A temporary casing with an external diameter of 219.1 mm was used for the construction of the model piles. For technical reasons, it was necessary to install the casing first. Afterwards, the sand was placed under water in layers and compacted. For the construction of model piles with excavation supported by support fluid, the suspension was first placed under the protection of the temporary casing. Before concreting, the casing was pulled except for a small part that remained as lead-in tube and the borehole was left under fluid support for 30 min.

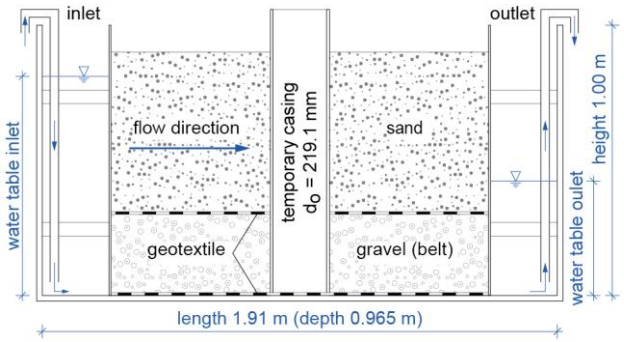

Figure 1. Test set up for the test with gravel belt, before concrete placement.

A pump circuit ensured a continuous flow through the experimental box. Inlet, outlet and flow direction are shown in Figure 1. For an evaluation of potential cement erosion at the pile cubature due to flow, the cured piles were recovered, visually inspected, and measured.

2.2 Experimental boundary conditions

Flow velocity, soils and concrete mixtures were varied in two series of tests. In the first series of tests, the filter velocity and the support of the borehole wall were investigated in particular. Two different sands were used as surrounding ground. The second series of tests focussed on the influence of the concrete mixture and a more coarse-grained soil as surrounding soil. The test stand allows for medium gravel as an upper limit. An overview of all tests and selected boundary conditions is given in Table 1.

Narrowly graded soils were investigated as surrounding ground, as these have a high permeability. In addition, they have a lower filter stability towards cement paste than wide-graded soils. For the second test series with gravel as surrounding soil, the challenge was to create a flow velocity as high as possible in the experimental box. This was achieved by arranging a gravel belt.

The grain size distributions of the three soils tested are shown in Figure 2. The estimation of the permeability coefficients was carried out according to Darcy and Beyer & Schweiger.

Table 1. Matrix of the physical model experiments.

soil		**concrete / suspension mix design**				**support**	**filter velocity v_f**
type	k_f	max. grain size	distribution	fly ash	plasticiser		in m/day
sand1	$k_{f,1}$	(cement paste)	-	yes	-	TL	100
		8 mm	B8	yes	p1	SF	120
			B8	yes	p1	TL	15 / 115 / 150
		16 mm	B16	yes	p1	TL	145
sand2	$k_{f,2}$	(cement paste)	-	yes	-	SF/TL	280/290
		2 mm	-	no	-	TL	435
		8 mm	B8	yes	p1	SF	380
			B8	yes	p1	TL	65 / 350 / 700
		16 mm	B16	yes	p1	TL	670
			A16	yes	p1	TL	280 / 295
gravel (belt)	$k_{f,3}$	2 mm	-	no	-	TL	1310 / 1540
		8mm	B8	yes	p1	TL	>> 846
			B8	no	p1 / p2	TL	1445 / 1320
			C8	no	p1	TL	1355
		16 mm	B16	yes	p1	TL	1365
			B16	no	p1/p2	TL	1330 / 1335
		32 mm	A32	no	p1	TL	1380

			B32	no	p1 / p2	TL	1575 / 1350

Explanation of abbreviations:
- $k_{f,1}$, $k_{f,2}$, $k_{f,3}$: permeability coefficients of the soils tested;
- distribution: grain size distribution as standardised in the German National Annex DIN 1045-2 to EN 206-1;
- p1, p2: different types of superplasticiser used for the concrete mixture;
- SF: support fluid;
- TL: temporary casing.

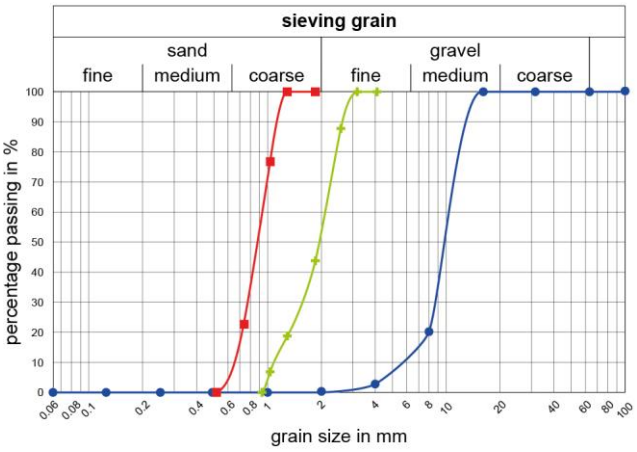

Figure 2. Grain size distribution of the surrounding soils. red = sand1, green = sand2 and blue = gravel (belt).

This results in the following permeability coefficients for the investigated soils:

- sand1: $k_{f,1} \sim 4 \cdot 10^{-3}$ m/s
- sand2: $k_{f,2} \sim 1 \cdot 10^{-2}$ m/s
- gravel: $k_{f,3} \sim 4 \cdot 10^{-1}$ m/s.

Different filter velocities were investigated. The filter velocity (v_f) is calculated as the ratio of the flow rate to the cross-sectional area of the groundwater flow at the location of the model pile. Depending on the soil and the flow velocity, different phreatic lines occur between inflow and outflow. As a result, only the lower part of the piles are exposed to groundwater flow (Figure 3 and Figure 4).

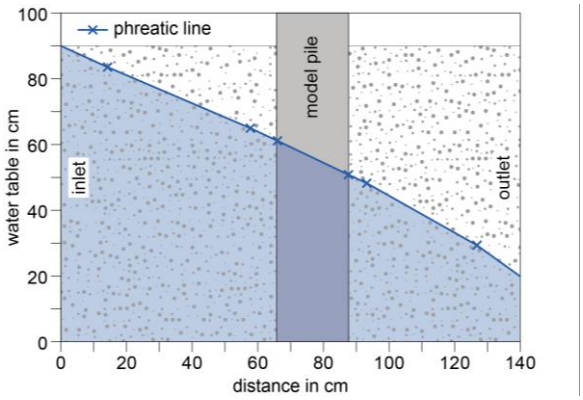

Figure 3. Exemplary phreatic line of the sands with representation of the level measurement points for sand1 with v_f = 120 m/d, according to Fierenkothen et al., 2022.

The mix design for the concrete consists of water, cement (CEM III/B 42,5), fly ash, aggregate and superplasticiser. In order to exclude the possibility of a different result when using a particle size distribution with a drop-out grain size or other admixtures, the

grain size distribution and the admixtures were also varied in the concrete mixture.

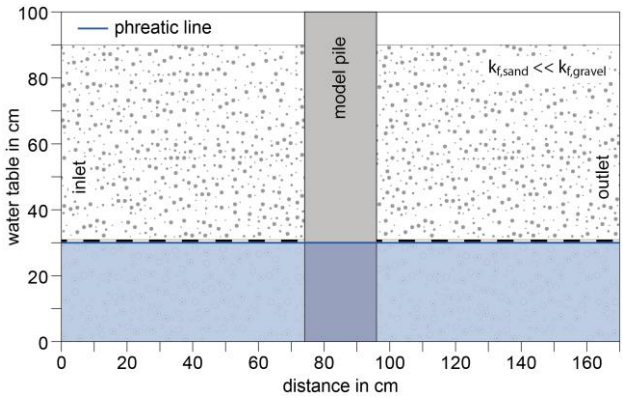

Figure 4. Exemplary phreatic line for the gravel belt.

Fly ash and superplasticizer have a strong influence on the consistency and stability of fresh concrete. Since the mode of action of the superplasticizer depends on the type of superplasticizer, a second type was used for the investigation. Superplasticiser p1 is based on a polycarboxylate ether and superplasticiser p2 is based on melamine/naphthalene sulphonate. In order to investigate the influence of fly ash, mix designs with and without fly ash were examined.

In addition, model piles were made using cement paste and mortar.

3 RESULTS

3.1 Bored pile excavation supported by casing

The cast in situ concrete model piles with temporary casing in both sand and gravel showed no visible anomalies in the contour after uncovering (Figure 5). Likewise, no visual anomalies could be observed on the cured and excavated model piles after pile installation in gravel (belt), regardless of the concrete mix.

For all cast-in-place concrete model piles with temporary casing, no critical flow velocity could be achieved which lead to anomalies. It was not possible to determine significant differences in pile diameter in and across the flow direction. Even though the flow velocities examined were often significantly higher than those occurring in practice (Table 1).

In contrast the model piles made of pure cement paste (in sand1 and sand2), clearly showed redistribution of the cement particles (Figure 6). The redistributions were significantly greater in the model pile with the higher flow velocity in sand2.

The cement particles have deposited as a plume in the shadow area of the model piles. The investigations showed that the strength of the deposits decreased with increasing distance from the pile.

a) *b)* *c)*

Figure 5. Contour of cast in situ model piles with temporary casing and max. grain size 8 mm: a) sand1: v_f = 115 m/d; b) sand2: v_f = 700 m/d (Fierenkothen et al., 2020); c) gravel (belt): v_f = 1445 m/d.

Figure 6. Exposed cement/sand plume of the model pile from cement suspension in sand2: v_f = 290 m/day (Fierenkothen et al., 2020).

3.2 Bored pile excavation supported by fluid

While a redistribution of cement particles was observed on the model piles made of cement paste with excavation supported by casing, in contrast, with support fluid (bentonite slurry), no discharge of the cement particle could be detected (Figure 7c).

Similarly, no visible discharge of cement particles was detected on the model piles made of concrete in sand with support fluid. During production, the support fluid was able to penetrate approx. 5 cm into the soil – except for the area of the lead-in tube at the pile head (Figure 8). A filter cake was formed due to penetration of the support fluid into the soil. No visual removal or displacement of penetratet support fluid resulting from groundwater flow could be detected.

a) b) c)

Figure 7. Contour of model piles constructed under support fluid: a) sand1: concrete with max. grain size 8 mm, v_f = 120 m/d; b) sand2: concrete with max. grain size 8 mm, v_f = 380 m/d; c) sand2: cement paste, v_f = 280 m/d (Fierenkothen et al., 2022).

a) b)

Figure 8. Penetration of the support fluid into the soil for sand2: cement paste, v_f = 280 m/d (Fierenkothen et al., 2022).

The model piles could be produced without anomalies in the contour due to the protection of the filter cake of the support fluid. It has been shown that the filter cake forms a protective layer against the discharge of cement particle.

All tests with the gravel belt with concrete as pile material and temporary casing showed no visual discharge of cement particles of the concrete. Therefore, concreting under support fluid was not further investigated.

4 CONCLUSIONS AND FUTURE PERSPECTIVES

During the investigations which were carried out in this study, no visible discharge of cement particles could be detected for the cast in situ concrete piles with excavation supported by casing or by support fluid. The investigated flow velocities were significantly higher than those generally observed in nature.

During the tests with cement paste (supported by casing), cement particles were redistributed into the surrounding soil. The production under support fluid prevented discharge. The filter cake of the suspension support forms a protective layer against an influence from groundwater flow.

The restrictions from standards and recommendations could not be confirmed for cast in situ concrete piles in sand and medium gravel. The contours of the piles did not show any changes. Additional investigations of the hardened concrete properties of the model piles are planned. In particular, it should be investigated whether there has been a change in the structure and strength of concrete in the edge area of the piles.

ABSTRACT: The aim of this article is to present the solutions for the main retaining walls and pavement strengthening, adopted in an industrial warehouse at Quinta do Adarse, in the proximities of the Tagus River right bank, at Alverca, Portugal. The existent cantilever reinforced concrete wall with 300m of length and 6m of maximum height, was strengthened with a cap distribution beam due to excessive deformation. The cap distribution beam was supported by inclined steel struts and founded on micropiles. At the warehouse pavements, some differential settlements were detected around the stiffer structural foundations, mainly due to the water inflow at the pavement earth fill foundation, which required a strengthening solution. Therefore, injections were used to avoid the replacement of the pavement and minimize the impacts on the warehouse's normal operation.

RÉSUMÉ: Le but du présent article est de présenter les solutions pour les principaux murs de soutènement et le renforcement de la chaussée, adoptées dans un entrepôt industriel à Quinta do Adarse, à proximité de la rive droite du Tage, à Alverca, Portugal. Le béton armé en porte-à-faux existant, qui est un mur de 300 m de longueur et 6 m de hauteur maximale, a été renforcé avec une poutre de répartition de couverture en raison d'une déformation excessive. La poutre de distribution du chapeau était soutenue par des entretoises en acier inclinées et fondée sur des micropieux. Au niveau des revêtements de l'entrepôt, certains tassements différentiels ont été mobilisés autour des fondations structurelles plus rigides, principalement en raison de l'afflux d'eau au niveau des fondations en terre de la chaussée, ce qui a nécessité une solution de renforcement. Par conséquent, des injections ont été utilisées pour éviter le remplacement du revêtement et minimiser les impacts sur le fonctionnement normal de l'entrepôt.

Keywords: Strengthening; wall; micropiles; pavement; injection.

1 INTRODUCTION

The aim of the present work is to present the adapted solutions for strengthening the retaining walls and pavements of an operating industrial warehouse, by using micropiles, cap distribution beams, and ground consolidation with polyurethane resin injection.

The reinforcement and strengthening of retaining walls and pavements at operating industrial warehouses require solutions with minimum impact on the normal operation.

Strengthening solutions with micropiles have advantages due to their diversity and execution possibilities for small spaces with difficult access, or sensitive to noise and vibrations, as well as soils with the presence of boulders, rock, concrete, and voids. The micropiles are also distinguished by the fact that they can be carried out on slopes (Barbosa, 2019).

To strengthen the pavements, a non-invasive technique may be required, with the physical-mechanical characteristics of the injected material remaining unchanged over time, so the solution of injecting expansive resin to treat the pavement foundation ground allows for a safe and practical intervention (Favaretti et al., 2014).

2 THE INDUSTRIAL WAREHOUSE

The site is a warehouse with an area of 20,250 m^2 (270 m x 75 m), built in the 1990's at Quinta do Adarse, Alverca, Portugal (Figure 1). The retaining wall is a reinforced concrete cantilever structure with 6 m of height extending over 320 m of length. The wall was designed to support the difference of approximately 4 m, existing between the lot where the warehouse is located and the adjacent areas.

The pavements with 5.0 m x 5.0 m panels were built with 0.10 m concrete industrial ground floor reinforced with steel mesh AR 30. The pavements

were founded on a 0.20 m thick layer of crushed stone or aggregates fill, separated from the underlying ground, most likely pre-existing landfills by a geotextile blanket. As it was an operating industrial warehouse under operation (Figure 2a), the stresses on the pavement are related to the weight of the materials stored on shelves (Figure 2b) as well as to the traffic of loading and transport equipment (forklifts).

Figure 1. Aerial view of the site (Google Earth).

Figure 2. a) External view of the warehouse and b) Internal view of the materials stored on shelves.

3 GEOLOGICAL AND GEOTHECNICAL PROFILE

The site under study is located, from a geological point of view, over an alluvium (a) and river terrace deposits (Qf), from the Quaternary, associated with the Tagus River basin, according to Sheet 34 B - Loures of the Geological Chart of Portugal at scale 1/50.000. It is constituted of clays, silty clays, sands, and silty sands with pebbles and sometimes conglomerates with limestone elements. These formations are based on Miocene layers of sands, sandstones, mudstones, and limestones from the Tortonian (MT).

The solutions proposed are based on the results of the tests carried out in the geological-geotechnical study, and in the values presented in the reference bibliography for alluvial soft silty-clay in Portugal (Esteves, 2014).

4 PATHOLOGIES

4.1 Retaining wall pathologies

There are occasional and localized phenomena of instability in the walls leading to cracks and excessive deformation (Figure 3).

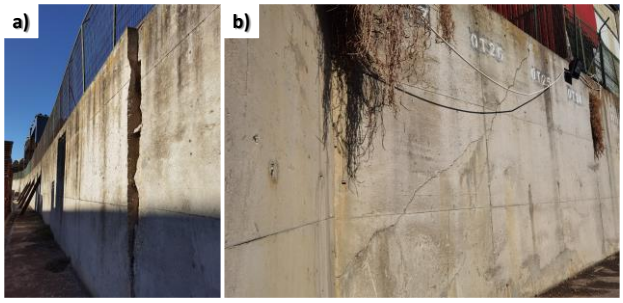

Figure 3. Pathologies at the retaining wall: a) excessive deformations b) cracks.

It should be noted the presence of four silos on the upper level, whose foundation solution was unknown. These structures may have increased ground pressure on the retaining walls. It can also be seen that, in some cases, the walls have already been reinforced in the past, with steel bracing solutions (Figure 4a) and nails or using tie rods (Figure 4b), which failed to stabilize the wall.

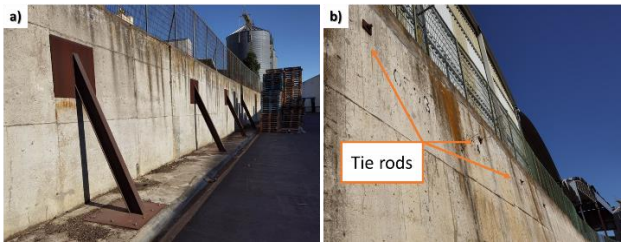

Figure 4. a) Steel bracing b) nailing or tie rods on the retaining wall.

4.2 Pavements pathologies

The loads to which the warehouse pavements are submitted are due to the weight of the materials stored on the shelves as well as the loads associated with the passage of loading and transport equipment (forklifts). It was seen that the pathologies worsened in the southern part of the warehouse indicating an increase in the pavements loads (Figure 5).

The pathologies, which required the adapted strengthening solutions, were identified in the pavements, facades, unloading dock, and stairs.

Close to the facades and columns, the presence of cracks in the concrete pavement was observed, as well as evidence of differential settlements between the pavement and the remaining structural elements (Figure 5a-b). On the walls of the east and west

facades, which were built of prefabricated concrete slabs, horizontal cracks were also observed (Figure 5c).

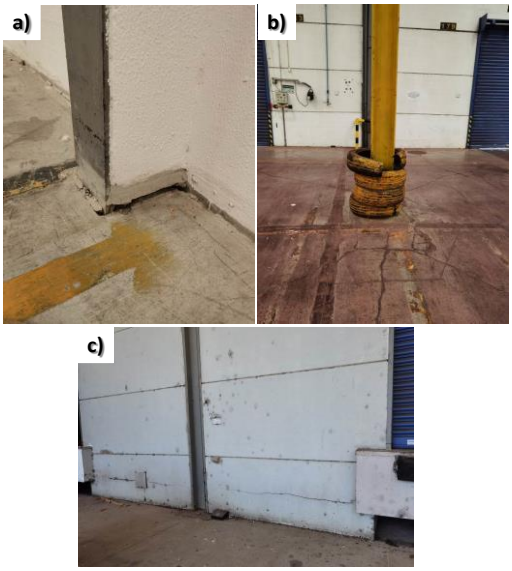

Figure 5. Main pathologies. a) differential settlements between the pavement and the facade, b) degradation of the pavement around a pile cap, c) cracking in the east side of the warehouse.

5 COMPRESSION STRENGTH TESTS ON CONCRETE

To find out the compressive strength of the existing wall concrete, six drillholes were made along the length of the wall, located at a height of 2.0 m perpendicular to the wall face. The collected specimens had a diameter of 82 mm and a length between 37.5 cm and 41.5 cm.

In general, the specimens were homogeneous, with a good distribution of limestone aggregate, but with some voids. These voids may indicate a lack of vibration during pouring.

Figure 6. Uniaxial compression-strength testing – UCS.

Uniaxial compression strength (UCS) tests were carried out on five of the collected specimens (Figure 6) to measure the mechanical resistance of the existing concrete wall. The uniaxial compression strength of the samples ranged between 16.56 MPa and 28.30 MPa.

6 STRENGTHENING SOLUTIONS

6.1 Retaining wall strengthening

The proposed solution includes the construction of a bracing element with the aim of increasing the wall resistance to horizontal pressure. This element consists of a 0.45 x 0.70 m distribution beam at the wall's mid-height, which is designed to transfer the horizontal forces to inclined micropiles, with tubular section of Ø88.9 x 12.0 mm and Ø88.9 x 9.5 mm, spaced 4.50 m, in the direction of the wall's development. The micropiles had a variable length of between 14 m and 15 m, thus guaranteeing minimum sealing lengths of 8 m and 9 m in the ground layer (natural ground with a NSPT of more than 20 blows).

To accommodate the increased vertical load caused by the axial force on the inclined micropiles, capping and distribution beams, were also built. Vertical micropiles were installed, also spaced 4.50 m. The vertical micropiles had an estimated variable length of between 11 m and 13 m, thus guaranteeing minimum sealing lengths of 6 m and 8 m in the stiffer ground layer.

The boreholes for placing the micropiles were at least Ø220 mm, and the tubes were subjected to filling and sealing injection. The injection was carried out using an appropriate system – I.R.S. (Repetitive and Selective Injection), using non-return valves and a double plug, for the length corresponding to the sealing bulb.

As the beam is supported directly on the micropiles, part of the steel tube was exposed permanently. Therefore, the micropiles were properly protected against corrosion, with a sacrificial thickness, compatible with the conditions of the environment and the life of the structure. Figure 7 shows the typical cross-section of the proposed solution.

Sub-horizontal geodrains with a diameter of Ø50 mm, creped and wrapped in 300 gr/m^2 geotextile, with a length of 3 m, were also installed, to relieve hydrostatic pressures. In addition, cracks in the existing wall were filled with non-shrinking mortar. To prevent the reoccurrence of pathologies, AISI316 stainless steel staples were also installed, spaced 0.40 m, whenever the cracks were larger than 10 mm.

Compression tests were performed in the concrete to evaluate the state of degradation of the wall. The structure was initially modelled using the GEO5

software to represent the current situation of the existing reinforced concrete wall, which only resists the static conditions, with a unitary safety factor. Subsequently, a second model was developed also considering the actions correspondent to earth pressures and surcharger to estimate the respective efforts and, therefore, to calculate the reinforcement structure in accordance with current regulations.

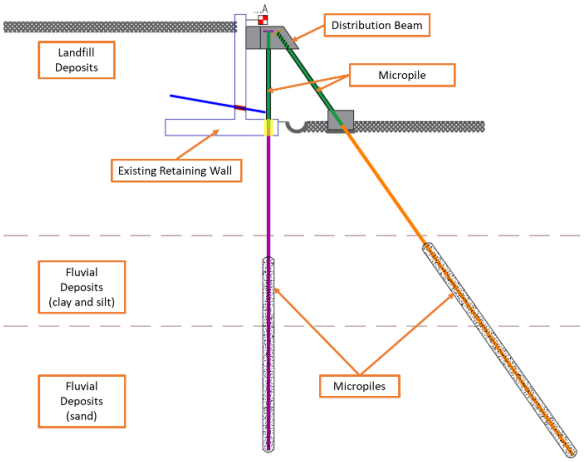

Figure 7. Cross section of the wall reinforcement solution

6.2 Pavement strengthening

The locations where internal erosion of the soil underlying the pavement was suspected a ground consolidation solution using the Uretek - Floor Lift type resin, or equivalent, was chosen. The resin has a density of 45 kg/m^3 (minimum) and expansion capacity up to 30 times its initial volume in free expansion.

This technique makes it possible to increase the compactness of the ground immediately below the pavement, without excavations, vibrations, or mechanical forces, thus minimizing the risk associated with possible damage to existing structures. The injections were made through small diameter holes, thus avoiding the need to build a new pavement structure (Uretek Floor Lift, 2023). In addition, this technology allowed to restore the pavement's planimetry and re-establish its contact with the ground (Figure 8).

In this context, the adapted solution consisted of drilling small diameter holes, arranged in a square grid of 1.20 x 1.20 m. Injection tubes were installed in these holes, approximately 6 and 12 mm in diameter. Through these tubes, a polyurethane resin was injected between the base of the industrial floor and up to approximately 1.0 m depth. In the first injection phase, the polyurethane resin, which is in liquid form, penetrates the voids in the soil and subsequently expands, sealing the surrounding soil, forming a rigid foam that increases the ground compactness. The injection process is monitored by reading equipment based on laser technology, indicating the increase in the soil's load-bearing capacity and the recovery of the differential settlements.

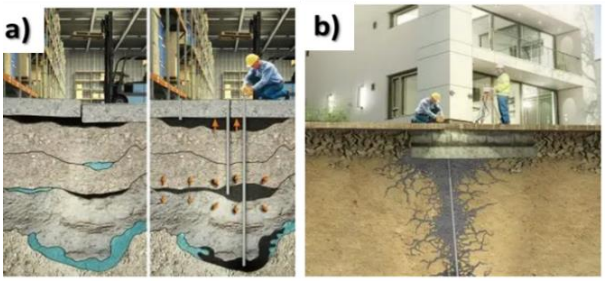

Figure 8. Injection system - Uretek Floor Lift (https://www.uretek.pt).

7 FINAL REMARKS

The aim of the present work was to present the designed solutions for strengthening main retaining walls and warehouse pavements. The strengthening solutions were defined considering the constraints, the severity of the detected pathologies and economic viability, with the aim of improving and guaranteeing the continued safe use of the warehouse area.

In the case of the retaining walls, the solution was associated to the construction of a bracing element for the existing support structure, which is a 0.45x0.70m distribution beam at the wall's mid-height, designed to transfer the horizontal forces to inclined micropiles. For the pavement, a ground consolidation solution of the Uretek - Floor Lift type was used, followed by drilling of holes in a square grid where polyurethane resin was injected.

Application of Cutter Soil Mixing technology in retaining walls

Application de la technique Cutter Soil Mixing dans les structures de soutènement

A. Peixoto*, P. Gomes
Artur Peixoto Lda., Braga, Portugal

**artur.peixoto@apgeotecnia.pt*

ABSTRACT: This article describes the Cutter Soil Mixing (CSM) technology as a solution for constructing peripheral retaining walls, presenting its characteristics, advantages over other technologies used in retaining walls, and how to design a retaining wall solution with CSM panels, which can be adapted to braced, anchored or top-down excavations. At the end, three case studies are listed, two braced retaining walls, one of which is prestressed, and one supported by slab bands, where the use of this technology proved to be important for the solution of excavation in an urban environment.

RÉSUMÉ: Cet article décrit la technique du Cutter Soil Mixing (CSM) comme une solution de construction de murs de soutènement périphériques, en présentant ses caractéristiques, ses avantages par rapport aux autres techniques utilisées dans les murs de soutènement, et la conception d'un mur de soutènement avec des panneaux CSM, qui peut être adapté à des excavations étayées, ancrées ou de haut en bas. Pour finir, trois études de cas sont indiquées, deux murs de soutènement contreventés, dont un précontraint, et un soutenus par des bandes de dalles, où l'utilisation de cette technologie s'est avérée importante pour la solution de l'excavation dans un environnement urbain.

Keywords: Urban excavations; deep excavations; Cutter Soil Mixing; CSM, retaining walls.

1 INTRODUCTION

The continued concentration of the world's population in large centres is forcing the construction of large habitable areas on an ever-smaller surface area. This is leading both to an increase in the height of buildings and the utilisation of the subsoil.

Due to the limited space and confinement of the available areas, excavations have to be made with a vertical face, requiring retaining walls near buildings or other structures that must be preserved.

Taking into account the growing public concern about environmental issues, it has become necessary to look for solutions that minimise the environmental impact of buildings, whether during exploration or construction. Over time, innovative and versatile techniques have been developed that allow local soils to be used as a construction material by mixing them in situ with stabilising compounds.

This article presents the Cutter Soil Mixing (CSM) technology as a solution for the construction of vertical, impermeable retaining walls capable of reaching great depths of known geometry, using soil as the construction material.

From a list of successful projects, it can be said that CSM technology is an interesting solution both technically and economically, and has been applied in various projects all over the world. This article lists three projects where this technology has been used to build vertical retaining walls in urban environments.

2 DESCRIPTION OF CSM TECHNOLOGY

Cutter Soil Mixing technology derives from Deep Soil Mixing (DSM) technology, combining its concepts with some of the principles of diaphragm walls, such as the use of hydromill and the geometry of the panels, as shown in Figure 1. A cutting tool for making CSM panels consists of two sets of cutting wheels that rotate around horizontal axes to produce soil-cement panels with a rectangular cross-section, unlike the DSM technology, which uses cutting tools that rotate around vertical axes to produce soil-cement columns (Stoetzer et al., 2006).

The cutting tool is attached to the bottom of a kelly bar, in a crawler crane fitted with a vertical tower.

The process of making a CSM panel comprises essentially two phases, the cutting phase and the extraction and mixing phase.

Figure 1. CSM equipment with rotation around horizontal axes and view of a CSM panel.

The cutting phase takes place during the descending movement of the tool to the required depth. As the cutting tool advances in depth, the hydraulic binder (usually cement grout) is added. The speed of the cutting tool and the volume of hydraulic binder added must be adjusted by the operator to optimise the use of energy and create a mass of homogeneous material that allows the tool to be lowered and raised easily. In difficult geological conditions or for CSM panels at great depths, it may be necessary to use bentonite during the cutting phase, with the cement grout being added to the panel only during the extraction and mixing phase (Peixoto et al., 2012a).

Once the desired depth has been reached, the kelly bar begins to rise by reversing the rotation of the cutting wheels and continuing to inject cement grout at low pressure. Figure 2 shows the execution process described.

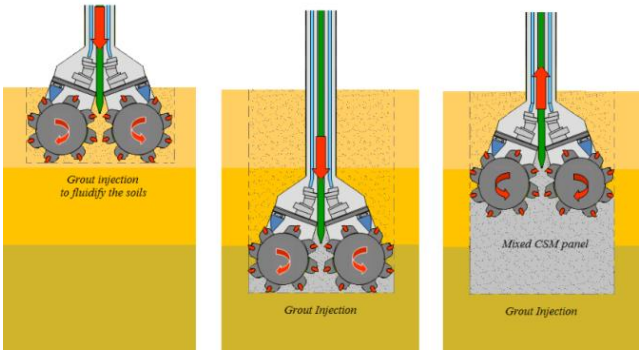

Figure 2. Illustration of the main phases of the execution of a CSM panel.

One of the particularities of this technology is that it allows the soil to be incorporated in situ into the retaining structure itself, with the retaining walls being executed sequentially by primary and secondary panels with a project-defined overlap length between them to obtain a continuous CSM wall. The fact that this technology allows soil to be used as a construction material, avoiding large volumes of material going to waste, is an advantage from an environmental and economic point of view compared to traditional technologies such as pile walls or diaphragm walls. A second advantage that should be emphasised is the knowledge of the exact geometry of panels in depth, since the equipment allows real time monitoring of the cutting tool's deviations during its advance in depth, making it possible to correct its positioning at any time. The process of mixing the hydraulic binder with the disintegrated soil can be influenced by various factors. In order to obtain CSM panels with the right characteristics, ensuring the homogeneity and reproducibility of the characteristics of the resulting material, it is essential to effectively control the execution parameters such as the speed of the cutting tool, the volume of grout added at depth, deviations of the cutting tool, among others (Bringiotti et al., 2009). Other advantage of this technology is that it can be applied to all types of soil, although the effectiveness of the application is not the same on all types of soil. Generally, the best results are obtained in sandy soils, as lower strengths are obtained in clay and silty soils for the same quantity of cement.

As illustrated in Figure 3, the use of soil-cement panels with a rectangular cross-section made using CSM technology for retaining walls has advantages when compared to the use of soil-cement columns made using DSM methods that use cutting tools that rotate around vertical axes (Fiorotto et al., 2005), and the following main advantages can be highlighted:

- reduction in the volume of soil treated to obtain the same effective treatment section and the consequent reduction in costs associated with this;
- reduction in the number of wall joints;
- the possibility of using different types of reinforcing elements for the panels, whose positioning in the panel itself can also be optimised.

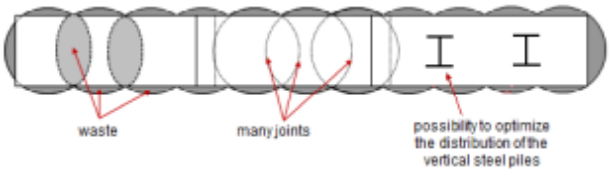

Figure 3. Comparison of the rectangular geometry of the CSM panels with the columns of the DSM methods.

3 RETAINING WALL SOLUTION

The most widely used peripheral retaining wall solution using Cutter Soil Mixing technology is the construction of a continuous wall of successive panels

2.4 metres wide and a constant thickness of 55 to 80 cm, depending on the project.

In order to ensure a continuous wall, panels are executed sequentially between primary and secondary panels, with an overlap length of 0.20 metres between them to ensure a good connection between adjacent panels in depth, as shown in Figure 4 (Peixoto et al., 2012b).

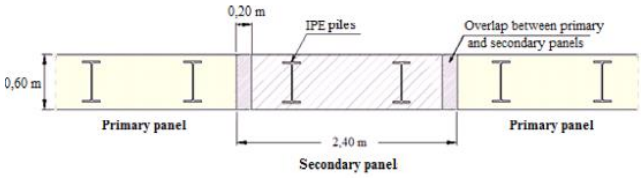

Figure 4. Primary and secondary panels of the CSM retaining wall.

The panels are made long enough to ensure the structural stability of the bottom and minimise the inflow of water into the excavation area.

Panels usually need to be reinforced to resist bending stresses. The most common method is to place steel sections inside the panel immediately after it has been made. The preference for IPE sections is due to the better flexural modulus to weight ratio. Placing the sections inside the CSM panels also protects them from possible buckling phenomena due to the confinement provided, and also minimises corrosion phenomena caused by the aggressiveness of the surrounding terrain.

The steel sections can be joined together with a reinforced concrete beam at the top of the wall.

The horizontal stability of the retaining wall is achieved in a similar way to the other types of peripheral retaining walls, such as horizontal bracing between elevations or for the excavation bed, temporary or permanent ground anchoring, or even through permanent slabs in top-down solutions. Due to the low shear resistance of CSM panels, horizontal forces must be redistributed to the anchors or struts through distribution beams.

The distribution beams or slabs that will resist the horizontal forces are supported on the retaining wall by steel sections, as shown in Figure 5.

In the case of permanent peripheral retaining walls, it is usual the construction of a reinforced concrete wall against the CSM panels. This wall can be built from the top down as the excavation progresses or from the bottom up when the structure is built. It is common to build this covering wall with a thickness between 0.15 and 0.20 m.

Figure 5. Photo of the HEA sections for connecting the slab at "Largo do Ambiente".

The Figure 6 shows a typical cross-section of a peripheral retaining wall executed with CSM panels and provisionally braced.

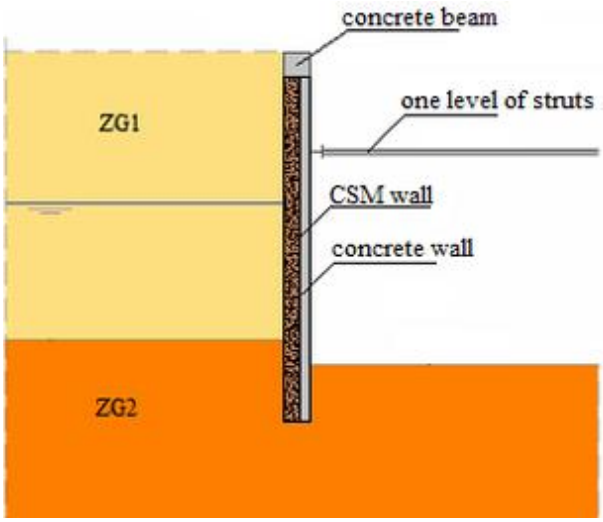

Figure 6. Cross-section of the retaining wall of the "Villa Paradisio" project.

4 DESIGN METHODOLOGY

In order to analyse the retaining wall, one or more calculation sections are defined that together represent the entire retaining structure.

The behaviour of each representative section is studied using analytical methods, such as free-earth support" or "fixed-earth support", or using automatic calculation programmes, such as PLAXIS® or PHASE2®.

All the elements of the retaining wall are designed in accordance with the legal standards, namely the Eurocodes in the European Union and Norway.

The vertical steel sections are designed to resist all the forces acting on the wall, disregarding the resistance of the soil-cement mixture, except for the seismic action in which the resistance is taken into account.

The soil-cement mixture, when in service, must have a sufficient compressive resistance to transmit the pressures to which it is subjected to the vertical steel sections. The transmission of these pressures is verified through the arc effect, as shown in Figure 7.

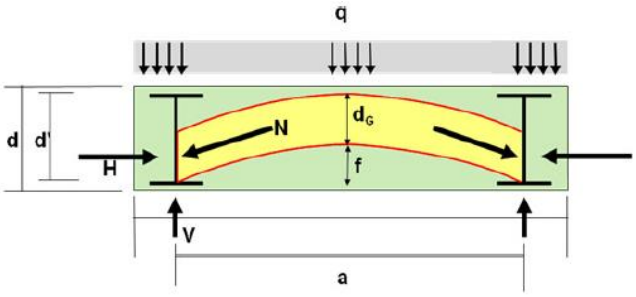

Figure 7. Distribution of horizontal stress in the cross-section of the retaining wall.

Horizontal support elements, such as anchors or struts, are designed in the same way as for other retaining wall construction techniques.

In the case of excavations below the water table, the hydraulic stability of the bottom of the excavation must also be verified, namely hydraulic uplift and internal erosion (piping), and the estimation of the volume of water that will flow into the excavation for designing the pumping system.

5 QUALITY CONTROL

The variability of the resistance and deformability parameters of the soil-cement resulting from the application of CSM technology is directly related to the degree of homogeneity of the mixture and it is influenced by various factors such as the type of soil involved, the presence of water, the distribution of the binder in the disintegrated soil mass, the presence of air as a component, the chemical reactions that take place during the mixing process, among others. For these reasons, it is necessary to take special care and carry out effective monitoring, both during execution and afterwards when evaluating the quality of the mixture according to the design requirements.

One of the main advantages of CSM technology over other alternative techniques, apart from the economic and environmental aspects (the use of in situ soil as a construction material), is the possibility of real-time control of the execution parameters by the equipment operator (Larsson, 2005). The operator has an instrument panel, as shown in Figure 8, that allows him to monitor and correct, in real time, parameters such as the advance speed of the cutting wheels, the amount of binder added, the density of the fluids involved (water-cement ratio) and the verticality of the panel, among others.

Figure 8. Cutter control panel.

In addition to the control made by the operator during the execution of CSM panels, the control is also achieved through laboratory tests combined with field tests on panels constructed for this purpose, which allow the execution parameters to be calibrated. Once the execution parameters have been calibrated, the construction of the CSM panels of the retaining wall can begin, from which samples are also taken for laboratory tests.

During excavation, monitoring is done following the Observation and Instrumentation Plan, which may include the placement of topographic targets on the retaining wall and neighbouring buildings, marks on the pavements, inclinometers, strain gauges installed in the struts and load cells in the soil anchors.

6 CASE STUDIES

6.1 Initial considerations

Cutter Soil Mixing technology is already being applied to retaining walls all over the world. This chapter presents two projects realised in the south of France and one in Luanda, Angola.

6.2 "Villa Paradisio" project

One of case studies is an excavation in Cannes for the construction of four underground floors of the "Villa Paradisio" building. The excavation site has a floor area of around 840 m^2, with an average excavation depth of 12 m, and directly faces neighbouring buildings and streets.

Despite the fact that the excavation is 12 metres deep in an urban context with the water table at about half the height of the excavation, the presence of the fractured dolomitic bedrock detected above the maximum excavation depth provided good support for the lower part of the retaining wall, allowing a solution

that included only one level of horizontal metal struts. This solution, in addition to containing the excavation with a vertical face, had a second objective of limiting the inflow of water into the excavation area (Peixoto et al., 2012c).

In this context, a retaining wall solution was proposed and designed consisting of a continuous wall of soil-cement panels with a rectangular cross-section with a thickness of 0.55 metres, up to an average depth of 15 metres, in order to guarantee a minimum length of 3 metres below the bottom of the excavation, reinforced with two IPE 450 beams in each CSM panel. A horizontal support level was defined for the approximately 12 m of total excavation height, materialised by tubular metal struts associated with metal distribution beams built along the perimeter of the site, as shown in Figure 9.

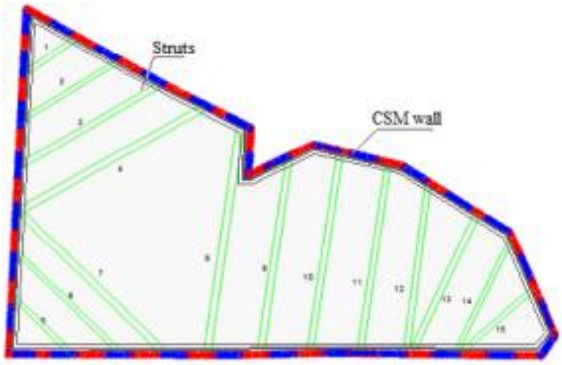

Figure 9. Plan representation of the retaining wall solution adopted for the "Villa Paradisio" project.

6.3 "May Flower" building

The "May Flower" building, located in Antibes, France, consists of eight elevated floors and four underground floors over an area of 317 m^2 and is bordered by streets and buildings.

The main challenge encountered in this project consisted of excavating to an average depth of 11 m in a densely constructed area, in the presence of soils with very variable mechanical characteristics, generally with low resistance values and high deformability to depths below the excavation base, and in the presence of a water table close to the surface (Gomes et al., 2016).

The solution proposed and designed consisted of a continuous wall of CSM panels, temporarily supported by four levels of metal bracing, with the lower three levels prestressed.

Limiting the inflow of water into the excavation was one of the project's concerns. To this end, a minimum embedment length of 6 metres was set from the bottom of the excavation and the panels were built to an average length of 17 metres.

Figure 10. Photo of the "May Flower" construction site before the application of the second level of bracing.

6.4 "Largo do Ambiente" underground parking

The "Largo do Ambiente" is an underground car park built in the city of Luanda, Angola. With capacity for 525 cars, it has two to five underground levels, corresponding to a variable excavation height between 8.0 and 17.4 metres. The excavation site directly faces existing buildings and streets and has a rectangular layout with an area of approximately 4,735 m^2.

Figure 11. Photo of the execution of the fifth and final slab band at "Largo do Ambiente".

The retaining wall was executed through soil-cement panels by the application of Cutter Soil Mixing (CSM) technology, reinforced with vertical steel piles. Taking in account the constrains related to the urban surrounding, including the proximity of buildings and streets, two to five levels of reinforced concrete slab bands were implemented, creating a rigid support system of the four elevations. The slab bands were incorporated on the final structure of the building and with this solution the execution of ground-anchors with big lengths that would lead to the occupation of the neighbour underground was dispensed. Furthermore, this solution brought some economic benefits, especially due to the incorporation of elements used in the final structure at the preliminary

stage of the work. The main objectives of the retaining wall were allowing the vertical excavation assuring simultaneously the stability of nearby structures and infrastructures, and also reduce the inflow of water into the interior of the excavation during the construction (Peixoto et al., 2016).

7 CONCLUSIONS

The application of CSM technology in retaining walls allows, with different geological and hydrogeological scenarios, to carry out excavations to the desired heights without compromising the stability of neighbouring structures.

With regard to the advantages of applying CSM technology compared to traditional techniques, should be emphasised the possibility of knowing the exact geometry of the soil-cement panels and the deviations that occur in depth, as well as the versatility of the equipment used. In these cases, the advantages were particularly important since, on the one hand, the knowledge of the exact geometry of the panels and the deviations in depth made it possible to achieve an effective connection between panels and a reduction in the inflow of water into the excavation area and, on the other hand, the versatility of the equipment made it possible to pass through the different materials that form the subsoil.

ABSTRACT: Currently, the particular context of each underground work leads to the choice of different constructive methodologies in view of the wide variety of existing options and in this sense the article will focus on the description of underground works evolution, in an urban environment, on Porto Metro, specifically the Hospital Santo António station. Hospital Santo António station is part of the future circular line, section Liberdade / S. Bento - Boavista / Casa da Música, and its location is conditioned by: proximity to a road tunnel (Túnel de Ceuta); by an underground water line (Rio Frio); the need to preserve tree species in the existing garden (Jardim do Carregal) and to minimize disturbances to adjacent buildings and traffic during construction. These constraints led to a unique geometric solution and constructive methodology, consisting basically of two large-section tunnels (approximately 200 m^2), which intersect obliquely, two large-diameter shafts with an approximate area of 400 m^2 (for access, ventilation and emergency exit) and two inclined tunnels to arrive at distribution floor for access to the dock platform. The methodology adopted in the tunnels is the NATM "New Austrian Tunneling Method", while in the large diameter shafts the vertical sequential excavation method was chosen. These methodologies are an excavation procedure with minimal support, which depends on the geomechanical and hydrogeological properties of the terrain, because it considers that the tunnel surrounding terrain contributes to its own support.

RÉSUMÉ: Actuellement, le contexte particulier de chaque ouvrage souterrain conduit au choix de différentes méthodologies constructives compte tenu de la grande variété d'options existantes et, en ce sens, l'article se concentrera sur la description de l'évolution des travaux souterrains, en milieu urbain, dans le Métro de Porto, plus précisément la station Hospital Santo António. La station Hospital Santo António fait partie de la future ligne circulaire, section Liberdade / S. Bento - Boavista / Casa da Música, et son emplacement est conditionné par: la proximité d'un tunnel routier (Túnel de Ceuta); par une conduite d'eau souterraine (Rio Frio); la nécessité de préserver les espèces d'arbres dans le jardin existant (Jardim do Carregal) et de minimiser les perturbations des immeubles adjacents et de la circulation pendant la construction. Ces contraintes ont conduit à une solution géométrique et une méthodologie constructive uniques, constituées essentiellement de deux tunnels de grande section (environ 200 m^2), qui se croisent obliquement, de deux puits de grand diamètre et d'une superficie approximative de 400 m^2 (pour l'accès, la ventilation et la sortie de secours) et deux tunnels inclinés pour arriver au plancher de distribution pour accéder à la plateforme du quai. La méthodologie adoptée dans les tunnels est la méthode NATM "New Austrian Tunneling Method", tandis que dans les puits de grand diamètre, la méthode d'excavation séquentielle verticale a été choisie. Ces méthodologies sont une procédure d'excavation avec un soutènement minimal, qui dépend des propriétés géomécaniques et hydrogéologiques du terrain, car elle considère que le tunnel entourant le terrain contribue à son propre soutènement.

Keywords: Underground infrastructure; urban environment; large diameter shafts; tunneling; Porto Metro.

1 INTRODUCTION

The "Santo António Hospital's" station, which is currently under construction, belongs to the Porto Metro circular line project, also known as Pink Line. The circular line extends through the central axis of the city of Porto, with a length of approximately 3.1 kilometers, and it foresees the construction of four new stations: Liberdade/S.Bento, Hospital de Santo António, Galiza and Boavista/Casa da Musica (Sener/CJC/NSE, 2020).

The Hospital Santo António (HSA) station is located in the Carregal garden, in the center of Porto and in the vicinity of the hospital with the same name, and its construction is influenced by several

constraints (Figure 1). One of them is the Ceuta tunnel (road tunnel), which crosses over the tunnel of the future circular line, immediately before the station, requiring a special care during the station's implementation. Furthermore, once the construction takes place in one of the most emblematic and ancient gardens in the city, there's a need to preserve, as much as possible, the tree species in the Carregal garden and minimize the disturbances on the surrounding environment and traffic during the construction phase, to ensure the easy access to the hospital. These factors had a significant impact on the decision to locate accesses and shafts, on the surface, as well as on the construction solution and method (Pereira, 2023).

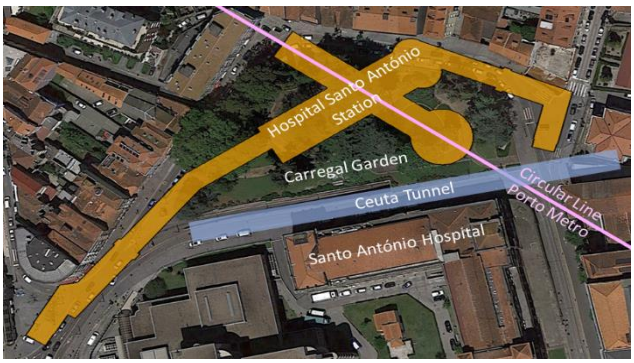

Figure 1. View of the Hospital Santo António station location.

2 CONSTRUCTION SOLUTION

The execution project, (Sener/CJC/NSE, 2019a), of the Hospital de Santo António station consists in the interconnection of two galleries with an angle of 66 degrees and a minimum cover of 11 meters.

The first gallery, named *Caverna Cais* (CC), extends for approximately 61 meters, covering an excavated area of approximately 172 m². In its cross section, the CC has a width of 18 meters and reaches a maximum excavation height of 12 meters. At the southeast end of the CC is the emergency exit shaft (EES). The EES has a circular configuration, with an average excavation diameter of around 24 meters (corresponding to an area of approximately 450 m²) and reaching a depth of approximately 27 meters.

The second gallery, named *Caverna Mezanino* (CM), extends approximately 62 meters, occupying an excavated area of around 260 m². In its cross section, the CM has a maximum excavation width of 20 meters and reaches a maximum excavation height of 17 meters. At the northeast end of the CM is the elevator shaft (ES). The ES has an elliptical shape, with an average excavation width of around 23 meters on the major axis and 18 meters on the minor axis (which corresponds to an approximate area of 325 m²) and has a depth of around 27.5 meters.

From the ES, there will be a connection with the surface through the construction of the east access tunnel (EAT). This tunnel will be approximately 25 meters long and its cross section will be variable. Initially, in the shaft-surface direction, the excavation section will be larger, covering around 130 m², with a height of 10.5 meters and a width of 15 meters. At the end of the tunnel, the excavation section will decrease to approximately 57 m², with a height of 8.3 meters and a width of 8.5 meters.

From the southwest end of the CM, a connection with the surface will be established through the construction of the western access tunnel (WAT). With an approximate length of 70 meters, this tunnel will feature a single excavation section, with an area of approximately 57 m², a height of 8.3 meters and a width of 8.5 meters and it will connect to the open ditch at its end. A three-dimensional modelling is presented in Figure 2.

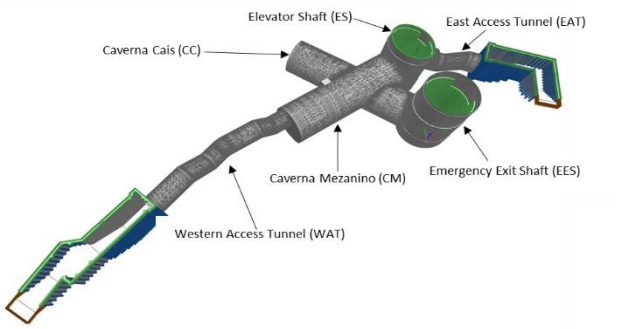

Figure 2. Three-dimensional modeling of the Hospital Santo António station (Pereira, 2023).

2.1 Construction methodology

The Hospital Santo António station will adopt three different methodologies: the underground station, composed of CM, CC, EAT and WAT, which will be carried out according to the NATM methodology; the connection of the east and west accesses to the surface, which will be executed through an open ditch and the two attack shafts to the station will be executed using a vertical sequential methodology (Sener/CJC/NSE, 2019a).

2.2 Geological-geotechnical background

The city of Porto is closely linked to its impressive granite massif. This massif stands out in the outcrops along the coastline and on the city's cliffs. However, the geotechnical conditions are complex due to the tectonic setting of the granite massif and the hydrothermal changes and weathering that occurred after its formation.

This granite massif, called *Granito do Porto*, has two micas, with a predominance of muscovite, and has a medium grain, sometimes coarse. Fine-grained aplite-pegmatite transitions are also common.

The geology in the region, of the future circular line of the Porto Metro, is characterized by the granite massif covered by landfills and, frequently, by alluvial soils (Sener/CJC/NSE, 2019b).

The geological-geotechnical characterization of the region where the HSA station is located (Figure 3), defines that the upper lands, made up of landfills and alluvium whose development follows the morphology of the paleo valley represents, as a whole, the filling of the Rio Frio valley and are part of the geotechnical unit G7 which reaches 10 to 12 meters deep. The landfills are sandy and heterogeneous, including granite blocks, organic levels and debris remains. The lower alluvial soils are essentially made up of silty-clayey sands and sandy-clayey silts, brown or dark grey (Sener/CJC/NSE, 2019b).

The G6 and G5 units follow the G7 unit in depth. These geotechnical zones consist of very compact granite alteration soils and decomposed granite, respectively, characterized by a sub-horizontal development, with corrugated boundaries, which reaches a depth of 21 to 24 meters. In some areas of the station, the decomposed granite massif (G5) transitions to highly altered granite massifs (G4). The G3 geotechnical zone occurs below the G5 unit, occasionally appearing in the form of loosely continuous blocks within the G5 unit. The granite massif of unit G3 is classified as moderately altered, with closely spaced and moderately spaced, oxidized and open fractures. In the center of the station, the G3 granite massif quickly evolves into G2, characterized as little altered. Locally, there are intersections of sub-vertical fracture alignments, mainly without filling, which represent preferential zones of percolation and water storage in the rock mass. Before excavations began, the average water level was approximately 7 meters deep from the surface (Sener/CJC/NSE, 2019b).

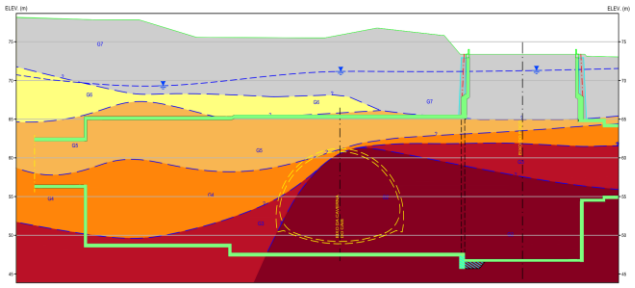

Figure 3. Geological-geotechnical longitudinal profile of the Hospital Santo António station.

3 EXECUTIVE SEQUENCE

Before the beginning of the excavation works, preparatory works were meticulously carried out in March 2021. These preparations were essential to enable the construction of the station and included the following tasks: alteration of local road traffic routes; execution of infrastructure diversion, including the diversion of the Rio Frio; carrying out an archaeological survey campaign and installation of the geotechnical instrumentation system in the massif and adjacent structures.

After the preparatory work are completed, the construction of the HSA station began. At this point, it is important to highlight that the construction process took place in a progressive and structured way. A concise summary of the activities that have been carried out up to the beginning of October 2023 will be now presented, as following.

The works on the HSA station began with the construction of the EES. Considering the presence of G7 surface terrain, it was necessary to implement a perimeter treatment into the massif surrounding the two attack shafts, which consisted in vertical drying jet-grouting columns with 0.8 meter in diameter. Once the jet-grouting columns were completed, the excavation works for the shafts started. The excavation works and application of the primary lining was carried out dividing the shaft into levels, with 1 meter high and panels 6 meters long, up to 27 meters deep, according to the execution project. From a depth of 9 meters, geodrains were installed to relieve hydrostatic pressure in the temporary lining, without causing a sharp lowering of the water level. The primary lining around the main tunnel and CC were reinforced to allow the excavation works to begin on both structures, dismissing the execution of the definitive lining of the shaft at this stage.

Subsequently, the works on the CC proceeded, interspersed with the advancement of the main tunnel, using the NATM methodology and divided into two phases: top heading divided into side-drift and enlargement and undercut. After advancing 6 meters, a stoppage wall was created. This front is on hold until the CM definitive lining work is completed.

When the execution of the EES was 15 meters deep, the ES excavation work began, following the same sequential methodology for executing the EES. The ES excavation was temporarily halted at a depth of 17 meters, which is the depth coinciding with the height of the CM top heading, EAT and WAT invert. After the completion of the excavation work on the top heading and the first undercut of the CM, the excavation of the ES will be resumed.

The CM excavation is expected to be carried out in a sectional manner: in a top heading (divided into side-drift and enlargement), first and second undercut, respecting the NATM methodology (Figure 4).

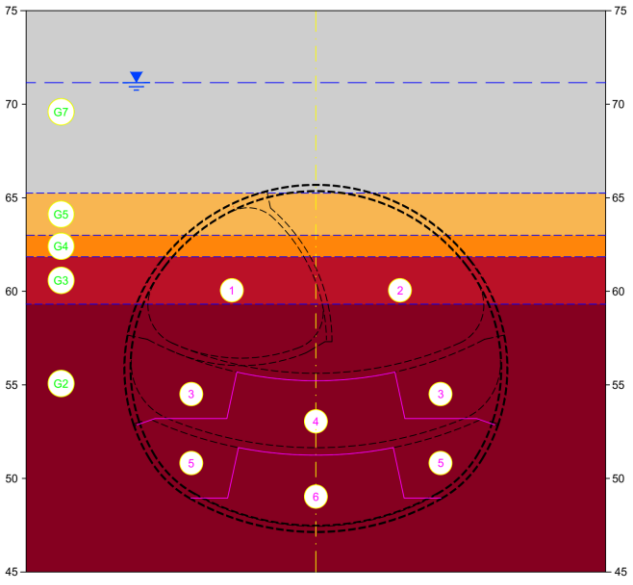

Figure 4. Executive phasing of Caverna Mezanino.

The excavation works, from the ES, began with the contour and front treatments of the CM and EAT portal. After the excavation of the CM side-drift was able to proceed. The enlargement of the CM's top heading began as soon as the side-drift was in the middle of the CM. After completion of the CM top heading, the stop wall and treatments of the WAT portal were carried out. The first undercut will begin once all the works for the WAT are concluded, from this work front.

While the CM was excavated, the excavation of the EAT also began, following the NATM construction sequence, up to approximately 12 meters in advance. Regarding WAT, underground excavation works advanced by around 12 meters. On the date of completion of this article, the EAT and WAT excavation fronts were being stopped, waiting the progress of the works being held from the surface, for the completion of the EAT and WAT excavation work.

At the same time and in order to guarantee the success of the project, a team of geologists and geotechnical engineers were designated to monitor the development of the works, on a daily basis. This group of professionals played a fundamental role in carrying out detailed cartography of the excavation fronts, carefully documenting the geological, geotechnical and hydrogeological characteristics found.

A geotechnical instrumentation plan was also implemented, during all the progress. This plan is based on a flexible project philosophy, providing a systematic control of the works and ensuring the project's assumptions. It also allows to adapt and adjust the project, if necessary, to ensure the compliance with deadlines and eases the management in case of geological-geotechnical and urban context unforeseen events, without underestimating safety.

4 CONCLUSIONS

The construction of the Santo António Hospital station, as part of the Porto Metro circular line, faced a series of constraints that required a careful designed constructive solution. This solution, with a bold and avant-garde approach, has proven to be suitable, even in an urban environment.

As the works approaches to the completion, it will be relevant to consider producing a scientific article addressing the geological complexities faced during construction, the performance of support structures over time and the impacts on the massif and structures adjacent. This will allow a critical assessment of what was predicted in the execution project compared to what was found during the construction phase.

ACKNOWLEDGEMENTS

The authors express their gratitude to Metro do Porto for the authorization granted to use elements of the project and photographs of the work in the presentation of this article.

ABSTRACT: Improving the soil in place by adding lime, hydraulic binder and increasing compaction is widely used to carry out geotechnical works. Laboratory test campaigns are conducted to validate the treatment and its consistency with the expected mechanical properties. They allow on the one hand to follow the mechanical evolution due to hydration of the cement phases and on the other hand to observe the soil response under various stresses. The standards for treated soils recommend carrying out tests on specimens which have undergone curing conditions in airtight packaging, at a temperature of 20°C and atmospheric pressure. However, if these normalized conditions represent the conditions of a low height embankment, when the structure is of great height it is interesting to take into account the pressure to which the material is subjected during its curing. The study focused on comparing the evolution of the mechanical properties of silt treated with lime and hydraulic binder then compacted, when it was subjected to a normalized cure or a confined cure of 500 kPa. In order to monitor the mechanical gain of the confined specimen regularly and without modifying its curing conditions, a resonant column apparatus (RCA) in torsion mode was used. With this device carrying out measurements of the shear modulus in very small deformations, the curing and testing phases could be coupled, the tests not being destructive. The curing stress brings the expected properties more quickly and confers superior properties of around 15% in the long term.

RÉSUMÉ: L'amélioration des sols en place par ajout de chaux, liant hydraulique et compactage est largement employée pour réaliser des ouvrages géotechniques. Des campagnes d'essais en laboratoire sont conduites afin de valider le traitement et sa cohérence avec les propriétés mécaniques attendues. Elles permettent de suivre l'évolution mécanique liée à l'hydratation des phases cimentaires et d'observer la réponse du sol sous diverses sollicitations. Les normes sur les sols traités préconisent de conduire les essais sur des éprouvettes ayant subi des conditions de cure dans un emballage hermétique, à température constante de 20°C et à pression atmosphérique. Cependant, si ces conditions normalisées représentent bien les conditions d'un remblai de faible hauteur, pour un ouvrage de grande hauteur, il est intéressant de prendre en compte la pression à laquelle le matériau est soumis. L'étude s'est portée sur la comparaison de l'évolution des propriétés mécaniques d'un limon traité à la chaux et au liant hydraulique puis compacté, soumis à une cure normalisée ou une cure confinée de 500 kPa. Afin de suivre le gain mécanique de l'éprouvette confinée de manière régulière et sans modifier ses conditions de cure, une colonne résonnante en mode torsion a été utilisée. Avec cet appareil réalisant des mesures du module de cisaillement en très petites déformations, les phases de cure et d'essais ont pu être couplées, les essais n'étant pas destructifs. La pression pendant la cure apporte plus rapidement les propriétés attendues et confère sur le long terme des propriétés supérieures d'environ 15%.

Keywords: Stabilized soil; lime and binder treatment; resonant column apparatus; curing stress conditions; shear modulus.

1 INTRODUCTION

The use of stabilized soils in geotechnical infrastructure works is widespread today because it provides ecological and economic gain. This reduces CO^2 emissions linked to the transport of excavated and backfilled material, and minimises the use of non-renewable materials from quarries. In order to predict

the reaction of the soil to the treatment and the mechanical gain that could be provided over time, experimental campaigns in the laboratory are carried out. Overall, laboratory experimental conditions tend to represent *in situ* conditions as closely as possible (state of stress, saturation and draining condition, compaction etc.). In the case of improved soils, the mechanical properties of these materials vary according to the curing time, as they are a function of the hydration reactions of lime and binder's cementitious phases. This is because the hydrated phases form shells around the soil that has flocculated after the lime has been added (Cabane, 2004). To ensure these reactions, the standards recommend curing conditions in laboratory for treated specimens: stored hermetically at a temperature of 20°C and at atmospheric pressure (LCPC/SETRA, 2000). These test conditions generally make it possible to well simulate the *in situ* soil conditions in low-rise structures. However, previous authors have noted that notable differences in terms of mechanical properties were measured between specimens of materials cemented in the laboratory and specimens cored when the soil was taken at great depth (Consoli et al., 2000). This phenomenon is studied in the field of Cement Paste Backfill (CPB) (Zhao et al., 2021) or cemented sands (Basas et al., 2020) but currently little for treated fine soils (Åhnberg, 2006).

The objective of this article was to highlight the mechanical property differences for a stabilized silty soil with two curing conditions: one curing at atmospheric pressure and the other with isotropic curing stresses (500 kPa) applied throughout the curing time (up to 70 days). For this purpose, it was necessary to measure the evolution of the mechanical properties of the confined specimen without modifying its curing conditions. A resonant column apparatus (RCA) in torsion mode was therefore used in the study. It allowed the measurement of the shear modulus G as a function of the distortion in very small deformation (between $10e^{-7}$ and $10e^{-4}$) (Lang et al., 2020). Furthermore, this test being non-destructive, it was possible to carry out all measurements on the same sample kept confined throughout its treatment. The results of these tests were compared to tests carried out on specimens which had had a standardized cure and a specimen of untreated silty soil.

2 MATERIALS AND METHODS

2.1 Materials

The material used was a low plasticity silty soil that comes from northern France. In the 0.2 mm sieve, 80% of the granulometry corresponds to silts. The X-ray diffraction (XRD) analysis indicated a composition of quartz, carbonate phases (calcite and dolomite), silicates (muscovite, microcline and clinochlore) feldspaths (albite), clay minerals (kaolinite) and hematite. To this soil with poor geotechnical properties was first added 1% lime. This lime is made up of approximately 90% quicklime (CaO). Then 5% of a hydraulic binder was added. This binder has a claimed composition of approximately 35% Portland cement clinker and 65% blast furnace slag (similar to a CEM III/A).

2.2 Specimen preparation

The freshly treated soil was then placed in a single layer in a mould for static compaction. The force was applied on both sides of the cylinder until 96% of optimal density and w = OMC+1% (Optimum Moisture Content). displayed by the proctor curve was reached (Figure 1). This curve indicates that the maximum dry density measured (ρ_d = 1.75 Mg/m^3) corresponds to an OMC = 17.5% The saturation ratio (Sr [%]) lines on the figure correspond to 100%, 90% and 80% pore water saturation.

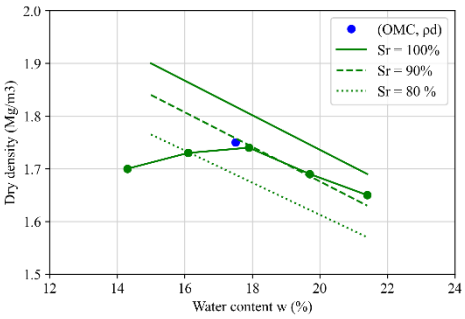

Figure 1. Proctors curve and saturation lines (Sr).

A compaction curve was plotted for each compacted specimen. The curves with e, the void index, as a function of sigma, the axial stress [kPa] in Figure 2 illustrate the homogeneity of the specimens produced. The average void index of the 10 specimens was e = 0.58, the minimum 0.55 and maximum 0.59. The standard deviation of these measurements is 0.014. To be able to compare mechanical results tests, the initial void index of the specimens must be equal.

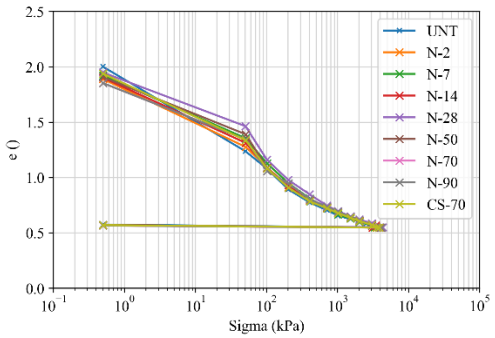

Figure 2. Compaction curves.

2.3 Curing and testing conditions

The characteristics of the 9 tested specimens are listed in. The untreated specimen (UNT) did not require any curing time and was tested immediately after being compacted with an isotropic confining pressure of 500 kPa. Normalized specimens (N-2, N-7, N-14, N-28, N-50, N-70 and N-90) were hermetically protected and placed in an air-conditioned room at 20°C without being subjected to curing stresses. Those were maintained in this condition for a define curing time and a different specimen was used for each curing time test. In contrast, to study the specimen subjected to curing stress, the soil specimen was not packed but directly placed in the RCA cell with an isotropic curing stress (CS) of 500 kPa for 70 days (CS-70). At the beginning of this curing time, one test per day was done, with one test per week conducted at its end. All the present tests were conducted on unsaturated specimens with drain open to the air, at testing pressure of 500 kPa.

Table 1. Curing and testing conditions.

Specimen	Curing time (days)	Curing stress (kPa)	Testing pressure (kPa)	Gmax modulus (MPa)
UNT	untreated		500	175
N-2	2	0	500	512
N-7	7	0	500	571
N-14	14	0	500	632
N-28	28	0	500	860
N-50	50	0	500	966
N-70	70	0	500	1069
N-90	90	0	500	1127
CS-70	70	500	500	1267

*UNT: untreated **N: normalized curing conditions ***CS: curing stress conditions

2.4 Resonant column apparatus tests

The evolution of the shear modulus as a function of distortion is obtained by torsion tests in the RCA. In this apparatus, the specimens are held fixed at the base and torsionally excited at the top. For each step of imposed amplitude, the resonance frequency corresponding to the maximum measured amplitude is determined. The tests were performed starting at the lowest amplitudes (0.005 V) up to the highest (1 V) with about 25 measurement points. At each point, the resonance frequency f_n [Hz] of the material can be used to calculate an angular frequency ω_n [rad·s^{-1}] (1). The resonance frequency is the lowest frequency at which the torsion is 90° out of phase with the rotational displacement. From the angular frequency it is possible to calculate the shear wave velocity V_S, which is used to calculate the shear modulus G [MPa] (1).

$$\omega_n = 2\pi f_n \qquad V_s = \frac{\omega_n L}{\beta} \qquad G = \rho V_s^2 \quad (1)$$

Where L [m] is the length of the specimen and β depends on the apparatus specificities and the specimen geometry. ρ is the specimen density [g.cm^3]. The maximum amplitude A_{max} [V] corresponding to the resonance frequency provides the distortion ϒ (2):

$$\Upsilon = \frac{4{,}596.A_{max}.D}{f_n.L} \quad (2)$$

The G modulus measured at the smaller amplitudes (0.005 V) and distortions is called Gmax.

3 RESULTS

As detailed above, torsional RCA tests provide shear modulus decrease curves as a function of distortion. The test results are presented for each curing condition (standardised then confined) and compared with an untreated and compacted silty specimen. A total of 38 tests were carried out.

3.1 G modulus as function of distortion

The results of tests carried out on specimens under normalized curing conditions are shown in Figure 3 in which each curve corresponds to a specimen. The results of the tests on the curing stress specimen (CS-70) are shown in Figure 4. During 70 days of curing, each of the 30 tests was carried out at a curing time specified in the legend (e.g. CS-70-2 d; for a test at 2 days curing time). In these two figures, the blue curve (▼) corresponds to the untreated silty specimen which has a Gmax of 175 MPa at a shear deformation of 5e^6. By comparison, the specimens of treated soil are located on much smaller deformations.

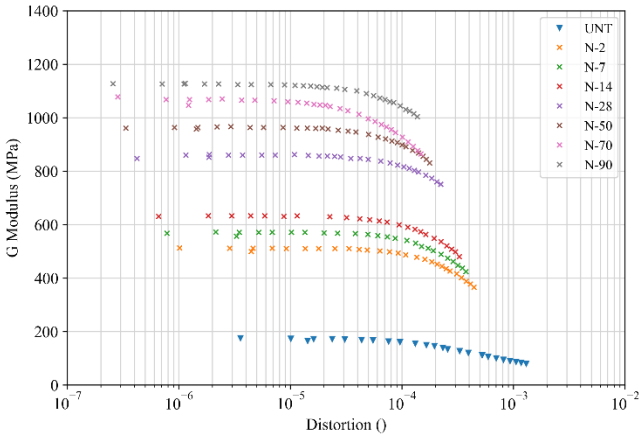

Figure 3. G modulus as function of distortion for normalized curing conditions.

The mechanical evolution within the specimen as a function of curing time is visible at several levels: the evolution of the shape of the curves, the increase in Gmax as a function of time, and the shift of the curve towards smaller deformations. In these figures, it is remarkable that the greatest mechanical gain takes place in the first 2 days of curing time.

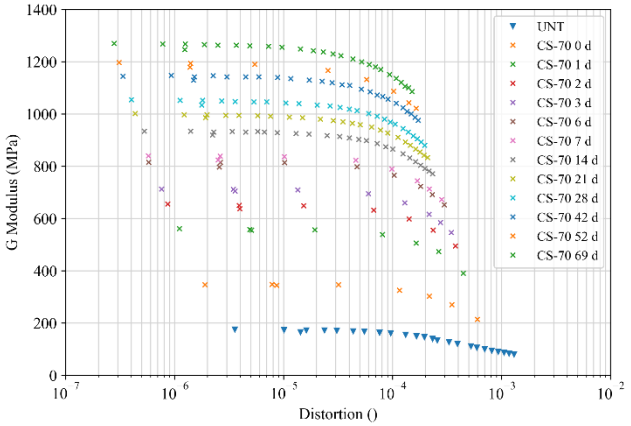

Figure 4. G modulus as function of distortion for curing stress conditions.

3.2 Kinetics comparison

The Figure 5 shows the Gmax as a function of time for the 35 tests performed. It highlights two different hydration kinetics. The first one corresponds to the specimen cured with a curing stress (CS-70) and second one corresponds to specimens cured without stress and tested at different curing times with the RCA (N, green curve). Therefore, the specimen CS-70, after 42 days with a curing stress of 500 kPa (CS-70-42 d on Figure 4), reaches the Gmax as the specimen N-90 curing without stress (CS-70-41 d, Gmax = 1137 MPa; N-90, Gmax = 1127 MPa).

A difference of approximately 200 MPa between the Gmax of the two curing conditions is measured from 14 days and up to 90 days.

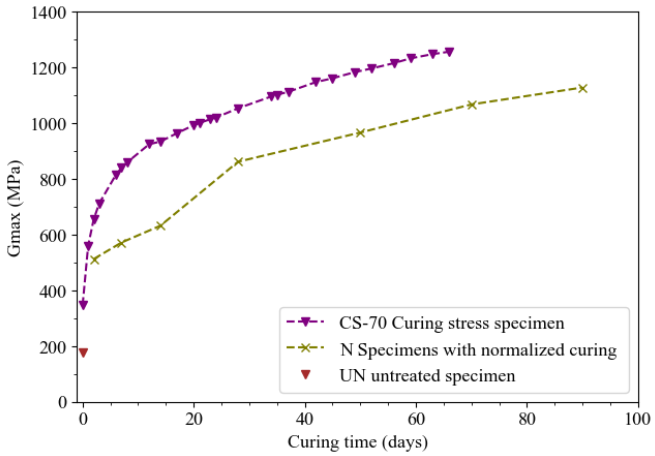

Figure 5. Gmax as function of time.

4 CONCLUSIONS

This experimental campaign showed that there was indeed a difference between the evolution of the shear modulus measured for the confined and unconfined soil specimen during its curing time. It also highlighted the fact that the resonant column is a good tool for studying soils treated in the laboratory (allowing small deformation and non-destructive measurements). Further work is underway to investigate the microstructure and chemical composition inherent to these mechanical tests.

ABSTRACT: The North Lisbon Logistic Platform is located over soft soils at Tagus river right bank. At the Plot 1 an industrial warehouse with about 100.000 m^2 was built. For the warehouse foundations the following solutions were adopted: i) structural elements: reinforced concrete driven piles; ii) indoor pavements: load transfer platform, granular fill reinforced with geosynthetics, over rigid inclusions, geoconcrete columns (GCC) with under reamed base and capped by stone columns; iii) outdoor pavements: load transfer platform, granular fill reinforced with geosynthetics, over stone columns. The main design and execution criteria are presented, as well as the main results of both site monitoring and full-scale load tests.

RÉSUMÉ: La plateforme logistique du nord de Lisbonne est située sur des sols meubles sur la rive droite du Tage. Sur la parcelle 1, un entrepôt industriel d'environ 100.000 m^2 a été construit. Pour les fondations de l'entrepôt, les solutions suivantes ont été adoptées: i) éléments structurels: pieux battus en béton préfabriqué; ii) revêtements intérieurs: plateforme de transfert de charge, remblai granulaire renforcé de géosynthétiques, sur inclusions rigides, colonnes en géobéton (GCC) avec base sous alésage et coiffées par des colonnes ballastées; iii) revêtements extérieurs: plateforme de transfert de charge, remblai granulaire renforcé de géosynthétiques, sur colonnes ballastées. Les principaux critères de conception et d'exécution sont présentés, ainsi que les principaux résultats du suivi du chantier et des essais de charge en vraie grandeur.

Keywords: Driven piles, rigid inclusions, stone columns; load transfer platform; soft soils

1 INTRODUCTION

The North Lisbon Logistic Platform (NLLP) is located in Castanheira do Ribatejo, Portugal. This platform was built with the intend of creating an interconnection point for international, national and regional logistical flows within the Lisbon and Tagus Valley region. An example of recent construction in NLLP is presented in Lopes et al (2023) .

On plot 1 of the NLLP a new industrial building with an area of approximately 100.000 m^2 was built. In the aerial view in Figure 1, it is possible to identify its location.

The target area of intervention is located on the right bank of the Tagus River, that, from a geological-geotechnical point of view, is dominated by the alluvial terrain of the lower Tagus, characterized by the presence of soft soils with reduced bearing capacity. In the particular area where the new structure is located, the alluvium reaches considerable depths, of the order of 12.0 to 18.0 m, posing serious challenges to the construction of any structure in that location.

Figure 1. Aerial view of the construction site (image taken from Google Earth).

2 GEOLOGICAL AND GEOTECHNICAL CONDITIONS

The site under study fits, from a geomorphological point of view, in the middle of the alluvial plain of the Tagus river, close to the right bank of this main watercourse.

Local geological conditions therefore indicate alluvial formations, of Holocene age, deposited over a sedimentary substrate, called terrace deposits, attributed to the Plio-Pleistocene.

According to the information obtained during the geotechnical investigations, it appears that the local geological-geotechnical scenario is characterized by a layer of surface deposits, developing to a depth variable between 2.0 m and 3.0 m. According to the available sampling, it is a heterogeneous layer made up of a mixture of very soft to medium consistency clays, silts and sands ($0<N_{SPT}<8$). It is considered likely that these materials present an overconsolidated state, as a result of fluctuations in the water table.

Immediately below the layer of surface deposits, to a maximum depth of 12.0 to 18.0 m, there are alluvial soils, essentially made up of (i) very loose to loose sandy-silty horizons detected with thicknesses varying between 1.5 and 6.0 m ($0<N_{SPT}<8$); and (ii) very soft to soft silty clays with thicknesses varying between 6,0 and 11.0 m ($0<N_{SPT}<4$).

Underlying the alluvial layer, there are deposits of Plio-Pleistocene terraces, characterized by the interspersed occurrence of clay, sand and of gravel horizons, all with significant lateral continuity.

As depth advances, an increase in the resistant behaviour exhibited by this formation is observed, as shown by the generally increase of N_{SPT} values in depth, with the lowest values, generally varying between 14 and 30 blows, coming from the top of the formation, showing the occurrence of a more weathered surface zone, with behaviour of moderately dense to dense materials and generally hard to very hard consistency. An exception is made for some specific levels where the SPT tests indicate soft to medium consistency soils among the most compact materials.

The position of the water table is dependent on the water level in the Tagus river, being influenced not only by seasonal variations, but also by the daily tidal cycles felt in the estuary. During the prospecting geotechnical works, the presence of the water table was detected at a depth varying between 1.68 m and 2.12 m.

3 SOLUTIONS

Given the existence of highly compressible cohesive soils, the presence of geological and geotechnical conditions that are globally unfavourable to the accommodation of high and/or persistent loads is evident, with the risk of accentuated and evolving deformable behaviour over time. Consequently, there is a concern about mitigating immediate and deferred deformations, in accordance with the structure serviceability requirements. In this context, the following solutions were adopted:

a) Pile foundations for the warehouse resistant structure;
b) Ground improvement solutions of the foundation soil of interior and exterior pavements using (i) rigid inclusions, using the GEOPIER® GCC system, with a bi-module gravel and concrete cap and (ii) stone columns, using the GRAVA IMPACT® system.

3.1 Pile foundations

The proposed deep foundation solution consists of prefabricated reinforced concrete driven piles, of the TERRA® type, capable of accommodating compression, tension, flexural-compression, flexural-tension and shear loads.

T-350 piles (350x350mm) with a minimum length of 25.0 m were considered, with a seismically reinforced section in the first 12.0 m to be considered from the base of the pile cap. In Figure 2 a photograph of the prefabricated reinforced concrete driven piles on the construction site is presented.

Figure 2. Driven piles.

The stated piles are capped by reinforced concrete pile caps of 1, 2, 3, 4, 5, 6 and 7 piles that, whenever submitted to bending moments that are not possible to accommodate by the binary of forces achieved by axial stresses developed on the vertical piles, are interconnected by a grid of foundation beams, also in reinforced concrete.

Along the peripheral alignment, a solution using sub-verticals piles (10º from the vertical) was also defined. These will have the function of accommodating the vertical and horizontal forces coming from the earth retaining walls on the periphery of the building.

In addition to what was mentioned above, the piles must also be responsible for dissipating the shear coming from the pillars and walls, as well as ensuring the accommodation of the bending stresses developed in depth due to the action of the shear forces.

In Figure 3 a view of the 3D geometric model of the structure's foundation solution is presented.

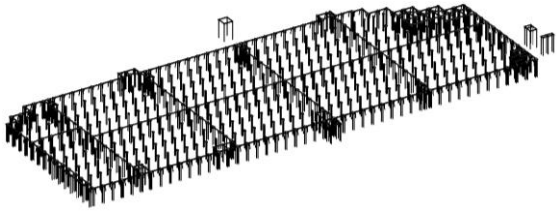

Figure 3. 3D geometric model of the structure's foundation solution (not to scale).

3.2 Ground improvement

Considering the geotechnical conditions described, aiming to reduce total and differential settlements, it was decided to implement, for the indoor pavement as well as the exterior loading/unloading docks pavement area where heavy vehicles will be parked, a ground improvement solution comprising the execution of rigid inclusions, using the Geo-Concrete Columns (GCC®) of the GEOPIER system, with under reamed base, under a load transfer platform, consisting of layers of granular fill reinforced with geosynthetics

The aforementioned rigid inclusions are arranged in different square arrays depending on the magnitude of the expected service live load. In Figure 4 and Table 1, a schematic plan is presented, with the location, spacing and magnitude of the different service live loads considered.

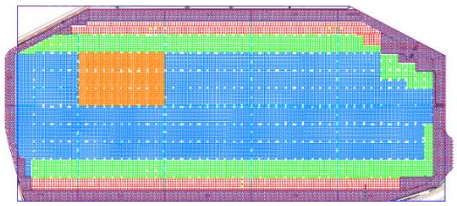

Figure 4. Schematic plan with the ground improvement solutions (not to scale).

Table 1. Live loads and ground improvement techniques considered for the pavement's foundation soil.

Zoning	Live load	System	Spacing
1	75 kN/m^2	GCC Rigid inclusions	2,30 m
2	50 kN/m^2		2,60 m
3	32 kN/m^2		3,10 m
4	20 kN/m^2		3,25 m
5	20 kN/m^2	IMPACT Stone columns	2,50 m

Prior to the installation of the rigid inclusions, in order to reach the levels foreseen for the pavements, an embankment with an average thickness of approximately 2.0 m was built. In this context, to minimize the excavation works, it was decided to execute pre-drilling works and install a stone column cap on top of the concrete columns.

For the exterior pavements, in the area intended for car traffic, likewise aiming to minimize total and differential settlements, a ground improvement solution using stone columns, using the GRAVA IMPACT® system was adopted. The stone columns are arranged in a triangular mesh spaced 1.2 m, under a load transfer platform, consisting of layers of granular fill reinforced with geosynthetics.

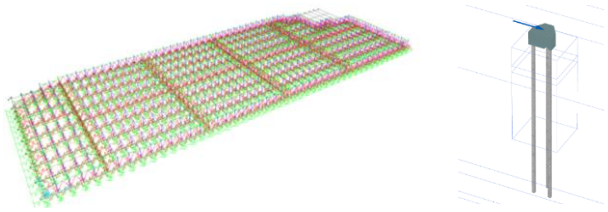
In Figure 5 a photograph of the load transfer platform is presented.

Figure 5. Load transfer platform.

4 DESIGN

4.1 Pile foundations

The foundations as well as the building's structure were modelled using the SAP2000 finite element software, in which the various structural elements were represented with their true dimensions and stiffness. In Figure 6 the 3D foundation model is presented.



a) *b)*

Figure 6. a) Foundation's structure 3D SAP2000 finite element model. b) Pile Plaxis 3D finite element model.

For a more realistic analysis of the forces and displacements to which the structure and its foundations will be subjected, spring elements with vertical, horizontal and flexural stiffness of the various types of pile cap and prefabricated piles in each vertical structural element (columns and façades) were considered. The vertical and flexural spring stiffness were estimated based on the vertical static load tests carried out. The Plaxis 3D finite element software was

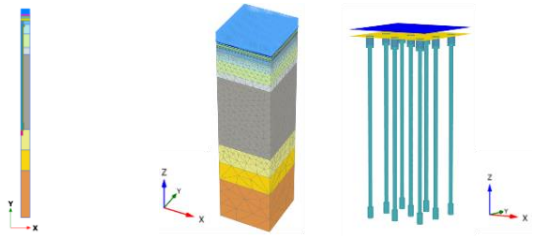
used to determine the horizontal stiffness of the piles, as well as to quantify the axial stresses due to the effect of negative skin friction and bending moment distribution along the piles.

4.2 Ground improvement

The study of the ground improvement solutions was based on an initial calibration phase through stress-strain analyses, namely, two-dimensional finite element analysis, in axisymmetry condition, using the Plaxis 2D software, simulating two of the static vertical load tests carried out on site.

In a second phase, the project ground improvement solutions were modelled, also through two- and three-dimensional finite element analysis using the Plaxis 2D and Plaxis 3D software respectively.

With this analysis the stresses, strains and displacements in the rigid inclusions, stone columns and geosynthetics were estimated. The settlements on the pavements were also calculated and compared with the floor's serviceability requirements. In Figure 7 some of the 2D and 3D calculation models are presented.



a) *b)*

Figure 7. Ground improvement finite element calculation models a) Plaxis 2D, axisymmetry conditions. b) Plaxis 3D.

5 MONITORING AND FULL-SCALE LOAD TESTS

Prior to the execution of the work, a set of static and dynamic load tests on vertical prefabricated driven piles were carried out. The aforementioned tests allowed the analysis of the behaviour of the piles with regard to force-settlement curves, being therefore fundamental elements in the design stage.

As part of the quality and execution control of the stone columns, as well as the GCC rigid inclusions, a set of static vertical load tests were also carried out, considering loads higher than the expected service load.

Additionally, in order to evaluate the performance of the ground improvement solution in the medium and long term, a full-scale test was carried out, through the construction of an experimental landfill over four GCC rigid inclusions lasting approximately 5 months, up to 200% of the service load. The results, presented in Figure 8, confirmed that the expected settlement was inferior to the considered admissible value. In Figure 9, it is possible to view the full scale and static vertical load tests.

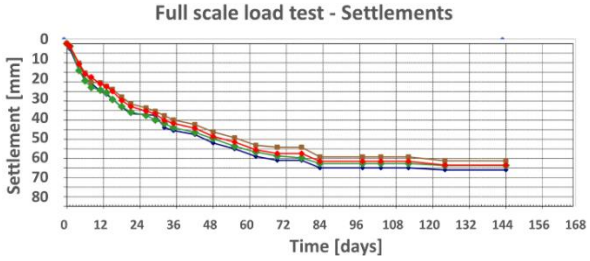


Figure 8. Full scale load test – Settlement evolution over time.

a) *b)*

Figure 9. a) Full scale load test. b) Static vertical load test.

6 FINAL REMARKS

The framework of the work described determined the need to develop economic foundation solutions compatible with the structure serviceability.

In this context, it should be noted that the adopted ground improvement solutions allow for the reduction, in the foundation structural elements, of the design seismic horizontal forces originating from the expected high magnitude pavements live loads.

It also made it possible to reduce shear stresses and bending moments at the floor slab, thus allowing for considerable savings in the reinforced concrete pavement structure.

ACKNOWLEDGEMENTS

The authors would like to thank the site owner and GSE for authorizing the presentation of this paper. It is also worth highlighting the fact that the pile and ground improvement works were carried out by the company "Terratest".

ABSTRACT: This paper describes the special foundations solutions adopted at the cycle-pedestrian bridge built over the Trancão River, connecting Lisbon to Loures. The bridge structure is a laminated wood deck, supported by steel cables, with a 65m central main span. Considering the very low resistance and high deformability of the superficial alluvial layers, it was necessary to design a deep foundation solution, resting at the Miocene bedrock. Reflecting the local geological scenario, as well as the restraints related with the use of heavy equipment at the riverbanks, the foundation solution consists of micropiles, vertical and inclined, executed using the self-drilling methodology, associated with the execution of 500mm diameter mini jet grouting columns, ranging from about 30 to 20m. The main quality control / quality assurance (QC/QA) results, including two full scale tension load tests, are presented.

RÉSUMÉ: Cet article décrit les solutions de fondations spéciales adoptées pour le pont cyclable-piéton construit sur la rivière Trancão, reliant Lisbonne à Loures. La structure du pont est un tablier en bois lamellé collé, soutenu par des câbles en acier, avec une travée centrale de 65 m. Compte tenu de la très faible résistance et de la déformabilité élevée des couches alluviales superficielles, il était nécessaire de concevoir une solution de fondation profonde, reposant sur le substratum rocheux du Miocène. Compte tenu du scénario géologique local, en plus des contraintes liées à l'utilisation d'équipements lourds sur les berges, la solution de fondation consiste en des micropieux, verticaux et inclinés, exécutés selon la méthodologie de auto forage, associés à l'exécution de mini colonnes de jet grouting de 500 mm de diamètre, allant de 30 à 20 m. Les principaux résultats du contrôle de la qualité e du contrôle de l'exécution (CQ/QA), bien aussi que deux tests de charge de traction à grande échelle, sont présentés.

Keywords: Jet grouting; micropiles.

1 INTRODUCTION

The new cycle and pedestrian bridge over the Trancão river was built before the World Youth Day 2023 (WYD), with the main objective to connect the paths already existent at both banks of the Trancão river (Loures at North and Lisbon at South).

With this purpose, a three span (28m+65m+28m, 121m overall length) cable stayed bridge, with laminated wood deck, steel towers and cables, resting over reinforced concrete columns and abutments, was built. At Loures and Lisbon sides, respectively, access ramps with 82m and 70m were built, the last one parallel to the Trancão river (Figures 1 and 2).

Figure 1. Bridge location (Google maps, without a scale).

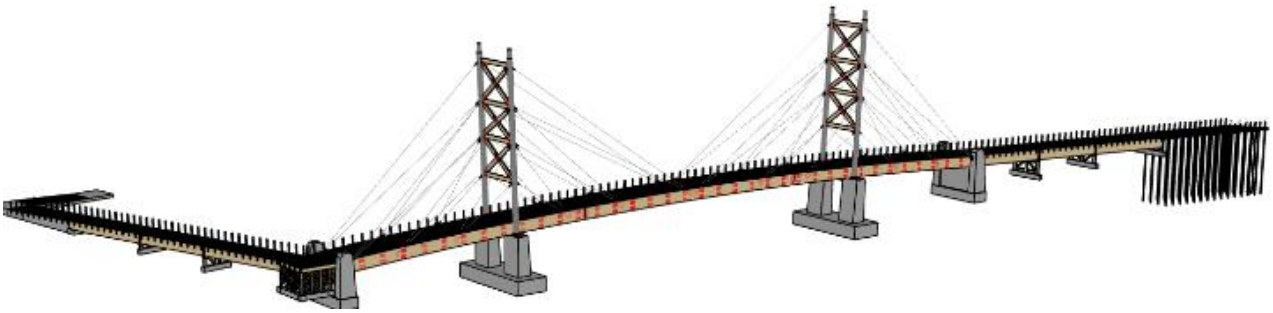

Figure 2. Bridge 3D view (JETsj project).

2 GEOLOGICAL CONSTRAINS

The geological investigation campaign included the execution of four boreholes and allowed the confirmation of the ground geotechnical zones (ZG). It was possible to confirm, from the surface, the existence of 2.5m heterogeneous landfills (ZG1), resting over very soft alluvial (Tagus River basin) materials with overall thickness ranging from 14 to 22m, with N_{SPT} blows not bigger than 2 and undrained shear strength (Su) not bigger than 20kPa (ZG2).

Under that layer, the Miocene loose sandy soils (ZG3) over the sandstone bedrock (ZG4) were found, the last one with very good resistance and deformation characteristics (Figure 3).

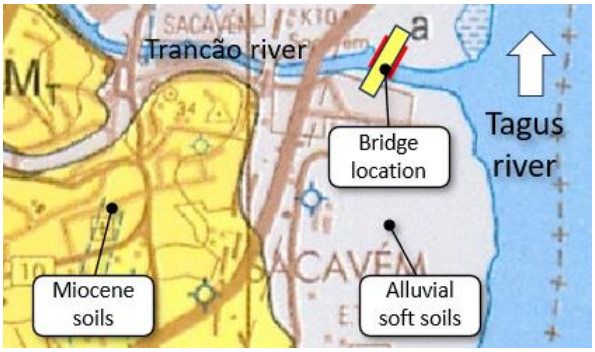

Figure 3. Geological scenario plan with bridge location (Portugal geological map, without a scale).

3 FOUNDATIONS SOLUTION

Considering the geological and geotechnical restraints, the compression and tension loads to be transmitted by the bridge to the ground, as well the restraints related with the use of heavy equipment at the riverbanks soft soils, the foundation solution consisted on micropiles ANP ϕH1600-76mm, ϕH0950-51mm and ϕH0550-38mm hollow steel bars with sacrificial grouting bits, vertical and inclined, executed using the upper – bottom self-drilling methodology, associated with the execution of 500mm diameter mini jet grouting columns at the ZG1, ZG2 and ZG3 geotechnical zones, ranging from about 30 to 20m (Figure 4).

Maximum jet grouting pressure was 200bar, compatible with the micropiles coupler's resistance. Due to the Atlantic Ocean proximity, leading to water chlorides, for durability reasons, pozzolanic cement with a consumption ratio of 160kg/m^3 was used.

