAY, with minor interbedded layers of silty sand and silt. The bottom of this layer has not been encountered and extends to more than 160 m depth.

Table 2. HSM soil stiffness values.

Unit	$E_{50,ref}$ (MPa)			M		
	LB	BE	UB	LB	BE	UB
S0	8.1.	13.5	27.0	0.5	0.5	0.5
S1	20.3	37.8	13.5	0.8	0.5	0.5
LC1	8.1	13.5	20.3	0.6	0.6	0.8
C1	10.8	20.3	31.1	0.6	0.8	1.0
S2	13.5	23.0	43.2	0.8	0.6	0.5
C2	5.0	13.5	40.5	0.7	0.6	0.5
SC	10.8	21.6	47.3	1.0	0.9	0.7
C3	4.7	7.4	14.9	1.0	1.0	0.8

Table 3. Shear strength parameters.

Unit	S0	S1	LC1	C1	S2	C2	SC	C3
γ (kN/m^3)	18	19	18	19	19	20	20	20
ϕ' (°)	30	34	28	28	34	28	32	28

Three levels of soil stiffness have been estimated for settlement calculations and liquefaction analyses: best estimate (BE), upper bound (UB) and lower bound (LB).

Hardening Soil Model (HSM) parameters, calibrated from soil data, were used for calculations. The pressure of reference (P_{ref}) is equal to 100 kPa. The oedometers modulus ($E_{oed,ref}$) is taken equal to the modulus at 50% of axial deformation (E_{50}). Unloading-reloading modulus (E_{ur}) is equal to three times E_{50}. Apparent cohesion was taken equal to 0 for all layers.

2.2 Seismic hazard

In order to evaluate the site soil potential to liquefaction, a Probabilistic Seismic Hazard Analysis (PSHA) has been performed to define the design motions and the cyclic shear stress for the two return periods required in the specifications: 475 years and 2 475 years, corresponding to the Operational Basis Earthquake (OBE) and the Safe Shutdown Earthquake (SSE) respectively. Most of the seismic events used to define the design motions have a magnitude (Mw) of 7.5.

The minimum factors of security against liquefaction required in the design phase, as per Standards, are 1.25 for OBE and 1.00 for SSE.

2.3 Codes and standards

The design and construction of the tank is governed by a list of Standards and Codes as defined in the project specifications. The order in which they are applied in the project is as follows, among other documents applicable:

Project Specifications (JFJV, 2016 & 2018);
DEP specifications (Shell, 2014);
American Standards (ACI 376-11, CFEM);
British Standards;
European Standards;
French ASIRI guidelines (IREX, 2012).

In case of any discrepancy between the recommendations given by the Standards, the instruction from the Owner is to apply the most conservative one. This point was source of discussion concerning the Factor of Safety (FoS) for the axial pile bearing capacity.

The other subject of debate was the design of the rigid inclusions system, considering that the design of this technique is defined by the French ASIRI guidelines (IREX, 2012), while neither the project specifications nor the Canadian codes include such recommendations.

A discussion on this is presented in section 5.

3 CHARACTERISTICS OF THE FOUNDATION SYSTEM

3.1 FEED Foundation system

The foundation system proposed by the Company at FEED design stage includes about 1800 stone columns up to 40m depth to mitigate the risk of liquefaction, and 500 driven open steel piles of 1m diameter and 40 to 45m length, connected to the slab, to control settlement and to ensure the bearing capacity.

This system has been optimised by the Contractor as presented below.

3.2 Foundation system for optimized design

The foundation system of the LNG tank is composed by a reinforced concrete raft of variable thickness (Figure 2), and ground improvement consisting of 1937 driven closed-ended driven steel rigid inclusions and a granular load transfer platform (Mattress).

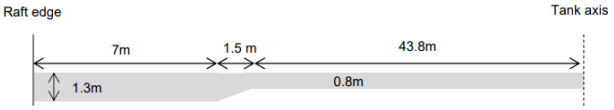

Figure 2. Cross section of the slab.

3.3 Foundation properties

The rigid inclusions used have the following characteristics: 1937 driven closed-ended steel tubes with diameter of 610mm, length of 18.5 m and thickness of 12.7 mm; top plate with diameter of 810 mm and thickness of 38 mm; and, steel conical shoe with diameter of 610 mm.

The inclusion mesh or spacing depends on the bearing layer at the inclusion toe level, and on the concentration of loads in the edge of the raft due to the weight of the tank wall. The tank area has been divided in four zones with different spacing (Figure 3). The toe of inclusions (20 m depth) is on silty soils in the North area and on sandy soils in the South area. Site sands are denser than silts, thus, spacing is bigger at the South area.

The load transfer platform located between the raft and the head of the rigid inclusions have the following properties: bulk unit weight (γ) of 20 kN/m^3; apparent cohesion (c') of 0 kPa, internal friction angle (ϕ') of 38°, and deformation modulus of compacted material (E) of 80 MPa.

In addition, the mattress material is complying with the following requirements: maximum particle size 100 mm; minimum 97% passing 75 mm sieve; 0 to 8% passing 63 µm sieve; D60/D10 minimum 7.5; and, maximum Los Angeles coefficient = 40.

3.4 Design loads

The static load cases are represented in Figure 4 for the main phases of the project: End of construction, Hydrotest (i.e. maximum pressure), and Operation (full tank condition).

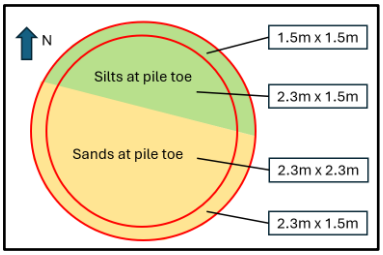

Figure 3. Inclusions' spacing.

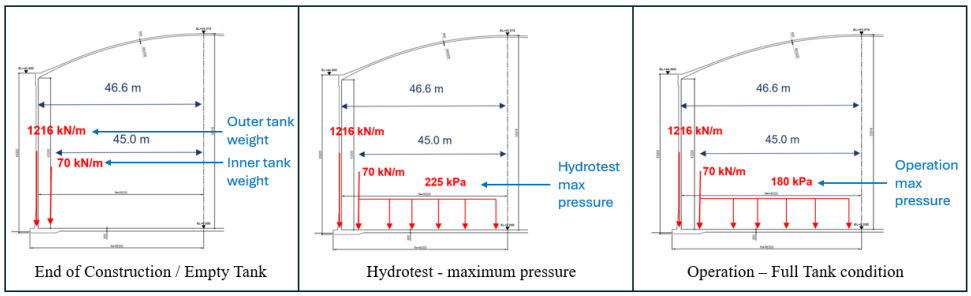

Figure 4. Load cases at the main phases of the project.

4 FIELD MEASUREMENTS TO VALIDATE THE DESIGN

4.1 CPTs after installation

The driving of closed-ended piles into the soil increases the global stiffness of the soil and helps to mitigate the liquefaction potential. While driving, the rigid inclusions displace the soil laterally, generating an increase of the density of the soil between the inclusions.

Several CPT tests have been performed to prove the effectiveness of the optimised foundation system. Figure 5 shows the characteristic values of cone tip resistance (q_c) for three situations: initial value before foundation works, estimated value of improved q_c in the design, and measured value after the installation of inclusions. The values are given for the three soil layers traversed by the inclusions.

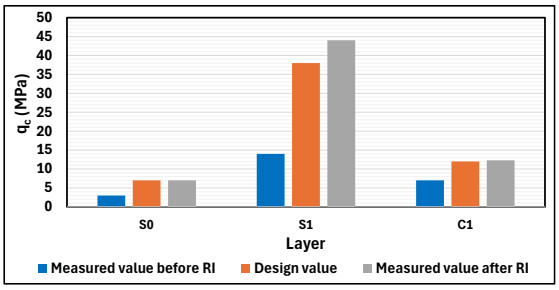

Figure 5. Characteristic values of q_c.

Figure 6 shows the profiles of factor of safety (FoS) against liquefaction for one measurement point under the higher seismic level, SSE. The potential of liquefaction is analysed from CPT data, using the methodology proposed by Boulanger & Idriss (2014). The analyses are done for the conditions before and after soil improvement.

The results show a clear improvement at the first 20 m soil layers; the densification is significant and even greater than what was expected. These measurements prove the effectiveness of the rigid inclusions system to mitigate the risk of liquefaction.

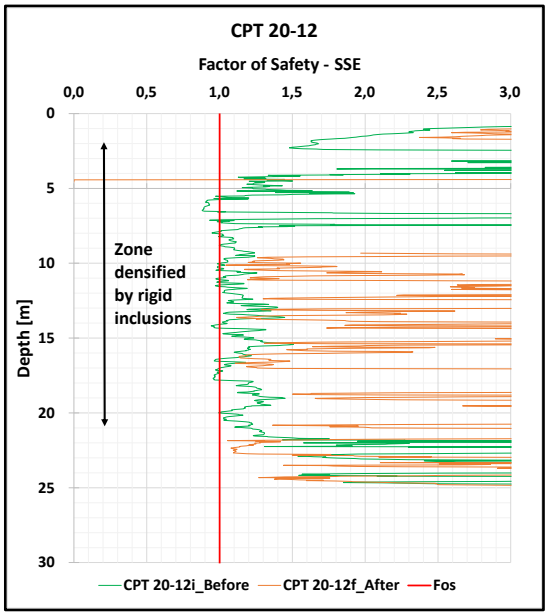

Figure 6. FoS liquefaction – CPT 20-12 – SSE.

4.2 Static and dynamic pile load tests

Figure 7 and Figure 8 present the values of pile bearing capacity for the North zone and the South zone, respectively. This division was done considering the pile toes are in different soil conditions.