The jet grouting columns had three main functions: i) increase the micropiles stiffness mainly against buckling; ii) increase the micropiles protection against corrosion; iii) reduce the micropiles overall length at the Miocene bedrock, particularly when the columns intersected the Miocene loose sands, at the South riverbank.

Figure 4. View of the micropiles hollow bars and bits.

The micropiles were capped by reinforced concrete caps, supporting the bridge columns and abutments. The loads were transmitted to the Miocene layer mainly by shaft resistance: i) at the South riverbank, starting at the loose sandy materials taking advantage of the 500mm jet grouting columns shaft resistance (qs); ii) at the North riverbank, at the Miocene bedrock, where the maximum diameter was only 250mm (Figure 5).

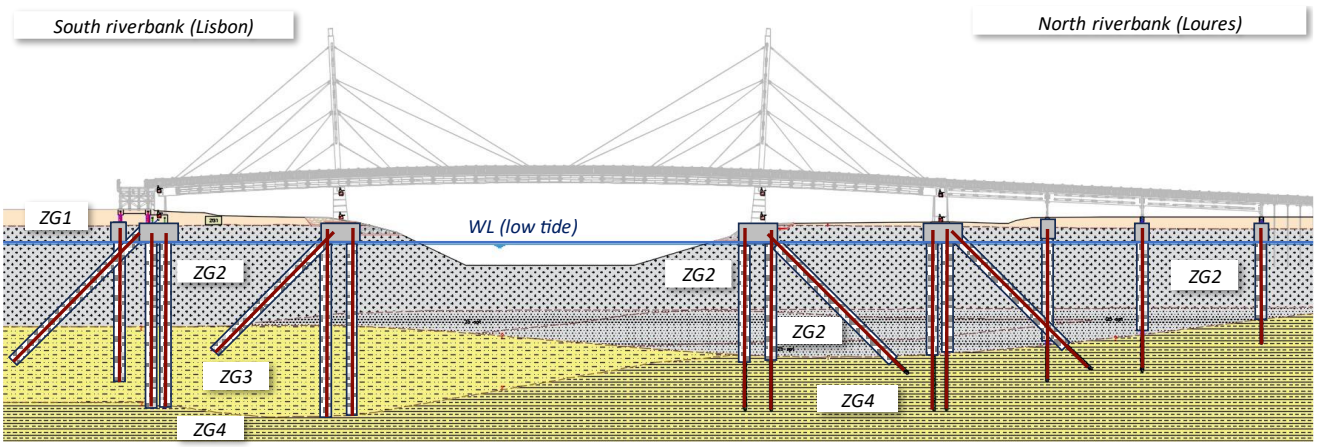

Figure 5. Bridge elevation with geotechnical zones (JETsj project, without a scale).

4 QUALITY CONTROL AND QUALITY ASSURANCE

4.1 Trial columns

Before the execution of the full-scale load tests, several jet grouting trial columns, with different cement consumption, were performed to check both the columns geometry and resistance at the very soft resistance alluvium layer (ZG2).

The columns resistance was evaluated trough unconfined compression strength (UCS) tests, performed trough cores collected from the columns at 28 days. At UCS tests both the columns unconfined compression resistance and Young's modulus were checked and compared with the design requests at 28 days: 3MPa and 1GPa, respectively (Figure 6).

Figure 6. Trial column view.

4.2 Tension full scale load tests

To confirm the design main assumptions, mainly the micropiles and jet grouting shaft resistance (qs), two suitability tension full scale load tests were performed, one in each riverbank, close from the bridge central columns.

The reaction structure was a reinforced concrete cap (2x2x1m^3) supported by four inclined self-drilling micropiles. The central tested micropile was reinforced with one ϕ35mm Gewi Plus S670/800 bar, protected by a smooth sheath at the landfill (ZG1) and alluvium (ZG2) layers, ensuring the unbonding length. A hollow plunged jack was used to apply a maximum load of 500kN to the micropile through the ϕ35mm bar (Figure 7). The maximum applied load was 1.67 times bigger than the maximum tension service load, approximately 350kN (Figures 8 and 9).

Figure 7. Full scale tension test: reaction structure view.

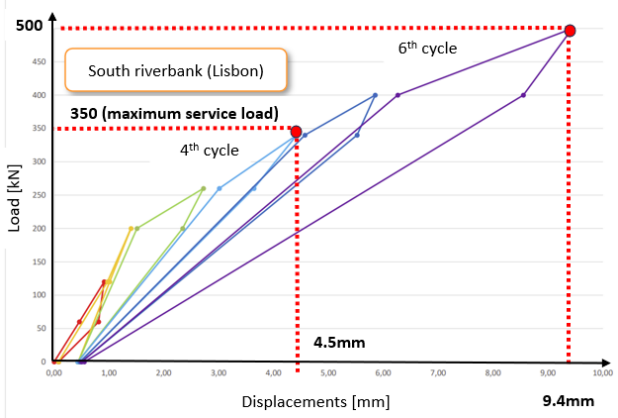

Figure 8. Load vs head displacements (South riverbank).

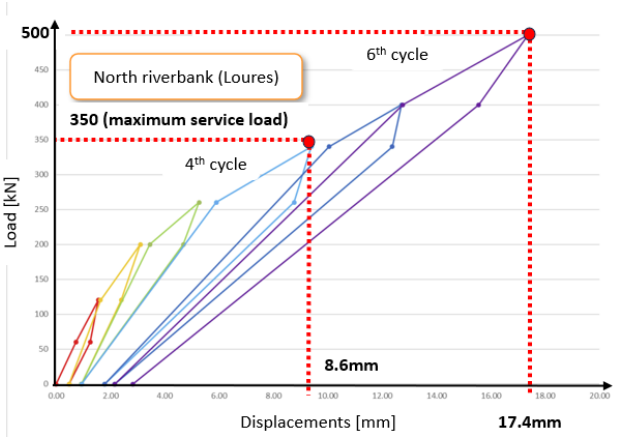

Figure 9. Load vs head displacements (North riverbank).

After 6 load and unload cycles the maximum displacements were 9.4mm and 17.4mm at, respectively, the South and North riverbank load tests. The plastic displacements were, respectively, 0.5mm and 2.5mm. The explanation for those differences could be related with the micropiles stiffness, as on the South riverbank the loaded micropile full length was inside a jet grouting column at the Miocene loose sandy soils (ZG3, with qs not lesser than 25kPa) and the alluvium (ZG2) thickness is lower (Figure 5).

Despite the tension loads at the micropiles are mainly due to wind and seismic loads, on both load tests the creep coefficient, for a minimum permanent load time of 30 minutes, was lesser than 1mm. The obtained results allow to confirm the suitability of the design and execution parameters.

4.3 Execution parameters recorder

All the jet grouting execution parameters were automaticallty recorded using a computer device and compared with the ones established based on the trial columns and suitability full scale load tests results.

5 DESIGN

The bridge foundations were designed using PLAXIS 2D, FEM stress-strain software. The shaft resistance values were initially estimated using reliable proposals (Bustamante, 2002) for jet grouting. The model was adjusted by back analysis after the full-scale load tests. According to the bridge monitoring, using prisms and topographic readings, since its opening to cycling and pedestrian traffic (Figure 10), the deck displacements have been in accordance with the estimated ones at the design stage.

Figure 10. Bridge view just before the YWD, August 2023 with the deck being reinforced for the pope's car crossing.

6 FINAL REMARKS

The presented case study allowed to confirm the advantages of foundation solutions using mini jet grouting columns combined with self-drilling micropiles in complex geological and geotechnical scenarios. As main advantages, compared with conventional solutions, can be pointed out: light, small and versatile equipment, minimum ground extraction, schedule prediction, and overall costs.

ABSTRACT: This article presents the design and execution guidelines of the Carvoeira, Portugal, electrical facility road embankment stabilization. The embankment is 15 m high and has a history of pathologies since construction. In 2011, the embankment collapsed. Despite the implementation of stabilization and reinforcement measures, carried out in 2012, in the last few years, the embankment has showed signs of a continuous and evolutive process that could lead to a new collapse. The failure patterns are discussed based on the initial project data, the history, and main constraints, especially concerning geological, geotechnical and hydrogeologic conditions. The impact of the existing infrastructures and the need to maintain the electrical facility operational are discussed as well. In 2020, a new rockfill solution is presented, highlighting the design process, the criteria to select the rock materials and the strength and drainage capacity of the solution. The main points of the execution phase and some unforeseen events and respective solutions are presented.

RÉSUMÉ: Cet article présente les directives de conception et d'exécution de la stabilisation du remblai d'accès à la sous-station électrique de Carvoeira, Portugal. Le remblai, avec 15 m de hauteur, présente diverses pathologies d'instabilité, depuis sa construction. En 2011, l'accès s'est effondré. Malgré les mesures correctives adoptées en 2012, l'accès a continué à présenter des signes d'un processus continu et évolutif qui pourrait conduire à un nouvel glissement. L'instabilité a été analysée sur la base des données initiales du projet, l'historique et les principales contraintes, en particulier les conditions géologiques, géotechniques et hydrogéologiques. L'impact des infrastructures existantes et la nécessité de maintenir l'installation électrique opérationnelle ont été également discutés. En 2020, une nouvelle solution constituée par un remblai en enrochement a été développée. La conception de la nouvelle solution est présentée, ainsi que les critères de sélection des matériaux rocheux, l'importance de la résistance et la capacité de drainage de la solution étudiée. Les principales étapes de la phase d'exécution et quelques événements imprévus, ainsi que leurs solutions respectives, sont également présentés.

Keywords: Embankment; collapse; rockfill; stabilization.

1 INTRODUCTION

The access to the Carvoeira substation is made through a 550 m road, of which 130 m are constructed in an embankment with a maximum height of 15 m. All the infrastructure is in a natural hillside with slight unfavorable inclination. The embankment slopes had a 1V:1,5H and one middle bench. Since its construction in 2008, the platform has shown several pathologies resulting in the collapse of the fill in 2011. Different stabilization measures were considered. A gabion wall and a group of rockfill drains at the base of the embankment were executed to achieve a higher level of safety and improve the drainage capacity. Part of the fill was excavated and replaced by material with better properties. Part of the foundation material was excavated, too. The slopes geometry has been changed accordingly.

Despite all the corrective measures, through the years, several pathologies have been registered and the instrumentation shows a movement tendency.

The different phases of the study will be presented from the geotechnical survey to the execution.

2 SITE CONSTRAINTS

2.1 Geology and hydrogeology

The substation is in a natural hillside of Jurassic materials characterized by intercalations of clays, claystones, sandstones and limes. Due to the

deposition process and the proximity of a water course, the material layers thickness has important variations resulting in different foundation horizons. In some areas colluvial and deposit materials were identified, even after the embankment construction.

To characterize all the existing materials, four geotechnical campaigns were conducted in the area, as represented in Figure 1. The first in 2011, in orange, before the construction works, the second, in red, after the collapse and the last two, in 2019, in blue, and 2020, in green, in the context of the new project. Based on the obtained results a geotechnical zoning was defined:

- GZ 1 – Heterogeneous clayed fill.
- GZ 2 – Decompressed Jurassic clays.
- GZ 3 – Jurassic clays intercalated with marls and limestones.

A geotechnical profile is represented in Figure 1.

The water level was measured at 2,4 to 6 m depth, and at the toe at 7 to 7,5 m depth. This data indicates the presence of water inside the embankment and the percolation of water between GZ3 and GZ2.

2.2 Existing infrastructure

Apart from geological and geotechnical, the existing substation and the related infrastructure (water supply and electrical distribution wires and poles) were the main constraint to the stability and execution of the future works. All the electricity distribution facilities were kept operational in their original locations, which was considered in every stage of the project in different ways. The water supply and sewage system contributed to the existing pathologies and were moved to guarantee its operation and the conservation of the future platform.

3 DIAGNOSE AND RETROANALYSIS

The analysis of the existing situation was based on different types of information, like the results of instrumentation and geotechnical campaigns, reports of inspection and diagnose of external entities (Cardoso, 2020), parts of previous projects and site observation.

The presence of several cracks and abatements of the pavements showed the development of a new rupture mechanism. To confirm this situation inclinometers and piezometers were installed. The results show the formation of slip surface in depth approximately at the GZ2. The piezometers show a stabilized level of water at the base of the GZ3, both at the base and top of the embankment.

Based on this evidence, it was concluded that the collapse of the embankment was caused by the combination of several situations:

- The presence of high plastic clays at the base of the embankment.
- The material used in the construction of the embankment had a high percentage of fine materials resulting in inappropriate characteristics in terms of granulometry, strength and permeability.
- It was observed a relation between the piezometer's levels and the increase in horizontal movements. The presence of water at fill and the low permeability of its materials were considered key aspects that contributed to the collapses.

To confirm this evidence and to establish a coherent scenario with the *in-situ* situation, a set of retroanalysis models were created using the finite element analysis program Plaxis 2D.

To obtain the unitary factor of safety, the "phi-c reduction" method was used. In this the soil parameters are reduced until the slip surface with lower FS is formed. The soil behavior was simulated with the Hardening-Soil model (Brinkgreve et al. 2017), an elastic-plastic model with a multi-surface yield criterion that simulates the increasing of soil stiffness with deformation. In Figure 2 are represent both the retroanalysis slip surfaces of the initial configuration of the embankments and of the geometry before the project.

4 PROPOSED SOLUTION

Several solutions for the stabilization of the embankment were studied. The developed and implemented solution involved the excavation and complete removal of the fill materials corresponding to GZ3, which had a strong clay component and inappropriate geotechnical characteristics.

Subsequently, the embankment was constructed using rockfill material. The excavation of the layers belonging to GZ2 and the superficial zone of GZ1 was also considered. To ensure proper connection of the rockfill to the foundation ground, a keyed excavation was planned, ensuring greater stability of the materials in this area. To ensure a better granulometric transition and filter conditions, a layer of gravel 10/30 mm was placed between the natural ground and the rockfill.

The compaction of the rockfill materials prescribed pretended to concentrate the deformation in the early stages of the works and guarantee the adequate resistant characteristics of the materials. To accomplish this, for each layer, the particles with large diameter are placed first decreasing the diameter with the height of the layer. Large quantities of water are used to promote the breakage of the rock material and adequate interlocking of the different blocks.

The thickness of the layers and the compaction processes implemented were determined based on experimental embankments. The materials were characterized following Ferreira et al. (1995) and Rocha (2013). This analysis also considered the characteristics of the existing rockfill in nearby quarries and the desired performance requirements. The rockfill prescribed characteristics are resumed in Table 2 and Table 3.

To achieve the desired drainage capacity, the configuration of the excavation base was conceived in such a way that all the waters are guided to two drainage trenches, 1 m width and 2 m height, with 300 mm PVC tubes wrapped in gravel. These elements were positioned at the transition between the fill material and the natural soil and at the lowest point of the embankment. Minimum inclinations of 0,5% were considered and, at the discharge points, dissipation structures were created.

Several complementary works, like the access reconstruction (pavement, signage, and safety equipments) and the redefinition of the water supply system were included in this project.

In terms of design, a model based on the retroanalysis conclusions was used. The safety of the different phases of excavation and fill were checked, considering the position of the expected water level. For the final geometry, the stability was verified considering the seismic action according to the pseudo-static method of Part 5 of Eurocode 8.

5 CONSTRUCTION PHASE

The construction phase started in December of 2020, a very rainy month, which was an additional challenge for the works. Considering the presence of clay materials in the existing fills and natural soils, a close monitorization of the excavation works was implemented. This measure was essential to anticipate and correct some local instabilities observed in the weaker materials. In Figure 3 to Figure 5 are represented the different work phases, from excavation to compaction. In Figure 6 is represented a view of the area after the works.

Figure 3. View of the slope and protective measure.

Figure 4. View of the final excavation stage.

Figure 5. Embankment construction and compaction.

6 CONCLUSIONS

The history of instabilities, the characteristics of the embankment and especially the geological complexity of the site, determined the need for an in-depth study to address the current situation.

The rockfill solution ensures the strength and drainage characteristics necessary to guarantee the appropriate safety levels. In this type of geotechnical structure, the design, control and testing of execution methodologies are key aspects to guarantee the expected behavior of the embankment.

Finally, it should be noticed the importance of a proper instrumentation and observation plan, to control the behavior of materials, continuously validate the project assumptions, and to ensure the safe execution of the works.

Consideration of the variable contact geometry between the drum and the soil surface in vibratory roller compaction

Prise en compte de la géométrie de contact variable entre le cylindre et la surface du sol lors du compactage par rouleau vibrant

ABSTRACT: The paper presents a comparatively simple mechanical model, which describes the dynamic interaction between the drum of a vibratory roller and the underlying soil during compaction. The main non-linearities of the dynamic system are the continuously varying contact conditions and geometry between the drum and the subgrade as well as the curved drum geometry. As the drum penetrates the soil during the loading phase, the contact area between the two contact partners increases, which in turn affects the resulting soil reaction force and influences the motion behaviour of the drum at the same time. Moreover, a periodic loss of contact between drum and soil during the unloading phase may occur, and the two subsystems move separately and independently from each other for a short period of time. The model introduced in the paper allows for a consideration of the challenging contact conditions and the variable drum contact geometry. Moreover, it enables the consideration of varying soil resistance as a result of the changing contact conditions. The model is tested on the example of a typical vibratory roller and the results are compared to a simulation with a constant contact geometry between drum and soil. The presented findings allow for a more accurate consideration of the actual contact conditions between the drum of a vibratory roller and the soil and are considered valuable for the further development of measurement values of Intelligent Compaction.

RÉSUMÉ: Cet article présente un modèle mécanique relativement simple, qui décrit l'interaction dynamique entre le tambour d'un rouleau vibrant et le sol sous-jacent pendant le compactage. Les principales non-linéarités du système dynamique sont les conditions de contact et la géométrie continuellement variables entre le cylindre et le sol de fondation, ainsi que la géométrie incurvée du cylindre. Au fur et à mesure que le cylindre pénètre dans le sol pendant la phase de chargement, la surface de contact entre les deux partenaires augmente, ce qui affecte la force de réaction du sol et le comportement de mouvement du cylindre. En outre, une perte de contact périodique entre le tambour et le sol pendant la phase de déchargement peut se produire, et les deux sous-systèmes se déplacent séparément et indépendamment l'un de l'autre pendant une courte période. Le modèle présenté dans cet article permet de prendre en compte les conditions de contact difficiles et la géométrie variable du contact entre le tambour et le sol. En outre, il permet de prendre en compte la résistance variable du sol résultant de l'évolution des conditions de contact. Le modèle est testé sur l'exemple d'un rouleau vibrant typique et les résultats sont comparés à une simulation avec une géométrie de contact constante entre le tambour et le sol. Les résultats présentés permettent une prise en compte plus précise des conditions de contact réelles entre le tambour d'un rouleau vibrant et le sol et sont considérés comme précieux pour le développement ultérieur des valeurs de mesure du compactage intelligent.

Keywords: Roller compaction; soil dynamics; intelligent compaction; non-destructive testing.

1 INTRODUCTION

This paper presents a comparatively simple semi-analytical vibratory roller-soil simulation model to describe the interaction system, characterized by its challenging contact conditions. Previous models consider, if at all, only a constant geometry of the contact area between drum and soil (Adam, 1996). However, the width of the contact area increases during the loading phase, making the drum contact width a variable parameter. The presented model can account for this variability of the drum contact width in the loading phase of vibratory roller compaction. The model is part of an ongoing research project to develop a novel Intelligent compaction meter value (ICMV) for roller compaction (Pistrol et al., 2023).

2 MECHANICAL MODEL

2.1 Modelling of the roller subsystem

The cylindrically curved drum of the roller is excited at a specific frequency f by an unbalance, which is mounted on a drive shaft in the axis of the drum. The resulting vibration of the drum yields a predominantly vertically directed loading of the soil.

The drum is connected to the frame of the roller using rubber buffers. If the rubber buffers and the frame are suitably designed, the frame and drum can be regarded as largely decoupled. Therefore, the influence of the frame on the motion behaviour of the drum is limited to its dead weight ($m_f g$) and the roller subsystem is reduced to a single degree of freedom with the position coordinate z_1 (see Figure 1).

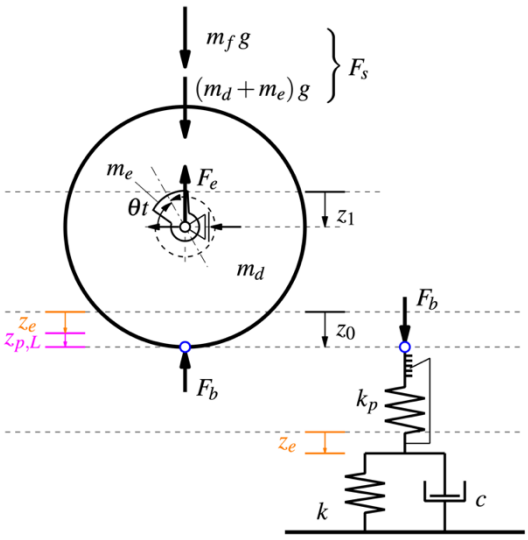

Figure 1. Free-body diagram of the simplified simulation model at time t during the first load cycle.

The application of the principle of linear momentum yields the equation of motion for the roller subsystem by means of the resulting soil contact force F_b which comprises the inertia force F_a, the static load F_s, and the excitation force F_e:

$$F_b = -F_a + F_s - F_e = -(m_d + m_e)\ddot{z}_1 + (m_d + m_e + m_f)g - m_e e\theta^2 \sin(\theta t) \quad (1)$$

where m_d and m_e are the masses of the drum and the eccentric, e is the eccentricity of the unbalance and θ is the angular frequency of the excitation.

2.2 Modelling of the soil subsystem

The soil subsystem is modelled as a Kelvin-Voigt element, which is extended by an additional spring connected in series (see Figure 1). The calculation of the spring stiffness k and the dashpot coefficient c is based on considerations by Wolf (1994). Therefore, the approximately rectangular contact area between drum and soil with half side lengths a and b is converted into a circle with an equivalent radius, which represents the top surface of a downward unlimited truncated cone. The parameters are defined as (Wolf, 1994):

$$k = \frac{Gb}{1-\nu}\left[3.1\left(\frac{a}{b}\right)^{0.75} + 1.6\right] \quad (2)$$

$$c = \kappa 4\sqrt{2\rho G \frac{1-\nu}{1-2\nu}}ab \ldots \text{(adapted)} \quad (3)$$

where G, ρ, and ν are the shear modulus, density, and Poisson's ratio of the soil, and κ is a factor for increased damping to account for spatial effects. The Kelvin-Voigt model is only able to capture the elastic soil behaviour in the far-field of dynamic compaction. Therefore, an additional elastic spring with stiffness k_p is introduced. The spring deforms proportionally during loading but remains locked otherwise (during unloading and separation) and, therefore, simulates the plastic behaviour in the near-field. The stiffness k_p is estimated by the introduction of a dimensionless condition factor ε that describes the ratio of elastic to elasto-plastic deformations and provides a relationship between k_p and k (Adam, 1996):

$$\varepsilon = \frac{z_e}{z_e + z_p - z_{p,p}} = \frac{k_p}{k_p + k} \Leftrightarrow k_p = \frac{\varepsilon k}{1-\varepsilon} \quad (4)$$

where z_e and z_p are the absolute elastic and plastic deformations of the soil, and $z_{p,p}$ is a compensation variable to account for the periodic increase in vertical displacements under cyclic loading. In this paper, a condition factor of $\varepsilon = 0.85$ is defined to simulate the "partial uplift" mode of operation.

2.3 Coupling of roller and soil subsystem

The coupling and separation of the two subsystems is characterized by three operating phases – loading, unloading, and separation – which may occur during each period of excitation.

2.3.1 Loading phase

The soil with its position coordinate z_0 follows the movement of the drum during the loading phase ($z_0 = z_1$) and the soil contact force F_b, as well as its gradient have a positive sign. The spring k_p is active during loading and, therefore, elastic (z_e) and relative plastic ($z_{p,L}$) deformations occur. The sum $z_e + z_{p,L}$ is the basis for the calculation of the variable drum contact width (see section 2.4).

The soil contact force for the roller subsystem is given in Equation (1). For the soil subsystem, F_b comprises the forces in the elastic spring (F_k) and the viscous dashpot (F_c):

$$F_b = F_k + F_c = kz_e + c\dot{z}_e \quad (5)$$

Roller and soil subsystem are coupled by the spring with stiffness k_p:

$$F_b = \left[(z_0 - z_e) - z_{p,p}\right]k_p + F_{p,p} = z_{p,L}k_p + F_{p,p} \quad (6)$$

The variable $z_{p,L}$ compensates the periodic increase in plastic deformations due to cyclic loading and allows for the calculation of the relative plastic deformations during each load cycle. Therefore, $z_{p,p}$ describes the cumulative pre-deformation of spring k_p, which increases by $z_{p,L}$ at each transition from loading to unloading. If the drum does not lose its contact after the unloading phase, a residual preload $F_{p,p}$ of the spring k_p must be taken into account.

The loading phase ends when the soil contact force stops increasing and its gradient is less or equal to zero. The loading phase is always followed by an unloading phase.

2.3.2 Unloading phase

During the unloading phase, the soil continues to follow the movement of the drum ($z_0 = z_1$), and Equations (1) and (5) remain applicable for the calculation of the soil contact force. F_b is still positive, while its gradient is negative ($\dot{F}_b \leq 0$). The spring with stiffness k_p is locked ($k_p = \infty$) and therefore only elastic deformations occur.

The unloading phase ends, if the soil contact force starts to increase again without a full unloading and another loading phase begins. In this case, the residual preloading of the spring k_p is taken into account by the variable $F_{p,p}$.

The unloading phase also ends if the soil contact force becomes zero. The separation phase begins since the soil cannot bear tensile forces and the two subsystems move independently from each other.

2.3.3 Separation phase

Drum and soil move separately and independently of each other and the soil contact force in Equations (1) and (5) is zero. The soil creeps back towards its initial position during the separation phase. The preload $F_{p,p}$ of the spring k_p is set to zero in case of separation.

The separation phase is always followed by a loading phase.

2.4 Variable drum contact width

The contact area between the two subsystems decisively determines the dynamic interaction between drum and soil. Due to the cylindrically curved drum geometry, the contact area is a variable quantity during the loading phase. The drum increasingly penetrates the soil, and the contact width between the subsystems steadily increases, while the length of the load area remains largely constant and equals the length of the drum ($2a$).

In contrast to previous research (Adam, 1996), the presented model enables the consideration of the variable contact width $2b$ during the loading phase. The instantaneous drum contact width is determined using the circular arc segment shown in Figure 2, which is defined by the sagitta Δz and the circular chord s.

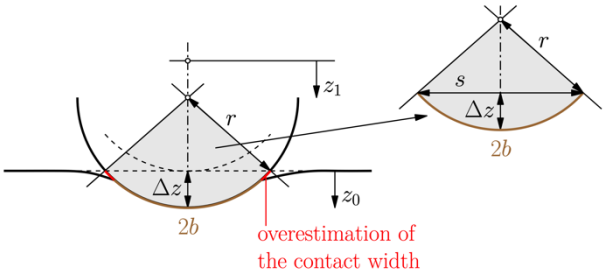

Figure 2. Calculation of the variable drum contact width.

With the known drum radius r and the elasto-plastic deformations $\Delta z = z_e + z_{p,L}$, the circular chord s and the circular arc length $2b$ can be calculated according to Equations (7) and (8).

$$s = 2\sqrt{2r\Delta z - \Delta z^2} \quad (7)$$

$$2b = 2r\,arcsin\left(\frac{s}{2r}\right) \quad (8)$$

During the unloading phase, $2b$ is assumed to be constant and corresponds to the value at the end of the loading phase since only elastic deformations occur.

The variable drum contact width results in a variable spring stiffness k and dashpot coefficient c during the loading phase. The definition of k_p by means of a condition factor ε according to Equation (4) also makes k_p a variable quantity.

3 CALCULATIONS AND RESULTS

Selected results from simulations with the presented mechanical roller-soil model are presented for a HAMM H13i single-drum roller. The roller and soil parameters of the simulations are given in Table 1. The soil parameters were selected to ensure the "partial

uplift" mode of operation. Ninety revolutions of the eccentric mass were simulated (duration = 3 s), to guarantee a steady state of the simulation.

Table 1. Roller and soil parameters of the simulation.

Parameter	Value
Radius of the drum r	0.752 m
Length of the drum $2a$	2.14 m
Eccentricity e	23.21 mm
Mass of the frame m_f	3323.0 kg
Mass of the drum m_d	3722.5 kg
Mass of the eccentric m_e	69.47 kg
Excitation frequency f	30 Hz
Shear modulus G	50 MN/m^2
Poisson's ratio ν	0.3
Density ρ	1800 kg/m^3
Damping factor κ	4
Condition factor ε	0.85

Figure 3 shows the calculated soil contact force F_b (black) and its components for four periods of excitation. For the roller subsystem, the contact force is calculated from the inertia force F_a of the vibrating mass shifted upwards by the static axle load F_s (blue) and reduced by the excitation force F_e (green). If the blue and green lines coincide, the soil contact force does not contribute to the inertia force (Equation 1), drum and soil are separated, and the soil contact force becomes zero. The soil contact force shows a recurring pattern for each unbalance revolution, amplitudes and contact times are identical, which means that the roller operates in the "partial uplift" mode.

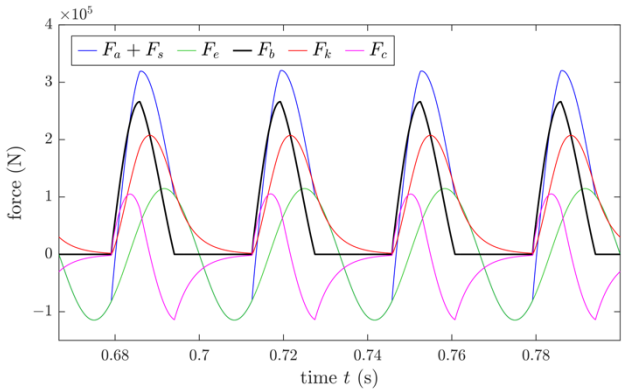

Figure 3. Soil contact force F_b and its components for the roller and soil subsystem over four periods of excitation.

The soil contact force F_b can also be calculated for the soil subsystem as sum of the elastic spring force F_k and the force F_c in the dashpot. It becomes zero in the separation phase since the spring and damping forces have the same magnitude.

The force-displacement diagram in Figure 4 shows the relation between the soil contact force F_b (black) and the corrected relative vibration displacement of the drum z_1. The curved force-displacement line of the spring force F_k (red) results from the nonlinearities of the compaction process: the variable drum contact area and plastic deformations during the loading phase. The change in contact conditions due to the separation phase results in a pronounced kink in the development of the damping force F_c (magenta).

Additional simulations were performed, considering a constant contact width, only. The results are shown in orange ($2b = 6$ cm) and cyan ($2b = 12$ cm) colour in Figure 4.

A comparison of the force-displacement diagrams with and without variability of the contact width shows that only the described model extension leads to results that are close to reality and comparable with measured data (Adam, 1996).

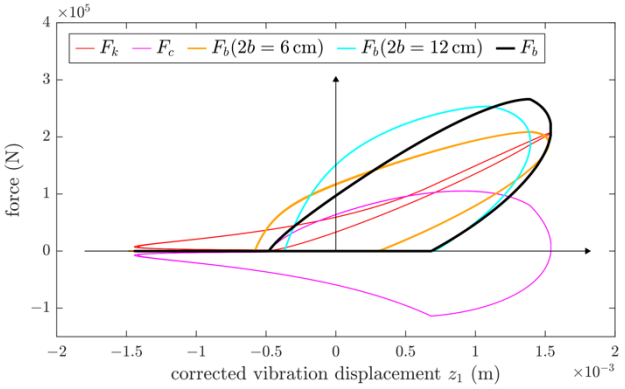

Figure 4. Force-displacement diagrams for a variable and two constant contact widths in comparison.

4 CONCLUSIONS

The presented semi-analytical model allows to consider the vertical drum motion of a vibratory roller, while considering the variable drum contact width during the loading phase. The theoretical force-displacement diagram in Figure 4 provides the basis for the development of a novel Intelligent Compaction Meter Value (ICMV) for vibratory roller compaction.

ABSTRACT: This article presents a case study regarding a circular retaining structure adopted for a technological shaft constructed within an aluminium processing plant in Mediești Aurit, Satu Mare County, Romania. Works were carried out in 2023 in order to accommodate a monolithic reinforced concrete structure with dimensions of 6.3m x 3.95 m, with the bottom slab level of -11.07m (from the reference elevation level, ±0.00m), and a piston with a diameter of approx. 1 m, laid at -18.30m. Geotechnical investigation indicates cohesive and semi-cohesive soils to a depth of 6.4 m, followed by a layer of gravel with sand and boulder to the depth of about. 39.4 m. The groundwater level is located at -6.4m with respect to natural ground level. A self-supporting circular diaphragm wall shaft was the adopted solution, which has been modelled by means of finite element method (FEM) in the two critical stages: Excavation down to -14.7m, taking into account the existence of water and water exhausting down to -11.30m, after high permeability soils in the bottom of the diaphragm wall have been replaced with low permeability layers of soil. The diaphragm wall shaft was executed from the working platform (constructed at level -2.70 m) down to -17.8 m, creating an internal diameter of 8.0 m, inside which, soil was excavated down to -14.70m (under water) and a concrete plug was poured with a thickness of about 3 m (replacing the excavated soil), to ensure up-lift resistance during temporary stage.

RÉSUMÉ: Cet article présente une étude de cas sur une enceinte circulaire pour un puits technologique dans une usine de transformation de l'aluminium à Mediești Aurit, située dans la région de Satu Mare, Roumanie. Les travaux ont été exécutés en 2023. L'objectif des travaux consistait de l'étude et l'exécution d'un puits circulaire afin d'accueillir une structure monolithique en béton armé de dimensions 6,3m x 3,95 m, avec le niveau de fondation de -11.07m (à partir de l'élévation de référence, ±0.00m) au niveau du sol, et un piston d'un diamètre d'environ 1 m, avec le niveau inférieur de -18.30m. Les conditions géotechniques montrent des sols cohésifs et semi-cohésifs jusqu'à une profondeur de 6,4 m, suivis d'une couche de gravier avec du sable et des rochers jusqu'à une profondeur d'environ 39,4 m. Le niveau de la nappe phréatique se trouve au niveau -6,4 m. La solution proposé a été un puits circulaire de paroi moulée autoportant qui a été numérisé par la méthode de l'élément fini (MEF) dans les deux étapes critiques: excavation jusqu'à -14,7 m, en tenant compte de l'existence d'eau et le stage après l'évacuation de l'eau, après le débouchage du béton. Le puits de la paroi moulée a été réalisé depuis la plateforme de travail (niveau -2,70 m) jusqu'à -17,8 m, avec un diamètre intérieur de 8,0 m, à l'intérieur duquel le terrain a été excavé jusqu'à -14,70 m (sous l'eau) et un bouchon en béton a été coulé sur une épaisseur d'environ 3 m pour assurer la résistance au soulèvement lors de l'étape temporaire.

Keywords: Circular shaft; deep excavation; diaphragm wall; uplift.

1 INTRODUCTION

The project's scope of works consisted in the design and execution of a deep excavation undergone inside a circular shaft in order to ensure conditions for the bottom up construction of an interior structure, part of the vertical casting machine objective, a technological facility serving the future investment (Figure 1).

In order to facilitate an efficient productivity for the Client and the Contractor, the project required a solution regarding the rapid construction of the future underground equipment (part of the expansion of the Aluminium extruded profiles factory), while minimizing the influence on the facility's technological flow and logistics.

The site is located in Mediești Aurit, a city in the county of Satu Mare, situated in the north-western region of Romania, close to the Hungarian border.

The aim of the special foundations works was to obtain an efficient structural system in terms of correlation with the future structure and equipment, by adopting a solution optimally adapted to the particularities of the project that will ensure the work flow is enhanced for carrying out the construction works.

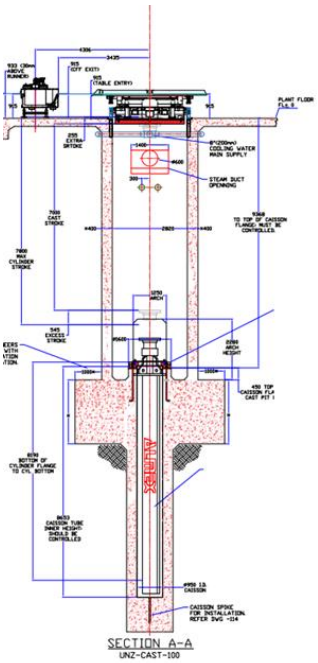

Figure 1. Technical concept – Vertical casting machine.

Due to its underground positioning, the casting shaft dimensions and adjacent operating equipment which are designed to function inside a reinforced concrete infrastructure, the foundation level was designed at a depth of 11,3 meters with respect to natural ground level.

2 GEOTECHNICAL CONDITIONS

The on-site geotechnical report is based on several boreholes, with a maximum depth of 50 meters, determined by in-situ tests and electrometric investigations.

The general site lithology indicates thick layers of sand and gravel (down to over -40.0 meters),

- ±0.00 m ... -1.00 m – organic fillings;
- -1.00 m ... -5.20 m – stiff clay;
- -5.20 m ... -6.40 m – sandy clay;
- -6.40 m ... -40.00 m – sand and gravel;

The theoretical water level indicated by the geotechnical report is set at -6.50 meters.

The sand and gravel layer contains minor percentages of fine particles, 10-20% clay & silt, thus, in order to reach the designed depth, in common projects, the high permeability of the stratum would generate the need to adopt a difficult dewatering system that would interfere with the factory's water supply.

The local design norms related to geotechnical documentations offer maximum score in terms of the theoretical solution to be adopted regarding the dewatering necessary for constructing the reinforced concrete under an approximate water table of 6.0m.

3 CIRCULAR DEEP SHAFT SOLUTION

3.1 General information

In order to construct the aforementioned structure laid at -11.30m, considering the project's particularities, the adopted solution consists in a circular shaft of 8 meters diameter, constructed as diaphragm wall (slurry wall) reinforced concrete panels which will ensure construction and installation of the interior vertical casting machine's structure in conditions of maximum safety and efficiency.

Following dedicated calculations, the diaphragm wall thickness has been set at 60 cm and the specific polygonal shape generated by the panelling layout was executed aided by shaped guiding walls (Figure 2).

Figure 2. Isometric view of circular shaft and casting shaft geometry.

In the design process, multiple excavation support solutions have been regarded (ground anchors, horizontal or inclined temporary struts, top-down excavation method, etc.).

Calculations were performed with design approaches according to current regulations such as Eurocode 7 with corresponding national annexes, or local Romanian regulations, NP 120 (2014) and NP 124 (2010).

In order to achieve a retaining system which can provide excavation protection, as well as an increased productivity of execution, by implementing the circular shaft solution, for which earth and water pressure loads are transferred as compression by means of arch effect of in the concrete mass, resulting in a self-supporting diaphragm wall, no internal or external bracing is required.

The length of the designed diaphragm wall panels is 15 meters, embedded in sand and gravel ground layers.

Due to the presence of large packs of sand and gravel, in terms of financial efficiency, embedment in a lower clay layer has not been feasible, thus generating the necessity of adopting a soil improvement method for isolating the base of the diaphragm wall below excavation level in order to limit dewatering works that could generate multiple exploitation risks.

The adopted soil improvement solution consists in substituting permeable layers of soil with hydraulic concrete on a certain length under the designed foundation level.

The resulting concrete layer is designed with a thickness of approximately 3 meters.

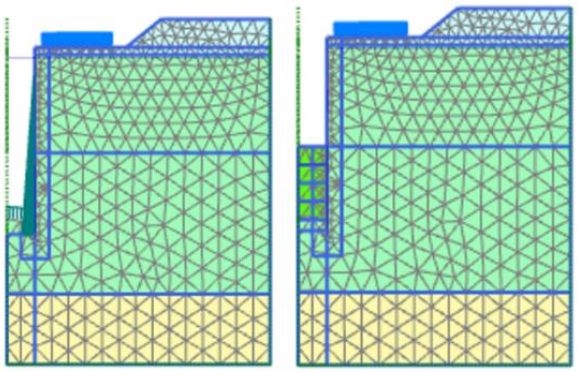

Figure 3. Finite Element Model of circular shaft (axisymmetric model).

The axisymmetric model is used in cases where circular structures are modelled, with uniform sections and loads distributed around the central rotation axis. The basic premise for this model is the identical configuration in any radial direction regarding soil lithology and loads (Figure 3).

3.2 Design particularities

Due to the particularities of the project and to the fact that the diaphragm wall is not embedded in a clay level, FEM modelling of the circular shaft has been performed for critical stages such as excavation down to -14.7 meters, with no water evacuation, as well as water evacuation down to -11.70 meters, after the execution and hardening of the concrete soil improvement.

To establish the geometry of the soil improvement, thus leading to the thickness of the newly poured hydraulic concrete layer, dimensioning has been performed for several structural internal verifications that were required for internal stability of the pit, both for temporary and permanent phases.

The most important verification for uplift checks consists in validating the thickness of the concrete layer so it withstands the under pressure generated by the difference between the exterior water table and the interior water table resulted after water exhaustion takes place.

The inferior level of the VCM (vertical casting machine) structure is situated at -18.00 meters under the natural terrain level and is laid on a reinforced concrete raft laid at a level of approximately -11.10 meters with respect to natural ground level (Figure 4).

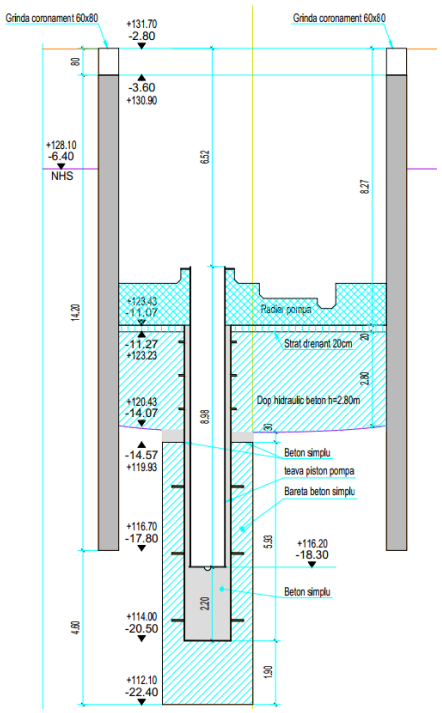

Figure 4. Shaft's cross section with concrete plug.

The casting shaft's piston is designed to slide inside a technological steel pipe with a section of 1400x10 mm, from -11.10 meters level, down to approximately -18.00 meters.

In order to accommodate the future pipe and to ensure verticality is obtained, a supporting barrette, has been constructed inside the shaft, as support of the casting shaft's pipe, and as a supplementary support for the casting shaft against water under pressure due to uplift.

4 MONITORING OF THE RETAINING STRUCTURE

Lateral pressure generated by the soil massif acting on the exterior surface of the diaphragm wall is transferred by arching effect in the concrete structure as hoop forces.

The diaphragm wall's thickness is dependent on the diameter of each circular cell with a direct impact on the arching effect of the lateral loads.

A higher diameter of the circular cell generates an amplified soil pressure, caused by the decreasing arching effect.

Monitoring of the circular shaft was obtained by means of strain gauges, installed on steel rebar cages (Figure 5).

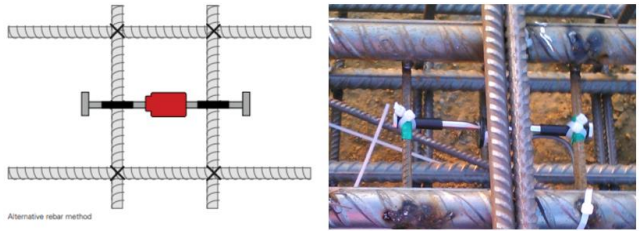

Figure 5. Concrete strain gauge installation.

Values resulted from monitoring indicate variation of stresses that are situated below dimensioning value (maximum 5 MPa measured value with respect to 10.2 MPa corresponding to the designed value).

Other factors that have to be considered in the design process are related to non-uniform loads that may appear from various equipment and logistics at ground level as well as excavation sequencing, or discontinuity in soil layers and their relevant parameters (Figure 6).

Figure 6. Excavation inside the shaft.

5 CONCLUSION

This particular project combines previously acquired information and return of experience in similar projects that allowed the proposal for a much more effective solution, with reduced quantities (approximately up to 35% less materials) and a performant execution time management.

The reduction of the materials' quantities also resulted in a reduction of the CO2eq emissions of 45%.

Using the right materials and minimising as much as possible the distances for their supply, proved to be particularly effective in reducing the project's carbon footprint (Figure 7).

The monitoring performed during the execution process provided valuable information for future developments of similar projects, both in heavy or light industry for factories and other special facilities, as well as other private applications or research & development purposes.

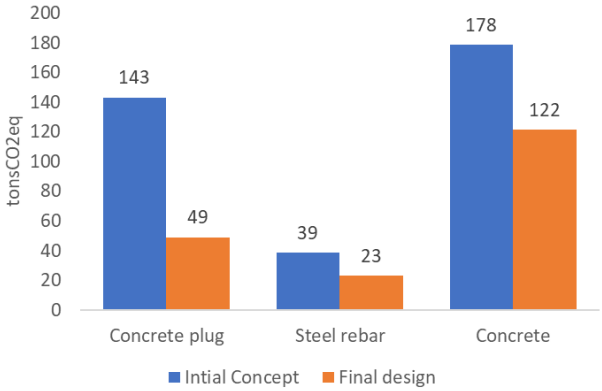

Figure 7. Comparison of materials' CO2eq emissions between initial concept and final design.

In conlusion, using right technology, considering a circular design of the shaft taking into account arching effect in the concrete structure, using proper reduced CO2 emissions materials, prove to be a proper solution of small technological shafts.

ABSTRACT: The paper describes the designed deep foundation system of a future multi-storey commercial center laid at -23.0m below natural ground level with considerations on the particularities of the superstructure's configuration being addressed. A particular aspect within the paper consists in the presentation of the analyses performed for various stages of construction with respect to soil-structure interaction thus resulting in an iterative design methodology. The necessary parameters to be considered in order to validate and optimize the initially tendered design are determined on a dedicated testing procedure carried out by means of Osterberg cells that have been performed within the initial phases of the project. A full assessment has been obtained by processing data from the Osterberg cell testing, allowing advanced numerical modelling of the soil-structure interaction and resulting in an optimal layout of the foundation elements. The paper presents essential results obtained from numerical analyses and performed in situ testing resulting in a full simulation of the final soil-structure interaction fundaments.

RÉSUMÉ: L'article décrit le système de fondations profondes conçu pour un futur centre commercial à plusieurs étages posé à -23,0 m sous le niveau du sol naturel en prenant en compte les particularités de la configuration de la superstructure. Un aspect particulier de l'article consiste en la présentation des analyses effectuées pour les différentes étapes de la construction en ce qui concerne l'interaction sol-structure, aboutissant ainsi à une méthodologie de conception itérative. Les paramètres nécessaires à prendre en compte pour valider et optimiser la conception initialement proposée sont déterminés sur la procédure de test de barrette réalisée au moyen de cellules Osterberg qui a été réalisée dans les phases initiales du projet. Une évaluation complète a été obtenue en traitant les données des tests de la cellule Osterberg, permettant une modélisation numérique avancée de l'interaction sol-structure et aboutissant à une disposition optimale des éléments de fondation. L'article présente les résultats essentiels obtenus à partir d'analyses numériques et d'essais in situ effectués aboutissant à une simulation complète des fondements finaux de l'interaction sol-structure.

Keywords: Deep foundation; load testing; barrettes; soil-structure interaction; finite element.

1 INTRODUCTION

The New Promenada Mall extension project represents an undergoing commercial development in Bucharest, Romania, comprising roughly 100 000 sqm of parking infrastructure constructed beneath ground level, and approximately 120 000 sqm of superstructure representing an investment that will consist in a cinema, shopping area, offices and entertainment facilities for one of the city's most active business hubs.

In terms of geotechnical aspects, due to its size and complex architectural conformation (Figure 1), the future development represents an important challenge on the local engineering market.

The site layout is a land lot of roughly 12 500 sqm and the designed depth of the future 7 storey basement is generally 23.0m beneath natural ground level.

Figure 1. General render of the future Mall extension.

The paper aims to describe the main aspects of the deep foundation design and study, with focus on the technical methodology and challenges encountered.

2 GEOTECHNICAL CONDITIONS

The site is located in an area where several investments were carried out over the last decade and valuable geotechnical information was available for the site and neighbouring locations, as well as information gathered from site monitoring. The geotechnical report indicates an uniform alternation of soil layers, as following, with respect to the working platform level set up at an inferior level (considered -7.00m);

- -7.00m ... -17.30m – clayey silt;
- -17.30m ... -21.30m – sand and gravel;
- -21.30m ... -29.30m – stiff silty clay;
- -29.30 m ... -31.60 m – sand and gravel;
- -31.60 m ... -37.20 m – clay;
- -37.20 m ... -43.20 m – sand and gravel;
- -43.20 m ... -54.90 m – clay with concretions;
- -54.90 m ... -60.00 m – fine sand.

The raft is laid at approximately -23.00m with respect to natural ground level.

Parameters provided by the geotechnical report are determined based on 7 (seven) boreholes drilled down to depths of 70.0m (circa 50.0m beneath final excavation level).

Following the design methodology adopted in similar documented soil-structure interaction response, the adopted material parameters are derived from soil investigations and correspond to the Mohr Coulomb, Hardening Soil and Hardening Soil with Small Strain stiffness constitutive models. Several sensibility analyses were performed in order to assess the influence of the uncertainties in the soil profile (Tschuchnigg, 2011) for a preliminary setup of design hypotheses.

3 FOUNDATION SYSTEM

The superstructure presents several geometry changes both in height as well as in layout distribution. As a result, the building is divided into several modules with 2 main cores (approximately 250 sqm per each core) and 2 secondary cores (approximately 120 sqm per each core) and a general distribution of columns in the basement levels of 8.0x8.0m that bear loads from superstructure columns which span over a 16.0x16.0m distribution and support loading from asymmetrical conditions.

One main advantage for the general layout of columns (with dimensions of 80x80cm up to 140x140cm) is the high unitary capacities (large section and high strength concrete allowing up to 55 MN loads), allowing an equal distribution of columns in the underground levels and allowing foundation elements to be embedded in the construction's technological staging, by efficiently adopting the "top down" excavation method and including temporary metallic profiles into the final concrete columns as part of the final superstructure.

Furthermore, the architectural configuration allows that the high point loads generated from the superstructure to be directly transferred to deep foundation elements (piles or barrettes constructed under bentonite slurry).

Several levels of loads in RC columns for the different designed stages of construction have been studied, both for temporary and final loading sequences and have been considered for the numerical models that were developed (Figure 2).

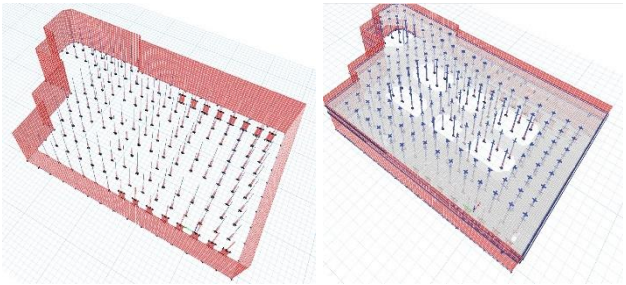

Figure 2. Distribution of pile loads based on staged construction sequence.

Variable loads were considered in the design of the temporary phase when the excavation's retaining system (top-down system) imposed several technological limitations, requiring a rigorous study. Examples of eccentric loading scenarios are represented by the crane positioning next to the excavation pit, technological shafts and openings, positioning of concrete trucks or other temporary deposits for materials.

4 ANALYSIS OF SOIL-STRUCTURE INTERACTION

4.1 Instrumented barrette loading

Due to the fact that excavation is undergone at minimum 23.0m below ground level under a top-down construction sequence, the proper and practical solution to achieve the high testing load values necessary for validating the design was considered by means of the Osterberg cell procedure.

Preliminary load tests were performed on two 2800x800mm barrettes (TB01 and TB02), that were each set up with single level 2x330mm hydraulic cells in order to properly estimate skin friction and end bearing capacity values.

Figure 3. Installation of O-cells in instrumented barrettes.

The Osterberg cell load tests were conducted in 17 nominally equal increments in order to reach their initially considered hydraulic capacity of 15.40 MN, after which increment size was increased to 150% of the previous increments until loading reached a maximum of 9.32 MN applied to the barrette above and below the O-cells, thus completing the test at 18.64 MN.

The instrumented barrettes (Figure 3) constructed for testing purposes were completed under bentonite slurry with an excavated depth of 58.50 metres and a concreted length of approximately 41.00 metres. The adopted lengths were designed in order to ensure both sections (top segment and bottom segment) can generate sufficient friction and results could produce the proper information in order to optimize the foundation system.

Skin friction was evaluated on six (6) layers of four sister bar vibrating wire strain gauges installed on different levels that were fixed on the reinforcement cages. The adopted positions were considered relevant for the determination of the required information.

4.2 Numerical modelling

Preliminary design of the foundation system was based on assumptions on parameters that were considered with the aid of prescriptions provided by the local norm regarding pile design (Romanian Design Norm NP 123:2010).

The results of the O-Cell testing allowed for full stage construction analyses to be carried out by means of finite element method, as well as calibration of results to be implemented in the aforementioned soil-structure interaction study.

The assessment of the soil structure interaction phenomena required the use of several numerical models, as well as advanced constitutive models (Zehentner et al., 2012), in order to process and back analyse the significant volume of available information.

In terms of results, by taking into account the shape of the foundation (broadly consisting in a vast area of symmetry due to the architectural configuration), an initially adopted approach was to model the foundation subjected to vertical forces by means of an axisymmetric model (Pereira et al., 2017), as well as tri dimensional models for local areas which were of interest in terms of the superstructure's response (loads and settlements), such as core areas and areas with extreme localized loads where high capacity RC columns were distributed next to low capacity ones, thus resulting in differential settlements, or areas for which uplift pressure effects imposed the infrastructure's dimensions.

Reduced size numerical models (Figure 4) enable parametric analyses to be performed for interpreting the variation in geometry or soil stiffness, also considering that the results are not significantly influenced by the nonsymmetric outer part of the structure.

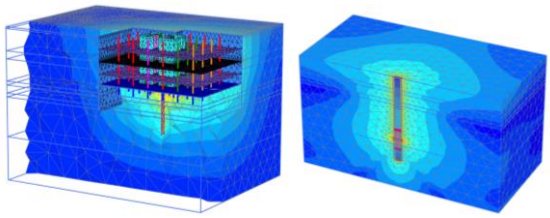

Figure 4. Strain development in calibration models for preliminary dimensioning of foundation elements.

The calculations developed for the final proposed layout of the deep foundation elements generated an extended full tri dimensional model, enabling a refined review for the dimensioning of all elements in the infrastructure.

The superstructure's architectural complexity involves several shifts in the superstructure's height; thus, foundation loads vary in a wide range of values for forces between 6000 kN/point of compression, to over 8000 kN/point of tension.

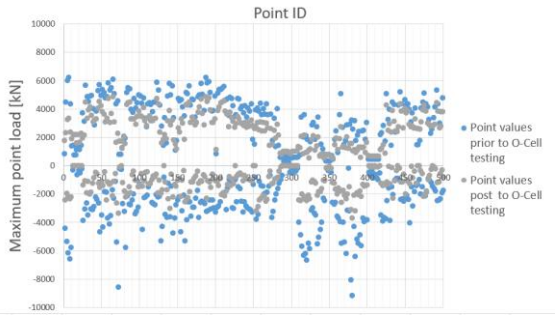

Figure 5. Point load distribution of forces in foundation elements as per numerical model simulation and calibration.

Individual deep foundation elements are defined by several points, associated with loads plotted in Figure 5. The sum of the point values per each element generates the final dimension of the deep foundation geometry and depth, resulting in the final distribution of the foundation system consisting in bored piles with

a diameter of 100cm up to 140cm and barrettes with dimensions of 80x280cm.

Maximum compression loads for the foundation elements have reached up to 15 MN in some positions for seismic loading and 10 MN for temporary loading in the execution stage from the top-down sequence mostly generated by the construction process (equipment and materials).

The infrastructure is constructed inside an excavation pit consisting of perimetral diaphragm walls. Due to the depth of the excavation and the presence of the inferior under pressure aquifer, special attention was necessary for complementary checks regarding the final design stages, such as uplift in the exploitation phase.

The final difference in water quota and effects due to buoyancy have been evaluated, loads of up to 180 kPa being generated at raft level as forces are significant with regard to the underground structure's configuration.

Following on site testing and calibration of numerical models, different stiffness values were computed for several loading scenarios and an optimized version of the foundation system was implemented in the project as shown in Figure 6.

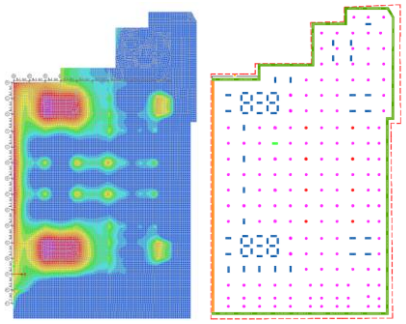

Figure 6. Distribution of soil pressure diagrams and resulting foundation elements.

Although the designed foundation level is considered at a depth where the superstructure's loads will transmit similar pressures to the ones of the excavated soil massif, the designed foundation system's stiffness is adjusted to ensure a proper compatibility both for reduction of maximum settlements and for limiting differential settlements between areas subjected to different loading conditions, due to the project's configuration.

The foundation system has been dimensioned for the ultimate limit states with respect to the provisions of Design Approach 1 from EN 1997-1:2004.

In order to properly assess the structural response, load-settlement diagrams for compressive and tensile loads were derived based on the determined soil parameters and settlement predictions have been verified by comparison to the construction's design limitations. Results of iterations for soil structure interaction indicate that the initially adopted parameters considered for the dimensioning generated a fairly conservative preliminary design if the processed data is limited to regular geotechnical investigations and references from local norms.

5 CONCLUSIONS

The paper has presented a deep foundation system and its study on soil-structure interaction was undergone in order to correctly address the design of an advanced geotechnical engineering project.

A number of analyses and interpretations of data have been performed for designing the deep foundation system. Finite element analyses and in situ testing were carried out for supporting the structural design, as several calculations and iterations were carried out in order to properly adapt and adjust the foundation system and infrastructure of a large-scale project (Figure 7).

The final design generated significant saving compared to the preliminary stages as back analysed data generated relevant results and in-situ testing proved utmost importance, particular emphasis being required for the soil structure iterative design process in order to validate and improve the considered design assumptions.

Analysis and re-sloping for slope stabilization in São José neighbourhood, João Pessoa, Paraíba, Brazil - case study

Analyse et re-profilage pour la stabilisation des pentes dans le quartier de São José, João Pessoa, Paraíba, Brésil - étude de cas

ABSTRACT: The disorderly occupation of slopes and hillside by socioeconomically vulnerable populations has caused changes in vegetation and topography in these areas, which can accelerate the occurrence of mass movements, resulting in material and human losses. Although there are available technologies and slope stability solutions, they are often inaccessible to communities in high-risk areas due to high costs and lack of investment from public authorities. This study was conducted in the São José neighbourhood, located in João Pessoa, Paraíba, Brazil. The soil involved belongs to the Barreiras Formation and has been analysed geologically and geotechnically. Currently, a section of the slope experiences active seasonal mass movement, aggravated during periods of high rainfall. The objective is the slope stability analyses under natural conditions and perform a back analysis for the triggering of the mass movement. As a proposed stabilization measure, the analyses results show the necessity and feasibility to adopt slope flattening, along with surface drainage works and the application of vegetative protection using Vetiver grass as a stabilizing action to guarantee the safety of the residents in the region.

RÉSUMÉ: L'occupation désordonnée des pentes et des collines par des populations socialement vulnérables a provoqué des modifications dans la végétation et la topographie de ces domaines, ce qui peut accélérer la survenue de mouvements de masse, entraînant des pertes matérielles et humaines. Bien que des technologies et des solutions de stabilité de pentes soient disponibles, elles sont souvent inaccessibles aux communautés situées dans des zones à haut risque en raison de leur coût élevé et du absence d'investissement des autorités publiques. Cette étude a été ramenée dans le quartier de São José, situé à João Pessoa, Paraíba, au Brésil. Le sol concerné appartient à la Formation de Barreiras et a été analysé sur le plan géologique et géotechnique. Actuellement, une section de la pente subit un mouvement de masse saisonnier actif, aggravé pendant les périodes de fortes précipitations. L'objectif est d'analyser la stabilité de la pente dans des conditions naturelles et d'effectuer une analyse rétrospective pour déterminer les causes du mouvement de masse. Comme mesure de stabilisation proposée, les résultats indiquent la nécessité et la faisabilité d'adopter un aplanissement de la pente, accompagné de travaux de drainage en surface et de la mise en place d'une protection végétative à l'aide de l'herbe de Vetiver en tant qu'action de stabilisation pour garantir la sécurité des habitants de la région.

Keywords: Back analysis; mass movement; slope stability; re-sloping; risk areas.

1 INTRODUCTION

This study proposes slope reinforcement as a low-cost stability solution in risk areas in João Pessoa, the capital of the Paraíba state, Brazil.

The uncontrolled urban expansion of major towns in recent decades has led socioeconomically vulnerable populations to seek residence in hillside areas. Therefore, this work aims to address the issue of the lack of accessible and effective solutions for slope stabilization in risk areas within the city of João Pessoa. The research is justified by the significance of developing low-cost solutions in the field of civil engineering.

Most risk areas are in underprivileged communities that lack the financial resources to afford complex and costly solutions. Furthermore, the adoption of low-cost solutions can significantly reduce the risk of accidents caused by mass movements, saving lives, and preserving public and private property (Alheiros *et al.*, 2003; Ministério das Cidades, 2006).

In this context, the present study analyses the slope stability and proposes a low-cost and secure solution for the high-risk area in the study region.

2 THEORETICAL FOUNDATION

2.1 Triggering agents

2.1.1 Rainfall

According to Highland and Bobrowsky (2008), mass movements primarily occur during periods of cumulative rainfall, presenting a risk to the population living in landslide-prone areas. According to Lima (2002) *apud* Ramos *et al*. (2022), there is a correlation between cumulative rainfall and landslides, as rainfall is classified as one of the main triggering factors, leading to increased soil saturation and erosion at the top, body, and foot of slopes, reducing cohesion and the angle of friction, resulting in a drastic reduction in soil resistance.

2.1.2 Geomorphological and morphological factors

Geomorphological factors are related to the properties of the soil type in which the process takes place. In this context, the terrains will be prone to the influence of certain landslide or erosion phenomena, according to their lithological properties, texture, structure, and pre-consolidation (Simões, 2023).

Morphological factors are related to the shape in which the slope presents itself, that is, the susceptibility to landslide occurrence, which, according to Alheiros et al. (2003), is related to how high and extensive the slope is and its characteristics, such as low sinuosity, concave profile, and high slope.

2.1.3 Anthropogenic actions

Anthropogenic factors are strongly related to the composition of risk, as they correspond to human activities and how the population interacts with the environment in which they live. According to Oliveira (2021), this interaction occurs in various ways, such as excavation and filling for housing, leakage in supply and drainage pipelines, the discharge of wastewater and/or sewage, the construction of septic tanks, irregular disposal of garbage and/or debris, as well as changes in vegetation, all of which are susceptibility factors. In addition, the population density is considered a vulnerability factor.

2.2 Climate characteristics in João Pessoa

The climate of the municipality of João Pessoa, Paraíba - Brazil, is characterized by its location at low latitudes and its proximity to the Atlantic Ocean. According to the National Institute of Meteorology-INMET (2023), the region climate is characterized by an average annual precipitation of 1837 mm and an approximate annual average temperature of 26.9°C, with the rainiest period occurring from April to July, as shown in Figure 1.

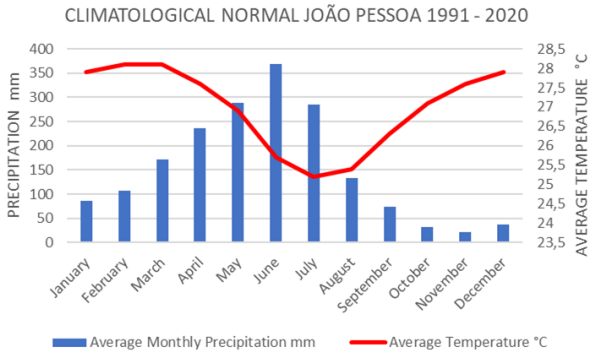

Figure 1. Climatological Normal João Pessoa 1991 - 2020.

2.3 Characterization of the soil

Some soils of João Pessoa-PB were characterized by Nascimento (2008) *apud* Soares (2011), confirming the predominance of Red-Yellow Argisols in the Coastal Plateaus of the Barreiras Formation. According to Barbosa (2015) *apud* Bezerra (2017), the majority of João Pessoa's territory is situated on the Barreiras Formation, covering approximately 67% of the municipality's total area.

2.4 Landslide risk areas in the city

The city of João Pessoa experienced significant urban growth starting in the 1960s, following the pattern observed in many other cities in Brazil. However, this growth occurred without proper urban planning, leading to the occupation of hillsides and river valleys by low-income residents and, consequently, an increase in population density in risk areas.

Currently, according to the Municipal Coordination of Protection and Civil Defense of João Pessoa, as evidenced by Ramos *et al*. (2022), the city of João Pessoa has 27 areas located in mass landslide risk zones.

2.5 Neighbourhood data

The neighbourhood began with the occupation of land along the banks of the Jaguaribe River by families from the former Beira-Rio community, with predominantly substandard residential characteristics. The neighbourhood reflects the land parceling and occupancy typical of spontaneous settlements (Filipeia, 2023).

According to data from the last Demographic Census conducted by the Brazilian Institute of Geography and Statistics-IBGE (2010), the neighbourhood covers a territorial area of approximately 34,98 hectares and is home to a population of 7.078 residents. It is characterized by

social inequality, with the river and slope acting as physical barriers that separate it from more affluent neighbourhoods.

Over the years, there have been eight occurrences of mass movements in the neighbourhood recorded between 2000 and 2016, as reported by Silva (2018). The frequent landslides in the area could be attributed to factors such as the extremely steep slope profile, with some sections having inclinations exceeding 45 degrees, as well as the presence of large trees at the top of the hillside and constructions at the toe of the slope. These factors contribute to an increased vulnerability to mass movements.

2.6 Re-sloping

Re-sloping can be directed towards a specific slope angle or aimed at altering the entire profile of the slope. These are interventions designed to stabilize the slope by reshaping its form through cuts in the uppermost part, with the goal of regularizing the surface and, as much as possible, artificially restoring the topography of the barrier, thereby enhancing soil stability. This solution is often combined with compacted fills to act as stabilizing loads at the toe of the slopes.

Alheiros *et al*. (2003) provides some important analysis characteristics. For cut sections, cuts with a height of less than five meters can be continuous, while cuts with heights exceeding five meters should be terraced in steps through berms or benches.

Each soil or sediment variety, when subject to denudation, defines its equilibrium profile, which stabilizes when vegetation becomes established. Cuts disrupt this equilibrium, thus enhancing erosive processes and mass movements. According to Alheiros *et al*. (2003), these changes can be offset by reshaping, ensuring that fill slopes do not exceed a ratio of 1:2 (vertical:horizontal), cut slopes maintain a ratio of 1:1,5 (vertical:horizontal), constructing berms whenever possible at the toe of the fill, restoring surface cover, and implementing drainage at the cut-off drain, berm drain and toe drain the slope.

2.7 Vegetative protection

One of the most important mechanical properties of vegetation in soil is its roots, due to their tensile strength in contrast to the soil's resistance to compressive forces. Therefore, the combined action of the soil and roots results in reinforced soil (Baets *et al.,* 2008 *apud* Júnior, 2019). However, according to Simões (2023), it is advisable to avoid planting large trees on the top or along the slope, since, due to the action of gravity combined with strong winds, it causes tensions in the soil due to the lever effect, which can disaggregate the soil, triggering mass landslides or tree toppling.

3 METHODOLOGY

3.1 Studied slope

The study was conducted in the São José neighbourhood, through field visits and a bibliographic survey of the area's landslide history. Subsequently, in collaboration with Federal University of Paraíba, the mass landslide risk map for the São José neighbourhood was generated, as shown in Figure 2.

Figure 2. Landslide risk map of São José.

Next, the Z3 zone (purple), classified as high risk of mass movement, was selected for the study. The studied area exhibits a well-defined soil crack, indicating a soil rupture zone due to a seasonal mass movement process that began in 2015 and intensified further in 2021 up to the present day. The crack is approximately 13,20 m in length and 3,50 m from the top of the hillside, as shown in Figure 3.

Figure 3. Crack at the top of the slope.

Through field visits and photogrammetric survey using a drone, the local features were obtained, described as: natural hillside with concave terrain and average inclinations of 45 degrees, the presence of tree

vegetation on the slope surface, and banana trees at the toe of the slope.

3.2 Characterization studies

3.2.1 Laboratory tests

The tests were conducted in the Geotechnical Laboratory of the Department of Civil Engineering at the Federal University of Paraíba, following all applicable technical standards from the Brazilian Association of Technical Standards (ABNT). The laboratory tests were conducted:

- Soil - Grain size analysis;
- Specific gravity of solids;
- Determination of Atterberg limits:
  - Liquid limit;
  - Plastic limit;
- Compaction test;
- Direct shear test.

3.2.2 Soil classification using correlations with SPT sounding parameters

A nearby borehole on the slope was used to establish a correlation between the Standard Penetration Test (SPT) and soil classification based on the methods proposed by Godoy (1972) and Teixeira (1996) *apud* Neto (2018). This correlation was utilized to determine cohesion, friction angle, and natural unit weight values through the number of blows in the test.

3.2.3 Instrumentation

The landslide area was instrumented with crackmeters using 2 mm thick glass plates measuring 52 mm x 40 mm to monitor the displacement of cracks. In total, four glass plates were strategically placed. Figure 4 shows two of the glass plates used in the instrumentation.

Figure 4. Crack instrumentation.

4 RESULTS

4.1 Results of the characterization studies

Table 1 presents the data used in the slope stability study. The parameters of friction angle, cohesion, and specific weight were determined through back analysis for layers 1 and 2. Thus, the back analysis was conducted based on the data obtained from laboratory tests, in which the friction angle, cohesion, and specific weight varied between the natural and saturated soil states to obtain the parameters at the slope failure moment (FS≈1,00). For layers 3, 4, 5, and 6, the parameter values were obtained through correlation with the samples borehole data.

Table 1. Adopted parameters of angle of friction, cohesion, and specific weight.

Layer	Friction angle (°)	Cohesion (kPa)	Specific weight (kN/m³)
1 natural	25°	7,19	16
1 back analysed	22°	5	18
2 natural	25°	7,19	16
2 back analysed	22°	6	18
3	31°	10	20
4	35°	10	20
5	35°	20	20
6		(rock)	

4.2 Slope modelling

Using georeferencing, the cross-sectional profile of the slope was plotted, with the slope having an approximate elevation of 13,79 meters and a distance of 20 meters from the dwellings, displaying a concave profile, as shown in Figure 5.

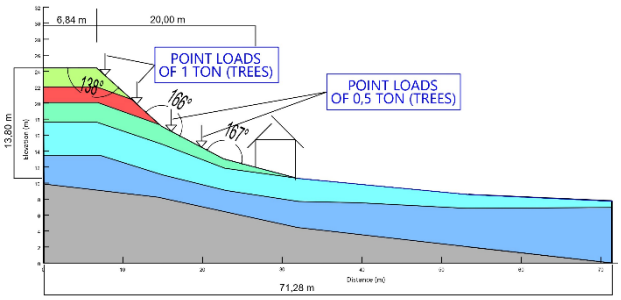

Figure 5. Profile of the relief of the studied slope.

During the field visits, the presence of large and medium-sized trees along the slope was observed, and their loads were modeled pointwise on the slope face in the GeoStudio software.

4.3 Results of back analysis

In the back analysis, the objective was to determine the safety factor (FS) for the natural conditions of the slope during rainy seasons, which triggered the crack growth. For this purpose, the analysis was conducted using GeoStudio 2022.1 software through a student license, with the SLOPE/W module. Based on the soil

data, the hillside was modeled and analysed, considering two scenarios: saturated soil for the back analysed condition and the other scenario for the natural soil condition. In this way, the safety factor was calculated for scenario 1 and scenario 2, through three analysis methods: Bishop, Fellenius, and Janbu, with the purpose of obtaining a thorough analysis in the region. The results are expressed in Table 2.

Table 2. Results of the slope analysis.

Method	FS - back analysis	FS - Natural Soil
Bishop	1,035	1,203
Fellenius	1,007	1,268
Janbu	0,986	1,186
Average	1,009	1,219

It is evident that, in all the analyses conducted, that the safety factor (FS) found is less than the minimum value of 1,4 recommended by NBR 11682 (ABNT, 2009). The low Safety Factor found can explains the slow movement of the slope that has been occurring in the region since 2015, characterizing a seasonal process of mass movement during periods of heavy precipitation and accumulated rainfall. This leads to soil saturation and, consequently, an increase in density, a decrease in the angle of friction, and a decrease in apparent cohesion, which can become virtually negligible.

4.4 Stabilization proposal

For the study slope, a stabilizing action is necessary to ensure the safety of the residents in the area. The soil in the region exhibits well-graded particle sizes, with a significant percentage of sand, providing good cohesion and friction angle results for the natural and submerged scenarios. These results are considered suitable for use in the stabilization of the slope.

Considering the favorable soil characteristics and the fact that the slope has sufficient space at the top and toe, along with a favorable height, it supports the feasibility of stabilizing the slope through the process of re-sloping, using the excavated soil itself as fill material. This solution allows for a more cost-effective construction.

In the project, the original slope was divided into two distinct slopes, separated by a 2-meter-wide berm. The profiles of the new slopes were reshaped to smooth the inclinations, adopting a 30-degree slope, with a width-to-height ratio of 2:1,15, as shown in Figure 6.

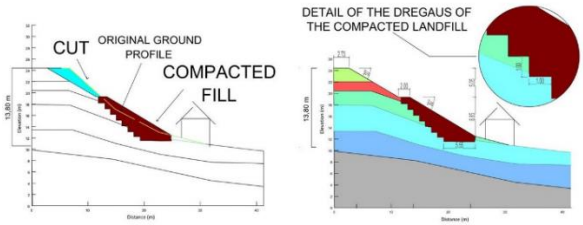

Figure 6. Re-sloping profile.

For the study, the parameters of the compacted fill from the sample taken from the slope were adopted and input into SLOPE/W (2022). Stability analysis was conducted in two scenarios: scenario 1, representing the conditions identified in the back analysis, and scenario 2, representing the natural soil conditions. This allowed the calculation of the safety factor using the analysis methods: Bishop, Fellenius, and Janbu, as shown in Table 3.

Table 3. Results of slope stabilization analysis.

Method	FS – Scenario 1	FS – Scenario 2
Bishop	1,46	1,80
Fellenius	1,62	1,77
Janbu	1,40	1,68
Average	1,49	1,75

The analysis results indicate that in all the scenarios considered, the Safety Factor (FS) found is higher than the minimum value recommended by NBR 11682 (ABNT, 2009) of 1,4. Therefore, it can be stated that the proposed re-sloping project complies with the criteria established by the standard.

To complement the stabilization through re-sloping, the implementation of vegetative cover and a surface drainage system was proposed. In this study, the use of Vetiver grass as a vegetative cover was chosen due to its rapid growth, especially in the Northeastern coastal region, as documented by Júnior (2019). Additionally, the design of the surface drainage system followed the recommendations of Institute of Technological Research-IPT (1991) with the aim of collecting and directing surface runoff water and part of the internal percolation water from the slope, as shown in Figure 7.

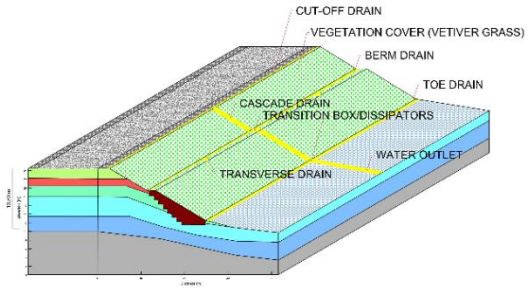

Figure 7. Isometric perspective view of the re-sloping project.

5 CONCLUSION

The results obtained indicate that the São José neighbourhood, located in João Pessoa, Paraíba, Brazil, is predominantly composed of substandard housing and individuals with low income per capita. This is further exacerbated by frequent landslides due to the following characteristics: extremely steep slopes, tree vegetation on the slope's crest, and constructions at the base of the slope. The soil in the region belongs to the Barreiras Formation, displaying well-graded particle sizes, a high percentage of sand, low plasticity, and satisfactory cohesion and friction angle.

The studied slope features an actively behaving crack, which moves seasonally during periods of high accumulated rainfall. Therefore, it is recommended to stabilize the slope through the re-sloping process, considering its technical and economic feasibility, complemented by vegetative cover and a surface drainage system. Consequently, this stabilization project should be promptly executed by the responsible authorities to prevent a disaster from occurring at the site.

ABSTRACT: The use of underground space in urban environment has increased considerably in recent years due to the construction of tunnels and underground stations. Shafts appear as one of the main structures associated with these works because they permit direct access to the underground. Generally, the shaft construction methods can be divided into two main categories: SBE – where the support is placed before excavation; and EBS – where the excavation is performed before the application of a support. Having as reference the case of the Shaft WA2, built as part of the Dublin Port Tunnel project, and excavated using the SBE method, this paper investigates the advantages and limitations of each construction method by performing a numerical study. After the calibration of the model based on the results of the instrumentation, the shaft excavation is alternately simulated using the EBS method. The comparison of the achieved results shows that although both methods have merits, the construction using the EBS method was probably the most adequate solution given the soil conditions at the site. In this particular case, the use of the EBS method would permit to employ a thinner support while keeping the deformations of the ground induced by the excavation at very small values.

RÉSUMÉ: L'utilisation de l'espace souterrain en milieu urbain a considérablement augmenté ces dernières années en raison de la construction de tunnels et de stations souterraines. Les puits apparaissent comme l'un des principaux ouvrages associés à ces ouvrages car ils permettent un accès direct au sous-sol. Généralement, les méthodes de construction de puits peuvent être divisées en deux catégories principales: SBE – où le support est placé avant l'excavation; et EBS – où l'excavation est réalisée avant l'application d'un support. Ayant comme référence le cas du puits WA2, construit dans le cadre du projet de tunnel du port de Dublin et creusé selon la méthode SBE, cet article étudie les avantages et les limites de chaque méthode de construction en réalisant une étude numérique. Après l'étalonnage du modèle sur la base des résultats de l'instrumentation, l'excavation du puits est simulée en alternance à l'aide de la méthode EBS. La comparaison des résultats obtenus montre que, même si les deux méthodes présentent des avantages, la construction selon la méthode EBS était probablement la solution la plus adéquate compte tenu des conditions du sol du site. Dans ce cas particulier, l'utilisation de la méthode EBS permettrait d'employer un support plus fin tout en gardant les déformations du sol induites par l'excavation à des valeurs très faibles.

Keywords: Shaft excavation; numerical modelling; construction method.

1 INTRODUCTION

The use of underground urban space has increased considerably due to the construction of tunnels and underground stations. In this context, shafts appeared as one of the main structures associated with this type of works because they permit direct access to the underground. Shaft excavation methods can be classified in two main groups: SBE (Support Before Excavation) – where the support, such as diaphragm walls, is installed prior to the excavation; and EBS (Excavation Before Support) – where the excavation is performed and only after the support, such as shotcrete, is installed. The analysis of case studies (Faustin et al., 2018) shows that, depending on the design requirements and site conditions one technique may be more applicable than the other. However, in some cases, it is not clear which one would be the most appropriate and there are few well-documented cases in the bibliography that discuss the impact of adopting a certain constructive method on the behaviour of

shafts. Having as reference the case of the Shaft WA2, built as part of the Dublin port tunnel project, this paper aims to evaluate through numerical analysis the advantages and limitations of adopting the abovementioned construction methods.

2 SHAFT WA2

The shaft WA2 was built in 2001 and served as a launching platform for the twin tunnel excavation of the Dublin Port Tunnel (DPT). The circular shaft with an internal diameter of 56.6 m has a depth of around 29.0 m and it was built following the SBE method, with the support being materialised by a 1.5 m-thick diaphragm wall. The depth of the wall varied slightly, but it was approximately 32.5 m, coinciding with the top of the bearing stratum, a Limestone layer. Beside the capping beam, a ring concrete beam with a section of 2.5x2.5 m^2 at the depth of 13 m was also executed. A 1 m-thick concrete base slab was built once the excavation reached its bottom. Figure 1 shows a photograph of shaft WA2 at the time of its completion where all the supporting structures can be seen.

Ground conditions at the site comprised the well-known Dublin boulder clays overlying a limestone layer. A complete description of the Dublin boulder clays can be found in Long & Menkiti (2007). At the site of shaft WA2, the Dublin Clays stratigraphy was composed of 2 m of the Upper Brown (UBrBC) layer, followed by the Upper Black (UBkBC) layer, which had a thickness of around 12 m. The third layer was the Lower Brown (LBrBC) layer, with a thickness of 11 m and, finally, the Lower Black (LBkBC) layer with 7.5 m thick was found. The stratigraphy and the shaft dimensions and support can be seen in Figure 2.

The performance of the shaft excavation was monitored by 9 inclinometers, which were installed inside the diaphragm wall panels.

3 MODELLING PROCEDURES

3.1 Dimensions and mesh

In order to simulate the shaft excavation, the finite element program RS2 was employed. All analyses were performed considering an axisymmetric model and a total stress condition given the nature of the materials simulated. Figure 3 presents the model adopted in the SBE analysis. A width of 200 m and a depth of 100 m were considered so that all stresses and deformations fields would not be influenced by the presence of the boundaries.

Figure 1. Shaft WA2 (Looby and Long, 2007).

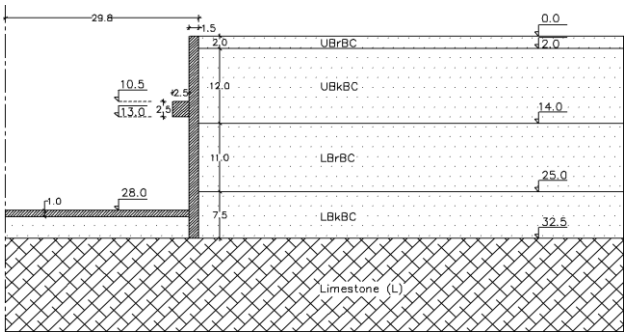

Figure 2. Stratigraphy and geometry of WA2 shaft.

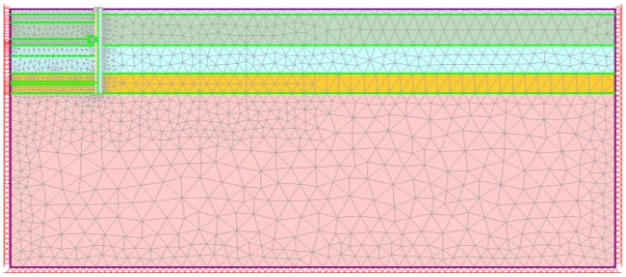

Figure 3. Mesh employed in the SBE numerical model.

The shaft dimensions, its support and ground profile were simulated accordingly with Figure 2. The mesh is constituted by isoparametric triangular finite elements with 6 nodal points and has a total of 1961 elements, with a refinement in the shaft vicinity. Boundary conditions were assumed as standard for axisymmetric conditions: free at surface, only vertical displacements allowed in the vertical boundaries and all movements restrained at the base of the model. Elastic interface elements were considered between the soil and the diaphragm wall so that relative movements could occur. The diaphragm wall was considered to be elastic while for the soil layers a linear elastic-perfectly plastic constitutive model with a Tresca failure criterium was adopted.

3.2 Construction sequence

The definition of the construction sequence followed the description presented by Cabarkapa et al. (2003), so that the obtained results could be compared against the inclinometer data. A total of 6 stages were considered in the SBE shaft excavation: 1) initial stress state, considering geostatic conditions and a K_0 profile; 2) installation of the diaphragm wall as

wished-in-place; 3) excavation up to a depth of 13m; 4) installation of the ring beam; 5) final excavation of the shaft to a depth of 29m; and 6) construction of the base slab.

3.3 Calibration of the numerical model

A class A prediction of the shaft performance was presented by Cabarkapa et al. (2003), where a coupled-consolidation analysis to simulate the short-term behaviour of the excavation was employed. The final horizontal displacements obtained by Cabarkapa et al. (2003) are presented in Figure 4. Superimposed in the figure are also the results of the inclinometers (and its envelope) to facilitate the comparison. The results show that both the trend and magnitude of the displacements are not correctly captured by the analyses, with the authors claiming that the parameters adopted for the materials at the design stage were very conservative and also justifying that the poor connection between the diaphragm panels permitted a cantilever deflection in the upper part of the shaft, which is not possible to simulate in the numerical model.

Having as reference the inclinometer data and also the extensive geotechnical characterisation on the Dublin boulder clays performed by Long & Menkiti (2007) and Long et al. (2013) a back analysis study was performed in order to calibrate appropriately the mechanical parameters of the Dublin boulder clay layers. The obtained final horizontal displacements are also presented in Figure 4, where it is possible to observe that, although the displacements near the surface are smaller than those measured at site, overall, a reasonable agreement, well within the inclinometer's envelope, is obtained. As mentioned previously it should be noted that with an axisymmetric model it is not possible to simulate the poor connection of the panels and therefore to improve the adjustment near the ground surface.

The parameters adopted as reference for the Dublin boulder clay layers in the analyses are presented in Table 1. For the structural elements (diaphragm wall, ring beam and base slab) a linear

Table 1. Soil parameters adopted in the analysis.

Material	γ (kN/m³)	S_u (kPa)	E_u (MPa)	ν	K_0
UBrBC	21	60	60	0.49	1.5
UBkBC	22.5	225	450	0.49	1.5
LBrBC	22	375	750	0.49	1.35
LBkBC	22.5	375	750	0.49	1.2
L	26	500	1000	0.3	1.0

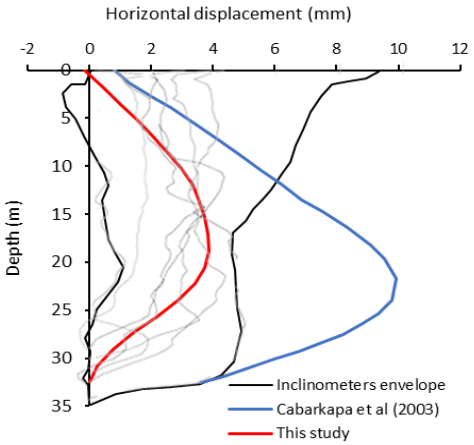

Figure 4. Calibration of the numerical model having as reference the inclinometer data.

elastic behaviour, characterised by a Young's modulus of 25 GPa, Poisson's ratio of 0.15 and unit weight of 25 kN/m³, was adopted. For the interface elements, an elastic model was assumed with normal and shear stiffness of 1×105 kPa/m and 1×104 kPa/m, respectively.

4 EBS SHAFT EXCAVATION

The EBS shaft excavation followed the typical principles of a sequential excavation. An excavation step of 2 m was adopted, which resulted in a total of 15 excavation stages until a depth of 29 m was reached (the last stage was only 1 m deep). Support for the excavation was provided by a shotcrete layer with a thickness of 0.5 m. For ease of comparison the parameters of the shotcrete were considered as equal as those of the diaphragm wall. In total, 31 stages were simulated in the EBS model. After the initial stress state, the first 2 m excavation step was performed followed by the installation of the shotcrete. These 2 stages were then repeated continuously until the bottom of the excavation was reached and the base slab installed.

5 COMPARISON OF THE RESULTS

The comparison between the main results obtained for the final stage of the excavation of the SBE and EBS models is presented in Figure 5. Although the horizontal displacements (a) obtained with the EBS model show a similar trend to the displacements obtained from the SBE, they are considerably higher as a consequence of the soil decompression which is inherent to the unsupported excavation performed. Is also interesting to verify that, had the excavation been performed without support (blue line) the horizontal

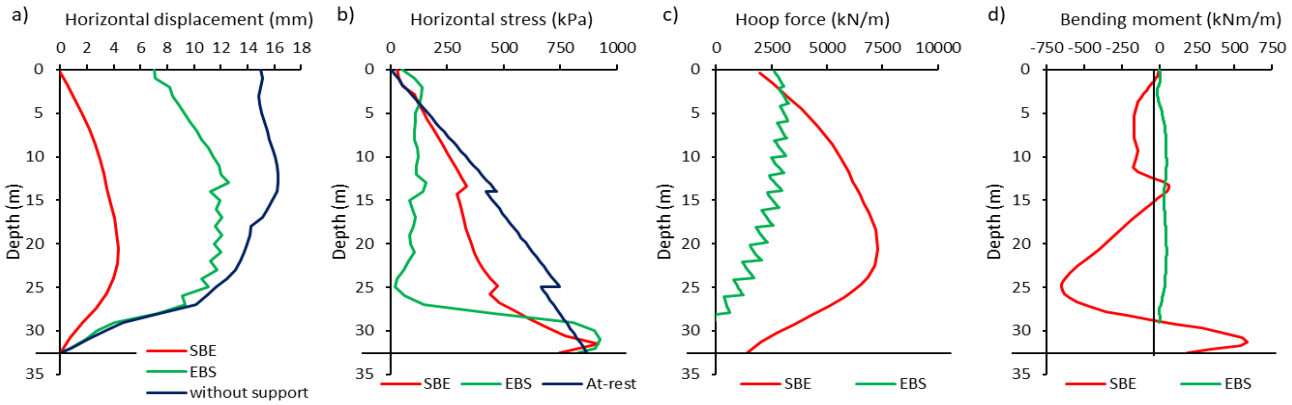

Figure 5. Comparison between the SBE and EBS methods: a) horizontal displacement; b) horizontal stress; c) hoop force; d) bending moment.

displacements would have been only slightly larger than those observed in the EBS model, implying that the ground strength is very high. Nevertheless, given that the overall movements do not surpass 16mm they can be considered very small. The results of the horizontal stress (b) are in agreement with the horizontal movements with the EBS model showing a much smaller final stress as consequence of the soil decompression. In the SBE a much smaller soil decompression is observed with the horizontal stress values being much closer to those adopted in the initial stress state. The structural forces in the diaphragm / shotcrete wall show that with SBE methodology much higher forces, both hoop (c) and bending moments (d) are to be expected. Those come as consequence of small reduction of horizontal stresses that are allowed due to the installation of the diaphragm wall before the beginning of the excavation.

6 CONCLUSIONS

Having as reference the case of the WA2 shaft in Dublin the following conclusions can be drawn:

- A SBE construction reduces considerably the decompression of the ground during the excavation process, which results in very small deformations. As a result, this method is ideal to minimize the impact of shaft excavation on nearby infrastructure. However, since the soil decompression is not allowed, the forces in the support, both hoop and bending moments, are expected to be very high and demand a robust support;
- The almost exact opposite was observed in the EBS model, where the excavation without support allowed for a maximum soil decompression, which resulted in higher horizontal movements but much smaller horizontal stresses and structural forces;
- Based on the achieved results for the case of WA2 shaft, the application of the EBS method would be feasible and highly competitive, as it would allow to considerably reduce the volume of materials used and the execution time, without significantly increasing the ground deformations or compromising the shaft stability.

  It should be noted that these conclusions relate to the specific case of the WA2 shaft and should not be directly generalised to other projects where the geotechnical conditions would be different.

ABSTRACT: Geosynthetic solutions offer sustainable alternatives, delivering long-lasting, stable embankment foundations that are easier and faster to build compared to traditional methods, reducing not only construction time and costs but also contribute to carbon footprint savings. This publication describes cellular foundation mattresses technology called Stratum that consists of 1m high bespoke geocell structure, as described in BS 8006-1: 2010. This solution has been utilised on infrastructure projects such rail and highways, acting as embankments foundations. This paper presents a case study of a highway embankment built in 1990s and is supplemented by recently obtained information on the performance of a road embankment after 30 years from its installation. This example proves the long tracked record of 1m high, bespoke geocell mattresses economical advantage over the alternative traditional solutions. 1m high geocells offer reduction of excavation volumes of unsuitable soils that typically would be replaced with engineered fill, or remove the need for piling works, delivering solutions without compromising on performance.

RÉSUMÉ: Les solutions géosynthétiques offrent des alternatives durables, fournissant des fondations de remblai durables et stables, plus faciles et plus rapides à construire par rapport aux méthodes traditionnelles, réduisant non seulement le temps et les coûts de construction, mais contribuant également à la réduction de l'empreinte carbone. Cette publication décrit la technologie de matelas de fondation cellulaire appelée Stratum qui consiste en une structure géocellulaire sur mesure de 1 m de haut, comme décrit dans la norme BS 8006-1: 2010. Cette solution a été utilisée sur des projets d'infrastructure tels que les chemins de fer et les autoroutes, agissant comme fondations de remblais. Cet article présente une étude de cas d'un remblai routier construit dans les années 1990 et est complété par des informations récemment obtenues sur la performance d'un remblai routier 30 ans après son installation. Cet exemple prouve l'avantage économique des matelas géocellulaires sur mesure de 1 m de haut par rapport aux solutions traditionnelles alternatives. Les géocellules de 1 m de haut permettent de réduire les volumes d'excavation de sols inappropriés qui seraient généralement remplacés par des remblais techniques, ou suppriment le besoin de travaux sur pilotis, offrant ainsi des solutions sans compromettre les performances.

Keywords: Geomattress; embankments; soft soils; monitoring instrumentation.