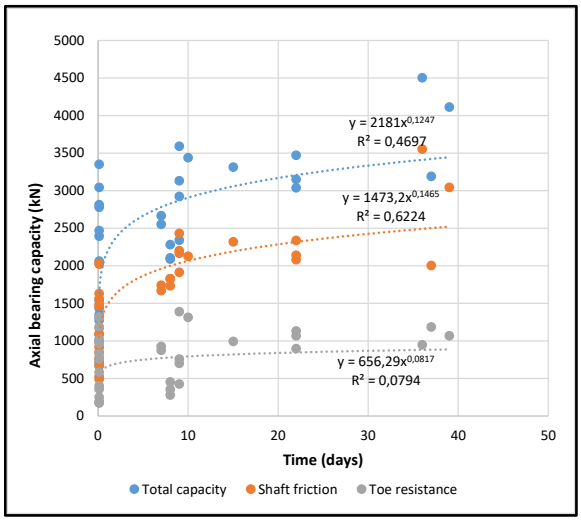

Figure 7. Pile capacity measured with PDA – North zone.

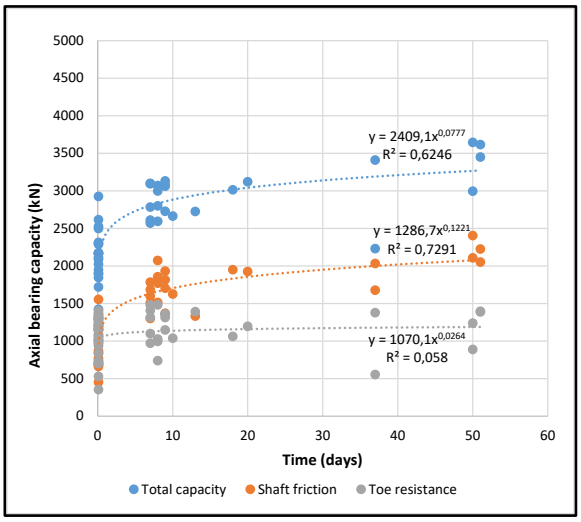

Figure 8. Pile capacity measured with PDA – South zone.

The bearing capacity is estimated from PDA (Pile Driving Analyzer) tests. 80 PDA tests have been performed on 40 piles across the tank area. Half of them were done at the End of Initial Driving (EOID), and the other half at the Beginning of Restrike (BOR) few days after EOID. For the EOID, the tests were performed by recording the driving data at the last 4 or 5 blows of the initial driving during pile installation.

The expected total capacity in the design is between 2387 kN (centre) and 2413 kN (outer ring) in the North zone, and, between 3653 kN (centre) and 3734 kN (outer ring) in the South zone. These values were estimated in the design considering the CPT data before improvement and the recommendations from the Canadian Foundation Engineering Manual (2006).

The data in Figure 7 and Figure 8 show an increase of pile bearing capacity with time. The comparison between the measured values with PDA and the expected values in the design shows: the expected bearing capacity is reached 7 or 10 days after driving in the North zone; and, the measured bearing capacity is lower than the expected in the South area at the time of measurement. Using the regression equation shown in the figures, the design expected capacity would be reached in about 250 days.

Further verifications of the bearing capacity of the tank were done using the measured values. The analyses show the bearing capacity is ensured with factors of safety in accordance with the Standards.

In addition, one static control load test has been performed on a working pile of the foundation. The test was performed one month after the pile installation. The results show the application of the maximum test load of 2065 kN (i.e. 1.5 times the maximum service load as per the design) generates a maximum settlement of about 8 mm, which is close to 1% of pile diameter and lower than the failure criteria displacement, set at 22mm.

4.3 Settlement monitoring

Tank settlements are measured by two systems: 1) topographical monitoring of survey markers at the tank periphery (Figure 9, left); and, 2) two chains of inclinometer sensors fixed along two horizontal tubes, placed perpendicularly each other across the slab (Figure 9, right).

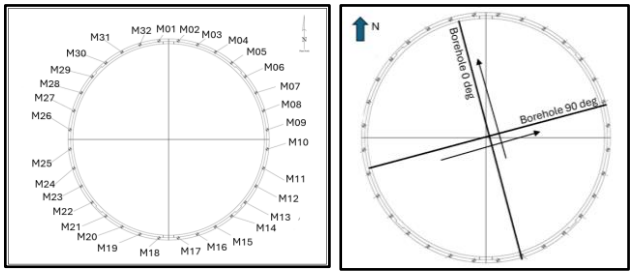

Figure 9. Survey markers and inclinometer pipes

The settlement model, developed using Plaxis 2D axisymmetric, has been updated with the real construction dates (Table 4). Due to the silty nature of the in-situ soils, a consolidation phase between each phase has been included in the calculation. Geotechnical parameters have been used as defined in the design.

Table 4. Construction dates.

Milestone	Start	Finish	Duration (days)
Raft construction	Jul. 20	Nov 20	129
Wall construction	Oct. 20	Jul. 21	287
Roof construction	Aug. 21	Nov. 21	76
Modules top side	Sep. 22	Dec. 22	78
Inner tank	Mar. 22	Feb. 23	361
Hydrotest	May 23	Jun. 23	32

Figure 10 and *Figure 11* show the vertical displacements at the center and the edge of the raft, respectively (purple triangles). The estimated values of vertical displacements are presented for each phase, based on the settlement model developed in the design, which considers the bounds of soil stiffness (Table 2).

The measured settlements follow the theoretical design settlements and are between the Upper Bound and Best Estimate curves. This fact implies that the design is validated. The measured values also follow the general trend of settlement with time, as predicted in the model, which confirms the hypothesis taken in terms of consolidation parameters.

The analysis also shows the measured settlement follow the project criteria in terms of the slope of the slab (1/300), general tilt (1/500), and perimetral settlement (1/500).

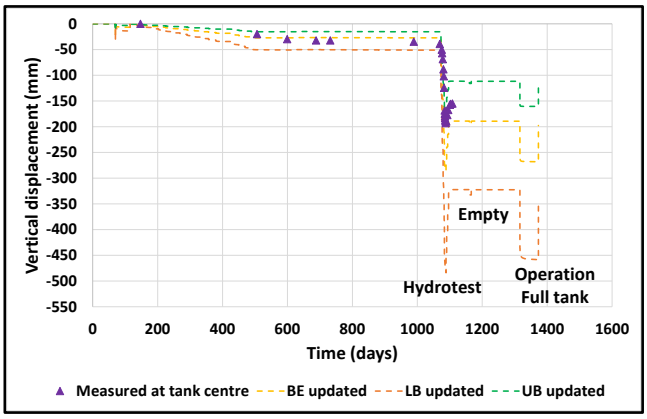

Figure 10. Settlement curves at the center of the tank.

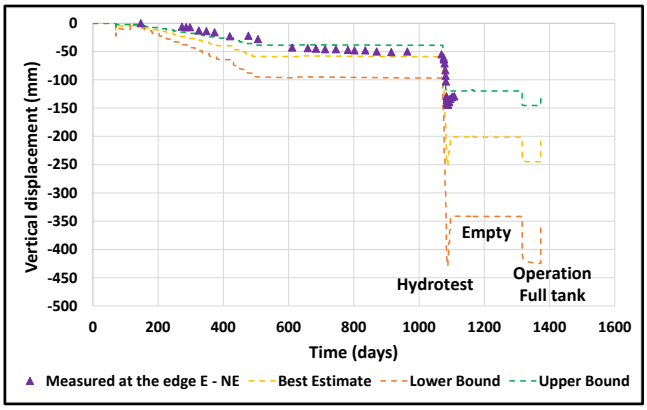

Figure 11. Settlement curves at the edge of the tank.

5 COMPLIANCE TO STANDARDS

In the tender design, the Contractor applied the recommendations from the Canadian Foundation Engineering Manual (2006), in which a global FoS of 2.0 for the axial pile bearing capacity is recommended.

However, the American Standard, ACI 376-11 (2013), requires a FoS of 3.0 for operation and OBE and 2.5 for SSE. This point has been solved by adding a larger top plate, 0.81 m in diameter instead of 0.61 m in the initial design, which helped to reach the required FoS.

6 CONCLUSIONS

The analysis and data presented in this paper show the effectiveness of the closed-ended driven steel piles, working as rigid inclusions, used as foundation system for a large diameter LNG tank. The solution allows to improve the bearing capacity, to mitigate the risk of liquefaction and to control the differential settlement. The last one is the main criteria to guarantee the integrity of the structure during the life cycle of the project.

Compared with the foundation system proposed in the FEED, the system designed and constructed by the Contractor helped to save in quantities and to reduce the time of construction of the slab, as piles and slab are not connected.

In other hand, the verifications performed during the design together with the control tests performed during construction helped to give confidence to the parties of the project on the solution, and thus, it is an open door to propose it for future projects.

ACKNOWLEDGEMENTS

The authors are grateful for the support of the parties in the project: the Owner, LNG Canada Development Inc. (LNGC, Shell); the Company, JGC - Fluor BC LNG JV (JFJV); and the Contractor, Entrepose Contracting - Vinci Construction Grands Projets JV (EVJV). Special thanks to Darren Beaumont from Advisian for his invaluable advice and support during the design of the tank foundations.

Soil biocementation using the carbonic anhydrase metabolic pathway

Biocimentation des sols par la voie métabolique de l'anhydrase carbonique

ABSTRACT: Biocementation, i.e., the soil cementation using cements produced biomimetically, has recently been introduced as a method of ground improvement, which is potentially more eco-friendly than conventional ground improvement methods. To date, the vast majority of researchers have used the urea hydrolysis metabolic pathway to biocement soils. We present instead work focusing on a less researched and potentially more interesting pathway, the carbonic anhydrase route, which produces biocement while sequestering CO_2. In this paper we present experimental results of bioprecipitate analysis and biocementation using CA producing bacteria; indicative results using the same bacteria though the ureolytic pathway are also shown; their modelling is then discussed instructed by studies on the ureolytic pathway. The results of this study based on bioprecipitate characterisation prove the precipitation of calcium carbonate using the CA pathway. The biocementation by biostimulation of the soil using the CA pathway was also proven, based on the unconfined compressive strengths of the treated soil ranging 0.5-1 MPa depending on cementing solution molarity vs the zero unconfined compressive strength of the untreated soil.