1 INTRODUCTION

Embankments are a key feature of many infrastructure projects such highways, railways or flood defence schemes. It is vital that these structures are built on firm and stable foundations ensuring minimal maintenance required over their service life. This can be challenging when dealing with weak, variable and saturated subgrade soils. Traditional solution for construction of foundation embankments, involve digging and replacing soft deposits with engineered fill, piling an embankment or to utilising other deep ground improvement methods such as, e.g.: vibro concrete, stone columns, dynamic compaction, deep ground mixing, load transfer platforms etc. These approaches are technically valid, but they are also expensive, time consuming, heavy on carbon footprint and often involve extensive temporary works.

A 1m high, bespoke geocell foundation mattresses, as defined by BS 8006-1 (2010) constructed using uniaxial geogrids (Figure 1), offers a cost-effective solution alternative to the traditional methods.

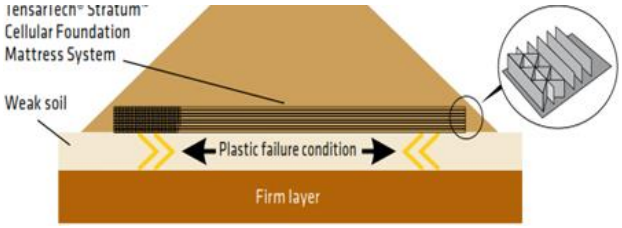

Figure 1. Typical section through embankment constructed on Cellular Foundation Mattress System.

To the Authors's knowledge the technology is still relatively uncommon and underutilised. Kuznietzowa and Doulala-Rigby (2015) and Pyne (1993) present cost comparison between this and alternative technologies that is based on site efficiencies and production costs. This shows already considerable advantage of geosynthetic solution over the alternative methods. However, these do not consider additional savings due to programme time reductions or more importantly carbon footprint reductions that geosynthetic solutions offer (Rimoldi et al. 2021).

Geocell mattress technology involves construction of a three dimensional, typically 1m high, honeycombed structure on site using uniaxial geogrids that form interlocking cells (Figure 1). These get filled with suitable aggregate and form foundation of the embankment (or are used for temporary working platforms construction).

Embankments built on geocell mattresses are characterized by an even distribution of typically heterogeneous settlements (e.g. Pyne 1993, Jenner et al. 2008, Lees et al. 2020). The mattress built into the base of an embankment creates a stiffened platform, which allows an application of higher loads directly on the mattress, and the stresses transmitted by the mattress are distributed over a larger area, reducing unit stresses acting directly on the base. BS 8006-1: 2010 presents an analytical method of calculating the bearing capacity of embankments reinforced with geocell mattresses on cohesive soils.

The method presented in BS 8006-1 (2010) and described in more detail in Jenner et al (1988) is based on the conditions of plastic deformation of the substrate under a wide embankment. The bearing capacity resulting from the slip line analysis should be compared with the additional stresses resulting from the installation of the embankment and its weight in order to estimate the safety factor and check if the equilibrium condition is met.

It should be noted that this method does not apply to geosynthetics of smaller dimensions (so-called geocells 0.15 m to 0.3 m high). The method applies to geomattresses that reach at least 0.5 m in height, but more typically 1 m or 1.2 m height. The method allows to estimate bearing capacity of the mattress, as well as to select the appropriate type of a uniaxial geogrid from which the mattress will be constructed.

Whilst utilisation of cellular foundation mattresses on projects globally is not widespread, there exists a lot of evidence of their performance, in a variety of applications, e.g.: embankments (Jenner et al. 2008), temporary working platforms (Lees et al. 2020) and shallow foundations for steel structure - warehouse (Duffin and Jenner 2000).

2 CASE STUDY: DARTFORD HIGHWAY EMBANKMENT 1992 (UK)

The current records of the project are scarce, however, the site of Dartford Highway Embankment was monitored and information about the historical project details were reported by Payne (1993). In addition, Payne (1993) described the design and construction stages of the embankment built at Dartford, UK, in 1992 (East London).

To summarise, the embankment was built using geocell mattresses technology. In addition, prefabricated vertical drains at 1.5 m intervals (in a triangular grid) were used to accelerate the process of consolidation under the embankment. The embankment was 4.3 m high, the width in the crest was 27 m to accommodate the total of 4 lanes (2 in each direction). The length of the section of the embankment on the weak subsoil was 350 m. The site geology was dominated by alluvial deposits of the Thames River, which flows in the immediate vicinity of the embankment. This also resulted in a high level of groundwater table in the subsoil. The layer of plastic clay was 10 m deep with subsurface interlayer of peat (Figure 2). The subsoil was characterized by an undrained shear strength Su value of 10 kPa, although in some areas this was considered an overestimated assumption and the actual value of Su was in the range 4.5 – 8 kPa (Pyne 1993).

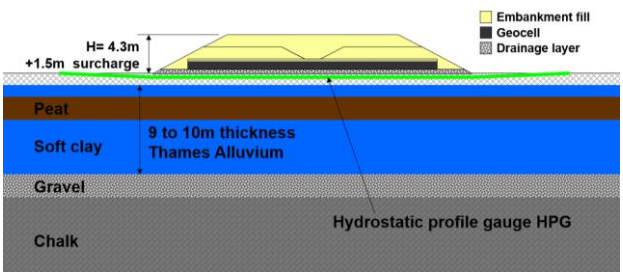

Figure 2. Geological setting of the Dartford road embankment (source Jenner et al. 2008).

The designed solution for this project took advantage of the rigid bespoke 1m high geocell foundation mattresses ensuring even load distribution

over weak soils in the sub-base. All four lanes of the roadway were constructed on one mattress.

Embankment deformation was monitored at the level between the mattress and the subsoil. The profile of vertical displacement (Figure 3) showed a very even settlement across the embankment with a mattress providing load distribution and control necessary to achieve the required bearing capacity and stability of the embankment. Figure 3 shows the values of settlement during construction and embankment overload. Settlement over time is clearly visible, with a very even deformation over the entire width of the base of the embankment and very limited differential settlement across the embankment. This is an essential feature considering long term use of the efficient, economical and durable structure. The monitoring confirms the assumptions of the cellular mattress technology, which refer to the creation of a semi rigid foundation structure at the base of the embankment that allows uniform settlements at the base of the embankment.

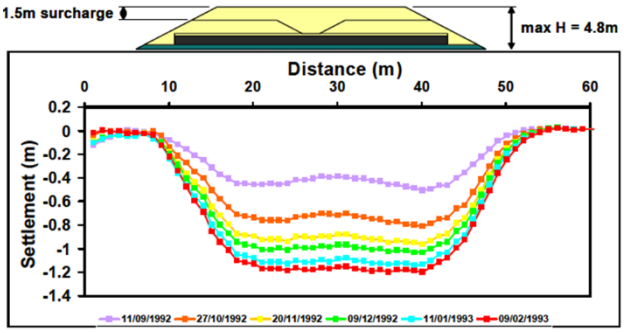

Figure 3. Settlements records under the embankment with time (source Jenner et al. 2008).

3 CURRENT STATE OF THE EMBANKMENT

Up to date quantitative data on the embankment performance are not available, however, the authors of this paper investigated the qualitative in-service performance of the embankment during a recent site visit. The authors interviewed the local road maintenance contractor who has been engaged with resurfacing works on the relevant section of the road by the local County Council. The following remarks and statements were collected from the contractor:

- There has been no major works undertaken on the embankment after its installation,
- The only works undertaken on the section, were the scheduled cyclic resurfacing maintenance works,
- Major resurfacing works took place in late 2000s, there was no need for major restorations to the structure of the embankment,
- No works related to kerbs alignments were needed, as all of them were in place with no noticeable horizontal or vertical displacements,
- No works related to manholes and drains relating to embankment settlement took place.

Moreover, during the site visit by the authors, the examination of the road and photo records (Figure 4 & 5) were collected, as a part of the evidence to support the Contractor's statement. Whilst no quantitative data is available to assess scientifically the performance of the embankment 30 years after its installation, the above statements are satisfying and the site visit with the surface examination confirmed long term performance of geocell mattresses under highway embankments from the user and owner perspective. It is evident that the majority of the settlements of the embankment occurred during the first months after the installation (Figure 3). Following that the embankment remained stable with not recorded differential settlements or stability problems that would cause issues to the asset owner or maintenance contractor.

Figure 4. Current photos of the embankment showing high water table – water ponds in close vicinity of the embankment (on Thames River side).

Figure 5. Current photo of the embankment: Pavement and footpath photo showing smooth, even surface.

The mechanism of the reduction of subsidence (with vs without cellular foundation mattresses), however, is not yet sufficiently well understood to be able to accurately estimate the reduction of subsidence at the design stage. Typically, settlements should be monitored during the project implementation by installing measuring instruments that verify the results and assumptions of the project. Recent publication of a project back analysis using numerical modelling approaches, advance the understanding and predictions made for serviceability limit state where settlements and differential settlements reductions of the cellular mattresses solution can be quantitatively estimated (Lees et al 2020).

4 CONCLUSIONS

Cellular foundation mattresses comprise a cost-effective and carbon footprint saving alternative to more traditional ground improvement technologies. Dartford embankment shows an example where after 30 years from embankment installation on extremely soft grounds, no issues with the solution was recorded. The technology is versatile it can offer the asset owner or contractor multiple benefits:

- Provides significant carbon reductions compared with any other ground deep improvement methods
- Can be installed on most types of weak or heterogeneous soils (as well as in municipal landfills, i.e. Duffin and Jenner (2000),
- Eliminates or limits the need for excavation, as it is a trenchless solution, performed directly on the existing ground. This allows the work to be carried out without damaging the natural structure of the substrate,
- Requires a short time of execution and implementation - proper arrangement of geogrids and filling the cells is not a time-consuming task, an additional advantage is the fact that geocell mattresses are part of the embankment. The construction of the cellular foundation mattresses is therefore a phase in the construction of the embankment, which reduces the time needed to build the entire embankment,
- Does not require specialised workforce - installation of geocells is very simple, there is no need to use special construction machines. Typical earthmoving construction machines are sufficient to properly install a geocells in the ground,
- Can be installed in conjunction with prefabricated vertical drains accelerating the consolidation of the substrate.

Cellular foundation mattresses reduce uneven settlement as well as contribute to the reduction of total settlement. More research and construction of structures with long term monitoring will be beneficial to advance the knowledge on the mechanisms of the cellular foundation mattresses performance.

ABSTRACT: As part of the future circular line of the Lisbon Metro System, Estrela Station stands out for being the deepest in the network, with a depth of around 60m. Excavated using the NATM methodology from a shaft with quadrangular and circular sections in Miocene and Cretaceous limestone, it posed challenges inherent to this type of work due to its section size, geological singularities or the need to increase productivity. Production was optimized with the excavation of a pilot tunnel from the T33 track tunnel in order to have another front for debris extraction and also serving for geological reconnaissance. Intercepted rock faults, recognized or not in the previous design phases, were addressed in order to mitigate excessive deformations or even potential instabilities. The presence of the second unit of the "Caneças Formation" in the lower section of the station chamber, of a more marl-clayey nature and potentially more deformable, led to the adoption of complementary support solutions foreseen in the project, as well as specific reinforcements.

RÉSUMÉ: Faisant partie de la future ligne circulaire du métro de Lisbonne, la station Estrela se distingue pour être la plus profonde du réseau, avec une profondeur d'environ 60 mètres. Creusée selon la méthodologie NATM à partir d'un puits à sections quadrangulaires et circulaires dans des calcaires du Miocène et du Crétacé, elle posait des défis inhérents à ce type de travaux en raison de la taille de ses sections, des singularités géologiques ou de la nécessité d'augmenter la productivité. La production a été optimisée avec le creusement d'un tunnel pilote à partir du tunnel ferroviaire T33 afin de disposer d'un autre front d'extraction des débris, partialisant la demi-tronçon et servant également à la reconnaissance géologique. Les failles interceptées dans le massif, reconnues ou non lors des phases de conception précédentes, ont été considérées afin d'atténuer les déformations excessives voire les instabilités potentielles. La présence de la deuxième unité de la « Formation Caneças » dans la partie inférieure de la chambre de la station, de nature plus marne-argileuse et potentiellement plus déformable, a conduit à l'adoption de solutions complémentaires prévues dans le projet, ainsi que de solutions de renforcement spécifiques.

Keywords: NATM; shaft; underground station; deepest Lisbon metro station.

1 INTRODUCTION

The newest Lisbon Metro expansion unites the existing Rato and Cais do Sodré stations from the yellow and green lines, respectively, forming a close ring line. This paper refers to Lot 1 with an extension of 1320m, which includes, the Estrela Station, the T33 and T34 double track tunnels (figure 1). Due to the surface level and the track slope limits, the station had to be located approximately 60 meters below surface, which presented some challenges.

The circular section shaft and the station as whole were excavated and monitored using the principles of NATM.

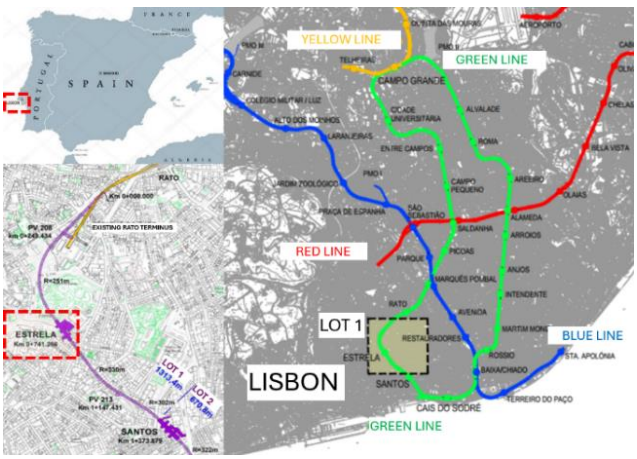

Figure 1. Estrela Station location map.

2 GEOLOGICAL AND GEOTECHNICAL FEATURES OF THE SITE

In the Estrela station area, the geology and geotechnical parameters were previously well known, complemented by a specific survey and in situ and laboratory tests during design phase. Three units were identified with different lithologies and geotechnical parameters (2021a) as shown in figure 2:

-Landfills, with little expression;

-Miocene of Lisbon, namely clays and calcarenites;

-Upper Cretaceous formations having very varied deformability and resistances. Caneças Formation, the lowermost, is characterized by limestones, marls and clays, thus with a wide range in compressive strength and deformability. This formation was intersected at the shaft base and at the northernmost station section. The circular shaft and the station gallery were built within the 40m thick Bica Formation, made of crystalline limestones with high strength and low deformability. All these formations have a 15º tilt to southeast.

Underground water was almost absent and restricted to a level in the Miocene and to sporadic vertical infiltrations in the cretaceous limestones.

Symbology	Formation	Depth (m)	Lithology
Landfill		0-2.0	Landfill, dark brown silty clay with lithic and ceramic fragments
M_{ag}	Prazeres Fm.	2.0-3.4	Brown to grey silty-marly clay, with hardened shell layers.
M_{cal}		3.4-13.0	White to yellowish marly limestone, with levels of calcarenites, somewhat vacuolar.
C_{c1b}	Bica Fm.	13.0-18.2	Yellowish nodular limestone with marls.
C_{c1c}		18.2-25.4	Whitish and very fractured and weathered limestone.
C_{c1c}		25.4-40.0	Yellowish crystalline limestone, very weathered, fractured and slightly karstified.
C_{c1d}		40.0-52.1	Whitish to yellowish compact limestone with veins, weathered and fractured.
C_{c2a}	Caneças Fm.	52.1-60.2	Weathered and fractured marly limestone, with dark gray clay.
C_{c2b}		52.1-68.3	Weathered and fractured marly limestone, with dark gray clay.

Figure 2. Geological-geotechnical profile (M- Miocene; C – Cretaceous).

3 DESIGN FEATURES

The preliminary design defined the need to install the station shaft in a restricted space, limited by buildings and without occupying public roads (figure 3).

Its first level has a square section with dimensions of ~32x32m^2, and containment walls made up of 57 piles with 800mm diameter. On the sides facing the existing buildings, 126 micro piles with 280mm diameter were used, reinforced with HEA160 steel beams. Depending on the height of the containment, between two and four anchoring levels were installed, with variable lengths and net working loads between 365 and 635kN. Their lower section is inbeded in the limestones and locked by a reinforced concrete transition slab to the top of the circular shaft.

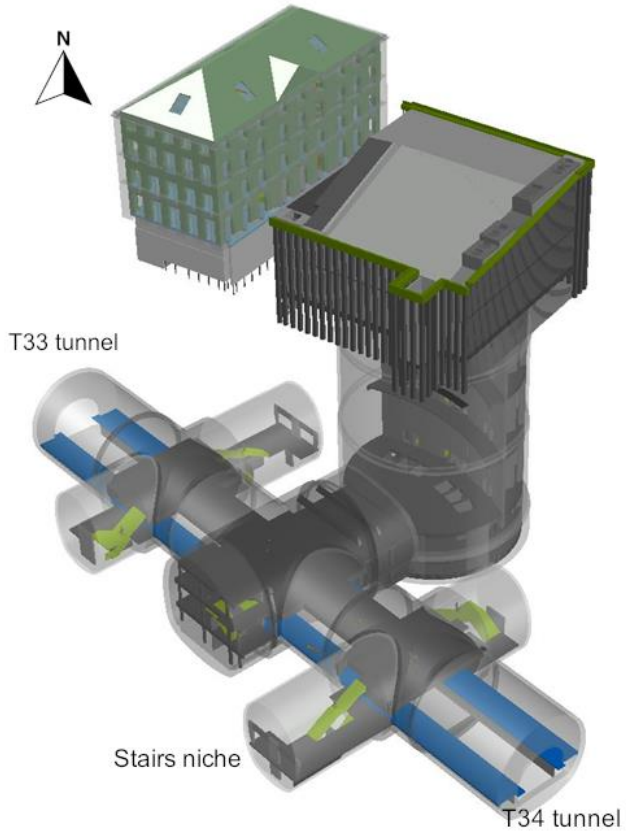

Figure 3. Estrela Station 3D model.

With a diameter of ~30 meters and a stepped and progressivelly larger section in depth, the primary lining of the circular section shaft is 0.20m to 0.30m thick, consisting of shotcrete and double wire mesh. This was complemented by a mesh of 4.0m long Swellex PM12 rockbolts and occasional 2.0m long geodrains. The advance depth was initially 0.90m, increasing to 2.10m, divided into eight segments, or panels, of the perimeter.

Figure 4. Transition between the square and circular section shafts.

A transversal gallery connects the circular shaft to the station main gallery which is 104m long, 15m high and 16m wide with a total section varying between 220 and 223m2. Four transversal niches accommodate stairs and elevators.

Figure 5. Upper piled wall with temporary ground anchors.

The presence of too closed existing buildings in two sides of the shaft required the use of micro piles with 260mm diameter reinforced with HEB160 steel beams instead of typical 800mm piles. The transition to the circular section shaft was made with a transition concrete slab as illustrated in the following figures.

Figure 6. Piled retaining wall and the transition slab to the circular section shaft.

Figure 7. Micro pile retaining wall and beginning of excavation of circular section shaft.

4 SPECIAL OCCURENCES

As the shaft excavation rate was slower than expected, due to limestone with high compressive strength, and as the T33 double track tunnel reached the station face early on, it was studied a smaller section pilot tunnel (figure 8) to attack the station top head section from the double track tunnel. Thus, a considerable volume of rock could be retrieved earlier, leading to an output increase, but also there was the opportunity to make extra geologic mapping since a major fault was a possibility inside the northern station section, as foreseen in the project.

Figure 8. Pilot tunnel section against the station top heading section.

In the south section, an unexpected fault (figure 9), with a *terra rossa* infill, promoted some instability leading to adoption of local reinforcement with extra rockbolts, mesh and shotcrete to smooth the gap. In the falt zone, the transversal niches were also reinforced with longer and less spaced forepoles.

Figure 9. Fault materialized by the reddish-brown clay.

In the station northern section, not only a fault was considered to occur, but also the lower part of the Caneças Formation, with fine bedded grey marls and clays. As the fault was not confirmed during the pilot tunnel survey - it occurred in the final meters of the T33 tunnel- the primary lining that consisted of 0.30m thick lattice girders, shotcrete and, in the bench section, of 6m long Swellex PM16 rockbolts, was maintained.

The Caneças Formation, although dry, were found at the invert level to the middle of the station, and in the bottom of the shaft. This led the designer to request the increase in the reinforcements at the interface with the limestones. These consisted of two lines of 12m long, 25mm diameter steel bars grouted in a 78mm diameter bore with a 30º downward attitude.

Figure 10. Lattice girders extensions at bench height, were the limestone-clay transition is clearly visible.

Figure 11. Southern station section showing in the middle the double track tunnel and side niches for the stairs and elevators.

5 CONCLUSIONS

The executed project was delivered according to expectations, without major issues. We should note that in this kind of underground works underneath urban areas, there are always some uncertainties concerning the rock mass quality, geologic fault occurrences or underground water behaviour, mainly in long tunnels where survey is, sometimes, very spaced with major gaps in between. The few unexpected conditions were addressed by the designer, the designer representative on site and the contractor to successfully adapt the project.

ABSTRACT: The extension of the Yellow Line of the Lisbon Metro between Rato and Santos Stations, to be integrated into the future circular line, included the creation of the 60m deep Estrela Station, a ventilation shaft and two new track tunnels executed with the NATM methodology. The construction solutions foreseen in the design phase, the monitoring and Special Technical Assistance to the construction, the analysis of the instrumentation and the additional measures adopted in the execution of about 1300m of tunnel in Cretaceous calcareous rocks, with a maximum cover of 50m, are addressed. The waterproofing works, the secondary lining execution in the terminus track tunnel which had the unique feature of having a variable section, the excavation of marls and clays from the Caneças Formation and the final stretch of the T34 tunnel partially excavated in tuffs and basalts of the Lisbon's Volcanic Complex are highlighted.

RÉSUMÉ: L'extension de la Ligne Jaune du métro de Lisbonne entre les stations Rato et Santos, à intégrer dans la future ligne circulaire, a prévu la création de la station Estrela de 60 m de profondeur, un puits de ventilation et 2 nouveaux tunnels de voie exécutés avec la méthodologie NATM. Les solutions constructives prévues dans la phase de projet, le suivi et l'Assistance Technique Spéciale à la construction, l'analyse de l'instrumentation et les mesures complémentaires adoptées dans l'exécution d'environ 1300 m de tunnel dans le massif calcaire du Crétacé, avec une couverture maximale de 50 m, sont adressées. Sont soulignés les travaux d'étanchéité, l'exécution du revêtement secondaire du tunnel de la voie terminus avec section d'élargissement, l'excavation des marnes et argiles de la Formation de Caneças et le tronçon final du tunnel T34 partiellement creusé dans tufs et basaltes du Complexe Volcanique de Lisbonne.

Keywords: NATM; rock excavation; monitoring; technical assistance.

1 INTRODUCTION

Sections T33 and T34 of the Lisbon Metro are double-track tunnels, included in the Design and Construction Contract for the Lisbon Metro Expansion Plan – Extension of the Yellow and Green Lines (Rato – Cais do Sodré), more specifically in Lot 1 – Execution of civil works between the end of Rato Station and Santos Station, from km 0+000 to km 1+319,729.

This extension aims to better serve the southern area of Lisbon's metropolitan network and extends in a N-S corridor, connecting Marquês de Pombal and the riverside area of Lisbon at Cais do Sodré, starting at the Rato Terminus on the Yellow Line (Figure 1). When completed, this expansion will form the Circular Line connecting the Green to Yellow line.

This connection solution between the two lines – Yellow and Green – will improve mobility in the central area of the city of Lisbon.

2 GEOLOGY

From top to bottom, the following formations occur (CJC 2021a):

- Landfills - Silty clay, sometimes with blocks, resulting from intense human activity;
- Miocene of Lisbon, namely clays and calcarenites;
- Lisbon Volcanic Complex - Formation of a volcano-sedimentary nature, not always

present, consisting of basalt flows with alternating deposition of clayey volcanic tuffs;

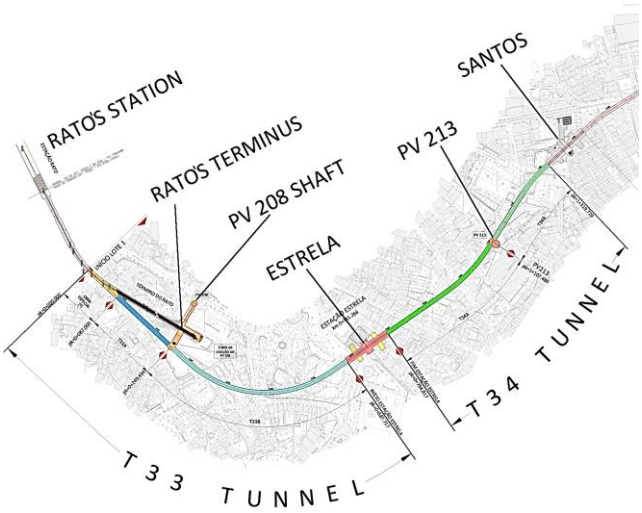

Figure 1. Lisbon Metro Lot 1 extension.

- Upper Cretaceous Bica Formation, with crystalline limestones, sometimes karsified, very permeable and generally dry. Caneças Formation, the lowermost unit, consists of limestones, marls and clay (figure 2).

In the T33 double track tunnel, groundwater was limited to vertical infiltrations in cretaceous limestones settling at first impermeable layers. In the T34 final hundred meters, the water table was found at level 1.20 m with high productivity occurring in a very karsified layer.

Figure 2. Lowermost Caneças formation with limestones, marls and fine layers of clays at the T33 tunnel.

3 DESIGN FEATURES

The design has foreseen several lining sections for the double track tunnels, T33 and T34, to be used according to the materials to be excavated. The cross sections have areas from 61.46 to 64.70 m^2, with a height of 7.50-8.70 m and a width of approximately 10 m (figure below). The construction phasing was designed for sequential excavation following the NATM principles, with variable advance length from 1 to 3.60 m and excavation in full section or top heading and invert.

The primary lining system was dependent on the Rock Mass Ratio (RMR). Consisted of sections R1 (RMR>56) and R2 (55>RMR>40), with a shotcrete thickness of 0.10m and 0.15m respectively. Both were reinforced with wire mesh and 4m long Swellex PM12 rockbolts. For section M, foreseen for the main tunnel junctions with the primary galleries and shafts or when RMR<40 (figure 3), shotcrete reinforced with steel lattice girders and 4m long Swellex PM12 rockbolts at foot level were used. Section S was specific for soils, basically a M section but with an invert arc without rockbolts.

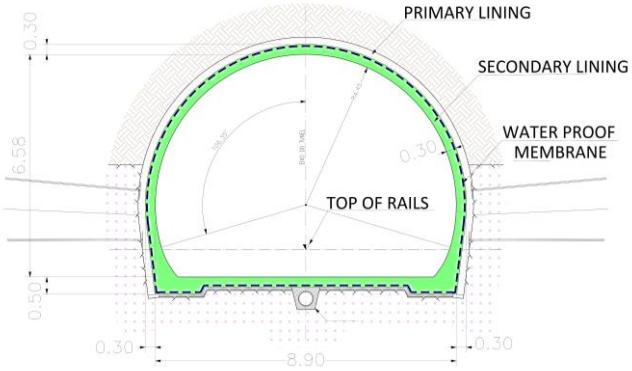

Figure 3. Primary and secondary lining for section M (CJC,2021b).

In the specific case of Tunnel T34, between Estrela and Santos, the section E used under the library building, was reinforced with an inside wire mesh and shotcrete, to minimize deformation near the foundation piles (figures 4).

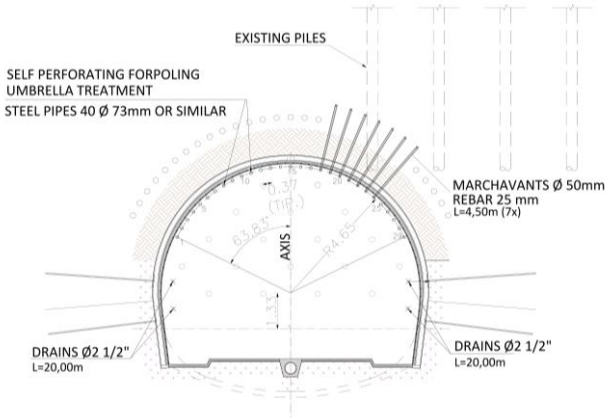

Figure 4. Section E used under the library (CJC,2021b).

Locally, as shown in figure 4 and 5, in substitution of the forepoling, 4,5m long, 25mm diameter rebars were used as *marchavants*.

The forepoling umbrella treatments, specified for the whole T34 tunnel (sections M, E and S) due to its RMR<40, were carried out with injected 10m long Schedule 40 tube with a diameter of 73mm introduced into 100mm holes spaced 37cm apart.

The front face treatments were carried out with 10m long 20mm diameter fiberglass bars introduced into 50mm diameter holes filled with cement grout, in a 1.00x1.00m mesh. Groundwater control was carried out using temporary short geodrains, designed to relieve hydrostatic pressure in the primary lining without lowering the water table very far. This water control system is suitable for rock masses with medium to low permeability, such as the case studied.

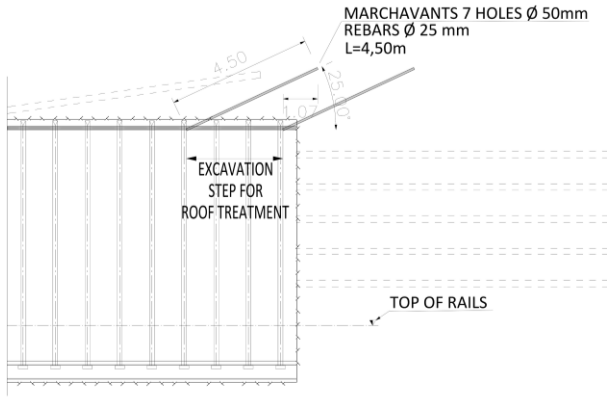

Figure 5. Special section E treatment in longitudinal view (CJC,2021b).

The tunnel is waterproofed by a 2mm PVC sheet membrane, protected by a 500g/m² geotextile around its entire contour making it completely watertight. The definitive or secondary lining is cast in situ with a 10m long formwork and reinforced with steel bars.

4 THE T34 TUNNEL SPECIAL CASE

The last section between the ventilation shaft PV213 and the Santos Station underneath the university campus, featured an increasingly thinner overburden with some geotechnical singularities:

- Crossing under the library building, with pile foundation, was the object of a particular reinforced section, as stated before;
- The final hundred meters were partially executed in the Cretaceous limestones with volcanic clayed tufts and breccia at top, sometimes with irregular karsified contact surface (figure 6);
- The inverted tunnel arc reached the level -5m, with the water table at 1.20m as previously stated, creating a potentially hazardous scenario if the limestones proved to be very karsified. Fortunately, the karsified layer was not intersected and the water flow was much lower than the worst scenario considered (figure 7);
- Initially, the T34 tunnel would connect in to the Santos Station body, but due to changes in construction schedules, this was not possible. A transition zone with new forepoling with fiberglass, face reinforcement and temporary drainage(figures 8 and 9).

Figure 6. Limestones and volcanic breccia with large blocks and irregular contact.

Figure 7. TunnelT34 final section after primary lining was completed.

Figure 8. Waterproof lining.

Figure 9. Secondary lining at the Santos Station face.

5 EXCAVATION METHODS

Since the geology was constituted mostly by sedimentary rocks, mechanical methods were primarily used. These included hydraulic hammers and roadheaders couple to Liebherr 944 excavators.

At some point, in the tunnel T34, between the Estrela Station and the ventilation shaft PV213, the limestone got so hard, with the uniaxial compression strength over 80MPa, that production turned very uneconomical. A drill and blast alternative were envisaged, studied and approved to increase production while minimizing impacts at surface, either in the buildings or people. Vibration velocities and frequencies were kept bellow the standard´s recommended values.

6 MONITORING AND OBSERVATION

In accordance with the principles of NATM, an instrumentation, monitoring and observation plan was implemented, based on the risk assessment and numerical models carried out.

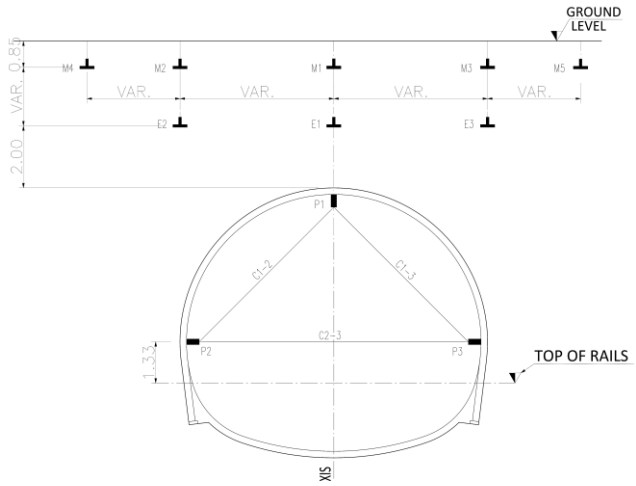

Figure 10. Monitoring section with both internal and external devices. (CJC,2021b).

Instruments such as inclinometers, piezometers, tiltmeters and seismographers were used, the latter to measure vibrations associated with heavy hydraulic hammers operation and rock blast. The tunnel sections, as shown in figure 10, included surface settlement pins (M), extensometers (E), convergence pins (P) and were widely used to monitor the lining performance.

The monitoring data was provided in a daily basis and checked against the design expected values.

7 CONCLUSIONS

The project was executed according to expectations, without major issues. We should note that in this kind of underground works underneath urban areas, there are always some uncertainties concerning the rock mass quality, geologic fault occurrences or underground water behaviour, mainly in long tunnels where survey is, sometimes, very spaced and with major gaps in between. The few unexpected conditions were addressed by the designer, the designer representative on site and the contractor.

The tunnel support solution used under the library was quite successful, with reported reduced displacements and of the order of magnitude of the predicted. Another example was the use of explosives in an urban area without major impact.

Erosion testing on sloped ground treated with enzyme-induced carbonate precipitation

Essais d'érosion sur un terrain en pente traité avec une précipitation de carbonate induite par une enzyme

L. Rivera, P. Bandini*
New Mexico State University, Las Cruces, New Mexico, United States of America
*paola@nmsu.edu

ABSTRACT: Enzyme-induced carbonate precipitation (EICP) is a novel biogeotechnical soil improvement technique in which calcium carbonate is precipitated abiotically from the hydrolysis of urea catalysed by plant-derived urease enzyme. The EICP technique and solution application methods are in development to control soil erosion induced by rainfall. The paper presents the results of preliminary erosion tests on two EICP-treated and untreated soil plots on the slope of an earthen dam. The mobilised soil volume during simulated rainfall in the treated plot was approximately eight times smaller than in the untreated plot. Raking the soil surface prior to treatment helped reduce the solution runoff and increase solution percolation. Applying the treatment solution with two-step percolation prevented early precipitation and equipment clogging.

RÉSUMÉ: La précipitation de carbonate induite par une enzyme (EICP) est une nouvelle technique biogéotechnique d'amélioration des sols dans laquelle le carbonate de calcium est précipité de manière abiotique à partir de l'hydrolyse de l'urée catalysée par l'enzyme uréase d'origine végétale. La technique EICP et les méthodes d'application de solutions sont en cours de développement pour contrôler l'érosion des sols induite par les précipitations. L'article présente les résultats d'essais préliminaires d'érosion sur deux parcelles de sol traitées et non traitées avec l'EICP sur la pente d'un barrage en terre. Le volume de sol mobilisé lors de pluies simulées dans la parcelle traitée était environ huit fois plus petit que dans la parcelle non traitée. Le ratissage de la surface du sol avant le traitement a permis de réduire le ruissellement de la solution et d'augmenter percolation de la solution. L'application de la solution de traitement avec percolation en deux étapes a permis d'éviter la précipitation précoce et le colmatage des équipements.

Keywords: Soil improvement; erosion; biogeotechnics; cementation; calcium carbonate.

1 INTRODUCTION

Enzyme-induced carbonate precipitation (EICP) is an abiotic biogeotechnical method that precipitates calcium carbonate via hydrolysis of urea between soil particles to form a lightly cemented soil mass or crust. EICP differs from microbially-induced calcite precipitation (MICP) in that the hydrolysis of urea is catalysed by plant-derived free urease enzyme instead of microbially produced urease, thus no microorganisms are involved in the EICP treatment. The net reaction is:

$$CO(NH_2)_2 + 2H_2O + CaCl_2 \xrightarrow{Urease} CaCO_3 + 2NH_4Cl \quad (1)$$

where aqueous solutions of urea and calcium chloride react to precipitate calcium carbonate. The most desirable precipitate is calcite because it is the most stable and least soluble of the calcium carbonate polymorphic forms. Ammonium chloride is a bioproduct of the reaction and should be considered depending on the concentration, use, and site characteristics. Engineering applications of the EICP technique are in development for fugitive dust mitigation (Hamdan and Kavazanjian, 2016), water erosion (Ossai et al., 2020; Ossai, 2021), and foundation support with biocemented soil columns (Martin et al., 2020). The treatment solution can be applied to the soil by percolation, spraying, injection, or soil mixing.

Using the EICP technique to create a cemented crust in sand has the potential to be an alternative to current practices for controlling soil erosion caused by rainfall and runoff in civil engineering infrastructure. EICP treatment can improve the strength and other properties of sand. The level of cementation of the treated soil depends on several factors, such as the soil gradation and mineralogy, particle packing, number of treatments, and composition and concentration of the treatment solution (e.g., Almajed et al., 2018; Ossai 2021). Jack bean (*Canavalia ensiformis*), soybean

(*Glycine max*), sword bean (*Canavalia gladiata*), and watermelon seeds have been used as sources of urease for EICP because of their high concentrations of the enzyme. Crude extract of urease can be produced from jack beans with a simple method at a considerably lower cost than the refined, laboratory-grade urease (Khodadadi Tirkolaei et al., 2020).

This paper presents the results of erosion tests on two EICP-treated and untreated soil plots on the slope of an earthen dam. The volumes of mobilised soil particles during the simulated rainfall in the EICP-treated and untreated plots are compared.

2 METHODS AND MATERIALS

2.1 EICP treatment solution and urease

The EICP treatment solution was prepared with 1 mol of urea, 0.67 mol of calcium chloride dihydrate, 4 g of non-fat powder milk, and 20 ml of crude urease extract (all amounts per litre of tap water). The crude extract of urease was prepared by crushing unhusked jack beans in water with a food blender for at least two minutes, until the solution had uniform, smooth consistency. Prior to crushing, the beans were soaked in water for about 24 hours. The liquid was extracted from the bean paste using a juicer. To produce approximately 110 ml of crude extract of urease, 63 g of unhusked beans and 200 ml of water were used. Adding non-fat powder milk increases the precipitate at interparticle contacts rather than on the particle surface (e.g., Martin et al., 2021).

2.2 Test site and soil

The test plots were on the East (upstream) slope of the embankment of Tortugas Site 2 Dam, located in Doña Ana County, New Mexico, USA. It is a dry flood control earthen dam, built in 1962 and modified in 1967 and 1993. The site was selected because the area is closed to public access and has slopes with sandy soil amenable to EICP treatment. The slope angle was about 45°. The soil was silty sand (SM) according to the Unified Soil Classification System and had 24.0% particles finer than 75 μm (No. 200 sieve), determined by washing. The coefficients of uniformity and curvature were 8.9 and 1.9, respectively. The maximum and minimum void ratios were 0.90 and 0.49, respectively. The specific gravity of the solids was 2.69. The in situ dry unit weight was 17.4 kN/m^3.

2.3 Block specimens

Prior to treating field plots, block specimens were prepared in triplicates for each condition and treated with the ECIP solution in the laboratory to confirm that the soil from the test site was amenable to EICP cementation and to select an appropriate solution application method and the number of treatment cycles for this native soil. In a previous study, Ossai (2021) found that EICP cementation of some New Mexico native sands increased when the soil was washed or rinsed prior to EICP treatment. Thus, some specimens were prepared with soil that was previously rinsed with tap water and oven dried.

The block specimens had the shape of a square prism. The internal length, width, and height of the moulds were 102, 102, and 51 mm, respectively. The dry unit weight of the soil specimens ranged from 15.3 and 16.1 kN/m^3. A first series of block specimens of rinsed sand were treated with either percolation, two-step percolation, or modified mix-compact methods (Ossai, 2021) and cured at room temperature (20-23°C) for ten days. Based on the results of the first test series, a second series of block specimens of unrinsed sand was prepared with the two-step percolation method. The percolation method consisted of slowly pouring the solution on the soil surface using a large syringe (without a needle). The two-step percolation method divided the EICP solution in two parts, first pouring slowly on the soil the crude extract urease and non-fat powdered milk solution (step 1), followed by percolating the calcium chloride and urea solution (step 2). For the modified mix-compact method, the EICP solution was mixed with the dry soil in a bowl using a spatula for approximately one minute. The soil was transferred to the mould and compacted to the target density with a small tamper. Subsequent treatment cycles applied the solution by percolation.

The specimens received three or five applications of EICP solution. The total volumes of EICP solution applied in the first and second treatment cycles were equal to 100 and 40% of the estimated pore space (Ossai, 2021). In subsequent treatment cycles, the solution volume was 30% of the pore space. Larger solution volume was needed in the first treatment because the soil was dry. After curing, the specimens were removed from the moulds and submerged in water several times to remove the uncemented or loose particles and determine the percent cemented mass.

2.4 Field plot treatment and erosion tests

Preliminary field treatment application trials were conducted. Two 1.2 m by 1.2 m plots (also called trial plots) were treated with EICP solution to test the feasibility of the application method and equipment on a slope in the field. In one of these trial plots, half of the surface was raked to create small horizontal channels (parallel to the dam crest) and the other half

of the plot surface was unraked (each area was 0.6 m wide) to compare crust formation with these two conditions. Two 2.4 m by 2.4 m plots (also called erosion test plots) were used for the erosion tests. One plot was treated with EICP, and the other plot was left untreated. The surface of both plots was raked.

The EICP treatment was applied with 15-liter backpack chemical sprayers with the spout set at the largest opening. The solution components were measured in the laboratory and mixed on site shortly before application. All the plots received five treatments with the two-step percolation method. The treatment cycles were spaced three days. Grass and gravel-size particles on the soil surface were removed.

The simulated rainfall was applied with a calibrated portable rainfall simulator (Figure 1). The rainfall intensity and duration were 96 mm/h and 30 min; the average raindrop speed was 2.52 m/s; and the average droplet size over the plot area was 0.85 mm. Soil particle mobilization due to raindrops and surface water erosion was assessed before and after the erosion tests using a Trimble SX10 Scanning Total Station. This equipment measured three-dimensional differences in elevation of the soil plots and attributed these differences to either cut or fill as a result of surface erosion. The mobilised soil volume after the simulated rainfall was estimated as the difference between the fill and cut volumes. The erosion tests were conducted when the wind speed was minimal and below the threshold that could affect the rainfall characteristics. After the erosion tests, the crust thickness, cementation strength, and precipitated calcium carbonate content (CCC) were assessed. The relative strength of the crust was appraised with a portable Mecmesin shotcrete penetrometer. The CCC precipitated was determined with acid digestion, as described by Ossai (2021), for two cemented soil samples from nine locations on the treated plot (total of 18 samples). The net CCC values reported were calculated as the difference between the acid digestion results for the cemented soil and the untreated soil.

3 RESULTS AND DISCUSSION

3.1 Results of block specimens

Table 1 shows the average values of the cemented mass as a percentage of the total soil mass prior to treatment for each test condition of the block specimens. In the first series of rinsed soil, two-step percolation produced the greatest percentage of cemented mass. There was either a small reduction or minor improvement in the average percentage of cemented mass of rinsed soil when increasing the treatment cycles from three to five (from 52.5% to 50.5% for percolation and from 75.4% to 78.3% for two-step percolation for three and five treatments, respectively). The results for the mix-compact method were not included in Table 1 because the cementation was negligible. This method was not considered in the rest of the testing program. The reason for the lack of cementation with the mix-compact method could not be confirmed but interaction of the treatment solution with the surface of the mixing bowl was suspected. When preparing block specimens with percolation (in one step), the syringe tip often clogged because the carbonate precipitation began before the EICP solution was poured on the soil. Unless the application equipment for the field tests could prevent the mixing of the solution components prior to being applied on the soil surface, the percolation method was expected to cause clogging of the spout. On the other hand, the two-step perolation avoided the challenges of early carbonate precipitation. In additon, soil rinsing prior to EICP treatment was not feasible when treating large soil volumes. Thus, the focus of the second specimen series was on two-step percolation with unrinsed soil.

The series of block specimens of unrinsed soil prepared with the two-step percolation method resulted in less cementation (in terms of percentage of cemented mass) compared with the rinsed soil specimens. For unrinsed soil, five treatment cycles produced much greater cemented mass (on average 40.2%) than three treatment cycles (on average 11.3%) using the two-step percolation method. Despite lesser cemented mass in unrinsed soil, five cycles provided sufficient cementation to form a crust in the field plots.

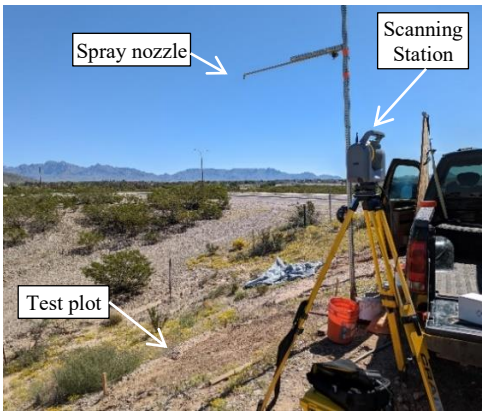

Figure 1. Erosion test plot, rainfall simulator (stand and spray nozzle), and Trimble SX10 Scanning Total Station.

Table 1. Cemented mass (%) for block specimens.

Soil pretreatment	Treatment method	Treatment cycles	
		3	5
Rinsed	Percolation	52.5	50.5
Rinsed	Two-step percolation	75.4	78.3
Unrinsed	Two-step percolation	11.3	40.2

3.2 Results of field plots

When the treatment was applied to the unraked plot surface, excessive downward runoff of the solution and pooling at the bottom of the plots were observed.

Horizontal raking before EICP treatment created small surface channels or grooves that helped retain the solution on the soil surface to allow percolation. In the trial plots, the average penetration resistance of the crust of the raked and unraked portions was 41.5 N and 26.3 N, respectively. Raking the soil surface prior to treatment increased the uniformity of crust strength and the average penetration resistance.

The average crust thickness of the EICP-treated erosion test plot was 12.5 mm (after the erosion test), which was considerably less than the target thickness of 50 mm. The net CCC of the soil after five treatments varied throughout the plot, ranging from nearly 0 to 7.4%, with an average and standard deviation of 2.4% and 2.1%, respectively. When the results were averaged based on sample location, the net CCC values in the upper third, middle, and lower third of the plot were 2.6, 2.0, and 2.8%, respectively.

Table 2 shows the cut and fill volumes and net mobilised soil volume after the erosion tests in the treated and untreated plots. The bottom 100 mm of the erosion test plots were not considered because it was the location of most accumulation of eroded soil particles, so the plot area considered for the results in Table 2 was 5.52 m^2. The volume of mobilised soil in the EICP-treated plot was about 8.3 times less than that in the untreated plot. These results show promise of EICP treatment to reduce erosion in sloped sandy soil.

Table 2. Mobilised soil in plots during erosion tests.

	Untreated	EICP-treated
Cut volume (m^3)	0.01699	0.00453
Fill volume (m^3)	0.00283	0.00283
Mobilised soil (m^3)	0.01416	0.00170

4 CONCLUSIONS

The two-step percolation method showed feasibility for creating an EICP crust in a native soil in the field, avoiding early precipitation and equipment clogging issues. Despite having the viscosity similar to water, the EICP solution drained downwards excessively when applied on a 45° slope, which is a concern to be addressed in future testing. Surface raking prior to treatment helped reduce considerably the solution runoff and obtain more uniform cementation throughout the plot. The relatively high fines content of the soil also affected the EICP reaction, leading to a thinner crust than wanted. Stronger, thicker crust is expected in sand with lower or no fines content.

ABSTRACT: This study investigates the effectiveness of ground improvement between stone columns in various soil types, including coarse and fine tailings, clay with organic traces, and overconsolidated fine grained soils. A series of trial pads were constructed to evaluate the performance of stone columns with different replacements ratios. CPTu tests were conducted outside the improved area and between the stone columns, and variations were analysed to understand the improvement achieved in each soil type, in terms of soil behaviour type, state parameter, peak and residual strength. The findings of this research demonstrate the viability of stone columns as an effective ground improvement technique across some of the coarser soil units and provides insights into their impact on finer materials.

RÉSUMÉ: Cette étude examine l'efficacité de l'amélioration du sol entre des colonnes ballastées dans différents types de sol, y compris les résidus grossiers et fins, l'argile contenant des traces organiques et les sols fins surconsolidés. Une série de plateformes d'essai ont été construites pour évaluer les performances des colonnes en pierre avec différents taux de remplacement. Des tests CPTu ont été réalisés à l'extérieur de la zone améliorée et entre les colonnes en pierre, et les variations ont été analysées pour comprendre l'amélioration obtenue dans chaque type de sol, en termes de comportement du sol, de paramètre d'état, de résistance maximale et résiduelle. Les résultats de cette recherche démontrent la viabilité des colonnes en pierre en tant que technique d'amélioration du sol efficace pour certaines unités de sol plus grossières et fournissent des informations sur leur impact sur les matériaux plus fins.

Keywords: Ground improvement; stone columns; tailings; in-situ testing; CPT.

1 INTRODUCTION

Stone columns (SC) are widely used to mitigate the risk of liquefaction of loose non-plastic soils with fines. Vertical inclusions made of clean crushed rock are installed in a grid pattern using a vibro-replacement method, expecting that these columns will increase the density of the surrounding soil, contribute to the average shear strength of the ground, and provide drainage for the dissipation of pore pressure. This technique has been used successfully to reinforce the foundation of several dams, e.g. Salmon Lake Dam (Luehring et. al., 2001); Mormon Island Auxiliary Dam (Nickell, 1994) and Steel Creek Dam (Keller, 1987).

This study presents the procedure used to characterize and quantify the effectiveness of SC to improve the foundation of a downstream-raised tailings dam, which comprises tailings, clay with organic traces, and overconsolidated fine soils of alluvial origin. Two trial pads were constructed near the toe of the dam; SC were installed with five different replacement ratios (RR), ranging from 14.5% to 35.8%; Cone Penetration Tests (CPTu) were conducted outside the improved area and in between SC (Figure 1). Frequency analyses were performed on the data to assess the ground improvement between SC in terms of peak and residual undrained shear strength and state parameter.

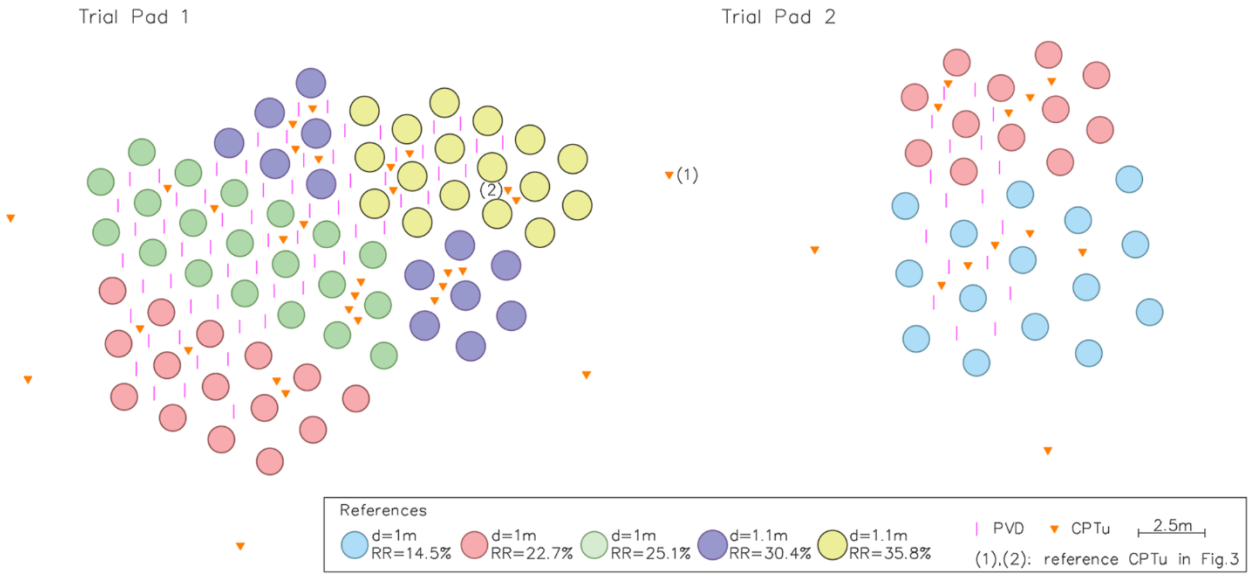

Figure 1. Trial pads: pattern of stone columns (SC), prefabricated vertical drains (PVD) and CPTu test locations.

2 GROUND MODEL

The dam is founded atop of historically deposited fine and coarse tailings within a broad valley. The natural foundation is formed by fine-grained alluviums, roughly split in an upper, soft unit and a lower overconsolidated unit. The upper alluvium contains layers of coarse, free-draining material interbedded with silts and clays. No surface clearing was undertaken prior to the historic tailing's deposition, leaving a very soft clay layer with organic underlying the impoundment area.

Although slightly irregular in thickness, the stratigraphy of the trial pad area can be summarized as: topsoil, tailings, organic clay, upper alluvium and lower alluvium (Table 1). This stratigraphy is rather uniform throughout the site, as confirmed by more than 200 CPTu soundings and 35 boreholes.

Table 1. Foundation stratigraphy.

Layer	Thickness (m)
Topsoil	0.5 – 1.0
Tailings	3.5 – 4.0
Organic clay	0.5 – 1.0
Upper Alluvium	5.0-15.0
Lower Alluvium	> 15.0

The coarse and fine tailings were placed together, with the coarse frequently encountered in the upper tailings layer and the fine in the lower tailings layer. Classification data is presented in Table 2 and Figure 2. The phreatic level is approximately 3.15 m below ground level at the trial pads. A largely hydrostatic pore pressure field was measured throughout the site.

Table 2. Classification test results.

Layer	γ (kN/m³)	LL (%)	PL (%)
Tailings	16.5	Non plastic	
Organic clay	17.0	23-51	13-25
Upper Alluvium	19.0	18-65	11-44

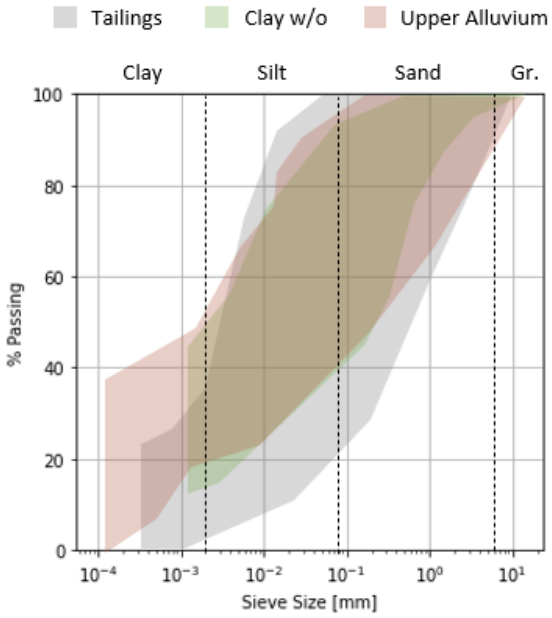

Figure 2. PSD distributions of the main geotechnical units.

3 TRIAL PADS

For the construction of the two trial pads, the topsoil layer was removed, and a working platform, 0.8 m thick, was built on top of the exposed tailings surface. SC were installed with five different RRs: 14.5%, 22.7% and 25.1% (1 m diameter SCs); and 30.4% and 35.8% (1.1 m diameter SCs).

Prefabricated vertical drains (PVD) were installed in some regions prior to installing SCs, to study their effectiveness as a draining path for excess pore pressures generated during the installation of the SCs. Figure 1 shows the location of the different SC configurations and PVDs.

4 CONE PENETRATION TESTS

4.1 Location

CPTu was the main test method employed for the foundation characterization. Figure 1 shows the location of each sounding, both in the unimproved areas and between SCs. The location of each test was selected to cover improved areas with different RR, with and without PVDs.

4.2 Change indicators

The Soil Behaviour Type (SBTn) employing Robertson (2016) formulas, the state parameter (ψ) employing the Plewes method (1992), the peak undrained shear strength ratio, using Mayne and Peuchen (2022) method and the residual undrained shear strength ratio, using Robertson (2022) correlations were employed as change indicators due to ground improvement. Also, the normalized friction ratio (f_s/σ'_{v0}) was employed as a lower bound estimate for the residual undrained shear strength ratio. Materials are considered potentially liquefiable when ψ>-0.06. An example of unimproved vs improved ground is shown in Figure 3. The relevant correlations characterizing the strength and behaviour of each foundation were processed using frequency analysis and are presented in Section 5.

5 IMPROVEMENT CHARACTERIZATION

5.1 Scope of the interpretation effort

This section aims to quantify the strength improvement of materials between SCs. The improved soil strength is later used as an input to compute equivalent strength parameters (SC + improved soil) to perform stability analyses.

The analyses only consider data below the water table since typical CPTu correlations don't account for partially saturated soil conditions. Therefore, the platform, topsoil, and the upper portion of the tailings are not included in the analyses. Additionally, only data for depths shallower than 12 m, the SC length, is presented; therefore, the lower alluvium and the bottom of the upper alluvium are also neglected in the analyses.

5.2 Soil Behaviour Type

Figure 4 presents the Soil Behaviour Type (SBTn, Robertson 2016) for areas outside and inside the ground improvement zone on both trial pads. It is observed that the installation of SCs in their various arrangements and RR consistently reduce the frequency of data points indicating contractive behaviour in the coarser materials, but do not change fine materials: i) in the tailings, a reduction from 36% to 16%; ii) in the organic clay, a slight increase from 65% to 69%; iii) in the coarse upper alluvium, a reduction from 30% to 15%; and iv) in the fine upper alluvium, an increase from 56% to 67%. The improved areas consistently show fewer data points within the CCS (claylike-contractive-sensitive) region.

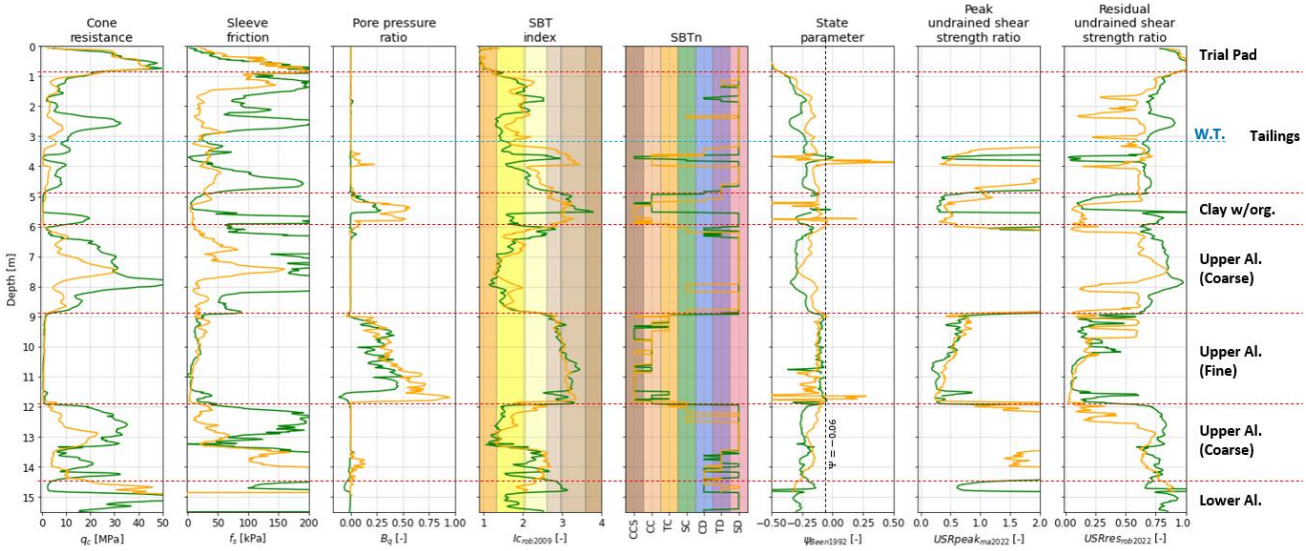

Figure 3. Example of the CPTu interpretation for an unimproved (yellow – 1) and improved region (green -2).

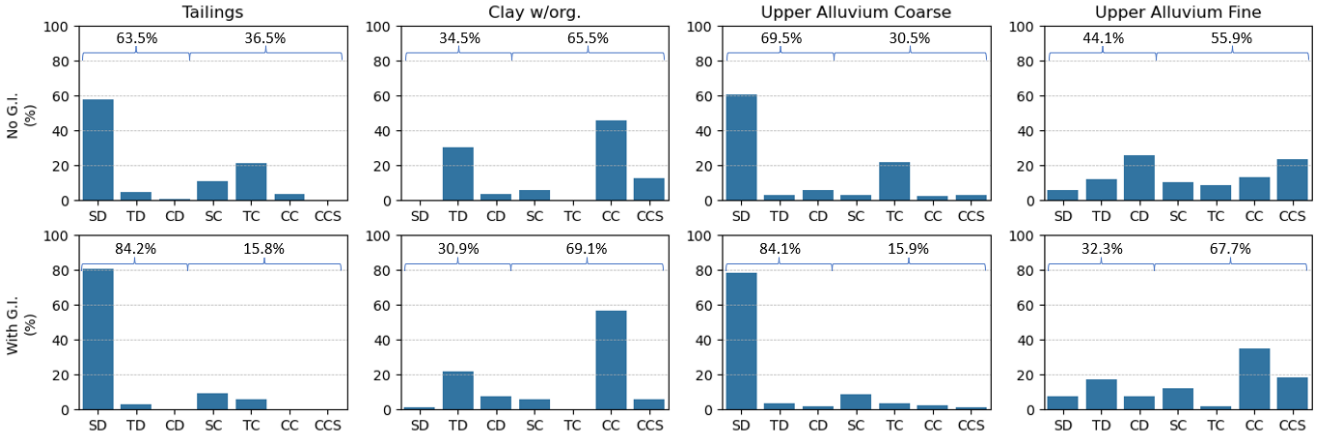

Figure 4. SBTn distribution in each layer, with and without ground improvement.

5.3 State parameter

As expected, densification of coarse tailings and upper alluvium produce a noticeable reduction in their state parameters for all RR (Figure 5). At a confidence level of 70%, state parameter goes from -0.15 to -0.20 in the tailings, from -0.11 to -0.09 in the organic clay, from -0.13 to -0.18 in the coarse upper alluvium and from -0.11 to -0.08 in the fine upper alluvium. Even for the finer materials, the state parameter falls in the dilative behaviour zone. The shift is the state parameter is consistent with the shift in the SBTn: coarser materials display a decrease in contractiveness while finer materials display an increase.

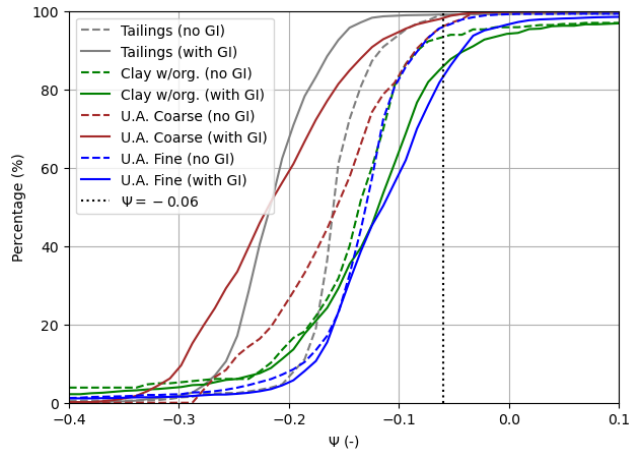

Figure 5. State parameter cumulative density function.

5.4 Peak Undrained Shear Strength

Figure 6 shows the cumulative histogram for the computed peak undrained shear strength ratios; only values smaller than 0.6 are shown, as higher values would be capped by the materials drained shear strength.

Finer layers (clay and fine upper alluvium), show a decrease in peak USR, likely due to a remoulding effect produced by the installation of the SC. Coarser layers (tailings and coarse upper alluvium) showing very high USR, denoting the likely effect of partial drainage during CPTu penetration.

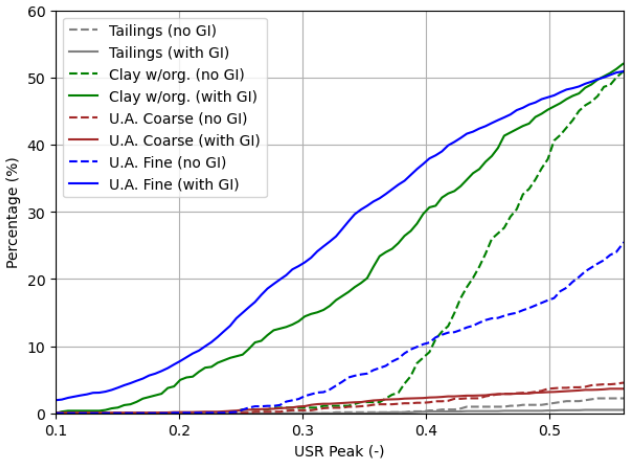

Figure 6. Peak USR cumulative density function.

5.5 Residual Undrained Shear Strength

Figure 7 shows the improvement in residual strength. Note that in coarse materials there is a significant amount of data with USR < 0.3 in unimproved ground but, after the SC installation, more than 90% of the data displays USR > 0.60, suggesting that drained shear strength would cap the adopted USR.

Fine upper alluvium shows a similar trend, slightly increasing its USR in the full range of pre-improvement USR. However, improvement in the organic clay was only evident for USR values less than 0.3. Although the mean USR remained largely unchanged, the SC installation seems to reinforce the weakest zones while potentially remoulding the stronger segments. This is an overall improvement in behaviour, as the design USR at the adopted confidence level in improved.

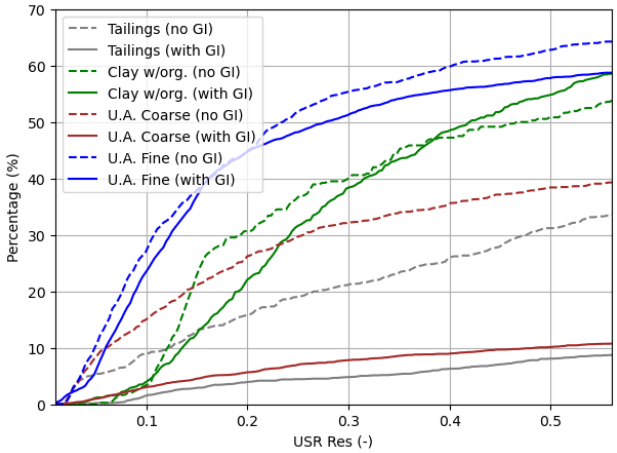

Figure 7. Residual USR cumulative density function.

Figure 8 shows the normalized sleeve friction. As expected, the curves are similar to those of Figure 7, in particular for finer materials as the definition of residual USR is the same.

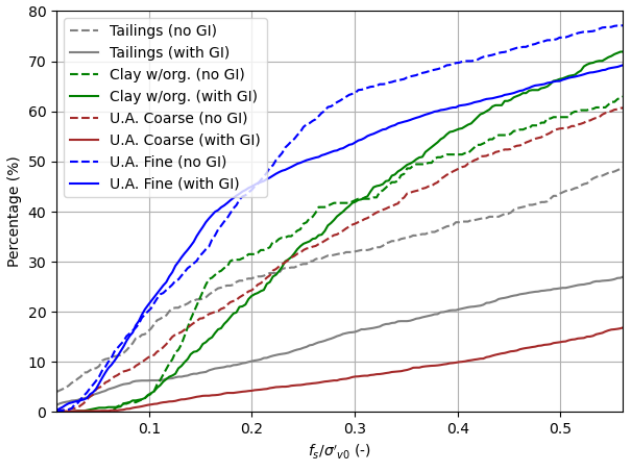

Figure 8. Normalized sleeve friction cumulative density function.

5.6 Replacement ratio and prefabricated vertical drains effect

No correlation was found between the RR and the degree of improvement. As an example, Figure 9 shows the cumulative density function of residual USR in the fine upper alluvium for all the RR employed. It can be observed that the highest strength is achieved at a RR = 25.1%, which is on the lower end of the range. This is not surprising for fine compact soils that might undergo destructuration and remoulding during SC installation. The average design strength, which includes both the post-improvement USR and the shear strength of the SCs, does increase with the RR.

It was also not possible to identify an effect of using PVDs, as shown in Figure 10. This could be due to the tailings being rather coarse, and therefore the effect of improved drainage negligible.

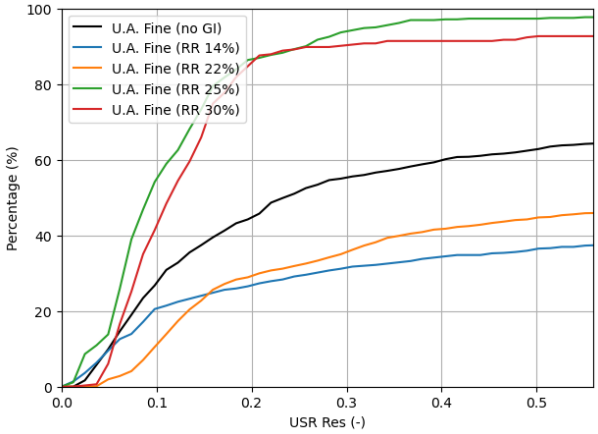

Figure 9. Residual USR cumulative density function for different RR in the fine upper alluvium.

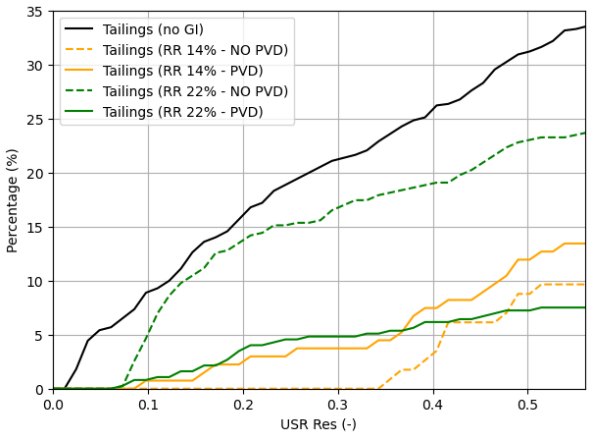

Figure 10. Residual USR distribution with and without PVD in tailings.

6 CONCLUSIONS

In this study, CPTu testing was employed to assess the improvement of soft soils at the foundation of a tailings dam, using SC. Two trial pads and a range of RR were employed. The analysis was performed in terms of state parameter, peak and residual undrained shear strength ratio, using state-of-the-practice correlations.

Significant improvement was observed in the coarse materials, whereas the finer soils, including fine tailings, exhibited negligible improvement and, in some cases, a reduction in strengths. It is interesting to note that the residual undrained shear strength of finer materials did improve in the weaker lenses and pockets, a result which allows for an increase in the design USR at the confidence level selected for the analyses.

No correlation could be established between the SC RR and the degree of ground improvement. The average design strength, which includes both the post-improvement USR and the shear strength of the SCs, does increase with the RR.

ABSTRACT: The capacity of bored cast in situ concrete piles in clay is typically governed by shaft resistance, which is usually achieved through skin friction. Skin friction is dependent on the proportion of the soil strength that is mobilised by the pile – and can vary depending on the roughness of the pile. Valuable insights into the behaviour of piles under loading can be obtained through physical model testing at reduced scale in a geotechnical centrifuge if the soil pile interface can be modelled appropriately. Therefore, it is important to consider how the surface of a pile should be modelled to achieve a comparable roughness between the model and the prototype pile. In this paper, a method for designing a pile with a specified roughness using stereolithography, also known as 3D printing, is described. The normalised roughness of the model pile is determined based on the likely failure mechanism of the pile and the mean soil particle size. The rough surface profile is then designed using 3D modelling software with the calculated arithmetic average surface roughness. Data are presented from preliminary centrifuge model tests on piles with different surface roughness.

RÉSUMÉ: La capacité des pieux en béton coulés forés dans de l'argile est généralement déterminée par la résistance à la traction, qui est généralement obtenue par friction latérale. La friction latérale dépend de la proportion de la résistance du sol mobilisée par le pieu, et peut varier en fonction de la rugosité du pieu. Des informations précieuses sur le comportement de ces pieux sous charge peuvent être obtenues grâce à des essais de modélisation physique à échelle réduite dans une centrifugeuse géotechnique si l'interface sol-pieu peut être modélisée de manière appropriée. Par conséquent, il est important de réfléchir à la manière dont la rugosité d'un pieu doit être modélisée pour obtenir une rugosité comparable entre le modèle et le pieu prototype. Dans cet article, une méthode de conception d'un pieu avec une rugosité spécifiée à l'aide de la stéréolithographie, également connue sous le nom d'impression 3D, est décrite. La rugosité normalisée du pieu modèle est déterminée en fonction du mécanisme de défaillance probable du pieu et de la taille moyenne des particules du sol. Le profil de surface rugueux est ensuite conçu à l'aide d'un logiciel de modélisation 3D avec la rugosité moyenne arithmétique calculée. Des données seront présentées à partir d'essais préliminaires de modélisation en centrifugeuse sur des pieux ayant différentes rugosités de surface.

Keywords: Centrifuge modelling; stereolithography; pile roughness; skin friction.

1 BACKGROUND

The ultimate capacity of a pile typically depends on the pile end bearing capacity and the friction between the pile shaft and the soil in which the pile is installed. The installation method and soil type have an effect on the proportion of base capacity and shaft friction generated by a pile (Mandolini *et al.*, 2005; Panchal *et al.*, 2019). The end bearing capacity of bored, cast in situ piles in clay is usually mobilised at a vertical pile displacement of about 30% of the pile diameter (Budhu, 2010), which is beyond the typical magnitude of the working load of a pile foundation. However, the shaft resistance in these conditions is mobilised at much smaller vertical displacements.

2 INTRODUCTION

As most of the capacity of a bored, cast in situ pile at working load is typically generated via pile shaft resistance, the interface between the soil and pile is an important aspect when conducting pile load tests. Previous studies assessing the effect of surface roughness on clay-interface shear behaviour observed greater mobilisation of shear in tests with rougher surfaces than those with smoother surfaces (Martinez & Stutz, 2019). Taha & Fall (2014) found that increasing the surface roughness also increased interface strength.

Hammoud & Boumekik (2006) and Feligha *et al.* (2016) observed three modes of interface shearing which depend on the roughness parameter *R* (the

relative roughness of a surface). The relative roughness is defined as the centre line average value of roughness divided by the mean particle diameter, D_{50}, of the soil particles with which it interacts. The three proposed modes are: full sliding at the interface (when $R < 0.3$), shear failure within the soil (when $R > 1$), and both sliding and shear failure within the soil occurring simultaneously (when $0.3 < R < 1$).

Lemos & Vaughan, (2000) found that for a very smooth interface, the interface shear resistance is lower than the soil-on-soil residual strength, although it is unlikely that such surfaces would occur in practice.

In geotechnical centrifuge testing, pile foundations are typically modelled as steel (Ebeido *et al.*, 2018; Netietd *et al.*, 2023), or aluminium (Haffar *et al.*, 2017) tubes. Some authors have also utilised cast resin (Lalicata *et al.*, 2023) and mortar (Ganiyu *et al.*, 2018). The use of steel and aluminium tubes is commonly used as they are inexpensive and relatively quick to machine. However, unless a roughness is applied to the profile, these model piles would essentially present a smooth surface during testing – thus reducing the interface shear resistance between the pile and the soil. In addition, when conducting a series of centrifuge pile tests, this applied roughness to the model pile is not repeatable throughout the test series.

Some researchers, in order to make steel or aluminium model piles more representative of prototypes, have added rough profiles to the model pile surface by either machining a roughness on the pile surface (O'Hara & Martinez, 2022) or by gluing sand particles, or sandblasting the outside of model piles (Ouzzine *et al.*, 2023). Although these methods provide the required roughness for testing piles in sand, it is extremely difficult to replicate the exact roughness profile on all piles used in a series of centrifuge tests.

Using cast resin and mortar also has drawbacks for geotechnical centrifuge testing. Although cast mortar piles have been effective in reproducing the behaviour of prototype piles, their implementation has been relatively time consuming due to the curing time necessary in the mould before testing (Ganiyu *et al.,* 2018). A proposed solution to overcome these time constraints has been to use fast cast resin. However, drawbacks were noted as the curing process of the resin in the clay model appears to affect the soil-pile interface properties owing to possible chemical bonding between the clay and the resin (Lalicata *et al.,* 2023).

The aim of this paper is to establish a quick and reliable method of producing representative and repeatable model piles for centrifuge testing with the aid of stereolithography. The relative roughness of five 3D printed blocks with different surface roughness has been determined and compared to that of a cast concrete block.

3 MEASURING ROUGHNESS

The relative roughness, R, value can be calculated from the measured centre line average, CLA, roughness value, R_a, for a sample. R_a is measured by defining a centre line for a surface profile (Figure 1) where the area between the peaks of the surface and the centre line are equal to the area between the troughs of the surface and the centre line.

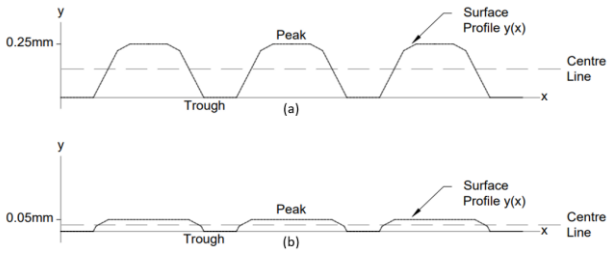

Figure 1. Schematic diagrams of surface profiles with offset distances of (a) 0.25mm, (b) 0.05mm.

R_a is then calculated as the mean value of the vertical deviation from the centre line of the surface profile using

$$R_a = CLA = \frac{1}{L}\int_0^L |y(x)|dx \qquad (1)$$

With L being the profile sampling length. In order to define the roughness value in terms of the scale of the soil grains at the interface, R_a is expressed in terms of the average diameter, D_{50}, of the soil grains, giving R:

$$R = \frac{R_a}{D_{50}} \qquad (2)$$

For the purpose of this paper, the piles are assumed to be in contact with Speswhite kaolin clay, which is commonly used in centrifuge model tests in clay. Thus, the average diameter of the soil grains is assumed to have a maximum value of 2.00µm.

4 ROUGHNESS SAMPLES

Five rough gauge blocks were drawn using the 3D modelling software SolidWorks. Each block was modelled with an inclusion in which a standard

polyhedron pattern with varying offset distances was applied. The offset distances ranged between 0.05 to 0.25mm at 0.05mm intervals. Figure 2 shows two rendered roughness gauge blocks which were then 3D printed using a micro carbon fibre filled nylon filament, known as Markforged Onyx, and their roughness measured using a Mitutoyo Surftest SJ-210 surface roughness measurement instrument.

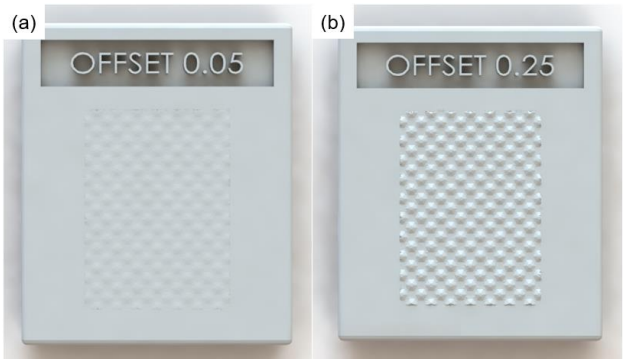

Figure 2. 3D modelled roughness gauge blocks with an offset distance of (a) 0.05mm, and (b) 0.25mm.

The roughness parameters of the rough gauge blocks were compared to the roughness of a 100x100x100mm concrete block, with a cement to sand to aggregate ratio of 1:2:3, in order to see which offset distance would be the most appropriate to employ when applied to the model piles in geotechnical centrifuge testing. The roughness of the concrete block was measured using the same instrumentation, taking an average roughness value. In addition, the roughness parameters of a resin pile, as used in a study by Gorasia & McNamara (2016), a pile coated in sand, and a smooth aluminium pile (Figure 3) were also measured, in order to investigate which mode of interface shearing would likely take place between the model piles and clay during a geotechnical centrifuge test.

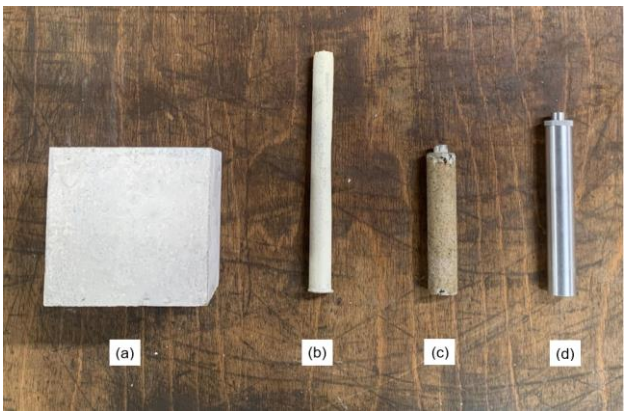

Figure 3. Samples used for roughness parameter comparison (a) concrete block (b) resin cast pile (c) sand coated pile (d) smooth aluminium pile.

5 RESULTS AND DISCUSSION

The centre line average and relative roughness of the four sample elements (concrete block, resin pile, sand coated pile, and aluminium pile), in addition to the five rough gauge blocks are presented in Table 1. The surface roughness measuring instrument was calibrated to an accuracy of 0.13% against a machined roughness gauge with a roughness of 3μm, to ensure the readings were correct.

All five roughness gauge blocks were found to have a relative roughness greater than 1. This means that applying any offset distance equal to or greater than 0.05mm onto a model pile would lead to an interface shear resistance equal to that of soil-on-soil shear resistance. However, comparing the values of relative roughness on the gauge blocks to that of the concrete block, it is evident that an offset of 0.25mm provides the most comparable surface profile for concrete pile modelling.

It can be observed that the relative roughness of the resin pile would also provide an interface shear resistance equal to the soil-on-soil shear resistance. However, as noted above, due to the curing process of the resin, the soil-pile interface is affected.

The smooth aluminium pile was found to have the lowest surface roughness, with the relative roughness smaller than 1.00. Therefore, when testing this pile in clay, the interface shear resistance would be lower than that of soil-on-soil shear resistance, and marginally greater than 0.30, leading to a combination of sliding and soil-on-soil shear at the interface during testing. Although the smooth aluminium pile surface can provide ease for repeatable testing, the low roughness renders the pile unrepresentative of the prototype.

The surface profile of the sand coated pile presented difficulties for measuring its roughness as the values were beyond the measurable range. However, it can easily be assumed that this pile would have a relative roughness greater than 1, providing an interface shear resistance between the pile and a clay soil sample to be that of soil-on-soil shear resistance. Nonetheless, it is difficult to replicate the exact surface finish with this method for a series of piles as the pile is simply coated in an adhesive and submerged in, or covered with sand. Hence, each pile is likely to possess a random distribution of sand particles. In addition, when testing these piles at elevated ***g***-levels in clay, there is a risk of the adhesive separating from the pile, thus changing the interface between the pile and the clay.

Table 1. Surface roughness parameters of sample elements and roughness gauge blocks.

Roughness parameter	Samples					Roughness gauge block texture offset distance (mm)				
	Calibration sample	Concrete block	Resin pile	Sand coated pile	Aluminium pile	0.05	0.10	0.15	0.20	0.25
R_a (μm)	3.00	12.06	3.37	N/A	0.63	4.90	7.88	8.79	10.56	11.98
$R_{(avg)}$	1.5	6.03	1.69	N/A	0.32	2.45	3.94	4.40	5.28	5.99

6 CONCLUSIONS

The surface roughness of five roughness gauge blocks was measured, quantified and these values compared to that of the surface roughness of a 100x100x100mm concrete block, with a cement to sand to aggregate ratio of 1:2:3.

The roughness profiles of three different piles were also measured and their potential modes of interface shearing analysed.

It was found that although the roughness gauge block offset texture does not have an effect on the mode of interface shear, comparing the relative roughness value with that of the concrete block, it can be seen that applying an offset distance of 0.25mm to a model pile would make it most representative to that of a prototype.

Performance of segmental driven geothermal energy piles subjected to impact and bending loads

Performance d'un pieu géothermique à entraînement segmentaire soumis à des charges d'impact et de flexion

H. Sadeghi, R.M. Singh*
Norwegian University of Science and Technology, Trondheim, Norway
**rao.m.singh@ntnu.no*

ABSTRACT: Geothermal energy pile foundations can extract and store geothermal energy as a renewable, sustainable, and affordable solution for heating and cooling buildings, besides providing structural support. The majority of energy piles are cast-in-place concrete piles that require drilling which is expensive and time-consuming. Another competitive option is driven energy piles made from precast concrete segments, that are cast in a concrete factory in large quantities and of high quality, then transported and installed on a construction site using innovative steel joints presented in this paper. Apart from providing structural integrity, these steel joints can provide leak-proof couplings for fluid circulation pipes inside sidewall channels, which are shielded using a steel cover plate riveted to the joint. Precast-driven pile foundations can be manufactured from high-strength concrete quadratic segments with 27 cm or 35 cm width, which are assembled via steel joints. There can be one U-loop in 270-mm piles or two U-loops in 350-mm piles. Steel pins connect the joints, and easy couplings connect the pipes quickly. The steel joints presented in this paper provide the opportunity to utilize segmental precast concrete pile foundations as energy piles. Field-scale impact tests and laboratory bending tests were carried out to ensure the piles were not affected by installation and service dynamic forces due to the incorporation of new joints. It was found that the segmental driven energy piles could easily take a minimum of 1000 blows without structural or leakage failure and also demonstrated a satisfactory bending stiffness.

RÉSUMÉ: Les fondations sur pieux d'énergie géothermique représentent une solution renouvelable, durable et abordable pour le chauffage et le refroidissement des bâtiments, tout en assurant un support structurel. La plupart des pieux énergétiques actuels sont en béton coulé sur place, nécessitant des forages coûteux et chronophages. Une alternative plus efficace réside dans l'utilisation de pieux énergétiques battus préfabriqués, composés de segments de béton de haute qualité, fabriqués en grande quantité en usine, puis transportés et installés sur site à l'aide d'innovants joints en acier présentés dans cet article. Outre leur rôle dans le maintien de l'intégrité structurelle, ces joints en acier assurent l'étanchéité des canaux latéraux destinés à accueillir les tuyaux de circulation de fluide. Protégés par des plaques de recouvrement en acier rivetées aux joints, ces canaux garantissent un fonctionnement optimal. Les fondations sur pieux battus préfabriqués peuvent être conçues à partir de segments de béton de 27 cm ou 35 cm de largeur, assemblés grâce à des joints en acier, avec une boucle en U pour les pieux de 270 mm ou deux boucles en U pour les pieux de 350 mm. Des broches en acier relient les joints, tandis que des raccords facilitent la connexion rapide des tuyaux. Les joints en acier présentés ici ouvrent la voie à l'utilisation de fondations segmentaires sur pieux en béton préfabriqué comme solution énergétique. Des essais sur le terrain et en laboratoire ont démontré la capacité de ces pieux énergétiques à supporter plus de 1000 impacts sans défaillance structurelle ni fuite.

Keywords: Precast concrete driven piles; geothermal energy piles; segmental piles; steel joint.

1 INTRODUCTION

Geothermal energy pile foundations can be used as a sustainable heating and cooling energy source for buildings (Hashemi et al., 2023). Based on the method of construction, energy piles can be categorized into two groups of cast-in-place and precast energy piles (Sadeghi & Singh, 2023c). Cast-in-place concrete energy piles dominated the market of energy piles, mainly due to some existing unresolved issues with precast concrete energy piles. The main limitation of precast concrete driven energy piles is that they are manufactured in segments of 12 m so that they can be transported to the installation site. In order to install these piles up to the competent bedrock level, several segments must be connected using steel joints. The main challenge about these steel joints is to couple the heat transfer loops between the segments, which was solved previously using a novel type of joint (Sadeghi & Singh, 2023a). Precast concrete driven energy piles have a higher quality, as they are manufactured in a concrete factory. Additionally, they require no

drilling, so they are more cost-effective, and their payback time is shorter compared to cast-in-place piles, and borehole heat exchangers (Sadeghi et al., 2022). Driven energy piles can also be used for storing thermal energy on a seasonal scale for buildings (Sadeghi et al., 2024).

In this study, the impact and bending performance of two sizes of concrete segmental driven energy piles, which are made of two segments connected by a novel steel joint are presented. The piles demonstrated a promising performance, which proves that they can be used in construction projects as a CE-certified product and with minimum risk.

2 DRIVEN ENERGY PILE JOINT

To connect precast concrete driven energy piles, a novel joint was previously designed and patented at the Norwegian University of Science and Technology (NTNU), known as driven energy pile (DEP) joints (Sadeghi & Singh, 2023d). DEP joints were developed in two sizes of 270 mm and 350 mm, which have two and four side wall channels, respectively, as shown in Figure 1.

DEP joints have two male and female dowels which are connected by strong steel pins, which are inserted into the joint from the pin ports on the side walls as shown in Figure 1. The heat transfer pipes are coupled inside the two sidewall channels, using commercially available fusion welding pipe couplings and the channels are subsequently covered using a shielding plate to protect the pipes from severe frictions in the ground.

Casting pile segments using the DEP joint is very simple and similar to the normal precast concrete piles. The only difference is that heat transfer pipes should be installed in the steel rebar cage before pouring the concrete into the formwork. The method of manufacturing the piles using driven energy pile joints was explained elsewhere (Sadeghi & Singh, 2023b).

Before using DEP joints in the construction industry, they must be tested according to the BS EN 12794 standard (Precast Concrete Products - Foundation Piles BS EN 12794:2005, 2005) to ensure their impact and bending performance. For this purpose, a total of six piles, which included three 270-mm and three 350-mm piles, were tested.

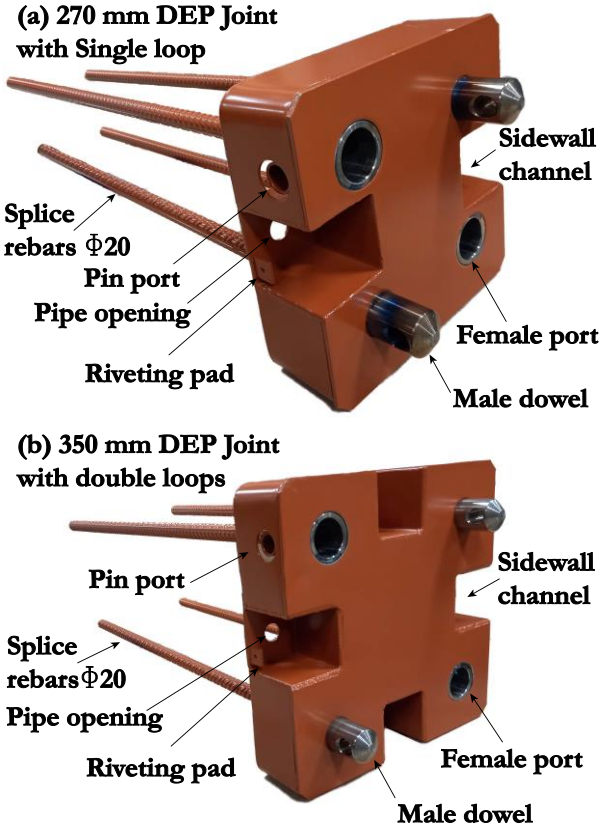

Figure 1. Details of DEP joint components, (a) 270-mm joint; (b) 350 mm joint (Sadeghi & Singh, 2024).

3 IMPACT TEST

According to the BS EN 12794 standard, the impact test consisted of applying 1000 impacts imposing a minimum of 28 MPa of compressive stress. Three piles were tested in each size (350 mm and 270 mm), which were composed of two segments that were 3 meters long. The pile segments had to stand vertically over a stiff bedrock or a flat steel plate in such a way that after applying the 1000 impacts, the joint remained above the ground. The pile segments were assembled, heat exchange pipes were coupled at the joint, and then the pile was taken inside a rigid steel box. The steel box could maintain the pile in place during the impact tests, without any penetration into the ground.

The stress level was monitored using pile driving analyzer (PDA) sensors that were installed below the joint as shown in Figure 1 (a). The number of the blows was counted both using a PDA device and also using the pile driving rig as shown in Figure 1 (b). After every 500 blows, the structure of the pile and the joints were visually inspected, and no cracks were observed. Additionally, the top and bottom segments were well-aligned (no inclination larger than 1:150). The impact test results are summarized in Table 1. The piles P4, P5, and P6 were 270 mm and piles P12, P9, P8 were 350 mm.