RÉSUMÉ: La biocimentation, c.a.d. la production de ciments biomimétiques, a été récemment introduite comme une méthode d' amélioration du terrain potentiellement plus éco-respectueuse que les techniques d' amélioration du terrain conventionnelles. Jusqu' à présent la plupart des chercheurs ont adopté la voie métabolique par uréolyse pour biocimenter les sols. En revanche, notre étude a pour objectif d' examiner une voie métabolique mois étudiée mais potentiellement plus intéressante, à savoir la voie métabolique de l'anhydrase carbonique, qui permet à la fois la biocimentation du sol ainsi que la séquestration du CO_2. Cette communication présente des résultats expérimentaux portant sur l' étude des minéraux bioprécipités et la résistance à la compression non confinée, confirmant la biocimentation du sol traité. Des résultats indicatifs obtenus par la voie métabolique par uréolyse (utilisant les souches isolées) sont aussi présentés. Nous traitons enfin du sujet de la modélisation de ce processus en puisant dans les exemples de la modélisation de la biocimentation par la voie uréolytique.

Keywords: Biostimulation; carbonic anhydrase; biocementation.

1 INTRODUCTION

To meet the objectives of net-zero carbon transition and environmental sustainability, geotechnical engineering practices must change radically. Whilst ground improvement will become increasingly important towards sustainable industry practices, ground improvement methods are still machinery-heavy and energy-intensive and often rely on Portland cement or lime to improve the ground; thus, they involve considerable GHG emissions for their production (Mavroulidou et al, 2022). Biomimetic cements, i.e., biocements, produced by the metabolic action of non-pathogenic microorganisms, have recently emerged as potentially more environmentally-friendly alternatives. Recent Life Cycle Assessment (LCA) research however, which considered different metabolic pathways to obtain biocements, questioned the actual sustainability of most processes and pathways (Porter et al, 2021). Porter et al's results showed that different metabolic pathways used for biocementation may have considerably varying and potentially negative environmental impact (especially considering the extent of industrial scale projects). These may be linked to the by-products of the particular metabolic pathway and also the purity of the input chemicals. However, they pointed out that the biotic metabolic pathway of interconversion between CO_2 and the bicarbonate ion HCO_3^- mediated by heterotrophic carbonic-anhydrase (CA) producing bacteria, would be the most environmentally friendly

and sustainable metabolic biocementation pathway. This pathway has the potential of consuming CO_2 (e.g. captured, industrial CO_2), while biocementing the soil, thus offering a dual way of addressing net zero carbon targets within the ground improvement industry. In this process CA utilises gaseous CO_2 to form hydrated aqueous CO_2 (aq) (Eq. 1), which reacts with water to form H_2CO_3 (Eq. 2). Once the H_2CO_3 is formed it ionises in water to generate H^+ and HCO_3^- (Eq. 2); under alkaline conditions, the HCO_3^- further ionises to form CO_3^{2-} and H_2O (Eq. 3). To form a biomineral, metal ion (e.g., Ca^{2+}, Mg^{2+} or Fe^{2+}) precipitates are formed from the reaction. For example, Ca^{2+} with CO_3^{2-} (Eq. 5) forms calcium carbonate. This reaction can occur either with CA-producing bacteria or purified CA enzyme (E) serving as nucleation sites.

$$CO_2\,(g) \leftrightarrow CO_2\,(aq) \quad (1)$$

$$CO_2\,(aq) + E.ZnH_2O \leftrightarrow H_2CO_3 \quad (2)$$

$$H_2CO_3 \leftrightarrow H^+ + E.ZnHCO_3^- \quad (3)$$

$$E.ZnHCO_3^- + E.ZnOH^- \leftrightarrow CO_3^{2-} + E.ZnH_2O \quad (4)$$

$$Ca^{2+} + CO_3^{2-} \leftrightarrow CaCO_3(s) \downarrow \quad (5)$$

Recent work of our team, funded by the European Commission (project *NOBILIS*, 101025184), has focused on the study of biocementation using the CA metabolic pathway (Mwandira et al 2023a-d). The study involved isolation and screening of CA-producing bacteria from a railway embankment foundation fine-grained soil in East Anglia. Bacteria with high CA activity were applied to biocement the native soil. Some salient results of the laboratory study are shown in this paper. This is followed by a discussion on the modelling of the processes, which is the next task of our ongoing work. Although CA metabolic pathway was the main focus of this study, results based on the ureolytic pathway using the same isolated strains are also shown indicatively, as this is a pathway used in most other biocementation research.

2 MATERIALS AND METHODS

The soils studied came from two trial pits accompanying the corresponding window samples from two boreholes (labelled BH01 and BH02 respectively in Table 1) from a site in East Anglia, UK. They came from depths of 0.6-2.9m. They were sandy clay or silty sandy clay soils except for soil sample BH01_0.6-1.1m, which was clayey sandy silt.

CA-producing bacteria were isolated from the accompanying window samples. Namely, 1 g of soil was placed in 10 mL of sterile deionised water and homogenised using a vortex mixer. The soil suspension was serially diluted to 10^{-4} using sterile deionised water; 0.1 mL of the dilution was plated on CM0003 Nutrient agar (Oxoid) consisting of 1g/L meat extract, 2g/L yeast extract, 5g/L peptone, 5.0g/L sodium chloride and 15 g/L agar); 3 mM p-Nitrophenyl acetate (p-NPA), was used as an indicator for CA-positive-producing bacteria. Bacteria colonies with CA-producing ability gave an intense yellow colouration as a result of the hydrolysis of p-NPA into paranitrophenol (pNP). The plates were placed in an incubator for 3 days at 30 °C, At the end of the incubation period the soil yielded 41 CA-producing bacteria with different morphologies. A preliminary microorganism identification was performed using matrix-assisted laser desorption/ionization time-of-flight/time-of flight tandem mass spectrometry (MALDI-TOF/TOF MS) proteomic-based biotyping approach, using a Bruker Daltonics MALDI Biotyper (Mwandira et al, 2023a).

Table 1. Basic physicochemical characteristics of site soils.

ID	LL %	PL %	PI %	W %	pH	Organ. cont. %
BH01_ 0.6-1.1m	-	-	-	32.4 %	7.9	7.8%
BH01_ 1.2-2.2m	63	33	30	47.6 %	7.7	3.9%
BH02_ 0.6-1.1m	35	22	13	34.4 %	7.8	5.5%
BH02_ 1.2-2.2m	39	23	16	36.1 %	7.8	5.8%
BH02_ 2.2-2.9m	40	26	15	34.3 %	7.7	4.0%

The CA enzyme activity was determined colorimetrically as follows: the activity of p-nitrophenyl acetate hydrolysis was determined at room temperature in a reaction mixture (1.35 ml) containing freshly prepared 3 mM p-nitrophenyl acetate in phosphate buffer (0.13M and pH 7.2). The reaction was allowed to proceed for 5 minutes, and the change to A348 per min recorded. Then the CA activity was characterised by the amount of p-nitrophenol produced per unit of time, and enzyme activity expressed as shown in Eq 6.

$$\text{A activity}\left(\frac{\text{U}}{\text{mL}}\right) = \frac{(\Delta A_{348}T - \Delta A_{348}B)\times 1000}{5\times V} \quad (6)$$

where $\Delta A_{348}B$ is the initial uncatalysed reaction (Blank) at a wavelength of 348 nm; $\Delta A_{348}T$ is the final reading of absorbance; 1 U (μmol/min) is the

amount of the enzyme that catalyses the conversion of 1 micromole of substrate per minute; and V is the volume of bacterial suspension added to the cell.

The urease activity of the isolated strains was also determined using the electrical conductivity (EC) method. It was expressed in mM of urea hydrolysed per minute, calculated as shown in Eq. 7, where EC_1 and EC_5 are respectively EC measured at 1 and 5 min.

$$\text{Urease activity}\left(\text{mM}\frac{\text{Urea}}{\text{min}}\right) = \frac{EC_1 - EC_5}{5} 10 \cdot 11 \quad (7)$$

Bioprecipitate analyses were conducted using precultured bacteria in peptone agar p-NPA and B4 (0.4% yeast extract,0.5% dextrose, 0.25% calcium acetate, 1.4% agar) agar media respectively for CA and ureolytic bacteria) at a concentration of 9×10^8 cells/L (i.e., suspension of OD_{600} of 0.5 -MacFarland Standard). This cell concentration was diluted in the applied bioaugmentation solutions ($Ca(CH_3COO)_2$ and $NaHCO_3$ and $CaCl_2$ and $CO(NH_2)_2$ respectively for the CA and ureolytic pathways). The mixtures were incubated for 6 hours at 37°C with shaking (160 rpm) and then further centrifuged (15,000 rpm for 5 minutes) to collect the bioprecipitates, which were then characterised.

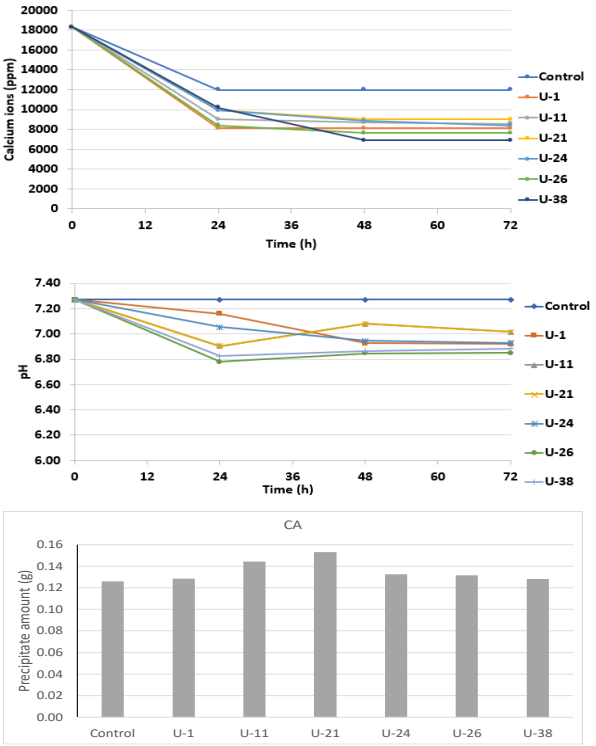
To induce biocementation, biostimulation was used. The treatments used are shown in Table 2. This study refers to the treatment of the clayey sandy silt soil BH01_0.6-1.1 (see Table 1), which was just about coarse enough to allow treatment by injection. Soil layers which were more fine-grained were treated electrokinetically (see Mwandira et al, 2023a). The biostimulation process was conducted as in Mwandira et al 2023(a), according to optimised conditions. Biostimulation media were injected first; then after 3 days (i.e., the optimal growth time of the isolated bacteria, see Mwandira et al, 2023a,d), the optimised cementation reagent solutions respectively for CA and UA pathways (see Table 2) were injected.