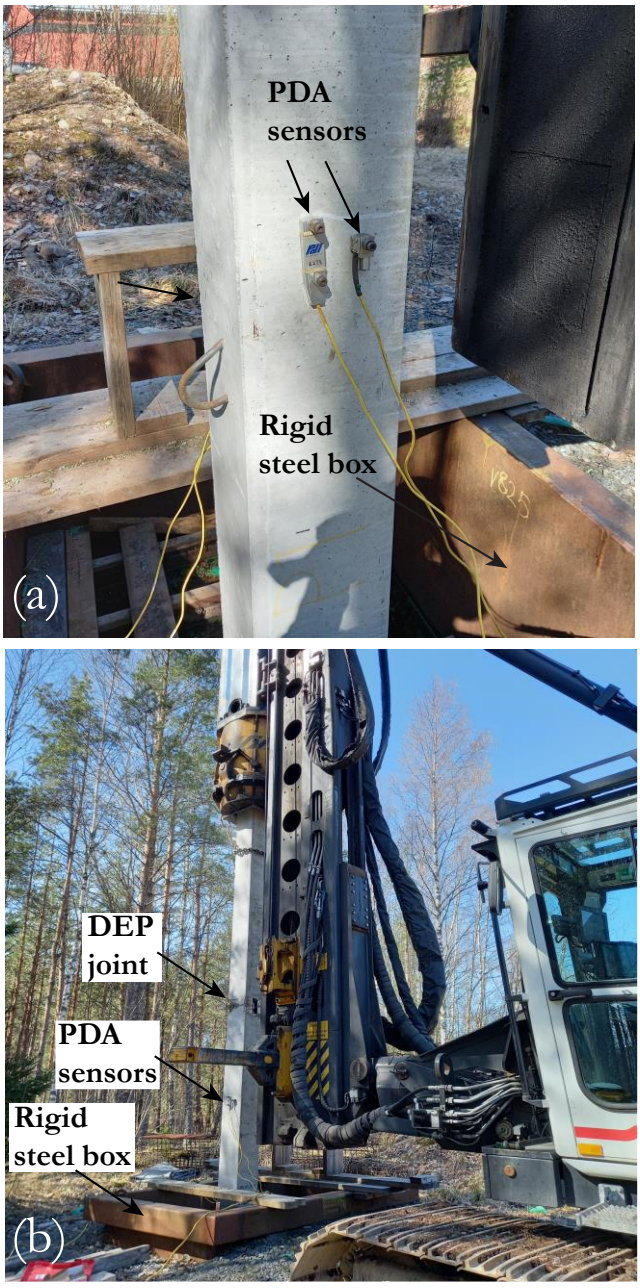

Figure 2. Impact test setup (Sadeghi & Singh, 2024).

Table 1. Measured stress levels and settlements during impact and blow tests.

Test piles	Average CSX [MPa]	Average CSI [MPa]	Blows	Settlement for 500/1000 blows [mm]
P6	32.1	39.2	≥ 1000	8 / 9
P5	29.9	40.0	≥ 1000	5 / 7
P4	30.5	42.6	≥ 1000	6 / 8
P12	29.3	32.9	≥ 1000	6 / 9
P9	28.8	30.7	≥ 1000	6 / 8
P8	29.5	35.3	≥ 1000	8 / 9

4 BENDING TESTS

After finishing the impact tests, the same piles were cut from both ends, so that their slenderness (width/length ratio) was between 11 and 12, and then they were sent to the structural laboratory for bending tests. Before doing the bending tests, the gap between the joints was measured due to its weight, and the weakest direction of the pile was chosen for the bending test. The setup for the measurement of the initial gap of the joint due to the self-weight of the pile is shown in Figure 3 and the results are summarised in Table 2.

Figure 3. Setup for the measurement of the initial gap of the joint due to the self-weight of the pile.

Table 2. Measured pile deflection values due to self-weight.

Test piles	Deflection due to own weight, Δy [mm] Side 1	Side 2	Side 3	Side 4	Opening Angle [°]
P6	0.27	0.27	0.27	0.27	0.020
P5	0.18	0.24	0.19	0.24	0.018
P4	0.23	0.36	0.23	0.37	0.028
P12	0.29	0.29	0.28	0.29	0.018
P9	0.37	0.31	0.35	0.32	0.022
P8	0.27	0.3	0.27	0.3	0.018

In the bending tests, two point-loads were applied to the piles at a distance of 1/3 of the total length of the piles from the supports. Three displacement sensors were used to measure the vertical displacement and also the changes in the gap between the two segments at the interface of the joints. The bending test setup is shown in Figure 4. The bending test results are summarized in Table 3. The yielding load and the maximum bending load were calculated using moment deformation curves for each pile.

The piles were loaded until the flexural failure occurred. As the flexural failure happened in the concrete structure of the piles after the calculated bending was reached, all of the piles passed the bending tests. Figure 5 shows the flexural failure, which happened in the concrete and the joints remained undamaged.

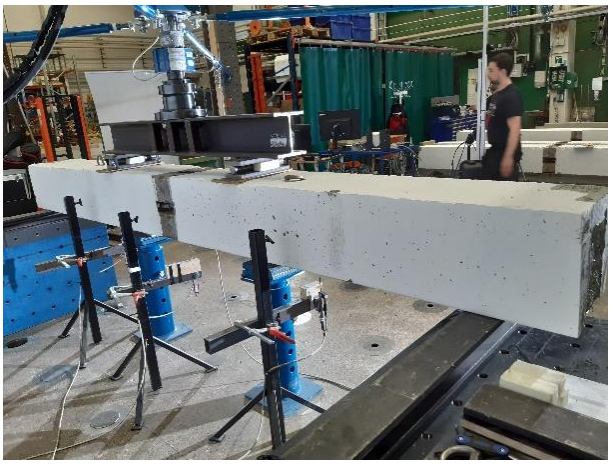

Figure 4. Bending test setup.

Table 3. Bending capacity results for the test piles.

Test piles	Max. external load [kN]	Max. moment [kN.m]	Yielding moment [kN.m]	Calculated Max. moment [kN.m]
P6	136	69.9	64	70
P5	140	71.1	65	70
P4	137	70.5	65	70
P12	180	109.8	96	103
P9	180	109.7	96	103
P8	180	109.8	97	103

Figure 5. Flexural failure outside the steel joint.

5 CONCLUSIONS

Large-scale impact and bending structural tests were performed on an innovative segmental precast concrete driven energy pile, which is composed of two segments connected using a steel joint.

The results of this study show that segmental driven energy piles have promising structural performance, similar to normal pile foundations. Driven energy piles can be considered as an option for future energy piling projects.

ACKNOWLEDGEMENTS

The authors are grateful for the financial support provided by the Research Council of Norway (project number: 332839). The authors are also grateful for the technical support from Leimet Oy, Finland for the production of the steel joints, and Sandnes and Jærbetong AS, Norway for manufacturing the concrete piles.

Influence of soil constitutive models on settlement prediction of urban tunnelling

Influence des modèles constitutifs du sol sur la prévision du tassement des tunnels urbains

B. Salehi*, B.S. Muntau
Universität Innsbruck, Innsbruck, Austria

**Bahram.Salehi@student.uibk.ac.at*

ABSTRACT: The validity of material models is a major field of research in soil mechanics. Different constitutive models have distinct stress-strain behavior, which can affect the results of the predicted deformation, failure mechanism, and load-bearing capacity of a geotechnical structure. In this regard, in this contribution, the application of three constitutive models in a Finite Element Analysis (FEA) of a well-documented case study is presented. This case study - Arash-Esfandiar tunnel - is a particular under-passing tunnel in the north of Tehran, Iran, starting from Modares highway and running to Niayesh highway. The tunnel project has a total length of 1532 m and was constructed with shallow overburden. The results indicate the necessity of using axial and bending elements as tunnel support measures at the same time. According to the large span of the tunnel and the geotechnical conditions, a combination of 4 different support elements was propose which includes, nails, micropiles, fore poling and, lattice girder. Various monitoring stations, including settlement points and geodetic points, have been installed as part of this project, providing extensive records of subsidence and tunnel deformation. The main goal of the numerical simulations is to investigate the influence of the material models on the results of accumulated subsidence for the stage construction method. The analysis outputs have been validated on available monitoring results of this actual tunnelling project. The results show a significant better performance of the hardening soil model when simulating the tunnel construction effects on the deformations of the excavation area and comparing them with the measurements results.

RÉSUMÉ: La validité des modèles de matériaux est un domaine de recherche majeur en mécanique des sols. Différents modèles constitutifs ont un comportement contrainte-déformation distinct, qui peut affecter les résultats de la déformation prévue, du mécanisme de rupture et de la capacité portante d'une structure géotechnique. À cet égard, dans cette contribution, l'application de trois modèles constitutifs dans une analyse par éléments finis (FEA) d'une étude de cas bien documentée est présentée. Cette étude de cas - tunnel Arash-Esfandiar - est un tunnel souterrain particulier dans le nord de Téhéran-Iran, partant de l'autoroute Modares et allant jusqu'à l'autoroute Niayesh. Le projet de tunnel a une longueur totale de 1532 m et a été construit dans un déblais peu profound peu profond. Les résultats indiquent la nécessité d'utiliser simultanément des éléments axiaux et de flexion comme mesures de soutènement du tunnel. Compte tenu de la grande portée du tunnel et des conditions géotechniques, une combinaison de 4 éléments de soutènement différents a été proposée : clou, micropieu, avant-pieu et poutre en treillis. Diverses stations de surveillance, y compris des points de règlement et des points géodésiques, ont été installées dans le cadre de ce projet, fournissant des enregistrements détaillés de l'affaissement de surface et de la déformation du tunnel. L'étude de l'influence des modèles de matériaux sur les résultats d'affaissement cumulé pour la méthode de construction d'étage est l'objectif principal des simulations numériques. Les résultats de l'analyse ont été validés sur les résultats de surveillance disponibles de ce projet de tunnel réel. Les résultats montrent une performance significativement meilleure du modèle de sol durcissant lors de la simulation des effets de la construction du tunnel sur les déformations de la zone d'excavation et en les comparants aux résultats des mesures.

Keywords: Tunnel; constitutive soil models; FEM, instrumentation.

1 INTRODUCTION

Any major cities worldwide require underground transportation systems, especially those grappling with issues related to population density and traffic congestion. The construction of tunnels and underground spaces may potentially impact the ground, leading to ground movement and settlement. These effects can be critical enough to disrupt the functionality of nearby structures. Consequently, one of the foremost concerns in tunnel construction revolves around ensuring the safety of the construction process itself, as well as safeguarding nearby structures, particularly in urban areas.

Geotechnical engineering is an evolving field focused on enhancing the precision of numerical analysis tools employed in simulating the interaction between soil and structures under complex load conditions. A critical aspect of this improvement is the development and validation of constitutive models that accurately represent the soil behavior. This paper endeavors to tackle the challenges associated with the selection of appropriate soil models for conducting realistic design analyses. In this regard, a specific case study has been chosen to examine the application of three different constitutive models (including: mohr-coulomb, hardening soil and hardening soil model with small strain) within a Finite Element Analysis (FEA) framework and to corroborate the findings with the data obtained from on-site monitoring.

2 SOIL CONSTITUTIVE MODELS

Material constitutive models range from simple elastic perfectly plastic models (Drucker and Prager, 1952 and Mohr-Coulomb, by Jaeger and Cook, 2009) to models using critical state concepts models using multi-yield surfaces (Prevost, 1977), and double hardening models (Lade, 1977), to name a few.

In this research Mohr-Coulomb model (MC) is chosen from the available models due to its simplicity and widespread use in practical applications. Numerical modelling of the tunnelling with MC has proven inaccurate due to the lack of ability to properly simulate the phenomenon of unloading and the lack of distinction between the hardships of initial loading and unloading/reloading (Schanz et al, 1999). To overcome that disadvantage the Hardening Soil model (HS) selected as second model. HS is an advanced elastoplastic constitutive model that is used for simulating both stiff and soft soil behaviors (Schanz et al, 1999). HS also relates stiffness parameters to the stress-level and simulates the development of plastic strains under compressive loading. HS can distinguish between loading and unloading path.

The third model used is the hardening soil model with small strain stiffness (HSS). This model is an extension of HS considering increased stiffness for small strains (Benz, 2007). At low strain levels, most soils exhibit a higher stiffness, and this stiffness varies non-linearly with strain.

3 CASE STUDY

In this research, an underground tunnel located in the northern region of Tehran, the capital of Iran, will be examined. This tunnel, known as the Arash-Esfandiar-Niayesh Tunnel, is situated within the third district of Tehran Municipality. It is constructed to facilitate east-to-west connectivity in this locality, connecting East Arash Street with the starting point of Niayesh Highway. (Figure.1). The current study is modified after Salehi et al (2023).

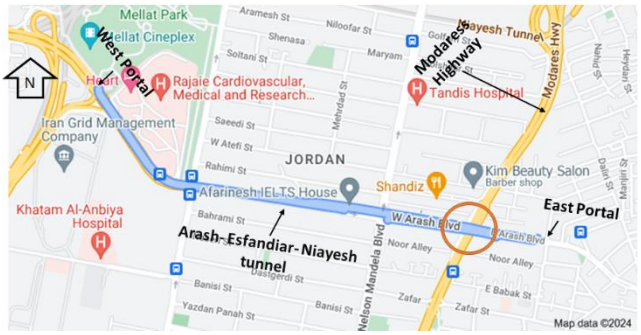

Figure 1. Plan of Arash- Esfandiar tunnel.

This project is constructed by New Austrian Tunneling Method (NATM). NATM was introduced in Austria during 1957-1965 by Rabcewicz. The idea of this method is to allow a certain amount of deformation in the surrounding rock or soil to reduce the stresses acting on the final support of the tunnel, (FHWA, 2009).

3.1 Soil Condition

The geological and geotechnical characteristics of the different soil types were established through laboratory assessments conducted on numerous samples obtained from seven boreholes and four test pits. For this study, we focused on four boreholes, each with a depth of 50 meters, and one test pit with a depth of 19 meters, all located within the project area. There was no sign of water table level up to the end of borehole (50m). After conducting laboratory tests and on-site investigations, the soil types were classified cemented granular and as follows: medium dense silty gravel up to 3.5 m depth, very dense silty sandy gravel and dense clay sand (located beneath the gravel layer). (found at depths of -3.5 to -50 meters),

Table 1 presents an overview of the key geotechnical parameters essential for our research and based on each constitutive soil model. Shear strength parameters are extracted from in situ shear, direct shear and triaxial tests. Stiffness parameters are extracted from pressuremeter test and plate load test is carried out to investigate the ratio of loading and unloading. Instead of using the Young's modulus as a stiffness parameter, alternative stiffness parameters were used (Eoed and G) and the young's modulus calculated automatically. Oedometer modulus (Eoed) is obtained for 90 kPa stress level to account to the tunnel depth at the top of the excavation.

Table 1. Geotechnical parameters.

First layer (0 to -3.5)	Second layer (-3.5 to -50) m
$\varphi = 30^\circ$	$\varphi = 37^\circ$

$E_{oed} = 4.0$ e04 kN/m^2	$E_{oed} = 7.0$ e04 kN/m^2
G = 1.15 e04 kN/m^2	G= 2.625 e05 kN/m^2

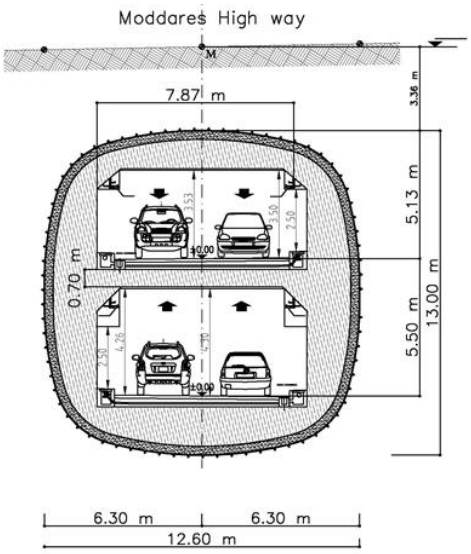

Figure 2. Modares two-level tunnel section

3.2 Tunnel Geometry

On one hand, there was a need to establish multiple entry points to access the project site from West Arash Street and Esfandiar. On the other hand, project constraints made it necessary to employ various geometric configurations during construction. To address the requirement for a two-way traffic option beneath Modares Highway, despite limited available space, the decision was made to implement a two-level tunnel. Thus, the Modares two-level tunnel became a component of the Arash-Esfandiar-Niayesh tunnel project. The tunnel section measures 12.2 meters in width and 13 meters in height, as shown in Figure 2. Given the shallow depth of the tunnel and its passage beneath major urban arteries close to tall buildings, the New Austrian Tunneling Method (NATM) was chosen as the construction method for this project.

3.3 FEM Model

The tunnel structure and the surrounding soil have been simultaneously simulated using the PLAXIS 2D finite element program. The construction stages and the continuous implementation of tunnel excavation were incorporated into the model to align with the actual construction process. To represent the various layers of the ground, 15-node triangular elements were employed, as shown in Figure 3. To comprehensively assess the extent impacted by the construction of underground structures, a model with a width of 80 meters and a height of 40 meters was created, which is 10 times the tunnel's diameter in width and 3 times in height. The tunnel's overburden within the investigated sections is a minimum of 4 meters, which has been considered in the geometric definition of the model. In this paper, the stress reduction or relaxation method is utilized to simplify the model and simulate the 3D problem. The relaxion factor are estimated based on previous research concerning this project (Golshani et al., 2018),) according to a 3D model and the Vlachopoulos and Diederich (2009) methods. The relaxation factors (RF) for each excavation phase are as follows: 35% in Top (Stage I to III), 20% in Bench (Stage IV to IX) and 15% in Invert (Stage X to XII).

3.4 Support System

Within the New Austrian Tunneling Method (NATM), various elements are employed to provide both temporary and permanent support for tunnels. Shotcrete is a commonly utilized material for temporary support during tunnel excavation. This choice is primarily made because no other support method can effectively bond the ground surface, preventing it from deteriorating or loosening in the same manner that shotcrete does.

A rock bolt or nail serves as a supporting element to enhance the stability of rock excavations, often employed in tunnels or rock cuts. Its primary function is to shift the load from the less stable outer areas to the more solid and robust interior of the rock mass. Rock bolts function by essentially "knitting" together the rock mass, preventing it from moving significantly and potentially coming apart piece by piece, which could lead to instability or failure.

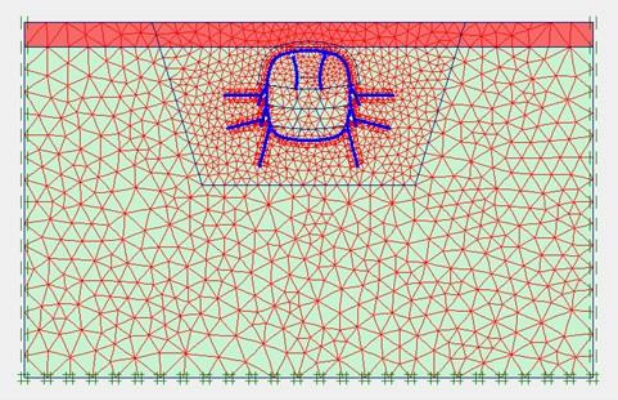

Figure 3. Meshing plot of Modares two level tunnel

One way to mitigate ground movements caused by tunneling is to employ in-tunnel support methods, such as the forepoling umbrella system. This system consists of steel pipes that offer structural support to the soil surrounding and above the tunnel excavation. Forepoling arches are specific tunnel heading reinforcements utilized to bolster the unsupported section of the tunnel heading during the excavation of tunnels in soft ground or loose soil conditions. In the current research according to the large span of the tunnel and the geotechnical conditions, a combination of 4 different support elements was proposed. A classification of the suggested support system and their combination is provided in Table 2.

In the two-level section, known as the Modares Tunnel, the primary walls will receive support through a combination of 35 cm thick shotcrete and lattice girder truss metal structures. In cases where additional support is needed, forepoling elements will be incorporated alongside micropiles and nails.

Additionally, the temporary walls will be reinforced with 25 cm thick shotcrete and lattice structures. In the numerical model, the shotcrete support is simulated with parameters corresponding to 7-day and 28-day settings, including Elastic Modulus values of 18.7+06 kPa and 23.4+06 kPa, respectively. The loading in this section is primarily static and results from the overburden of the tunnel. Additionally, the model takes into account the load imposed by the traffic on Modares Highway, which amounts to 20 KN/m per meter.

The initial lining of the tunnel was constructed with thicknesses of 35 cm and 25 cm, using shotcrete of class C25 and lattice girder steel bars of type III. In the modeling process, the lining structure was represented using plate elements, and a linear elastic behavior was assigned to the reinforced shotcrete material. Once stable initial conditions were established, and traffic-related loads were activated, simulations of the excavation and stage stabilizations is proceeded. It should be mentioned that the term "top" refers to stages 1 to 3 of excavation, "bench" refers to stages 4 to 9 and "invert" refers to stages 10 to 12, presented in Figure. 4.

Table 2. Classification of the examined support systems in Modares two-level tunnel.

Support system	Class
Lattice+shotcrete	A
Lattice+shotcrete+forepoling	B-I
Lattice+shotcrete+micropile	B-II
Lattice+shotcrete+nail	B-III
Lattice+shotcrete+forepoling+nail	B-IV
Lattice+shotcrete+forepoling+micropile	C-I
Lattice+shotcrete+nail+micropile	C-II
Lattice+shotcrete+forepoling+nail+ micropile	D

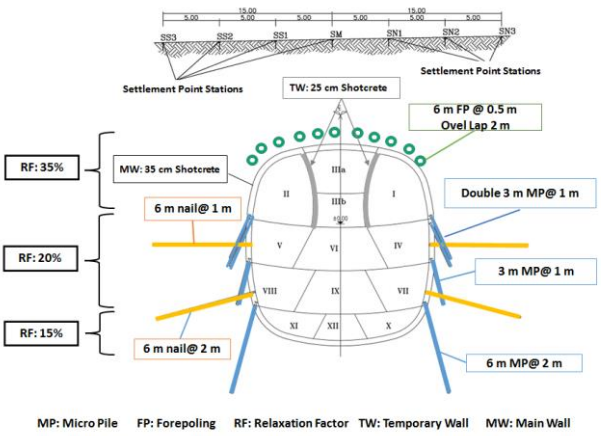

Figure 4. Excavation stages, initial support (Class D), and settlement points on Modares two-level tunnel.

3.5 Instrumentation

In the Arash-Esfandiar-Niayesh tunnel project, several measurement techniques were employed to monitor ground settlements and validate the numerical model across different profiles. In the two-level section of the project, a settlement measurement system was implemented to capture surface deformations, denoted as Settlement South (SS), Settlement Middle (SM), and Settlement North (SN). The layout of the instrumentation plan is depicted in Figure 4. It's important to note that the internal deformation is measured using optical reflectors, but since this research does not encompass internal convergence, it won't be discussed in this paper.

4 RESULTS

After solving the model, it was determined that using only shotcrete and lattice for temporary support would lead to develop a shear zone during the second bench excavation and tunnel will collapse. Consequently, to ensure a stable excavation process, 76 mm pipes with a 5 mm thickness were introduced for forepoling. However, despite the inclusion of forepoling in the model, structural instability resurfaced in tunnel excavation section VIII. To reduce the stresses from the initial support (shotcrete and lattice), additional axial elements were introduced. In this scenario, self-drilling nails with a 32 mm diameter (86 mm drilling diameter) and spaced 1 meter apart were chosen and implemented at two different heights.

Furthermore, the potential use of micropile elements was investigated as a meansof managing the vertical displacements. The calculations for the characteristics of micropiles resembled those of self-drilling nails. However, when micropiles were employed in isolation, the model once again exhibited instability during excavation in section X. As a result, the subsequent step involved investigating the combined use of forepoling and nails.

Given the project's sensitivity and its passage beneath a major urban traffic road, a decision was made to reinforce the tunnel using a class D support system. By combining axial and bending support structures, such as forepoling and nails, not only can displacement be minimized, but tunnel stability can also be ensured.

The overall pattern of recorded displacements aligns with the outcomes derived from the Finite Element calculations. The HS model oversestimates the displacements. In contrast, the MC and HSS models consistently produce results that underestimate the observed displacements. On the other hand, the absolute maximum settlement values align with the result of the numerical analysis. For example, when the temporary wall was removed, a measured settlement of 1 cm corresponded to the numerical results. It should be noted that in nearly all stages, there is a significant and immediate increase in settlements (a change in slope) in the FEM analysis results earlier than what's observed in the monitoring data. The results of the Finite Element Method (FEM) analysis indicate total vertical displacements of 2.7 cm, 2.1 cm, and 1.4 cm for the Hardening Soil, Small Strain Hardening Soil, and Mohr-Coulomb soil models, respectively.

In contrast, according to the settlement point records, the maximum vertical displacements at the ground surface were observed to be 2.6 cm as shown in Figure 5.

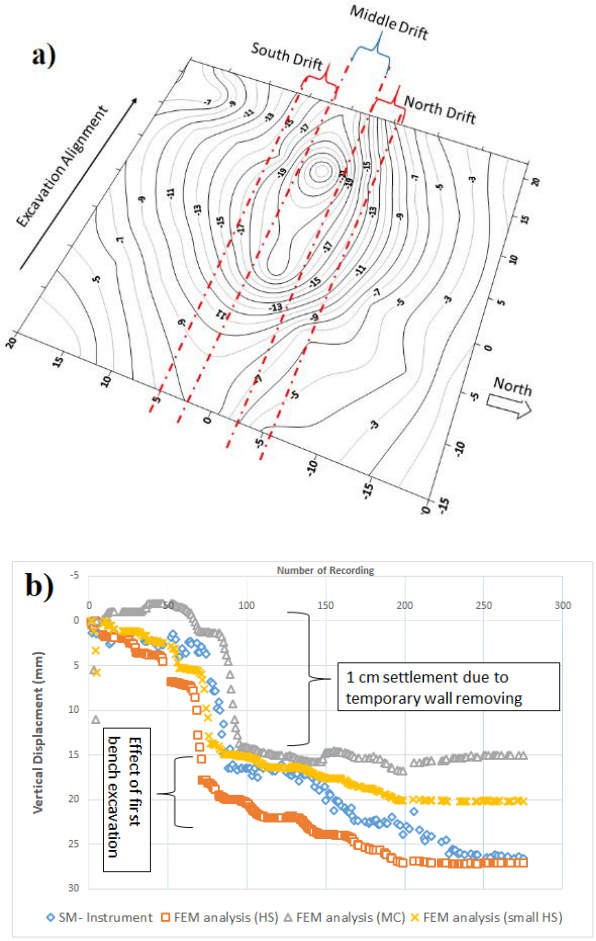

Figure 5. Surface Settlement: a) Normalized recording charts, b) Comparison of onsite measurements and FEM results in SM station (above the tunnel axis).

In Figure 5b, The horizontal axis is the number of instrument recordings (can be interpreted as time) in the construction site which is synchronized by the excavation and FEM model construction stages. The cumulative sum of settlements is selected to illustrate the progressive subsidence attributed to the excavation stages.

5 CONCLUSIONS

The findings from both the analysis and field data highlight the substantial influence of the tunnel's geometric shape on its stability and the distribution of stress. Prior to commencing operations, various options for stabilization methods were thoroughly reviewed and subjected to numerical modeling. The results obtained underscore the inadequacy of conventional support systems for shallow tunnels with an ovoid section. In such cases, relying solely on shotcrete and lattice girder elements, even in combination with forepoling, proves insufficient to ensure both structural and geotechnical stability of the

tunnel. This limitation is primarily attributed to the significant height of the tunnel section and the high bending moment experienced by the beam elements. In addition to employing micropiles and forepoling to control surface settlement, the use of nails at two levels becomes imperative to alleviate stresses on the shotcrete and lattice and ensure the structural stability of the tunnel.

The results from the numerical model indicate that the incorporation of forepoling elements results in arching around the structure, leading to a decrease in surface settlements as well as a reduction in bending moments and shear forces. The minimum settlement achieved with the selected support system (type D) amounts to 2.7 cm at the surface.

The settlement monitoring records indicate a maximum vertical displacement of 2.7 cm at both the surface and within the tunnel. The absolute value of the final settlement in the numerical analysis method (based on the HS model) aligns with the measured data. However, there are some differences in the trends of the two diagrams (as shown in Fig. 5 (b)). In the on-site measurements, the slope in settlement curve becomes zero after the temporary lattice girders are removed, and despite the excavation of the first bench, the displacements exhibit a constant trend. In contrast, numerical model still show increase in displacements. This could be attributed to the application of relaxation factors during the excavation of the first bench. In practice, no increase in displacement was observed until the excavation of the middle part of the first bench (excavation section VI, Figure 4). This trend is also evident in the second bench excavation but with less impact. Furthermore, the final stage of excavation (invert) had minimal effect on surface displacements.

However, in complex situations with quasi-rectangular geometric sections, complicated support systems and high side walls, 3D modelling is required for accurate assessment. If the 2D method is used, simplification requires a more specific approach. In particular, the relaxation factor should be calibrated based on each soil constitutive model. This topic is an ongoing research in our team and results will be presented at the upcoming events.

Pressure cell results for a ballasted railway track section tested in the CEDEX Track Box

Résultats de la cellule de pression pour un tronçon de voie ferrée testé dans la boîte à outils CEDEX Track Box

M. Santana*, S. Merino, J. Estaire
Laboratorio de Geotecnia/CEDEX/Madrid, Spain

**Maria.S.Ruiz@cedex.es*

ABSTRACT: CEDEX Track Box (CTB) is a 21 m long, 5 m wide and 4 m deep facility whose main objective is to test, at 1:1 scale, complete railway track sections of conventional and high-speed lines for passenger and freight trains, at speeds up to 420km/h. Its special characteristics allow the testing of different railway sections, types of trains, passing by velocities and materials in advance of their use in the real railway. In this work, we present the results obtained from pressure cells located at several depths inside the railway track section, after testing two different types of trains at eight different passing-by speeds (from 50 to 400 km/h). The railway train section tested in this work has the same requirements as the Spanish ballasted high-speed track sections. These tests show the distributions of pressures underneath the superstructure and how they are affected by the different loads of each type of train and the several passing-by speeds.

RÉSUMÉ: Le CEDEX Track Box (CTB) est une installation de 21 m de long, 5 m de large et 4 m de profondeur dont l'objectif principal est de tester, à l'échelle 1:1, des tronçons complets de voies ferrées de lignes conventionnelles et à grande vitesse pour les trains de passagers et de marchandises, à des vitesses allant jusqu'à 420km/h. Ses caractéristiques particulières permettent de tester différents tronçons ferroviaires, types de trains, vitesses de passage et matériaux avant leur utilisation dans le réseau ferroviaire réel. Dans ce travail, nous présentons les résultats obtenus à partir de cellules de pression situées à plusieurs profondeurs à l'intérieur de la section de voie ferrée et après avoir testé 2 types de trains différents à 8 vitesses de passage différentes (de 50 à 400 km/h). La section de voie ferrée testée dans ce travail répond aux mêmes exigences que les sections de voies à grande vitesse ballastées espagnoles. Ces essais montrent la répartition des pressions sous la superstructure et la manière dont elles sont affectées par les différentes charges de chaque type de train et les différentes vitesses de passage.

Keywords: Railway track section; pressure cells; train velocities.

1 INTRODUCTION

Mobility policies in the European Union are encouraging the use of rail transport to promote more sustainable mobility. Considering the lower environmental impact of railway transportation mode compared to other modes of mass transportation (road, air, maritime), the European Green Deal aims to shift to rail transport to reduce CO_2 emissions.

Spain has an important network of high-speed lines, with more than 3,400 km. The vast majority of the railway sections of these lines are built with a ballast layer instead of slab track. In recent years, comparative studies of the pros and cons of one construction system versus the other have pointed to the need for greater maintenance on the sections built with ballast (Charoenwong et al. 2023).

Ballast maintenance operations consist mainly of tamping the layer or replacing the material when track movement levels are excessive. Since one of the main functions of the ballast layer is the absorption of loads transmitted by the train, it is interesting to study how these loads are transmitted to the lower layers of the section and what factors may be involved.

One of the tasks carried out by Laboratorio de Geotecnia - CEDEX is the auscultation of railway sections. This auscultation on real tracks is the perfect complement to the tests carried out at the CEDEX Track Box (CTB) facility.

2 CEDEX TRACK BOX

CEDEX Track Box (CTB) is a 21 m long, 5 m wide and 4 m deep facility whose main objective is to test, at 1:1 scale, complete railway track sections of conventional and high-speed lines for passenger and freight trains, at speeds up to 420 km/h. Figure 1 shows

a general view of the testing facility and the hydraulic actuators that apply the loads to simulate the railway traffic (Estaire et al., 2018).

Figure 1. General view of the CEDEX Track Box and the hydraulic actuators.

Its principal advantage is the possibility of performing fatigue tests in a fast way as in 10 working days, the effect of a train passing-by during a year in a real section can be modelled.

The reproduction of the effect of the approaching, passing-by and departing of a train in a test cross-section, as it occurs in a real track section, is performed by application of loads, unphased as a function of the train velocity which is being simulated, produced by three pairs of hydraulic actuators (each of them can apply a maximum load of 250 kN at a frequency of 50 Hz), placed on each rail and 1.5 m longitudinally separated.

The railway track response, in terms of displacements, velocities accelerations and pressures, is collected from LVDTs, geophones, accelerometers and pressure cells installed both inside the embankment and the bed layers of the track. The railway superstructure response is recorded with mechanical displacement transducers, laser sensors, geophones and accelerometers installed on the different track components (rail, sleeper and railpad).

CTB has been used to research different matters, such as the measurement of track vertical stiffness under different track conditions and the determination of track lateral stability. More detailed information is described at Estaire et al. (2018).

In this work, the tests carried out on the installation were used to determine the vertical pressure in the different layers of the railway section, produced by different types of trains and passing speeds.

3 TESTS DESCRIPTION

3.1 Introduction. General aspects

This work is part of a larger study of ballast degradation as a function of the type of trains and speeds modelled in the tests. The results shown were obtained from the analysis of static and dynamic tests and focused on measurements obtained with pressure cells placed inside the layers of a ballasted track model built in CTB.

The load applied by the trains is transmitted from the rail to the sleepers and the layers constituting the railway section. One of the ballast layer main functions is to absorb these loads. The placement of pressure cells at the different transitions between layers will make it possible to analyse how loads are transmitted from the rail to the embankment and whether the speed of the train passing through has any effect on those pressures.

3.2 Static load tests

The static load is applied by two hydraulic actuators (one in each rail) installed in the central cross-section of the model under study: a typical ballasted rail track.

The static tests, whose aim is to determine the track stiffness, consisted of three loading-unloading cycles in which a maximum load of 95 kN (per actuator) was reached, applied step by step, simulating the effect of a passenger train. The duration of each static test was around 50 minutes. This test is inspired by ADIF technical specification ET 03.360.570.0. Figure 2 shows the three load cycles of each static test.

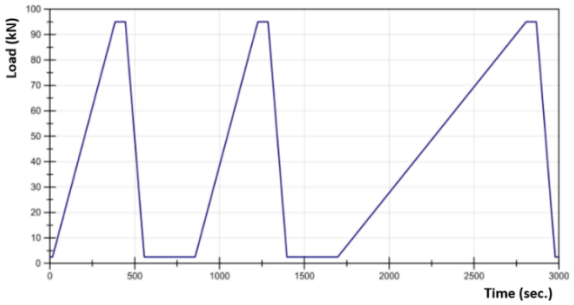

Figure 2. Sequence of load-unload cycles applied in the static tests.

3.3 Dynamic load tests

Dynamic load tests allow the modelling of the passing-by of trains at different speeds. For this purpose, the three pairs of hydraulic actuators (Figure 1) are synchronised in such a way as to reproduce the effect of the approach, passing-by and departure of the train in the central section of the model for any kind of train running up to 420 km/h.

3.4 Description of trains

The following table shows the most relevant characteristic of the trains modelled in the CTB: train type, number of axles and their total weight. Of the types of trains operating on the Spanish network, the following two trains were chosen because of their different axle configuration: bogies (Siemens S103) and isolated wheels (Talgo S112).

Table 1. Main characteristics of trains used in the study.

Train	Number of axles	Total Weight (t)
Talgo S112	21	357.0
Siemens S103	32	463.3

3.5 Passing-by train speeds

For each of the trains described above, dynamic tests were carried out at 50, 100, 150, 200, 250, 300, 350 and 400 km/h. Therefore, a total of 16 tests were performed.

It can be highlighted that the two greater speeds (350 and 400 km/h) are above the current nominal speeds (300 km/h) at high-speed train lines, although 350 km/h is usually used for the approval tests.

3.6 Instrumentation

The railway track section is profusely instrumented. In this work, only the results obtained with pressure cells are analysed. Figure 3 shows the location of pressure cells in the central section of the test and Figure 4 a detail of these cells placed at the sleeper bottom.

Rectangular and circular pressure cells of 25x15 cm and 17 cm diameter were used respectively. The measuring range of these cells varies according to the interface analysed: 0-1 MPa at sleeper-ballast, 0-0.5 MPa at ballast-subballast, 0-1 MPaat subballast-form layer and 0-0.2 MPa at form layer-embankment interfaces. Cell pressures are located under the rails to measure the stress peak since it is known that the contact surface and the stress distribution beneath the sleeper are not uniform.

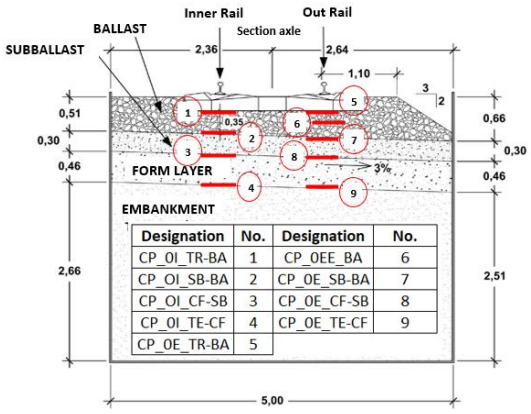

Figure 3. Load configuration for each train at CTB.

Figure 4. Pressure cell placed under the sleeper.

4 RESULTS OBTAINED

4.1 Results in the different layer interfaces

Figure 5 shows the variation of pressure with depth, measured by pressure cells, during the third cycle of static tests. The vertical stress distribution due to a rectangular load according to Fadum's theory is also shown.

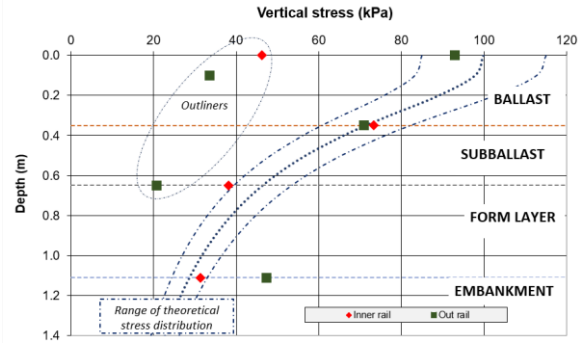

Figure 5. Pressure values measured by a pressure cell and theoretical stress distribution.

The measured values globally follow Fadum's theory which shows the stress distribution inside the track bed layers. This implies that in the subballast top surface, the stress is reduced to 70% of the stress transmitted by the sleeper while in the form layer and the embankment below, the vertical stress is around 30-40% of the initial stress.

On the other hand, three of the nine measures can be considered as outliners, two of them being relative to the ballast layer. This is due to the great size of the ballast particles which provokes that the stress in the ballast layer is transmitted through contact points whose loads are difficult to capture by the measuring surface of the pressure cells. This difficulty in obtaining accurate pressure measurements with this type of instrumentation is one of the main aspects to be highlighted as a result of the present work.

4.2 Results obtained with train speed variation

This section shows the measurements obtained with the pressure cells placed under the inner rail in the dynamic tests for different train speeds. Figure 6 shows the maximum pressure values, relative to the values obtained at 50 km/h, for the two trains modelled, as a function of the train speed. The graphs also include the dynamic amplification factor DAF $[DAF = \frac{1}{\sqrt{1-\left(v/v_{crit}\right)^2}}]$ for a critical velocity (v_{crit}) of

- 600 km/h, a typical value of a high-speed line, to model the platform layers, and
- 430 and 450 km/h, to model the ballast layer.

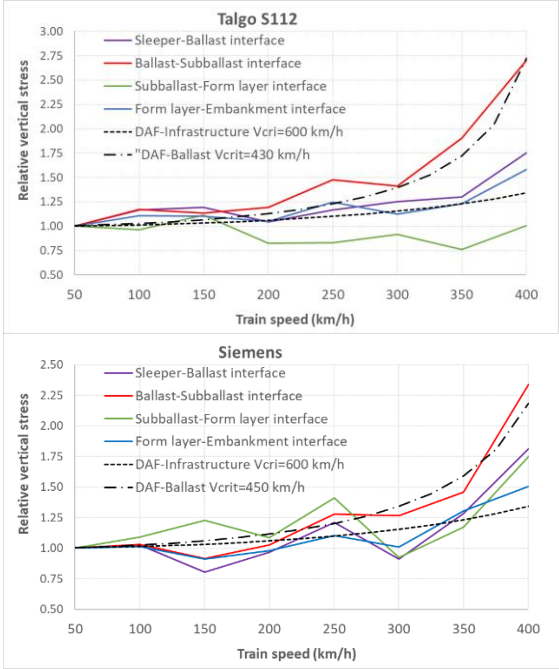

Figure 6. Relative pressure cell measurements placed under the inner rail and Dynamic Amplification Factor.

These graphs show that the vertical stresses are fluctuant due to the problems derived from this kind of measurements, although an increasing trend can be seen, similar to the one shown by DAF. An increase of around 20%, relative to the static value, when the speed is 300 km/h is seen. However, two aspects show a significant increase, out of the general trend: the measurements done in the ballast-subballast interface (plotted with red lines) and the ones obtained in the tests performed at 400 km/h.

Finally, Figure 7 and Figure 8 show the vertical stress measured in the ballast-subballast interface during the tests in which trains were modelled running at 50 and 300 km/h. The stresses measured follow quite well the loads imposed by the train axle.

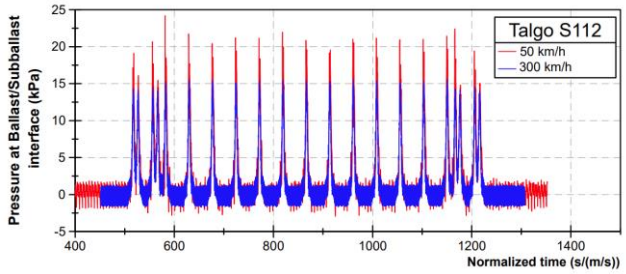

Figure 7. Vertical stress measured during the modelling of Talgo S112 train at 50 and 300 km/h

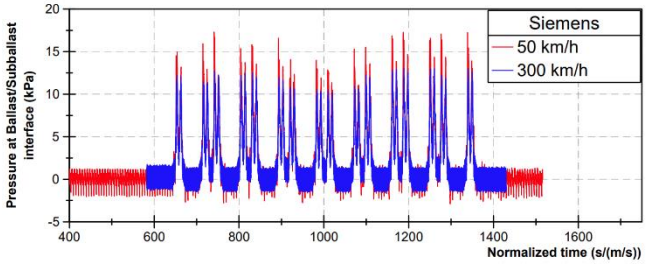

Figure 8. Vertical stress measured during the modelling of Siemens train at 50 and 300 km/h

5 CONCLUSIONS

The CTB allows modelling and measuring the response of a railway track section under laboratory conditions. This work shows the results obtained on pressure cells placed at different depths of the section, which were tested with the passage of two types of trains at different speeds.

The results show that the measurements obtained with this instrumentation are a bit erratic, on many occasions, due to the difficulty of measuring normal pressures in a granular medium by a flat surface where several contact points are produced. The fact that the pressure, in the different interfaces present in railway sections, transmitted by the trains, follows Fadum's law of load distribution under a rectangular load was verified. The increase of the vertical stress with the speed of the trains and the fact that, during the pass-by of trains at different speeds, the normal pressure varies according to the loads imposed by the train axles were also observed.

Foundation piles and submerged wall of berths 6, 7 and 8 at the Port of Maputo

Pieux de fondation et mur immergé des quais 6, 7 et 8 du Port de Maputo

J. Santos*, L. Tomás
Mota-Engil Engenharia e Construção, S.A., Lisbon, Portugal
**joao.p.santos@mota-engil.pt*

ABSTRACT: The Maputo Port Development Company decided in June 2018 to proceed with the rehabilitation of berths 6, 7, and 8 of the Port of Maputo, with 630 meters long, which involved the demolition of the existing quay, to build new quay infrastructures ready to service depths of -16,0 m (CD). The existing berths with construction dates between 1913 (Berth 6) and 1951 (Berth 8) were extremely damaged and partially destroyed, and the future quay consisting of a combiwall of ∅2032 x 22 mm piles and double AZ28-700 intermediate sheet piles, required the execution by maritime means, with significant disturbance in the port operations. Based on the experience developed over the years in maritime works, Mota-Engil proposed an alternative solution to the Employer's design, consisting of a pile supported concrete deck and a submerged combiwall to retain the existing slope to be dredged, which minimized the mobilization of human and material resources using a more simplified and systematized approach of construction processes. This communication addresses the construction aspects, namely the cantitravel method adopted for the execution of the piles in maritime environment and the driving of the combiwall to be installed under water.

RÉSUMÉ: La Maputo Port Development Company a décidé en juin 2018 d'avancer dans la réhabilitation des postes d'amarrage 6, 7 et 8 du port de Maputo, d'une longueur de 630 mètres, qui a impliqué la démolition du quai existant, pour construire de nouvelles infrastructures de quai prêtes à fonctionner profondeurs de -16,0 m (CD). Les postes d'amarrage existants dont les dates de construction sont comprises entre 1913 (poste 6) et 1951 (poste 8) ont été extrêmement endommagés et partiellement détruits, et le futur quai constitué d'un mur combiné de pieux ∅2032 x 22 mm et de doubles palplanches intermédiaires AZ28-700, a nécessité l'exécution par voie maritime, avec des perturbations importantes dans les opérations portuaires. S'appuyant sur l'expérience développée au fil des années dans les travaux maritimes, Mota-Engil a proposé une solution alternative à la conception de l'Employeur, composée d'un tablier en béton soutenu par pieux et d'un mur combiné immergé pour retenir la pente existante à draguer, ce qui minimisait la mobilisation des humains. et les ressources matérielles en utilisant une approche plus simplifiée et systématique des processus de construction. Cette communication aborde les aspects constructifs, à savoir la méthode cantitravel adoptée pour l'exécution des pieux en milieu maritime et le battage du combiwall à installer sous l'eau.

Keywords: Combiwall; cantitravel; piling works; underwater combiwall; water jetting.

1 INTRODUCTION

The Maputo Port Development Company (MPDC) is a private Mozambican company, which resulted from the partnership between the Caminhos de Ferro de Moçambique, CFM, and a joint venture mainly constituted by Grindrod and DP World, one of the main maritime operators of the world.

Within the scope of development and optimization of the entire concession area, MPDC has made several investments to modernize the Port of Maputo in the last 10 years, including the deepening of the access channel, the increase of capacity of the several terminals, and the rehabilitation of the old berths, including the contract for rehabilitation of berths 6, 7 and 8 of the Port of Maputo.

2 CHARACTERIZATION OF THE EXISTING STRUCTURE

The existing platforms were all constructed in a similar way with rows of quadrangular piers along the quays at typical intervals between 3.1 and 3.6 m, which extended between 14 and 52 meters landwards beneath the quay surfaces and warehouses. The quay structures were closed at the back by a concrete retaining wall (Figure 1).

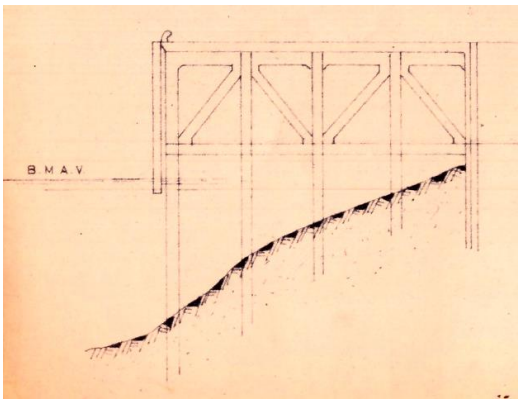

Figure 1. Cross section of the existing structure of berth 6.

The Maputo Port Investigation (NIRAS 2000) reported that the piles, lower beams and the lower part of the vertical elements below mean sea level were generally in good condition, with the concrete layer on the reinforcement remaining intact. However, the vertical elements and diagonal bracings were generally in poor condition, with severe deterioration above the high tide level, between +3.5 and +4.5 m (CD), with several cracks and exposed reinforcement. (Figure 2 and Figure 3).

The condition of the edge beam was also poor, with missing or loose concrete, probably due to ship impacts, and at Pier 8, the deck slab had collapsed.

Figure 2. View underneath the old quays.

Figure 3. Reinforced concrete columns and bracings.

3 GEOTECHNICAL INVESTIGATION

The Geotechnical Investigation report (Aucamp 2014) describes "the regional geology of the area is composed of recent clayey and sandy alluvial material, covering the Ponta Vermelha Formation (from 2 million years (Ma) to 5 Ma) which is composed of silty sand that becomes yellowish red sandstone with depth". The synthesis of geotechnical parameters is presented on Table 1.

4 STRUCTURAL SOLUTION

The alternative project executed was an open berth with a reinforced concrete beam slab supported by reinforced concrete piles ∅1000 mm, in a 7.2 m x 6.0 m mesh and built at the intervals between the existing piles, without having the need to extract the old piles and only to demolish the current deck slab, as presented in Figure 4.

The concrete piles were encased in steel pipes and had typical embedment between 5 m and 20 m at "Ponta Vermelha" geological layer with SPT – N > 60 (up to -28.5 m CD). To validate the embedding depth of the piles in the competent ground, were carried out three Bi-directional load tests using Osterberg cells. From the results obtained in the strain gauges placed along the entire length of the piles, it was possible to measure with greater accuracy the lateral friction in each layer of soil and the tip resistance of the pile.

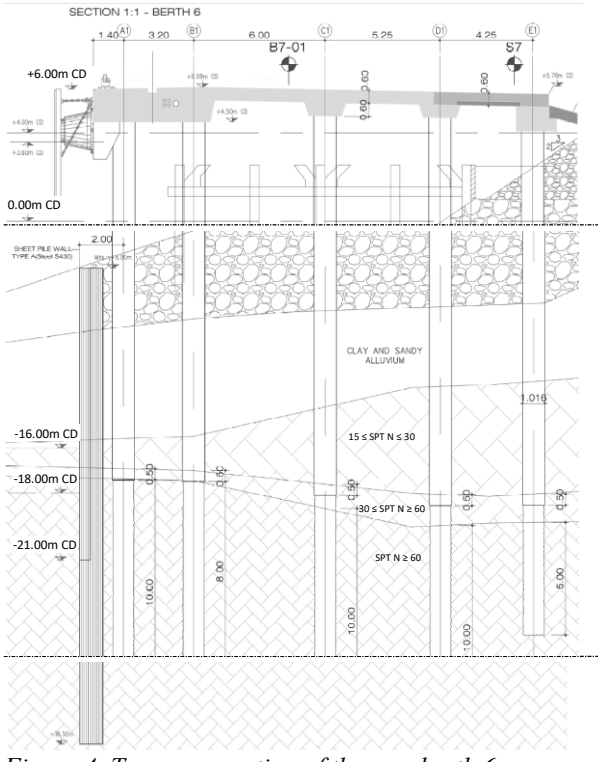

Figure 4. Top cross section of the new berth 6.

Table 1. Synthesis of geotechnical parameters.

Geological layer	Material description	Dry density (kN/m³)	Static Young's modulus (MPa)	Φ (º)
Alluvium	Very loose/ very soft sediment	15	< 1 – 7	< 32
Ponta Vermelha SPT – N < 30	Loose to medium dense zones	14 – 16	5 – 20	< 32
Ponta Vermelha SPT – N > 60	Dense to very dense	14 – 16	50 – 100	28 – 41

These tests allowed a significant reduction in the embedment length of the piles in the Ponta Vermelha layer, by less than 40%.

To increase the depth of the berth to -16.0 m (CD), a self-supporting submerged combiwall was installed, with a variable cantilever between 6 and 10 m, to guarantee the stability of the existing embankment, which would later be dredged.

The type of sheet piles applied varied according to the inclination of the existing natural ground, being the largest in berth 6 (area with a steeper slope and greater height) and decreasing towards berth 7. For the most unfavourable situation, the principal elements were 2xHZ1180M weighing 23.5 t and 28.5 m long, that were driven up to -36.5 m (CD), with 18.5 m driven into very dense soil, of the "Ponta Vermelha" layer SPT – N > 60. This solution was designed for a design life of 100 years and allows future dredging of the service area to -18.0 m (CD).

5 CONSTRUCTIVE ASPECTS

To complete the project, 871 units of reinforced concrete piles were executed, totalling 30,678 ml, and to hold the submerged slopes, 3,050 t of steel profiles and 8,430 ml, were applied over an extension of 544 m long.

The specificity and complexity of the project was fundamentally due to the current condition of the existing deck and the difficulty of the works taking place in a live terminal, with the consequent need to find solutions that could reduce maritime and road traffic, and thus minimize interference in the port's operations.

5.1 Execution of reinforced concrete foundation piles

For the construction stage of the piling works, the cantitravel methodology was adopted, which allows the work to progress independently of maritime conditions, avoiding the mobilization of both floating equipment and heavy equipment for driving piles, which were not available in the region, and without stepping in water also means less impact on the environment and port traffic. The sliding platform worked in two ways: laid on the recently new deck, executed in longitudinal bands using a deck sliding formwork; and supported by the recently executed piles, as shown on Figure 5.

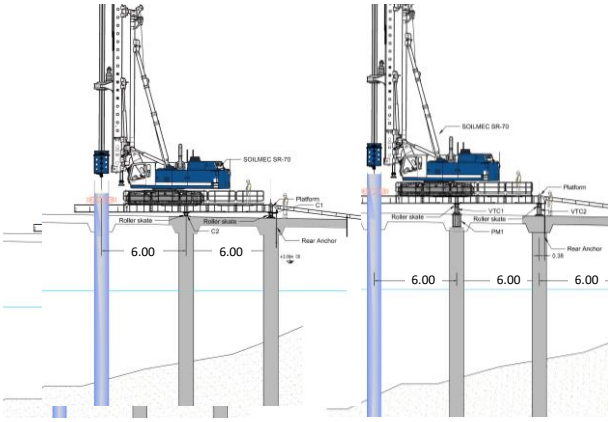

Figure 5. Sliding cantitravel for execution of piles.

The steel pipes were driven up to the SPT layer – N > 60 using a vibrofonceur, and then cleaned on the inside using a Kelly bar, without the need of any methodology to stabilize the drilled hole, given the ability to self-support for a period.

5.2 Execution of the submerged combiwall

The installation of the combiwall proved to be a very complex activity due to the geological environment that is very unfavourable for driving (granular soils with SPT – N > 60), the considerable penetration lengths in very dense soils, the size of the wall, and also the fact that it is submerged, and it is not possible to see the actual work on the surface.

With this scenario, auxiliary techniques had to be used to facilitate the installation, given that the energy developed by the hammers was not enough to fully drive the profiles, with refusal occurring before accomplishing the project levels. On the other hand, for smaller profiles, there was a tendency for the profile to be destroyed at its head, firstly by the energy of the vibrohammer and then of the impact hammer.

Figure 6. Water jetting and impact hammer activities.

To be able to drive the profiles up to the final project levels, pre-drilling was used before installing the principal elements, and water jetting with a similar method to jet grouting (JET 2 system), as per Figure 6, with the injection of air and water at high pressure to break the cohesion of the soil in the extent where the profiles were installed.

The water jet loosens the soil, reducing the resistance to penetration of the pile tip during driving. Under some soil conditions, water flowing along the pile acts as a lubricant and can also reduce surface friction. The jetting allowed sheet piles to be successfully driven into the dense ground.

The pressure applied was 260 bars (3 nozzles) during drilling until the end of the driving level, and 380 Bar (2 nozzles) during cut and upward movement, as illustrated in Figure 7.

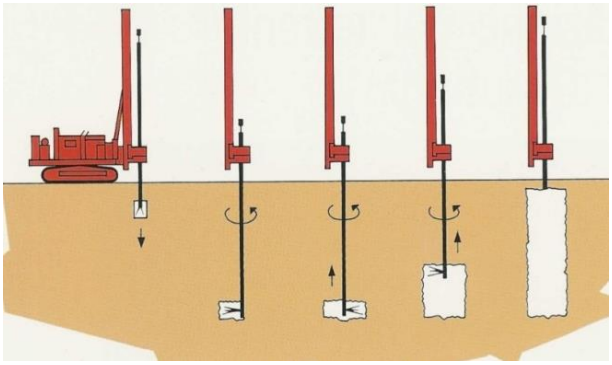

Figure 7. Sequence of the water jetting works.

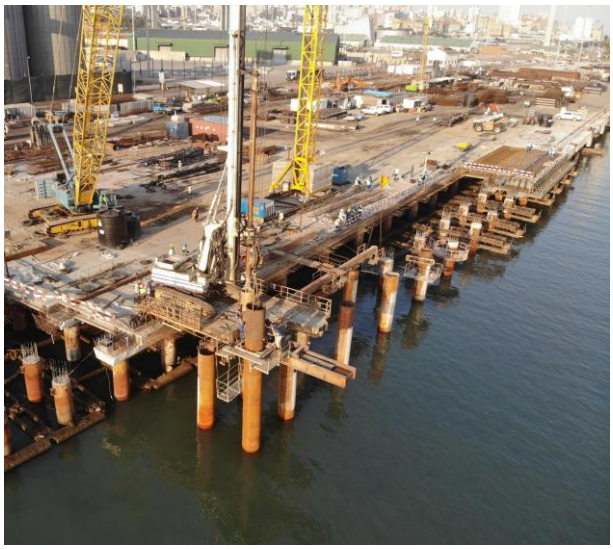

Figure 8. Execution of piles with cantitravel.

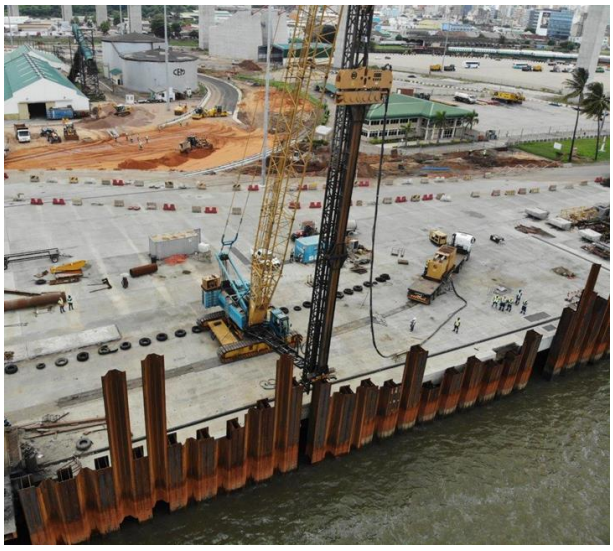

Figure 9. Execution of the submerged combiwall.

Given the very limited space available for driving the profiles, 18 m followers were attached to the driving equipment, an APE300-6 vibrating hammer and a D100-13 impact hammer, that allowed the driving to be done next to the new quay edge and underwater.

The threaded displacement piling system technical and economical efficiency leading to sustainable foundations solutions

L'efficacité technique et économique du système de pieux vissés conduisant à des solutions de fondations durables

L. Sata*, S. Manea
Technical University of Civil Engineering, Bucharest, Romania
**sata@sbr.ro*

ABSTRACT: The search of the economic and sustainable alternatives to lower the costs and to reduce the carbon footprint of the foundations by the diversification of the piling technologies is a continuous task for the special foundation industry. Even though the displacement piles usually have increased bearing capacities compared with the bored piles, their execution is associated with vibration, dynamic and phonic pollution of the local environment. One of the recent economical deep foundation solutions is the threaded displacement piling system, the "screw" concept. The pile identified by two diameters (core / threads) is successfully applied in the range 330/500 to 530/700mm not only in Great Britain, France, but also in Central – East Europe in Romania, Poland, Hungary, recent successes being registered as well in South Africa. The technique is fully covered in Europe by the standard EN 12699:2015 adopted in Romania as SR EN 12699:2015. The paper present by means of more than 250 simple and instrumented loading tests the technological details, the constructional principles and the choosing of dimensions, the application possibilities, the design approaches according to Eurocode 7 as well as to the Romanian Pile design norm NP123, and finally the ecological impact analysis and sustainability evaluation of the Screwsol threaded displacement piling system.

RÉSUMÉ: La recherche d'alternatives économiques et durables pour diminuer les coûts et réduire l'empreinte carbone des fondations par la diversification des technologies de pieux est une tâche continue pour l'industrie des fondations spéciales. Même si les pieux à refoulement latéral du sol ont généralement des capacités portantes accrues par rapport aux pieux forés, leur exécution est associée à des vibrations, à une pollution dynamique et phonique de l'environnement local. L'une des solutions économiques récentes pour les fondations profondes est le système de pieux vissés, le concept de « vis ». Le pieu identifié par deux diamètres (noyau/filetage) est appliqué avec succès dans la gamme 330/500 entre 530/700mm non seulement en Grande-Bretagne, en France, mais aussi en Europe Centrale et de l'Est en Roumanie, en Pologne, en Hongrie, des succès récents étant également enregistrés en Afrique du Sud. La technique est entièrement couverte en Europe par la norme EN 12699:2015 adoptée en Roumanie sous le nom de SR EN 12699:2015. A l'aide de plus de 250 tests de chargement simples et instrumentés, l'article présente les détails technologiques, les principes de construction et le choix des dimensions, les possibilités d'application, les approches de conception selon l'Eurocode 7 ainsi que selon la norme roumaine NP123, et enfin l'analyse d'impact environnementale et l'évaluation de la durabilité du système de pieux vissés Screwsol.

Keywords: Displacement piles; screw piles; design approach; sustainability.

1 INTRODUCTION

One of the recent optimal soil displacement drilling solutions is given by the rotary displacement piling system, the Screwsol concept, defined as follows:

Pile in which the pile or pile tube comprises a limited number of helices at its toe, and which is installed under the combined action of a torque and a vertical thrust. By the screwing-in and/or by the screwing-out, the ground is essentially laterally displaced, and no soil is removed. The technology is covered by the standard ASRO SR EN 12699:2004.

The article presents a list of simple and instrumented loading tests for several load types; technological details, design approaches; constructional principles and the choosing of dimensions; application possibilities; the ecological impact analysis and evaluation of the Screwsol rotary displacement piling system (Sata, 2005, Kaltenbacher et al., 2008).

The pile identified by two diameters (core / threads) is applied in the range 330/500 to 530/700mm (Figure 1) (Sata and Manea, 2012).

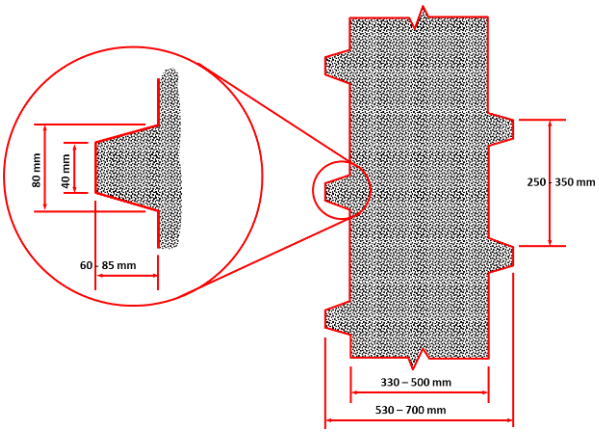

Figure 1. Screwsol pile longitudinal section and thread details.

2 ALIZEU WIND FARM TEST / 2013

The test pile was a Screwsol pile with a diameter of d=330/500 mm (meaning 330 mm cylinder diameter and 500 mm external diameter) and a toe depth of H = 20.95 m from ground level (actual pile length of L = 20.60 m), reinforced on its entire length, to provide support for the strain gages and to protect the pile head from local crushing at high loads. Four reaction piles were used for the load test, executed with the same technology.

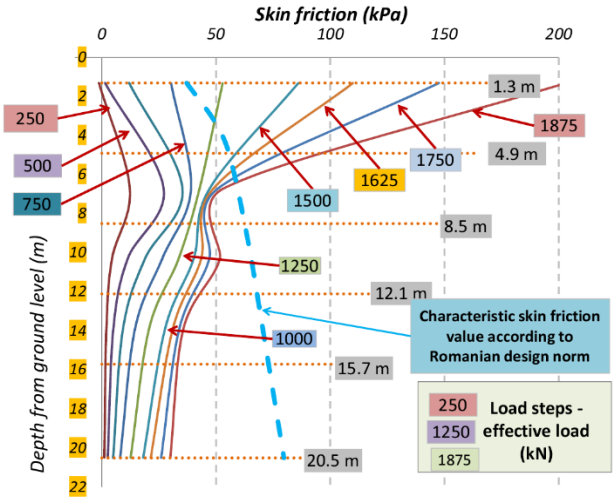

Figure 2. Skin friction diagram.

The static load test was carried out in equal steps of 125 kN, until failure. Application of a load increment was conditioned by stabilization of settlements for the previous step. Additionally, the pile was equipped with 17 extensometers and during the load test the deformation of the concrete was monitored with a frequency of 1 reading / minute.

Pile failure occurred at the 16th load step (2000 kN), most likely by crushing of the pile head due to eccentrical application of the load. This observation is supported by the load-settlement diagrams of the four individual sensors that measured the settlement of the pile, located at the four corners of the pile.

Strain gauge measurements were processed in several steps to determine the detailed pile behaviour, and to confirm or contradict the preliminary conclusions based on the classical load test results.

In case of the Screwsol pile, the most important uncertainty is the choice of the cross-sectional area A (which automatically influences the lateral surface considered in the calculation of skin friction – Figure 2). Also, the displacement of the soil needs to be taken into consideration when computing pile forces and skin frictions. A third uncertainty is the elastic modulus of the combined concrete-steel pile, which can be safely evaluated for design purposes.

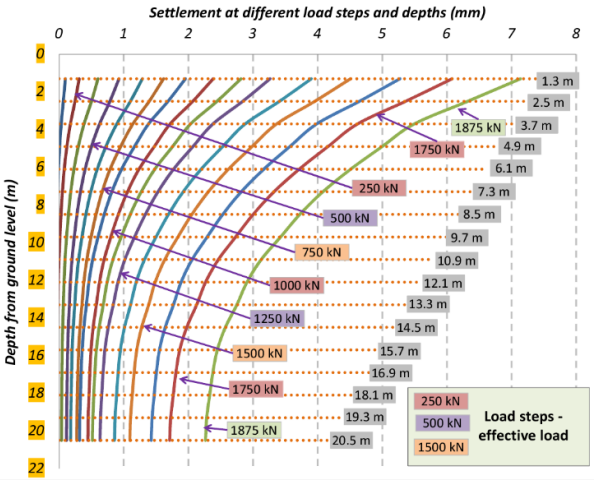

Figure 3. Settlement diagrams.

The results presented (Figure 3) consistently reveal the pile's tendency to consume most of the loads in the upper half of its length. In case of efficiently designed non-displacement piles it is expected that most of the loads are transferred through the lower part of the shaft (skin friction) and by tip resistance. Skin frictions in the upper few meters reach values of 200 kPa and more, compared to a maximum of 80 kPa given by the design norm.

However, in this case there are factors that suggest a different behaviour. Due to the presence of the threads, combined with the displacement of the soil, larger shear stresses may develop in the upper part of the shaft. Equally importantly, the soil is homogenous, even at the pile toe level, while in most design scenarios the soil layers towards the pile toe are significantly stiffer.

3 LIDL LOGISTIC CENTER CRAIOVA / 2021

The CPT-based design of the foundations was performed according to EC7:

$$R_{c;k} = \left(R_{b;k} + R_{s;k}\right) = \frac{R_{b;cal} + R_{s;cal}}{\xi} = \frac{R_{c;cal}}{\xi} = \text{Min}\left\{\frac{\left(R_{c;cal}\right)_{med}}{\xi_3}; \frac{\left(R_{c;cal}\right)_{min}}{\xi_4}\right\} \quad (1)$$

Based on the calculations few of the determined pile lengths were the following:

D330/500 – 950kN – L=16.05m

D330/500 – 1100kN – L=17.25m

D430/600 – 1450kN – L=16.55m

Five preliminary, instrumented load tests were executed on area A2. The instrumentation consists of strain gauges and base plates. The strain gauges were placed on the reinforcement cage at a vertical spacing of 1.5 m, with 3 gauges per each level being installed to achieve more precise results (Figure 4) and to confer redundancy in case some gauges would be damaged during pile installation. The base plates were installed on the bottom of the reinforcement cages, practically at pile toe level.

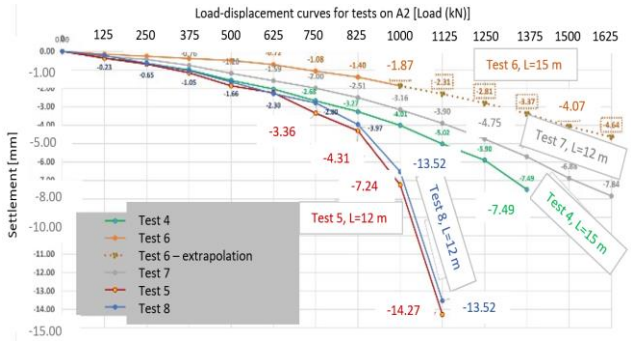

Figure 4. Load-settlement curves for all tests (5 piles).

It is noted that all 5 test piles exhibited a load-displacement pattern which is characteristic for friction piles, represented by a considerable quasi-elastic domain until 875 kN to 1625 kN, which represents 17.5% up to 32.5% of the representative diameter, considered as 50 mm, given that most of the load (and practically all service load) is carried by the shaft. These values are also very close or even exceed the structural capacity of the pile, which can be approximated as Aint x fc,d = 0.085 m2 x 16.7 MPa = 1425 kN.

However, it is noted that all other tests exhibited an extremely favourable pile behaviour. In case of two tests (test 4 and 7) the cracking of the pile head occurred after 1375 to 1625 kN, which are sufficiently large values of ultimate capacity to allow for an efficient pile design after division with partial safety factors. In case of test 6, for which pile head cracking occurred after 1000 kN, an extrapolation was performed, given the large pile length and the extremely small pile displacements (<2 mm) up to this point, to avoid unnecessary overdesign.

The distribution of the skin friction and toe resistance is presented in Figure 5, using a first approach in which the skin friction was calculated while the toe resistance was determined by subtracting the total skin friction from the load step applied during testing.

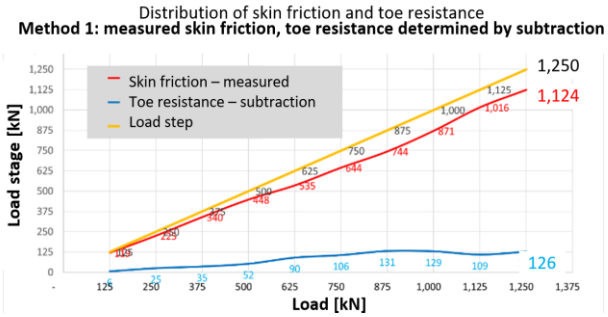

Figure 5. Distribution of skin friction and toe resistance – method 1, test 4.

The diagram shows that the pile shaft carries the largest part of the loads, approximately 90% and practically constant during the load steps.

4 DESIGN OF SCREWSOL PILES

4.1 Design based on CPT results (SR EN 1997-2: Annex D, D.7)

The maximum base resistance can be derived as:

$$p_{max;base} = 0{,}5\ \alpha_p\ \beta\ s\left(\frac{q_{c;I;mean} + q_{c;II;mean}}{2} + q_{c;III;mean}\right) \quad (2)$$

The maximum shaft resistance can be derived as:

$$p_{max;shaft;z} = \alpha_s \times q_{c;z;a} \quad (3)$$

Based on more than 250 load test evaluations, values proposed for α_p and α_s are presented in Table 1.

Table 1. Proposed values for α_p and α_s.

Soil type	q_c	α_p	α_s
non cohesive	for min values as per EC7	0.9 - 1.0	0.004 - 0.007
	for medium values	0.6 - 0.7	
cohesive	for min values as per EC7	0.8	0.020 - 0.028
	for medium values	0.5	

4.2 Design according to NP123:2022

$$R_{c,d} = \frac{A_b \cdot q_{b,k}}{\gamma_{b,2}} + \frac{U \sum(q_{s,k_i} \cdot l_i)}{\gamma_{s,2}} - G \qquad (4)$$

where $q_{b,k}$ is the base resistance and $q_{s,ki}$ the shaft resistance.

For the shaft resistance a correlation factor, k_x, is introduced with the values:

1.0 – cohesive soils

0.4 - 0.6 – non cohesive soils

The safety coefficients related to the shaft and base resistance of the Screwsol threaded piles:

$\gamma_{s,i,2}$ = 1.9 (cohesive) / 1.2 (non-cohesive)

$\gamma_{n,k}$ = 1.2 (cohesive / non-cohesive)

5 ANALYSIS AND EVALUATION OF THE CO2 FOOTPRINT OF SCREWSOL

The use of materials (concrete, steel) is responsible for approximately 95% of total CO2 emissions generated by construction activity.

For the example, it was considered a project with 500 piles with a length of 10.0 m, in two versions: executed with CFA technology and diameter of 600mm, respectively Screwsol technology and diameter 430/600, their bearing capacities being considered to be similar.

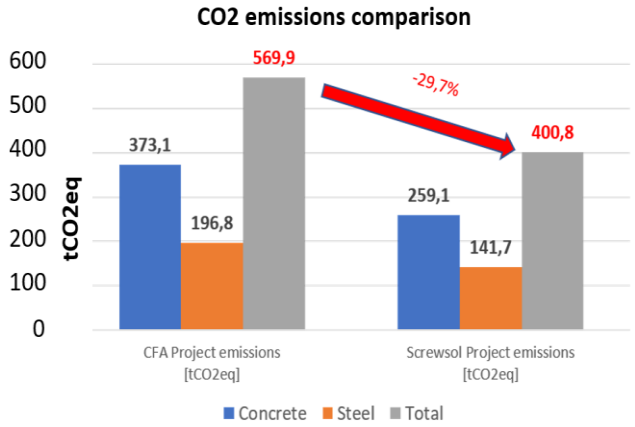

Figure 6. CO2 emissions for CFA and Screwsol.

The solution with CFA technology and a diameter of 600mm is responsible for a carbon footprint approximately 30% higher than the Screwsol piles of diameter 430/600.

6 CONCLUSIONS

The applicability of Screwsol has been successfully proven both in non-cohesive soils, but also in medium stiff and plastic clay conditions. The execution length of the piles is limited by the characteristics of the in situ soil and the refusal criteria of the soil – drilling torq combination.

The maximum efficiency of the piles is obtained for non-cohesive soil conditionsterrain – fine and medium – in loose or medium density. In the case of cohesive soils, the efficiency is high plastic clays. Due to the fact that the dynamic effects produced during execution are reduced through the execution technology, they can also be used to treat soils with liquefaction potential. The presence and level of the groundwater has neither negative influence to the execution technology nor to the efficiency of the piles.

ABSTRACT: This paper presents a novel large-scale test setup at TU Darmstadt to investigate the behaviour of basal reinforced piled embankments. The study focuses on the impact of welded steel mesh reinforcement. The study addresses key questions related to soil arching, deformations, strain distribution in the embankment and the steel mesh grid. The large-scale test setup, 25 m^2, at a 1:1.6 scale, includes 16 piles, a dry medium coarse river sand fill, a steel mesh reinforcement and a two-step system to model the soft soil compaction. State-of-the-art Distributed Fibre Optic Sensing (DFOS) technology enabled precise monitoring of soil and reinforcement strain and 3D deformation. Results indicate that the reinforcement stiffness minimally affects soil arching, matching the Concentric Arches (CA) model (van Eekelen et al., 2013, 2015) that was developed for geosynthetic reinforced piled embankments (GRPS). The deformation pattern and strain distribution in the steel differ from GRPS, illustrating the need for a specific load-deflection model. The measured critical height matches the prediction of Topolnicki and Kłosiński et al. (2022). The study contributes to understanding the complex interaction between steel reinforcement and soft soil in piled embankments, guiding future design considerations.

RÉSUMÉ: Cet article présente un nouveau dispositif d'essai à grande échelle à l'Université Technique de Darmstadt pour étudier le comportement des remblais sur pieux renforcés par une nappe de treillis soudés. L'étude se concentre sur l'impact de l'armature en treillis soudé sur les mécanismes de transferts de charge. L'étude aborde des questions clés liées à l'effet d'arche du sol, aux tassements et à la distribution des déformations dans le remblai et dans le treillis soudé. L'installation d'essai à grande échelle, 25 m^2, à l'échelle 1:1,6, comprend 16 pieux, un remblai de sable fluviatile moyennement grossier sec, un renforcement en treillis soudé et un système double pour modéliser le tassement du sol meuble. La technologie de pointe de la détection par fibre optique répartie (DFOS) a permis un contrôle précis du tassement du sol et du treillis soudé ainsi qu'une visualisation de la déformation en 3D. Les résultats indiquent que la rigidité du renforcement affecte peu la formation d'arches dans le sol, ce qui correspond au modèle d'arches concentriques (van Eekelen et al., 2013, 2015) qui a été développé pour les remblais sur pieux renforcés par des géosynthétiques (GRPS). La déformation et la distribution des contraintes dans l'acier sont différentes de ceux du GRPS, illustrant la nécessité d'un modèle charge-déformation spécifique. La hauteur critique de remblai mesurée correspond à la prédiction de Topolnicki et Kłosiński et al. (2022). L'étude contribue à la compréhension de l'interaction complexe entre le treillis soudé et le sol mou dans les remblais sur pieux, guidant les considérations de dimensionnement futurs.

Keywords: Piled embankments; steel basal reinforcement; large-scale physical modelling; distributed fibre optic sensing.

1 INTRODUCTION

Reinforced piled embankments with a geosynthetic reinforcement (GR) are commonly built in soft soil areas (van Eekelen and Han, 2020). Replacing GR for steel reinforcement (SR) is particularly appealing to reduce deformations caused by high embankments (Topolnicki et al., 2019).

This paper presents a large-scale test setup, nearly in full scale, 1:1.6, constructed at TU Darmstadt to allow investigation of piled embankments with basal reinforcement made of steel or geosynthetics. The test setup is part of a broader research initiative called PEBSTER (Piled Embankments with Basal Steel Reinforcement), including small-scale tests (van Eekelen et al., 2024) to investigate the following:

1. Does the soil arching in a piled embankment differ if SR is used instead of GR?
2. Are deformations different with SR instead of GR?
3. What is the influence of flexible vs. rigid piles?
4. Do the answers to these questions depend on the scale of model tests?
5. Can the current design methods for piled embankments using GR be applied for SR or do they require a modification?

2 LOAD DISTRIBUTION

Soil arching develops when soil between piles deforms more than the piles, resulting in a non-uniform load distribution. A significant portion of the vertical load (labelled as 'A' in Figure 1) is directly transferred to the piles. The residual load, 'B+C' in Figure 1, is supported by the subsurface between the piles.

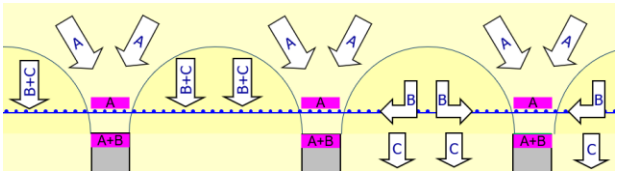

Figure 1. Load distribution in a PS embankment.

Several design guidelines and standards, such as BS8006 (2010), EBGEO (2011), ASIRI (2013), CUR226 (2016), and Topolnicki and Kłosiński et al. (2022), provide equations to divide the total vertical load into A and B+C. These guidelines then offer methods for calculating the strain in the reinforcement from the acting load B+C, considering the load-deflection behaviour of the reinforcement.

Many researchers have investigated the influence of geometry and material properties on soil arching. Van Eekelen et al. (2012) showed that the soil arching quickly develops, even when the deflection of the GR is minimal. In line with this finding, they showed that the GR tensile stiffness has a limited impact on soil arching, while the shear properties of the fill (internal friction angle) play a significant role. These conclusions were valid for GR. An important question of the PESBTER project is, whether the high axial and bending stiffness of the SR affects the soil arching in the fill.

3 LARGE-SCALE TEST SETUP

Figure 2 depicts the test setup designed to model piled embankments with a steel basal reinforcement. The model embankment represents a prototype embankment of 4.7 m height above the pile head.

This test setup was constructed within a part of the geotechnical test pit at the Institute of Geotechnics of TU Darmstadt. It occupies a base area of 5 by 5 m and has a total height of 5.5 m. The test setup includes 16 piles passing through the layer of soft soil model.
The embankment fill was modelled using dry medium coarse river sand ('Darmstadt Sand'). The soil model was installed by means of air pluviation achieving a mean density of 1.735 g/cm³, equivalent to 92 % relative density, and $\varphi'_{cv} = 34.8^{o}$.

The choice of a model embankment height of H = 2.9 m was determined by geometric scaling, in line with typical dimensions found in real piled embankments. This decision also took into consideration to safely surpass the critical height estimate of 1.52 m according to Topolnicki and Kłosiński et al. (2022), where the critical height represents the minimum vertical distance above the pile heads to reach a plane of uniform settlement above and between the supports. Concentrating soil pressure, strain and deformation measurements in the range between piles and critical height allows a thorough analysis of soil arching behaviour in the embankment.

3.1 Piles

The 16 piles are modelled using hollow S235 steel tubes with an outer diameters d = 244.5 mm and a wall thickness of t = 6.3 mm.

To better recreate the surface roughness found in concrete piles, the very smooth surface of the steel tubes was altered. The pile skin in contact with the sand layer above the soft soil model was covered with epoxy resin and poured sand. The pile skin below was not modified but kept smooth.

Previous experiments usually neglected pile settlements by using rigid supports. Natural load-bearing layers are stiff, but usually not rigid. To investigate the effect of flexible supports on the soil arching and load distribution behaviour the pile bases were equipped with springs with a stiffness of 5 MN/m (Figure 2). The LVDT transducer in the centre measures pile settlement and allows to derive the pile base force using spring calibration.

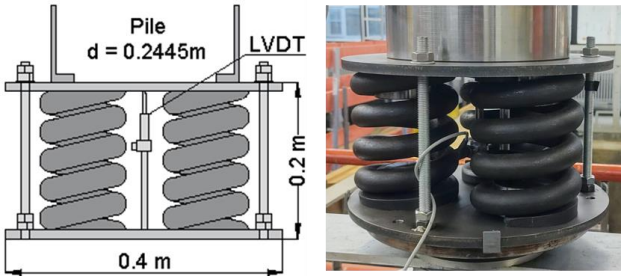

Figure 2. Three springs below each pile base, modelling a system with flexible supports.

Vertical loads acting on pile heads and pile settlements at the pile base were measured on 10 out of 16 piles to capture the behaviour of centre, edge and corner piles (Figure 2). Specially constructed pile heads, accommodating a standard load cell, allowed to measure the resulting vertical pile load directly.

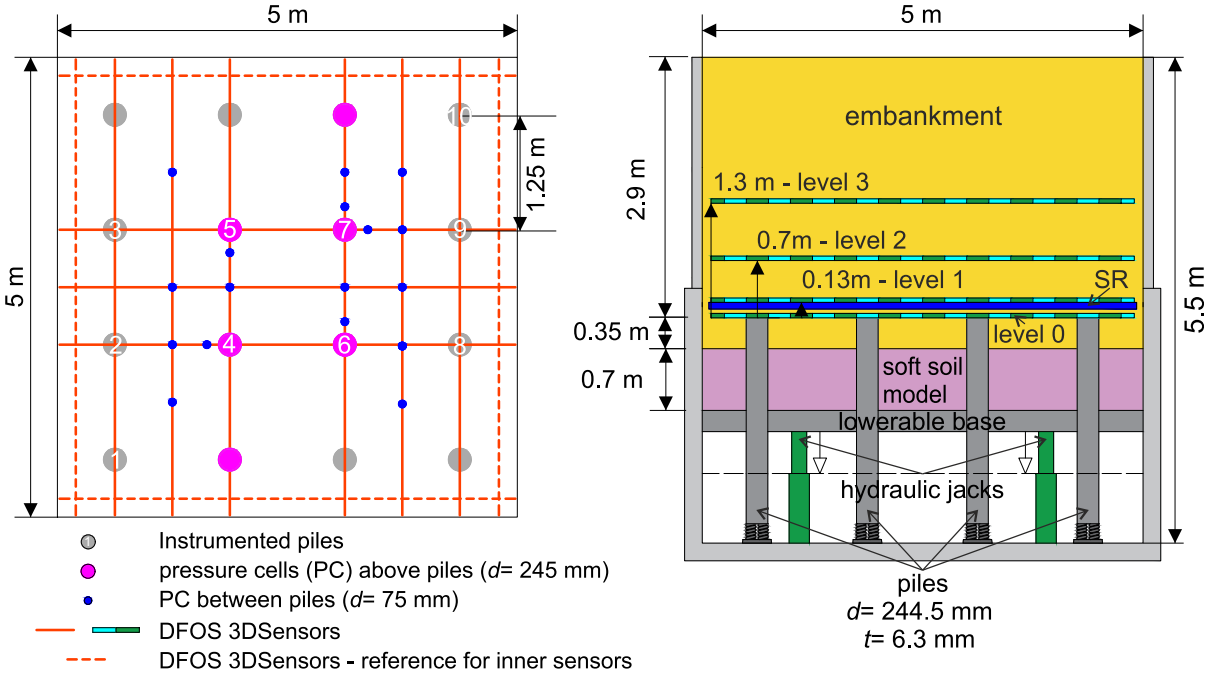

Figure 3. Large-scale test setup for basal reinforced piled embankments.

3.2 Soft soil model

The soft soil below the embankment was modelled using crumb rubber with grains of 1.5 to 5 mm in diameter. The rubber layer thickness was 0.7 m, with an average density of 0.48 g/cm³. To investigate the one-dimensional compressibility of the rubber, a special oedometer test was carried out using a specimen 285 mm in diameter and 50 mm in height and with a comparable initial density. The data presented in Figure 4 illustrate that crumb rubber tends to creep after each loading step.

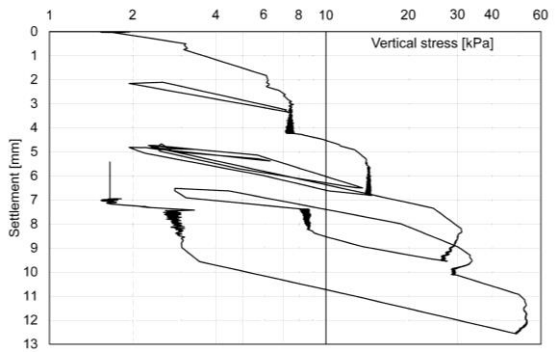

Figure 4. Large oedometer test of crumb rubber.

Also, after unloading steps there is a noticeable rebound of deformation under a stable load. Further analyses of the crumb rubber behaviour will therefore be required.

Due to consolidation and creep of soft soils, the subsoil reaction C can disappear over time. To model this situation, the rubber layer was placed on a stiff base supported by four hydraulic jacks. At the end of the test, the base plate was lowered incrementally 220 mm in total, creating a partial void below the steel mesh.

3.3 Steel mesh reinforcement

The basal steel mesh reinforcement consists of 8 mm ribbed bars (S235 steel), welded with a c/c spacing of 100×100 mm. The resulting tensile and bending stiffnesses of the mesh are EA = 105558 kN/m and EI = 0.2577 kN·m²/m, respectively.

In practice, steel meshes are produced in sheets and are connected on site using overlapping across and steel hooks along the embankment. The model arrangement consists of three sheets S1 to S3 (Figure 5). Sheet S1, with a size of 2.5×5 m, is connected with hooks to two smaller meshes S2 and S3, while S2 and S3 are connected by overlapping. In total, 49 hooks were used, and 16 of them were equipped with strain gauges to measure strain and study the interactions between the separate sheets.

3.4 Instrumentation

The development of soil arching begins near the pile heads when the soil in between piles starts to settle more than the piles themselves. To study this, the majority of the sensors were placed close to the pile heads and above or surrounding the piles. In total, 52 carefully selected sensors were used to measure forces, pressures and displacements in the system to allow an insight into the load distribution pattern as well as total loads at the system boundaries. Table 1 lists the mentioned sensors.

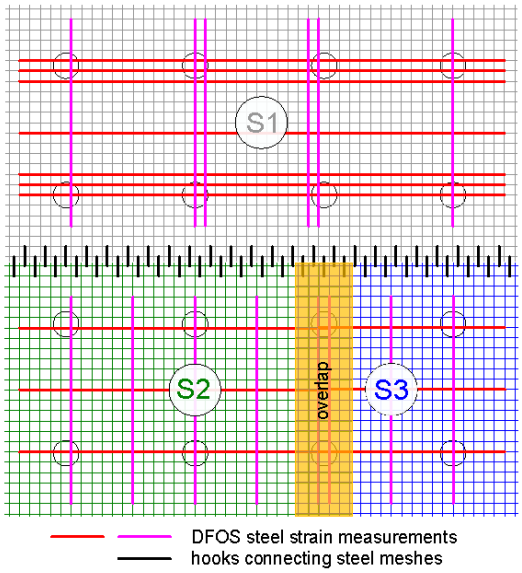

Figure 5. The arrangement of steel sheets S1, S2 and S3 in the test setup, and the location of the overlap and hooks.

Table 1. Measurement equipment for loads, pressures and vertical displacements.

Sensor Type	Quantity	Location [level]
Force	10	Pile head [0]
Pressure	6	Above pile locations [1]
Pressure	18	Distributed on SR between piles [0, 1]
Total load	4	Below model base frame
Displacement	10	Pile base
Displacement	4	Model base frame

Table 2. Measurement equipment for soil and reinforcement strains and displacements.

Sensor Type	Quantity	Location [level]
Strain in steel bars	8	DFOS steel strain, glued to the bars [1]
DFOS EpsilonSensor	2	DFOS soil strain [1]
DFOS 3DSensor	40	All levels [0-4]
Reference displ. DFOS	16	Outer test setup walls

Table 2 gives an overview of the sensors used to capture strains and deformation in the system, either by conventional strain gauges or by distributed fibre optical sensors (DFOS) from the Nerve-Sensor family.

In total, 40 DFOS 3DSensors were used to capture soil and steel deformation at four different levels (Figure 2). Each 3DSensor consists of four strain fibres that measure strains along the sensors' length and allow calculation of deformations in three directions. However, the results shown in this paper solely consider vertical displacements due to the mainly vertical nature of deformation of the system.

The 3DSensors were installed in a grid to measure deformations and strains above and between the piles. Figure 2 (left) shows the DFOS grid at level 1. The DFOS sensors at level 2 were identical, while levels 0 and 3 had a reduced number of sensors.

Furthermore, eight optic fibres were glued to the steel mesh to capture steel strains, and two DFOS EpsilonSensors were installed to measure soil strains.

The level 1 DFOS 3DSensors were placed directly on the SR, effectively measuring the deflection of the steel bars. Levels 2 and 3 were located at chosen elevations to study soil deformations inside the embankment in the middle and close to the upper boundary of the expected soil arching.

4 RESULTS

4.1 Load distribution

Figure 6 compares the measured load part that was transferred to the piles via soil arching (load part A) during embankment construction with values calculated using established analytical models, developed for geosynthetic reinforcement. They do not consider reinforcement bending stiffness as an input parameter. Nevertheless, the measured values match the calculations reasonably well.

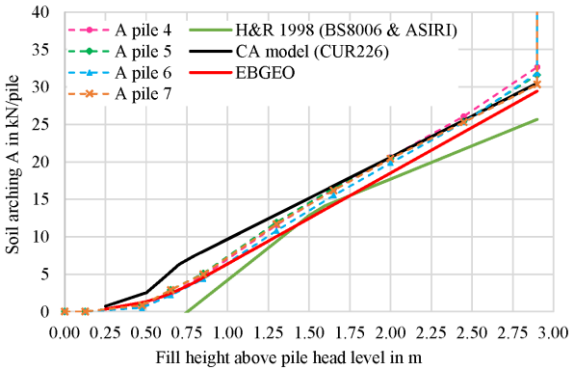

Figure 6. Load part A measured in the test and calculated with analytical models during embankment construction.

This analysis together with the findings of van Eekelen et al., 2024 supports the statement that the reinforcement stiffness does not have a significant impact on the load distribution pattern in the system (arching). Since the test only displays one combination of reinforcement stiffness and soil friction angle, further investigations are needed to experimentally confirm this conclusion.

4.2 Observed deformation pattern

Figure 7 a shows the measured vertical deformations at level 1, just above the steel. The graph includes two perpendicular directions over the whole model width, at the moment the full embankment height had just been achieved (test stage T2). In all unit cells, the deformation pattern is rather similar, validating the expected model performance and confirming the high quality of the applied monitoring system. Each of the following plots in Figure 7 shows data solely for the unit cell comprising the four inner piles.

Figures 7 b and 7 d show the absolute vertical deformation of the steel mesh at level 1 and levels 2 and 3, respectively, observed during three stages of the test, including the lowering of the model base frame (T3). To facilitate a direct and consistent comparison of these measurements, obtained at different locations and levels, the data have been normalized with respect to 'base lines'. These base lines connect the peaks in the deformed steel grid, above the (relatively rigid) piles. The measured deformations were normalised with respect to these base lines, and the normalised results are plotted in Figures 7 c and 7 e. They illustrate a more or less symmetrical deformation pattern at all levels and increasing deformation during successive stages of the test. Soil arching is caused by the differential deformation of the steel mesh above and between piles (Figure 7 c). Differential deflections of the steel bars running through the centre between the piles start to develop already during early embankment construction with average field centre deflections of 15.6 mm for 1.05 m high embankment. With progressing embankment height and the subsequent reduction of subsoil support, the differential deflections increase significantly, up to 32.4 mm in-between piles.

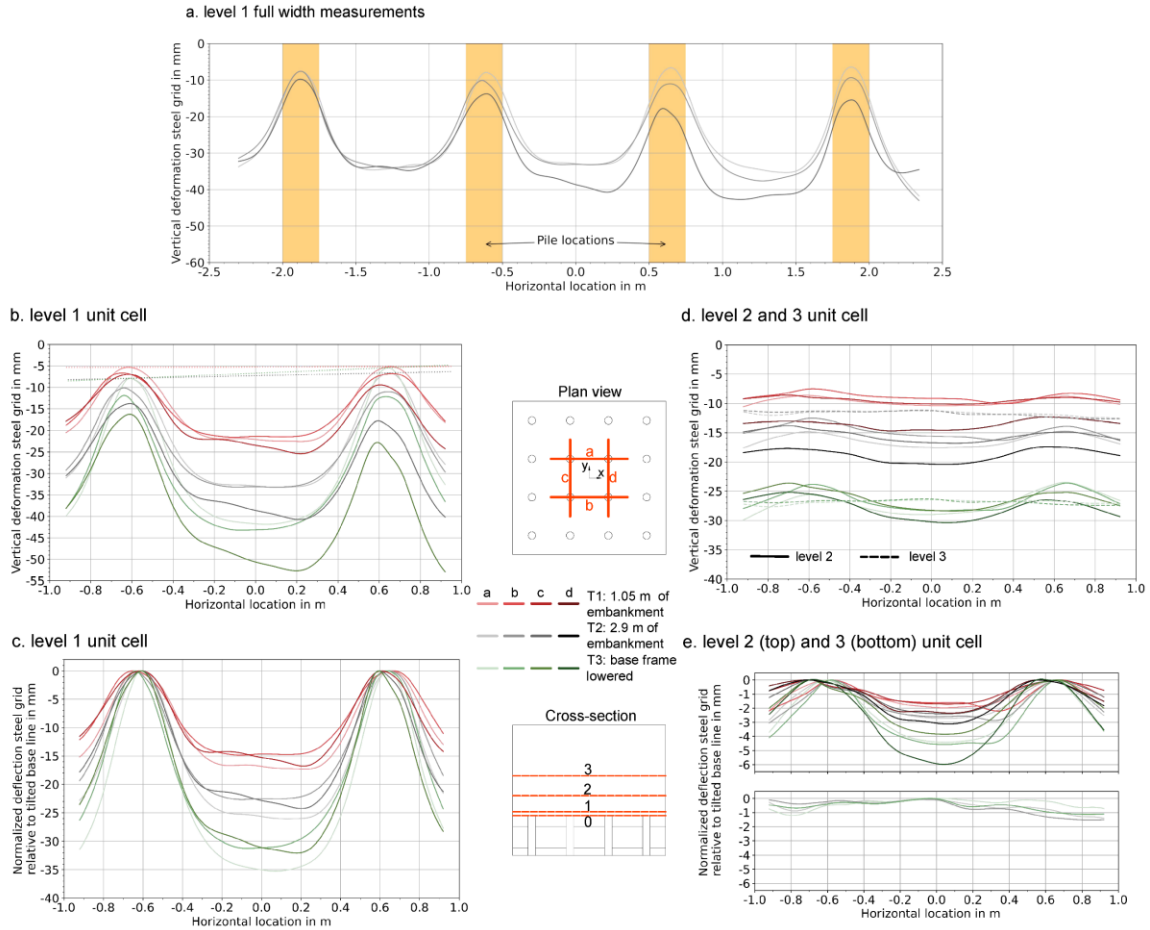

Figure 7. Measured vertical displacements of the steel mesh during and after embankment construction and after the removal of the subsoil support. a. full width, unaltered measurements above piles at stage T2. B. and d. Measured deflections of levels 1, 2 and 3 at stages T1, T2 and T3, along lines a, b, c, d and tilted base lines (b for level 1, and d for levels 2 and 3). c. and e. as b and d, but presented relative to the tilted base lines.

When comparing deformations in levels 2 and 3 (Figures 7 d and 7 e), a significant decrease of absolute and differential settlement is visible, indicating that the plane of equal settlement (critical embankment height) is located slightly above level 3, which is in line with the prediction of Topolnicki and Kłosiński et al. (2022).

5 CONCLUSIONS

This paper presents a large-scale model test on steel-reinforced piled embankments. This is part of a larger research, that also includes a series of small-scale tests and numerical analyses. Based on the test results presented in this paper, we draw the following preliminary conclusions.

- The reinforcement tensile and bending stiffness do not significantly affect the soil arching. This is supported by the test data of the stiff SR matching analytical calculations for load A for GR and the observations made by van Eekelen et al. (2024).
- Three main European design methods for GRPS embankments closely align with the measured soil arching, with the CA model exhibiting the best match.
- The high spatial resolution of DFOS sensors allows a unique look into the soil model and a thorough comparison of measured deformations and strains with calculated values.
- The steel reinforcement shows significant differential deflection and steel strain in the bars that bridge adjacent piles. This is in line with the deformation pattern observed in geosynthetic-reinforced piled embankments.
- The strain distributions in steel reinforcement differ from geosynthetic reinforcement. The main calculation models for geosynthetics assume zero reinforcement strain above the piles, assuming that the geosynthetic is clamped between soil and pile cap. The steel reinforcement in this test shows strains both in between and above the piles.

ABSTRACT: The pile inspector allows to measure the geometrical enlargement of pile bases during the construction phase. Either connected to the kelly bar or attached to the service crane, the pile inspector is lowered into the drilled hole and measures the geometrical profile at the pile base, using 4 prestressed arms. Once the pile inspector is lifted out of the drilled hole, the installed reader transfers the gained data to the computer of the site engineer. The installed visualisation programme allows to visualise the results within a short period of time and displays the shape of the base of enlarged pile and the profile of the pile shaft.

RÉSUMÉ: L'inspecteur de pieux permet de mesurer l'élargissement géométrique des bases de pieux pendant la phase de construction. Connecté à la tige kelly ou à la grue de service, l'inspecteur de pieux est descendu dans le forage et mesure le profil géométrique de la base du pieu à l'aide de 4 bras précontraints. Une fois que l'inspecteur de pieux est sorti du forage, le lecteur intégré transfère les données acquises à l'ordinateur de l'ingénieur sur site. Le programme de visualisation installé permet de visualiser les résultats en peu de temps et affiche la forme à la base et le profil du pieu.

Keywords: Bored pile; base enlargement; increased load capacity; shaft profile; pile inspector.

1 INTRODUCTION

Pile base enlargement allows to increase the design load for bored piles. Areas of application for base enlarged piles are the transfer of high individual and surface construction loads into the ground.

The enlarged bored pile contact area enables an adjustment to the actual pile load and can therefore enable a significantly more favourable pile layout considering the internal pile load capacity. It may therefore be possible to replace a group of piles with a base enlargement and thus save pile concrete. The increased pile contact area also leads to reduced pile shaft diameters at lower drilling depths.

The technical developments in recent years like post-grouting or deep soil mixing have pushed pile base enlargement into the background. Another reason why the design of a bored pile with base enlargement is not often used is the increased additional effort involved in checking the actual geometry of the enlarged pile base.

With the help of the new construction of the pile inspector, the geometry of the base expansion can now be measured and evaluated during the production of the bored pile.

2 GEOTECHNICAL REQUIREMENTS

According to EA-Pfähle 2012 [Chapter 2.2.1.6], base enlargement can only be created in sufficiently stable soil. In unstable soils or if the expansion area is below the groundwater level, the base expansion must be secured with the help of a bentonite or cement suspension.

The geometry is limited and depends on the stability of the ground conditions. For non-cohesive soils or cohesive soils, limit values for the ratio of foot height to foot projection are set in accordance with EA-Pfähle [Chapter 5.5]. The ratio values are:

- In cohesive soils 2:1;
- In non-cohesive soils 3:1.

The extent of expansion is determined based on the soil encountered and the boundary criteria according to the static requirements.

The pile design postulates a complete filling of flawless concrete into the enlarged pile base.

2.1 Construction of the pile base enlargement

The type of bored pile depends on the existing soil and the groundwater conditions. Various drilling methods can therefore be used to produce the borehole. These include kelly bar drilling, auger drilling, displacement drilling, either with water or bentonite slurry support.

Depending on the encountered soil conditions, the borehole must be supported with casings or with partial casings. After completing the drill hole, the reaming tool is connected to the kelly bar. (see Figure 1).

Figure 1. Pile base cutter in operation.

After reaching the designed depth, the cutting arms of the pile toe cutter are extended by pressing vertically with the kelly bar. The removed drilling material is collected in the drilling bucket. In EA-Pfähle 2012 [Chapter 2.2.1.6] the geometry of the pile base produced is described as a truncated cone with a dome-shaped base and a lower cylindrical extension.

2.2 Evidence of pile base enlargement

There are several technical options available for verifying the enlargement of the pile base, which are usually carried out in combination.

Verification methods when producing the pile base expansion are:

- Climb measurement control The contact angle of the measuring arms, which are evenly distributed at a 90-degree angle across the cross section, is measured (see Figure 3). The arms are preloaded via springs and are released by a predetermined signal.
- Ultra-sonic profile reading
- Geotechnical confirmation
- Depth adjustment
- Concrete volume balancing

After the construction of the pile, the following methods are possible:

- Temperature distribution along the pile axis
- Pile load tests

When comparing the concrete volume in relation to the rise of concrete level, a first conclusion of the geometry of the pile base can be drawn, however no remediations or corrections are possible. The actual shape of the pile is unknown until the pile has been concreted.

A new approach to verify the geometry of the pile base is provided by the pile inspector which can verify the generated geometry of the pile base via the hydrostatic pressure recording and the angle measurement of the measuring arms. The following chapter goes into more detail about the manufacturing process and the use of the pile inspector.

3 PILE INSPECTOR

The pile inspector is a newly developed measuring concept that mechanically records the borehole wall and records its depth. The pile inspector is comparable to a drilling tool. After reaching the final depth, it is coupled to the kelly bar of the rotary drilling rig via the kelly box and lowered to the embedment horizon (see Figure 2).

The measurement data is saved in the pile inspector. The measuring run takes place from bottom to top. Both the cased and uncased part of the hole as well as a possible foot extension can be accommodated. The measurement accuracy is so precise that the transition from the uncased to the cased bore can be recorded. There is no coupling of the pile inspector with the data acquisition of the rotary drilling rig. The depth measurement required for later evaluation takes place in the pile inspector, which registers the depth using hydrostatic pressure sensors.

After the end of the measuring cycle, the pile inspector is pulled out of the borehole and the data transfer from the built-in measuring box to the project engineer's notebook takes place immediately using bluetooth technology.

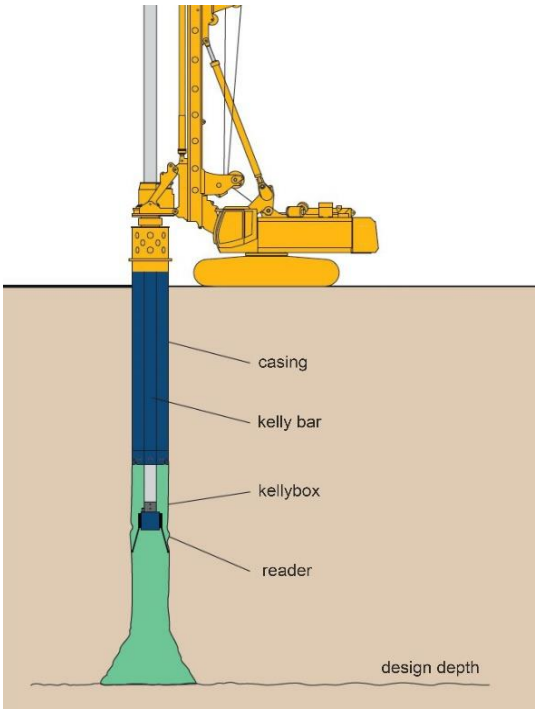

Figure 2. Use of the pile inspector.

In practical terms, this means that the pile inspector is placed at the bottom and remains there for a period of approximately 2 minutes. The associated constant pressure triggers the pre-stressed joints and the arms are pressed against the wall (see Figure 3) with spring force. The joints are electrically connected to the data logger and are transferred to the central unit. The angle that the arms make to the wall is the relevant measurement that is recorded to capture the distance to the wall of the hole. The angle detection is linked to the self-sufficient depth measurement, so that the measured angle is always depth-related. Contact with the wall occurs via rollers, runners or contact strips.

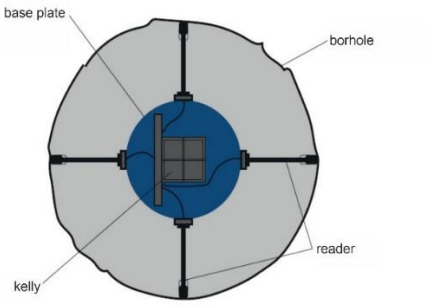

Figure 3. Arrangement of the measuring arms.

After the pile has been expanded by the pile base cutter, the pile inspector is lowered into the depth and the arms are triggered to unfold. The lowering of the pile inspector is not necessarily linked to the kelly bar of a rotary drilling rig, but can also be done using a service crane. With the exception of the upward pulling force, no forces have to act for the measuring process. What is important is the change in angle that has formed in the transition area between the expansion and the shaft profile.

This means that the essential parameter for the pile base expansion can be measured. In fact, the pile inspector records three pile sections, namely the opening angle of the pile base expansion, the contour of the uncased pile shaft and the cased part. The transition to the cased part will be discretely measurable.

The specific dimensions for the pile inspector have been implemented in steel construction drawings (see Figure 4). The control connection to the drilling rig is made via the kelly box. The data logger with the battery unit to power the sensors is located centrally. A total of 4 arms can be connected. The length of the arms can be adjusted on site. The main frame of the pile inspector is a steel structure. The attachments are aluminum components. The entire construction is transported on a carrier pallet. The energy is supplied by batteries that are charged before use. The duration of the energy charge allows operation of 8 hours. The construction has been designed for drilling operations using appropriate spacers and protective profiles.

The geometric details of the pile inspector and the measuring distances can be found in Figure 4 below. The construction is designed so that the pile inspector fits into a casing with a diameter of 900 mm. With a maximum arm length of approx. 115 cm, an expansion of up to 218 cm can be recorded. The support structure below is designed so that sedimentation residues can be driven through. This mechanical form of scanning offers the advantage that the measurement recording is independent of the slurry properties and the measurement can therefore be carried out either before desanding or after desanding.

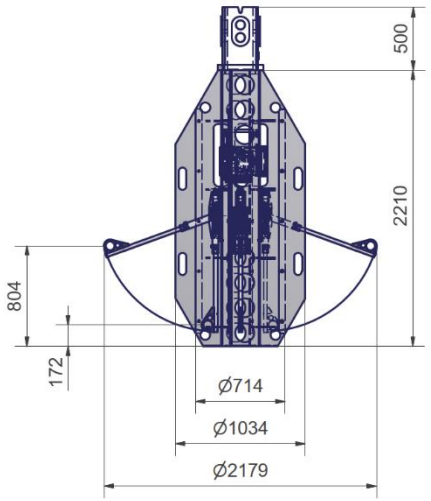

Figure 4. Technical dimensions of the pile inspector.

3.1 Data transmission and visualization of the measurement data

The measurement data is recorded in the pile inspector and stored in the data logger. The construction site name, pile number, index of the measurement trip and the target depth of the drilling can be entered in advance. The measuring journey takes place from bottom to top.

The time, depth and angle of the measuring arms are recorded as measured variables. The measuring depth is recorded by a hydrostatic sensor that records the hydrostatic suspension pressure. This continuous measurement data recording is coupled to the angles of the arms at predetermined time intervals, which allows to determine the distance to the wall. This continuous data recording creates a continuous profile of the pile wall.

The start of data recording is set so that when the hydrostatic pressure stays constant for a defined period, the arms are unlocked and come into contact with the wall as a result of the pre-stressed arms. The measurement accuracy is very high. When the pile inspector is lifted out of the borehole, the data is transferred to the project engineer's notebook in already prepared graphics so that the relevant dimensions of the borehole contour can be read, right after the reading cycle. The measured distances are displayed individually for each arm. This graphical preparation of the measurement trip immediately afterwards allows a short-term decision to be made as to whether the trip needs to be repeated.

4 GEOLOGY AND GROUNDWATER

Figure 5 shows the results of the site investigation and the possible position of the bored pile with the base expansion. The position of the pile is designed in relation to the geological profile and the pile length is determined based on this profile. It can also be seen from the drilling results that the pile base lays below the groundwater level and therefore stabilization with a supporting fluid is necessary during production.

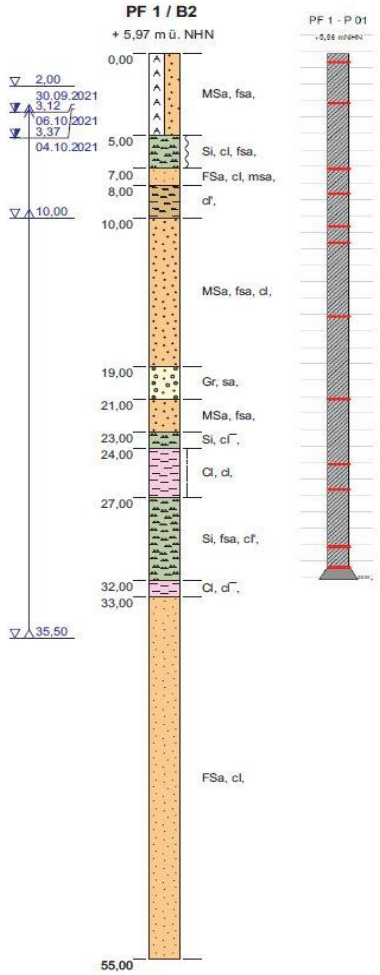

Figure 5. Idealized drilling including position of the bored pile with base expansion.

5 CONSTRUCTION PROCESS

The following chapter introduces the construction process for cutting the pile base expansion. Once the designed borehole depth has been reached, the drilling tool is changed and the pile base cutter is mounted on the kelly bar of the drill rig. On the planned depth of the pile, the cutting blades extend via the vertical force of the kelly and thus create the rotationally symmetrical pile base. Following the expansion, the pile cutter is removed from the borehole again. A detailed manufacturing sequence is shown in Figure 6 and 7.

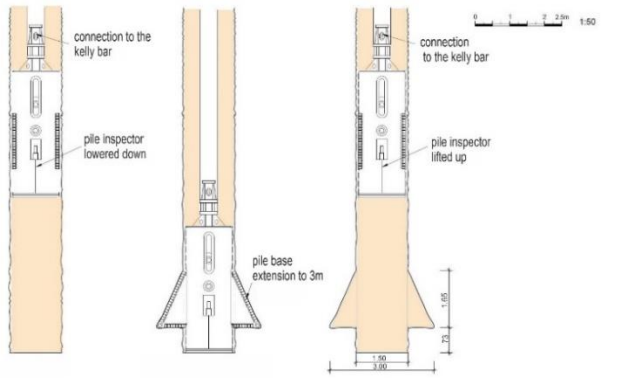

Figure 6. Expanding the pile base.

After the expansion has been completed, the pile inspector will be connected to the drilling rig's kelly bar or a service crane and guided into the borehole. After reaching the target position, the measuring arms of the pile inspector fold out and record the geometry of the pile base that has actually been produced (see Figure 7).

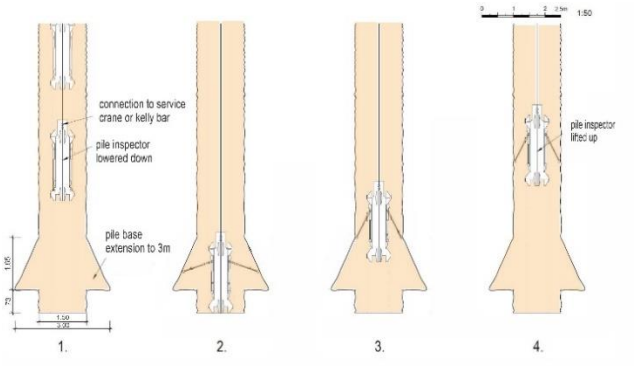

Figure 7. Measuring the pile base with the pile inspector.

Due to the high measurement accuracy, deviations in the geometry can be identified during the installation process and corrected before the reinforcement cage is installed. It may be necessary to repeat the cutting and measuring process.

6 SITE APPLICATION

The field application offered the possibility to check the pile inspector in two operational ways, the kelly bar mounted (see Figure 8) and the crane mounted operation (Figure 9). Since the drilling rig is essential for the overall progress on site, the crane application proved to provide significant time advantages. Once the final depth is reached and the pile base cut, the rig moves to the next drilling location, while the profile of the base expansion is scaled by the pile inspector.

Figure 8. Kelly mounted pile inspector.

7 INTERPRETATION OF THE READINGS

The readings are taken at pre-determined depth and show the distance to the casing and to the cut profile at the pile base. A hydrostatic pressure meter in the pile inspector is calibrated on the actual drilling depth and allows to define reading levels at constant distances. The addition of opposite reading arms confirms the internal diameter of the casing.

At the level where the casing ends, an increase in pile diameter is recorded. All four arms prove this changeover at the same depth. The soil at this transition zone has been flushed out during the piling works with the drilling bucket.

The enlargement in the pile base area reaches over the pile shaft diameter and shows an uniform inclination of the cutting profile in all directions. This profile angle in combination with the construction drawings of the cutting tool enables a confirmation of the cutting width.

Figure 9. Service crane mounted pile inspector.

8 ALTERNATIVE VERIFICATION METHODS FOR THE CONTOUR VERIFICATION OF BORED PILES

8.1 Thermal evidence

Alternatively, the base expansion of a concrete pile can be demonstrated by thermal measurements during hydration.

The sensors are most expediently mounted on the longitudinal reinforcement of the bored piles and read during the setting process. The distribution of the setting heat during the hydration time is recorded and evaluated across both the cross section and the pile length.

An even distribution is evidence of a planned enclosure of the sensors, lower temperatures indicate constrictions, cracks or imperfection of the concrete enclosure.

Obviously, the temperature development in the area of the foot expansion will be significantly higher than the normal range along the pile shaft.

8.2 Ultrasound measurements

The geometry of the wall can also be recorded using ultrasound measurements.

The sensor is positioned over the borehole before the pile is concreted and the ultrasonic transmitter is lowered into the borehole. The measurement results are visualized simultaneously with the measurement.

The ultra-waves run through the suspension and the running time is measured. The diameter can be derived indirectly from this. The purity of the suspension has a decisive influence on the speed of sound transmission.

9 CONCLUSIONS

The results of a pile base reading are displayed in Figure 10.

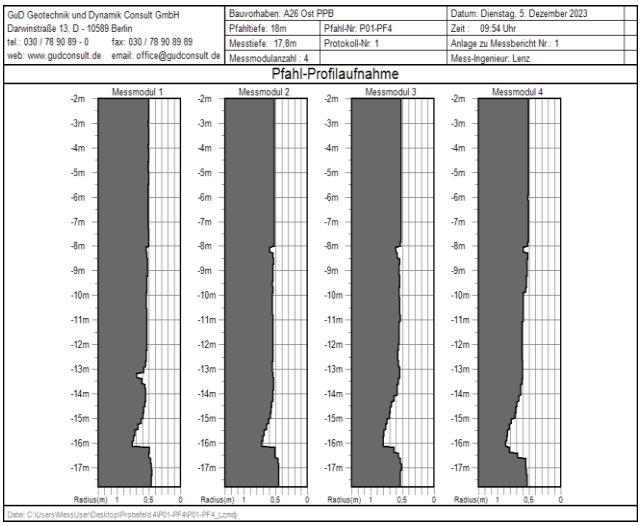

Figure 10. Visualisation of reading results.

The presented pile inspector is a tailored form of evidence for the quality assurance of bored piles. This allows the geometry of pile base expansions and the borehole walls of the piles to be verified.

The kelly-adaptable measuring device allows it to be used effectively before concreting the pile, without significantly intervening in the construction processes. If necessary, the pile inspector can also be operated by a service crane.

The mechanical measuring principle enables high measuring accuracy. By linking the measurement data of the depth and angle of the measuring arms, the results can already be processed in the pile inspector and are available to the project engineer immediately after the measurement trip.

By using the pile inspector, the quality of the base expansion of bored piles can be assured. The associated higher utilization of the load-bearing capacity with reduced material use in the pile shaft and the simultaneous increase in tensile and compressive loads can sustainably improve the economic viability and sustainability of pile foundations.

Highrise building NION with a combined pile-barrette-raft foundation

Immeuble de grand hauteur NION avec fondation mixte radier-pieux-barettes

M. Seip*, S. Fischer, R. Katzenbach
Ingenieursozietät Professor Dr.-Ing. Katzenbach GmbH, Darmstadt, Germany

**seip@katzenbach-ingenieure.de*

ABSTRACT: For the NION project, a highrise building with roughly 100 m height in Frankfurt am Main, Germany, a 4-story basement is planned directly next to a railroad embankment, in the settlement active Frankfurt soils. A diaphragm wall up to 1.2 m thickness is planned as retaining wall with the cut-and-cover method, which will also be the permanent outer basement wall of the final building. Due to the necessity of watertightness, great attention had to be paid to a compatible settlement between foundation slab and diaphragm wall during the design. Due to the near-edge column positions of the high-rise building and the partial load transfer of the high-rise loads into the diaphragm wall, the compatibility of the deformations of the individual diaphragm wall elements had to be investigated numerically. The foundation of the highrise building is planned to be a combined pile-barrette-raft foundation. A variation of the well-known and often used combined pile raft foundation (CPRF) in Frankfurt am Main.

RÉSUMÉ: Un immeuble der grande hauteur d'environ 100 m est prévu à Francfort-sur-le-Main dans le cadre du projet NION. Le site se trouve directement à coté d'un remblai des chemin de fer. Le bâtiment est projeté avec 4 étages du sous-sol et sera fondé dans les sol actifs de Francfort. Le mur de soutènement de la fouille est prévu avec une paroi moulée d'une épaisseur de 1,2 m qui sera également le mur extérieur permanent des sous-sols du bâtiment final. Pour assurer l'étanchéité, une grande attention a été nécessaire à la compatibilité des tassements entre le radier et la paroi moulée dans la phase de conception.Donc, la compatibilité des déformations des différents panneaux de la paroi moulée a dû être étudiée numériquement respectant la position proche des colonnes de l'immeuble de grande hauteur et le transfert partiel des charges du bâtiment dans la paroi moulée. En raison des charges élévées de terre et de pression d'eau, la fouille est planifiée avec une construction de haut en bas.La fondation du bâtiment est prévue avec une composition du radier, des pieux et des barettes. Il s'agit d'une variation des la fondation mixte radier-pieux (CPRF en anglais) bien connue et réalisée souvent à Francfort-sur-le-Main.

Keywords: combined pile-barrette-raft foundation, highrise building, settlement active soils, cut-and-cover, diaphragm wall

1 BUILDING AND LOCATION

The highrise building NION is planned with 26 upper storeys and a 4-storey basement as an office tower (Figure 1).

The site is located in the city centre of Frankfurt am Main, Germany, directly on a railway embank-ment opposite the exhibition centre (Figure 2). The high-rise building is accompanied by a 7-storey base building with one underground garage. Figure 3 shows a cross section through the building NION.

Figure 1. Rendering of the NION highrise building.

The approx. 17,5 m deep excavation pit will be executed as a watertight cut-and-cover construction with a diaphragm wall, which will also be the permanent outer wall of the basement. Due to this planning the foundation slab as even the ceilings are

connected to the retaining wall in order to avoid differential settlements. The excavation base is located around 13.5 m below the groundwater level.

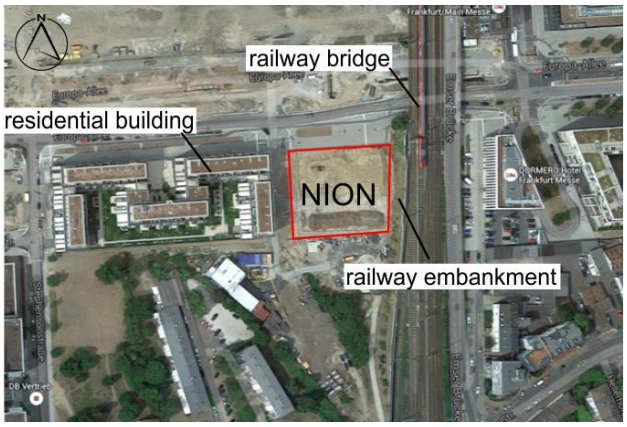

Figure 2. location of the NION highrise building.

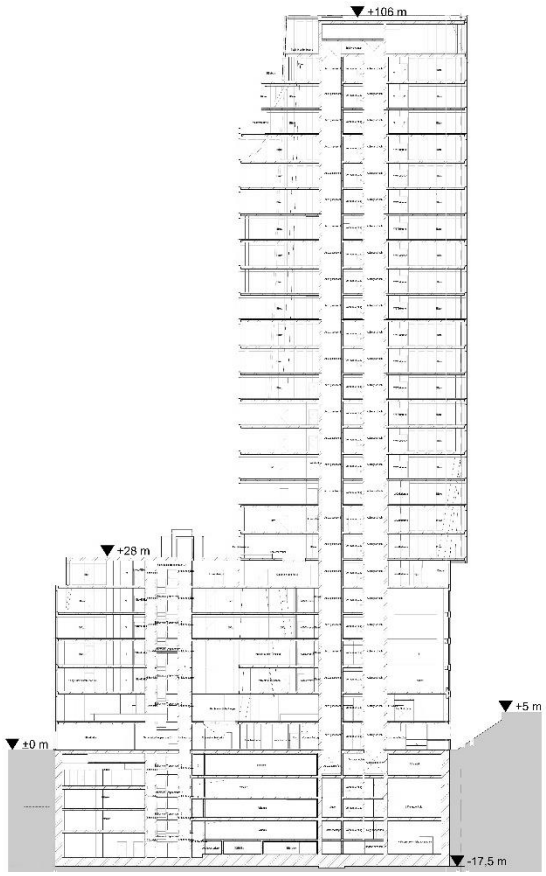

Figure 3. Cross section through the NION highrise building.

2 SOIL AND GROUNDWATER

Due to the 4-storey basement, deep soil investigations up to a depth of 100 m were carried out.

Based on exploration drillings and the soil investigations from adjacent sites the following soil model has been elaborated:

- Layer I : filling
- Layer IIa : quaternary clay
- Layer IIb : quaternary sand and gravel
- Layer III : tertiary sand/gravel/silt
- Layer IV : tertiary “Frankfurt Clay”

Figure 4 shows a simplified cross section through the subsoil of Frankfurt am Main in west (left) to east (right) direction.

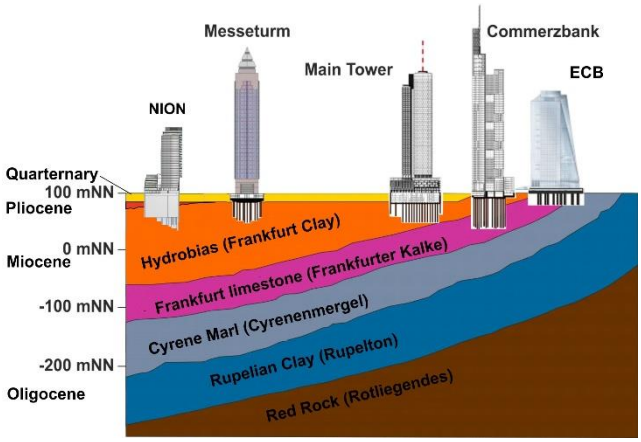

Figure 4. Cross section through the subsoil of Frankfurt am Main (west to east).

The settlement of the building is decisively influenced by the settlement behaviour of the Frankfurt clay. The Frankfurt Clay essentially consists of settlement active clay. In detail the Frankfurt Clay appears as an alternating sequence of clay, limestone banks, hydrobien sand layers and dolomite banks. Figure 5 shows a drill core from the site in a depth of 32 m to 36 m.

Figure 5. Drill core in a depth of 32 m to 36 m.

Regarding this drill core, in a depth of 34.15 m a limestone bank of approx. 0.5 m thickness begins. This limestone banks (and the dolomite banks, too) are fissured and strongly aquiferous.

The groundwater circulates in different (mostly three) partly interconnected groundwater levels in the project area. The free groundwater level is in the quaternary sand and gravel, approx. 4 m below ground elevation.

3 EXCAVATION PIT

The excavation is carried out under the protection of a 1.2 m thick and up to 46 m long diaphragm wall.

The diaphragm wall is planned as a retaining wall with the cut-and-cover method and will also be the permanent outer basement wall of the final building and part of the foundation.

Figure 6 shows a cross section through the basement of the building. The ceilings aren‘t continuous in east-west direction. This so-called split-level construction method means that the ceilings have to transfer horizontal loads into the lateral diaphragm walls.

Due to the high loads, among others caused from the groundwater, the retaining wall is planned with different depths as a dissolved diaphragm wall. One diaphragm wall element is made of three stitches, whereby one stitch (the one in the middle) is shorter than the surrounding ones to create a so called hydraulic window and reduce the water pressure onto the retaining wall. Figure 7 shows the formation of the hydraulic windows.

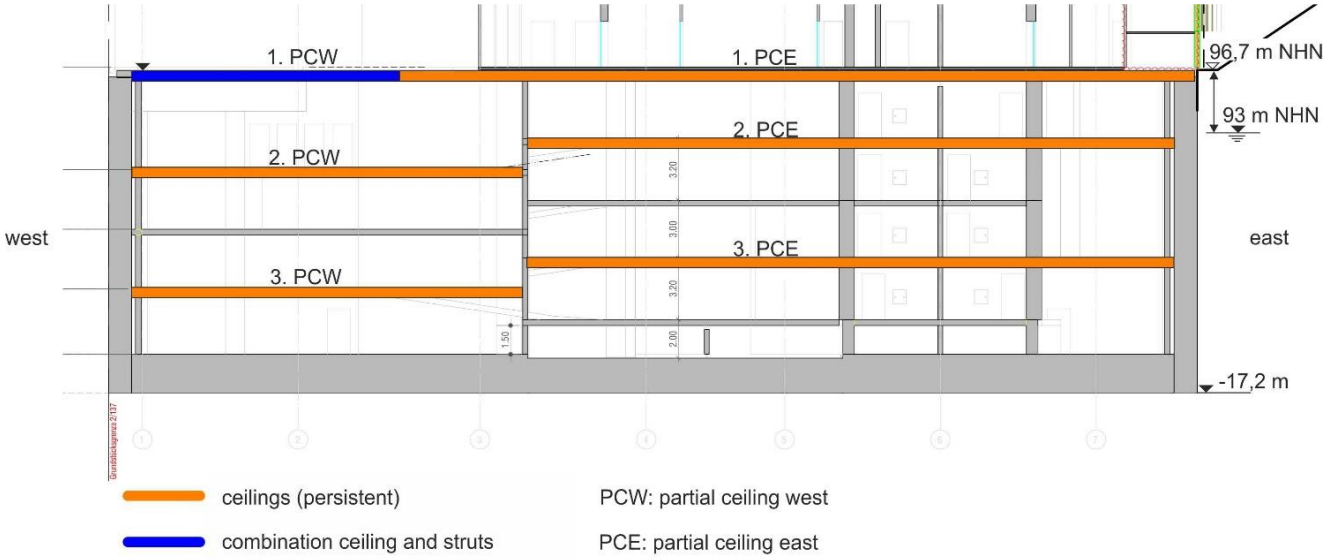

Figure 6. Cross section through the basement of the building.

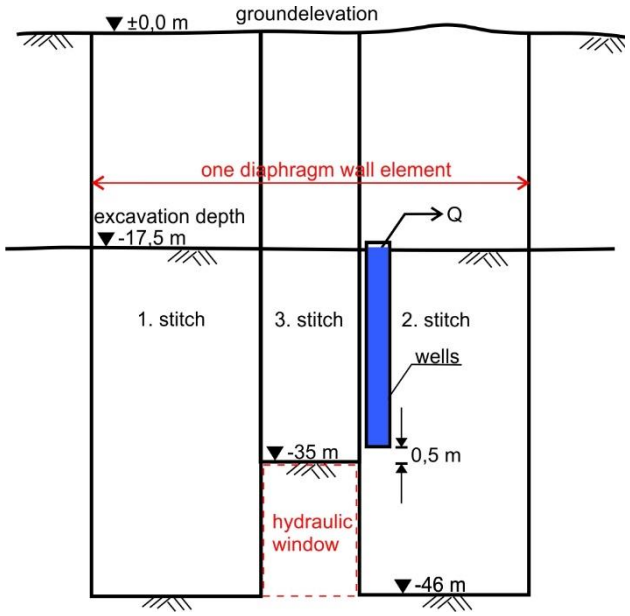

Figure 7. Formation of the hydraulic windows.

Wells are installed to keep the excavation pit dry and to establish safety against hydraulic failure (limestone and dolomite banks), whereby the impermeable Frankfurt Clay is used as a sealing base. Due to the previous usage of the area as a railway freight station these wells have to be shorter than the watertight diaphragm wall in order to avoid the mobilisation of existing contaminations of the groundwater. For this reason the hydraulic windows starts 0.5 m below the lower edge of the wells (Figure 7).

4 DEEP FOUNDATION

The Foundation of the NION consists of a foundation slab with varying thickness (1.3 m and 1.8 m, see Figure), 39 piles with length up to 40 m which will also be used through the construction state for founding the supports of the ceilings, the retaining wall and six diaphragm baretts with lengths up to 44 m (Figure 8).

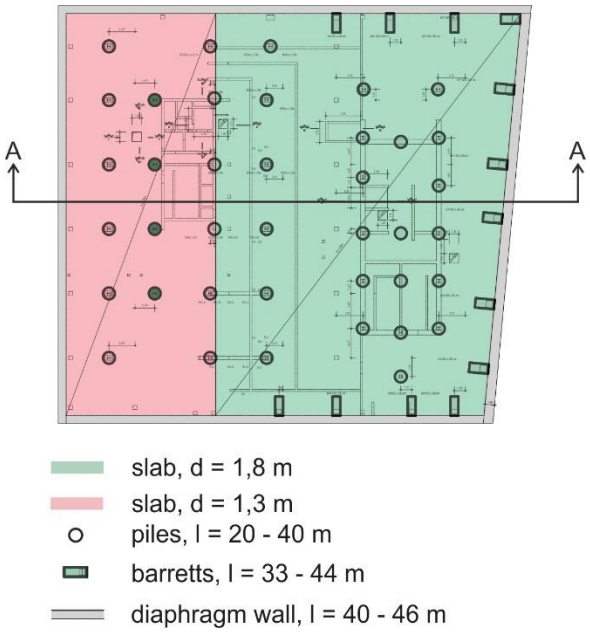

Figure 8. Foundation of the NION.

An overview on the design of piled rafts and its behavior, especially in Frankfurt am Main, is given in Reul (2000). For the prediction of the settlements and especially to proof the acceptable differential settlement between retaining wall (persistent basement wall) and foundation slab, various three dimensional numerical calculations were executed. For consideration the general interaction between the different parts of the foundation, scientific works like Randolph (1994), Katzenbach et al. (1998) etc. were taken into account. For the special conditions in Frankfurt the scientific work of Moormann (2002) were taken into account, too. Figure 9 shows the dimensions of the numerical model.

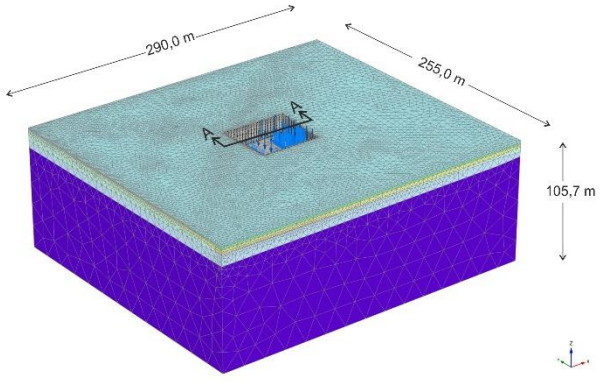

Figure 9. Dimension of the numerical model for the prediction of the settlements.

Figure 10 shows the cross section A-A from Figures 8 and 9 with the soil stratification used in the numerical calculations.

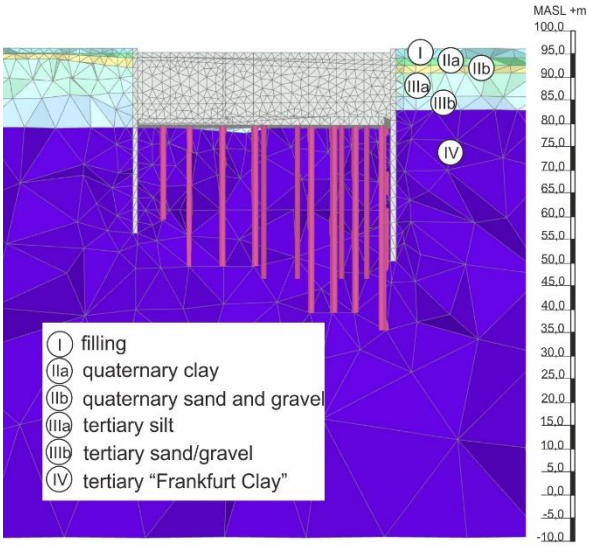

Figure 10. Cross section A-A with soil stratification.

In order to be able to make a statement about the differential deformations of the diaphragm wall elements and thus about the watertightness of the joints, the diaphragm wall had to be modelled in its individual elements. Modelling was done with interface elements between the single diaphragm wall elements and also the foundation slab (Figure 11).

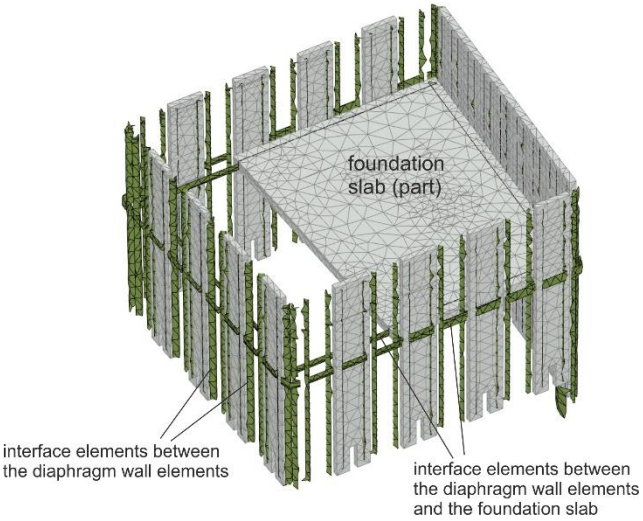

Figure 11. Modelling of the connection between diaphragm wall and foundation slab.

Due to the very robust foundation, no incompatible displacements were calculated either in the area of the joints between the foundation slab and diaphragm wall or in the area of the joints between the individual diaphragm wall elements.

Table 1 shows the loads of the high-rise building NION, where $G_{tot,k}$ are the characteristic dead loads and $Q_{tot,k}$ are the characteristic life loads.

Table 1. loads of the high-rise building NION.

$G_{tot,k}$	920 MN
$Q_{tot,k}$	180 MN
$P_{tot,k} \triangleq R_{tot,k}$	1.100 MN

The bearing behaviour of a CPRF (see Katzenbach and Deepanker 2013) can be specified by the so called CPRF coefficient α_{CPRF}. The coefficient gives the ratio between the resistance of the piles ($\Sigma R_{pile,k,i}$ = 980 MN, including also the resistance of the barretts and the diaphragm wall) and the total resistance of the whole CPRF ($R_{tot,k}$ = 1.100 MN). If the CPRF coefficient becomes 0, the foundation works as a raft-foundation. If the CPRF coefficient becomes 1, the foundation works as a pile-foundation.

$$\alpha_{CPRF} = \frac{\sum R_{pile,k,i}(s)}{R_{tot,k}(s)} = 0{,}89 \qquad (1)$$

Figure 12 shows the prediction of the settlements for the NION building (load case P_{sett}, Eq. 2) which is calculated smaller than 4 cm and also compatible torsions for the foundation slab. A_{mid} is the buoyancy force at mean groundwater level.

$$P_{sett} = G_{tot,k} + \frac{Q_{tot,k}}{3} - A_{mid} \qquad (2)$$

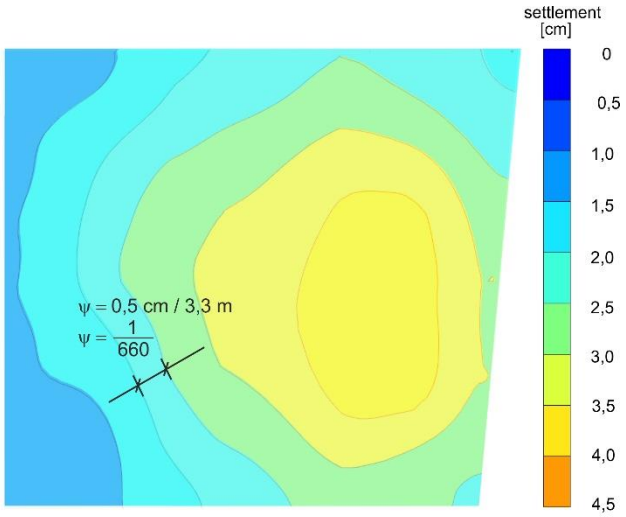

Figure 12. Prediction of the settlements for P_{sett}

5 CONCLUSIONS

For a new highrise building – NION – in Frankfurt, the retaining wall for the 4-storey basement should be used as persistent outer wall for the basement. Due to the high water pressure on the diaphragm wall and very high supporting loads next to the retaining wall, the client was concerned about the watertightness of the later exterior wall.

By means of complex numerical calculations, the deformations between the individual diaphragm wall elements and also between the diaphragm wall and the foundation slab could be predicted. In the numerical simulation, the foundation elements could be adjusted in that way that the differential displacements at the joints were reduced to a level which is suitible for the joint sealings.

Deep excavation solutions in an urban environment - Distrikt residential project, Lisbon

Solutions d´excavation profonde en milieu urbain – Projet résidentiel Distrikt, Lisbonne

J. Silva*, I. Braz, A. Pinto
JETsj – Geotecnia, Lda., Lisbon, Portugal

** jsilva@jetsj.com*

ABSTRACT: This paper describes the main design and execution criteria adopted for the peripheral earth retaining solutions, required for the construction of three underground floors for the Distrikt Residential Buildings, located in the south of Parque das Nações, in Lisbon. The excavation, with 11 m of maximum depth, mainly intersected landfill layers and Lisbon Miocene soils (Areolas do Cabo Ruivo e Areolas do Braço de Prata). The excavation site is confined by several underground infrastructures, which are mostly inside a technical gallery, close to the excavation pit boundaries. It is also noteworthy the proximity to two buildings with several basements, as well as the possibility that the excavation can coexist with the construction of an underground car park, under Rua Mário Botas. To minimize the ground disturbance, as well as the deformations of the mentioned structures, a reinforced concrete bored pile wall with 600mm diameter was defined, braced in general by steel props and temporary ground anchors. In the elevations where the neighbourhood conditions didn't allow the execution of ground anchors, the retaining wall was braced by concrete slab's strips, which were connected to pile buttresses and supported by HEB200 micropiles. The main results of the monitoring plan are drawn and presented, including the analyses and comparison with the estimated values from the design phase.

RÉSUMÉ: Cet article décrit les principaux critères de conception et d'exécution adoptés pour les solutions de retenue périphérique du sol nécessaires à la construction de trois étages souterrains pour les bâtiments résidentiels Distrikt, situés au sud du Parque das Nações, à Lisbonne. L'excavation, d'une profondeur maximale de 11 mètres, a principalement traversé des couches de remblai et des sols miocènes de Lisbonne (Areolas do Cabo Ruivo et Areolas do Braço de Prata). Le site d'excavation est confiné par plusieurs infrastructures souterraines, principalement à l'intérieur d'une galerie technique, à proximité des limites de la fosse d'excavation. Il est également à noter la proximité de deux bâtiments avec plusieurs sous-sols, ainsi que la possibilité que l'excavation puisse coexister avec la construction d'un parking souterrain, sous la rue Mário Botas. Pour minimiser la perturbation du sol, ainsi que les déformations des structures mentionnées, un mur de palplanches en béton armé de 600 mm de diamètre a été défini, renforcé en général par des étais en acier et des ancrages temporaires. Aux endroits où les conditions du quartier ne permettaient pas l'exécution d'ancrages au sol, le mur de soutènement était renforcé par des bandes de dalle en béton, reliées à des contreforts de pieux et supportées par des micropieux HEB200. Les principaux résultats du plan de surveillance sont présentés, y compris les analyses et la comparaison avec les valeurs estimées de la phase de conception.

Keywords: Earth retaining walls; pile walls; slab bands; buttress; temporary ground anchors.

1 INTRODUCTION

The present article describes the solutions adopted for the excavation and peripheral soil containment, necessary for the construction of 3 underground floors of the Distrikt enterprise. The enterprise is located in the southern area of Parque das Nações.

The project envisages the construction of 4 towers with 13 elevated floors and 3 common underground floors, which occupy the total area of the plot and are expected to be used for car parking and technical areas. Figure 1 displays an aerial perspective of the intervention site.

Figure 1. Virtual view of the future residential building´s.

Previous research, such as Carvalho & Pinto, 2019; Tomásio & Pinto, 2019 and Pinto et al., 2017, have developed similar earth-retaining solutions for deep excavations in urban environments, as it will be presented in the following chapters.

2 MAIN CONSTRAINTS

2.1 Geological and geotechnical conditions

To characterize the geotechnical behaviour, associated with the soils present at site, a prospecting campaign was conducted involving the execution of 16 mechanical boreholes accompanied by Standard Penetration Tests (SPT) and the collection of samples for macroscopic classification. Additionally, 5 hydraulic piezometers were installed in some of the boreholes. According to the results obtained, the geological structure of the site is characterized by the presence of Miocene substrates corresponding to Areolas do Cabo Ruivo (M_{CR}) and Areolas do Braço de Prata (M_{BP}), overlaid by modern anthropogenic materials, Landfill Deposits (At), with a thickness ranging from 1.5 m to 7.9 m. The Miocene formations are mainly composed of fine silty sands with carbonate nodules or fossil remains. This units have a considerable thickness, reaching the end of the boreholes. Bio-calcarenite levels (pebble beds) with variable thicknesses ranging from 0.1 m to 2.0 m were also identified.

In the sample collection, it was identified the contamination of the uppermost layers of fossiliferous limestone (pebble beds), revealing the presence of hydrocarbons in 6 of the boreholes conducted, all located on the north of the plot.

In terms of hydrogeology, the Miocene layers function as a multilayer system, consisting of alternating permeable layers (sands, sandstones, and some limestones) with other semi-permeable layers, such as clays and siltstones. Therefore, the higher the percentage of fines (silt and clay), the lower the permeability. On the other hand, bio-calcarenite layers are often highly permeable due to their high porosity and can constitute more productive layers.

2.2 Neighbourhood conditions

The excavation site, bordered by roads, infrastructures, and buried networks, is notably close to the Parque das Nações technical gallery, where diverse service infrastructures are established. The integrity and operability of these infrastructures must be maintained during construction work, thus influenced the design of peripheral earth retainment solutions.

During the project´s development, excavation works could potentially occur simultaneously with the construction of the underground levels of the parking lot to be developed immediately adjacent to the plot. In this context, and for this elevation, it had to be defined interior bracing solutions that did not require occupying neighbouring plots. In the following figure it is possible to observe the main boundaries of the excavation site.

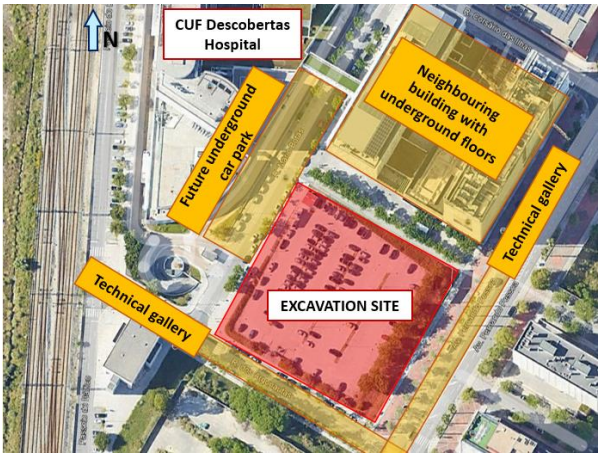

Figure 2. Main boundaries of the excavation site.

3 EXCAVATION AND PERIPHRAL EARTH RETAINING SOLUTIONS

In the design of the adopted peripheral earth retaining solutions, the following fundamental principles were sought to be respected, beyond the necessary horizontal retainment of the excavated grounds:

- Control soil deformations and surrounding structures and infrastructures to the excavation, allowing the adaptation to possible geological and geotechnical singularities;
- Ensure minimal interference with all adjacent structures and infrastructures.

Considering the existence of several conditioning factors, a reinforced concrete bored pile wall with 600 mm diameter piles and spaced 1.20 m, was defined. The bored pile walls were constructed using a telescopic Kelly bar technology, with temporary casing employed only at the top of the terrain to penetrate through the fill layers, when necessary.

During the excavation phase, the exposed soil between bored pile walls was generally protected with sprayed concrete with a minimum thickness of 8 cm, reinforced with metallic fibers, applied in two layers and properly drained through drainage pipes. These devices were served to collect and conduct water to the building's drainage system through vertical drainage pipes installed at the back of the wall and between the bored piles. In the regions where there was a higher probability of increasing locally the permeability

and/or contamination of the soil, it was constructed a permanent reinforced concrete wall with 25 cm thickness, properly integrated to the bored pile walls.

The reinforced concrete bored pile wall was braced, in general, by multiple levels of steel props and pre-stressed ground anchors, to ensure the horizontal balance of the provisional earth retaining structures.

To ensure a better distribution of the forces along the curtain wall, as well as to prevent the excessive concentration of loads, the temporary ground anchors and steel props were connected to distribution concrete beams and crown beams. In the definitive phase, the stability of the curtain wall is provided by concrete slab strips, which will integrate the definitive concrete slabs of the underground floors, and the temporary ground anchors and steel props are deactivated after the completion of the definitive structure.

In elevations where the presence of neighbouring infrastructures or structures constrained the execution of ground anchors, a bracing system was defined, consisting in reinforced concrete slab bands, which function has horizontal beams (with the section of the future underground floors). The slab bands offer high stiffness to the earth retaining wall, resisting and transmitting the impulses acting on the curtain wall directly to the buttresses, which were also formed by bored piles. Considering the excavation depth, bracings were implemented at levels -1 and -2, with the initial excavation section carried out under a curtain wall that will be functioning as a cantilever. The design of the structural elements considered not only the necessary strength and stiffness to ensure safety and proper functionality but also the construction process associated with both the excavation and the execution of the underground floors. Figure 3 and 4 shows 2 plan views of the peripheral earth retaining structures and the respective shoring elements at each underground floor level.

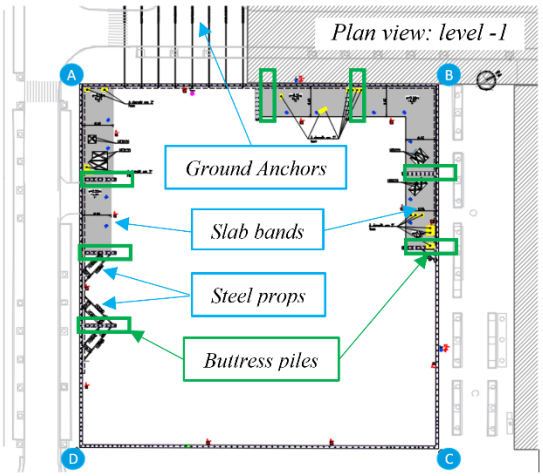

Figure 3. Design plan view of the peripheral earth retaining solution at level -1.

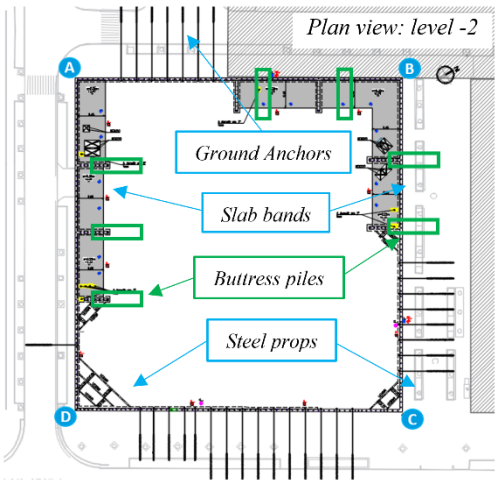

Figure 4. Design plan view of the peripheral earth retaining solution at level -2.

The ground anchors comprised 6 and 7 strands, each with a diameter of 0.6 inches, spaced at intervals of 3.60 m. A tensile load ranging from 600 kN to 800 kN was applied to these anchors, which varied in both length and inclination. The anchors inclination was specifically determined to prevent potential intersections with existing infrastructures and structures. Additionally, these inclinations facilitated the execution of the primary grout in geologically stable soil concerning the excavation´s geometry (Figure 5). The bond lengths were accomplished using the IRS system, incorporating double obturators and non-return valves, with a minimum hole diameter of 200 mm.

Figure 5. Bored pile wall shored by temporary ground anchors.

The configuration of the slab sections was defined with the aim of minimizing interference with the construction of the pillars and other structural elements within the ground floors. The slab bands exhibited an average width and thickness of 6.50 m and 25 cm, respectively. During the excavation phase, the slab

bands were supported on the retaining walls and on HEB200 profiles, spaced approximately 6.50 m apart (Figure 6). These profiles were bonded for a length of 2.0 m within sections of Ø600 mm piles, reaching a depth of 4.0 m below the excavation´s bottom. The execution of the slab strips took place during the excavation phase, involving concreting against the ground over a layer of levelling concrete and plastic film.

Figure 6. Concrete slab strips supported by HEB200 micropiles and buttresses.

To ensure the bored pile wall essential´s drainage conditions, sub-horizontal drainage pipes were installed between the curtain´s piles, measuring 4 m in length and 50 mm in diameter. These pipes were made from high density polyethylene (HDPE), covered in a geotextile with a density of 150 g/m^2. It´s primary function was to facilitate internal drainage within the massif, thereby averting potential hydrostatic impulses resulting from rainwater infiltration. To guarantee the gravitational flow of collected water, these drainage elements were positioned with an upward slope of 10º from the horizontal and with a horizontal spacing of 3.60 m.

The water collected by drainage pipes was directed into the peripheral rain gutter, which ran parallel to the retaining wall. Below the excavation bottom level, there was no interference with the hydrogeological system, as the piles, being discrete and spaced elements, did not form a barrier to the water flow.

4 GEOTECHNICAL AND STRUCTURAL DESIGN

The assessment of the presented peripheral earth retaining solutions in terms of forces and deformations was conducted for all major construction phases using finite element programs such as PLAXIS 2D and 3D, specifically designed for this purpose. A constitutive model was developed to simulate the soil behaviour characteristics of a "Hardening Soil", considering a nonlinear constitutive relationship and variations in the soil's stiffness under applied stress states. The parameters outlined in Table 1 were applied in PLAXIS to model the soils.

Table 1. Geotechnical soil parameters.

Soil Type	ZG_{1A}	ZG_{1B}	ZG_{2A}	ZG_{2B}	ZG_{2C}
N_{SPT}	<10	10-30	10-30	30-60	60
Υ [kN/m^3]	18	19	19	20	21
Φ' [º]	27	31	32	33	36
E_{50}^{ref} [MPa]	8	20	40	50	200
E_{ur}^{ref} [MPa]	24	60	120	150	600
m [-]	0,5	0,5	1	1	1
R_f [-]	0,9	0,9	0,9	0,9	0,9

Soil Type: ZG_{1A} – Loosely compact sandy-clay fill; ZG_{1B} – moderately compact sandy-clay fill; ZG_{2A}– moderately compact sandy-silt soil; ZG_{2B} – compact sandy-silt soil; ZG_{2C} – very compact sandy-silt soil.

Soil Parameters: Υ – Volumetric weight; Φ' – effective friction angle; E_{50}^{ref} – elastic modulus corresponding to 50% of the ultimate tensile stress defined for a reference pressure (p_{ref} = 100kPa); E_{ur}^{ref} - elastic modulus for unloading/reloading at a stress level equal to the reference pressure (p_{ref} = 100kPa); m – power that controls the stress dependency of the elastic modulus; R_f – failure ratio.

The study of the reinforced concrete bored pile wall sections braced by slab bands, steel struts or temporary ground anchors was conducted through the development of a Plaxis 2D model. In contrast, due to the distance of the buttresses and the interaction of the slab bands with these elements, an analysis of this solution was performed using a Plaxis 3D model.

In the developed models, the curtain wall´s, slab bands and buttresses were represented using "plate" elements with elastic behaviour, while the ground anchors were modelled as "node-to-node anchor" elements, with the respective bond lengths modelled using "embedded beam row" elements.

The behaviour of the peripheral retainment structure was analysed for the main excavation phases, assessing crucial design parameters such as forces of the containment structures, deformations, stress states and stability of the soils to be contained. Figures 7 and 8 present the deformed mesh of the developed models.

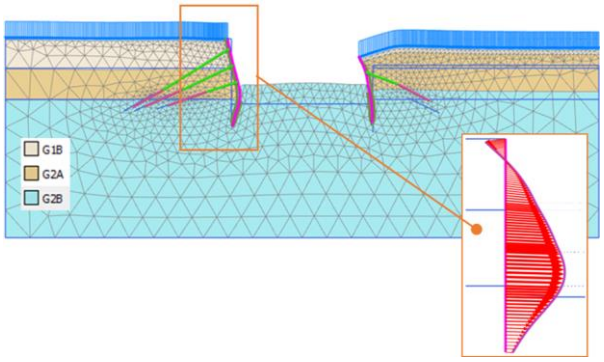

Figure 7. Deformed mesh of the excavation's base level phase - Curtain wall braced by temporary pre-stressed ground anchors model.

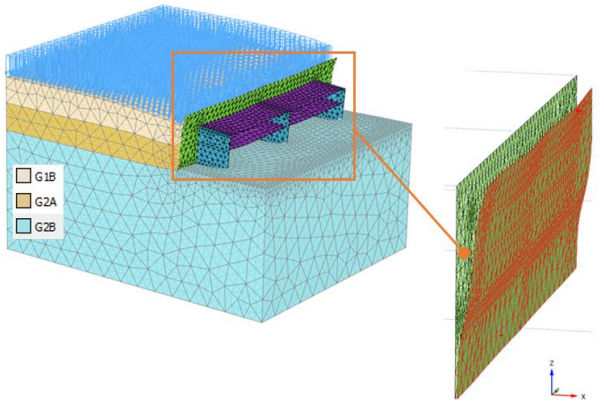

Figure 8. Deformed mesh of the excavation's base level phase - Curtain wall braced by slab bands and buttresses model.

The maximum horizontal displacement estimated for the curtain wall supported by temporary ground anchors was 9 mm, and with slab bands and buttresses, it measured 56 mm. The results obtained were as expected, considering that the model composed of passive elements (slab bands and buttresses) exhibits greater flexibility and can accomodate larger deformations in the surrounding ground and curtain wall compared to the model incorporating active elements (temporary pre-stressed ground anchors).

Throughout the construction phase, deformations were observed to be less pronounced than those projected during the design phase, as it will be presented in the following section.

5 MONITORING AND SURVEY PLAN

Based on the complex framework of the site, a Monitoring and Survey Plan (MSP) was established with the aim of ensuring safety conditions and optimal functionality during the excavation and the execution of the geotechnical structures, as well as neighbouring structures and infrastructures. In this context, the following instruments were installed:

- 27 topographic targets distributed along the bored pile walls and edges of the slab bands to measure horizontal and vertical displacements;
- 4 load cells to measure the load of the temporary ground anchors;
- 2 inclinometers positioned behind the peripheral containment walls, to measure ground horizontal displacements;
- 2 piezometers to measure underground water pressure;
- 1 seismograph for vibration control during the excavation of areas with higher resistance.

Based on the conducted modelling, alert and alarm criteria was established for all instruments and monitored structures. Overall, readings consistently remained below the alert and alarm criteria defined in the project. In Figure 9, the schematic location of the instrumentation devices and some of the most notable results are presented.

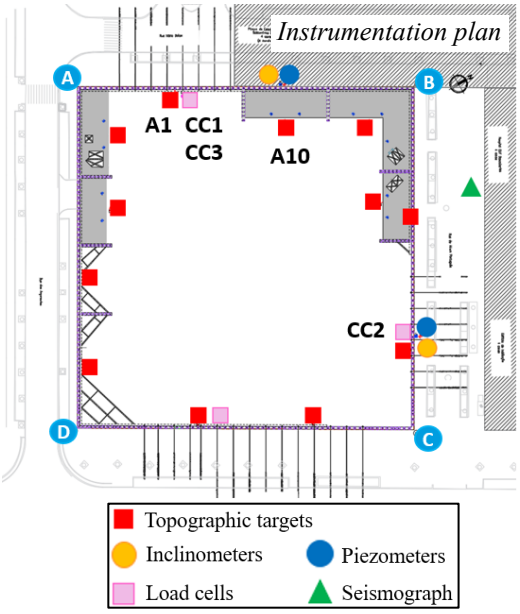

Figure 9. Instrumentation and monitoring plan.

As observed in the examples below, deformation values consistently remained below the alert criteria outlined in the project (yellow line in the graph), as shown in Figure 10. Regarding the monitoring of load cells, a minor adjustment to the initial load applied to the anchor tendons was noted, facilitated by a hydraulic jack. Subsequently, the load values remained nearly constant throughout the construction process (between June 2022 and January 2023), confirming the satisfactory performance of the project (Figure 11).

These conclusions are applicable to the remaining data instruments. However, in December 2022, a notable increase in water levels was observed due to heavy rainfall. In response, additional drainage pipes

and temporary water collection zones were established to address this issue.

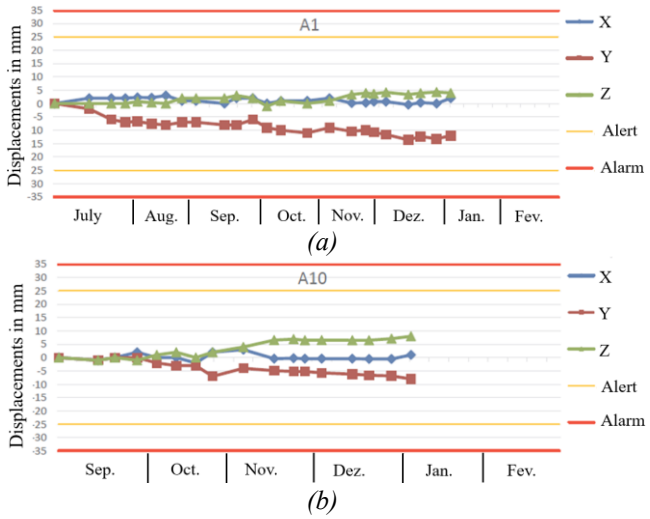

Figure 10. Displacement results on station A1(a) and A10(b).

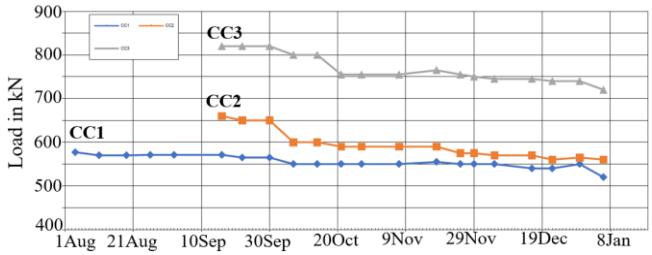

Figure 11. Load cell evolution of the ground anchors CC1, CC2 and CC3.

Considering the above, as of the present date with the conclusion of excavation and peripheral containment works, the instrumentation results serve to validate the suitability of the implemented solutions and the geomechanical parameters meticulously considered in the modelling. This paves the way for prospective optimization of similar geological and geotechnical solutions in the future.

6 CONCLUSIONS

In the scope of this article, it was possible to demonstrate the technical efficiency of reinforced concrete bored piles braced by various structural elements such as struts, temporary ground anchors and slab bands. The peripheral earth retaining solution presented displacements lower than those estimated in project and displayed a highly stable behaviour during the excavation works. Additionally, the use of slab bands not only overcame the encountered limitations due to the excavation´s site proximity to the technical gallery and the future underground parking lot, but also incorporated elements of the final structure, enhancing the economic efficiency of the solutions.

However, there were some on-site challenges that led to adjustments to the initial project solutions. The main challenge arose from an increased water flow into the excavation, given the intense rainfall experienced in December 2022 towards the end of the excavation works. To address this unforeseen circumstance and to ensure the integrity of the sprayed concrete between the piles, in response to the rising water flow into the excavation area, the number of drainage pipes was increased, and temporary water collection zones were established. In the definitive phase, the water collected by the pipes will be directed to the building's general drainage system.

ACKNOWLEDGEMENTS

The authors express their gratitude to Kronos, the Project Owner, for granting permission to publish this article, as well as to Casais and Ancorpor for their execution of excavation and earth retaining solution works, and finally to the project´s supervision, overseen by FICOPE.

Excavation, earth retaining solutions and facades underpinning of a historic building in Estoril, Portugal

Excavation, solutions de soutènement des terres et reprise en sous-œuvre des façades d´un bâtiment historique à Estoril, Portugal

J. Silva*, C. Martins, A. Pinto
JETsj – Geotecnia, Lda., Lisbon, Portugal

ABSTRACT: This paper aims to present the solutions for excavation, peripheral earth retaining walls and centenary facades underpinning of a future residential building, located in Estoril, Cascais, Portugal. Firstly, to preserve the building´s facades, a temporary structural system was installed, allowing the facades bracing, ensured by the execution of horizontal steel distribution beams and vertical steel frames, founded on vertical micropiles. Secondly, the facades were underpinned through the execution of two twin underpinning beams, connected by pre-stressed bars, founded also on vertical micropiles. For the execution of the underground floors, it was necessary to excavate a maximum of 9 m under the original building´s foundations, using the king post walls earth retaining technique braced horizontally by steel props, ensuring the compatibility of the underpinning and the retaining facades solutions. Lastly, the monitoring and observation of the peripheral retaining structure and facades is also pointed out, encompassing detailed analyses and comparisons with the initially estimated values from the design phase.

RÉSUMÉ: Cet article vise à présenter les solutions pour l'excavation, les murs de soutènement périphériques et la reprise en sous-œuvre des façades centenaires d'un futur immeuble résidentiel situé à Estoril, Cascais, Portugal. Tout d'abord, pour préserver les façades du bâtiment, un système structurel temporaire a été installé, permettant le contreventement des façades assuré par la réalisation de poutres de distribution horizontales en acier et de cadres verticaux en acier, fondés sur des micropieux verticaux. Deuxièmement, les façades ont été soutenues par l'exécution de deux poutres de soutènement jumelles, reliées par des barres précontraintes, également fondées sur des micropieux verticaux. Pour l'exécution des étages souterrains, il a été nécessaire d'excaver jusqu'à une profondeur maximale de 9 m sous les fondations originales du bâtiment, en utilisant la technique de soutènement des murs à paroi berlinoise, contreventée horizontalement par des étais en acier, assurant la compatibilité entre le soutènement et les solutions de soutènement des façades. Enfin, la surveillance et l'observation de la structure de soutènement périphérique et des façades sont également soulignées, englobant des analyses détaillées et des comparaisons avec les valeurs initialement estimées lors de la phase de conception.

Keywords: Earth retaining structures; king post walls; underpinning; facades; micropiles.

1 INTRODUCTION

The present article outlines the solutions adopted for the retention and underpinning of an existing old facade, as well as for the excavation and peripheral earth retaining structure, enabling the construction of an underground parking lot for a future residential building.

Within the intervened plot, there was a vacant building whose main facades were, for the most part, preserved. The exterior walls were composed by ordinary stone masonry, with a thickness of 0.80 m, decreasing in height. Generally, the facades exhibited a considerable state of degradation, particularly on the southern facade, with the possible risk of partially collapsing. Figure 1 presents an aerial perspective of the intervention site before the construction work´s.

Figure 1. Aerial view of the intervention site, in its current state.

The new building will be situated on Avenue Senhora Monte da Saúde, covering an approximate ground area of 670 m^2. It will comprise a parking lot, a ground floor, three elevated floors and a slopping roof. The intervention area, within which the building is situated, encompasses around 1446 m^2. Figure 2 depicts a virtual view of the future residential building.

Figure 2. Virtual view of the future residential building.

2 MAIN CONSTRAINTS

2.1 Geological and geotechnical conditions

To characterize the geotechnical behaviour, associated with the soils present at the site, a prospecting campaign was conducted involving the execution of two mechanical boreholes accompanied by Standard Penetration Tests (SPT) and the collection of samples for macroscopic classification. Additionally, one hydraulic piezometer was installed in one of the boreholes.

According to the results obtained, the geological structure of the site is characterized, superficially, by the presence of Landfill Deposits (At) mainly composed of rocky blocks and clayey sands with an average thickness of 1.0 m. Notably, no standard penetration test was conducted on these modern anthropogenic materials. Subsequently, underlying these fill deposits, Cretaceous formations (C^1_{Ba} e C^1_A) are manifested at this location by three geotechnical horizons. The conducted borehole surveys unveiled the presence of clays and sandy clays (ZG_{2A} - C^1_{Ba}), with variable thickness ranging between 7,50 m and 10,50 m and N_{SPT} values ranging from 15 to 41 blows. Addtionally, fine clayey sands to sandy clays (ZG_{2B} - C^1_{Ba}) were encountered at depths varying from 7,5 m and 12,0 m, with N_{SPT} values spanning from 23 to 46 blows. Lastly, a lower stratum was characterized by moderately to highly altered and fractured limestones (ZG_{2C}-C^1_A), interspersed with fine-grained sandstones, in which Rock Quality Designation (RQD) values ranged from 32% to 49%. This unit was identified at the dephs of 10.0 m and 11.8 m.

In terms of hydrogeology, there is no water level at the excavation site according to the conducted survey, which should not interfere with the local hydrogeological regime.

2.2 Neighbourhood conditions

The excavation site is situated in an urbanized area, bounded by Avenue Senhora Monte da Saúde to the West, and several other neighbouring constructions. To the North, the plot is bordered by two residential buildings with two and three elevated floors, respectively, and both without underground basements. To the South, it is delineated by the backyard and annex of a neighbouring plot. To the East, it is surrounded by a one-story church, also without underground basements.

Additionally, it is worth noting the presence of party walls along the lot boundaries and the proximity of an existing wall, located inside the lot, to the proposed king post wall solution at the rear of the façade to be preserved. In Figure 3 it is possible to observe the main boundaries of the excavation site.

Figure 3. Main boundaries of the excavation site.

3 ADOPTED SOLUTIONS

3.1 Facades retention and underpinning

Given the facades high deterioration level, particularly on the southern side, and the need to demolish/dismantle a portion of it, it was decided that, prior to the facades retention work, an extensive treatment to the existing cracks should be undertaken through the injection of grouts based on hydraulic lime. Subsequently, steel angle profiles were installed at the corners of the facades to be preserved, and three levels of tensioned 26 mm galvanized tie rods were

installed to ensure the maximization of safety during the facades retention works (Figure 4).

Figure 4. Prior facade retention works, involving the installation of steel angles and steel tie rods per floor.

The facade retention structure was composed by steel distribution beams, which had the primary objective of equalizing horizontal loads on the wall and directing it towards 8 bracing frames, particularly loads induced by wind action. These distribution beams were constituted by HEB 180 and UPN 260 steel profiles, while the bracing frames were constructed using steel trusses comprised by HEB 240 vertical columns, HEB 200 horizontal beams and LNP 150x150x10 diagonal steel angles.

In order to provide an appropriate foundation with adequate stiffness and strength for the bracing frames of the retention structure, considering tensile and shear forces to which the structure might be subjected, reinforced concrete massif´s were executed, indirectly founded on micropiles. The micropiles were executed using N80 Ø139.7x10mm profiles with external connections between sections and sealed through the Repeated and Selective Injection system (IRS), in competent and geologically stable ground, with N_{SPT} > 60 blows.

To underpin the facades, a system composed by two rows of micropiles was designed, connected by two underpinning beams (one on the exterior and another on the interior of the existing walls), joined by prestressed Gewi type bars. In Figure 5 , the defined facades retention and underpinning solution can be observed.

Figure 5. Facades retention and underpinning solution.

Additionally, given the high deterioration level of the facades, there was the need to reinforce the stone masonry walls by executing a reinforcement wall with a thickness of 8 cm. This wall consisted of a reinforcement mesh and shotcrete, executed from the interior and securely anchored to the existing facades (Figure 6). Upon completion of the facades retention and underpinning works, excavation and peripheral containment activities were initiated.

Figure 6. Strengthening of stone masonry walls with a reinforced concrete layer.

3.2 Excavation and peripheral earth retaining structures

The excavation and peripheral earth retaining structures were executed following the King Post Wall technology, with careful consideration given to compatibility with the facades retention and underpinning works. This solution involved a phased construction, from top to bottom, of reinforced concrete panels. The process commenced with the execution of the primary panels, followed by the secondary, and ultimately, the tertiary panels.

The panels were horizontally braced by provisional elements such as steel props, tie rods and temporary pre-stressed ground anchors, and vertically supported by micropiles. The bracing elements were composed by HEB 180 and HEB 220 steel profiles, braced by HEB 120 profiles with S275 JR steel grade. In convex corners, resistance to impulses was ensured by pre-stressed Gewi tie rods.

The executed ground anchors comprised 4 strands, each with a diameter of 1.5 cm, and with a tensile load of 450 kN. The bonded lengths were accomplished using the IRS system, incorporating double obturators and non-return valves, with a minimum hole diameter of 200 mm and minimum length of 4.0 m. To prevent potential intersections with existing infrastructures and structures, as well as to allow proper sealing in competent and geologically stable soil, these anchors were inclined at 30.0º and 35.0º horizontally.

Vertical micropiles were designed to support the vertical loads imposed on the peripheral earth retaining structure, particularly by the self-weight and by the vertical component of the ground anchors. These elements were executed using N80 Ø139.7x10.0 mm tubular profiles with external joints, made of high-strength steel (f_{syd} > 560MPa), placed inside a 200 mm hole diameter and bonded for a length of 6.0 m, using the IRS system. The micropiles were connected at the top by capping beams and were generally embedded in the king post walls, which had a thickness of 0.30 m.

In Figure 7, the excavation and peripheral earth retaining solution are depicted.

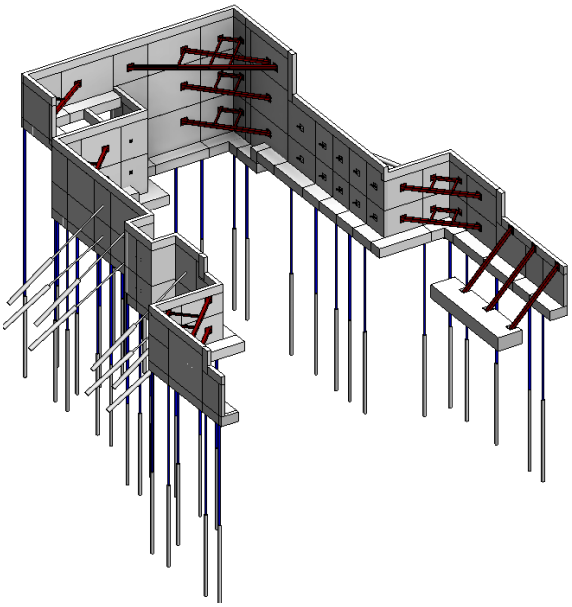

Figure 7. Excavation and peripheral earth retaining solution (BIM model in software Revit).

4 GEOTECHNICAL AND STRUCTURAL DESIGN

4.1 Facades retention and underpinning

The behaviour of the facades retention structure was analysed in terms of forces, reactions and deformations using finite element models created in the Autodesk Robot Structural Analysis Professional 2022 software (Figure 8). This allowed the simulation of the wind effects, the most critical factor to this case. The facades bracing system was modelled in the program using "steel members" type elements with their respective mechanical properties. The micropiles were depicted as fixed supports.

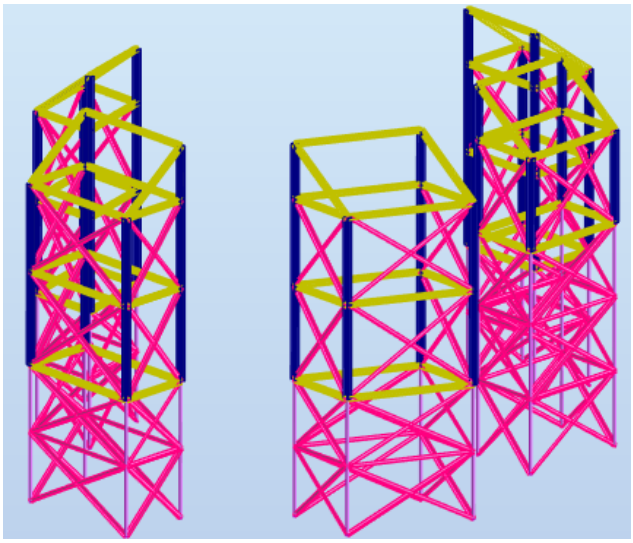

Figure 8. Facades retention structural model, developed in Robot software.

4.2 Excavation and peripheral earth retaining structures

The assessment of the presented peripheral earth retaining solution in terms of forces and deformations was conducted for all major construction phases using a finite element program, PLAXIS 2D. A constitutive model was developed to simulate the soil behaviour characteristics of a "Hardening Soil", considering a nonlinear constitutive relationship and variations in the soil's stiffness under applied stress states. In the context of soil geomechanical parameterization, the reference values obtained from the geological-geotechnical study were incorporated in PLAXIS software, to simulate the soils behaviour, as detailed in Table 1.

Table 1. Geotechnical soil parameters.

Soil Type	ZG_1	ZG_{2A}	ZG_{2B}	ZG_{2C}
N_{SPT}	-	15-41	23-46	> 60
Υ [kN/m^3]	19	20	20	21
Φ [º]	25	-	35	35
c_u/c' [KPa]	-	90	1	5
E_{50}^{ref} [MPa]	7,5	30	50	180
E_{ur}^{ref} [MPa]	22,5	90	150	540
m [-]	0,5	0,7	0,9	1

Soil Type: ZG_1 – *Loosely compact sandy-clay fill*; ZG_{2A}– *clay and sandy clay soil;* ZG_{2B} – *fine clayey sand to sandy clay soil;* ZG_{2C} – *fractured limestones interspersed with fine-grained sandstones.*

Soil Parameters: Υ – *Volumetric weight;* Φ' – *effective friction angle;* E_{50}^{ref} – *elastic modulus corresponding to 50% of the ultimate tensile stress defined for a reference pressure* (p_{ref} = *100kPa);* E_{ur}^{ref} *- elastic modulus for unloading/reloading at a stress level equal to the reference pressure* (p_{ref} = *100kPa); m – power that controls the stress dependency of the elastic modulus.*

In the developed models, the king post walls and micropiles were modelled using "plate" elements with elastic behaviour. However, the zones corresponding to the free length and the bond lengths of the micropiles were modelled using "embedded beam row" elements. The temporary ground anchors were modelled using "node-to-node anchor" elements and their respective bond lengths were modelled using "embedded beam row" elements. The steel props were modelled using "anchors", with the equivalent stiffness to the defined bracing system.

The behaviour of the peripheral retainment structure was analysed for the main excavation phases, assessing crucial design parameters such as forces of the containment structures, deformations, stress states and stability of the soils to be contained. The bonded lengths of the micropiles and temporary ground anchors were determined according to the methodology proposed by Bustamante and Doix (1985). Figure 9 and Figure 10 present the deformed mesh of the developed PLAXIS models.

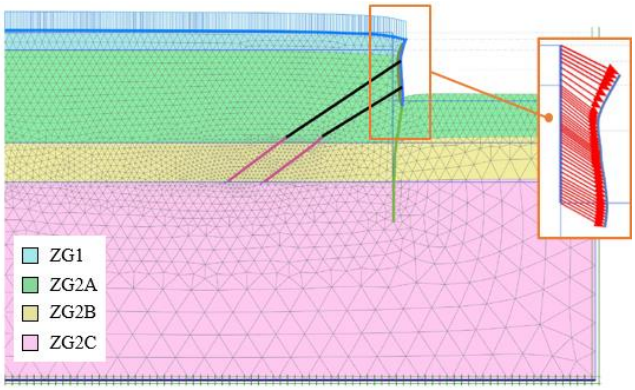

Figure 9. Deformed mesh of the excavation´s base level phase - King post walls braced by pre-stressed ground anchors.

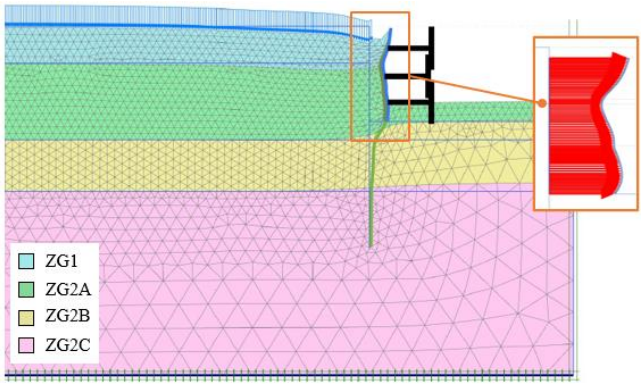

Figure 10. Deformed mesh of the excavation´s base level - King post walls braced by steel props.

The maximum horizontal displacement estimated for the king post wall supported by two levels of pre-stressed ground anchors was 10,90 mm, for a total excavation height of 5,90 m (L/540), meeting the ELS requirements.

For the scenario in which the earth retaining structure is braced by three levels of steel props, for a total excavation height of 8,20 m, the maximum horizontal displacement estimated was 9,40 mm (L/870), meeting the ELS requirements.

5 MONITORING AND SURVEY PLAN

The established Monitoring and Survey Plan (MSP) on site had as its main objective to ensure the safe execution of the demolition, retention and underpinning works of the facades, as well as the peripheral earth retaining structure of the underground floors. Additionally, it aimed to analyse the behavior of neighboring structures and infrastructures during the construction works.

In the initial phase, for the control of displacements, rotations and measurement of masonry wall crack openings during the demolition and reinforcement of existing structures, an automated monitoring system was implemented for a 2-month construction period.

The entire field data reading and acquisition system were fully automated, with readings taken every 1 hour. Sensors were installed for data acquisition and transmission to a wireless web platform. Figure 11 illustrates the application of the web monitoring system for this specific construction project.

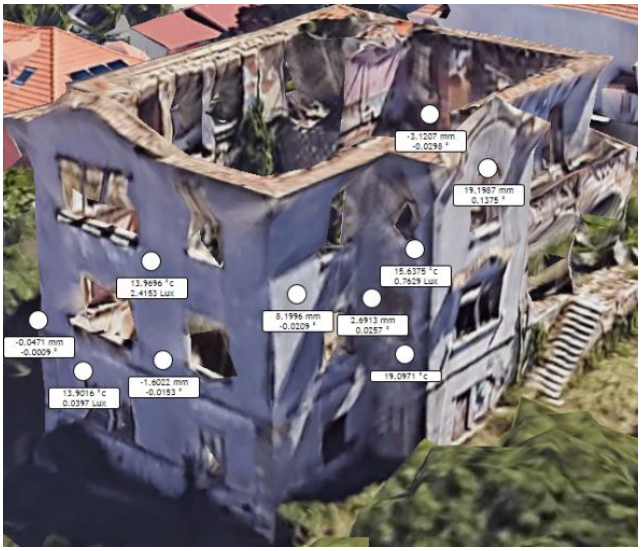

Figure 11. Aerial view of the intervention site (Google Earths image) – Web Monitoring System

The implementation of this automated monitoring system not only enabled a more accurate and systematic control of the behaviour of all critical structures, but also streamlined the adjustment of construction methodologies during the execution of the new structures, potentially resulting in enhanced productivity.

The implemented MSP on the existing facades included the following fully automated sensors/instruments:

- 12 triaxial tiltmeters for measuring rotations and displacements of the preserved facades and neighboring structures and infrastructures;
- 4 vibrating wire crackmeters (strain gauges) for measuring crack openings;
- 40 manually read crackmeters for measuring crack openings;
- 2 Gateways, which correspond to the data collection and network data transmission system via 3G;
- 2 solar panels for energy supply to the Gateway.

In the second phase, for excavation and peripheral earth retaining construction works, the following instruments were installed, for a 6-month construction period:

- 14 triaxial tiltmeters placed on the king post walls, to measure rotations and displacements;
- 4 electric load cells, to measure the pre-stressed loads applied to the temporary ground anchors;
- 1 inclinometer positioned behind the peripheral earth retaining walls, to measure horizontal and vertical displacements of the retaining walls;
- 1 piezometer to measure underground water pressure.

Based on the conducted modelling, alert and alarm criteria was established for all instruments and monitored structures.

6 CONCLUSIONS

In the scope of this article, it is expected to demonstrate the technical efficiency of the facades retention and underpinning solution as well as the king post walls solution, braced by various structural elements, such as struts and temporary ground anchors. Furthermore, it is expected that the peripheral earth retaining solution present´s actual displacements lower than those estimated in design and display a highly stable behaviour during the excavation works currently underway.

Behavior of geocell reinforced sandy soils under static load

Comportement des sols sableux renforcés par géocellules sous charge statique

M.C. Simsek, N. Huvaj*
Middle East Technical University, Ankara, Turkey
**nejan@metu.edu.tr*

ABSTRACT: Geocell is a three-dimensional cellular geosynthetic product to provide all-around confinement by the interaction of infill soil, cell walls and cell geometry. This study comprises of laboratory model tests of geocell-reinforced sandy soil with different dimensions of geocells to evaluate the amount of the contributions of the geocells with regards to height of the cell, width of the cell and loading location. In addition, the load is applied at the center of the cell and at the intersection of polymer boundaries of geocells. Tests are conducted in a tank with dimensions of 1 m width, 1 m length and various heights depending on geocell height, where static loading is applied via a steel plate on the sand surface. The results are presented in terms of pressure-settlement plots. It is observed that for a predetermined settlement value, presence of the geocells increased the bearing capacity of the footing by 38% to 73% compared to unreinforced cases and reduced the settlements under a given pressure. Bearing capacity increased with increasing geocell height independently from geocell width. Decreasing of geocell width increased the bearing capacity of the footing independently from geocell height.

RÉSUMÉ: Geocell est un produit géosynthétique cellulaire tridimensionnel destiné à assurer un confinement complet grâce à l'interaction du sol de remplissage, des parois cellulaires et de la géométrie cellulaire. Cette étude comprend des tests sur modèle de laboratoire de sol sableux renforcé de géocellules avec différentes dimensions de géocellules pour évaluer la quantité de contributions des géocellules en ce qui concerne la hauteur de la cellule, la largeur de la cellule et l'emplacement de chargement. De plus, la charge est appliquée au centre de la cellule et à l'intersection des limites polymères des géocellules. Les tests sont effectués dans un réservoir de dimensions 1 m de largeur, 1 m de longueur et différentes hauteurs en fonction de la hauteur de la géocellule, où une charge statique est appliquée via une plaque d'acier sur la surface du sable. Les résultats sont présentés sous forme de tracés de pression et de tassement. On observe que pour une valeur de tassement prédéterminée, la présence des géocellules augmente la capacité portante de la semelle de 38% à 73% par rapport aux cas non renforcés et réduit les tassements sous une pression donnée. La capacité portante augmente avec l'augmentation de la hauteur des géocellules, indépendamment de la largeur des géocellules. La diminution de la largeur des géocellules a augmenté la capacité portante de la semelle indépendamment de la hauteur des géocellules.

Keywords: Geocell; sand; bearing capacity; settlement.

1 INTRODUCTION

Geocell is a three-dimensional cellular geosynthetic product providing all-around confinement by the interaction of infill soil, cell walls and cell geometry, reducing the lateral movement of soil and forming a stiffened mattress to distribute applied loads to a wider area (Han et al., 2008). They have been successfully used worldwide to construct retaining walls, slopes and to reinforce road bases (Han et. al., 2008). They are effective in increasing the bearing capacity of the roads, while enabling faster application with easy deployment and transportation.

Behavior of geocell reinforced soil can be affected by many factors such as height, width, thickness and material of geocell, as well as type and density of basement and infill soils. Geocell width and height are two major factors that influence the geocell performance. Effects of these factors on the load carrying capacity and settlement performance of geocell-reinforced soils have been investigated (Shin et al., 2017; Gurbuz and Mertol, 2012; Latha et. al, 2006). However, most of the model experimental studies used only one cell and there is a need for studies with multiple geocells to better represent overall behaviour in the field. Furthermore, the size of geocells that are used widely in the market have not been used in most of the previous studies, which developed the need to investigate this topic. Additional study is needed to investigate the effect of loading location (in the middle of the cell or at the intersection of polymer cell boundaries) on the behaviour of the geocell-reinforced soils.

The objectives of this study are (i) investigation of the amount of improvement in the case of using different heights of geocells and different geocell openings, (ii) the effects of geocell width on the behaviour of the bearing capacity, (iii) investigation of the significance of loading location by applying the load at the center and also intersection of the boundaries of the geocell. For this aim, 13 static plate load tests were conducted. Contributions of the geocell usage on the bearing capacity performance of the footing were compared with tests on unreinforced soil.

2 TEST SETUP AND MATERIALS

The test box used in the experiments has base dimensions of 100 cm × 100 cm and 60 cm height. It comprises of ten aluminium box segments, each having 10 cm height (Figure 1, 2). Static loading is applied on the ground surface via a 26-cm-diameter, 2.5-cm-height rigid steel plate using pneumatic loading system. In order to examine the load-displacement characteristics of geocell reinforced and unreinforced sandy soil under static load, settlement of the loading plate as well as the force on the plate are measured by using two dial gauges and a load cell connected to a data logger, respectively.