Table 2. Biostimulation treatments.

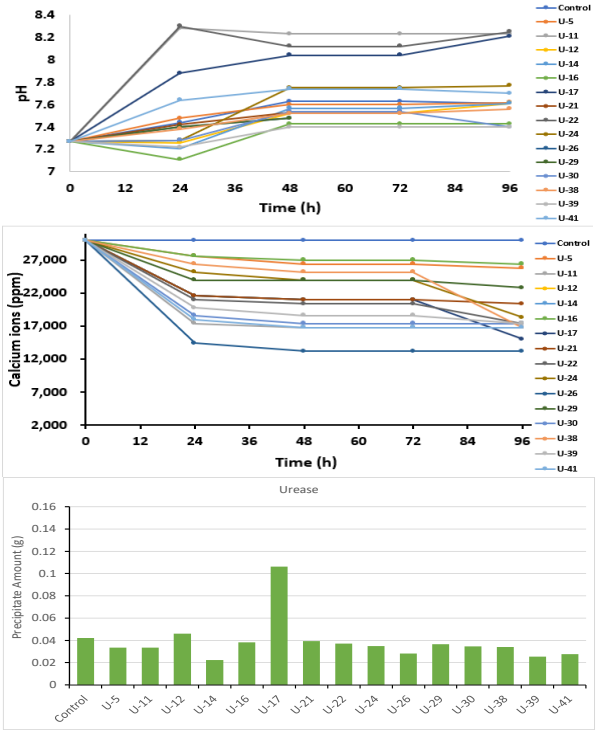
ID	Biostimulation	Cementation
CA pathway		
Yeast Extract	10 g/L	-
Sodium Bicarbonate	100 mM	0.25M/0.5M
Zinc Sulphate	1 µM	-
Calcium Acetate	-	0.25M/0.5M
Ureolytic pathway		
Yeast Extract	20 g/L	-
Urea	330mM	-
Urea	-	1M
Calcium Chloride	-	1M

3. RESULTS

Maldi-TOF results on the 41 CA-producing strains that returned matches of secure or probable genus identification were identified as of the *Bacillus* genus. Indicative results of bioprecipitate study on selected CA-producing strains which also showed ureolytic activity are presented in Figure 1.



(a)



(b)

Figure 1. Bioprecipitates (a) CA route; (b) ureolytic route.

Figure 2 shows indicative SEM-EDS results of bioprecipitates obtained from the CA and ureolytic pathways. Carbonate minerals were confirmed, in most cases showing the typical calcite morphologies but rounder vaterite crystals were also detected depending on cementing solution molarity (not shown, for brevity). Figure 3 shows indicative photos of biocemented samples (after biostimulation) using the CA pathway, against untreated soil samples (control) and Figure 4 their unconfined compression strengths. The biocement can be clearly seen on the surface of biostimulated samples, concurring with the unconfined strength increase of the treated samples. Note that the ureolytic results were produced using a higher cementing solution molarity and this could be a factor leading to their higher strength increase.

4. MODELLING

Biocementation modelling comes under the general heading of reactive transport, whose origins go back to the 1980s with concerns about various environmental issues generally involving the flow and/or removal of contaminating chemicals in the ground (e.g. Lichtner et al., 1996). Traditionally three coupled processes are modelled: advection, dispersion, and chemical reactions taking place between solutes in the groundwater. Applying mass continuity, we obtain the basic differential equation for 1D advection-dispersion:

$$D^* \frac{\partial^2 c}{\partial x^2} - v_x \frac{\partial c}{\partial x} = \frac{\partial c}{\partial t} \qquad (8)$$

where v_x is the Darcy velocity in x direction, t is time

Generalisation of (8) to 3-D is straightforward and solutions are normally obtained numerically. In the general case there will be several different solutes (say N with different initial distributions of concentration) and this will lead to all these concentrations varying with time. The problem of solving a set of equations for a single set of concentrations which vary with time and space has been transformed by multiplying the number of equations to be solved by N. The final part of the picture is that these different solutes may react together (possibly forming new chemical substances) in a process which continues with time until overall chemical equilibrium is achieved. Techniques for the computer-based modelling of simultaneous chemical reactions have been in use since the 1990s and are now well established (Bethke, 2022). The most basic approach of coupling chemical reactions with the transport processes is to carry out the chemical reaction calculations following each transport time step (known as the Sequential non-iterative approach or SNIA -it is important here to consider the relative time rates between the chemical and transport processes to determine the appropriate approach). There are some additional processes which are significant in modelling biocementation as bacteria play an important role in biocementation by producing

enzymes which catalyse up important chemical reactions in the precipitation of calcite; the bacterial growth and enzyme activity needs therefore to be included in the modelling. Bacteria are commonly modelled as chemical species, where the bacterium in suspension is considered irreversibly attached to solid surfaces in the soil profile and independent of velocity and bacteria growth. Biofilm creation (coating the soil particles help promote sites for the calcite to precipitate) has been discussed and modelled for ureolytic bacteria (e.g. Faesli et al, 2023). The rate of the forward reaction (r_e) of CO_2 hydration catalysed by generic carbonic anhydrase may be described e.g. according to the Michaelis–Menten model. The reaction mechanism of CA has been extensively studied in other scientific fields or applications but we found no work so far modelling CA biocementation. Kinetics of the recombinant CA from bacteria have been reported in some CO_2 sequestration studies (e.g., Russo et al, 2016) and can be instructive. The final step for CA biocementation would be the precipitation of $CaCO_3$ as an immobile mass. This can be incorporated in the CA-pathway models in a similar way as in existing ureolytic models (e.g., Cunningham et al., 2019; Martinez et al., 2014; van Wijngaarden et al., 2011).

5. CONCLUSIONS

The work has focused on the little researched CA biocementation pathway, studying the biocemntation potential of bacteria isolated from soil under a railway embankment. The results proved the formation of calcium carbonate precipitates with calcite morphology, following the CA pathway, and the biocementation potential of these strains, corroborated by the increase in the unconfined compressive strength of the soil. Future work is addressing the modelling of the CA biocementation process, for which no information has been found in the literature. However existing studies on biocementation via the ureolytic pathway can be instructive, whereas further laboratory testing can serve in providing modelling parameters.

ACKNOWLEDGEMENTS

The research was funded by the European Commission (project NOBILIS, 101025184).

ABSTRACT: Liberdade/São Bento station (L/SBS) is one of the four stations that are part of the new circular line, also known as "Line G" or "Pink Line". This new project will increment 3 km's to Oporto light rail system and will connect the existing stations of São Bento and Casa da Música. Once it is located in the heart of Oporto city centre, it was important to ensure the minimum impact at the surface and traffic disruption, which why Liberdade/São Bento station is being built using a mix of cut-and-cover and top-down construction methodologies. The station is formed by its main body, which develops longitudinally to the axis of the railway, and by its surface accesses, which develops perpendicularly to the railway axis at both ends and in the central area of the station body. Due to its location and dimension, the construction process has revealed himself as extremely challenging, once it combines the complexity of building in an high urban area, extremely affected by various services (water supply, wastewater network, rainwater, gas, electricity and all telecommunication services), but also historical (proximity to several monuments and the appearance of new archaeological monuments during excavations), along with the geological-geotechnical conditions considered in the design of excavations, retaining support and foundations (structural support and protection of buildings; high levels of groundwater; groundwater contamination). This paper aims to describe the main constraints that are being faced during the execution and explain how are they being managed and overcome.

RÉSUMÉ: La station Liberdade/São Bento (L/SBS) est l'une des quatre stations qui font partie de la nouvelle ligne circulaire, également connue sous le nom de "Ligne G" ou "Ligne rose". Ce nouveau projet ajoutera 3 km au système de métro léger de Porto et reliera les stations existantes de São Bento et Casa da Música. Une fois située au cœur du centre-ville de Porto, il était important de minimiser l'impact sur la surface et les perturbations du trafic. C'est pourquoi la station Liberdade/São Bento a été construite en utilisant un mélange de méthodologies de construction en tranchée couverte et de construction de haut en bas. La gare est formée par son corps principal, qui se développe longitudinalement à l'axe du chemin de fer, et par ses accès de surface, qui se développent perpendiculairement à l'axe du chemin de fer aux deux extrémités et dans la zone centrale du corps de la gare. En raison de son emplacement et de sa dimension, le processus de construction s'est révélé extrêmement difficile, une fois qu'il combine la complexité de la construction dans une zone urbaine élevée, extrêmement affectée par divers services (approvisionnement en eau, réseau d'eaux usées, eaux pluviales, gaz, électricité et tous les services de télécommunication), mais aussi historique (proximité de plusieurs monuments et apparition de nouveaux monuments archéologiques pendant les fouilles), ainsi que les conditions géologiques-géotechniques prises en compte dans la conception des fouilles, des confinements et des fondations (soutien structurel et protection des bâtiments; niveaux élevés des eaux souterraines; contamination des eaux souterraines). Ce document vise à décrire les principales contraintes rencontrées au cours de l'exécution et à expliquer comment elles sont gérées et surmontées.

Keywords: Metro; construction; cut-and-cover, top-down, granite.

1 INTRODUCTION / GENERAL FRAMEWORK OF THE WORK

Liberdade/São Bento station (L/SBS) integrates the new circular line (aka Line G, or Pink Line) of Metro do Porto light rail system, which will increment 3km's to the current network. It is located in a consolidated urban area of Oporto city centre, and it will connect the existing station of São Bento and Casa da Música.