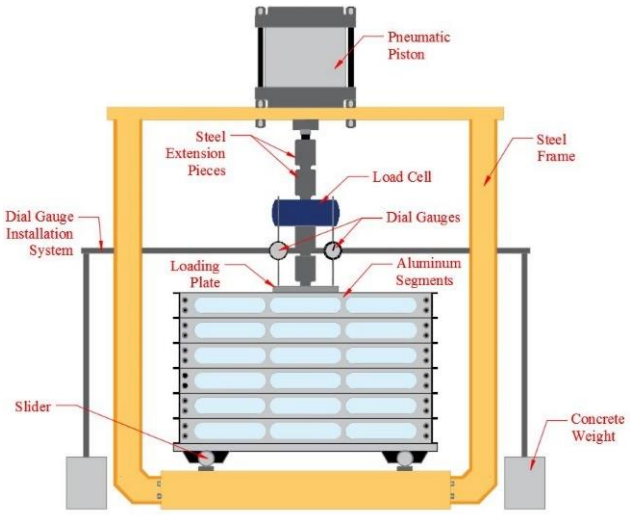

Figure 1. Schematic view of the front view of test set up.

2.1 Materials

Fine Sand from Türkiye is used as base soil and infill soil of geocells. The soil consists of quartz, feldspar and rock fragments having sub-angular to angular particle shape. Properties of the sand are given in Table 1, where all tests are carried out two or three times and average values are also presented in Table 1.

Two different HDPE type, perforated and ultrasonically welded geocells are used: Geocell 40 with 25 × 30 cm openings and 1.1 mm material thickness, and Geocell 60 with 35 × 40 cm openings and 1.3 mm sheet thickness (Figure 3). Each geocell had three different cell height versions: 10, 15 and 20 cm.

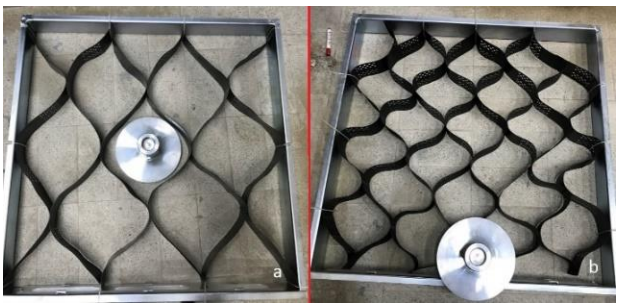

Figure 3. 26-cm diameter loading plate and (a) Geocell 60 (showing loading applied at the center/inside of a geocell), (b) Geocell 40.

2.2 Sample preparation

Dry air pluviation via a sand raining system is used to fill the tank with sand (Figure 4). Based on trial sand raining tests using different sieves; sieve hole diameter of 2.8 mm and 15 mm center-to-center distance between holes are used.

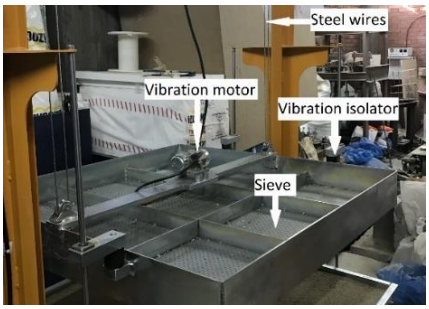

Figure 4. Dry air pluviation (sand raining) system.

Trial relative density tests are performed to investigate the effect of sand raining elevation on the variance of the relative density (Figure 5). Considering the geocell heights (10, 15, 20 cm), the sand raining elevations vary from 5 cm to 25 cm at any level of testing tank. For a 10-cm-high segment of the box, relative density values of the sand are found as 61%, 62% and 64% when sand raining height was 5, 15 and 35 cm, respectively. Increase in sand raining elevation slightly increases the relative density. When sand raining height was kept constant at 5 cm, the relative density was 62% and 67% at the uppermost and lowermost segment of the tank, respectively, in a test having total of 55 cm sand height. Relative density differences between the center, edge and corner at the same elevation (Figure 5) are less than 2%. It shows that an acceptable uniform sand raining was carried out at the any location of the tank. In all tests, sand raining height is 5 cm and relative density is between 61% and 67%.

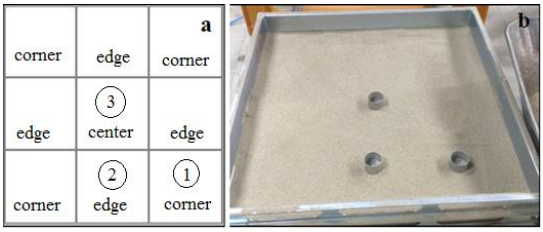

Figure 5. Air pluviation (sand raining) trial tests.

Sample preparation starts by filling the first (bottom) 10-cm-high segment of testing tank with sand by using sand raining system (sand raining height 5 cm). Adding new 10-cm-high segment and repositioning of the sieve continued till the setup reached to the desired height. With the difference of unreinforced tests, geocell is placed in the pre-determined levels in geocell reinforced tests. In all geocell reinforced tests, 30 cm height (3 segments of testing tank) of sand base layer and 5 cm height of sand cover above the geocell are kept constant. Only the height of geocells is changed between these sand layers and hence final height of sands are obtained as 45 cm, 50 cm and 55 cm for geocells that have 10 cm, 15 cm and 20 cm heights, respectively.

Geocells are tied with plastic clamps to the edge of the 10-cm-high segment of the tank to keep the cells open and also stressed during the sand raining process (Figure 6). After sand filling is completed, these clamps are cut and thus, getting additional strength of geocells are prevented. Filled testing tank is then moved under the loading system, and placed under the piston, a steel loading plate (diameter 26 cm, thickness 2.5 cm) is placed at the center of the tank on the ground surface (Figure 2).

Figure 6. Placement of geocell tied segments to sand filled testing tank (clamps are cut after tank filling is completed).

3 RESULTS

The results of 13 model static plate load experiments are summarized in Table 2 and in Figure 7.

Table 2. Summary of static plate load tests

Test No.	Total Sand Height (cm)	Geocell Width (cm)	Geocell Height (cm)	Loading Location*	Pressure at 5.2 cm** settlement (kPa)
1	45	No Geocell		-	430
2	50	No Geocell		-	457
3	55	No Geocell		-	480
4	45	35 x 40	10	center*	603
5	45	35 x 40	10	intersection	585
6	50	35 x 40	15	center	655
7	50	35 x 40	15	intersection	665
8 #	55	35 x 40	20	center	753
9	55	35 x 40	20	intersection	825
10	45	25 x 30	10	center	620
11	50	25 x 30	15	center	730
12	55	25 x 30	20	center	830
13 #	55	35 x 40	20	center	736

* loading is applied at ground surface, at the center (inside) of one cell, or at the intersection of the geocell polymer boundaries

** 5.2 cm is selected as the 20% of plate diameter of 26 cm.

Test No. 13 is a repeated test of Test No. 8; difference between results is 2.3%, which is considered sufficient repeatability.

A clear failure is observed in unreinforced (no geocell) tests (Test no 1, 2, 3) unlike geocell-reinforced ones (Figure 7). 430 kPa, 457 kPa and 480 kPa pressure values obtained under the loading plate at the 5.2 cm settlement indicate a

small/acceptable variation. Geocell reinforced test results are compared with corresponding unreinforced ones and amount of improvement is calculated as percentage (%). For a predetermined settlement value, the presence of the geocells increased bearing capacity of the footing by 38% to 73% compared to unreinforced cases (Table 2).

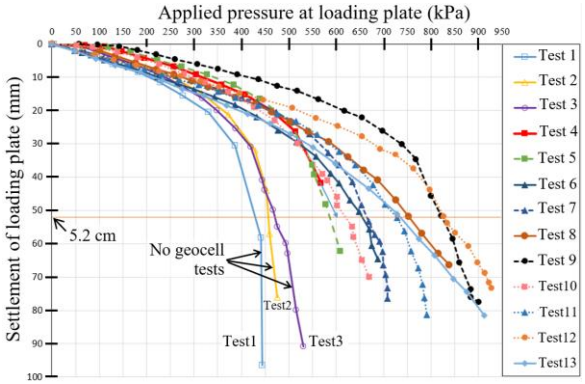

Figure 7. Results of 13 tests

Effect of loading location (tests 4, 5, 6, 7, 8, 9): Loading at the center of the cell and at the intersection of polymer boundaries of cells are applied to sand reinforced by Geocell having 35 cm x 40 cm opening, since the other geocell could not be used in these tests because the loading plate (26 cm diameter) is bigger than the geocell opening area (25 cm x 30 cm) and the plate could not be located at the center of the cell. For 10 cm, 15 cm and 20 cm geocell heights, -3.1%, 1.5% and 9.6% more load carrying capacities are obtained when loading plate placed at the intersection of the polymer boundaries rather than geocell center. As height of geocell increases, geocell starts to act as a load carrying beam, and this effect increases the load carrying capacity until settlement of plate reaches to 55.2 cm. Loading on the intersection of geocell polymer boundaries (as compared to the center) showed higher improvement in the case of using geocells with bigger heights. Loading location did not effect the ultimate bearing capacity more than 10%; geocell shows almost homogenous behavior regardless of loading location.

Effect of the geocell height and width: For a given geocell widh (25 × 30 cm), as height of geocell increases from 10 cm to 20 cm, a higher bearing capacity is obtained (620 kPa to 830 kPa). Independently from geocell width, increase in geocell height increases the load carrying capacity of the footing at the same settlement value. Additionally, for bigger geocell opening, percentage of improvement increases when geocell height increases. In other words, in the case of using 15 cm height geocell instead of 10 cm, improvement percentage increases from 38.14% to 44.42%. In a similar manner, using of 20 cm height geocell instead of 15 cm, improvement percentage increases from 44.42% to 63.54%. Independently from geocell height, decrease in geocell width, increases the load carrying capacity.

4 CONCLUSIONS

Major conclusions are summarized below:

1) Geocell reinforcement in any sizes contributed to bearing capacity of the footing corresponding to settlement value of 20% of diameter of it, compared to unreinforced ones. Geocells increased the bearing capacity of the footing by 38% to 73% compared to unreinforced cases.

2) A clear failure is observed in unreinforced tests however, it is not observed in geocell reinforced tests, in the other words, geocell reinforced sand showed a more ductile behavior.

3) Bearing capacity increased with increasing geocell height independently from geocell width.

4) Decreasing of geocell width increased the bearing capacity independently from geocell height.

5) Importance of the location of the loading plate is investigated. In any case, less than 10% difference on the bearing capacity of the footing at 52 mm displacement is observed, i.e. geocell shows almost homogenous behavior regardless of loading location relative to geocell structure.

It should be noted that only one type of loading plate, one type of geocell with different heights and widths and one type of sand were used in this study; the results obtained may be different than those of full-scale tests in field and also using of different materials.

Evaluating the effects of a deep excavation on monumental buildings: MarmorKirken station in Copenhagen

Évaluation des effets d'une excavation profonde sur des bâtiments monumentaux: gare MarmorKirken à Copenhague

F.M. Soccodato*, G. Tropeano
University of Cagliari, Italy

**soccodato@unica.it*

ABSTRACT: This paper describes the Building Risk Assessment (BRA) process implemented during the design and construction of MarmorKirken metro station in Copenhagen. Being the box station very near the monumental church, the evaluation of the effects induced by the excavation on the church was a key issue of the design. Surveys, structural and geotechnical investigations were carried out to setup reliable structural and geotechnical numerical models on which BRA, at the design stage, was based. During construction works, design predictions were systematically compared with monitoring measures, allowing to update the BRA. According to BRA results, no significant effects of construction works on the church was observed.

RÉSUMÉ: Cet article décrit le processus d'Evaluation des Risques liés aux Bâtiments (BRA) mis en œuvre lors de la conception et de la construction de la station de métro MarmorKirken à Copenhague. Le box étant très proche de l'église monumentale, l'évaluation des effets induits par les fouilles sur l'église a été un enjeu clé de la conception. Des études, des investigations structurelles et géotechniques ont été réalisées pour établir des modèles numériques structurels et géotechniques fiables sur lesquels BRA, au stade de la conception, s'est basé. Lors des travaux de construction, les prévisions de conception ont été systématiquement comparées aux mesures de suivi, permettant ainsi de mettre à jour le BRA. Selon les résultats du BRA, aucun effet significatif des travaux de construction sur l'église n'a été observé.

Keywords: Deep excavations; soil-structure interaction; numerical analyses.

1 INTRODUCTION

Deep excavations and tunnelling in the urban environment require a careful evaluation of the effects of works on existing structures. Very often, the building risk assessment (hereinafter referred to by the acronym BRA) process plays a major role in design, especially when monumental structures are involved.

In this case, at a given design stage, numerical analyses with different levels of complexity are carried out, geotechnical and structural aspects of the problem needing to be properly addressed (Rampello et al., 2012; Burghignoli et al., 2013; Pascariello et al., 2023). Expected building damage may be then evaluated by looking at stress and strain fields or patterns in the structure.

During construction stages, monitoring data are of primary importance to assess numerical predictions and, when needed, to update the BRA.

This paper describes some features of the BRA process carried out for the construction of MarmorKirken metro station in Copenhagen.

2 MARMORKIRKEN STATION

Marmorkirken station box is about 35 m in depth; diaphragm walls have a length of 40 m. The retaining walls are located only 3 m away from the foundations of the church (Figure 1). A full top-down construction technique was adopted to minimise excavation induced settlements of the church.

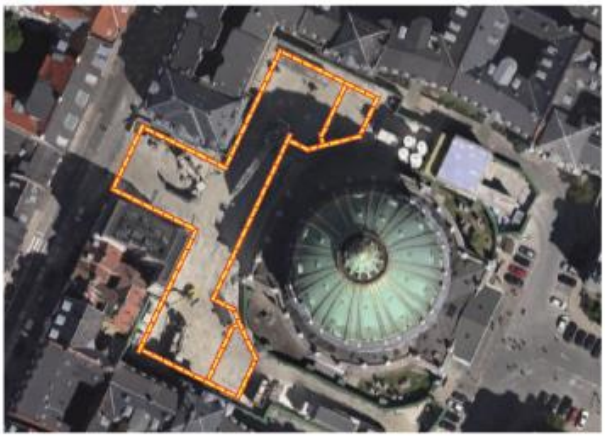

Figure 1. View of MarmorKirken area.

3 BRA PROCESS

The BRA process carried out consisted of different stages, starting from the acquisition of relevant data used for the setup of numerical models. BRA was based on the evaluation of predicted stresses and strain field changes due to construction activities. The interpretation of monitoring measurements allowed for checking and updating the BRA during construction works.

3.1 Survey and testing

It is worth noting that reliable structural and geotechnical numerical models should be based on reliable structural and geotechnical investigations, the first of them being rather difficult to be obtained for monumental buildings, often due to conservative issues. For MarmorKirken, the following activities were addressed:1) historical research (drawings and texts); 2) a laser scanner survey to define geometry; 3) endoscopy and lab testing on cored samples (marble); 4) flat jack and sonic tests on walls (masonry);
Before the construction activities, no significant crack patterns were observed in the structure.

The geotechnical investigation (boreholes, piezometers, seismic tests and samples tested in the laboratory) allowed for a reliable geotechnical characterization of the foundation soil. Boreholes and excavation pits enabled to identify materials and depth of the ring foundation of the Church.

3.2 Structural and geotechnical model

The church may be broadly divided in four main parts: foundation level (rock blocks), entrance level (marble blocks, for both inner and outer structure), drum and dome (masonry). The ring foundation has a thickness of about 3 m, with an inner and outer diameter of about 25 and 50 m, respectively. The dome has a diameter equal to 31 m, ant it reaches a height of about 46 m.

About 50000 finite elements were used to define the structural model of church (Figure 2). Both masonry and marble were modelled using a linear, isotropic elastic model due to the expected small strain levels. The estimated total load acting at foundation level was about 300 MN.

Figure 6 shows soil profile and geometry of the excavation in front of the church. Foundation soils, below shallow units of made ground (FY) and a clayey silt (ML), are constituted by a medium to dense sand and gravel level (DS/DG) with a thickness of about 9 m. At a depth of 13 m (10 m a.s.l.), the basal limestone formation, with increasing stiffness and strength properties with depth (UCL-HP, UCL, MCL), is found.

Figure 2. Structural model of the church (SAP2000 code).

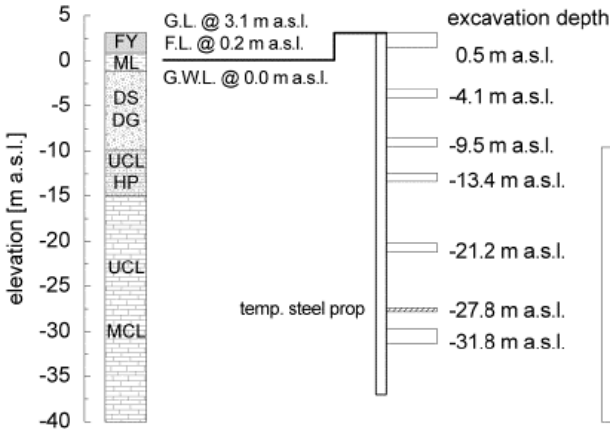

Figure 3. Soil profile and top-down excavation stages in front of the church.

Figure 4 shows the three-dimensional (3D) FEM computational mesh of the geotechnical model of both the excavation and the church. The church is modelled by an equivalent embedded linear elastic solid (Rampello et al., 2012), on which the average dead loads obtained from the structural analysis are applied. The HSM nonlinear, plasticity hardening model (Schanz et al., 1999) was used for soil and rock units. Calculation steps of the analysis followed, after the in-situ stage and the simulation of retaining walls construction, the top-down sequence depicted in Figure 3. Predicted maximum settlements of the Church were very small: about 0.5 mm due to retaining wall construction and about 1.7 mm at the end of excavation stages. Full details on soil parameters, numerical modelling approach and results of the 3D numerical soil-structure interaction analysis (class A prediction) are described in Soccodato and Tropeano (2021).

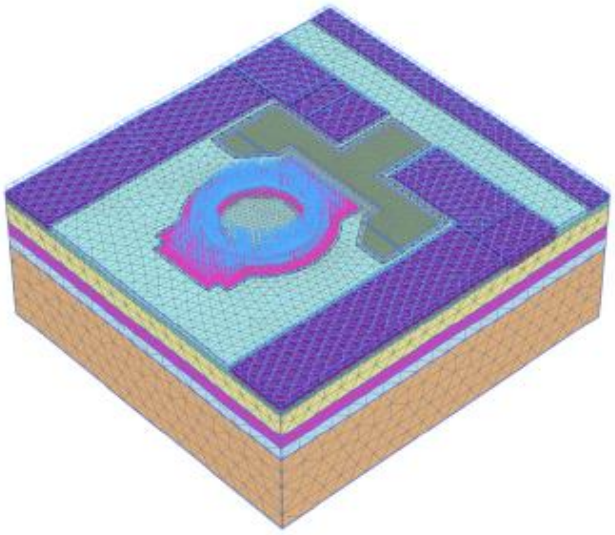

Figure 4. Geometry and mesh of the geotechnical model (PLAXIS 3D code).

3.3 Monitoring system

The project included a detailed monitoring plan, with an automatic remote acquisition system (KRONOS) to provide real-time information about the effects of construction activities. Precision levelling points were placed on the church structure and inclinometers were installed inside the retaining walls and in the soil behind (Figure 5).

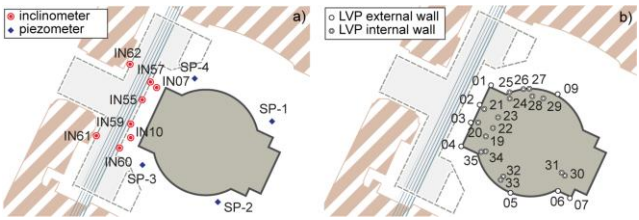

Figure 5. Monitoring system: a) inclinometers and piezometers; b) levelling points.

3.4 Evaluating the effects of construction

Settlement fields applied to the bottom nodes of the structural model of the church are shown in Figure 6. The reference stage is represented by the self-weight (SW) condition before the construction works. Predicted settlement field at the design stage (G1) was then applied, evaluating changes in stress and strain values.

During construction works, monitoring system recorded higher settlements than those predicted. Firstly, wall installation in front of the Church caused a maximum settlement of about 3 mm (KRONOS): a first correction to the applied settlement fields (G2) was thus considered, by adding to the actual settlement field recorded by measurements (KRONOS) the predicted settlement field induced by excavation stages. Furthermore, first excavation stages also gave rise to settlements of the church higher than those predicted. Considering the 'at time' available monitoring data compared to predictions, the settlement field obtained from numerical geotechnical analysis for the excavation stages was increased by a factor equal to 4, giving rise to the final settlement field (G3) used for BRA updating.

Maximum measured settlements of the church at the end of works were about 7 mm, in close agreement with the G3 displacement field used for BRA (Soccodato and Tropeano, 2021). It is worth noting that nearly one half of the total observed maximum settlement was due to retaining wall construction.

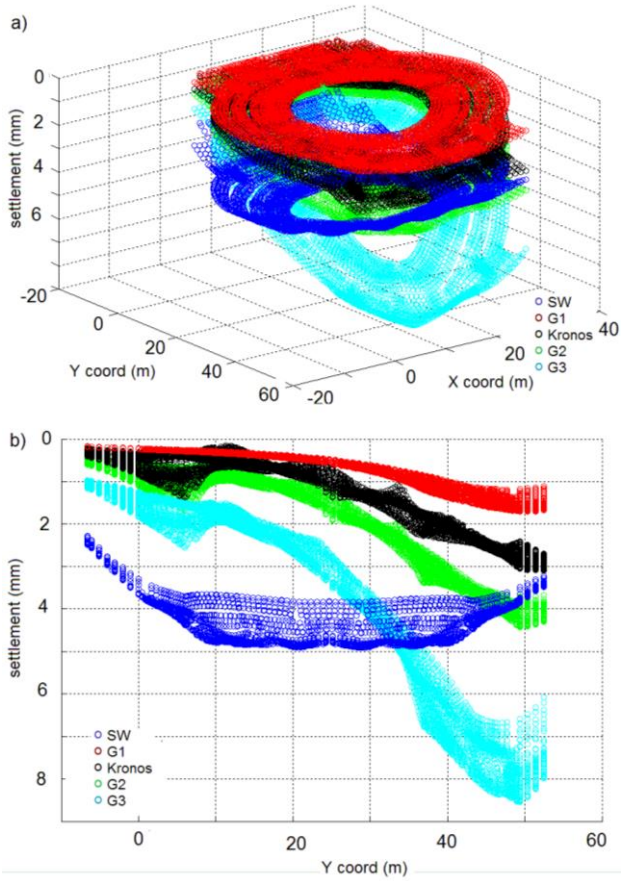

Figure 6. Foundation settlement fields used for BRA: a) 3D view; b) longitudinal view toward box station excavation.

As stated before, BRA was based on the comparison of stress and strain fields under different settlement fields, taking as reference the SW condition.

Figure 7 shows, as an example, the frequency distribution of principal tensile strain obtained from the structural model in the dome elements and in the inner structure. Maximum strain values are very small ($< 3 \cdot 10^{-4}$) and significantly lesser than those associated to 0.1 mm width cracks in masonry structures. Furthermore, changes (in value and frequency) due to construction works (both for G2 and updated G3 settlement fields) are quite limited, allowing for the

estimation of a negligible damage induced by the excavation.

Figure 8 shows the stress values for the inner structure, which allowed for a preliminary identification of the parts of the structure potentially affected by cracking.

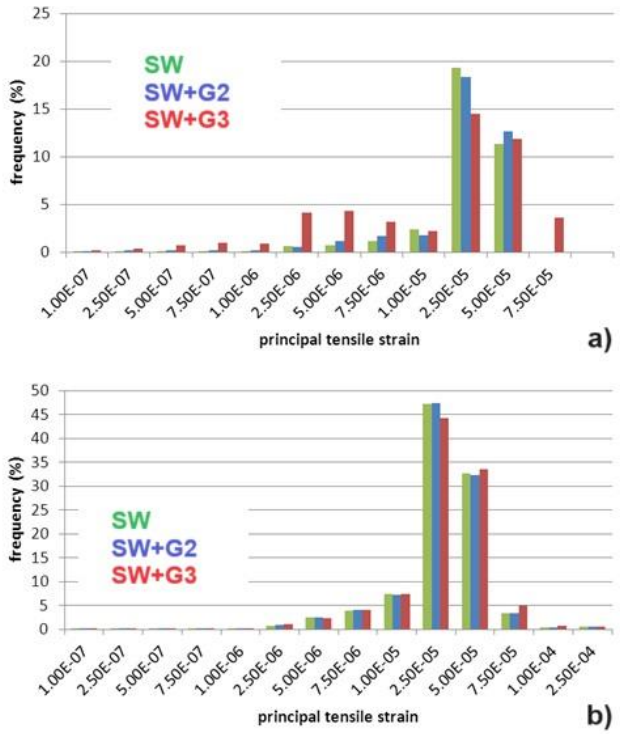

Figure 7. Distribution of principal tensile strain: a) in dome elements; b) in the inner structure (masonry).

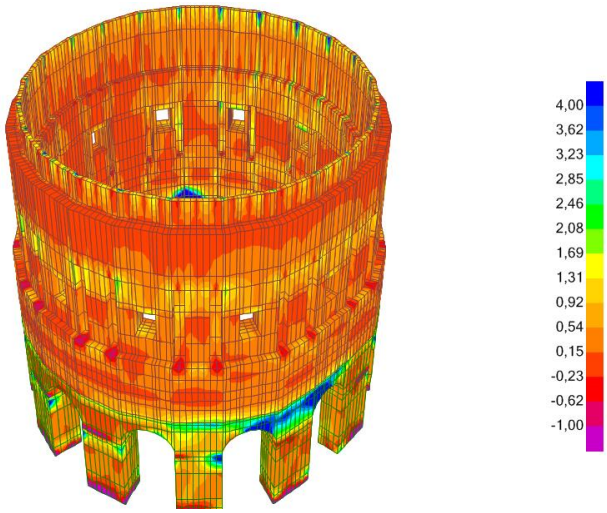

Figure 8. Inner structure, SW+G3 settlement field: maximum principal stresses (units: daN/cm², tensile if >0).

4 CONCLUSIONS

The Building Risk Assessment process carried out for MarmorKirken has been a very challenging task: archaeologist, structural and geotechnical engineers collaborated to define reliable models to be used in the evaluation of the excavation induced effects on the church. Negligible effects of construction activities on MarmorKirken were predicted at the design stage, as well as negligible damage appeared in MarmorKirken at the end of works. During construction, the real time automatic monitoring system allowed for successfully updating the Building Risk Assessment, pointing out the importance of real time measurements and of their interpretation in this kind of process.

Prediction model for strength of cement-stabilized clays for in-situ soil mixing using artificial neural network

Modèle de prédiction de la résistance des argiles stabilisées au ciment pour le mélange de sols in situ à l'aide d'un réseau neuronal artificiel

M. Swamynaidu*, A. Tyagi
Department of Civil Engineering, Indian Institute of Technology Roorkee, India,
**m_swamynaidu@ce.iitr.ac.in*

ABSTRACT: Unconfined Compressive Strength (UCS) is usually the design criterion for in-situ ground improvement projects, including deep soil mixing, mass soil stabilization, and cutter soil mixing. Unlike subgrade stabilization projects, such techniques involve cement-content as high as 50%. Thus, the paper intends to develop a prediction model for the strength of cement-stabilized clay from the laboratory test results performed on high-plastic illite clay. First, the UCS tests are performed for cement-content varying from 5% to 50% by dry weight, for two water-contents of 1.5 and 1.85 times the liquid limit (LL), and the curing time of 7, 28, and 90 days. Test results indicate that the UCS increases with the increase in curing time and cement-content while reducing with the increase in water-content. The prediction model for UCS is then developed using the artificial neural network (ANN), and the model performance is assessed based on root mean squared error (RMSE) and coefficient of determination (R^2). According to the multi-layer perceptron (MLP) approach, the developed model equation can be used to forecast the performance of the UCS for the given range of water-content, cement, and curing time. Relative importance shows that cement-content is the most significant parameter on UCS.

RÉSUMÉ: La résistance à la compression non confinée (UCS) est généralement le critère de conception pour les projets d'amélioration du sol in situ, y compris le mélange de sol en profondeur, la stabilisation massive du sol et le mélange de sol par coupe. Contrairement aux projets de stabilisation du sol de fondation, ces techniques impliquent une teneur en ciment pouvant atteindre 50%. Ainsi, l'article vise à développer un modèle de prédiction de la résistance de l'argile stabilisée au ciment à partir des résultats d'essais en laboratoire effectués sur de l'argile illite à haute plasticité. Tout d'abord, les tests UCS sont effectués pour une teneur en ciment variant de 5% à 50% en poids sec, pour deux teneurs en eau de 1,5 et 1,85 fois la limite de liquide (LL) et un temps de durcissement de 7, 28 et 90. jours. Les résultats des tests indiquent que l'UCS augmente avec l'augmentation du temps de durcissement et de la teneur en ciment, tout en diminuant avec l'augmentation de la teneur en eau. Le modèle de prédiction pour l'UCS est ensuite développé à l'aide du réseau neuronal artificiel (ANN), et les performances du modèle sont évaluées sur la base de l'erreur quadratique moyenne (RMSE) et du coefficient de régression (R). L'importance relative des variables d'entrée montre que la teneur en ciment influence l'UCS. Selon l'approche du perceptron multicouche (MLP), l'équation du modèle développée peut être utilisée pour prévoir les performances de l'UCS pour une plage donnée de teneur en eau, de ciment et de temps de durcissement.

Keywords: Deep soil mixing; mass soil stabilization; cement stabilization; UCS prediction model.

1 INTRODUCTION

Clayey soils are often characterized by low strength and high compressible characteristics. In situ ground improvement techniques viz. deep soil mixing (DSM), mass soil mixing (MSM), and jet grouting (JG) are often used to stabilise or reinforce these such problematic soils with the use of admixtures mostly by using ordinary Portland cement (OPC). The resulting improved ground produced by these techniques provides greater mechanical stability. The degree of enhancement depends on several factors, such as the type of in situ soil, in situ water-content, type of binder, curing time and conditions, etc. (Kitazume and Terashi, 2013). For such ground improvement projects, the design, quality control (QC) and quality assurance (QA) are mostly based on the UCS of cement-treated soil samples (Yohannes and Daramalinggam, 2019; BS EN 14679, 2005; Bruce et al., 2013). The prescribed design strength is often the minimum value of the field UCS obtained after testing the cement-treated soil samples (Liu et al., 2017). In recent years, nonlinear techniques such as ANN have been used successfully in the field of geotechnical engineering for e.g., to predict the UCS of cement-stabilized soil (Das et al., 2011), geopolymer-treated soil (Eidgahee et al., 2020; Maheela et al., 2023), and stabilized pond

ashes (Suthar, 2020). Eidgahee et al., (2020) and Maheela et al., (2023) reported that the ANN models can effectively improve the prediction of UCS of geopolymer-treated clayey soils. This approach has been convenient because it has acceptable nonlinear mapping capability and also prior expertise among input parameters is not required. However, the literature reporting the prediction models on UCS of cement-treated clays for in-situ mixing techniques with high cement content and longer curing periods is limited.

This study presents a laboratory investigation on UCS of cement-treated high plastic illite clay at different water-contents (1.5 LL and 1.85 LL), cement-contents (5-50%), and curing periods (7, 28, and 90 days). These mixing parameters are selected to those adopted for DSM, JG, and MSM ground improvement projects. Further, the UCS prediction model is developed using the nonlinear ANN with the Levenberg-Marquardt algorithm. The above mixing parameters are selected similarly to those adopted in DSM/MSM techniques.

2 TESTING MATERIALS AND SAMPLE PREPARATION

2.1 Materials used

The soil used in the present study is collected from a site near the Indian Institute of Technology (IIT) Roorkee, Uttarakhand, India. The soil has a liquid limit (LL) and plasticity index (PI) of 65% and 30%, respectively. As per the unified soil classification system (USCS), the soil is high-plasticity clay (CH). ASTM C150/150M type I ordinary Portland cement is used as the admixture.

2.2 Sample preparation

The method of sample preparation follows Tyagi et al., (2019). The high-plastic clay is soaked in water for about 2 days and then sieved through a 2 mm sieve to eliminate the unwanted waste. The clay slurry is then mixed in an electronic bowl mixer with a prescribed water-content of 1.5 and 1.85 times LL. The calculated amount of cement and distilled water are mixed in an electronic bowl mixer to obtain cement slurry for a given mix-ratio. This cement slurry is then mixed with the clay slurry in an electronic bowl mixer for not more than 10 minutes. After mixing, the final clay-cement slurry is poured into polyvinyl chloride (PVC) cylindrical molds of diameter and height of 50 mm × 100 mm for performing UCS tests at specified curing days. The moulds are placed horizontally submerged in a water tub at room temperature (27±3ºC). Table 1 presents the mix ratios for the present study.

Table 1. Mix ratios.

Mix ratio (s:c:w)	**cement (%)**	**water-content (%)**	**w/c**	**curing time (days)**
20:1:21	5		21	
10:1:11	10		11	
5:1:6	20		6	
10:3:13	30	(1.5 LL)*	4.33	
10:4:14	40		3.5

10:3:15.6	30	(1.85 LL)	5.2	
10:4:16.8	40		4.2	
2:1:3.6	50		3.6	

*Test data reported from Swamynaidu and Tyagi (2024).

2.3 Test methodology

2.3.1 Unconfined compressive strength (UCS)

UCS tests following the ASTM, 2013: D2166/D2166M are performed to determine the UCS of different soil:cement:water (s:c:w) ratios. The samples are loaded under compression at a fixed vertical displacement rate of 1 mm/minute. Five samples are tested for each mixing ratio, and the average UCS is reported for each mix ratio.

2.4 ANN model development

Figure 1 illustrates the architecture of ANN with the selected inputs, number of hidden layers, and output. In the present study, Out of 36 UCS observations, 25 and 11 UCS observations are used for training and testing the model, respectively. Backpropagated neural network is trained with the Levenberg-Marquardt algorithm, which is more efficient than the gradient descent algorithm (Maheela et al., 2023). For the best performance, tan-sigmoid and purelin activation functions are selected for the single hidden and output layer. The neurons in the hidden layer is chosen by trial and error until the optimum performance. All the input and output parameters are normalized in the range of -1 to 1 before training the database.

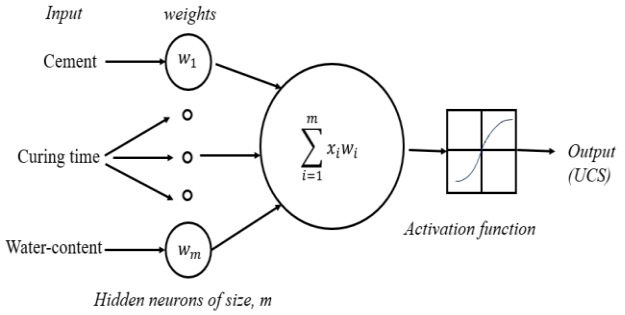

Figure 1. Showing the architecture of the ANN model.

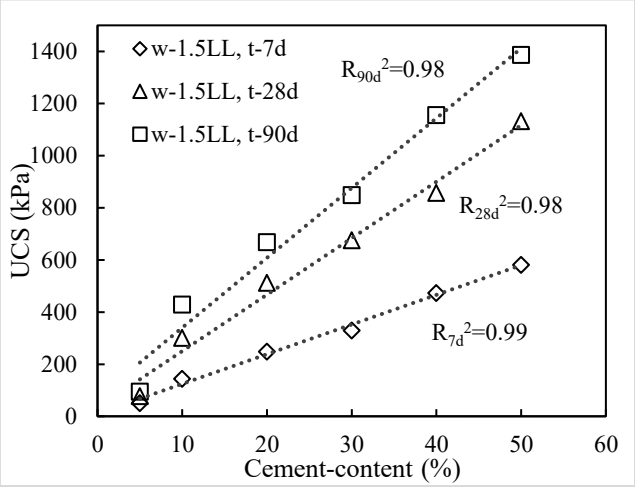
3 RESULTS

3.1 UCS

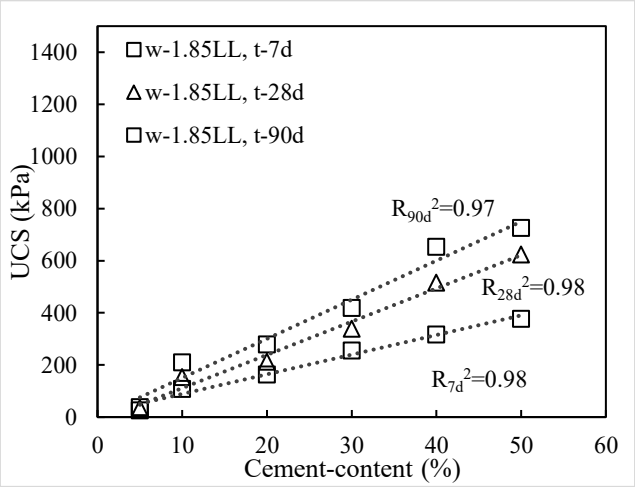
3.1.1 Effect of cement-content differentiated by water-content and curing time

Figure 2a and 2b show the variation of obtained UCS with the water-content and cement-content after 7, 28, and 90 days of curing. The lower the water-content higher the UCS, and the extent of UCS improvement is considerably dependent on the curing time and cement (%). Figure 2(a and b) show approximately a linear variation with the increase in cement-contents irrespective of curing times and consistent with the findings of Tan et al., (2002) and Chew et al., (2004). It is seen that there is a gradual increase in UCS for a lower cement-content of 5%; however, with the increase in cement-content, a sharp increase in UCS was evident. In contrast, for a water-content of 1.85 LL, shown in Figure 2(b), the trend of increase was relatively less compared to Figure 2(a). This indicates the effective network of reactive products viz. calcium silicate hydrate (CSH) and calcium alumina silicate hydrate (CASH) for a water-content of 1.5 LL that interlocks the clay and cement grains together in the presence of water, resulting in enhanced strength over curing time. Despite this, the low UCS observations for a water-content of 1.85 LL over time were probably with the aid of weaker fabric and inconsequential cementitious reactions. As a result, more interaggregate pores are left unfilled.

Further, with increased curing time, UCS was significantly increased except for 5% of cement-content. As seen in Figure 2a and 2b for 50% of cement-content, UCS_{7d}, UCS_{28d}, UCS_{90d} were 581.27 kPa, 1132.75 kPa, and 1386.96 kPa and 377.8 kPa, 623.6 kPa, and 726.55 kPa with a water-content of 1.5 and 1.85 LL, respectively. As hydration proceeds, the resulting reactive products (principally CSH) accumulate into the void spaces, consequently causing a higher increment in UCS. Nonetheless, the rate of change in UCS was moderate after 28 days, meaning that pozzolanic reactions or hardening continued at a slower rate. Therefore, the increment in UCS reflects the structure of the treated matrix for a specified curing time.



(a)



(b)

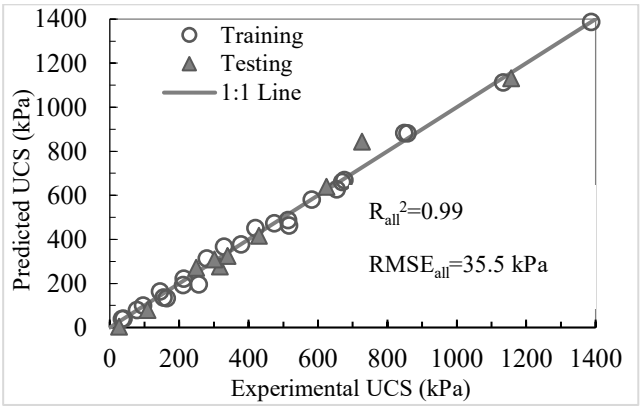
Figure 2. Showing the variation of UCS (a) 1.5 LL (Swamynaidu and Tyagi, 2024) (b) 1.85 LL.

3.1.2 ANN model

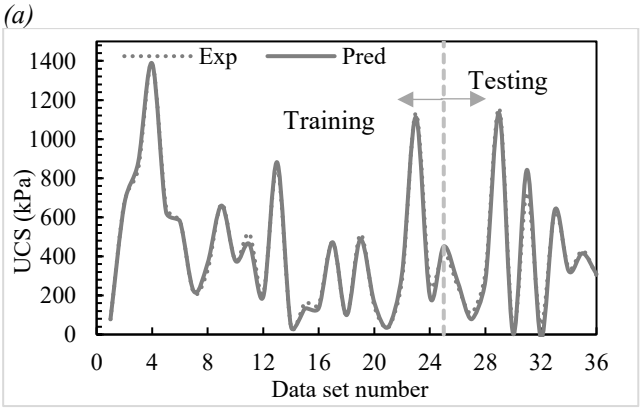
In the present study, cement-content, water-content, and curing time are considered as input variables to predict the UCS of cement-treated illite clay. Out of 36 data records, 70% and 30% are used for training and testing, respectively. After trial and error, three neurons in the single hidden layer are opted, for which the strong performance statistics (lowest RMSE and highest R^2) are achieved. Figure 3a shows the strong correlation between the predicted and experimental UCS for the training and testing databases. The performance of the model is evaluated by statistical indices such as RMSE and R^2. It is observed that the RMSE and R^2 for training and testing are 25 kPa and 0.99 and 46 kPa and 0.98, respectively.

Further, $RMSE_{all}$ and R_{all}^2 for the ANN model (32.9 kPa and 0.99) show better than the multilinear regression model (148.5 kPa and 0.84) for the same input parameters. Figure 3b compares predicted and experimental UCS to assess the reliability of the developed ANN model. Additionally, the prediction equation for UCS using connection weights is presented in eq. 1 to 1.9;

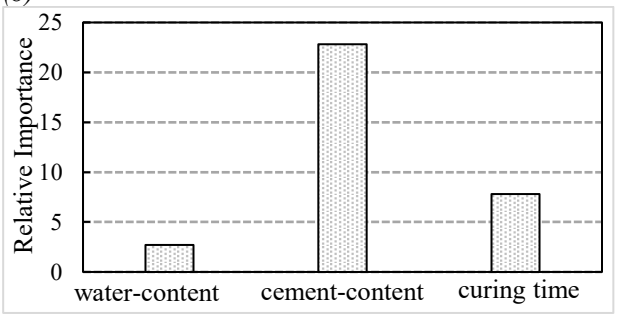
The relative importance is determined using the connection weights approach (Goh 1994; Duong and Tran 2023). Figure 3c shows the relative importance of each input variable on UCS. Accordingly, cement-content is found to be the most influential input variable, followed by curing time and water-content on the UCS. This is consistent with the experimental observations explained in the previous section 3.1.1.



(a)



(b)



(c)

Figure 3. (a) Plot of experimental vs measured UCS for training and testing (b) comparison of experimental and predicted UCS (c) relative importance on UCS.

$$UCS_{(n)} = b_k + \sum_{j=1}^{3}\left[w_{jk} \times tansig\left(\sum_{i=1}^{m=3} w_{ij}x_i + b_j\right)\right] \quad (1)$$

$$p_1 = -5.3-0.29w-4.68c+0.20t \quad (1.1)$$

$$p_2 = -0.68-0.22w+0.46c+0.12t \quad (1.2)$$

$$p_3 = 3.59+0.27w-0.49c+2.49t \quad (1.3)$$

$$q_1 = -0.50 \times \frac{(e^{x1}-e^{-x}1)}{(e^{x1}+e^{-x}1)} \quad (1.4)$$

$$q_2 = 1.85 \times \frac{(e^{x2}-e^{-x2})}{(e^{x2}+e^{-x2})} \quad (1.5)$$

$$q_3 = 1.16 \times \frac{(e^{x3}-e^{-x3})}{(e^{x3}+e^{-x3})} \quad (1.6)$$

$$r_1 = -0.89+y_1+y_2+y_3 \quad (1.7)$$

$$UCS_n = r_1 \quad (1.8)$$

$$UCS_p = 0.5 \times (UCS_n + 1)(UCS_{max} + UCS_{min}) + UCS_{min} \quad (1.9)$$

where w_{jk} and w_{ij} are the connection weights among the input, hidden, and output layer, b_j and b_k are the biases of the hidden and output layer, tansig is the transfer function, w is water content, c is cement content, t is curing time, UCS_p is predicted UCS, UCS_n is normalized UCS, and UCS_{max} and UCS_{min} are the maximum and minimum UCS of the experimental database.

4 CONCLUSION

The study presents the UCS test results of cement-treated high plastic illite clay at different water-contents (1.5 LL and 1.85 LL), cement-contents (5-50%), and curing periods (7, 28, and 90 days). UCS at different curing times increased with decreased water-content and an increase in cement-content, and this was because of the development of more reactive products over hydration and pozzolanic activity. ANN model equation for UCS is presented as per connection weights approach. However, it should be noted that the RMSE values for both training and testing showed higher values for the ANN model, which is attributed to the lower experimental database. The developed ANN model and findings have important applications, where the field operating variables can be selected to

achieve the design UCS for JG/DSM/CSM projects in the absence of a test database. Further, considering more database and other nonlinear techniques, such as support vector regression, random forest, Gaussian process, and others may be used for future studies to improve the test observations and to select the best model for strength prediction.

ABSTRACT: This paper discusses technical aspects of the experimental setup and calibration processing during centrifuge testing of single piles, instrumented with fibre Bragg grating (FBG) strain sensors, under vertical loads. Results illustrate the influence of the pile head connection method and data processing/correction of FBG readings. First, experimental data demonstrate issues encountered when adopting a rigid connection between a loading device, and how these can be tackled by adopting a point-to-surface contact. Second, the paper presents a method to minimise, in FBG strain sensor data, issues relating to pile bending during routine compression calibration and centrifuge testing.

RÉSUMÉ: Cet article aborde les aspects techniques de la configuration expérimentale et du traitement de la calibration lors des essais en centrifugeuse de pieux simples, instrumentés avec des capteurs de contrainte à réseaux de Bragg en fibre optique (FBG), sous des charges verticales. Les résultats illustrent l'influence de la méthode de connexion de la tête de pieu et du traitement/correction des données des capteurs FBG. Tout d'abord, les données expérimentales mettent en évidence les problèmes rencontrés lors de l'adoption d'une connexion rigide entre un dispositif de chargement, et comment ceux-ci peuvent être résolus en adoptant un contact ponctuel avec la surface. Ensuite, l'article présente une méthode pour minimiser, dans les données des capteurs de contrainte FBG, les problèmes liés à la flexion du pieu lors de la calibration de compression de routine et des essais en centrifugeuse.

Keywords: Centrifuge; pile; calibration; fibre Bragg grating (FBG).

1 INTRODUCTION

Geotechnical centrifuge testing is extensively used for modelling axial loading and force transfer mechanisms of piles in various scenarios, including external loading and during excavations. The configuration and calibration of model piles are crucial to ensure the reliability of the measured pile axial force.

Researchers have used a variety of methods to apply external loads to a pile head, such as fixing dead weights (Loganathan et al., 2000), or using mechanical load actuators (Song et al., 2022). The use of a rigid connection between the pile head and the load actuator components has advantages with respect to pile-load alignment and the ability to apply both driving and pulling forces to the pile. This method may, however, cause bending of the pile and/or experimental errors at the attached load cell.

FBG sensors can be used to measure strains/loads within structural elements in centrifuge tests (Li et al., 2020; Song et al., 2022). Song et al. (2022) incorporated embedded FBGs to measure pile axial force F_i using its positive correlation with FBG wavelength shift $\Delta\lambda_{B_i}$ at particular FBG strain sensors B_i (Figure 1(a)). FBG strain sensors are not affected by electrical noise and their size (diameter of 0.22 mm) makes them ideal for being glued inside hollow model piles for force measurement.

This paper presents data from a recent centrifuge modelling study concerning tunnel-pile interactions. The effect of two actuator-pile connection methods is examined first; an improved calibration method for FBG strain sensors placed inside model piles prior to and during centrifuge tests is proposed.

2 CENTRIFUGE TEST SETUP

Tests were conducted at 60 g within the 2 m radius, 50 g-tonne NCG centrifuge. Dry Leighton Buzzard Fraction E sand (0.14 mm average diameter, 1.58 uniformity coefficient, 2.65 specific gravity, 1.01/0.61 maximum/minimum void ratio, 90% relative density) and an eccentric rigid boundary mechanical tunnel model (90 mm diameter, 180 mm cover depth, 225 mm buried depth; Song et al., 2022) were adopted. The 60 g level was applied at half the tunnel's burial depth, i.e. 113 mm from the surface. The pile models, made of aluminium tube, have a 12.6 mm outer diameter (including a 0.3 mm thick layer of sand bonded to the shaft to get a rough shaft-soil interface), 9.3 mm inner diameter, and 150 mm length below the surface. Pile models were pushed vertically into the sand at 1 g using guides after the sand was prepared. The pile head load was applied by a stepper motor driven actuator during tests. FBGs were fixed on the smooth inner wall of the pile models using superglue (Figure 1). A "dummy pile" with similar specifications but with temperature sensors located inside was buried used to obtain data for temperature compensation of the FBGs.

The centrifuge test configuration represents a full-scale prototype scenario of 0.756 m diameter and 9 m deep piles located above/adjacent to a 5.4 m diameter tunnel with a 10.8 m cover depth.

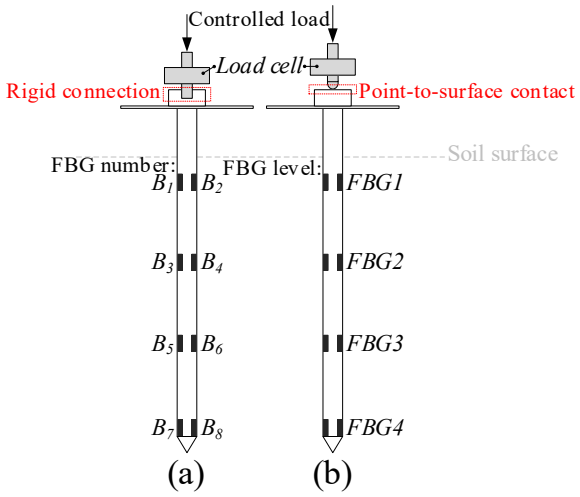

Figure 1. Diagrams of (a) rigid connection and (b) point-to-surface contact between load cell and pile head.

3 EXPERIMENTAL RESULTS

3.1 Influence of the connection at the pile head

Figure 1 illustrates the standard model piles, as well as the two types of connection methods between the pile head and the load cell above it: a "rigid connection", where the lower part of the load cell is threaded onto the pile head, and a "point-to-surface contact", where a hemispherical base of the lower part of the load cell makes contact with the top plane of the pile head. The upper end of both load cells is threaded to the loading device above, delivering only vertical force. Figure 2(a) shows the difference in pile axial forces for the two FBG sensors at each level (i.e. $\Delta F = F_i - F_{i+1}$, where i and $i+1$ refer to the FBGs on opposite faces, Figure 1(a)). The discrepancy in axial force serves as an indicator of the magnitude of pile bending.

The rigid connection increased the pile bending. In contrast, the point-to-surface contact reduced the force difference ΔF compared with the rigid connection. Whilst in theory using the average FBG readings of the two sensors on opposite faces should still provide an accurate measurement of axial force, this relies on precise positioning and alignment of the sensors, which is difficult to achieve in practice. Figure 2(b) shows that the point-to-surface contact tended to give higher FBG load readings (also described later).

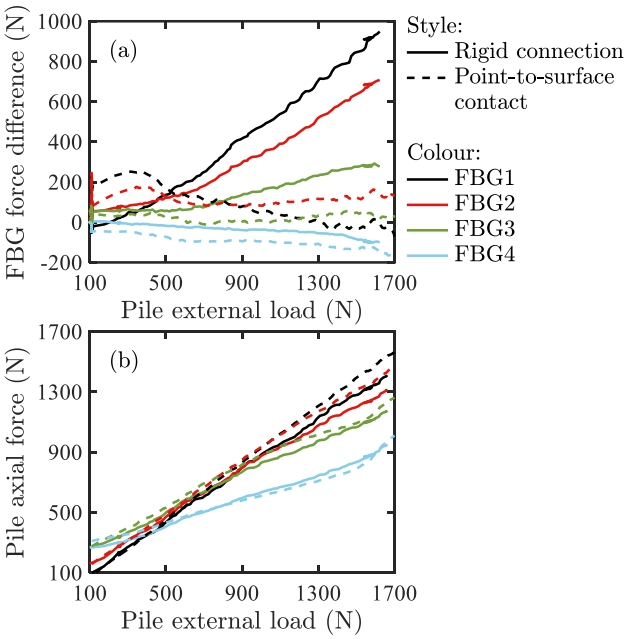

Figure 2. (a) FBG force difference between opposite positions at same level and (b) pile axial force with rigid connection and point-to-surface contact during loading.

3.2 FBG strain sensor calibration

In this paper, the axial force along the pile N_j is inferred from the average wavelength shift $\Delta\lambda_{FBG_j}$ of two FBGs at the same level (at FBG_j, Figure 1(b)) as:

$$N_j = K_{FBG_j}(\Delta\lambda_{FBG_j} - \Delta\lambda_{T_j}) + \Delta N_{exp} \quad (1)$$

where j is the FBG level reference number, K_{FBG_j} (in N/pm, pm=picometre) is FBG calibration coefficient,

$\Delta\lambda_{T_j} = K_t\,\Delta T$ is the temperature-induced wavelength offset proportional to the change in temperature ΔT by a factor K_t = 32-41 pm/°C estimated for no mechanical strains, and ΔN_{exp} is an offset introduced during centrifuge testing to correct for the disturbance resulting from the loading system. $\Delta\lambda_{T_j}$ and ΔN_{exp} are zero during K_{FBG_j} calibration tests performed at constant temperature.

3.2.1 Coefficient calibration

Table 1 shows the range, mean, and standard deviation (STD) of K_{FBG} from five sets of routine lab compression tests at 1 g within a standard loading frame (Lab C, two cycles from 0-600-0 N with an increment of ±100 N; a small cylindrical aluminium block with a conical groove matching the shape of the pile tip provides a surface for loading), two sets of compression tests using a loading/fixing system that fits on the centrifuge done at both at 1 g and 60 g (Cen 1 g, Cen 60 g, as above), and seven lab tension tests at 1 g (Lab T, from 0-200-0 N with an increment of ±20 N). After each cycle of loading-unloading, the position of the pile was altered through translation and/or rotation.

Table 1. FBG calibration coefficients from lab compression (C), centrifuge compression, and lab tension (T) tests.

		FBG1	FBG2	FBG3	FBG4
Lab C	K_{FBG}	2.5-2.6	2.5-2.6	2.5-2.6	2.4-2.6
	Mean	2.53	2.54	2.57	2.52
	STD	0.048	0.052	0.024	0.064
Cen 1 g	K_{FBG}	2.6-2.7	2.7-2.8	2.7-2.8	2.8-2.9
	Mean	2.63	2.74	2.71	2.83
	STD	0.016	0.043	0.043	0.090
Cen 60 g	K_{FBG}	~2.6	~2.7	2.6-2.7	2.7-2.8
	Mean	2.59	2.70	2.66	2.73
	STD	0.022	0.040	0.037	0.044
Lab T	K_{FBG}	2.3-3.0	2.5-2.7	2.5-2.8	/
	Mean	2.62	2.54	2.62	/
	STD	0.229	0.070	0.080	/

The deviation in 1-g lab compression coefficient K_{FBG} is likely caused by pile bending due to misalignment within the loading frame, despite attempts to reduce its effects. Overall, the values of lab compression coefficient K_{FBG} are stable and satisfactory, supported by the results of the centrifuge and tension tests discussed below.

Next, the centrifuge compression coefficient K_{FBG} under 1-g and 60-g levels are discussed. K_{FBG} at 60 g was slightly smaller (by ~2.1% on average) than the results obtained at 1 g (conducted prior to and after the 60 g tests, without adjusting any components), which implies a slight (and acceptable) overestimation of the pile axial force when using K_{FBG} from 1 g lab compression tests.

To minimise the effect of pile bending on K_{FBG}, lab tension tests were performed. The pile was fixed at the top and weights were hung from the pile via a clamp that was attached to the pile base, close to FBG4 (thus, FBG4 readings are unreliable). Neglecting the outliers for FBG1, $K_{FBG_{1-3}}$ are consistent with the compression results.

3.2.2 Offset at elevated gravity

The tunnel-pile interaction tests included "stabilisation cycles" in which the centrifuge was repeatedly spun up/down to achieve a more uniform stress distribution within the soil and at soil-structure interfaces, and ensuring consistency between tests (Song et al., 2022).

To minimise deviations in FBG readings due to misalignments and bending, $\Delta N_{exp} = \Delta N_{exp,1} + \Delta N_{exp,2}$ in Eq. (1) is estimated for each test in two steps: (i) $\Delta N_{exp,1}$ is estimated during the stabilisation cycles of a specific centrifuge test as the difference between the readings of FBG1 at 15 mm beneath the surface and the theoretical axial load at the surface (neglecting the shaft friction between FBG1 and the soil surface); next, (ii) $\Delta N_{exp,2}$ is a constant for the instrumented pile estimated at a given g-level in centrifuge calibration tests without soil to account for the (minor) effects of the self-weight of FBG sensors and the glue covering them when g-level is increased.

Figure 3 illustrates the uncorrected changes in pile axial forces (when $\Delta N_{exp} = 0$) in two centrifuge tests during stabilisation cycles from 1-60-10-60-10-60 g. Two scenarios are included: subplot (a) for a pile positioned directly above the tunnel; subplot (b) for a pile located 150 mm away from the tunnel centreline ("no tunnel"). The pile axial forces showed good repeatability subsequent to the first spin-up to 60 g. Specifically, in Figure 3(a)-(b), the axial force at FBG1 was 15/-30 N at the 1st 10 g, whereas it was 2/-60 N for the subsequent 2nd and 3rd 10 g.

In these tests, the "theoretical surface load" (i.e. theoretical pile load at the soil surface) is equal to 22 N and 110 N at 10 g and 60 g respectively: e.g. at 60 g it consists of 105 N from the self-weight of the components above the soil surface (adjusted for distance from centre of rotation of the centrifuge) and a constant load of 5 N applied by the stepper motor (controlled load in Figure 1).

The FBG correction of $\Delta N_{exp,1}$ = 20 N and 82 N were estimated, respectively, at the last spin-down to 10 g in Figure 3(a)-(b), so that the FBG1 load matched the theoretical surface load of 22 N. Note that $\Delta N_{exp,1}$

estimated for FBG1 is applied to all other FBG loads while considering $\Delta N_{exp,2} = 0$.

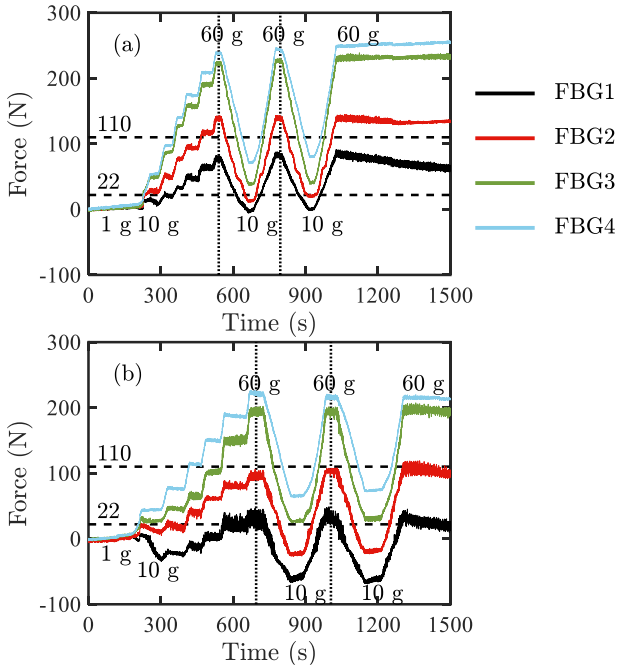

Figure 3. Changes in pile axial forces during centrifuge spin up/down for pile (a) above tunnel and (b) no tunnel.

Next, $\Delta N_{exp,2}$ is added to measurments at the end of the spin-up (or stabilisation cycles) once the final target 60 g is reached. This second offset $\Delta N_{exp,2}$ was estimated, at each FBG location, from the difference between the measured average pile axial forces and the theoretical pile self-weight in two calibration centrifuge tests at N-g without soil (while assuming $\Delta N_{exp,1} = 0$); as shown in Figure 4, $\Delta N_{exp,2}$ is within the range of 1-33 N, which is relatively small compared with the pile load capacity measured in centrifuge tests at 60 g (~1.6 kN, including base load and shaft friction).

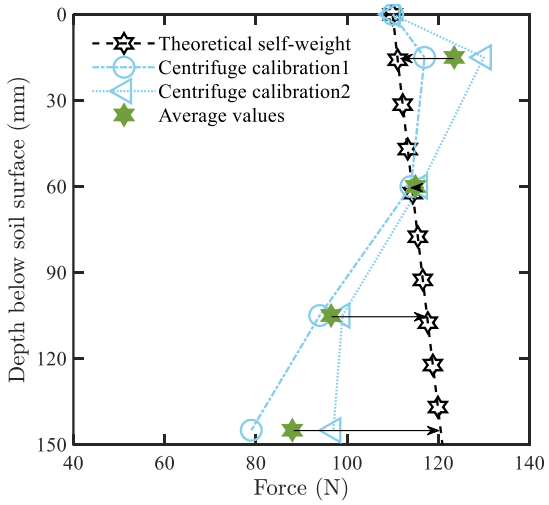

Figure 4. Pile axial force offset at 60 g

4 CONCLUSIONS

This paper summarised some "lessons learned" from recent centrifuge testing of FBG-instrumented model piles under vertical loads at the University of Nottingham Centre for Geomechanics (NCG). The following main conclusions can be drawn.

(1) The point-to-surface contact between the load actuator and pile head reduced errors in measurement of axial forces with respect to a rigid actuator-pile connection, as point-to-surface contact minimises pile bending from the misalignment between the load actuator and model pile.

(2) A systematic FBG calibration method for measuring pile axial force was applied: i) determine the calibration coefficient K_{FBG} between the axial force along pile centreline and the average wavelength shifts of two FBG strain sensors on opposite sides at the same pile level; ii) assign the theoretical load values to easily evaluated FBG positions at a stable small g-level before reaching the target gravity as a reference for correcting all pile axial forces; iii) correct the pile axial force again at the target gravity based on the deviation between the measured pile axial force in the absence of soil and the theoretical axial force from the pile self-weight. This method effectively reduces the effects of pile bending, soil movement, superglue and FBG self-weight, and other potential sources of error in the data processing.

Finite element simulation of biocement precipitation in soils

Simulation par éléments finis de la précipitation de biociment dans les sols

ABSTRACT: Microbially induced calcite precipitation is a soil reinforcement technique where bacteria are used to produce calcium carbonate, precipitated after the hydrolysis of urea promoted by the enzyme urease present in the microorganisms. This biocement clogs the soil pores and bonds its grains, increasing the soil strength and stiffness and decreasing its permeability. A two-phase porous medium model is created to analyse the precipitation process, where each phase has several species. The solid phase is composed by soil particles, bacteria and calcite while the fluid phase contains water, urea and other dissolved species that are present in the biochemical reaction. A finite element formulation embodying water seepage, advective diffusion of species and soil deformation is proposed to compute the generation of solid mass (the biocement), and a numerical simulation is presented to analyse the process under a given set of boundary conditions.

RÉSUMÉ: La précipitation de calcite induite par les micro-organismes est une technique de renforcement des sols dans laquelle des bactéries sont utilisées pour produire du carbonate de calcium, précipité après l'hydrolyse de l'urée promue par l'enzyme uréase présente dans les micro-organismes. Ce biociment obstrue les pores du sol et lie ses grains, entraînant une augmentation de la résistance et de la rigidité du sol et une diminution de sa perméabilité. Un modèle d'un milieu poreux à deux phases est créé pour analyser le processus de précipitation, où chaque phase est composée de plusieurs espèces. La phase solide est constituée de particules de sol, de bactéries et de calcite, tandis que la phase fluide contient de l'eau, de l'urée et d'autres espèces dissoutes présentes dans la réaction biochimique. Une formulation d'éléments finis incorporant l'écoulement d'eau, la diffusion advective des espèces et la déformation du sol est proposée pour calculer la génération de masse solide (le biociment), et des simulations numériques sont présentées pour analyser le processus sous certaines conditions aux limites.

Keywords: Chemo-hydro-mechanical coupled model; microbially-induced calcium carbonate precipitation; biocementation.

1 INTRODUCTION

Biocementation, also referred as microbially-induced calcite precipitation (MICP), is a ground improvement technique that involves the use of microorganisms (such as bacteria, and micro-algae) to precipitate calcium carbonate ($CaCO_3$) in the predominant form of calcite. This mineral precipitates subsequent to the urea ($CO(NH_2)_2$) hydrolysis by the urease enzyme present in the microorganisms, according to (1), and in the presence of a calcium source supplied in the feeding solution (2):

$$CO(NH_2)_{2\,(aq.)} + 2H_2O_{(l)} \xrightarrow{\text{urease}} 2NH_{4\,(aq.)}^{+} + CO_{3\,(aq.)}^{2-} \quad (1)$$

$$Ca_{(aq.)}^{2+} + CO_{3\,(aq.)}^{2-} \rightarrow CaCO_{3\,(s)}. \quad (2)$$

This research presents a chemo-hydro-mechanical coupled finite element model developed to predict precipitated calcite content in soils during biocementation and subsequent changes on soil's hydromechanical properties. The need for such type of models is justified by the fact that biocementation processes must be simulated in order to help predicting the improvement achieved with this treatment.

The formulation developed encompasses: (i) hydrogeologic aspects, as in (van Wijngaarden et al., 2011), (Minto et al., 2019) and (Faeli et al., 2023), addressing only diffusion couplings that involve water seepage and water advective diffusion of ionic species, and (ii) geomechanical aspects, as in (Fauriel and Laloui, 2012), that address hydromechanical couplings and where soil deformation is accounted for.

2 FORMULATION

A two-phase porous media is considered (assuming full saturation), where each phase has several species. The solid phase (S) contains soil particles and bacteria, denoted by symbol (s) and calcite (c). In this model, calcite is the only calcium carbonate morphotype that is considered as resulting product of the ureolysis induced calcium carbonate precipitation process. The fluid phase (W) contains water (w), urea (u), and ions calcium (Ca), chloride (Cl), and amonium (a).

The main hypotheses of the model are: (i) mass balance is required for each species; (ii) momentum balance is required for the porous medium as a whole; (iii) species in the fluid phase are endowed with their own velocities, being the velocity of the species in the solid phase equal to the velocity of that phase ($\mathbf{v}_{k\mathrm{S}} = \mathbf{v}_{\mathrm{S}}, k \in$ S); (iv) the urea hydrolysis reaction creates bicarbonate and ammonium ions; and (v) calcium and bicarbonate ions in the fluid phase precipitate forming calcite in the solid phase.

2.1 Mass balance of the species

The conservation mass law of the species can be written as (Loret and Simões, 2017):

$$\frac{\mathrm{d}^k \rho^{kK}}{\mathrm{d}t} + \rho^{kK}\,\mathrm{div}(\mathbf{v}_{kK}) = \hat{\rho}^{kK}, \qquad (3)$$

where the suffix kK is a designation for the species k in phase K; $\mathrm{d}^k/\mathrm{d}t$ is the derivative following the particles of the species k, $\rho^{kK} = M_{kK}/V$ is the apparent density of the species, M_{kK} is the mass of the species, V is the total volume of the porous medium, $\mathbf{v}_{kK}$ is the velocity of the species, and $\hat{\rho}^{kK}$ is the rate of mass of the species per unit volume that is created or lost during the reactions. Eq. (3) can be alternatively written as (Loret and Simões, 2017):

$$\frac{\mathrm{d}v_{kK}}{\mathrm{d}t} + \mathrm{div}(\mathbf{J}_{\mathrm{kK}}) = \frac{\hat{m}^{kK}}{\rho_k}, \qquad (4)$$

where $\mathbf{J}_{kK} = n_{kK}(\mathbf{v}_{kK} - \mathbf{v}_{\mathrm{S}})$ is the flux of the species through the solid skeleton, $v_{kK} = V_{kK}/V_0$ is the volumetric content of the species, $n_{kK} = V_{kK}/V$ is the volume fraction of the species, V_{kK} is the volume of the species, ρ_k is the intrinsic density of the species, V_0 is the initial volume of the porous medium and $\hat{m}^{kK} = \hat{\rho}^{kK}\det\boldsymbol{F}$.

Summing (4) for all the species $k \in$ W and for all the species $k \in$ S, and since $\frac{\mathrm{d}}{\mathrm{d}t}(\sum_{k\in\mathrm{W}} v_{k\mathrm{W}} + \sum_{k\in\mathrm{S}} v_{k\mathrm{S}}) = \mathrm{div}(\mathbf{v}_{\mathrm{S}})$, it is possible to obtain a global equation of mass balance:

$$\mathrm{div}(\mathbf{v}_{\mathrm{S}}) + \mathrm{div}(\mathbf{J}_{\mathrm{W}}) = \sum_{k\in\mathrm{W}} \frac{\hat{m}^{k\mathrm{W}}}{\rho_k} + \sum_{k\in\mathrm{S}} \frac{\hat{m}^{k\mathrm{S}}}{\rho_k}, \qquad (5)$$

where $\mathbf{J}_{\mathrm{W}} = \sum_{k\in\mathrm{W}} \mathbf{J}_{k\mathrm{W}}$ is the flux of water. The rates of mass created or lost during the reactions are defined by:

$$\frac{\hat{m}^{k\mathrm{W}}}{\rho_k} = v_k^{(M)} n_w m_k r, \qquad (6)$$

where $v_k^{(M)}$ is the molar volume of the k species, n_w is the porosity of the medium, m_k is the stoichiometric constant for the k species (according to (1) and (2), m_{u}=-1, m_{a}=2, m_{Ca}=-1, m_{Cl}=-1 and m_{c}=1) and r is the reaction rate for calcite precipitation.

The reaction rate for both urea hydrolysis and calcite precipitation, according to the Michaelis-Merten kinetics, is defined as in (van Wijngaarden et al., 2011):

$$r = v_{máx}\frac{C_{u\mathrm{W}}}{K_m + C_{u\mathrm{W}}}\left(1 - \frac{t}{t_{max}}\right), \qquad (7)$$

where $v_{máx}$ and K_m are constants that dictate, respectively, the maximum velocity of the reaction and the half-saturation of the medium, and t_{max} represents the bacteria lifespan.

The rate of loss of urea mass is equal to the sum of the rate of creation of bicarbonate and ammonium ions $\left(-\hat{m}^{uW} = \hat{m}^{bW} + \hat{m}^{aW}\right)$, and the rate of precipitation of calcite mass is equal to the sum of the rate of loss of calcium and bicarbonate ions ($\hat{m}^{cS} = -\hat{m}^{CaW} - \hat{m}^{bW}$). Although bicarbonate ions are involved in the reactions, bicarbonate concentration is not a part of the model since the mass that is formed during urea hydrolysis immediately precipitates when calcite is formed.

2.2 Global balance of linear momentum

The global equation for the balance of the linear momentum is given by:

$$\mathrm{div}(\boldsymbol{\sigma}) + \rho\mathbf{g} = 0\,, \tag{8}$$

where $\boldsymbol{\sigma} = \boldsymbol{\sigma}' - P_{\mathrm{w}}\mathbf{I}$ is the total stress tensor, $\boldsymbol{\sigma}'$ is the effective stress tensor, P_{w} is the pore-water pressure (the negative sign is introduced as it is a general convention to take tensile components of stress as positive (Zienkiewicz et al., 1999)), $\mathbf{I}$ is the identity matrix, $\mathbf{g}$ is the gravity acceleration and $\rho = \sum_{k\in \mathrm{W,S}} \rho^{kK}$.

2.3 Diffusion of the ionic species

The diffusive flux of the ionic species $\mathbf{J}^{\mathrm{d}}_{k\mathrm{W}} = n_{kW}(\mathbf{v}_{k\mathrm{W}} - \mathbf{v}_{\mathrm{wW}})$ is defined by Fick's law as:

$$\mathbf{J}^{\mathrm{d}}_{k\mathrm{W}} = -v_k^{(M)} n_w \mathbf{D}\cdot\boldsymbol{\nabla} C_{k\mathrm{W}}\,, \tag{9}$$

where $\mathbf{D}$ is the diffusion matrix and $C_{k\mathrm{W}}$ is the concentration of the *k* species in the water phase.

2.4 Water phase flux

Water flow is governed by Darcy's law:

$$\mathbf{J}_{\mathrm{w}} = -\mathbf{k}\cdot(\boldsymbol{\nabla} P_{\mathrm{w}} + \rho^{\mathrm{w}}\mathbf{g})\,, \tag{10}$$

where $\mathbf{k}$ is the permeability matrix, assumed to be constant and isotropic.

3 NUMERICAL MODEL

The finite element formulation is obtained by multiplying the global momentum balance equation (8), the global mass balance equation (5), the aqueous species mass balance equations and the calcium carbonate mass balance equation (4) by the virtual displacement ($\mathbf{u}^*$), water pressure (p^*), concentration (c^*) and mass per unit volume (m^*) fields, and integrating by parts over the element volume (Ω) providing the weak form of the problem as presented on eq. (11)-(14):

$$\int_\Omega \boldsymbol{\nabla}\mathbf{u}^* : \boldsymbol{\sigma}\mathrm{d}V - \int_\Omega \mathbf{u}^*\cdot\rho\mathbf{g}\mathrm{d}V = \int_{\partial\Omega}\mathbf{u}^*\cdot\boldsymbol{\sigma}\cdot\mathbf{n}\mathrm{d}S\,, \tag{11}$$

$$\int_\Omega \left[p^*\mathrm{div}(\boldsymbol{v}_{\mathrm{s}}) - \boldsymbol{\nabla}p^*\cdot\mathbf{J}_w - p^*\left(\sum_{k\in\mathrm{W}}\frac{\widehat{m}^{k\mathrm{W}}}{\rho_k} + \sum_{k\in\mathrm{S}}\frac{\widehat{m}^{k\mathrm{S}}}{\rho_k}\right)\right]\mathrm{d}V = -\int_{\partial\Omega} p^*\,\mathbf{J}_w\cdot\mathbf{n}\mathrm{d}S\,, \tag{12}$$

$$\int_\Omega c^* n_{\mathrm{w}}\frac{\mathrm{d}C_{k\mathrm{W}}}{\mathrm{d}t}v_k^{(M)}\mathrm{d}V + \int_\Omega c^*\left[\left(\sum_{k\in\mathrm{W}}\frac{\widehat{m}^{k\mathrm{W}}}{\rho_k}\right)C_{k\mathrm{W}}v_k^{(M)} - \frac{\widehat{m}^{k\mathrm{W}}}{\rho_k}\right]\mathrm{d}V + \int_\Omega \boldsymbol{\nabla}c^*\cdot\boldsymbol{\alpha}_k\mathrm{d}V + \int_\Omega c^*\mathbf{J}_w\cdot\boldsymbol{\nabla}C_{kW}v_k^{(M)}\mathrm{d}V = -\int_{\partial\Omega} c^*\,\boldsymbol{\alpha}_k\cdot\mathbf{n}\mathrm{d}S, \tag{13}$$

$$\int_\Omega m^*\left(\frac{\mathrm{d}\boldsymbol{m}_{c\mathrm{S}}}{\mathrm{d}t} - \widehat{m}^{c\mathrm{S}}\right)\mathrm{d}V = 0, \tag{14}$$

where $\partial\Omega$ is the element surface, $\boldsymbol{n}$ its unit normal vector and $\boldsymbol{\alpha}_k = -\sum_{l\in\mathrm{W}}\left(\mathbf{I}_{kl} - C_{k\mathrm{W}}v_k^{(M)}\right)\mathbf{J}^{\mathrm{d}}_{l\mathrm{W}}$.

The solid displacements, water pressure, concentration of the ionic fluid species and calcite mass per unit volume are approximated inside the finite element by using shape functions and node values and the final equation to be solved is:

$$\mathbf{F}^{\mathrm{int}}(\mathbf{X},\mathbf{V}) = \mathbf{F}^{\mathrm{ext}}, \tag{15}$$

where $\mathbf{F}^{\mathrm{ext}}$ is the vector of external forces, and $\mathbf{F}^{\mathrm{int}}$ is the vector of internal forces that depends on the global unknown vector $\mathbf{X}$ of nodal primary variables (displacements, water pressure, concentration of ionic species (u, a, Ca and Cl) and mass of calcite per unit of volume):

$$\mathbf{X} = [\mathbf{U}\quad \mathbf{P}_{\mathrm{w}}\quad \mathbf{C}_{\mathrm{uW}}\quad \mathbf{C}_{\mathrm{aW}}\quad \mathbf{C}_{\mathrm{CaW}}\quad \mathbf{C}_{\mathrm{ClW}}\quad \mathbf{m}_{\mathrm{cS}}] \tag{16}$$

and on its velocity $\mathbf{V} = \dot{\mathbf{X}}$.

The formulated semi-discrete equations are integrated in time. A midpoint scheme is employed for the integration, signifying that, at each increment the equations are computed at time $\mathrm{t}_{n+\alpha} = \mathrm{t}_n + \alpha\Delta\mathrm{t}$, with $\alpha = 0.5$ and $\Delta\mathrm{t} = \mathrm{t}_{n-1} - \mathrm{t}_n$.

Within each step, several iterations are performed until the system's convergence is reached, that is, the residual force is zero:

$$\mathbf{R}_{n+\alpha} = \mathbf{F}^{\mathrm{ext}}_{n+\alpha} - \mathbf{F}^{\mathrm{int}}_{n+\alpha} \simeq 0. \tag{17}$$

A linearization of the equations around the solution in the current iteration, through the development of the internal forces into a Taylor series, results in:

$$\mathbf{F}^{\mathrm{ext}}_{n+\alpha} - \mathbf{F}^{\mathrm{int}}_{n+\alpha} \simeq \mathbf{R}^{i+1}_{n+\alpha} - \mathbf{C}^{*\,i+1}_{n+\alpha}(\alpha\Delta\mathbf{V}) = 0, \tag{18}$$

where $\mathbf{C}^* = \mathbf{C} + \alpha\Delta\mathrm{t}\mathbf{K}$, $\mathbf{C} = \mathrm{d}\mathbf{F}^{\mathrm{int}}/\mathrm{d}\mathbf{V}$ and $\mathbf{K} = \mathrm{d}\mathbf{F}^{\mathrm{int}}/\mathrm{d}\mathbf{X}$, which gives the increment of velocity $\Delta\mathbf{V}$ that is used to update $\mathbf{V}$ and $\mathbf{X}$.

4 NUMERICAL SIMULATION

A one-dimensional version of the model was initially developed. The domain of the analysis comprises a soil column with a height of 6 cm and diameter of 2 cm. The adopted soil constants were: void ratio (e) = 0.44;

specific gravity (Gs) = 2.636; bulk density (ρ_d) = 1500 kg/m^3; initial solid mass (m_{s0}) = 0.0283 kg and hydraulic conductivity (k_h) = 1e-5 m/s. Regarding the chemical constants, the values used for the molar volume and molar mass of calcite were 36.9e-6 m^3/mol and 100.1e-3 kg/mol, respectively. The 1-D diffusive constant utilized was $D = \alpha_L \|\mathbf{v}_{wW}\|$, where α_L=0.01 (van Wijngaarden et al., 2011) and $\mathbf{v}_{wW}$ is the water velocity vector. The reaction rate coefficients used were: K_m = 10 mol/m^3 and v_{max} = 0.09 mol/(m^{3}s).

The soil column is discretized with a total of 40 bar (1-D) uniform finite elements with three nodes per element regarding the displacement variable and two nodes per element regarding the other primary variables, comprising a total of 327 global degrees of freedom.

Initially, it is assumed that the soil column is saturated and without presence of urea, calcium, chloride and calcite in the medium. At the bottom of the column the displacement is zero and there is no change in the pore-water pressure, from the beginning until the end of the analysis. At the top of the column, a constant raise in concentration of urea and calcium from 0 until 1 kmol m^{-3}, a raise in the chloride concentration from 0 until 2 kmol m^{-3} and a raise of the water pressure from 0 to 2 kPa, are applied during the first 10 seconds. Subsequently, all the concentrations remain constant until the end of the analysis.

Figure 1 presents the mass of calcite per unit of volume along the column in different instants of time. As it is expected, the formation of calcite can be seen first at the top of the domain (elevation 0. 06 m) due to the presence of urea and calcium ions in this region. As time goes by, as the ionic species are carried out deeper into the soil mass, the precipitation of calcite occurs in the whole domain.

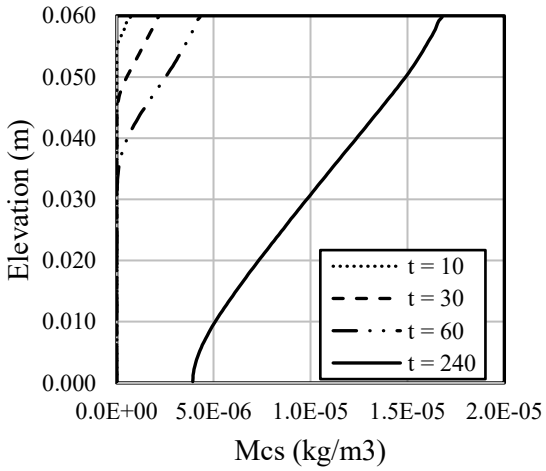

Figure 1. Mass of calcite per volume unit generated through the specimen along time (s).

5 CONCLUSIONS

This study gives an insight on the biocementation process and the main factor that controls the amount of precipitated calcite, which is the reaction rate. Therefore, more experimental research will be needed to improve the definition of the reaction rate equation and of the corresponding materials parameters. No calcite transport is considered in the model. In practice, this is a simplification, since non-attached calcite can be formed and transported along the pores. Further research will also be necessary to improve this aspect of the model, so that it can be used in the future to support the biocementation technique, in particular to predict the amount of biocement precipitated for specific treatment dosages and protocols.

ABSTRACT: Groundwater engineering and control is regularly used to lower the water table and pore pressure beneath and surrounding deep excavations for the construction of shafts, tunnels and other deep structures. The construction methodology will greatly influence the type of groundwater control system most appropriate. There is a different groundwater control system required for an open-cut excavation, than that required for an impermeable steel sheet pile, secant or diaphragm wall. Similarly, the type of groundwater control system designed can greatly influence the type of construction required. A professionally designed dewatering system can result in a substantial reduction in cost and carbon emitted. If mathematical modelling is used during the design, the groundwater control system can be optimised. This paper presents recommended stages in the design, modelling and construction of a groundwater control dewatering system. Examples are presented of efficient design and modelling for both abstraction and recharge systems. Presented is a case study where a groundwater control system was designed to lower the water table below a deep detention shaft, an open-face pipe jack operation, and a smaller reception shaft in a mature garden. Modelling resulted in the final design only requiring boreholes around the deep shaft, eliminating unnecessary construction of boreholes and pipework around other structures.

RÉSUMÉ: L'ingénierie et le contrôle des eaux souterraines sont régulièrement utilisés pour abaisser la nappe phréatique et la pression interstitielle sous et autour des excavations profondes pour la construction de puits, de tunnels et d'autres structures profondes. La méthodologie de construction influencera grandement le type de système de contrôle des eaux souterraines le plus approprié. Il existe un système de contrôle des eaux souterraines différent de celui requis pour une palplanche en acier imperméable, un sécant ou un mur moulé. De même, le type de système de contrôle des eaux souterraines conçu peut grandement influencer le type de construction requis. Un système d'assèchement conçu par des professionnels peut entraîner une réduction substantielle des coûts et des émissions de carbone. Si la modélisation mathématique est utilisée lors de la conception, le système de contrôle des eaux souterraines peut être optimisé. Cet article présente les étapes recommandées pour la conception, la modélisation et la construction d'un système d'assèchement des eaux souterraines. Des exemples de conception et de modélisation efficaces pour les systèmes d'abstraction et de recharge sont présentés. Une étude de cas a été présentée dans laquelle un système de contrôle des eaux souterraines a été conçu pour abaisser la nappe phréatique sous un puits de rétention profond, une opération de vérin à tuyau à face ouverte et un puits de réception plus petit dans un jardin mature. La modélisation a abouti à la conception finale ne nécessitant que des trous de forage autour du puits profond, éliminant ainsi la construction inutile de trous de forage et de tuyauteries autour d'autres structures.

Keywords: Groundwater control; construction dewatering; deep excavations; tunnels; shafts.

1 INTRODUCTION

The control of groundwater during construction of deep excavations, shafts and tunnels, is critical to the safety of the project and the individuals working on the project. Groundwater control utilising the abstraction of groundwater (known as construction dewatering), is a complex operation requiring skill and knowledge of the disciplines of geology, hydrogeology, geotechnical and civil engineering. Examples of groundwater control systems implemented on-site across the world have been published previously (Bock and Markussen, 2007; Goodfellow and Thomas, 2018; Margat and van der Gun, 2013; Powrie and Roberts, 1995). The objective of a groundwater control operation is to achieve the aims of reducing the water table (phreatic surface) or the pore water pressure to acceptable levels to reduce the risks from groundwater (Figures 1, 2) Another requirement is to mitigate the impact of dewatering on the surrounding infrastructure and

environment. This impact can involve the settlement of surrounding structures resulting from consolidation and reduction of groundwater resources caused by over-abstraction. Industry guidance is available outlining how to mitigate these risks (Powers, Schmall, 2007; Preene, Roberts, Powrie, 2016).

The safest and most cost-effective approach is to have a well-planned groundwater control operation, that is integral to both the temporary and permanent works design. This is best achieved by employing specialists with expertise and experience in this field.

Figure 1. A site without any groundwater control.

Controlling groundwater during a construction project, however, can have significant costs. It also takes up valuable project time and available space. For this reason, risks from groundwater are often ignored by a project team, with hazards and delays still emerging despite wishing otherwise.

Figure 2. A site with appropriate groundwater control.

A principal contractor who requires the control of groundwater for their deep excavation project, often chooses an expensive deep cut-off wall system instead of a more effective and efficient dewatering system, principally because of their familiarity. Construction dewatering is often seen as a complex art, in which the outcome, particularly the final cost, is uncertain. To remedy this uncertainty, the authors recommend the presentation of the dewatering process in colourful clear sequence drawings. This provides clarity and confidence to the contractor, who, as a result, is more likely to choose dewatering as a preferred option.

This paper does not aim to present to the reader all the expertise in this field, but instead serves to present understandable guidance in the form of key stages required to produce a safe and robust groundwater control system for a major construction project that requires excavation below groundwater levels.

2 GROUNDWATER CONTROL GUIDANCE

To provide a simple-to-understand guidance for the development of a safe and robust groundwater control system when constructing below the water table, or potentiometric surface, the following presents key stages in the process. Some of the stages can be undertaken by the principal contractor, some by the sub-contractor, and some by the consultant.

Whilst stages can be the responsibility of different parties, each stage must be managed by experienced and capable persons. All stages are to be integrated so that there are no gaps and shortfalls in the overall operation.

The following provides guidance that the authors have developed over decades of experience. The guidance is not to provide a strict specification, nor a construction standard, but is offered here as support to other guidance available within the industry.

2.1 Initial review of construction operation

A conceptual model of the ground and groundwater conditions is first required. An outline of the building structure can then be overlaid on the conceptual model to provide clarity of the risks during and after construction. It is then required to establish hydraulic boundary conditions to enable analysis and modelling.

Based on this information, an experienced and skilled groundwater engineer can then identify the critical risks to the construction process and provide an outline of groundwater control design. An example of a first-stage conceptual model is depicted in Figure 3.

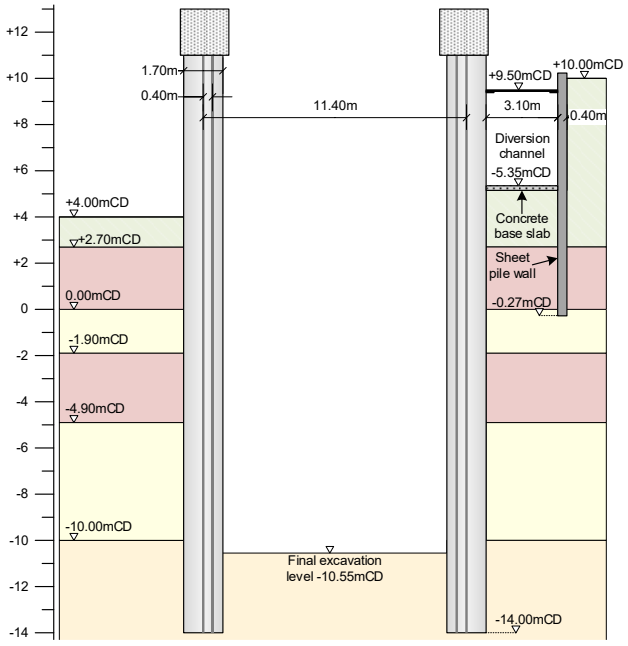

Figure 3. A conceptual model of the ground and structure.

2.2 Identification of critical success factors

With a first-stage conceptual model prepared, an initial dewatering design can be produced by an experienced designer. However, it is essential at this stage to further identify critical parameters that need to be quantified to enable a detailed design of a robust groundwater control system. Such parameters include: permeability, transmissivity, anisotropy, elevation of aquifer base, isolated artesian layers, and critical boundary conditions. Other factors can include (i) the ground compressibility if there are sensitive structures nearby, (ii) water supply wells or other water bodies that could be affected by the abstraction of groundwater, and (iii) factors that can affect the operation such as boulders, access, etc.

2.3 Preliminary groundwater control strategy

When developing a groundwater control design, it is good practice to produce a preliminary groundwater control strategy that includes an outline design based on a range of hydrogeological conditions established from the available groundwater information (Figure 4).

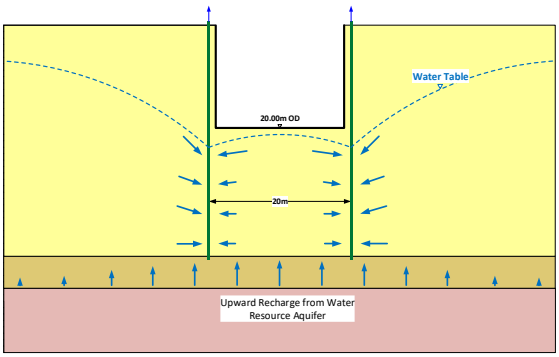

Figure 4. Preliminary groundwater control strategy.

In the authors' experience, information available from a standard site investigation is normally most inadequate as a basis for a final groundwater control design, especially in the case of the critical parameter of permeability. As a consequence, this preliminary strategy must emphasise that the design is based on a range of ground conditions, and that it is essential to undertake further specific pumping tests, together with additional groundwater-specific site investigation.

2.4 Design, implementation, analysis of project specific pumping test operation

Critical to the design of a groundwater control system, a pumping test and analysis is required, especially to establish the expected abstraction rate when applying for a permit from the UK environment agencies. Such tests normally require a minimum of constructing a groundwater pumping well, together with a series of piezometers to observe drawdown during pumping. It is good practice to undertake a series of tests, rotating the pumping from different wells and observation piezometers. Figure 5 provides an example plot of groundwater drawdown versus time, matched by a mathematical model, from which the required aquifer parameters can be back-calculated.

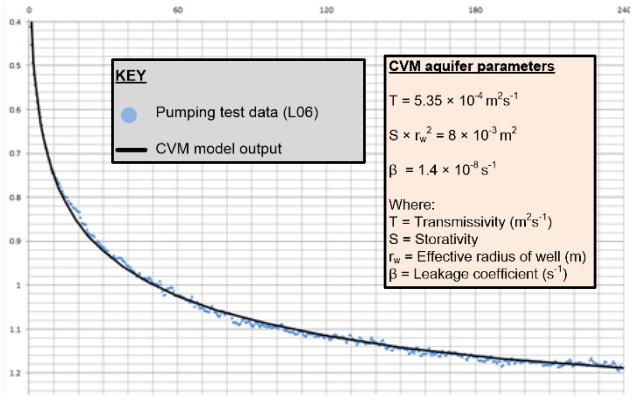

Figure 5. Pump test analysis to establish aquifer properties, where the x-axis is time, and the y-axis is drawdown.

With the site-based parameters calculated from a mathematical model, the same model can be used to calculate the range in expected abstraction rates based on the range of values obtained from the tests.

2.5 Development of mitigation strategies

Mitigation strategies are often required to mitigate the impacts that can result from groundwater abstraction. Strategies can include the deepening of cut-off walls to reduce groundwater inflow, or using recharge wells to provide a hydraulic barrier to reduce the radius of influence from the dewatering operation. Figure 6 depicts the proposed dewatering from boreholes inside a secant pile wall, with the abstracted groundwater pumped back to the ground to protect water resources.

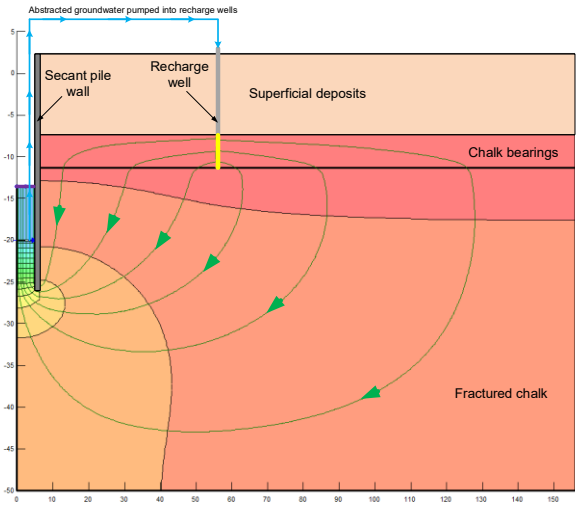

Figure 6. Groundwater pumping and recharge.

2.6 Detailed design and value engineering

Following the analysis of the pumping test results and any additional ground investigations, detailed design and value engineering are then undertaken. All parties then work together to value engineer the system in a collaborative manner. This value engineering takes into account constraints of working space, programme, geology, hydrogeology, and mitigation strategies. All play a part in the final detailed design (Figures 7 and 8).

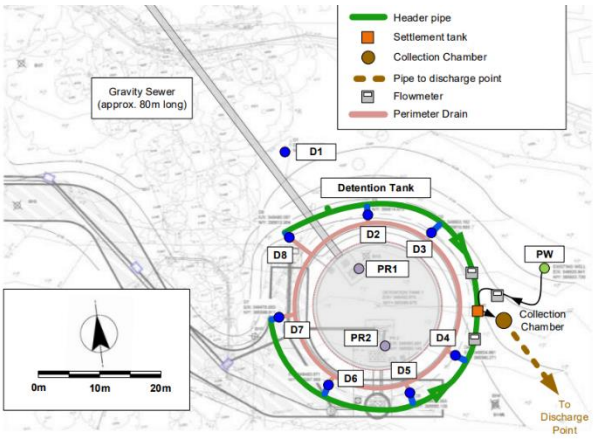

Figure 7. Location plan for dewatering boreholes.

After value engineering, the preliminary strategy document is updated to a strategy for construction. This document contains the detailed specifications for drilling and pumping, but always retains the flexibility to revise designs in light of the actual geology and hydrogeology encountered on site.

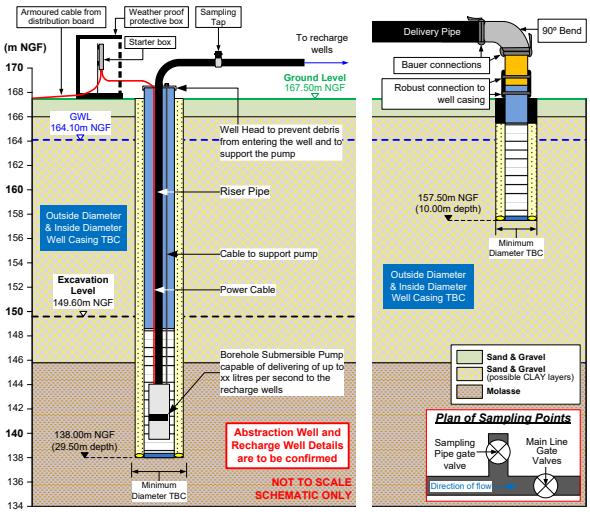

Figure 8. Drilling, pumping and recharge specifications.

2.7 Groundwater control system construction

Construction of a groundwater control system on site is required by an experienced, accomplished and specialist contractor (Figures 9 and 10). Drilling dewatering boreholes requires different skills to water supply boreholes, requiring experience in working on busy construction sites in close proximity to other trades.

Figure 9. Drilling of deep dewatering borehole.

Figure 10. Series of pressurised recharge boreholes.

2.8 Mathematical modelling of groundwater

Mathematical modelling uses computer software to solve the equations governing groundwater flow in a saturated or partially saturated porous material. The outputs are hydraulic heads, pore pressures and Darcy velocity. Modelling is highly valuable in predicting the groundwater behaviour of a dewatering operation.

Mathematical modelling of groundwater through soil or rock can be a major undertaking, with time and cost resources needed. It is recommended here to use a model only of sufficient complexity to solve a site situation. It is not recommended to use, for example, a fully three-dimensional model to apply to a simple pumping test operation from a single borehole.

For most applications, a multi-well analytical model is sufficient in a homogeneous aquifer, with most more complex transient and inhomogeneous aquifers being solved using a two-dimensional finite element model.

Figure 11 depicts the application of the finite element model SEEP/W to a shaft/tunnel project near Liverpool. Modelling was undertaken in advance of

the dewatering operation and during the pumping test. This enabled the ground properties, and the model boundary conditions to be established. Modelling was also undertaken in "real-time" during the dewatering operation to refine the dewatering design. The benefits of this procedure included a prediction of a wide drawdown, which determined that after some time, no groundwater control was then required in the reception shaft in a mature garden, and so mitigating operations.

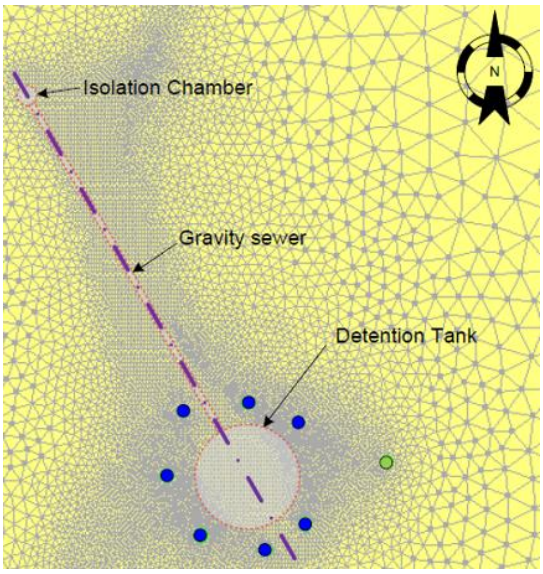

Figure 11. Finite Element modelling using Seep/W.

Another benefit to the project was the cost savings by predicting when additional pumps would be required. Only half the number of pumps was required for the dewatering operation, with pumping from boreholes only required for the deep shaft (Figure 12).

Using the groundwater model to enable the calculation of transmissivity, accurate predictions of the final groundwater abstraction could be made. This assisted with the application of licences and permits and enabled early appropriate pump selection.

2.9 Multi-well analytical modelling

To model a multi-borehole dewatering operation under steady-state conditions, OGI has developed efficient and effective models which use analytical solutions. These analytical models are extremely beneficial as they are simple to set up and fast to provide results.

Figure 13 depicts the conceptual model for an underground metro station, platform and tunnels, with Figure 14 depicting the simulated drawdown using a 2-D analytical groundwater model in plan.

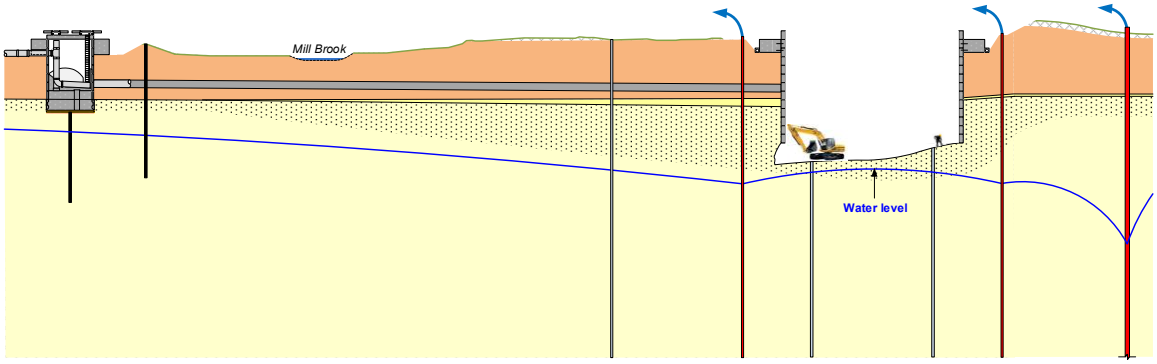

Figure 12. Simulation of dewatering from boreholes around a deep shaft, with drawdown reaching a smaller shaft.

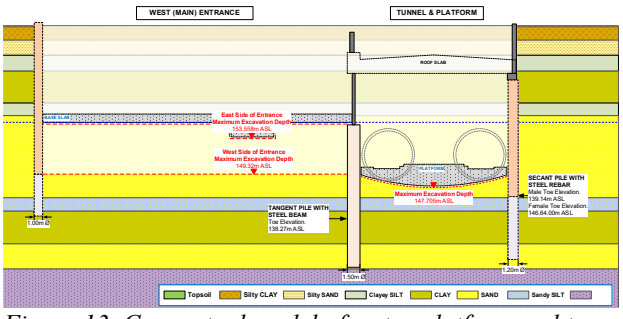

Figure 13. Conceptual model of metro platform and tunnel.

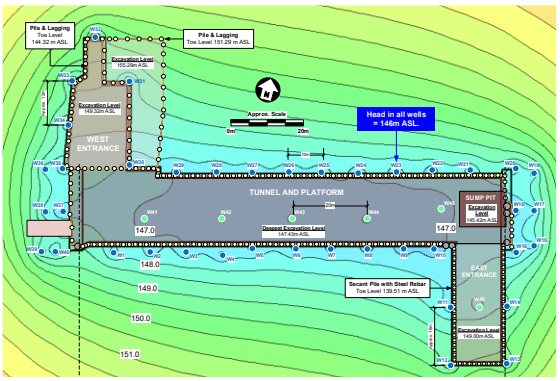

Figure 14. Simulated head using analytic modelling.

This analytical modelling enabled the simulation of abstraction wells and passive pressure relief wells in advance to the start of the dewatering operation. This capability greatly contributed to an efficient and effective groundwater control operation. At the start of pumping from only a few boreholes, drawdown was observed from non-pumping wells, after which aquifer properties were back-calculated using the analytical model to refine the design in real-time.

This enabled the additional pumping boreholes to be accurately positioned to provide the maximum impact. This was particularly valuable as the operation took place during the COVID-19 pandemic, where drilling crews were scarce, and optimisation was critical. Figure 15 demonstrates a successful outcome in challenging ground conditions.

Figure 15. Drawdown achieved beneath the metro station.

3 CONCLUSIONS

The principal stages in producing a groundwater control system are paramount within the Groundwater Engineering Industry. This paper outlines these stages and how their presence enhances a groundwater control system, and therefore, a project's success.

Conceptual models provide a visualisation of the subsurface and the proposed structures, which contribute to a preliminary groundwater control strategy. While useful, these strategies will always signify a requirement for further investigations to supplement the final design produced for a project.

Vital to these investigations are pumping tests and their subsequent analysis, which is inclusive of sensible mathematical modelling. The authors advocate that sensible modelling, encompassing only the required complexity, is needed to solve in advance the groundwater flow in the aquifer. The calculations using the aquifer properties feed into implementing mitigation strategies into the system design.

When these stages have been completed, they will augment the production of a detailed design that can be utilised to specify a robust groundwater control system to lower the water table to an acceptable level at a site, and so reduce the water risks accordingly.

ABSTRACT: The load eccentricity effect of a square foundation resting on 4 Rigid Inclusions is investigated with small scale centrifuged models. 3 tests have been performed on instrumented models with the robot of Uni Eiffel Centrifuge laboratory. The kinematics of the foundation and the load transfer towards the Rigid Inclusions are presented.

RÉSUMÉ: L'effet d'un chargement excentré sur une fondation carrée reposant sur 4 Inclusions Rigides est étudié sur des modèles réduits centrifugés. 3 essais ont été réalisés sur des modèles instrumentés en utilisant le robot téléopérateur du laboratoire Centrifugeuses Géotechniques de l'Uni Eiffel. La cinématique de la fondation et le transfert des charges vers les Inclusions Rigides sont présentés.

Keywords: Rigid inclusions; centrifuge; kinematics; load transfer; eccentricity.

1 INTRODUCTION

In the framework of the French National Project ASIRI+ devoted to the reinforcement of soft soils by rigid inclusions (https://asiriplus.fr), the behaviour of a square foundation on 4 Rigid Inclusions (RI) is studied with centrifuged models. This "composite foundation" includes, from top to bottom in Figure 1: 1) a shallow foundation; 2) a granular Load Transfer Platform (LTP); 3) deep foundations (RIs) installed in a soft clay; 4) a sand layer where the RI tips penetrate. The forces transmitted to the RIs as well as the kinematics of the shallow foundation are presented, for three different eccentricities.

2 EXPERIMENTAL SETUP

The set of experiments is inspired from in field tests' geometry (Briançon *et al.*, 2000). The scaling laws (*e.g.* Garnier *et al.*, 2007) applied for designing the centrifuge tests leaded to a reduced scale of 1/16.9, corresponding to a g-level of N=16.9. The results are presented at model scale.

The reconstituted soil mass includes, from the bottom to the top: 1) a filtration geotextile to avoid sandy particles to move towards the drainage circuit; 2) a dense saturated Hostun HN31 sand; 3) the soft soil, prepared in 3 layers with a loading programme adapted to a slightly over consolidated clay, is made of a mixture of kaolin clay and Fontainebleau sand NE34 (Baudouin, 2010); 4) the LTP, made of dense well-graded Hostun sand (Baudouin *et al.*, 2008). The rigid inclusions are jacked at 1mm/min, in the lab (under earth gravity), guided accurately together 4 by 4.

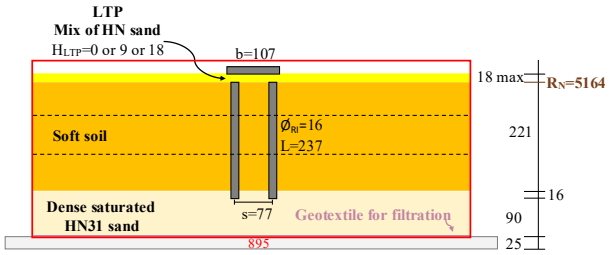

Figure 1. Scheme in elevation of the composite foundation in the circular container tested in the centrifuge (in mm).

The model foundation is made of aluminium (Figure 2), as well as the instrumented RIs (Figure 3). The foundation includes an upper part, with a T-shape, used to be hanged and downward loaded, inducing only a main rotation around the x-axis.

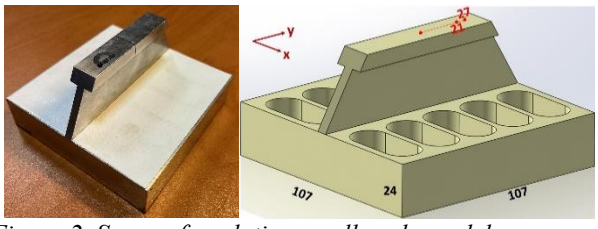

Figure 2. Square foundation small scale model.

A (white) scotch tape is stuck on the top surface.

The RIs are instrumented with a force sensor intimately linked to the top surface cap (Figure 3).

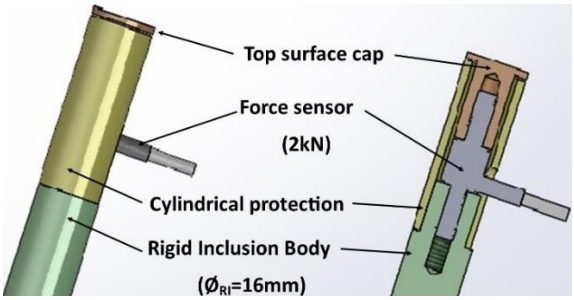

Figure 3. Drawings of Instrumented Rigid Inclusion.

To optimise the clay consolidation time in centrifuge, 4 tests are performed during the same centrifuge flight, thanks to the Uni Eiffel Robot (Gaudicheau *et al.*, 2014). A special tool has been developed for the foundation carriage and loading (Figure 4). The 4 foundations are stored on a board fixed on the container, and are installed on the expected location (where the RIs have been pre-installed) before being loaded (Figure 5).

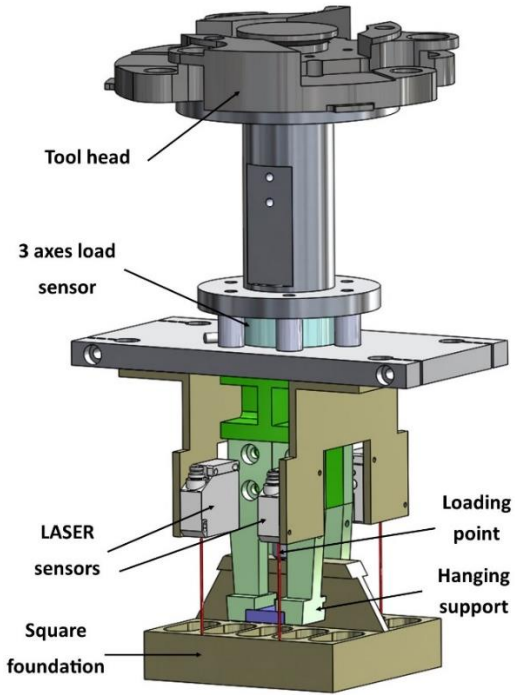

Figure 4. Multi-use tool for the centrifuge robot.

3 EXPERIMENTAL PROGRAMME

The centrifuge tests are performed in the same circular container, with an LTP height of 18mm (0.3m in prototype scale), and with 3 eccentricities e reported to the spacing s: e/s = 0, 0.27 & 0.35 (or to the foundation width b: e/b = 0, 0.19 & 0.25).

After a consolidation phase during about 2 hours in flight, the series of foundation loading start. The vertical loading of the foundations is performed in displacement control conditions at a velocity of 1mm/min. If the eccentricity is positive, the vertical loading generates a negative rotation around the x-axis (θ_x). The data acquisition is performed at a frequency of 10Hz, thanks to HBK Quantum DAS.

The laser sensors installed on the multi-use tool are pointed towards the foundation to access to its solid rotation. The distance between the laser rays is 100mm in the x direction and 40mm in the y direction. This induces a better accuracy of the rotation around y-axis (θ_y) than x-axis (θ_x).

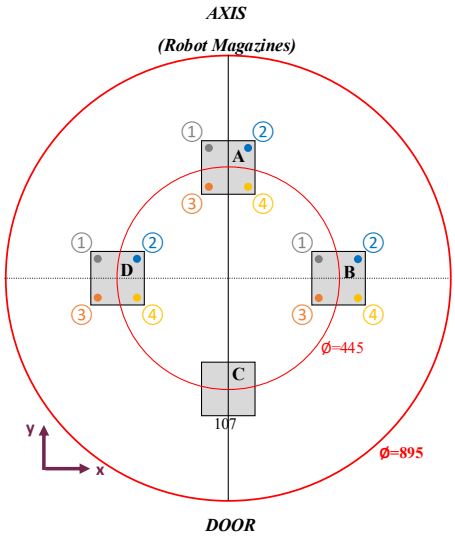

Figure 5. Top view implementation in the container (mm).

The load tests (Table 1) are devoted to eccentric loading, for investigation the load repartition and the kinematics of the square foundation.

Table 1. Load test configuration.

Test	e/s	Comment
A	0.35	
B	0.27	
C	NA	H loading, not included
D	0	

4 DISCUSSION

The results of loading (Figure 6) show the behaviour up to a settlement of 1/10th of the foundation width (107mm), at model scale. The settlement is calculated at the centre of the foundation.

For the vertical centred load, it can be seen that the loads are almost the same on the RIs until the symmetry is lost, generating a slight rotation towards RI 2 and 4.

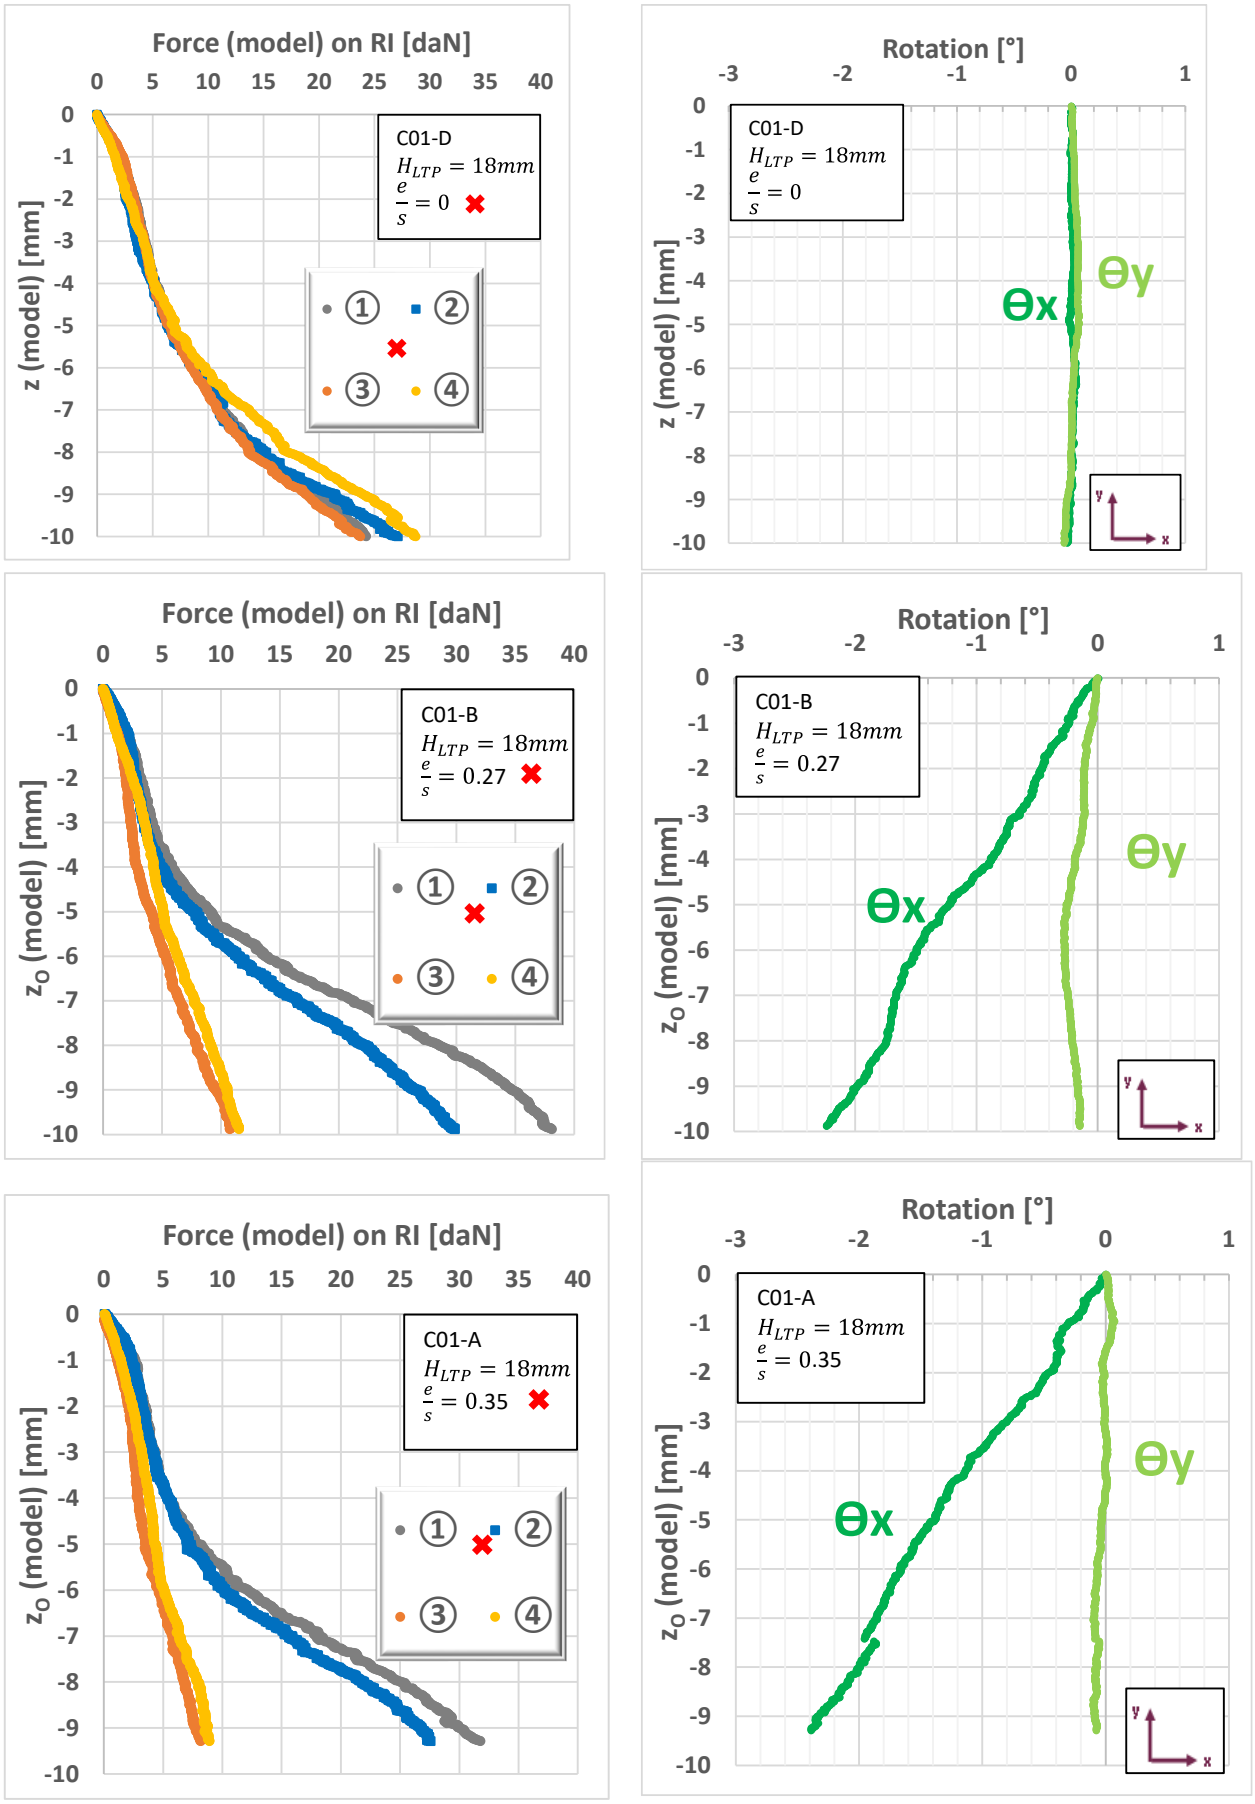

Figure 6. Forces transmitted to the Rigid inclusions(left) and rotations (right) versus settlement for 3 eccentricities: 0 (top), 0.27 (middle), 0.35 (bottom).

When an eccentric load is applied, the rotation of the foundation is immediately visible. The load transfer towards RIs 1 and 2 is emphasised after a settlement of few millimeters, showing a complex behaviour that includes first a mechanism inside the LTP and then the mobilisation of the RIs in an asymetrical way.

It can be observed that, even if a careful process has been followed in the preparation of the soil model, the RIs installation and the location of the loading points, very small rotations are observed on the y axis. This shows that there is small uncertainties relative to the loss of symetry.

The total load variation applied on the foundation is in the same proportion than to the sum of the load variation on RIs (Figure 7), whatever the eccentricity is. Two distinct mechanisms of load transfer may be identified. The initial slope for small settlements (and loadings) is about 0.38, when the final slope is close to 0.74, showing a progressive mobilisation of the RIs. For a similar settlement of the foundation center (*e.g.* the end of the curves correspond to the Service Limit State, 10% of the foundation width), loads decrease with the increase of the eccentricity, both for the total load and the transfered loads to the RI.

It could be said that to reach the same settlement at the centre of the foundation: 1) stronger force is required for centred load than for eccentred; 2) similar load proportion is transfered to the soft soil. In any case, the load transmitted to the RIs is smaller than the load applied to the foundation, but the ratio does not seem to be affected by the eccentricity.

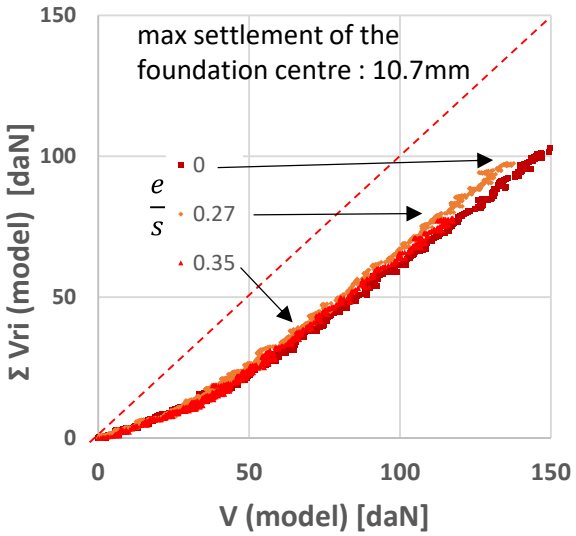

Figure 7. Total force variation applied on the RIs vs the total force variation applied on the foundation.

5 CONCLUSIONS

A series of centrifuge tests has been developed to investigate the eccentricity effect on complex foundation system made of a shallow square foundation resting on four rigid inclusions.

The first results show that for a settlement of 10% of the width of the foundation, the rotation reach a value of about 2 degrees, and that the rear RIs are overloaded up to 3 times the front RIs.

During the loading of each foundation, two mechanisms seem to appear: 1) load transfer mainly in the LTP; 2) a load transfer more active towards the RIs.

Additional investigation is under process for other test configuration such as the LTP height.

Mechanical properties of a gravel soil injected with a polyurethane binder

Propriétés mécaniques des sols graveleux injectés avec un liant polyuréthane

ABSTRACT: Chemical grouts refer to the use of polyurethane foams and gels, acrylates and epoxies. The usage of polyurethane (PU) is expanding for joint sealing in concrete construction work as well as for controlling seepage in cracked rock and concrete. As part of an experimental investigation, tests were carried out in soils with a constant granulometry (with grain diameter 1-4mm) grouted with a polyurethane binder. A hydraulic permeability of $k = 5.10^{-3}$m/s was specified as the target variable for the soils to be examined. Grouting tests were performed at a maximum pressure of 150kPa. After the grouting of the soils samples, three unconfined compressive strength and triaxial tests were performed in soils with relative densities of 1. Different binder quantities were injected into the soil. Results show that unconfined compressive strength values was about 6MPa. Triaxial tests performed on seven samples at relative densities between 0.89 and 0.94 showed peak deviatoric stress between 5.2 and 6.9MPa. PU binder is therefore suitable for permeation grouting in high permeable soils.

RÉSUMÉ: Les coulis chimiques font référence à l'utilisation de mousses et de gels de polyuréthane, d'acrylates et d'époxy. L'utilisation du polyuréthane (PU) se développe pour l'étanchéité des joints dans les travaux de construction en béton ainsi que pour contrôler les infiltrations dans la roche et le béton fissurés. Dans le cadre d'une investigation expérimentale, des essais ont été réalisés dans des sols à granulométrie constante (diamètre des grains 1-4 mm) injectés avec un liant polyuréthane. Une perméabilité hydraulique de $k = 5.10^{-3}$ m/s a été spécifiée comme variable cible pour les sols à examiner. Les tests d'injection ont été effectués à une pression maximale de 150 kPa. Après l'injection des échantillons de sols, trois essais de résistance à la compression libre et triaxiaux ont été réalisés dans des sols de densité relative 1. Différentes quantités de liant ont été injectées dans le sol. Les résultats montrent que les valeurs de résistance à la compression non confinée étaient d'environ 6 MPa. Les tests triaxiaux effectués sur sept échantillons à des densités relatives comprises entre 0.89 et 0.94 ont montré une contrainte déviatorique maximale comprise entre 5.2 et 6.9 MPa. Le liant PU convient donc aux injections de perméation dans des sols très perméables.

Keywords: Grouting; polyurethane; gravel; mechanical properties.

1 INTRODUCTION

The injection of a grout into a highly porous, granular soil to saturate and bind the particles together is known as permeation grouting. In general, the procedure is utilized to build a structural, load-bearing structure, a stabilized soil zone for tunnelling, and water cut-off barriers.

Chemical grouting is a technique where materials are fully dissolved in a fluid, i.e. called also solutions (Nicholson, 2015).

Chemical grouting is a technique used in geotechnical engineering to stabilize and strengthen soil or rock formations. It involves injecting chemical grout into the ground to fill voids, consolidate loose soil, or create impermeable barriers. Chemical grouts typically consist of a liquid or gel-like material that solidifies after injection.

Chemical grouting has various applications, including foundation repair, soil stabilization, tunnelling, and groundwater control. It is commonly used to address issues such as sinkholes, water infiltration, and unstable slopes. The process is relatively quick and can be performed in various soil and rock conditions (Karol, 2003). Among the different binder types used in chemical grouting (e.g. Fraccica et al., 2022), grouting with polyurethane (PU) resins is an efficient means of improving the mechanical and sealing qualities of soils and rocks (Bodi et al., 2012).

PU grouting materials are classified into three major classes based on their chemistry (Bodi et al., 2012):

- two-component (PU) organic resins;
- one-component organic resins;
- two-component organic-mineral resins (OMR).

In this paper a two-component PU binder was injected in a gravel sand (1-4mm grain) under low pressure (max. 150kPa injection pressure). Unconfined compressive strength and triaxial test values are presented. Similar tests were done in sand and presented by Spagnoli et al. (2023).

2 MATERIAL AND METHODS

The investigations were carried out with the injection of a two-component, fast-reacting, slightly flexible, silicate-based injection foam equipped with flame retardants.

2.1 Binder

The A component is based on a water glass solution (silicic acid) which has a density of 1.3 g/cm^3 and a dynamic viscosity of 30 mPas at a temperature of 23°C. The B component is based on an isocyanate mixture, which is characterized by a density of 1.21 g/cm^3 and a dynamic viscosity of 120 mPas at a temperature of 23°C.

The two components are mixed together for the reaction in a volume ratio of 1:1. At room temperature, there is a reaction between the two components about 30 seconds after mixing. A slowly hardening foam is formed. The foam volume is significantly larger than that of the two individual components (formation of air bubbles).

2.2 Soil

A hydraulic permeability of k = 5.10^{-3}m/s was specified as the target value for the soils to be examined. Table 1 shows the properties of the soil used in the experiment.

2.3 Grouting set up

The test stand consists of a 50cm long commercial PVC pipe (DN 110), which is sealed airtight with an associated socket plug on the bottom (see Figure 1). To fix it, the pipe was screwed to a wooden structure using pipe clamps.

Table 1. Properties of the soil used in the test

Property	Value
Grain dimension	1-4mm
High dry density	1.877g/cm^3
Low dry density	1.608g/cm^3
Grain specific gravity	2.76
Low k-value	$6.03 \cdot 10^{-3}$m/s
High k-value	$1.81 \cdot 10^{-2}$m/s
D_{60}	2.8mm
D_{30}	2.0mm
D_{10}	1.7mm

Small holes were drilled through the wall at the bottom of the tube to avoid uplift as a result of the injection. The air displaced by the foam could escape through these holes. In addition, a grid was fixed over the built-in soil on the pipe to produce test specimens with a constant volume. This prevented heaves due to volume expansion of the foam.

A cartridge gun operated with compressed air was used for the injection. The two individual components of the injection material were mixed and homogenized using commercially available static mixers.

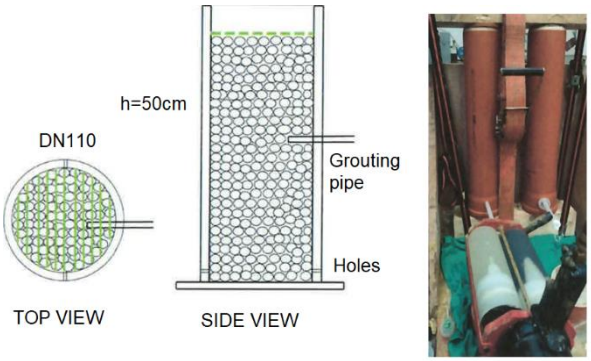

Figure 1. Set up for the grouting tests.

To investigate the vertical expansion behaviour of PU, 300ml, 400ml and 600ml of the mixed injection material were injected into soils, which had previously been installed in dense storage in the pipe, with an injection pressure of approx. 1.5 bar. The installation densities of the soils used were determined before the injection and ranged between 1.85 and 1.88 g/cm^3.

3 RESULTS AND DISCUSSION

Figure 2 shows the results for the grouted material injected into the 1-4mm gravel soil for 300, 400 and 600ml. The red arrow indicated the point of injection.

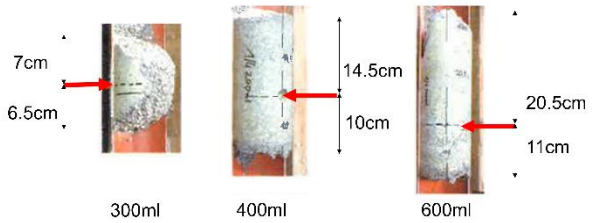

Figure 2. Results from the grouting test for 300ml, 400ml and 600ml injection material (from left to right).

Approximately 30 seconds after the start of the injection, the injected material hardens and foams at the lower end of the injection front. It forms the basis of the injected soil body.

Mechanical tests on the grouted samples were performed on 7 days curing age.

Three uniaxial compression tests according to DIN EN ISO 17892-7 (DIN, 2018a) were carried out on specimens (height-to-diameter ratio of 2) made from soil-foam mixtures. The installed soil dry density was 1.88 g/cm^3 (relative density Dr = 1.0).

The specimens were subjected to uniaxial loading and shearing at a constant rate of 0.2% of the initial height of the specimens per minute in accordance with DIN EN ISO 17892-7.

The determined stress-strain relationships of the three uniaxial compression tests on the soil-foam mixtures carried out under the same boundary conditions are shown in Figure 3. In addition, the test results are listed in Table 2.

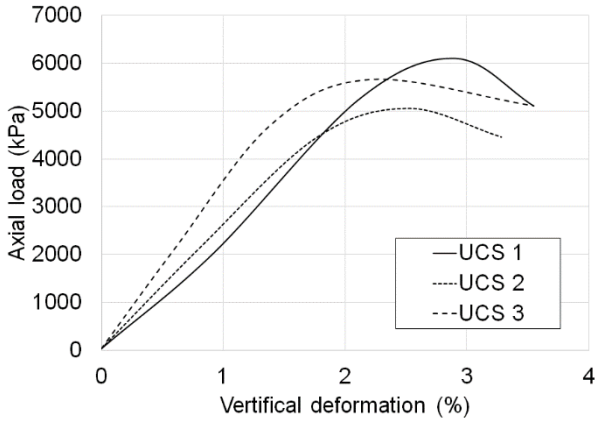

Figure 3. Results of UCS tests.

The modulus of elasticity secant E50 was determined in the stress range between 0kPa and 50% of σ_1 (i.e. the axial load).

Table 2. Data of UCS tests

Test	UCS (kPa)	E50 (MPa)
UCS 1	5100	269
UCS 2	5700	372
UCS 3	6100	239

The mean UCS and E50 values are respectively 5.6MPa and 293MPa.

Furthermore, triaxial tests were carried out on dry test specimens according to DIN EN ISO 17892-9 (DIN, 2018b). The specimens prepared with dry density between 1.84 and 1.86 g/cm^3. The cylinder samples (height 20cm, diameter 10cm) were sheared at a constant rate of 0.2% of the specimen height per minute (approx. 0.4mm/min).

A total of seven specimens were tested under triaxial conditions and sheared at different lateral pressures σ_3. The test boundary conditions are listed in Table 3.

Table 3. Data of triaxial tests

Test	Dr soil	σ_3 (kPa)	E50 (MPa)	Dr
TX 1	0.94	100	206	0.94
TX 2	0.94	200	293	0.94
TX 3	0.93	300	255	0.93
TX 4	0.93	500	282	0.93
TX 5	0.89	200	213	0.89
TX 6	0.89	300	216	0.89
TX 7	0.89	500	288	0.89

The triaxial tests show values of σ_1 - σ_3 between 5.2MPa and 6.9MPa, which occur at axial strains ε between 2.6% and 3.8% (see Figure 4). The stiffness E50 of the specimen varies between 200 MPa and 300 MPa. A clear increase in the strength and stiffness of the soil-foam mixtures with the lateral pressure σ_3 is not recognizable. The foam density is around 0.4 g/cm^3. A dependence of the results on the foam density cannot be determined given the small differences in foam density here.

To roughly determine the shear parameters of the soil-foam mixture, the results of the three uniaxial compression tests and the seven triaxial tests were transferred together into an t-s diagram (see Figure 5). For each individual test, the maximum value of the deviator stress ($t = \sigma_{1,max} - \sigma_3 /2$) and the associated mean principal stress ($s = \sigma_{1,max} + \sigma_3 /2$) are plotted in the t-s diagram. In the uniaxial compression test, $\sigma_3 = 0$. The black dots are the UCS tests, whereas the white dots the triaxial tests.

A regression line was then drawn through the points. Using the parameters α (angular coefficient) and b (intercept) according to Figure 5, the cohesion c and the angle of friction φ can be calculated as:

$$c = \frac{b}{cos\varphi} \quad (1)$$

$$sin\varphi = tan\alpha \quad (2)$$

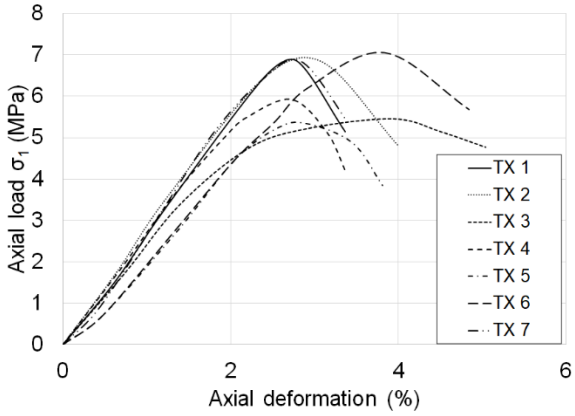

Figure 4. Results of the triaxial tests.

From the results of Figure 5, the cohesion is 887.5kPa and the friction angle φ is 48.7°, considering a value α of 36.9° and a value b of 585.5kPa.

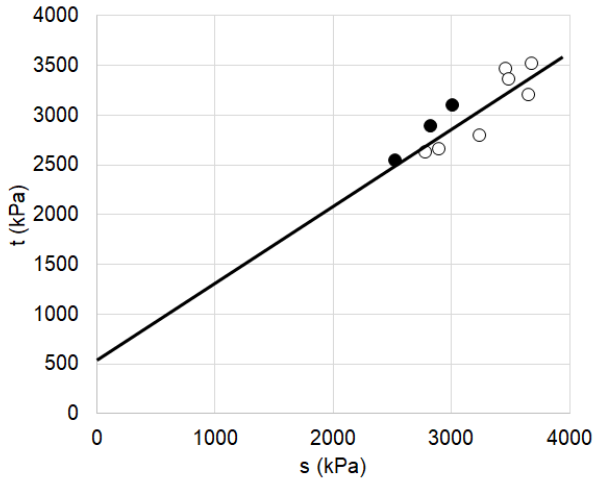

Figure 5. Results of the triaxial and UCS tests into the t-s diagram. Black dots are the UCS tests, white dots the triaxial tests.

4 CONCLUSIONS

The note showed some mechanical tests performed on a gravel soil with 1-4mm grains at a k value of $5 \cdot 10^{-3}$m/s. Axial load values for UCS tests range between 4 and 6MPa. Triaxial tests performed under different lateral pressure and relative density values demonstrate no discernible improvement in the strength and stiffness of the soil-foam combinations with lateral pressure σ_3. Given the modest changes in foam density here, a dependency of the results on foam density cannot be detected.

ABSTRACT: This paper presents the proposed solutions for the excavation works, retaining wall and deep foundations necessary for the construction of 4 underground floors of two office buildings at Alcântara, adjacent to Avenida da Índia, in Lisbon. The main existing constraints were archeological, geological, hydrogeological, geotechnical and the neighbourhood conditions, which determined the choice of the retaining wall solution and respective horizontal support. Diaphragm wall technology was used for the retaining wall combined with a top-down sequence to assure the horizontal support. The solutions adopted for the deep foundations are also described, namely the use of high-capacity base grouted bored piles. Particular emphasis is given to archaeological aspects, which strongly determined the top-down solution and construction sequence. Finally, the main results of the monitoring devices are presented as well as the changes implemented during the works determined by differences between the measurements and the design estimations.

RÉSUMÉ: Cet article présente les solutions proposées pour les travaux d'excavation, de mur de soutènement et de fondations profondes nécessaires à la construction de 4 étages souterrains de deux bâtiments de bureaux à Alcântara, adjacents à l'Avenida da Índia, à Lisbonne. Les principales contraintes existantes étaient les conditions archéologiques, géologiques, hydrogéologiques, géotechniques et de voisinage, qui ont déterminé le choix de la solution du mur de soutènement et son support horizontal. La technologie des parois moulées a été utilisée pour le mur de soutènement, combinée à une séquence descendante pour assurer le support horizontal. Les solutions adoptées pour les fondations profondes sont également décrites, à savoir l'utilisation de pieux forés de grande capacité avec injection the coulis de ciment dans la base. Un accent particulier est accordé aux aspects archéologiques, qui ont fortement déterminé la solution et la séquence constructive. Enfin, les principaux résultats des dispositifs de suivi sont présentés ainsi que les changements mis en œuvre au cours des travaux déterminés par les différences entre les mesures et les estimations de conception.

Keywords: Diaphragm wall; bored piles; top-down; excavation; ground anchor.

1 INTRODUCTION

The foundation, excavation and retaining wall solutions developed for the construction of the underground levels of the Alcântara Riverside project, located on Avenida da Índia in Alcântara, Lisbon, were defined to enable the construction of 4 underground levels under safe conditions and to guarantee the minimisation of the impact on the existing constraints in the surroundings (Figure 1).

Considering the location of the building, there was a set of extremely important natural and anthropogenic constraints that strongly determined the conceptual design of the works, namely: the proximity to the River Tagus, which determined the existence of a high water table; the existence of very permeable sandy alluvium which, together with the high water table, recommended that ground anchors should (prudently) not be used below the water table; and the existence of important archaeological findings scattered throughout the intervention area, which needed to be preserved and/or recorded before they suffered any affect resulting from the works.

To take into account all the existing constraints, a diaphragm wall solution was defined, anchored at the

top level (at the capping beam) and propped at the level of floors -1 and -3 by slab strips and metal struts.

Figure 1. Site location.

The foundation solution consisted of Ø1000mm and Ø1200mm high-capacity base grouted bored piles, embedded at the basalt rock and injected through the cross-hole tubes at a depth of 3.0m below the base.

2 MAIN CONSTRAINS

2.1 Geological and geotechnical scenario

An in-depth analysis of the geological conditions revealed sedimentary materials overlying volcanic formations, requiring specialized geotechnical solutions (Figure 2).

A first step in comprehending the geological and geotechnical intricacies scenario of the Alcântara region involved deploying advanced subsurface exploration techniques. The deployment of Cone Penetration Tests (CPT), borehole drilling, and geophysical surveys played a central role in mapping the subsurface layers and soils distribution. This section delves into the methodologies employed, emphasizing the importance of obtaining accurate and high-resolution data to support subsequent design phases.

The Alcântara site exhibited a diverse range of sedimentary layers, ranging from loose soils to compacted clays. Understanding these layers was fundamental to devising foundation strategies. The paper expounds on the challenges posed by the variability in sediment types and how these challenges were addressed in the selection of foundation elements. The stability of basalt formations, identified at deeper levels, provided a robust material for foundational elements.

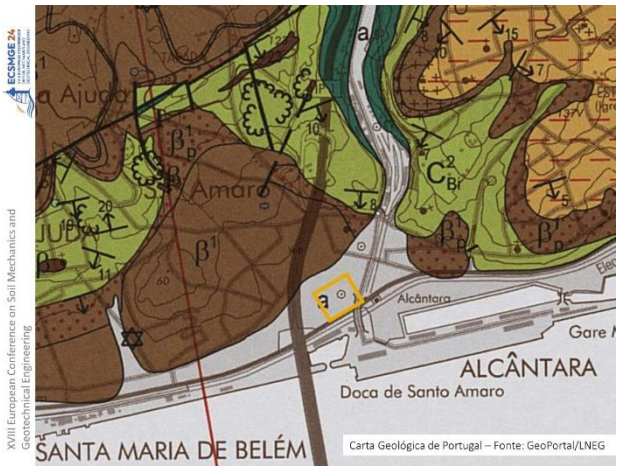

Figure 2. Portuguese geological map.

2.2 Hydrogeological scenario

The altered water flow resulting from human interventions demanded a thorough evaluation of hydrogeological conditions. In the present case, to assess the impact of the 4 basements on the underground flow regime, a global hydrogeological study was developed by LNEC (2018), in accordance with the provisions of PP Alcântara Poente (Figure 3). The result of the study indicates that the impact on the ground water table was neglectable and that no mitigation measures were needed.

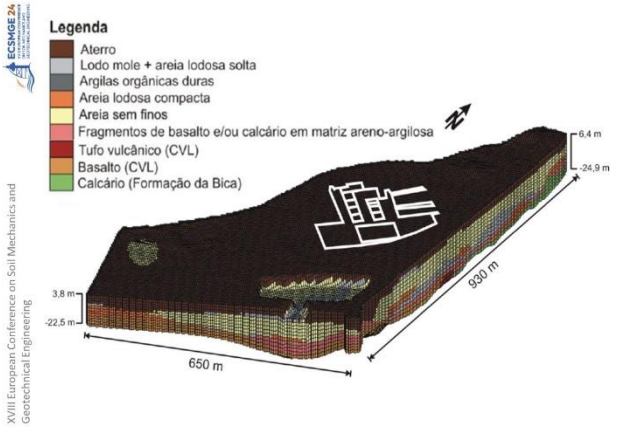

Figure 3. Hydrogeological study – Global model (LNEC 2018).

2.3 Archaeological factors

The existence of archaeological remnants, up to a depth of at least 6,0m, including several well-preserved quay walls, added an extra layer of complexity to the project (Figure 4).

Of all the structures identified, it was considered that the existing quay wall along the entire southeast alignment should be preserved in situ, with the remaining archaeological structures being demolished after proper registration.

In this context, the peripheral retaining wall, combined with temporary ground anchors allowed an unconditioned archaeological excavation to a general depth of 6.0m and an additional excavation up to 9.0m deep in the central area of the excavation.

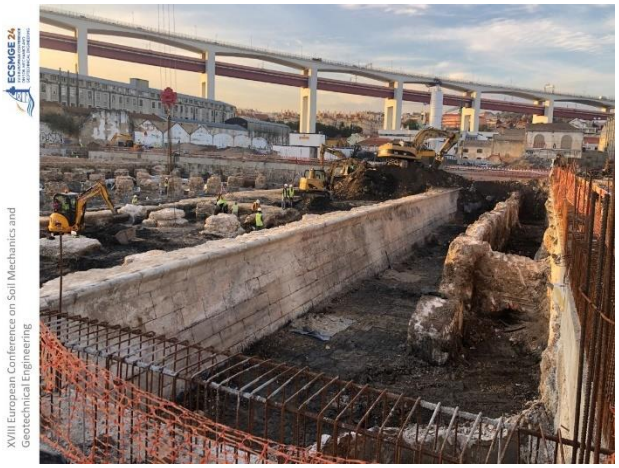

Figure 4. Archaeological remains.

3 SOLUTIONS

This section provides a detailed insight of the chosen geotechnical solutions. It includes the rationale behind opting for reinforced concrete bored piles, the structural considerations in designing a substantial raft foundation, and the application of diaphragm walls supported by temporary anchors and slab bands. The flexibility and adaptability of these solutions to address unforeseen challenges are emphasized.

3.1 Deep foundations

The selection of reinforced concrete bored piles as foundation elements was supported in a meticulous understanding of the geological strata. The Ø1000mm and Ø1200mm piles were designed to pass through the heterogeneous sedimentary layers and anchor firmly into the stable basalt formations. Detailed geotechnical analysis, combined with high pressure grouting of the pile bases, guided the precise placement of these piles, and allowed to maximize their load-bearing capacity (Figure 5).

The design of the raft foundation emerged as a critical aspect, considering the hydrogeological challenges inherent in the project site. A robust prestressed raft was designed to distribute loads uniformly and mitigate the impact of hydrostatic pressure.

In this context, the foundation piles were designed for two extreme scenarios: one in which the water table could reach 1.20m above the ground surface (in the long term due to sea level rise); and another in which the water table could not determine the installation of significant water pressure under the slab (in the short term and dependent on the permeability of the soil involved).

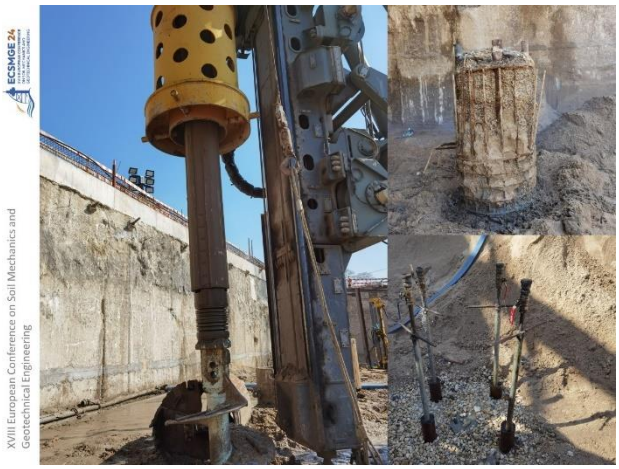

Figure 5. Bored piles drilling and base grouting.

3.2 Retaining wall and support system

The implementation of diaphragm walls as earth retaining solution was imperative for this project since it ensures high quality results, minimizing the number of joints between panels, reducing the vertical deviation of the wall, and decreasing the risk of water inflow into the excavation area. These aspects are quite important due to the height of the wall (up to 32,0m), the presence of high permeability sandy alluvium soils, and the existence of several important and settlement-sensitive city infrastructures (Figure 6).

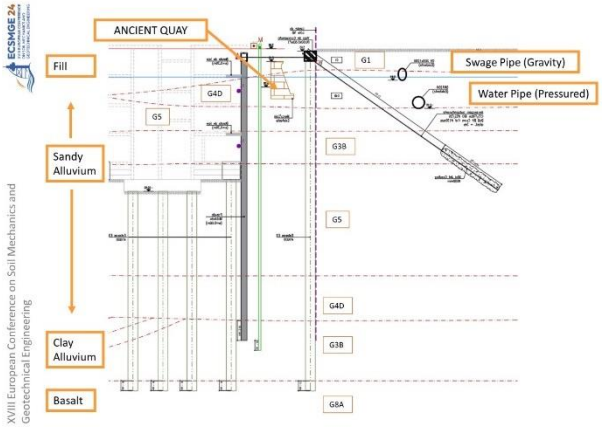

Figure 6. Cross Section of the retaining wall.

The design of the horizontal support of the wall was defined to use temporary ground anchors at the capping beam and two levels of slab bands (floor -1 and floor -3). The self-drilling ground anchors were made of tubular profiles ANP 52/26 with 10m to 17m of free lengh and 7.0m of pressure grouted lengh.

The execution of these anchors allowed the full excavation until the depth of 6.0 m and the necessary registry of all archaeological artefacts, ensuring compliance with the archaeological heritage preservation critiria. After that, the foundation piles were executed, including the teporary collumns to support the slab bands (Figure 7).

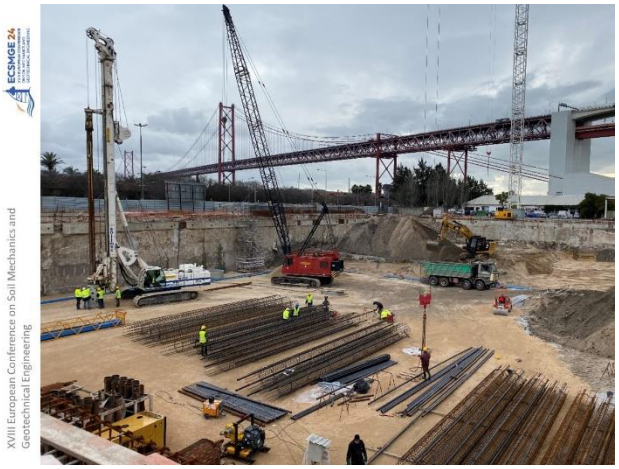

Figure 7. Excavation works at 6.0m depth.

The general design of the slab bands account not only the resistance and stiffness necessary to guarantee safety conditions of the retaining wall, but also the associated construction process, both the excavation phase and the construction phase. In this sense, the geometry of the slab bands was defined in such a way as to interfere as little as possible with the execution of the vertical elements of the structure of the building.

During the excavation phase, the slab bands were supported by the retaining wall at the external perimeter and HEB200 steel collumns sealed into the foundation piles of the definitive columns (Figure 8).

Figure 8. Execution of slab bands.

4 NUMERICAL MODELING

Advanced numerical modelling tools, such as PLAXIS 2D (Figure 9) and SAP2000 (Figure 10) were used to analyse the structural and geotechnical behaviour of the earth retaining system. The behaviour of the soil was simulated using the Hardening Soil constitutive model. The retaining walls and metallic profiles were modelled using “Plate” beam-type elements, with elastic behaviour. The anchors were modelled with spring-type elements, namely “node-to-node anchor”, while the slab bands were modelled using “Fixed-end anchor” spring-type elements. Finally, the foundation piles were modelled using “Embedded Beam Row” elements.

Regarding the high water table and the high permeability of several aluvium soil layers the Plaxis analysis were performed considering a steady state water flow and the flow rate was estimated to design the temporary water pumps.

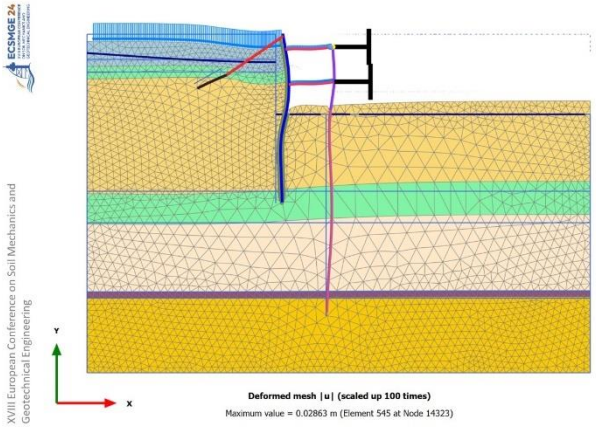

Figure 9. Plaxis 2D model. Final phase of excavation.

The slab strips on floors -1 and -3 and the additional steel struts, were analysed using the automatic structure calculation program SAP2000. The actions acting on the slab strips were determined in the PLAXIS 2D model and their stiffness was also incorporated in that model.

5 MONOTORING AND OBSERVATION PLAN

Figure 10 presents the monitoring plan implemented during construction, which involved various instruments to track displacements (inclinometers), rotations (tiltmeters), settlements (settlement marks), and groundwater levels (piezometers).

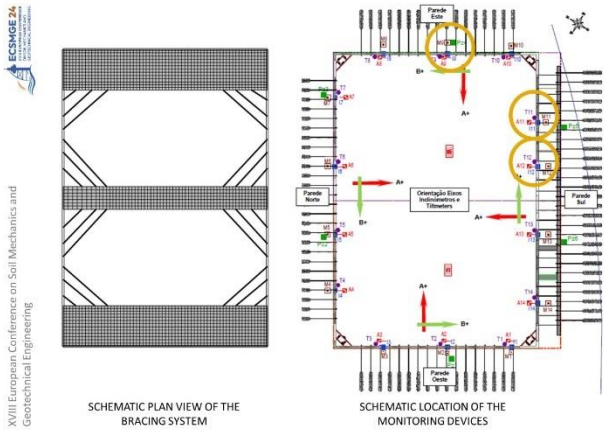

Figure 10. Monitoring devices (Inclinometer I9, I11 and I12).

During the progress of the excavation works, there was a general tendency to measure horizontal displacements of the wall greater than those foreseen in the design, particularly along the elevation supported by steel struts which are more deformable than the strip slabs.

The inclinometer graphs on Figure 11 allows the identification of much higher deformations (75mm) on I11 and I12 which are placed in a location where the diaphragm wall is supported by steel struts, than on I9 (20mm) which was placed in a location where the diaphragm wall is supported by a strip of the floor slab.

The estimated horizontal deformation of the wall for both section was 22mm and 27mm, respectively.

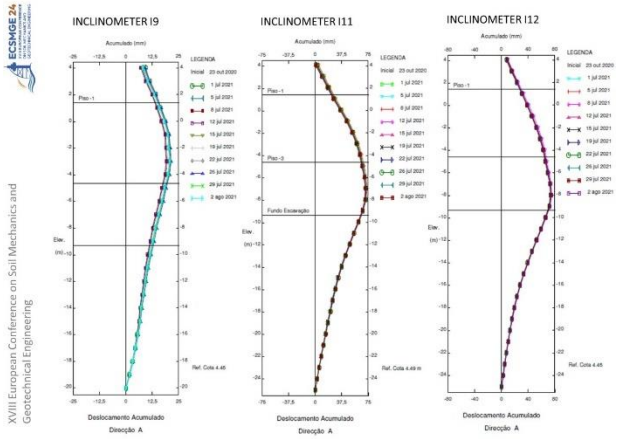

Figure 11. Inclinometer graphs.

The comparison of the wall deformation presented in Figure 9 with the real deformation measured by the inclinometers (Figure 11), and the retroanalysis performed during the construction works, indicated that the most probable cause of the higher deformation was a combination for two aspects:

- Overestimation of the steel struts' stiffness due to an underestimation of the slab strips stiffness. The smaller deformation of the slab strips decreases the induced deformation of the corner struts which reduces the efficiency of the struts on the perpendicular elevation;
- Underestimation of the stiffness reduction of the clean sand alluvial formations located at the passive zone of the wall.

6 CONSTRUCTION CHALLENGES AND ADAPTATIONS

Unforeseen challenges, including higher-than-expected deformations and anomalies in foundation pile tests, are addressed in this section.

Several steel struts were encased in reinforced concrete to increase their stiffness and, indirectly, to minimise the horizontal deformations of the retaining wall.

During the execution of the cross-hole integrity tests, planned for all foundation piles, the existence of some anomalies was detected, namely lack of covering, enlargements of the section, concrete segregation, and intercalation of soil pockets (Figure 12).

Figure 12. Foundation piles anomalies.

In some situations, where the pathologies were relevant for the future performance of the piles, due to their position on the building layout or the expect stress level, some reinforcement measures were implemented. In the most demanding situations, namely in a structural alignment where there was only one pile under each column, it was necessary to enhance the load capacity through the execution of additional large capacity self-drilling micropiles of 3200kN ultimate load.

During the excavation works, through the quantification of the flow rates pumped daily, it was possible to confirm that the inflow of water into the excavation area was extremely low when compared to

the estimates from the design phase (conditioned by the various permeability tests carried out during the initial surveys). Based on these results and previous experience (Pita, 2012), the planed raft foundation was replaced by a drainage mattress and individual pile caps connected by foundation beams (Figure 13).

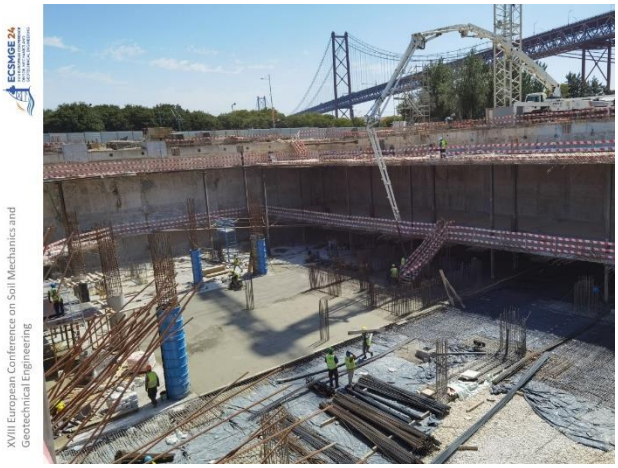

Figure 13. Bottom drainage gravel layer.

7 CONCLUSION

The success of the project is attributed to the careful integration of geological, hydrogeological, and archaeological considerations.

The adaptability of the proposed solutions, supported by systematic monitoring of the retaining wall was determinant in the timely implementation of corrective measures and cost optimization decisions.

ACKNOWLEDGEMENTS

The authors would like to thank the Owner of the building for authorising the writing and publication of this paper. They also would like to emphasise that the success of the solutions implemented was the result of teamwork of the following companies: JETsj Geotecnia as designer, Rockbuilding as project and supervision manager, Alves Ribeiro / HCI as general contractor, and Teixeira Duarte as geotechnical subcontractor.

ABSTRACT: Among the most useful methods of gathering geotechnical information from soils beneath the surface are drilling and applying permeability tests in it. The results obtained from such methods provide relevant data that can be used to predict and avoid natural and geotechnical disasters, such as slope and dam failures. A very common practice in drilling tropical soils is the usage of high viscosity fluids, in order to cool down the drilling row, provide stability to the borehole walls and ease the retrieval of samples. However, the use of such fluids causes impermeability in the borehole walls and impacts the hydraulic parameters obtained when the water is injected during the permeability test. A solution for this problem could rely on applying high-density fluids only in the internal edge of the sampling row, implying that no contact between the fluid and the borehole walls occurs. Therefore, this study aims to compare the results from permeability tests executed in the same geological layer, with and without the use of drilling fluids. The expected results indicate that there should not be relevant differences in the results of both methods, hence the fluid will not overflow to the borehole walls.

RÉSUMÉ: Parmi les méthodes les plus utiles pour collecter des informations géotechniques sur les sols sous la surface figurent le forage et l'application de tests de perméabilité. Les résultats obtenus grâce à ces méthodes fournissent des données pertinentes qui peuvent être utilisées pour prédire et éviter les catastrophes naturelles et géotechniques, comme les ruptures de pentes et de barrages. Une pratique très courante dans le forage des sols tropicaux consiste à utiliser des fluides à haute viscosité, pour refroidir la rangée de forage, d'assurer la stabilité des parois du trou de forage et de faciliter la récupération des échantillons. Cependant, l'utilisation de tels fluides provoque l'imperméabilité des parois du forage et impacte les paramètres hydrauliques obtenus lors de l'injection de l'eau pendant le test de perméabilité. Une solution à ce problème pourrait consister à appliquer des fluides à haute densité uniquement sur le bord interne de la rangée d'échantillonnage, ce qui implique qu'aucun contact entre le fluide et les parois du trou de forage n'est établi. Cette étude vise donc à comparer les résultats de plusieurs tests de perméabilité réalisés dans les mêmes strates géologiques, avec et sans utilisation de fluides de forage. Les résultats attendus sont qu'il ne devrait pas y avoir de différences significatives dans les résultats des deux méthodes, raison pour laquelle le fluide ne débordera pas vers la paroi du forage.

Keywords: Permeability test; hydraulic conductivity coefficient; high-density fluids; "quadrilátero ferrífero"; drilling.

1 INTRODUCTION

In order to determine the *in-situ* hydraulic conductivity coefficient (k) of soils, different permeability test methods can be applied, such as the tests executed inside of boreholes or standpipe piezometers (field testing).

In general, the methodology of execution of those tests consists of applying a variation in the water column (rising or falling) through injection or removal of water and measuring the absorbed/removed water volume due to time.

In both engineering and environmental geology study fields, those tests are systematically executed to establish permeability conditions and enable the

design and implementation of civil engineering works and environmental projects. Therefore, they are often employed in dams and tunnels projects, also for landfill conceptions, and investigation of contaminated sites, among many other types of projects (ABGE, 2020).

Due to the relation between the execution of field permeability tests and the prospection method applied, it is certain that operational factors may interfere in hydraulic conductivity results. As example, the use of drilling fluids can be mentioned. Under those circumstances, it is common to be required the non-utilization of those fluids in boreholes which are destinated to permeability tests execution.

On the other hand, the use of those fluids is essential to ensure effective drilling operation, since it provides better drilling rates and lower operational costs. Some of the advantages of the usage of drilling fluids stands out: lubrification and cooling of the drilling tools during rotary drilling process; efficient removal of debris inside the borehole; better recovery rates of unconsolidated materials; avoiding overcoming obstructions; and avoiding damages to drilling equipment.

A solution for this matter could rely on applying high density fluids only in the internal edge of the sampling row, implying that no contact between the fluid and the borehole walls is made.

Still, there are few published studies which intend to investigate the relation between the use of drilling fluids and hydraulic conductivity results.

Therefore, the present paper intends to compare the results from permeability tests made in the same geological layer, with and without the use of drilling fluids.

2 OBJECTIVES

The present study aims to stablish and understand the influence of using high density fluids in drilling operations, and the results obtained with permeability tests applied at the same geological layer.

The expected results indicate there should be no relevant differences in the results of both methods, hence the fluid will not overflow to the borehole wall. The methodology consisted of applying the following steps:

- Perforation of two boreholes, with a length of 19.0 m each: SM-01, with non-material recovering and without using high density fluid materials; SM-02, sibling borehole, with material recovering and using high density fluid;
- Execution of geological visual-tactile description of the SM-02 drilling soil samples;
- Carrying out permeability tests inside both boreholes, according to preestablished depth intervals;
- Calculation of the soil hydraulic conductivity coefficient (k) for each test, according to Zangar (1953);
- Comparison of the results obtained for each geological layer, in order to verify how the usage of high-density fluid influenced the k coefficient.

The study area belongs to a mining complex located at “Quadrilátero Ferrífero” geological province, more specifically at Itabirito city, Minas Gerais state, Brazil. Figure 1 illustrates the location of the two boreholes inside the study area.

The boreholes were executed using an hydraulic rotary drilling equipment. The equipment and tools employed at the permeability tests development are listed below:

- Water pump with a minimum 40 L/min capacity;
- 2 water meters (flow range: 10 to 40 L/min);
- Graduated cylinder;
- Threaded funnel attachable to the liner;
- Electric water level meter;
- Graduated bucket;
- Certified metal ruler;
- Stopwatch.

.

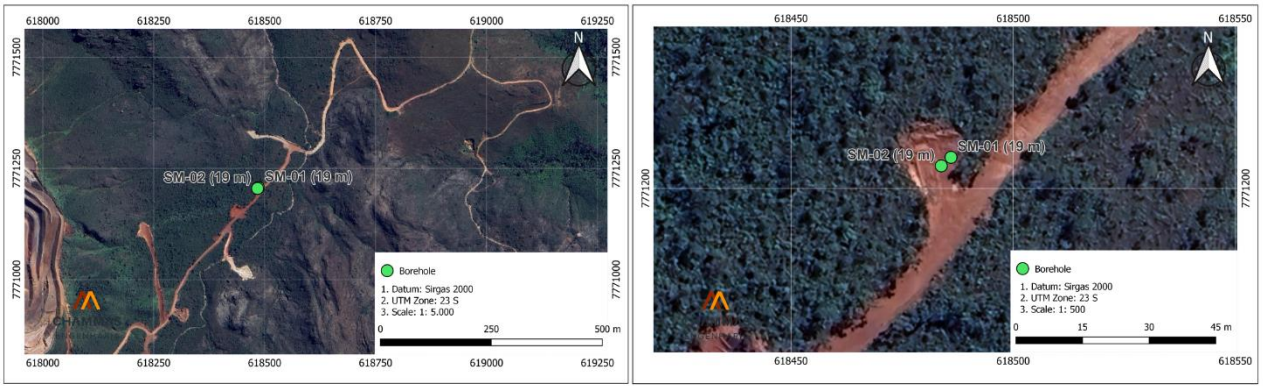

Figure 1. Location of the two boreholes inside the study area (left:1:5.000 scale; right: 1:500 scale).

The tests were carried out holding the water level column inside the borehole through water addiction. The equations proposed by Zangar (1953) allow obtaining the hydraulic conductivity coefficient (k).

For unsaturated strata, k coefficient is calculated using the Equation 1 below:

$$k = \frac{Q}{2\pi L_A\,(2h_1 - L_A)} \cdot \left[sinh^{-1}\left(\frac{L_A}{r_1}\right) - \left(\frac{L_A}{h_1}\right)\right] \quad (1)$$

For saturated strata, k is calculated using the Equation 2 below:

$$k = \frac{1}{C_s r_1} \cdot \frac{Q}{h_1}, where\ C_s = \frac{L_A}{r_1} \cdot \frac{2\pi}{ln\frac{L_A}{r_1}} \quad (2)$$

where k is the hydraulic conductivity coefficient (cm/s), Q is the steady state flow (cm³/s), h_1 is the head on well (cm), r_1 is the well radius (cm), L_A is the active or uncased length of well (cm) and C_s is the saturated strata conductivity coefficient.

3 RESULTS

Table 1 shows the permeability test results for both drilling holes. The geological description of the soil drilling samples is presented at Table 2 below.

Table 1. Permeability tests results for SM-01 and SM-02.

Test nº	Depth (m)	SM-01	SM-02
1	3.00 – 4.00	1.79E-04	1.51E-05
2	6.00 – 7.00	-	5.20E-06
3	9.00 – 10.00	-	-
4	12.00 – 13.00	2.29E-04	4.00E-05
5	15.00 – 16.00	7.44E-05	1.65E-05
6	18.00 – 19.00	2.49E-07	4.25E-05

Table 2. Geological description of the soil drilling samples (SM-02).

Depth (m)	Description
3.00 – 4.00	Clayey silt
12.00 – 13.00	Fine-to-medium silty sand
15.00 – 16.00	
18.00 – 19.00	Fine-to-medium silty sand (altered rock – quartzite)

Due to operational reasons, it was not possible to execute the test in SM-01 at depths 6.00 m to 7.00 m (test number 2) and 9.00 m to 10.00 m (test number 3- in this case, at both drillholes). Hence, these two intervals were not taken for analysis purposes, since there is no data related. Once the tests executed at the range 18.00 m to 19.00 m (test number 6) covers an altered rock layer, this must be taken in consideration. Figure 2 illustrates the permeability coefficients obtained for each range.

In general, it is possible to notice that the results obtained from permeability tests executed in SM-02 were influenced using high-density fluids, showing a reduction trend of permeability coefficient when high-density fluids were used at the drilling process.

Although, the same pattern was not observed in tests number 6 results (executed between 18.00 m and 19.00 m, covering the altered rock layer). In that case, the permeability coefficient for SM-01 (with high-density fluids) was higher than the result obtained for SM-02 (without using high-viscosity fluids).

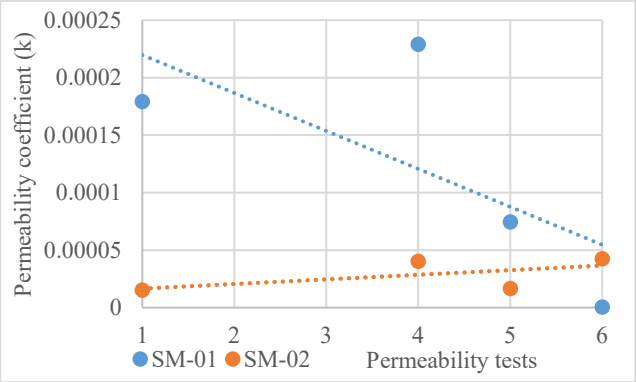

Figure 2. Results of permeability coefficients (k) obtained for SM-01 and SM-02.

4 CONCLUSIONS

Based on the obtained results, it is possible to conclude that using high-density fluids in drilling operations may compromise the permeability test results. The hydraulic conductivity coefficient results, calculated for tests made at SM-01 drilling, show a decrease rate around 10 times when compared to the same tests carried out in SM-02, which highlights the influence of using such fluids.

In order to deepen the analysis of the relation between using of high-density fluids and their influence in borehole walls permeability and hydraulic parameters, more data is necessary. Thus, the authors recommend the study to be continued, applying the same methodology in more samples.

De-construction as part of life cycle management

La déconstruction dans le cadre de la gestion du cycle de vie

A. Tuomela*, J. Majava, T. Luukkonen, P. Leviäkangas
University of Oulu, Oulu, Finland

**anne.tuomela@oulu.fi*

ABSTRACT: Finland has committed to utilizing 70% of construction and demolition waste (CDW) by 2020. However, the current re-utilization rate is still below 60%. Altogether 85% of the total CDW is generated by repair projects and demolished buildings, while the remaining 15% is coming from new construction. Hence, the main emphasis should be on the recycling of demolished or repaired buildings and constructs. Construction in urban areas start often with the demolition of old buildings and structures. At the same time, there is a need to construct new or upgrade old infrastructure such as streets, footpaths and bicycle lanes, parking areas, and noise barriers. The demolition materials should be utilized *in situ*, near the demolition site. This would result in apparent economic savings in terms of heavy transportation and thereby and lower emissions. Also, the strain on existing road structures and congestion on the city's street network would be relieved. Finally, the need for virgin raw materials would be less. This paper presents a novel operating model that combines demolition operations and construction operations by optimizing material quantities, quality, work scheduling, and site operations. Various demolishing aggregates, side flows and other fraction flows will be tested in experimental structures with the aim of finding out whether they meet the regulatory requirements and standards for infrastructure construction.

RÉSUMÉ: La Finlande s'est engagée à utiliser 70 % des déchets de construction et de démolition (CDW) d'ici 2020. Cependant, le taux de réutilisation actuel est toujours inférieur à 60 %. Au total, 85 % des déchets CDW sont produits par des projets de réparation et des bâtiments démolis, et les 15 % restants proviennent de nouvelles constructions. L'accent devrait donc être mis principalement sur le recyclage des bâtiments et constructions démolis ou réparés. Dans les zones urbaines, la construction commence souvent par la démolition de vieux bâtiments. Dans le même temps, il est nécessaire de construire de nouvelles infrastructures ou de moderniser les anciennes infrastructures telles que les rues, les sentiers piétonniers et les pistes cyclables, les aires de stationnement et les écrans antibruit. Les matériaux de démolition peuvent être utilisés à proximité du site de démolition. Cela se traduirait par des économies économiques apparentes en termes de transport lourd et donc par une réduction des émissions. De plus, la pression sur les structures routières existantes et la congestion du réseau routier de la ville seraient réduites. Enfin, le besoin de matières premières vierges serait moindre. Cet article présente un nouveau modèle d'exploitation qui combine les opérations de démolition et les opérations de construction en optimisant les quantités de matériaux, la qualité, la planification des travaux et les opérations sur le site. Différents agrégats de démolition, écoulements latéraux et autres flux de fractions seront testés dans des structures expérimentales dans le but de déterminer s'ils répondent aux exigences réglementaires et aux normes relatives à la construction d'infrastructures.

Keywords: Construction; demolition; waste; infrastructure; recycling.

1 INTRODUCTION

Construction and demolition waste (CDW) accounts more than a third of all waste generated in the European Union (EU). CDW contains a wide variety of materials such as concrete, bricks, wood, glass, metals, plasterboard, and plastic. EU set an ambitious target for 2020: recovery, re-use, and recycling of non-hazardous CDW materials should be increased to at least 70% by weight (Directive, 2008). Many countries are behind the target, including Finland in which the recycling rate is still less than 60% (Figure 1) (Statistics Finland, 2023).

The Finnish National Waste Plan for 2027 has objectives for CDW waste management as follows: a) the total amout of CDW waste should be decreased, b) CDW utilization rates should reach the level of 70%, and c) the high-quality recovery of CDW waste is increased by managing the risks (Ministry of Environment, 2022). The forthcoming risk management objective will be an important part in the circulation of CDW waste. The same principle has been followed in the rehabilitation of contaminated soils for a decade.

Figure 1. In Finland the recycling of construction waste is behind the recycling target set by the EU (green line) (Statistics Finland, 2023.

Ginga et al. (2020) considered the importance of future research in exploring new construction applications for CDW waste. Menegaki and Damigos (2018) collected data on the factors enhancing and hindering CDW waste recovery. More specifically, Kourmpanis et al. (2008) collected data on the challenges and benefits of on-site crushing and sorting. Disadvantages included, for example, noise and dust emitted in urban areas. However, today‘s technologies and machines are more advanced, as was the case almost 20 years ago. Also, the readiness to change many working practices and processes has increased.

This paper introduces the preliminary framework to be tested and evaluated in PURKU project. The project, Demolition as part of urban construction - eco-efficient utilization of demolition material in infrastructure and building construction, start in the beginning of 2024. The project is funded by the EU‘s Just Transition Fund (JTF). In addition, the paper introduces effective measures that will be executed in the project to enhance CDW waste recovery and recycling.

2 DATA AND METHODS

The PURKU project is divided into seven work packages including value network and life cycle analysis, development of project practices and operation methods, laboratory studies, demolition pilots, support for the industry change, and project management and communication. The main objective is to create new operating model that will be studied and tested at the test sites (demolition pilots). Particular attention is paid to new working methods for crushing rock to be suitable for reuse at or in the vicinity of the site, without the materials being transported to be processed away from the demolition sites and back after treatment. On the other hand, attention is paid to project management and that in the future demolition would be better managed in the life cycle of construction. Laboratory studies aim to investigate the properties of structures and the conversion of harmful substances to a less harmful form. The workshops will bring together different stakeholders to learn about sustainable demolition. Together with various actors the operation model is developed and implemented.

2.1 Value chain and project management practices

The project develops a new kind of value chain and project management practices for construction that assume that demolition is at the beginning of the value chain and life cycle models. Traditionally, demolition has been the end point of construction (e.g., Yeheyis et al., 2013). The construction industry involves various stakeholders at different stages of a building's life cycle. These include, for example, legislators, authorities, city planners, customers, designers, contractors, material suppliers, subcontractors, demolition companies, material, and waste handlers. The construction industry's operating models and practices are well-established and regulated in many ways, but the transition to a circular economy (CE) poses new challenges and needs for change. The transition to a more efficient material life cycle and the utilization of side streams and demolition material requires value chain and project practice development to comply with CE principles.

To achieve the goals above, our project will analyse the construction value chain and its development opportunities from building aggregates’ perspective by using life cycle, stakeholder, and business model analysis as tools. The analysis will be conducted on previous demolition-construction cases in Oulu area as well as the demolition pilots implemented in the project. Furthermore, the analysis will cover project management practices (including processes, actors, decision-making, tools) with the aim of identifying development opportunities in different phases of the project's extended life cycle (conceptualization, planning, implementation, operational phase). The use of CE thinking and strategies in case projects will be utilized to develop a project management model and a business model that integrates demolition with construction. The aim is to develop stakeholder management, procurement management, and risk management, as well as replicable project management procedures that take CE principles into account. Finally, demolition-construction related operating models, practices and material management will be developed. Figure 2 shows the current and

target life cycles and practices in the construction value chain.

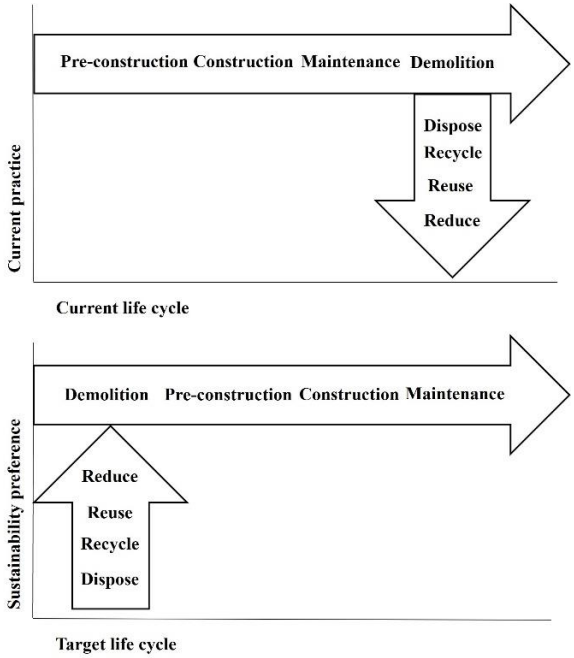

Figure 2. Current and targeted construction value chain.

2.2 Demolition pilots

The research pilots are in Oulu region, Finland. Oulu is home to Finland's largest demolition site, the old University Hospital, which is one of the selected research and pilot sites. In addition, there are other pilot sites coming from the area, but they are smaller.

The purpose of the pilots is to change the crushing activities of the materials so that the mineral based structures are crushed on-site in the urban area. During the crushing, the following parameters are monitored 1) dust, 2) vibration and 3) noise generated by on-site demolition pilots, and 4) other emissions that are harmful to the environment and the populations.

In Finland, a large part of the year is worked in winter conditions and it brings its own challenges e.g., to dust-binding. Water has typically been used for dust-binding, but water freezes, so other additives must be used economically end enviromentally wise for winter dust-binding. To achieve the best possible results, it is possible to test new additional equipment and alternative bio-based dust-binding methods at the sites.

Crashing and demolition is generally known to be loudly processes. Efforts are made to identify noise-sensitive activities at the site and find ways to prevent noise and vibration. Pilots require from contractors' equipment to be used to reach the permitted noise and vibration levels.

The non-hazardous CDW waste from the pilots are planned to be use in the sites or nearby infrastructure construction sites, like the foundation of bridges. Still, contaminated CDW waste is generated. The purpose is to build test fields in which those hardly utilized materials are used for bottom structures. The fields will be monitored for several years to provide information on environmental impacts. Similar smaller laboratory scale test structures will be built in parallel, in which climate conditions can be modified and accelerated to obtain information on the environmental impact of materials.

2.3 Laboratory studies

The laboratory-scale studies of the project support the demolition pilots but also make some completely new research openings (e.g., related to asbestos waste). The topics are (1) dissolution studies of asbestos fibres to render them non-hazardous; (2) studies of Polycyclic Aromatic Hydrocarbons (PAH) and heavy metal containing demolition waste fractions; (3) dust suppression during demolition; and (4) seepage water studies. For asbestos, the aim is to utilize additives enhancing the dissolution of the fibres with potential to utilize the dissolved asbestos (rich in silica (Si), calcium (Ca), magnesium (Mg), and iron (Fe)) as a raw material to the development of new recycled construction materials. PAH and heavy metal quantities and distribution in demolition materials are studied with their solubility under different conditions, which supports the material choices for the pilots. In terms of dust suppression, the goal is to conduct preliminary studies with enhanced dust-binding chemicals. The aim of seepage water experiments is to build laboratory-scale model systems simulating the behaviour of the materials when exposed to outdoor conditions.

2.4 Workshops

During the project training events and workshops will be arranged together with stakeholders to achieve new value chain-based operation model. In addition to public training events and seminars, the joint collaborative workshops will be organized with the key stakeholders that are involved in de-construction and construction value chain. The objective is to verify and elaborate the change requirements that are caused by the transition to more sustainable de-construction and life cycle management practices based on circular economy methods. The analyses of earlier de-construction projects and experiences gained during the de-construction pilots will be used as inputs in the work conducted in the workshops. The intended outcome of the workshops is to create a joint regional development plan to advance the use of de-

construction materials and circular economy in the construction industry overall.

3 RESULTS AND CONCLUSIONS

The project will officially start at the beginning of 2024. The first demolition sites will be started during the spring or summer. Preparations have already been commenced and will continue throughout winter 2024. The project will demonstrate how on-site demolition can make sense, by utilising life cycle calculation methods and narrating practical examples.

Direct positive effects are expected to be observed for example regarding reduced heavy truck traffic. This would improve road safety and reduce the load stress of the local roads and streets, as well as minimize emissions from heavy traffic.

Alternative project management concepts can be applied to enhance wider use of demolition materials. For instance, the project attempts to find new synergies between local construction projects to create local mass/material balance. This will improve local material circularity. The main ambition is to demonstrate that materials from demolition are valuable and usable building material, and it makes both economic and environmental sense to make maximum use of them.

ABSTRACT: This paper looks at the behaviour of welded steel mesh-reinforced piled embankments through a series of small-scale tests. Findings reveal that reinforcement axial and bending stiffnesses have minimal influence on soil arching. In contrast, the friction angle of the embankment fill plays a more significant role in shaping soil arching. The Concentric Arches (CA) model, adopted in CUR226 (2016), tailored for geosynthetics, matches the measured soil arching well. The study introduces the use of Distributed Fibre Optic Sensing (DFOS) technology, providing a 3D view of reinforcement and fill deformations.

RÉSUMÉ: Cet article examine le comportement de remblais en pieux renforcés par treillis soudés à travers une série de tests à petite échelle. Les résultats révèlent que la rigidité du renforcement a une influence minimale sur les transferts de charges. En revanche, l'angle de frottement du matériau de remblai joue un rôle plus significatif dans les mécanismes de transferts de charges. L'effet d'arche du modèle 'Concentric Arches' (CA), utilisé dans CUR226 (2016), dédiée aux géosynthétiques correspond bien aux mesures obtenues. L'étude introduit également l'utilisation de la technologie de détection par fibre optique répartie (DFOS), offrant une vision tridimensionnelle des déformations du renforcement et du remblai.

Keywords: Piled embankments; steel basal reinforcement; model scale tests; soil arching.

1 STEEL MESH BASAL REINFORCEMENT IN PILED EMBANKMENTS

Pile-supported (PS) embankments with basal geosynthetic reinforcement (GR) are commonly built in soft soil areas (van Eekelen and Han, 2020). Steel mesh reinforcement (SR) is particularly appealing for high embankments (Topolnicki et al., 2019). Its high axial stiffness, in comparison to geosynthetic, reduces horizontal deformation at the embankment base, minimizes bending moments in the piles, ultimately enhancing the embankment stability.

This paper presents a small-scale test series on steel-reinforced piled embankments, conducted in the Deltares laboratory. The tests are part of a broader research initiative called Piled Embankments with Basal Steel Reinforcement (PEBSTER), which also includes a large-scale test (Schneider et al., 2024).

The research aims to address the following questions:

1. Does the soil arching in a piled embankment differ if SR is used instead of GR?
2. Are deformations different with SR instead of GR?
3. What is the influence of flexible vs. rigid piles?
4. Can the current design methods for piled embankments using GR be applied for SR or do they require a modification?
5. Do the answers on these questions depend on the scale of model tests?

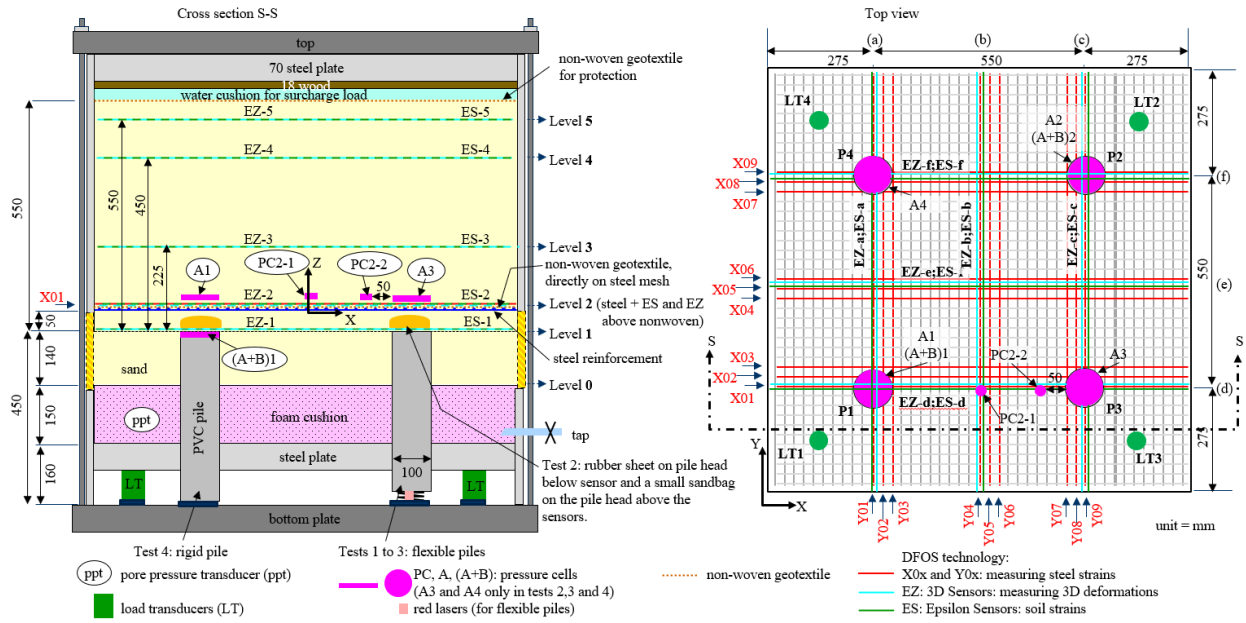

Figure 1. Test set-up small scale test steel-reinforced pile-supported embankments.

2 SET-UP SMALL SCALED TESTS

Figure 1 shows the test set-up, which is an extended version of the test set-up described by Van Eekelen et al. (2012a, 2024a). A steel plate supports a foam cushion, that is sealed and soaked. A tap allows for drainage of the foam cushion, simulating the consolidation of the subsoil between the piles. Four piles with a 0.1 m diameter pass through the steel plate.

The welded steel mesh-reinforcement was placed 50 mm above the pile heads. It consists of 43 bars in each direction. These bars have a 5 mm diameter and a centre-to-centre spacing of 25 mm, resulting in the axial stiffness EA = 164934 kN/m and bending stiffness EI = 0.2577 kN·m^2.

The fill material used is 'Darmstadt sand', sediments from the river Main, characterized as medium coarse sand. Table 1 lists test details, where the values of φ'_{cv} were derived from the relative density (RD) of the fill, using an empirical correlation obtained from 15 triaxial tests.

Table 1. Test details of the four small-scale tests.

Test no.	**1**	**2**	**3**	**4**
Fill height above steel (m)	0.55	0.55	0.55	0.56
Unit weight γ (kN/m^3)	16.7	16.9	17.0	16.6
Relative density RD (%)	68	72	75	64
Friction angle φ'_{cv} (°)	33.8	34.0	34.1	33.7

An equally distributed surcharge load is applied using a water cushion. A rubber sheet greased with Vaseline minimises the friction between fill, box walls, foam cushion and piles. The load distribution is measured by pressure cells and load transducers.

Soil strains and displacements were monitored at five elevations within the fill (Figure 1), utilizing distributed fibre optic sensing (DFOS) technology from the Nerve-Sensors family, as depicted in Figure 2. Additionally, the steel mesh reinforcement was extensively instrumented with optic fibres. In the x-direction, X01 to X09 were glued to the top of the top steel bars, while in the y-direction, Y01 to Y09 were attached to the bottom of the bottom steel bars.