Considered as a Unesco World Heritage area, the implementation of this new station demanded a careful and thorough study of the spatial, structural and planning constraints.

Figure 1. Plant insertion of Liberdade/S. Bento Station (L/SBS).

In order to enable the construction in such a narrow space (Figure 1) and ensure the safety of all the building and historical heritage on the surroundings, it was necessary for the design team to study and conceive new approaches and solutions, once the standard solutions (foundation piles, e.g.) were not possible to implement.

The density of utilities and services affected (namely wastewater, water supply, electricity, etc.) and the crossing of an ancient underground rainwater galleries (Rio da Vila), demanded a complex coordination between the several specialities projects, in order to achieve a feasible and integrated solution.

2 URBAN CONSTRAINTS

By way of background, it is important to highlight the existence of a combination of determining factors that led to an atypical metro station, especially in geometric and functional terms. These are summarised below: the small width of the urban roads for the insertion of a current metro station; intense road and pedestrian traffic on the surface as well as the presence of buildings next to the work, some of which are of heritage and historical importance; the convergence in "Praça da Liberdade" of a system of rain galleries (called Rio de Vila (RV)) that runs southwards towards the Douro river, which constitutes a barrier that is very difficult to overcome; the crossing of "Praça da Liberdade" through the tunnel of metro line C, heading north towards Aliados; the need for an underground pedestrian link between line C and the Circular line, connecting the new station to São Bento metro station.

Due to the above mentioned, a complex and dynamic coordination between design teams was needed, in order to ensure the feasibility of the technical solutions adopted.

3 THE STRUCTURAL SOLUTIONS ADOPTED

Due to the constraints presented, the L/SBS is being built, mostly, using the so-called top-down method, with peripheral retaining support in Diaphragm Walls (DW). Due to the proximity of the buildings and the need to drill through a relatively competent rock mas without percussion, an hydromill trench cutter was used, with specific dimension limitations.

This structural solution aims to ensure: structural continuity between the roof slab and the peripheral containment (first phase of the structure), labelled connections between diaphragm walls and the remaining station slabs (Mezzanine and Back Slab).

In order to simplify the work and enhance its durability, standard structural solutions were favoured, avoiding complex connections, mainly resulting from: intermediate vertical elements to be built in the first phase (top-down method), the support of the roof on walls to be built in the second phase (open excavation).

It should be noted, however, that it was necessary to use the support of the roof slab in an intermediate DW alignment in the body of the station, otherwise, considering the spans presented, it was necessary to increase significantly the thickness of the roof slab, what would have been unaffordable, because of the land cover intended.

Mainly due to the factors described and the need to minimize the traffic disruption, the construction had to be adapted to the several varied moments of diversions transition, with the execution of the station's structural elements being subdivided into 11 Phases (Figure 2).

Figure 2. Division of the Station for the execution of the structural elements.

The areas highlighted in red were executed entirely from the bottom up; the green area represents the top-down construction method.

4 GEOLOGICAL, GEOMORPHOLOGICAL AND TECTONIC SETTING

The route of the project is located in the Central Iberian Zone, where there is a characteristic granite massif with complex geotechnical conditions, marked by the tectonic framework of the granite massif and the hydrothermal and meteoric alteration that followed its installation (Santos et al, 2019).

According to Santos (2019), from a tectonic point of view, the influence of the Hercynian orogeny and the proximity of the Porto-Albergaria-a-Velha-Coimbra-Tomar Shear Belt, with a NNW-SSE orientation, which passes through the Foz do Douro and Nevogilde areas, stand out.

The granite massif of Porto is generally sandy and kaolinised, heterogeneous and geotechnically complex where granite soils and rock levels occur without a pattern. This is largely due to the proximity of an intense deformation zone which favoured a large fracture network and deep fluid circulation (hydrothermal alteration) which was intensified by meteoric alteration conditioned by the climate, surface water infiltration conditions and the relief in general.

From a geomorphological point of view, the route is located in a flattened region slightly inclined towards the sea, where low areas are followed by hills with flattened tops, intersecting the valleys of the tributary watercourses of the River Douro.

The L/SBS is built on several watercourses, which are currently channelled / diverted and substantially earthed, the main one being the RV, which means that the working levels reach minima close to 10m.

4.1 Geological-Geotechnical Zoning (GGZ)

In order to carry out the geological-geotechnical reconnaissance and elaborate the GGZ (Figure 3) of the massif, all the existing elements relevant to the project presented here were collected and analysed, two geotechnical prospecting campaigns were carried out and all the available data was subsequently analysed and systematised. Two prospecting campaigns were carried out with 48 geotechnical rotary boreholes, accompanied by the systematic execution of SPT tests and the complete collection of rock mass, with the installation of 24 open tube piezometers, 41 Lugeon tests and 43 Lefranc tests, plus 37 simple compressive strength tests.

The boreholes reached depths varying between 23.0 and 46.5 metres.

In order to determine the aggressiveness of the groundwater to the concrete, 8 samples were taken from boreholes along the route and chemical analyses of the groundwater were carried out to obtain pH values, sulphate content, aggressive carbon dioxide, nitrogen and magnesium.

51 samples were also selected to be subjected to tests to determine density, porosity and resistance to uniaxial compression with determination of the modulus of deformability.

GEOTECHNICAL ZONING	LITHOLOGY	WEATHERING GRADE		FRACTURATION GRADE	JOINTING CONDITIONS	N_{SPT}	GSI
G1	γ	W1	FRESH GRANITIC	F1-F2	d1-d2	NA	65-85
G2	γ	W2	SLIGHTLY WEATHERED GRANITE	F2-F3	d2-d3	NA	45-65

G4	γ	W4	HIGHLY WEATHERED GRANITE	F4-F5	d4-d5	NA	15-30
G5	γ	W5	COMPLETELY WEATHERED GRANITE	NA	-	>50	-
G6	γ	W6	RESIDUAL SOIL GRANITE	NA	-	<50	-
G7	EMBANKMENT /ALLUVIUM	NOT APPLICABLE (NA)		NA	-	VARIABLE	-

Figure 3. Geotechnical zoning adopted and its reference parameters (adapted from Santos, 2019).

The GGZ of the L/SBS was defined on the basis of information from 5 geotechnical boreholes, with depths between 21 and 25m, complemented by information available from the 1st phase of the construction of the Metro do Porto when the line was built to the existing ESB (Santos, 2019).

Through GGZ, the station mostly intersects G7 and G5, to a lesser extent G4, and occasionally G3. Unit G7 is made up of embankments and alluvium that cover the underlying granite formation, reaching depths of between 2 and 9 metres (Figure 4).

Unit G5 is made up of very compact granitic soils (NSPT>60 strokes), with occasional rocky cores and is located between 2 and 19m deep, exceeding the

station's implantation level in the central zone (Santos, 2019).

According to Santos (2019), in the central area of the station, the rock mass only occurs below the station's base level (G4 and occasionally G3). To the east and west, the G4 and G3 massifs are already found between the top and base of the station. Circumscribed G3 rock cores can, however, be intercepted above the station's base level.

The G3 rock unit occurs at depth, with some continuity from 8-24m deep, and the G2 unit is punctual and not very continuous, usually between 18 and 25m.

According to Santos (2019), the high oxidation of the granite massif's fractures, some filled with organic soils, and the interception of a passage of monogranular rolled sands within the decomposed massif (G5), indicate the presence of an uncompressed granite massif, with open fractures and high underground percolation.

The water table is close to 5 metres deep (Santos, 2019).

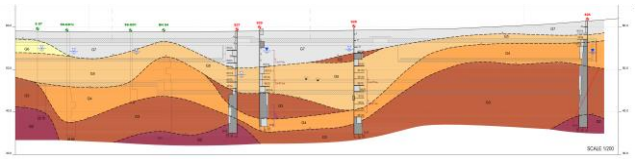

Figure 4. Longitudinal Geological-Geotechnical Profile of the L/SBS (excerpt from Drawing with code P-PR-LI-8000-GG-DS-SCN-000002-00), for legend of the GGZ see Figure 3.

5 CONCLUSIONS

Liberty/São Bento station represents a great example of the importance of exploring the underground space in urbanized cities. However, it also teaches us the importance of the existence of updated registrations and records for the underground services and utilities, which can compromise, severely, the construction process.

Location revelead itself as one of the major factors for the selection of the construction method, design and construction premisses: due to the proximity to residential, commercial and historical buildings, it was necessary to implement a solution which allowed to preserve the integrity of the built heritage, but also minimize the impact on the surface near the residents and population. Despite the careful and thorough coordination of the design teams for the several specialities during the design process, several question marks remained during the entire excavation, thus the importance of an high engagement of all the stakeholders involved (namely design teams, owner, constructor and municipality), such as a risk and expectation management.

An effective communication and engagement of the several competent authorities, are crutial to ensure the city dynamic, communication and disclosure of information near the population.

ACKNOWLEDGEMENTS

The authors are grateful for Metro do Porto allowing to publish data from the project presented here.

Finite element analyses of slurry trench stability and deformations – back-calculation of field tests in soft clay

Analyses par éléments finis de la stabilité et des déformations des tranchées à coulis - Rétro-calcul des tests de terrain en argile molle

**eirik.nilsen@ngi.no*

ABSTRACT: The slurry trench method has, since the early 1970s, been used in Norwegian soft clays to construct diaphragm walls to support deep excavations. The technique involves excavation of a deep trench stabilized by a fluid/slurry that exerts a pressure on the trench walls. When the method was used for construction of diaphragm walls for a subway and railway tunnel through central Oslo in the 1970s there was little experience with the method in soft clays. Therefore, a field test program with several test trenches was initiated which included monitoring of ground settlements, pore pressures, and horizontal deformations at depth. The present study analyses results from two slurry trenches at Vaterland, one of size 1×5 m and the other of size 1×1.8 m. These trenches were deliberately brought to failure by drawdown of the supporting slurry. Finite element analysis (FEA) is used to back-calculate the observed behaviour with respect to safety and deformations. The NGI-ADP model is used for the clay at the test site. The results are compared with the observed behaviour and the factor of safety calculated using a simplified analytical approach proposed earlier. The analyses show that the NGI-ADP model can predict failure with satisfying accuracy, and that effect of the trench shape on the stability is well captured.

RÉSUMÉ: La méthode des tranchées à coulis est utilisée depuis le début des années 1970 dans les argiles molles norvégiennes pour construire des parois moulées destinées à soutenir des excavations profondes. La technique consiste à creuser une tranchée profonde qui est stabilisé par un fluide/boue, en exerçant une pression sur les parois de la tranchée. Lorsque cette méthode a été utilisée dans les années 1970 pour la construction de parois moulées pour un tunnel de métro et de chemin de fer traversant le centre d'Oslo, il y avait peu d'expérience dans son utilisation avec les argiles molles. Un programme de tests sur le terrain impliquant plusieurs tranchées d'essai a donc été lancé. Le programme comprenait des mesures de tassement, des pressions interstitielles et des déformations. La présente étude analyse les résultats de deux tranchées à coulis à Vaterland, l'une de dimension 1×5 m et l'autre de dimension 1×1,8 m. Ces tranchées ont été délibérément poussées jusqu'à la rupture en abaissant le niveau du coulis de support. L'analyse par éléments finis (FEA) permet de rétro-calculer le comportement observé relatif à la sécurité et les déformations. Le modèle NGI-ADP est utilisé pour l'argile sur le site de test. Les résultats sont comparés au comportement observé, et le facteur de sécurité est calculé à l'aide d'une approche analytique simplifiée proposée précédemment. Les analyses montrent que le modèle NGI-ADP peut prédire la rupture, et que l'effet de la forme de la tranchée sur la stabilité est bien capturé.

Keywords: Slurry trench; stability; FEA.

1 INTRODUCTION

The slurry trench method for constructing, for example, diaphragm walls is a technique that has been used in Norwegian soft clays in the past and is seeing an increased relevancy today. The technique involves excavation of a deep trench that is stabilized with a suitable fluid, called slurry.

In Norway, the slurry trench method was used during the construction of the *Fellestunnelen* rail- and subway tunnel in central Oslo in the 1970s, involving construction of diaphragm walls to depths up to 28 m. At the time there was little experience with this method in soft clays typical to Norway.

Therefore, test sites were established at three locations in central Oslo. The tests included trenches of different sizes with extensive instrumentation and monitoring. The collected data include ground surface settlements, pore pressures, trench wall deformations, and horizontal deformations measured by inclinometers, collected from slurry trenches in Kongens gate, Vaterland (DiBiagio *et al.*, 2020), and Studenterlunden (DiBiagio and Myrvoll, 1972). Schäfer and Triantafyllidis (2004) and Grandas-Tavera and Triantafyllidis (2012) have previously analysed slurry trenches at the Studenterlunden test site using a visco-hypoplastic constitutive model.

In this study, the data collected at the Vaterland test site is revisited. The site includes two trenches, one 1×5 m and the other 1×1.8 m. Finite element analyses (FEA) is used to back-calculate the observed behaviour using the NGI-ADP constitutive model. The aim to investigate the ability of the NGI-ADP model to predict the safety and deformations of slurry trenches through 3D modelling of the field tests.

2 BACKGROUND

2.1 Soil conditions

The terrain at the Vaterland test site is approximately level and situated at elevation +2 m above sea level. The bedrock surface forms a gulley (Figure 1). The trenches are situated roughly at its centre, where the depth to bedrock is 18–22 m. In the northwest and southeast directions, the depth to bedrock decreases.

The soil consists of a 1–2 m thick layer of fill material over a deposit of normally consolidated marine clay. The top part of the clay has been weathered to form a dry crust extending to a depth of 2–4 m. Underneath, is a soft marine clay with liquid limit of 40–45 %, plastic limit of about 25 %, and water content of 35–40 %. The ground water table is located at a depth of about 1 m.

The undrained shear strength (c_u) of the clay is estimated based on vane tests and triaxial tests on piston samples from the site, and CPTUs from a nearby location (Figure 2). For the vane tests, the correction factor proposed by Aas (1986) is used to estimate the average field c_u. The active shear strength c_{uA} is obtained using a ratio of direct to active strength calculated as proposed by Karlsrud and Hernandez-Martinez (2013). The CPTUs were interpreted using the correlations presented by Karlsrud et al., (2005). An overall assessment of both the N_{kt} correlation and the $N_{\Delta u}$ correlation for six different CPTUs is the basis for the interpreted profile in Figure 2.

The final input profile for the FEA is determined by an overall assessment of the different data, considering the likely effect of sample disturbance on the anisotropically consolidated undrained compression test (CAUC) results (Karlsrud and Hernandez-Martinez, 2013).

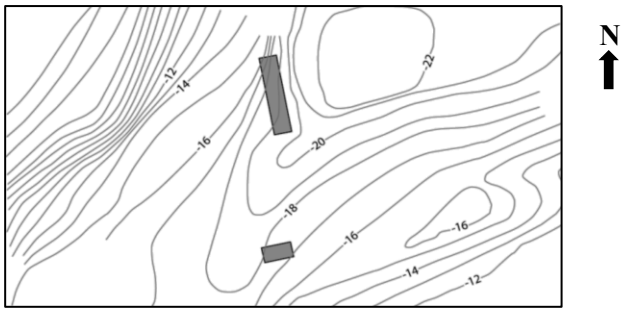

Figure 1. Map of bedrock elevation at the slurry trench test site and the location of the two trenches (shaded).

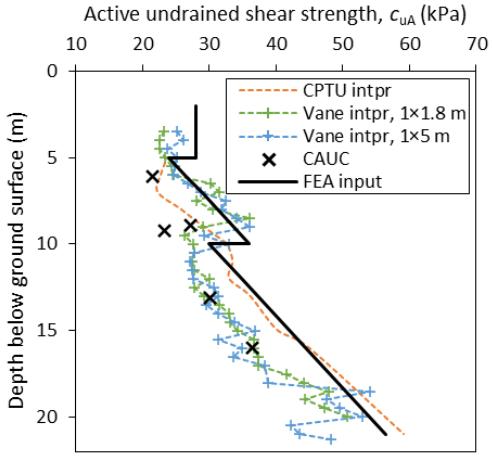

Figure 2. Active undrained shear strength vs. depth.

2.2 Instrumentation and test timeline

The trenches were instrumented and monitored with hydraulic deformation gauges, settlement anchors inclinometers, and pore pressure. The instrumentation layout is described by DiBiagio et al., (2020).

Excavation started February 26, 1970, by excavation of the 1.8 m trench. Then, the 5 m trench was excavated, followed by a series of tests involving replacement and drawdown of the stabilising fluids (Table 1). The slurry had an average specific gravity of 1.17, while the oil had a specific gravity of 0.85. Failure was initiated in the 1.8 m trench during drawdown to 8.3 m depth, while failure of the 5 m trench was initiated by drawdown to 4.7 m. Drawdown was performed at a rate of 1 m every 30 min.

Table 1. Timeline for the slurry trench test at Vaterland, reflected in the FEA calculation phases.

Phase	Date
Excavation of 1.8 m trench with slurry	26 Feb.
Excavation of 5 m trench with slurry	2 March
Replacement with water in 1.8 m trench	4 March
Lowering of water to 4.3 m in 1.8 m trench	5 March
Refilling of water in 1.8 m trench	5 March
Lowering of water to 8.3 m in 1.8 m trench	6 March
Refilling of water in 1.8 m trench	6 March
Replacement with slurry in 1.8 m trench	9 March
Replacement with water in 5 m trench	9 March
Replacement with oil in 5 m trench	11 March
Replacement with water in 5 m trench	14 March
Lowering of water to 4.7 m in 5 m trench	19 March

3 FEA MODEL

A 3D FEA model was established to analyse the slurry trench tests. The soil was divided into five layers. Down to a depth of 1.5 m is a layer of fill material. Then comes a layer of dry crust above clay which is divided into three sublayers. The geometry of the model is shown in Figure 3.

The model has normal constraints on vertical boundaries and the bottom boundary is fully fixed. The top surface is free, while distributed loads are applied on the inside surfaces of the trenches representing the pressure from the stabilising fluids. The calculation phases reflects the timeline s in Table 1. «

3.1 Soil parameters

3.1.1 Clay

Undrained behaviour is assumed for the clay, using the NGI-ADP material model Grimstad et al. (2012). The input parameters are based on the field and laboratory tests and are summarized in Table 2.

3.1.2 Fill material and dry crust

For the fill material and dry crust, the HS-small model (Benz, 2007) is used. The material properties are summarised in Table 3, and are mostly typical values.

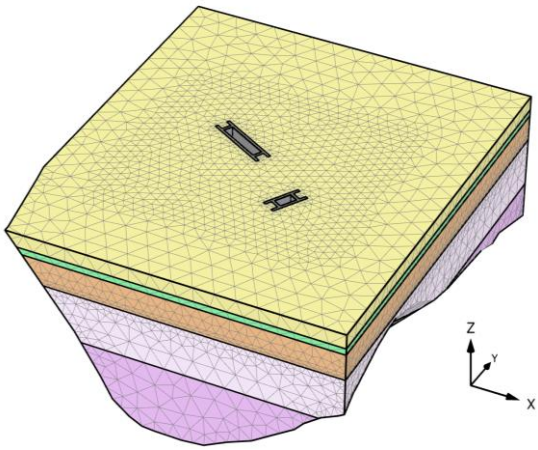

Figure 3. 3D perspective view of the FEA geometry.

Failure ratio, R_{f} (-)	0.90
Normal consolidation stress ratio, K_0^{NC} (-)	0.47

4 RESULTS

The FEA results show reasonable agreement with the observed/measured behaviour. As an example, Figure 4 compares the calculated reduction in trench width for the 1.8 m trench during drawdown to 4.3 m depth to the measured values. The agreement is generally good, particularly along the upper part. The difference seen at large depths can be due to inaccuracy in the geometry of the bedrock surface in the FEA and the effect the bedrock has on the stresses, and/or the shear strength being underestimated at large depths.

Furthermore, the FEA showed that the displacement in the 1.8 m trench increased rapidly when drawdown was continued to 8.3 m, reaching values of decimetres. The maximum displacement during this phase occurs at a depth of 8.5–9 m, that is, just below the top level of the water in the trench (Figure 5). Similarly, large, displacements were calculated for the 5 m trench during drawdown to 4.7 m depth. Consequently, these two drawdown phases can be considered close to failure. This is in line with the observed behaviour of both trenches.

Using the simplified analytical approach described by Aas (1976) the following factors of safety can be calculated for the two drawdown phases described above (DiBiagio *et al.*, 2020):

- Drawdown in 1.8 m trench to 8.3 m: 0.99
- Drawdown in 5 m trench to 4.7 m: 0.70

It is, thus, seen that the FEA using the NGI-ADP model is in line with the analytical method for the 1.8 m trench as both indicate failure for drawdown to 8.3 m. For the 5 m trench the analytical method results in a factor of safety of 0.7. Actually, a factor of safety of less than 1 is obtained for a drawdown of only 1 m.

This indicates that the analytical method underestimates the safety for this trench size as the field observations (and the FEA) shows that the 5 m trench is stable at this drawdown. The analytical method, thus, seems to underestimate the geometric effects for trenches with larger width to depth ratios.

5 CONCLUSIONS

The FEA using the NGI-ADP model can predict displacements with reasonable accuracy as well as accurately capture safety with respect to failure of the slurry trenches. The simplified analytical approach presented by Aas (1976) agrees well with the FEA and the measurements for the 1.8 m trench but seems to underestimate the safety for the 5 m trench.

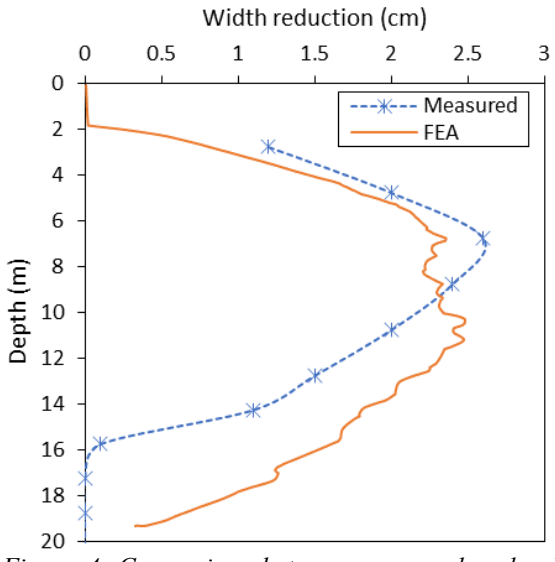

Figure 4. Comparison between measured and calculated trench width reduction during drawdown to 4.3 m in the 1.8 m trench.

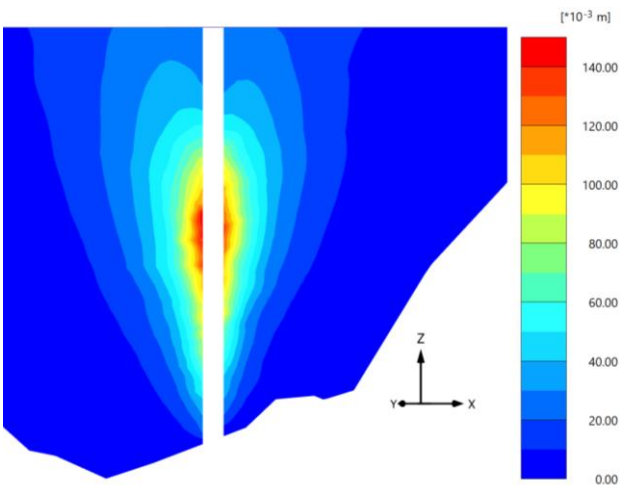

Figure 5. Contours of total displacement calculated in a cross section perpendicular to the 1.8 m trench after drawdown to 8.3 m depth.

ABSTRACT: In the field of soil mechanics, various initiatives have been launched recently to use Nano- Materials (NM) to enhance the characteristics of soils. Numerous studies have been done using various methods to determine how micro- and nano- particles affect the geotechnical characteristics of soils. Most of the research done over the last ten years is reviewed in this research paper. According to the new classification, clay particles vary between 0.1 and 2 mm, while NM specimens contain particles in the range from 1 to 100nm. All findings suggested that adding Nano-Particles (NP) as a Nano Soil-Improvement (NSI) technique to soil improved its mechanical and physical characteristics, the type, quality, and quantity of NM applied, as well as the properties of the native soil, all influence this enhancement natural soil properties. In this paper, a new categorization was introduced to investigate the important effects of NP and NM on soil properties as a Nano Ground-Improvement (NGI) method.

RÉSUMÉ: Des initiatives nouvelles dans le domaine de la mécanique des sols sont récemment introduites en ce qui concerne l'usage des nanomatériaux (NM) pour l'amélioration des sols. De nombreuses études sont effectuées pour déterminer l'influence des micro et nano-particules sur les caractéristiques des matériaux géotechniques. La majorité des études réalisées dans la décennie écoulée est analysée dans cette publication. Selon une classification nouvelle,la dimension des particules d'argile varie entre 0.1 et 2µm, tandis que NM contiennent éléments entre 1 et 100nm. Toutes les trouvailles suggérent que l'addition des nano-particules (NP) comme nano-technique d'amélioration des sols (NSI) revise leurs caractéristiques mécaniques et physiques. Une sorte, qualité et quantité de NM appliqués ainsi que les propriétés du sol naturel influencent l'état d'amélioration du sol concerné. Dans cet article, une classification nouvelle est introduite pour étudier les effets majeures de NP et NM sur les paramètres géotechniques par la méthode de nano-amélioration des sols (NGI).

Keywords: Nano-materials (NM), nano-particles (NP), nano soil-improvement (NSI), nano ground-improvement (NGI).

1 NANOTECHNOLOGY AND GEOTECHNICAL ENGINEERING

Nanotechnology is related to the nano-scale of materials. Most of the materials and minerals are in the micro-scale, although various materials have nano-scale components in their natural conditions. Existing knowledge is based on micro-scale analysis in geotechnical engineering. A few researchers and scientists have started various tests on the nano-scale of minerals and soils in geotechnical engineering. The performance of the nano-scale of soils and minerals in soil mechanics and rock mechanics is very important because nanotechnology in geotechnical engineering is a cutting-edge knowledge and high-tech technology. According to existing soil classifications, gravel, sand, clay and silt are included in soil mechanics, but a new term of nanosoil is needed. Nanosoil has a size range between 1-100 nm. According to new results, the nano-scale of soils improved various properties of different types of soils (Niroumand et al., 2023). Geotechnical engineering focuses on the behavior and performance of different soils, while nanotechnology focuses on the nano-scale of materials and their behaviors and feedbacks. Using nanotechnology in geotechnical engineering has two objectives:

First, nanotechnology can explore new knowledge about the structure of soils at the nano-scale rather than the existing knowledge at the micro-scale. A complete introduction and knowledge of the nano-scale of soils can develop new theories for advanced soil mechanics and foundation engineering.

Secondly, using the nano-scale of soils and additives can investigate soil behaviors and improve existing soils. The role of the nano-scale of additives in soil mechanics is related to soil stabilization as a technique of soil improvement.

A lot of soils have various problems worldwide. The role of the nano-scale of additives as soil stabilizers can change the role of micro-scale additives in current and ongoing projects. Existing knowledge for micro-scale additives in soil improvement has learned various lessons in geotechnical engineering, such as additive properties, soil type, additive percentages, water amount, improvement methods, etc., that are related to ground improvement methods in different projects. The nano-scale of materials is similar to the micro-scale of additives because existing factors are applicable for ground improvement in geotechnical engineering.

2 EXISTING KNOWLEDGE OF NANOTECHNOLOGY IN GEOTECHNICAL ENGINEERING

In this part, a few existing achievements on two objectives of nanotechnology in geotechnology are described, although various researchers have evaluated the performance of nano additives in various soils. Only selected experiences of authors are presented for this manuscript.

a) Niroumand et al. (2013) investigated the performance of nano-scale clay as an additive and soil stabilizer in bricks. Earth is a basic material in heritage, historic buildings and earth buildings in earth architecture style. Traditional bricks have been used in many countries, especially in the Middle East and Arabic countries. According to traditional methods, various additives such as Sarooj, straw, lime, cement, egg, and etc. were used as additives and stabilizers in bricks.

In this study, the authors used different percentages of nano-scale additives in earth bricks in a soil laboratory. Nano kaolinite was selected as a type of nano clay in this study. According to their results, the compressive strength of treated bricks with nano-scale additives was 4.8 times higher than untreated bricks at 14 days curing time. The best percentage of nano additives was 5% compared to untreated bricks. They mentioned that Nano-Bricks (NB) can be used as modern bricks rather than existing bricks as Micro-Bricks (MB) in various applications and projects as shown in Fig. 1. They used powder technique for brick improvement. (Niroumand et al., 2013)

Figure 1. Micro- and Nano- Earth Bricks (Niroumand et al., 2013).

b) Khaksar et al. (2023) produced a new spray for protecting and restoring historic adobe walls and buildings. They used nano-scale montmorillonite in their research. According to the results of various tests, such as scanning electron microscopy, atomic force microscopy, porosity tests, water capillary absorption, and compressive strength, they showed that the use of a 1% nanomontmorillonite clay solution exhibited the best results, filling cavities and reducing pores on the adobe surface, increasing compressive strength, and reducing water absorption and hydraulic conductivity. The study concludes that this innovative method using nanomontmorillonite clay can help address the challenges of historic adobe walls, such as erosion, cracking, and surface damage.

This research contributes to the growing field of nanotechnology applications in architecture and civil engineering, particularly in soil stabilization and improving the properties of building materials. It introduced new concepts of "Nano-Heritage", "Nano-Spray for Historic Buildings and Earth Houses", and "Nano Spray-Improvement" as shown in Fig. 2. (Khaksar et al., 2023)

Figure 2. Nano-Spray for Historic Buildings and Earth Houses (Khaksar et al., 2023).

c) Zyenali et al. (2023) investigated the role of micro- and nano-scale fly ash as a green material in geotechnical engineering. They used fly ash because it was an eco-friendly material and a waste additive that

can be used as a recycled material in the building industry. They evaluated the role of these additives at micro- and nano-scale in various soil mechanics tests. They used scanning electron microscopy (SEM), X-ray fluorescence (XRF), and X-ray powder diffraction (XRD) to evaluate the soil and additive structures at micro- and nano-scale. They also investigated various percentages of micro- and nano-fly ash in cohesive soils to explore the soil mechanic behavior of micro- and nano-scale additives in soil stabilization.

Nano Soil-Stabilization (NSS) is a new theory for improving soil in Nano Soil-Improvement (NSI) or Nano Ground-Improvement (NGI). The results showed that adding 7% of nano-fly ash to the soil improved its unconfined compression strength by 8.2 times and its triaxial strength by 8 times. The researchers concluded that nano-fly ash significantly improved the strength and stiffness of the soil-fly ash mixture by filling the pores and bonding the soil particles. They reported a cutting-edge knowledge for the performance of Nano-Additives (NA) in earth building technology that can be used to build new houses with high performance in the future. They used suspension technique for soil improvement as shown in Fig. 3. (Zyenali et al., 2023)

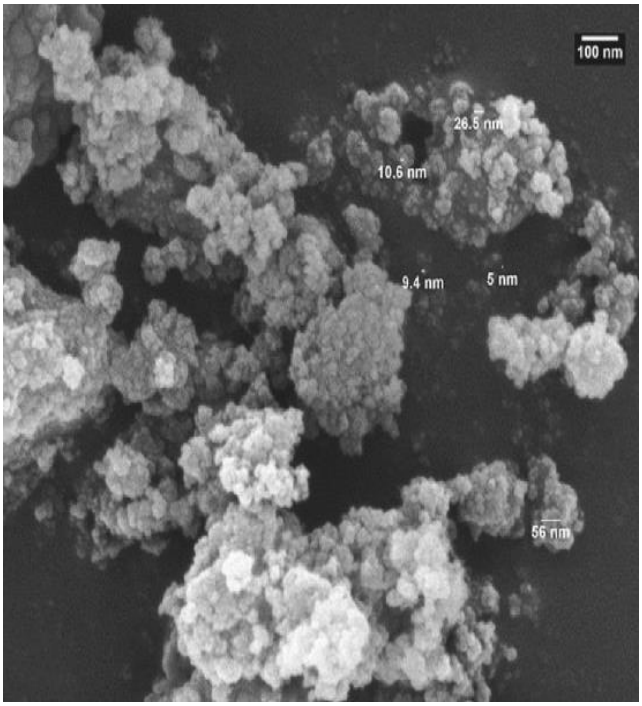

Figure 3. Nano – Fly ash (Zeynali et al., 2023).

d) Niroumand et al. (2023) described the role of micro- and nano-scale cement in geotechnical engineering. They selected a natural field soil site as untreated soil for soil stabilization objectives. They tried various percentages of micro- and nano-scale cement in soil stabilization as a soil improvement technique as shown in Fig. 4. They found that an optimum percentage of nano-cement was 7%, which increased the unconfined compressive strength by up to 29 times and reduced the strain at rupture by 74% compared to untreated soil. According to their results, they found a significant improvement of nano-scale cement on the strength and stiffness of the untreated soil-cement mixture. They used suspension method for soil improvement.

Figure 4. Micro- and Nano- Cement and NSI (Niroumand et al., 2023).

e) Cheraghalikhani et al. (2023) investigated the performance of micro- and nano-scale bentonite in geotechnical engineering. They used suspension technique for improving the cohesive soil properties. By using different percentages of micro- and nano-scale bentonite, they achieved good performance on the physical and mechanical properties in soil mechanics as shown in Fig. 5. They used SEM, XRD and XRF to control the properties, shape and size of soil and additive at micro- and nano-scale analysis. According to this investigation on clayed sand soil, at one day of curing time, the addition of 1% micro-bentonite increased the secant modulus to 2500 kg/cm^2, while 1% nano-bentonite increased it to 3000 kg/cm^2. The researchers emphasized the performance of suspension method rather than powder technique in micro- and nano-scale additives because suspension had a good performance in uniformity and soil mixing for various specimens and samples in soil mechanics laboratory.

3 THE FUTURE OF NANOTECHNOLOGY IN GEOTECHNICAL ENGINEERING

According to existing knowledge and results, the future of nanotechnology in geotechnical engineering, soil mechanics and rock mechanics looks promising. Existing knowledge proves the role of nano-scale soils as a good achievement for developing new techniques in the future of geotechnical engineering projects worldwide. The performance of nanotechnology started in soil stabilization and soil improvement, but it can be developed to various types of Nano-Foundations (NF), Nano-Additives (NA), Nano- Piles (NP), Nano Sheet-Piles (NSP), Nano-Geosynthetics (NG), NSI and subsidence as Nano-Subsidence, NSI and sinkhole as Nano-Sinkhole, and etc. The use of nano-scale materials has proven a good performance of the durability and soil properties in existing research. A new classification needs to be developed in soil classification; in other words, Nano-Soil (NS) needs to be added to existing soil classifications. These new terms emphasize new theories and techniques in soil mechanics and rock mechanics. It means a new way has opened in geotechnical engineering that requires various research and collaboration for modern types of materials in geotechnical engineering to improve the existing level of geotechnical engineering.

ABSTRACT: Bored piles are often installed below the groundwater level. During installation, it has to be ensured that groundwater flow does not lead to a reduction of the pile integrity from pouring until the concrete has stiffened. The European Standard EN 1536, the German Recommendations on Piling "EA-Pfähle" (2013) and international guidelines refer to possible problems resulting from groundwater flow. However, no information is given as to which groundwater flow velocity is critical in which ground. In order to be able to estimate the risk of cement particle removal or redistribution, model piles were installed with the tremie method at the University of Wuppertal in a joint research project. These piles were exposed to several water flow velocities during installation. The created flow velocities were substantially higher than the groundwater flow velocities which occur in field. In a first series of tests, the focus was on test piles made of tremie concrete which were placed in sandy soils. In a second series of tests, a variation of concrete mix design and surrounding soil was performed to obtain a more general statement. In summary, it could be shown that no critical flow velocity could be reached which lead to a "washing-out effect" of cement on the pile surface within the scope of both series of tests.

RÉSUMÉ: Les pieux forés sont souvent installés sous le niveau de la nappe. Lors de l'exécution, il faut s'assurer que l'écoulement des eaux souterraines ne remette pas en cause l'intégrité du pieu, à partir du bétonnage et jusqu' à la prise du béton. La norme européenne EN 1536, les recommandations allemandes sur les pieux "EA-Pfähle" (2013) et les recommandations internationales font référence aux problèmes possibles résultant de l'écoulement des eaux souterraines. Cependant, aucune information n'est donnée quant à la vitesse d'écoulement de la nappe phréatique qui est critique dans chaque terrain. Afin de pouvoir estimer le risque d'arrachement ou de redistribution des particules de ciment, des pieux tests bétonnés au tube plongeur ont été installés à l'université de Wuppertal, dans le cadre d'un projet de recherche partenariale. Ces pieux ont été exposés à plusieurs vitesses d'écoulement de l'eau pendant leur exécution. Les vitesses d'écoulement imposées étaient considérablement plus élevées que les vitesses d'écoulement des eaux souterraines observées in situ. Dans une première série de tests, l'accent a été mis sur les pieux d'essai bétonnés au tube plongeur, qui ont été réalisés dans des sols sableux. Dans une deuxième série de tests, des compositions du béton a été étudiée, dans des sols également différents, pour obtenir une analyse plus générale. En conclusion, il a pu être montré qu'aucune vitesse d'écoulement critique pouvant entraîner un "effet de lavage" du ciment à la surface du pieu lors des deux séries de tests n'a pu être atteinte.

Keywords: Bored piles; groundwater flow.

1 INTRODUCTION

Bored piles (EN 1536) are used in a variety of applications and often extend below the groundwater table. Below the groundwater table, they are produced by using the tremie method with temporary casing or with support fluid (e.g. EFFC/DFI Concrete Task Group, 2018). In international standards and recommendations, it is pointed out that high groundwater flow velocities can lead to erosion of particles from the fresh concrete. As a result, the

cement particles may be redistributed or removed from the freshly concreted pile.

The European Standard covering bored piles EN 1536:2010 points out that special attention must be paid to groundwater flow. Accordingly, groundwater flow can lead to a "washing-out" effect and reliable protection is advised, e.g., by permanent casing or lining. Related guidance can be found in other international standards and recommendations as:

- Finland: "Instructions for drilled Piling - Design and Execution Guide" (FINNRA, 2003)
- Germany: Recommendations on Piling "EA-Pfähle" (2013)
- United States of America: "Drilled Shafts: Construction Procedures and Design Methods" (Brown et al., 2018)
- Europe: Displacement piles (EN 12699: 2015).

There is consensus in all standards and recommendations that there is a potential risk of discharge of cement particles by groundwater flow. However, there are no limits given for a critical flow rate, neither could scientific studies be found which address this subject.

In 2012, laboratory tests were carried out on jet columns with cement paste at the University of Wuppertal (Department of Geotechnical Engineering). It could be shown that high groundwater flow can lead to a removal of cement paste which changes the shape and size of jet columns (Drzewiecki, 2012). However, the results cannot be transferred one-to-one to concrete piles, so further tests were carried out.

2 IMPLEMENTATION OF THE EXPERIMENTAL STUDY

2.1 Experimental set up

A test set up was designed at the University of Wuppertal for a systematic investigation of the influence of groundwater flow on bored piles (Fierenkothen et al., 2020). This set up enables the investigation of different groundwater flow velocities and different methods for the execution of bored piles such as borehole support by casing or by support fluid. The dimensions of the test set up are shown in Figure 1.