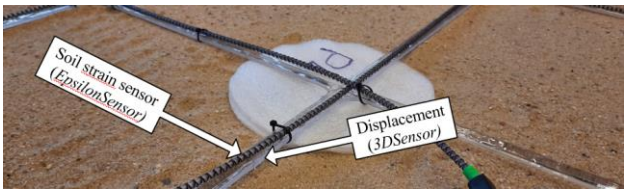

Figure 2. DFOS sensors (connected to a LUNA OBR 4600 reflectometer with 15-channel optical switch).

The series of four tests included:

Test 1: With SR, flexible piles (utilizing springs with a stiffness of 4605 kN/m below the piles) and stepwise consolidation;

Test 2: As Test 1, but continuous consolidation (the tap of the foam cushion was kept open permanently). This test closely aligns with the large-scale test described by Schneider et al., 2024.;

Test 3: As Test 1, but without SR;

Test 4: As Test 1, but with rigid piles (no springs).

3 MEASURED LOAD DISTRIBUTION

When the area between the piles deforms more than the piles, soil arching develops. In a piled embankment

with basal reinforcement, this results in a non-uniform distribution of the vertical load on the reinforcement. A significant portion of the vertical load (labelled as 'A' in Figure 3) is directly transferred to the piles since they deform less than the reinforcement. The residual load, 'B+C' in Figure 3, is supported by the subsurface between the piles.

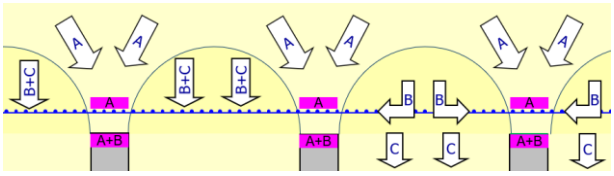

Figure 3. Load distribution in a PS embankment.

Several design guidelines and standards, such as BS8006 (2010), EBGEO (2011), ASIRI (2012), CUR226 (2016), and Topolnicki and Kłosiński et al. (2022), provide equations to divide the total vertical load into A and B+C. These guidelines then offer methods for calculating the strain in the reinforcement from B+C, considering the load-deflection behaviour of the reinforcement.

Many researchers have analysed how the geometry and material properties affect soil arching. Van Eekelen et al. (2012b) showed that the soil arching quickly develops, even when the deflection of the GR is minimal. In line with this finding, they showed that the GR tensile stiffness has a limited impact on soil arching, while the shear properties of the fill (internal friction angle) play a significant role.

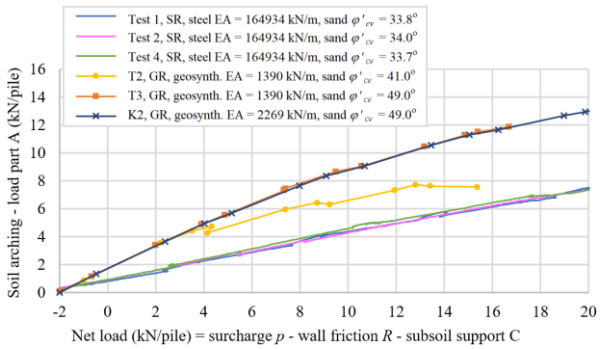

Figure 4. Measured soil arching A in the current tests with SR, compared to previous tests with GR in the same test box (van Eekelen et al., 2012).

These conclusions were valid for GR. An important question is whether the high axial and bending stiffnesses of the SR affect the soil arching.

Figure 4 compares Tests 1, 2 and 4 with SR with three previous tests with GR, conducted in the same test box. The data show much less soil arching in the SR tests than in the GR tests. The fill friction angle, however, seems to have a major impact on the soil arching, where the reinforcement stiffness does not show the same level of influence.

Since only one combination of SR stiffness and fill friction angle was tested, the pure test results cannot confirm this conclusion. However, it is possible to validate the impact of the fill and SR stiffness by comparing the measured and calculated soil arching, using three analytical methods, as shown in Figure 5 for four conducted tests.

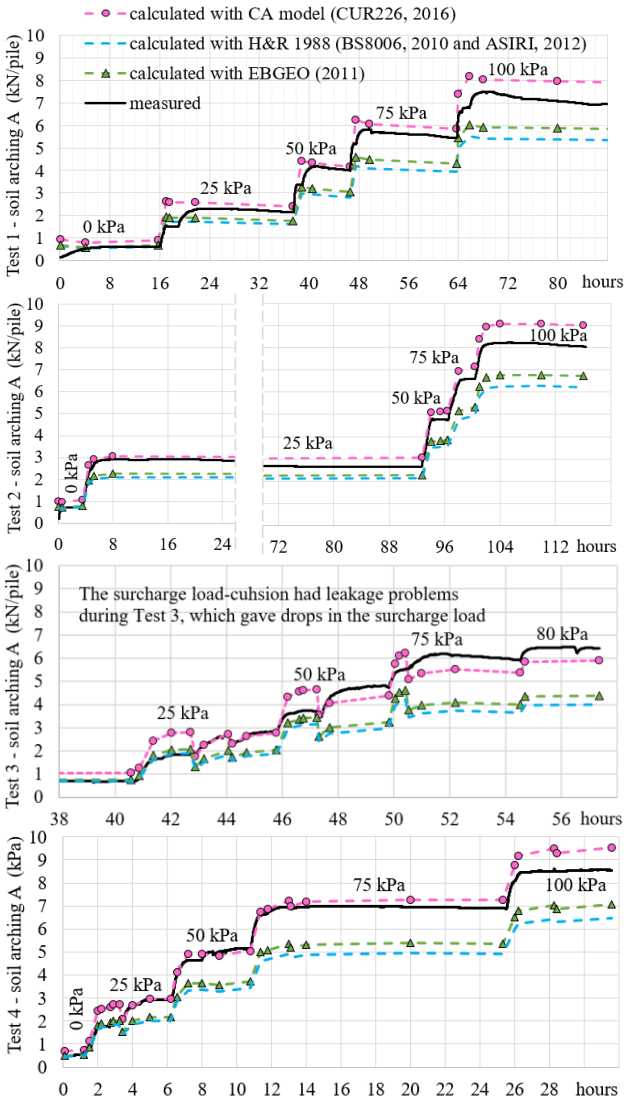

Figure 5. Measured and calculated soil arching A, using three European models. H&R refers to the model of Hewlett & Randolph 1988. Surcharge loads are indicated (0 to 100 kPa). Input parameters from Table 1.

The CA model (CUR226, 2016) consistently matches the measurements well, specifically for $p \leq 75$ kPa. It can therefore be concluded that the axial and bending stiffnesses of the reinforcement do not play a significant role because they are not considered in the soil arching part of the CA model.

4 MEASURED FILL DEFORMATIONS

For each test, the model was rebuilt. Some DFOS ruptured during testing (due to high local strains above 4%), and not all of them could be replaced in the next test. For this reason, this section focuses on Test 1, although Tests 1, 2 and 4 exhibit similar trends. This becomes evident when comparing Figure 6 and Figure 7, for example.

Figure 6 and Figure 7 show the settlements measured at different levels in the fill. The most significant differential settlements occur in the steel bars that bridge adjacent piles, denoted by lines (a), (c), (d) and (f).

The bars running through the centre of the test setup, represented by lines (b) and (e), show slightly more settlement, but notably less differential settlement. After the consolidation phase under a surcharge load of 25 kPa, the maximum settlement of the steel mesh (level 2), in the centre between four piles, is on average 8.6% greater than the settlement in the middle between adjacent piles. This finding is in line with the 3D FEM analysis of Zhang et al. (2019), who reported 6 to 8% difference. In contrast, the field measurements of Van Eekelen et al. (2020) showed a difference of approximately 25%.

The differential deflection of the steel mesh (level 2) between the piles causes soil arching. At level 3, located 225 mm above the pile heads, the differential settlement is noticeably less. At levels 4 and 5, it was only possible to reliably assess the deformations along lines (b) and (e). The settlements at these lines (b) and (e) at levels 4 and 5 are uniform. This does not prove that the 'plane of equal settlement' has been found, as there is no information about lines (a), (c), (d) and (f) at these high elevations, and these are the lines where most differential settlement occur.

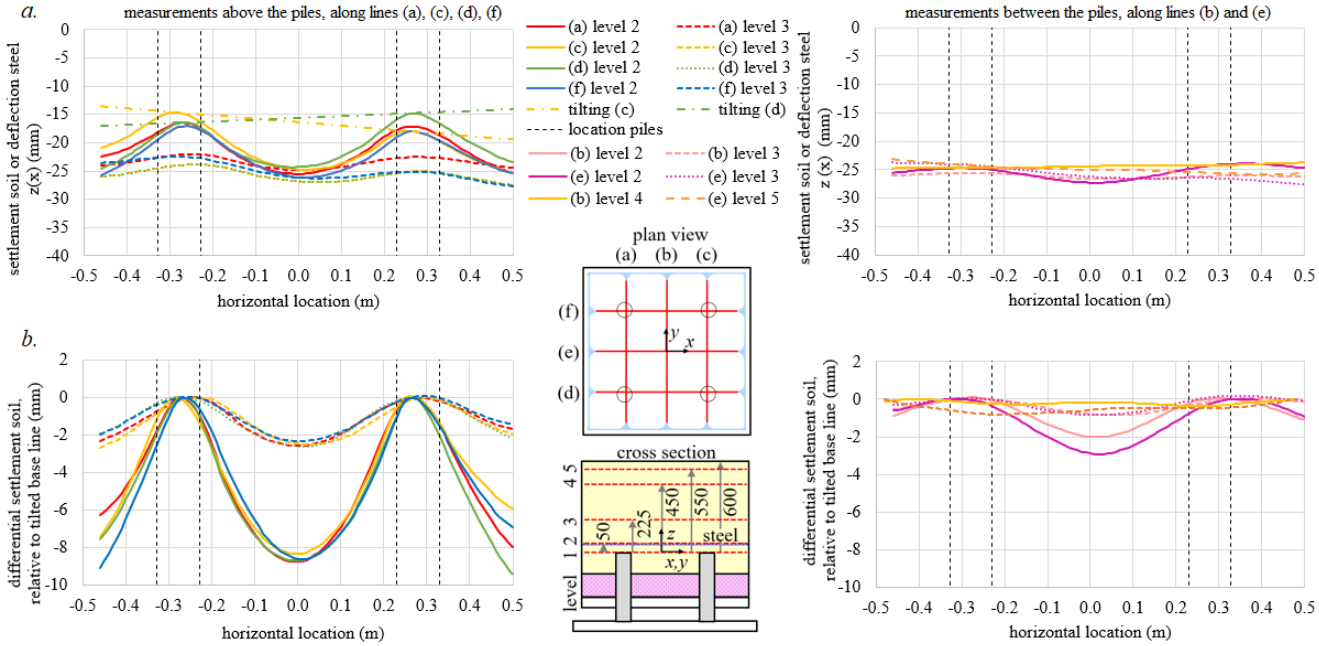

Figure 6. Test 1. Measured settlement in the fill at various levels under a 25 kPa surcharge load, after a consolidation phase. a. Measured settlements b. Settlement relative to the tilting baselines of each grid, as illustrated in top-left graph.

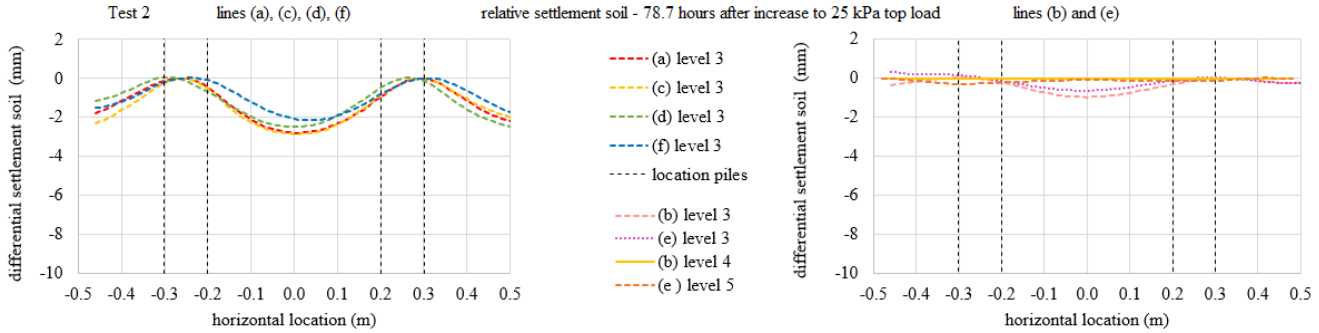

Figure 7. Test 2. Measured settlement in the fill at different levels at 25 kPa surcharge load after a consolidation phase. No data available for Test 2 – level 2.

5 MEASURED STEEL STRAINS

Figure 8 shows the strain at the top of the upper bars, all in x-direction. The left-side graphs show significantly higher strains in the steel bars above the piles, compared to those located between the piles, as shown in the right-side graphs. Bar X03 lies just next to a pile, resulting in 17 – 35% less tensile strain than the average strain in X01, X02 and X07 to X09 for the phases depicted in Figure 8.

Above the piles, we observe tensile strain in the top of the upper bars, indicated by positive values. These strains result from the bending of the steel bars above the piles. In Figure 8*b*, the maximum tensile strain reaches around 0.2%, while the maximum compression strain is around 0.06%. The presence of a 5 cm layer of sand between the steel mesh and pile heads facilitates a 'smooth' bending of the steel bars, contrasting a scenario where the SR has been installed directly on the pile heads.

In the area between the piles, we observe compression strain, represented by negative values in the top of the top bars. This is also caused by the bending of the steel (visible in Figure 7). This behaviour differs from GR, which experiences only tensile strain. Towards the edges of the piles, the steel bars exhibit an increasing tensile strain.

The alternation of compression and tensile strain underscores the importance of considering axial and bending stiffness of the steel mesh when performing calculations to simulate this situation.

The local spikes in Figure 8 are strain reading anomalies (SRAs), which are disturbances in the DFOS fibres. The higher the local bending, the more SRAs were found in the DFOS measurements. Van Eekelen et al. (2024b) further analysed these SRAs in the DFOS measurements.

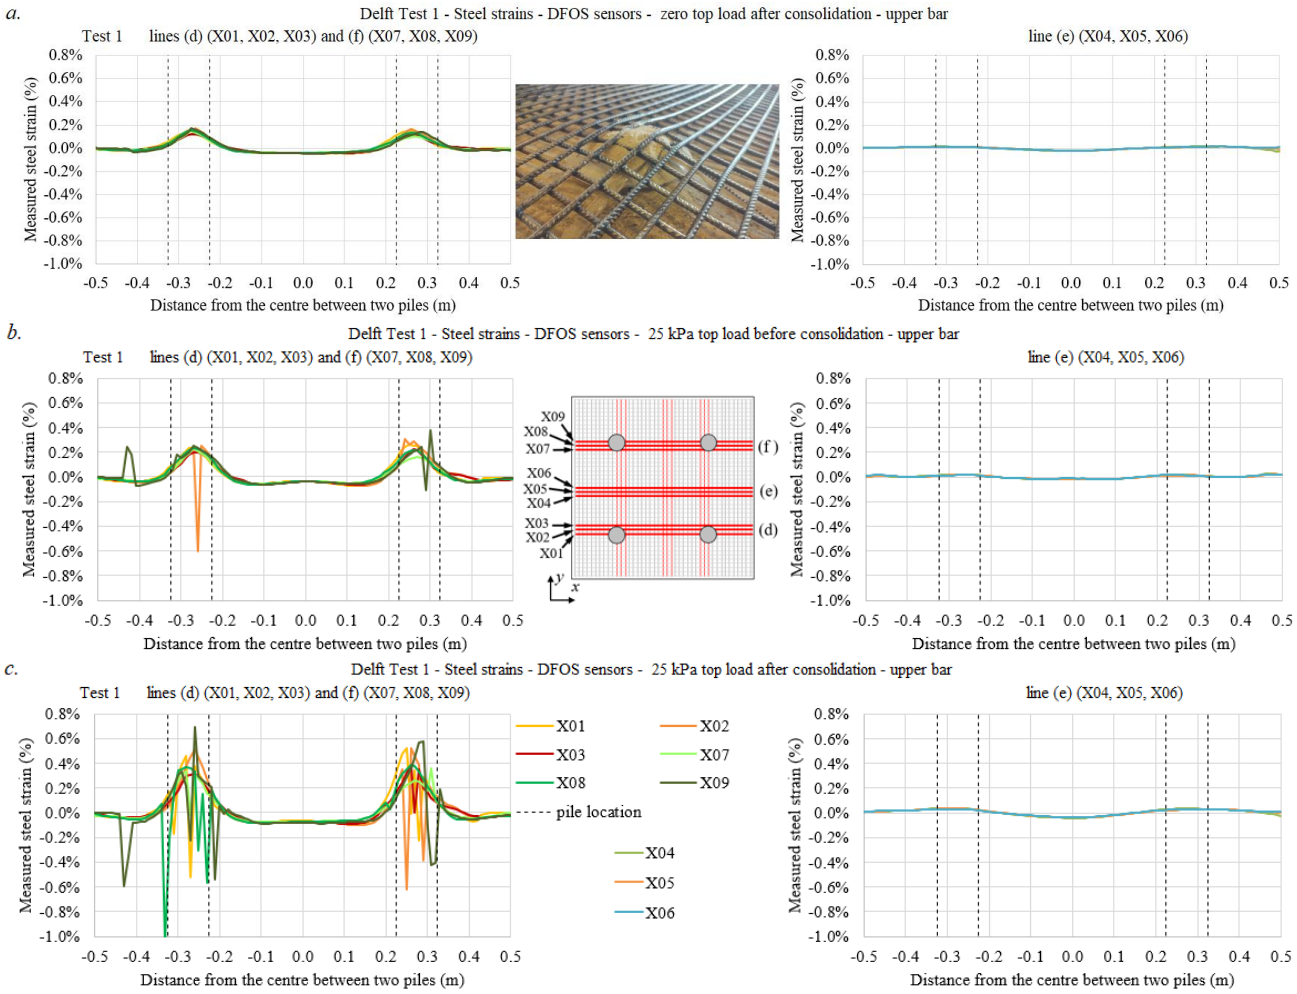

Figure 8. Test 1. Steel strains, measured on top of the top steel bar in x-direction. a. after consolidation without surcharge load, b. after increasing the surcharge load to 25 kPa, and c. after consolidation with surcharge load at 25 kPa.

6 CONCLUSIONS

This paper presents four small-scale tests on steel-reinforced (SR) piled embankments. This is part of a larger research, that also includes a large-scale test and numerical analyses. Based on the test results presented in this paper, we draw the following preliminary conclusions.

- The axial and bending stiffnesses of the SR do not significantly affect the soil arching in the fill above the piles. Consequently, the load part that is transferred to the piles directly (load part A) is similar for both types of basal reinforcement: geosynthetic and welded steel mesh reinforcement.
- The friction angle of the embankment fill has much more influence than the reinforcement type.
- Three main European design methods for GRPS embankments closely align with the measured soil arching, with the CA model exhibiting the best match.
- The DFOS sensors provide continuous and a unique 3D picture of the deformations of the reinforcement and the fill.
- The steel mesh reinforcement shows significant differential deflection and strain in the bars that bridge adjacent piles. The bars running through the centre of the square between the four piles, show slightly more settlement, but much less differential settlement and steel strain. This is in line with the deformation pattern observed in geosynthetic-reinforced piled embankments.
- Tensile strains due to bending are observed above the piles in the top bars of the reinforcement. Compression strains due to bending occur in the area between adjacent piles. This indicates that load-deflection design models for steel mesh and geosynthetic reinforcements should be different.

ABSTRACT: This paper investigates the influence of groundwater on geosynthetic-reinforced pile-supported (GRPS) embankments. 3D experiments showed that groundwater primarily reduces the load, mainly through uplift forces, but also causes a slight reduction in soil arching. However, the soil arching quickly recovers when the groundwater level decreases again. The Concentric Arches (CA) model (CUR226, 2016), combined with Archimedes' principle, provides the most accurate match compared to two other main calculation models. No significant correlation between groundwater levels and geosynthetic reinforcement strains was observed.

RÉSUMÉ: Cet article examine l'impact du niveau de la nappe phréatique sur les remblais renforcés par des géosynthétiques et des pieux (GRPS). Les expériences 3D montrent que la présence d'eau réduit principalement la charge par des forces de soulèvement, avec une légère réduction de l'effet de voûte de sol. Cependant, cet effet se rétablit rapidement lorsque le niveau d'eau souterraine diminue. Le modèle des arcs concentriques (CA) (CUR226, 2016), combiné avec le principe d'Archimède, offre la meilleure correspondance parmi les modèles de calcul. Aucune corrélation significative entre les niveaux d'eau et les déformations du renforcement géosynthétique n'a été observée.

Keywords: Groundwater; geosynthetic-reinforced pile-supported embankments; soil arching.

1 GROUNDWATER IN GEOSYNTHETIC-REINFORCED PILED EMBANKMENTS

The calculation model in the CUR226 (2016) design guideline for geosynthetic-reinforced pile-supported (GRPS) embankments was validated with over 100 measurements in experiments and field (van Eekelen et al., 2015). The validated application of a guideline is limited to circumstances like the ones from which the validation measurements were obtained. For GRPS embankments, this means for example that the entire embankment must be located above the groundwater table.

However, infrastructure needs to remain usable during or after heavy rain. In addition to that, in low, flat, subsidence-prone areas, it is often desirable to install the embankment at least partly below groundwater level. Therefore, insight is required in the influence of groundwater on the behaviour of GRPS embankments.

Limited research was done on the influence of water in a piled embankment. Briançon and Simon (2012), Sloan (2011), and Van Eekelen et al. (2020) observed that heavy rainfall affects measurements.

Song et al. (2018) presented small-scale 2D trapdoor tests with sand and concluded that water can degrade the soil arching. Wang et al. (2019), however, showed with full-scale 3D model experiments that the soil arching strengthened with an increasing water level.

In contrast, Van Eekelen et al., (2023) found no significant correlation between the groundwater table and GR strains during four years monitoring in a partly submerged GRPS embankment.

Various mechanisms can play a role when the groundwater rises in a GRPS embankment:

- An increase in uplifting forces, resulting in a reduction of effective stress. This study investigates whether this affects the soil arching mechanism, deformations and GR tensile strains.
- Swelling of the subsoil underneath the reinforcement, as measured by van Eekelen et al. (2020). The subsoil swelling reduces strain

in the reinforcement and the load on the piles. This situation is not addressed in this study.

- Dynamic liquefaction. It is essential to determine whether fill layers in the design may be liquefiable. This phenomenon is also not considered in this study.

The study aims to investigate the influence of high and changing groundwater levels in a GRPS embankment, addressing the following questions: How does the changing groundwater table in a GRPS embankment affect the soil arching in the fill, the deformations and the GR strains? For this purpose, the paper presents 3D laboratory experiments, analyses the results, and compares these with analytical calculations.

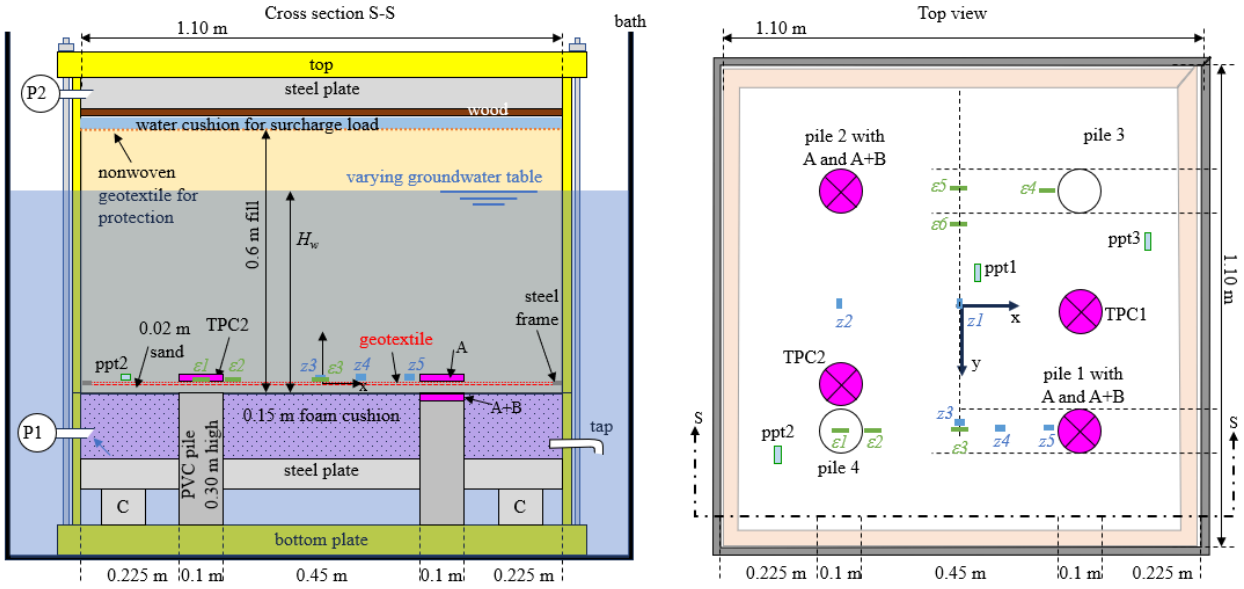

Figure 1. Test setup GRPS embankment in bath to induce a varying groundwater table in the fill.

2 SCALED EXPERIMENTS

Figure 1 shows the test setup (van Eekelen et al., 2012a, 2024). A steel plate supports a foam cushion, that is sealed and soaked. A tap allows for the drainage of the foam cushion. Four PVC piles with a 0.1 m diameter pass through the steel plate.

Two layers of Geolon 100-50 woven geotextile were placed perpendicular to and directly on top of each other. They were attached to a rigid steel frame. The combined geotextiles had a tensile strength of 100+50 = 150 kN/m and a tensile stiffness at 2% strain of $J_{2\%}$ = 1200 kN/m and 1013 kN/m for 10 and 1000 hours loading, respectively.

An equally distributed surcharge load was applied on the fill surface, using a water cushion. A rubber sheet greased with Vaseline minimised the wall-soil friction. The load distribution in the fill was measured by total pressure cells, GR deflection with a liquid levelling system (water pressure cells in a tube filled with water and connected to a reference box with water), and the GR strains were measured using cables (van Eekelen et al., 2024).

Two types of mixed demolition waste granulate were used; one with fine content (d/D = 0/31.5 mm) and one without fine content (d/D = 4/31.5 mm), where d and D are the lower and upper sieve sizes (EN13242, 2015). Table 1 lists fill details. The values of $\varphi'_{15\%}$ were obtained from four drained large-scale triaxial tests with a sample diameter of 0.45 m.

Table 1. Test details of the three small-scale tests.

Test no.	1	2	3
Fill height above steel (m)	0.65	0.60	0.60
Limiting sieve sizes d/D (mm/mm)	4/31.5	0/31.5	4/31.5
Median particle size D_{50} (mm)	18.8	7.0	18.8
Unit weight dry fill γ_d (kN/m^3)	13.19	14.60	13.20
Unit weight saturated fill γ_s (kN/m^3)	18.11	19.00	18.12
Unit weight initial fill γ_i (kN/m^3)	13.90	15.39	13.91
Porosity n (V_{pores}/ V_{total})	0.50	0.45	0.50
Friction angle unsaturated fill $\varphi'_{15\%}$ (°)	41.0	39.4	41.0
Friction angle saturated fill $\varphi'_{15\%}$ (°)	40.5	39.6	40.5

After the installation of the reinforcement, sensors and the fill, the box was closed and placed in a bath (Figure 1). Then, the subsoil support was removed by sucking the foam cushion vacuum.

Subsequently, the bath was filled. The groundwater table in the fill followed the water level in the bath easily. Then, (in Tests 2 and 3) the groundwater table was lowered again. After that, the surcharge load was increased in steps. After each surcharge load step, a groundwater cycle was applied again. In Test 1, the phreatic line was kept constant.

3 CALCULATIONS

The three main European design methods for GRPS embankments are:

- the Concentric Arches model of van Eekelen et al., (2013, 2015, adopted in CUR226, 2016);
- the model of Zaeske (2001), adopted in EBGEO, (2011);
- the model of Hewlett and Randolph (1988) adopted in both the French ASIRI (2012) and the British Standard (BS8006, 2010).

The first calculation step of these models divides the vertical load into two parts (Figure 2). Part A (kN/pile) is directly transferred to the piles and is relatively large, due to soil arching. The residual load, 'B+C' (kN/pile) is supported by the subsurface between the piles.

The second calculation step calculates the GR strain, and implicitly also divides B+C further into B and C. In the tests presented in this paper, the foam cushion underneath the GR was sucked vacuum, so that for all tests the subsoil support was zero during the entire test, so that C = 0.

3.1 Input parameters

Figure 1 gives the geometry properties, and Table 1 the fill properties. The groundwater table H_w was derived from the measured pore pressures (ppt 1, 2 and 3). The weighted value of γ in equations (2) to (5) was derived from γ_d below groundwater level (combined with Archimedes' p_{uplift} for the grains) and γ_i (kN/m^3) above groundwater level. γ_i is the initial fill unit weight that includes the 5.4% moisture content of the sand above the phreatic line.

The wall-soil friction R was 20-25% of the total load and was derived by subtracting the measured A+B+C from the total effective load. R was subtracted from the surcharge load. There was no subsoil support, so the subgrade reaction k = 0 kN/m^3. The geotextile tensile stiffness $J_{2\%}$ was chosen in line with the test duration: $J_{2\%}$ = 1106 kN/m.

3.2 Water in the calculations

Archimedes' principle states that a body immersed in a fluid is subject to an upward force equal to the weight of the displaced fluid. This aligns Terzaghi's effective stresses, which are the difference between the total stress and the water pressure.

In this paper, Archimedes' upward pressure (p_{uplift}) is used to bring into account the water in the fill. This upward pressure is defined as:

$$p_{uplift} = (1\text{-}n) \cdot H_w \cdot \gamma_w \text{ (kPa)} \quad (1)$$

where n (-) is the porosity, H_w (m) is the groundwater table above the piles, and γ_w is the unit weight of water (9.81 kN/m^3).

This p_{uplift} is integrated in the CA calculations by reducing surcharge load p with p_{uplift}. Theoretically, this aligns Terzaghi's effective stress calculations. However, using the Terzaghi's effective stresses is not possible for the CA model. This is explained as follows for the CA model (van Eekelen et al., 2013), but also applies for EBGEO:

Firstly, the CA model calculates the load distribution A% and (B+C)% without including the surcharge load (p = 0). This results in $A_{p=0}$ and $(B+C)_{p=0}$. So far, the calculation only uses the soil weight above the arches (besides geometry and material properties). Therefore, using Terzaghi's effective stress-approach would only impact the calculation for the fill part above the arches.

Secondly, the CA model includes the surcharge load:

$$A_{p>0} = \frac{\gamma H+p}{\gamma H} \cdot A_{p=0} \text{ and} \quad (2)$$

$$(B+C)_{p>0} = \frac{\gamma H+p}{\gamma H} \cdot (B+C)_{p=0} \quad (3)$$

In this study, we account for the groundwater by adjusting the equations as follows:

$$A_{p>0} = \frac{\gamma H+p-p_{uplift}}{\gamma H} \cdot A_{p=0} \text{ and} \quad (4)$$

$$(B+C)_{p>0} = \frac{\gamma H+p-p_{uplift}}{\gamma H} \cdot (B+C)_{p=0} \quad (5)$$

4 IMPACT GROUNDWATER

4.1 Impact groundwater on soil arching

Figure 2 compares the measured and calculated soil arching for Test 2. We observe the following:

- A rising groundwater level gives a limited decrease in both A and B.
- This decrease is primarily attributed to the uplift forces of Archimedes' principle rather than a change in soil arching. This is demonstrated by the calculations, which closely match the measurements. The calculations included the Archimedes uplift but did not reduce the soil arching due to a higher groundwater level.
- Figure 2c shows a slight decrease in soil arching A% due to groundwater. This shows that the decrease in A is not solely attributable to the Archimedes uplift, even though this remains the most significant mechanism at play.

The soil arching almost immediately rebounds when the phreatic line decreases. The soil arching (A)

changes less than 3.5% due to groundwater cycles, both up and down. The only exception is the first groundwater cycle which decreases the arching by 26%. At that stage, the arching had not found its equilibrium yet.

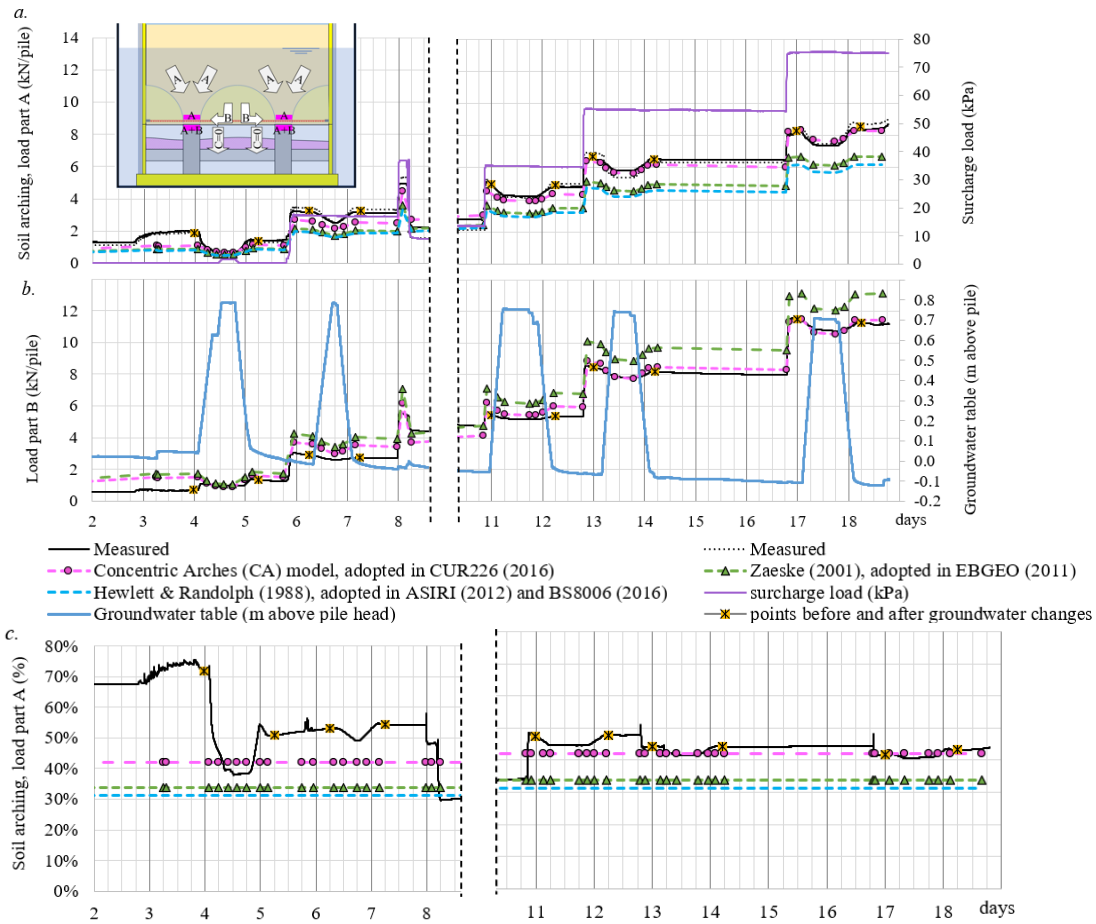

Figure 2. Comparison measured and calculated load distribution for Test 2. a. Soil arching (load part A). b. Load part B. c. Load part A in % of the total load. The 'measured' value of B was derived from the average measured values of A+B and A. p_{uplift} was integrated in all calculations by reducing surcharge load p with p_{uplift}. Between days 8 and 11, the surcharge load cushion leaked.

- The CA model matches the measurements better than the other two calculation models. Both EBGEO and Hewlett and Randolph (1988) underestimate the soil arching.

4.2 Impact groundwater on GR strains

Strain cables ('strain' or 'ε'), made from bicycle brake cables, were attached to the geotextile using tie wraps. The twisted steel wire that runs through an outer sleeve was pulled out by roughly 10 mm and fixed to the geotextile. A displacement transducer registered the difference between displacement of the twisted steel wire and the outer sleeve. This system provides only a qualitative result: many measured values are unrealistically large (van Eekelen et al., 2024): larger than the rupture strain, without rupture observed. Nevertheless, the measurements seem qualitatively reliable as in Figure 3a and Table 2, they match our expectations: the highest GR strains were measured in the strips between adjacent piles. The closer to the pile, the higher the strain. Outside the GR strip between adjacent piles (ε6), we observe much lower strains, typically around zero.

The GR strains do not show any significant response to changes in the groundwater level. This matches the findings of van Eekelen et al., 2023, who also found no convincing correlation between water and GR strain in field measurements. Temperature appeared to show a stronger correlation with the GR strain.

4.3 Impact groundwater on settlements

Figure 3b compares the measured and calculated GR deflection at the midpoint between two piles. The calculations were done for the middle of two adjacent piles. The CA model matches the measured deflection

nicely. Some settlement transducers show heave due to rising groundwater, specifically sensor z2. The calculations also show this effect, although to a lesser extent.

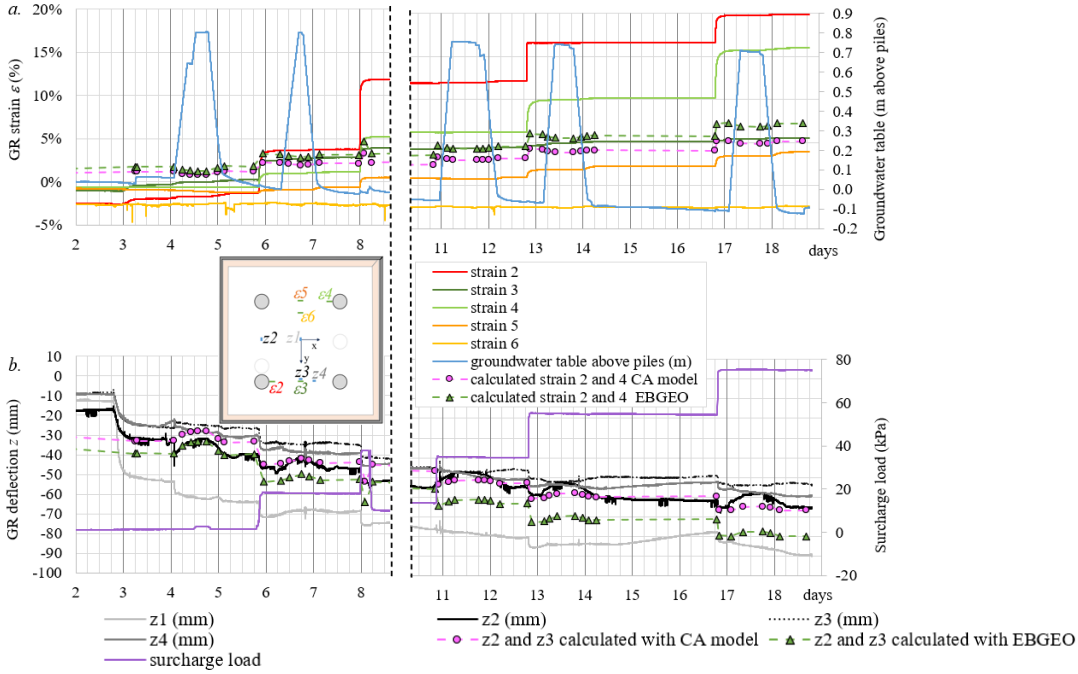

Figure 3. Measured and calculated deformations and strains. a. GR strains ε, and b. GR deflection z.

5 FILL WITH FINES OR NO FINES

Table 2 compares the measured and calculated values for Tests 1 to 3, for two surcharge loads (~ 17 and 55 kPa) and with and without groundwater.

The loading patterns of Tests 2 and 3 were comparable (after each surcharge load step a groundwater cycle), while Test 1 had surcharge load steps during one high groundwater period.

The deformations of Tests 2 and 3 match well, both with each other and with the CA calculations. The fill difference does not seem to have an impact.

The measured values of load part A, however, seem too high in the fill without fines of Tests 1 and 3. This difference is not in line with the measured GR deflections. Possibly, the issues that arose during Tests 1 and 3 play a role, such as leaks and malfunctioning sensors and pressure vessels. However, the high values of A in Tests 1 and 3 remain not fully explained.

As explained in Section 2, the strain measurements should only be considered qualitatively, they tend to be too large, sometimes larger than the rupture strain. In the average values of Table 2, these high values were not included.

All tests respond similarly to groundwater rise: a reduction in load and GR deflection, with a quick rebound after the high-water period. The CA calculations match the impact of groundwater well, if the uplift forces are taken into account.

Table 2. Comparison measurements and calculations for Tests 1, 2 and 3.

6 CONCLUSIONS

Experiments were conducted to investigate the impact of groundwater in a GRPS embankment. The following conclusions were drawn:

- Groundwater gives a reduction of load, due to uplift forces.
- The reduction of load part A, which expresses soil arching, is mainly caused by the uplift forces, but a groundwater increase also leads to a slight reduction in soil arching.
- The soil arching immediately recovers when the groundwater level decreases again.
- The CA model provides a closer match to the measurements than the other two considered calculation models (EBGEO and Hewlett and Randolph (1988)), both of which underestimate the soil arching.
- The response on groundwater rise is similar for both fill types, with and without fines.
- An increase of groundwater gives some heave of the GR, due to the uplift forces. This heave disappears upon lowering the groundwater again.
- The presented experiment did not reveal any significant response of GR strains to changes in groundwater. This is in line with the field measurements of van Eekelen et al., 2023, who observed a correlation between air temperature and GR strain, and not between the groundwater table and GR strain. However, some authors, like Briançon and Simon (2012) and van Eekelen et al. (2020) reported changes in deformation and load distribution after heavy rain. It is possible that changes in temperature resulting from such heavy rain showers played a role in those cases, or by swelling of the subsoil due to the increase in water content.

Effect of the variable discharge capacity of prefabricated vertical drains on the behaviour of an embankment built on soft soils

Effet de la capacité de décharge variable des drains verticaux préfabriqués sur le comportement d'un remblai construit sur des sols mous

P.J. Venda Oliveira*

**pjvo@dec.uc.pt*

ABSTRACT: In the past, the design of vertical drain systems considered an infinite discharge capacity. Although this hypothesis is suitable for sand drains with high coefficient of permeability, when prefabricated vertical drains (PVDs) are used, the decrease of the discharge capacity with elapsed time cannot be ignored. In this paper, a formula that relates the discharge capacity of PVDs to the consolidation time and the confining pressure around the drains is used to analyse the behaviour of an embankment built on a soft soil. The vertical and horizontal displacements predicted numerically considering infinite, reduced and variable discharge capacity of the PVDs are compared with one another and with field data. In general, the results show that the use of the formula proposed improves the numerical predictions of the settlement during the intermediate phases of consolidation. In terms of the horizontal displacement, the effect of the discharge capacity of the vertical drains seems to be negligible.

RÉSUMÉ: Dans le passé, la conception des systèmes de drains verticaux considérait une capacité de décharge infinie. Bien que cette hypothèse convienne aux drains de sable avec un coefficient de perméabilité élevé, lorsque des drains verticaux préfabriqués (PVD) sont utilisés, la diminution de la capacité d'évacuation avec le temps écoulé ne peut être ignorée. Dans cet article, une formule qui relie la capacité de décharge des PVD au temps de consolidation et à la pression de confinement autour des drains est utilisée pour analyser le comportement d'un remblai construit sur un sol mou. Les déplacements verticaux et horizontaux prédits numériquement en considérant une capacité de décharge infinie, réduite et variable des PVD sont comparés entre eux et avec les données de terrain. En général, les résultats montrent que l'utilisation de la formule proposée améliore les prévisions numériques du tassement pendant les phases intermédiaires de consolidation. En ce qui concerne le déplacement horizontal, l'effet de la capacité de décharge des drains verticaux semble être négligeable.

Keywords: Geosynthetics; soft soil; discharge capacity; PVDs.

1 GUIDELINES

The design of vertical drain systems has been based on the classical theoretical solution (Barron, 1948), in which the drains were considered as ideal drains, that is, with infinite discharge capacity. Although this hypothesis is suitable for sand drains with high permeability (Hansbo et al., 1981), when PVDs with low discharge capacity are used, the decrease of the discharge capacity with elapsed time cannot be ignored (Holtz et al., 1988).

The progressive blockage of the water flow inside the drain is due to the following issues (Chai and Miura, 1999; Indraratna and Redana, 2000; Indraratna et al., 2003; Karunaratne, 2011; Deng et al., 2013): (i) folding and crimping of the drain induced by excessive settlement, which happens in very compressible soils; (ii) reduction of the section of the drain core due to the increases of the confining pressure at depth; (iii) infiltration of fine particles of soil (silt and clay) through the filter; (iv) the existence of air bubbles inside the drainage path. Another issue that affects the consolidation rate of vertical drains arises from the reduction of the permeability in the soil around the PVDs (smeared zone) due to the disturbance induced by the method of installing the PVDs. In fact, this depends on of the characteristics of the mandrel (shape and size) and the dimensions of the anchor plate (Lin and Chang, 2009; Tripathi and Nagesha, 2010; Karunaratne, 2011).

In order to improve the numerical predictions of the behaviour of the PVDs, an empirical formula to evaluate the changes in the discharge capacity over time and with the confining pressure of the soil is

presented in this work. This formula was included in a three-dimensional (3D) finite-element (FE) code, which was used to predict the behaviour of an embankment built on a soft soil improved with PVDs. The ability of this formula to simulate real cases is examined by comparing the numerical results obtained with the numerical predictions using ideal vertical drains (i.e. with infinite discharge capacity) and using PVDs with a reduced discharge capacity constant over time. All the numerical predictions are compared with the field data in terms of settlement and horizontal displacement.

This investigation was carried out using a 3D FE code developed at the University of Coimbra (Almeida e Sousa, 1998; Venda Oliveira, 2013; Cruz, 2008). It allows elastoplastic analyses to be carried out with coupled consolidation and it incorporates several constitutive laws.

2 PROPOSED FORMULA

Regarding the experimental results obtained previously (Chai and Miura, 1999; Chai et al., 2004; Kim et al., 2011; Deng et al., 2013; Bergado et al., 1996; Karunaratne, 2011; Asha and Mandal, 2012), a new empirical formula to evaluate the discharge capacity of PVDs (q_w) is proposed, to evaluate the change of q_w with the confining pressure and the consolidation time:

$$q_w = q_{w,max} \cdot [r + (1-r)\exp(-a\frac{t}{t_1}).(1-m\frac{\overline{\sigma}_h}{\sigma_{h1}})] \quad (1)$$

where $q_{w,max}$ is the maximum discharge capacity of the PVD in m^3/s (defined as the rate of discharge of the drain under a unit hydraulic gradient); $\overline{\sigma}_h$ is the average total horizontal soil pressure (i.e., the confining pressure) surrounding the PVD in kPa; σ_{h1} is the total reference horizontal pressure (usually =100 kPa); t is the consolidation time expressed in days; t_1 is the reference time (usually t_1 = 1 day); r is the reduction factor which states the minimum discharge capacity ($q_{w,min} = r \cdot q_{w,max}$); m and a are the parameters that control the decay of q_w with $\overline{\sigma}_h$ and t, respectively. Parameter m is related to the structure and the stiffness of the PVD, while parameter a depends on the shape of the core of the PVD, the characteristics of the filter of the PVD and the soil characteristics around the PVD. r, a and m are dimensionless parameters, which can be evaluated from sensibility studies in order to approximate the variation of the q_w of the PVDs over time and with the confining stress obtained from formula (1) with the experimental results obtained from laboratory tests or field data.

Formula (1) does not consider the effect of the hydraulic gradient on the drainage capacity since the results published are not totally in agreement. Indeed, some studies show a reduction of drainage capacity over time for a lower hydraulic gradient (Chai et al., 2004; Müller et al., 2008; Asha and Mandal, 2012; Ali and Huat, 1992; Karunaratne, 2011), while others works describe the opposite, i.e., the discharge capacity increases when the hydraulic gradient decreases (Bergado et al., 1996; Tran-Nguyen et al., 2010).

3 CHARACTERISTICS AND NUMERICAL MODELLING OF THE EMBANKMENT

3.1 General description

The site studied is located in Portugal, at km 7.775 on the A14 motorway. The geotechnical profile of this cross-section (Figure 1) shows alluvial sandy-silts and clay-silts over limestone (Venda Oliveira et al., 2010). The water table changes with time, between 0.5 metres above and 1.5 metres below the surface.

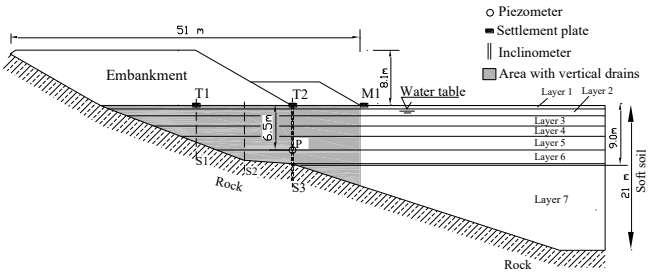

Figure 1. Geotechnical profile of the section of the embankment (based on Venda Oliveira, 2013).

The geotechnical characterisation of the foundation soils (Venda Oliveira et al., 2010) is shown in Table 1, where the mean physical and mechanical characteristics of the layers are presented. To account for permeability anisotropy, a ratio of k_h/k_v of 3 was considered. The embankment (Figure 1) was instrumented with: a sub-vertical inclinometer tube placed at the foot of the main embankment's slope and three settlement plates (T_1, T_2 and M_1).

To accelerate the consolidation of the soft soil, PVDs were installed down to the bottom of the soft soil deposit, in a square pattern with a spacing of 2.2 meters. In accordance with the manufacturer's specifications, the PVDs have a discharge capacity of about 25×10^{-6} m^3/s for a confining pressure of 200 kPa in a buckled condition.

The construction of the embankment is described by six sub-layers with elevations of 1.1, 1.85, 3.45, 4.7, 7.55 and 8.1 metres, applied at 0, 80, 240, 290, 385 and 420 days, respectively.

3.2 Numerical model

The mesh used in the 3D analyses consists of 10,406 nodal points and 1,917 twenty-noded isoparametric quadrilateral elements. Due to symmetry, only a row of half of the drains in the direction of the axis of the motorway is modelled.

To simulate the consolidation phenomenon in the soft soil, a coupled analysis of fluid flow and deformation is considered below the water table (at 0.5 metres of depth). Thus, each of the 3D elements have sixty eight nodal degrees of freedom, allowing the calculation of the displacement at twenty nodes and the excess pore pressure at eight corner nodes. The elements used provide quadratic interpolation of displacement and bilinear interpolation of pore pressure values. The boundary conditions are such that the right vertical side is restrained from horizontal movement, while the bottom and left boundaries of the soft soil have zero displacement both vertically and horizontally. In addition, the movement in the direction parallel to the axis of the motorway is also restrained. In terms of hydraulic boundary conditions, the top boundary, corresponding to the water table, is permeable. The other boundaries are impermeable. Above the water table, no water flow was considered in the numerical analyses.

3.3 Simulation of vertical drains

In the numerical analyses, the PVDs are simulated by equivalent square drains with a 52 mm edge to obtain the same draining surface. The smear zone is considered as a square area around the PVDs corresponding to an equivalent radius of 99.3 mm (r_s/r_w =3), where there is a reduction in the horizontal permeability of the soil surrounding the drain to $k_s=k_h/2$ (Hard et al., 1992).

Six cases of the discharge capacity for the PVDs are analysed, three cases with a constant discharge capacity (q_w= infinite; q_w= 1.0x10^{-6} m^3/s; q_w= 1.0x10^{-7} m^3/s) are compared with three other cases, which consider the variation of q_w with the following parameters of proposed formula (1): $q_{w,max}$ = 60x10^{-6} m^3/s, r = 0.001, m = 0.1, t_1= 1 day, σ_{h1}= 100kPa (usual reference value). Additionally, the variation of the parameter a (0.02, 0.03 and 0.04) is analysed.

The FE code evaluates the variation of the discharge capacity of the PVDs by changing the permeability of the FE elements of the vertical drains ($k_w = q_w/A_w$) with the current effective stress state and the time of consolidation. The FE code performs a recalculation of the current permeability of the PVDs at all steps (iterations) of the numerical computation. As the FE code uses a coupled consolidation analysis, the total horizontal pressure ($\bar{\sigma}_h$) is continuously evaluated by the FE code from the horizontal effective pressure and the pore water pressure.

During the calculation, the coefficients of permeability of the soil change with the void ratio, in accordance with the following expression (Taylor, 1948):

$$k = k_0 \times 10^{\frac{e-e_0}{C_k}} \qquad (2)$$

where e_0 represents the initial void ratio, k_0 is the coefficient of permeability corresponding to e_0, k is the current coefficient of permeability relative to the current void ratio e, and C_k is a constant equal to $e_0/2$ (Tavenas et al., 1983).

3.4 Mechanical characteristics

The behaviour of the soil foundation is predicted using the Modified Cam Clay (MCC) model and the parameters are shown in Table 1. The embankment material is characterized by an isotropic linear elastic law, with ν' equal to 0.3 and E' assuming the values of 30, 25, 20, 15, 10 and 5 MPa, from the bottom to the upper layer. This variation aims to reflect the lesser confinement of the upper layers (Venda Oliveira, 2010).

4 ANALYSIS OF RESULTS

4.1 Settlement

Figure 2 compares the evolution over time of the settlement (plate T2) measured in the field and predicted numerically. The numerical results show that the use of an infinite discharge capacity for PVDs induces a higher settlement rate, which originates a reasonable prediction of the settlement for t < 200 days. When a lower and constant discharge capacity for the PVDs is considered (q_w=1.0x10^{-7} m^3/s), the settlement rate predicted numerically decreases, which induces a poor prediction of the settlement during the initial phases, but induces a slight improvement with elapsed time (t > 200 days). This fact reveals that the discharge capacity of the PVDs changes over time, therefore the use of a constant value of q_w is not very suitable to predict the settlement during the consolidation phase.

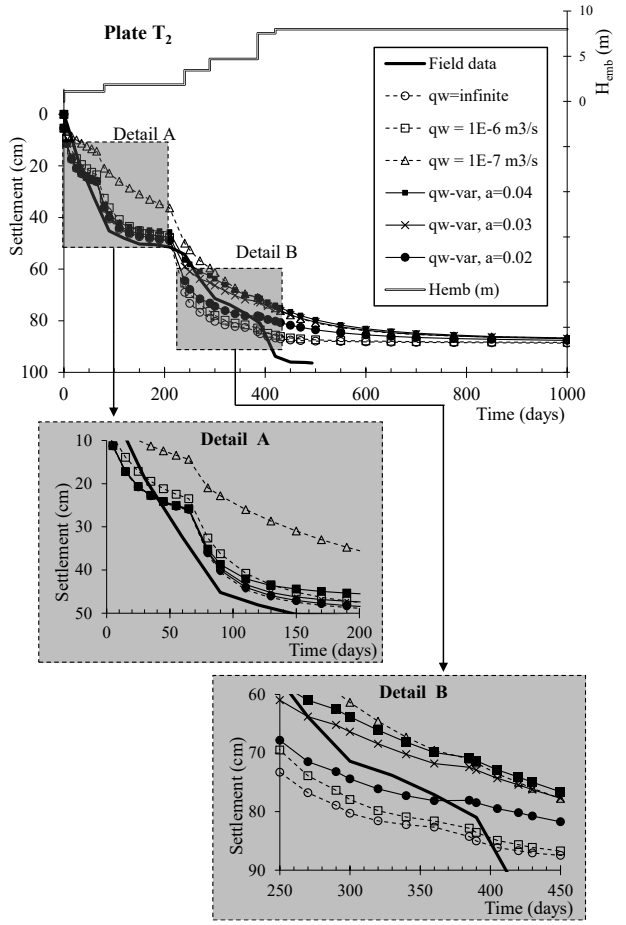

Figure 2. Evolution of the settlements with time (plate T2) (based on Venda Oliveira , 2013).

As expected, Figure 2 also shows that the use of a variable discharge capacity for the PVDs over time induces a decrease in the settlement rate with elapsed time. Thus, for time less than 200 days the effect of changing parameter *a* is negligible, however this effect is clearly visible with increasing time. This behaviour is due to the fact that the decreases of parameter *a* induces an accentuated reduction of q_w with elapsed time. The numerical results show that the value of parameter *a*, which best matches the field data for a time of up to 400 days, is between 0.02 and 0.03. As expected, for times higher than 800 days the differences between the diverse numerical predictions tend to be attenuated.

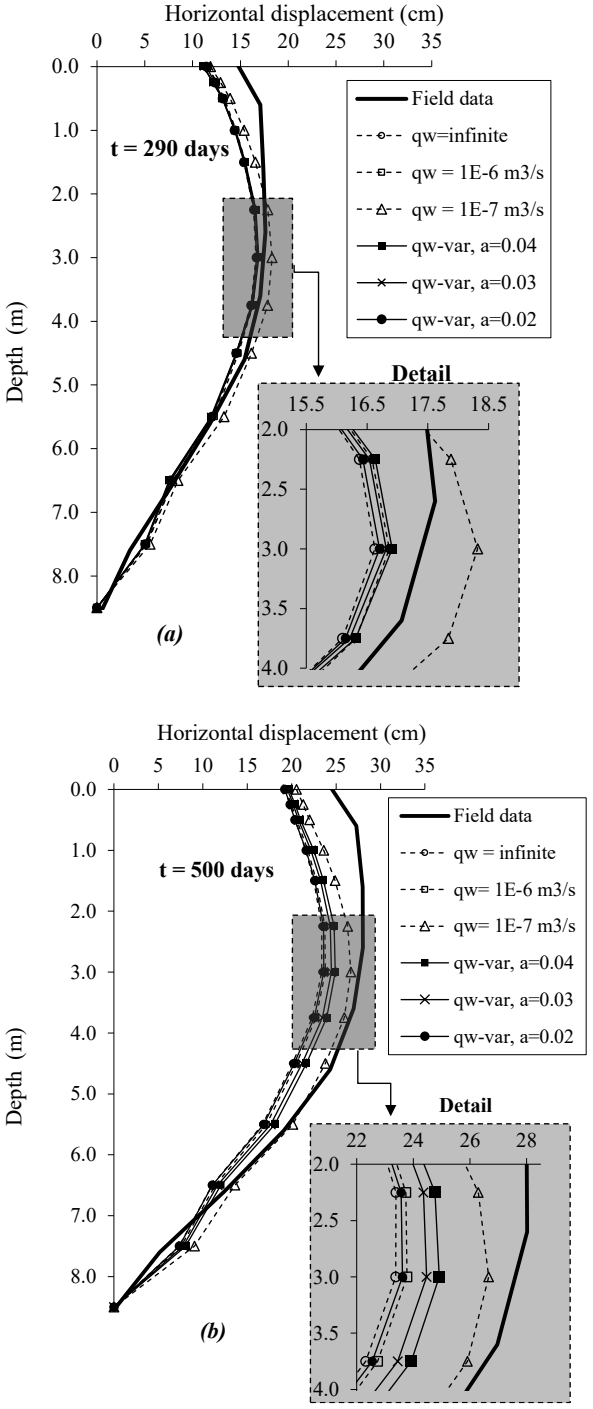

Figure 3. Horizontal displacements for: (a) 290 days; (b) 500 days (based on Venda Oliveira , 2013).

4.2 Horizontal displacement

Figure 3 illustrates the evolution of the horizontal displacement with depth under the foot of the main embankment slope, for 290 and 500 days. In general, the horizontal displacement predicted numerically for the six calculations are similar to the field data. The reduction of the discharge capacity of the PVDs, when q_w is constant over time, increases the horizontal displacement slightly. This effect is more marked for the variation of q_w from $1x10^{-6}$ m^3/s to $1x10^{-7}$ m^3/s (Δy_{max}= 8.6% and 12.2% for 290 and 500 days, respectively) in relation to the reduction of q_w from infinite to $1x10^{-6}$ m^3/s (Δy_{max} = 1.4% and 1.6% for 290 and 500 days, respectively). This behaviour is in accordance with the findings of Indraratna et al. (2003).

The reduction of parameter *a* [equation (1)] induces a slight decrease of the horizontal displacement with time, i.e., this is little affected by the variation of q_w. Thus, independently of the parameter *a* used, the horizontal displacement values predicted numerically by an infinite discharge capacity of the PVDs are quite similar to those obtained with variable q_w.

5 CONCLUSIONS

This paper proposes a formula to predict the variation of the discharge capacity of prefabricated vertical drains due to confining pressure and with consolidation time. This formula simulates the progressive blockage of the PVDs due to the clogging, folding and crimping effects.

The ability of the proposed formula to replicate the behaviour of the PVDs in-situ is analysed using the case study of an embankment built on soft soils improved with PVDs. The numerical results presented show that the use of a variable discharge capacity of the PVDs, improves the numerical prediction for the settlement for the time period between 200 and 400 days (intermediate phases of the consolidation), when the effect of the blockage of the PVDs is most significant, However, the use of a variable discharge capacity of the PVDs does not significantly affect the evolution of horizontal displacement.

Naturally, the effect of the variable discharge capacity of the PVDs would be more significant if longer PVDs were used.

ACKNOWLEDGEMENTS

The authors would like to express their thanks to the institutions that financially supported the research: project research grant FCT (POCI-01-0145-FEDER-028382) and ACIV. This work was partly financed by FCT/MCTES through national funds (PIDDAC) under the units ISISE (UIDB/04029/2020), and ARISE (LA/P/0112/2020).

ABSTRACT: The theoretical formula of the cylindrical diffusion model of radial tube flow for sand layer penetration grouting, considering the tortuous effect, was embedded in COMSOL Multiphysics to explore the curtain formation mechanism of ground drilling grouting in a water-rich sand layer. The grouting of three adjacent grouting holes during a ground drilling grouting project for the main shaft of Guotun Coal Mine was numerically simulated. Moreover, the formation of a grouting curtain and the distribution law of the pressure isosurface and velocity field during slurry diffusion were analyzed. The results revealed that the volume fraction of cement slurry gradually decreased along the diffusion direction, and slurry volume fractions of (0.6, 0.8] corresponded to the key areas for grouting reinforcement. The isosurface of formation pressure changed from dense to sparse along the direction of slurry diffusion, indicating that slurry pressure rapidly and slowly attenuates near and far from the grouting pipe, respectively.

RÉSUMÉ: Afin d'explorer le mécanisme de formation du rideau d'injection dans le forage souterrain d'une couche de sable riche en eau, nous considérons la formule théorique du modèle de diffusion cylindrique de la canalisation de rayonnement de coulis d'infiltration de couche de sable avec effet tortueux intégré dans COMSOL Multiphysics, et simulons numériquement le processus de coulis de trois trous de coulis adjacents dans le projet de forage de surface et de coulis du puits principal de la mine de charbon de Guotun, et analysons la loi de distribution du champ de surface et de vitesse équivalente à la pression pendant le processus de formation du rideau de coulis et de la diffusion de boue. Les résultats montrent que la fraction volumique de la boue de ciment diminue progressivement le long de la direction de diffusion, et que la région de la fraction volumique de la boue à (0,6, 0,8] est la région clé du renforcement de l'injection. Les isosurfaces de pression stratigraphique vont de denses à éparses le long de la direction de diffusion de la boue, ce qui indique que la pression de la boue diminue fortement près du tuyau d'injection et diminue lentement dans la région éloignée du tuyau d'injection.

Keywords: Water-rich sand layer; ground drilling grouting; penetration grouting; cylindrical diffusion; grouting curtain.

1 INTRODUCTION

Water leakage accidents often occur when servicing coal mine shafts, which severely threaten the safety of underground workers and lower production efficiency. Common measures for shaft seepage treatment are grouting after wall and ground drilling grouting. However, the shaft wall of the water-rich sand layer is at a high risk of water inrush after grouting and fails to meet current coal mine safety regulations. Accordingly, ground drilling grouting is preferred instead. Ground drilling grouting results in the formation of a grouting curtain around the shaft, which prevents disruption to normal shaft production. By isolating the groundwater seepage around the shaft wall, this method can effectively improve the deformation coefficient of the stratum and the stress state of the shaft.

Existing research on the formation of the grouting curtain has focused on tunnel engineering. Taking the curtain grouting reinforcement of Nanshibi Tunnel as an example, Yin et al. (2022) studied the creep behavior of grouting stone based on nonlinear Burgers' model and numerically simulated the grouting process of the operating tunnel. Chai and Cui (2012) validated the theory of optimal grouting curtain thickness via finite element numerical simulation based on one- and two-dimensional seepage models. Zhang et al. (2015) explored the influence of curtain grouting on the pore pressure field, stress field, and plastic zone rock surrounding tunnels using the fluid–solid coupling method and numerical simulation method. Taking a water-rich loess tunnel as an example, Wei et al. (2021) verified that curtain

grouting can effectively control surrounding rock deformation and surface settlement. Li et al. (2021) studied the propagation law of tunnel cracks under different curtain grouting parameters and described the characteristics of water inrush caused by excavation. These research efforts demonstrated the complex diffusion of slurry in a complex formation environment. These studies obtained grouting results under specific working conditions and captured the dynamic diffusion of slurry in the layer. These provide some reference for guiding grouting construction and optimizing grouting parameters.

The development of numerical calculation software has facilitated the numerical simulation of grouting. Han et al. (2022) used COMSOL multiphysics multifield coupled numerical simulation software to study the diffusion law of cement slurry in the surrounding rock of a tunnel by considering time-varying gravity and viscosity. Pan et al. (2022) and Guo et al. (2021) used similar methods to study the influence of different grouting parameters on the grouting effect. Zhang et al. (2018) and Yang et al. (2021) used discrete element numerical methods, such as PFC2D and EDEM, to simulate grouting in a soft coal seam and obtain the slurry diffusion range under given grouting pressures. Wang et al. (2021) used finite difference software FLAC3D to optimize the grouting parameters of an ultrashallow buried double-arch tunnel with a large section.

Therefore, reports on the curtain formation process of a coal mine shaft during ground drilling curtain grouting are few. As such, research is urgently needed to guide the selection of grouting parameters to control leakage in a coal mine shaft wall during ground drilling. The grouting process of three adjacent grouting holes in the main shaft during a ground drilling grouting project in Guotun Coal Mine, Shandong Province, was numerically simulated using COMSOL Multiphysics. The pressure isosurface and velocity field distribution during grouting curtain formation and slurry diffusion were analyzed. Notably, the results have reference value for shaft water disaster control in water-rich sand layers.

2 PROJECT OVERVIEW

The water inflow of the Guotun Coal Mine in Shandong Province is shown in Figure 1. During shaft construction, the water inflow is 50–60 m^3/h, whereas it was 500–600 m^3/h during coal mine production, an increase of approximately 10-fold. This resulted in uneven ground subsidence and shaft deflection of the industrial square, and the maximum shaft deflection of the main shaft and the auxiliary shaft were 348 mm and 336 mm, respectively, which pose a risk for coal mine production. Therefore, to maintain normal mine production, surface drilling grouting was used to control the unevenness and settlement of the shaft.

According to the water pressure, grouting, and core indoor geotechnical tests, as well as the results obtained from the test and grouting holes were distributed on the circumference, with a radius of 30 m and the wellbore center serving as the center. The pressure relief holes were distributed on the circumference, with a radius of 16 m and the wellbore center serving as the center. The grouting holes and pressure relief holes were misplaced, and the design grouting diffusion radius was 8 m. The layout of the boreholes around the main shaft are shown in Figure 2. The 12 grouting holes were spaced 13.84 m apart. Seven pressure relief holes (including the main hole and the main inspection hole) were arranged, with hole spacings of 9.81–16.00 m. Moreover, 9 directional drilling holes were arranged.

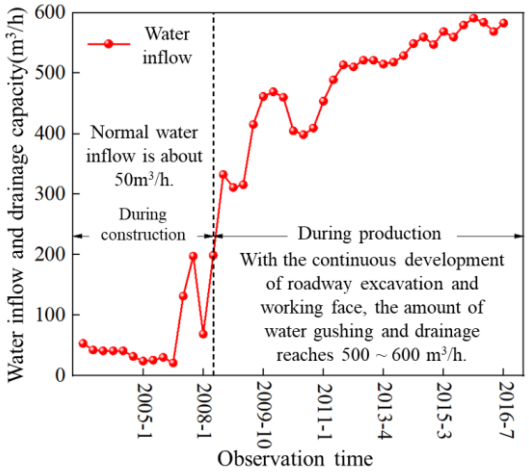

Figure 1. Statistics of water inflow in mining area.

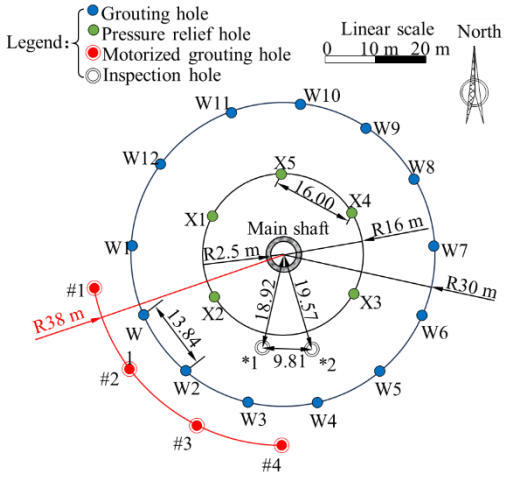

Figure 2. Layout plan of drilling hole.

3 NUMERICAL SIMULATION

To verify the rationality of the design parameters of the curtain grouting scheme and grout diffusion law, as well as the formation mechanism of the curtain, the grouting processes of holes W1, W2, and W3 in the main well were taken as the research object. Moreover, the slurry cylindrical diffusion theory formulas derived from the literature (Wang, 2022a, 2022b) were embedded into COMSOL Multiphysics. A numerical simulation of cylindrical diffusion of ground borehole grouting was then conducted.

3.1 Basic assumptions

1) The distance between the three grouting holes selected for the simulation was relatively small, and the stratum in the grouting section is a whole, the soil layer is incompressible, and the physical parameters are isotropic.

2) The slurry is an incompressible Bingham fluid, and the flow pattern does not change during grouting.

3) The percolation of slurry and water satisfies the generalized Darcy's law.

3.2 Model parameters and meshing

The grouting model is shown in Figure 3. The size of the model was 80 m × 80 m × 40 m. The three grouting holes were located on the circumference with a radius of 30 m and the center of the main shaft as the center. The same spatial positions as holes W1, W2, and W3 in the main shaft were used, and the distance between adjacent grouting holes was 13.84 m. Additionally, the length of the grouting pipe was 36 m, which does not penetrate the simulated formation, and the slurry flows into the formation along the radial flow after flowing out of the grouting pipe.

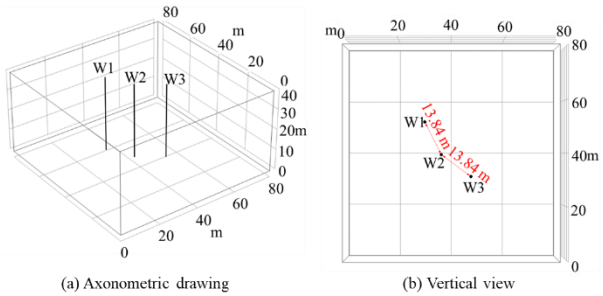

Figure 3. Grouting model.

The results of laboratory geotechnical tests of the sand revealed a density of 2000 kg/m^3, volume modulus of 100 MPa, shear modulus of 20 MPa, cohesion of 5 Pa, internal friction angle of 35°, lateral pressure coefficient of 0.42, and porosity of 0.35. The density of water was 1000 kg/m^3, and the dynamic viscosity was 1.0 mPa·s. The slurry density was 1310 kg/m^3, and the dynamic viscosity was 11.0 mPa·s. The Biot coupling coefficient was 1.0.

The meshing of the model is shown in Figure 4. First, a virtual grid domain was used to divide the vicinity of the grouting hole, the edges of the box were then encrypted, and the tetrahedral mesh was used to divide the model. Finally, the remainder of the model was refined. The complete mesh consisted of 479,102, 21,742, and 4080 domain, boundary, and edge elements, respectively.

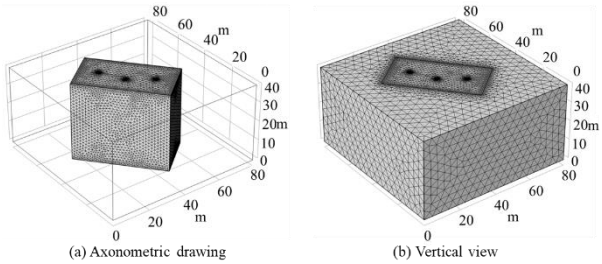

Figure 4. Model meshing diagram.

4 RESULTS AND ANALYSIS

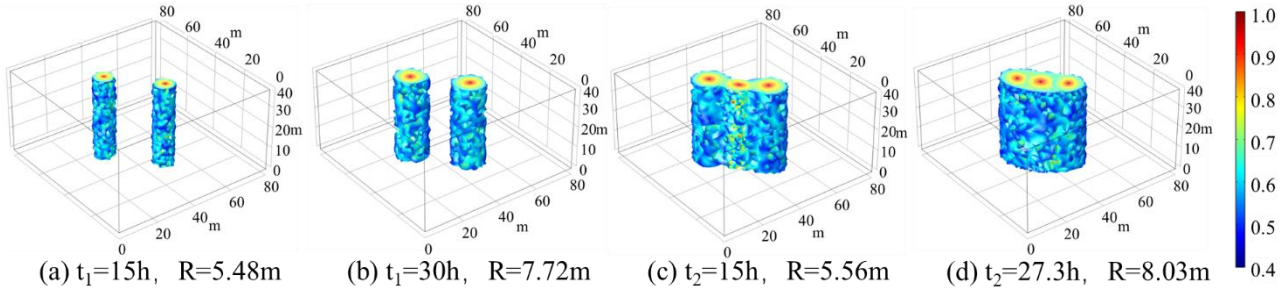
4.1 Slurry Diffusion Form

Under the action of slurry pressure, the cement slurry permeates and diffuses within the saturated sandy soil, sequentially forming the cement slurry, slurry–water mixing, and pore water zones along the diffusion direction. The volume fraction method was used to characterize the slurry–water mixing zone to characterize the volume percentage of the slurry occupying the slurry–water mixing zone with a continuously varying numerical interval (0,1). The process of cement slurry replacing pore water in the pore space of sandy soil via osmotic diffusion was simulated via the "two-phase Darcy's law" interface of COMSOL Multiphysics.

First, the two-phase Darcy's law physical field was accessed, and the theoretical formula of the cylindrical diffusion model of radial tube flow obtained from the literature (Wang, 2022a, 2022b) was embedded into COMSOL Multiphysics. Holes W1 and W3 were slurried first, and the pressure boundary conditions in holes W1 and W3 were set, with a measuring line arranged at the connecting line of holes W1 and W3. The time variable was controlled via transients, and slurry injection was stopped when the predetermined slurry radius was reached. Slurry injection was then repeated for hole W2 and stopped when the slurry body intersected the circle to form a complete curtain. The slurry diffusion form is shown in Figure 5.

Figure 5 shows that the slurry diffusion region of a

single slurry injection hole was approximated as a cylinder. The cement slurry volume fraction was higher near the grouting pipe and gradually decreased along the diffusion direction. In this study, the region where the volume fraction of the cement slurry was greater than 0.4 was taken as the effective slurry diffusion region, and the interface where the volume fraction of the slurry was equal to 0.4 was the slurry diffusion frontal surface (Cai, 2018). The distance from the diffusion frontal surface to the axis of the slurry pipe was the slurry diffusion radius.



(a) t_1=15h, R=5.48m (b) t_1=30h, R=7.72m (c) t_2=15h, R=5.56m (d) t_2=27.3h, R=8.03m

Figure 5. Slurry diffusion form.

The volume fraction of cement slurry can be divided into four regions along the radial distribution. The area with a slurry volume fraction of (0, 0.4] was the ineffective reinforcement area, which was omitted from the figure. The cement content in this area was too low to achieve water plugging or reinforcement effects. The area with a slurry volume fraction of (0.4, 0.6] was located at the outer edge of the effective reinforcement area, and the width of this area was small relative to the width of the slurry curtain. The region with a slurry volume fraction of (0.6, 0.8] had a higher cement content, with good water plugging and reinforcement effects, and was the primary region of slurry reinforcement. The region with a slurry volume fraction of (0.8, 1.0] was concentrated near the slurry pipe and accounts for a low percentage of the entire slurry diffusion region. This suggests that the cement slurry was diluted with pore water soon after flowing from the slurry pipe.

The radius of diffusion was 5.48 m when holes W1 and W3 were slurried for 15 h; when slurried for 30 h, the radius of diffusion was 7.72 m, which was close to the design value of 8 m, and the slurring was stopped at this time. After 18 h of grouting in hole W2, the slurry front was tangent to the grouted stones in holes W1 and W3, and the radius of diffusion at this time was 6.12 m. Afterward, the diffusion of the slurry in the tangent direction of the circumference of the grouted holes was hindered by the slurry stones in holes W1 and W3, and the diffusion of the slurry in the direction of the circumference of the slurry holes was dominated by slurry diffusion in the tangent direction of the circumference of the grouted holes. Therefore, the diffusion process gradually increased the width of the slurry curtain after the slurry front of hole W2 was tangent to the slurry nodule body of holes W1 and W3. After 27.3 h of slurry injection in hole W2, the width of the slurry curtain was relatively uniform (approximately 16 m). In this study, only three slurry holes were selected for simulation. Because the distribution of slurry holes had spatial symmetry, if skip-hole slurrying is performed over the entire circle diameter, a circular slurry curtain with a width of approximately 16 m will be formed at the periphery of the wellbore.

4.2 Pressure isosurface and velocity field distribution laws

The distribution of pressure isosurfaces and the velocity field in the slurry diffusion is shown in Figure 6. The arrows in the figure represent the velocity field, and their direction is the velocity field direction. The isosurfaces represent the pressure field, and the direction of the outer normal of the isosurfaces is the pressure direction. Figure 6 shows that the pressure isosurface is denser near the slurry pipe and sparser away from it, indicating that the slurry pressure is sharply attenuated near the slurry pipe. Attenuation was slow in the region away from the grouting pipe and gradually close to the formation stress. This change rule is consistent with the results in the literature (Wang, 2022a, 2022b) regarding the slurry pressure attenuation law.

Figures 6(a) and 6(b) show that the slurry pressure influence range is only in the vicinity of the slurry pipe during preslurrying in holes W1 and W3. The pressure was higher near the slurry pipe, and the pressure decayed faster near the slurry pipe. Almost no interaction occurred between the two grouting pipes, and the influence range of grouting pressure was not prominent. As slurry injection proceeded, the slurry pressure gradually affected the surrounding strata through the slurry in the formation. Meanwhile, the

pressure field between the two grouting pipes gradually began to interact, and the pressure dissipated faster in the slurry body and slower in the formation. Finally, a pressure fault was formed at the interface between the grouted caking body and the sandy soil, as shown in Figures 6(c) and 6(d).

As shown in Figures 6(e)–6(h), the slurry pressure was concentrated in the vicinity of the slurry pipe at the beginning of slurry injection in hole W2, and the influence of slurry injection in hole W2 on the change of formation stress was not prominent. As the slurry injection proceeded, the slurry diffusion was affected by the slurry injection nodule body of holes W1 and W3 after the slurry front was tangent to the slurry injection nodule body of the holes. The slurry and water need to bypass this region, and the slurry pressure equivalent surface and velocity field distribution were reduced to only one axis of symmetry. The influence range of the grouting pressure mainly acted on the nodule body; that is, the slurry pressure decayed toward the vicinity of the slurry nodule body, it was less than the shear force provided in the formation, and slurry spreading stopped. The pressure decay rate on the outside of the nodule body slowed, and the pressure was more evenly distributed within the formation.

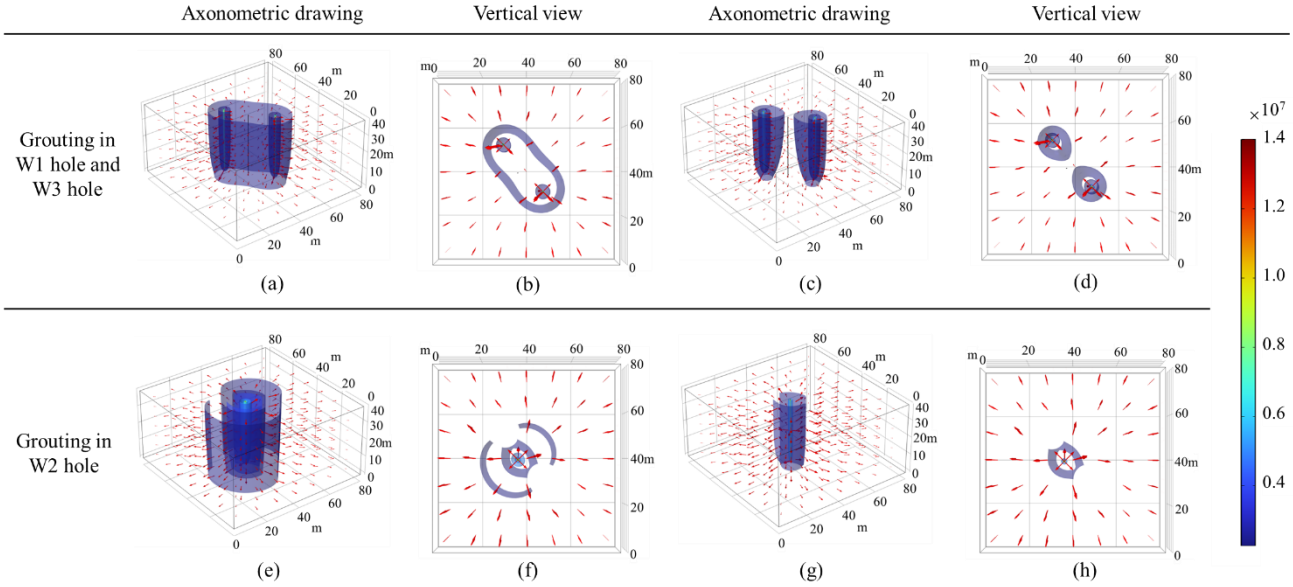


Figure 6. Pressure isosurface and velocity field distribution.

5 CONCLUSIONS

(1) The theoretical formula of the cylindrical diffusion model of radial tube flow was embedded in COMSOL Multiphysics, and the grouting process of holes W1, W2, and W3 holes in the ground drilling grouting project of the main shaft of Guotun Coal Mine was numerically simulated. The grouting construction involved designing a circle and determining the hole spacing, and a grouting curtain with a thickness of approximately 16 m was formed around the shaft.

(2) Cement slurry was gradually diluted by pore water along the direction of grouting diffusion. Only the area near the grouting pipe has a slurry volume fraction of (0.8, 1.0], and the area with a slurry volume fraction of (0.6, 0.8] was the key area for grouting reinforcement, accounting for the highest proportion of grouting curtain width.

(3) The slurry affects the pressure field around the injected formation. The pressure isosurface was dense near the grouting pipe, but sparse far from the grouting pipe. The slurry pressure decayed sharply near the grouting pipe and slowly far from the grouting pipe, gradually approaching the formation stress.

The geotechnical works for the construction of the Travis Brow link road, Stockport, UK

Les travaux géotechniques pour la construction de la route Travis Brow link, Stockport, Royaume-Uni

A. Willoner*, L. Allievi
Mott MacDonald, Sheffield, UK
**Alan.Willoner@mottmac.com*

ABSTRACT: The Travis Brow to A6 link road created a new highway connection in Stockport. The construction of the two-lane dual carriageway required the implementation of a variety of geotechnical construction techniques, including soil nailing, contiguous pile walls and the installation of prestressed rock anchors with hard facing to support the rock beneath the foundations of two piers of the Grade II* listed Stockport viaduct, which carries the West Coast main line rail service. This paper describes the design and construction of the geotechnical works carried out for the scheme, focussing particularly on the undercutting of the viaduct footings, which was carried out following a staged construction sequence, with excavation works carried out in bays both horizontally and vertically. The results of rock anchor testing are also discussed.

RÉSUMÉ: La route de liaison Travis Brow à A6 a créé une nouvelle connexion autoroutière à Stockport. La construction de la route à deux voies à deux voies a nécessité la mise en œuvre d'une variété de techniques de construction géotechniques, y compris le clouage du sol, des murs de pieux contigus et l'installation d'ancrages rocheux précontraints avec un revêtement dur pour soutenir la roche sous les fondations de deux piliers du viaduc de Stockport, classé Grade II*, qui transporte le service ferroviaire de la ligne principale de la côte ouest. Cet article décrit la conception et la construction des travaux géotechniques réalisés pour le projet, en se concentrant particulièrement sur la sous-découpe des piles du viaduc, qui a été réalisée selon une séquence de construction par étapes, avec des travaux d'excavation réalisés dans les travées horizontalement et verticalement. Les résultats des essais d'ancrage rocheux sont également discutés.

Keywords: Ground anchor; finite element analysis; stress testing.

1 INTRODUCTION

The new Travis Brow highway provides a link from the M60 Junction 1 to the A6 in Stockport. The project has several challenges associated with urban developments and steep topography as illustrated in Figure 1, as well as presence of contaminated soil and fitting works around an old buried cut and cover tunnel and buried masonry wall.

A variety of geotechnical works were required for the construction of the highway. A short initial section within traditional cutting is followed by a 100m long section supported by 555 No. soil nails with flexible complex facing and green finishing on a 45 degrees slope with a gravity wall at the toe of the slope. As the cutting deepens, contiguous pile walls are used as earth retention system for a 150m long section, with retained height between 5 and 8m, after which the road reaches the Stockport Viaduct.

The new carriageway bisects the Stockport Viaduct, with the alignment undercutting the pad foundations of the 1840s Grade II* listed structure, which carries the West Coast Main Line.

Figure 1. Image of the New Link Road looking east towards the Stockport Viaduct, with the M60 to the south.

Undercutting of the Viaduct pad footings was essential to achieve a safe gradient and standard highway width, but it also presented a complex geotechnical challenge and required approval from Network Rail, the owner and maintainer of the Viaduct.

2 THE STOCKPORT VIADUCT

Having been widened to accommodate four tracks in the 1880s, the Viaduct is founded at two significantly different levels featuring stepped profiles, with the foundations of the extension being deeper than the foundations of the original structure. The new road passes between span 23, where the piers are 3m thick and 12.2m high. An 'Archie-M' structural analysis of arch and piers carried out to assess the load at foundation level indicates that under live train loading, a trapezoidal pressure distribution develops under each pad with peak bearing pressure of 1220kPa.

The excavation for the construction of the proposed highway required undercutting the footings for a depth of up to 2.5m in temporary conditions and 1.7m permanently, with a 70-degrees rock slope as illustrated in Figure 2.

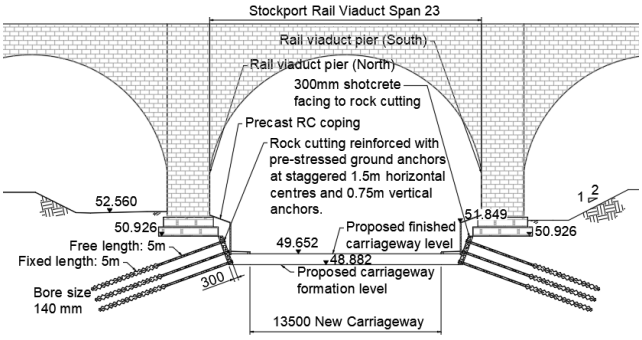

Figure 2. Section at span-23 illustrating anchor layout.

3 GROUND CONDITIONS

The formation to the viaduct pad footings comprises the Chester Pebble bed formation of the Triassic Sherwood Sandstone unit. This rock is typically very weak medium to closely bedded red SANDSTONE, with bedding dipping typically 20-degrees to the west. A less persistent steeply inclined joint set is also encountered in this formation. Project specific investigation revealed extrapolated Standard Penetration Test (SPT) N values in the range of 231 to 945. Point Load and Unconfined Compressive Strength laboratory testing verified the SPT results and gave an average UCS of 3.5MPa to be used for 'best estimate' SLS prediction of ground movement. Some judgement was applied to establish a worst credible UCS of 1.9MPa. The data on rock quality and strength was processed through the RSData software to obtain the equivalent Mohr-Coulomb strength parameters using the Hoek-Brown criteria, and provided best estimate ϕ_p' 49^0, c' 40kPa and E_r' 750MPa, and worst credible ϕ' 40^0, c' 20kPa and E_r' 400MPa, where ϕ_p' is effective peak friction angle, c' is effective cohesion and E_r' is drained rock mass modulus.

Figure 3. Trial trench perpendicular to pier at Arch 23 illustrating the quality of the rock and bedding.

4 DESIGN & CONSTRUCTION

A robust design solution was required due to the high bearing pressures of the Viaduct footings, the critical importance of the structure hosting 4 overhead tracks of the West Coast Mainline and its heritage value.

Conceptual design options considered were i) Top-down excavation after installation of a 450mm diameter contiguous piled wall with either propping in front of the walls below the new road or by means of ground anchors behind, ii) Pre-stressed rock anchors and hard facing with each unsupported excavation being confined to as small an area as practical.

The Contractor's preference was the second option due to cost and programme savings and for similarity with historical works at Pier 20 (Golders, 1977).

The design of the viaduct undercutting was carried out in accordance with BS EN 1997-1:2004, using the finite element software Plaxis 2D. Some judgment was required to analyse a 3D problem in a 2D FE program.

Several sensitivity tests were run to establish the optimum anchor pre-stress level, which was identified as the value of pre-stress above which there was very little improvement in reduction in SLS elastic deformation. The tightest practical anchor spacing was used to reduce the risk of large inelastic movement along unfavourably orientated rock discontinuities exposed by the excavation.

The Plaxis analyses predicted a distribution of elastic rock mass deformation as illustrated in Figure 4. This assumed plane strain conditions, with each anchor being stressed before excavating below.

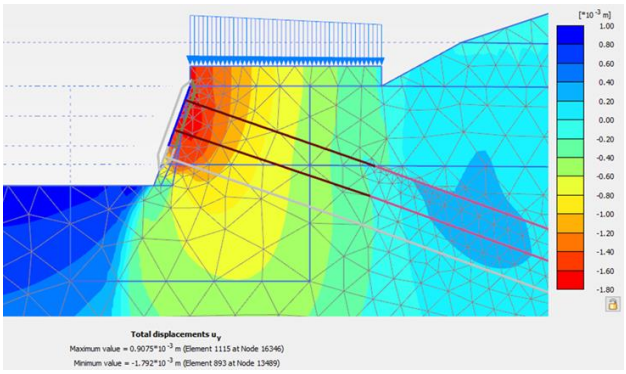

Figure 4. Output of SLS predicted elastic rock movements at finished excavation, before installation and prestressing of the bottom row of anchors.

However, in order to keep the sub-contractor working continuously, two vertical levels of anchors were installed at the same time with adjacent support being provided from a rock buttress (as illustrated in Figure 5) or by recently installed and stressed anchors, with the gang working on a horizontal 'hit-and-miss' basis across 5 bays on each side of the arch and then working down and along the bottom line of anchors.

Figure 5. Placing hard facing to the initial working bay below the north footing of arch 23.

The best estimate and worst credible predictions of elastic rock deformation on the cut face were 0.5 and 2.0mm respectively. The associated rotations of the base of the viaduct pier were also estimated, which were 1:10,000 and 1:4,000 for best estimate and worst credible cases respectively, hence acceptable.

The final design comprised on 32 anchors per footing at 1.5m horizontal and 0.75m vertical spacing. Anchors were 10m long with 5m fixed and 5m free (unbonded) length, inclined at 20-degrees to the horizontal and comprising a 40mm Gewi bar with double corrosion protection in a 140mm diameter grout filled bore. Design prestress was 250kN per anchor.

Anchors installation was carried out in accordance with BS EN 1537:2013 and BS 8081:2015.

5 INSTRUMENTATION & TESTING

Each face of the viaduct had 45 mini prisms installed to monitor the movement of the viaduct and establish baseline movement levels due to wind, temperature change and rail traffic.

Background movements of the Viaduct were greater than predicted movements due to the Works. It was therefore essential to directly measure the ground movements to understand if, and how much, these affected the superstructure.

Extensometers were installed into the new rock faces. These recorded maximum ground movements of 0.5mm beneath the north pier and 0.8mm beneath the south pier, as illustrated in Figure 6.

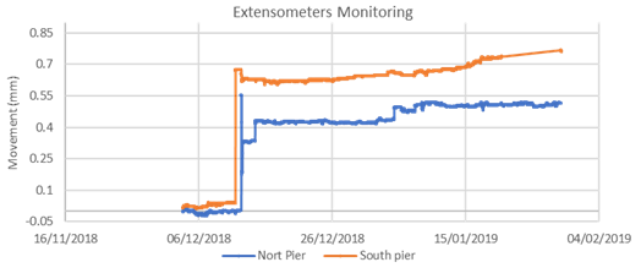

Figure 6. Extensometer results validating SLS predictions.

Selective anchors were fitted with load cells for future monitoring. During the first reading of the load cells, in June 2019, a measured load up to 60% less than the specified lock-off load was noted in all monitored anchors. The cause of the reduced load was investigated by an expert sub consultant.

Increased monitoring of the load cells was implemented, and lift-off tests were carried out on all accessible anchors. The tests confirmed that all anchors held a lower load than specified, with a

reduction ranging from 30% to 65% of the nominal 250kN lock-off load.

Following the results of the lift-off tests, restressing of two anchors, subsequent increased monitoring, and a review of the anchor drilling reports, it was established that the likely cause of the reduced load was the procedure adopted for the initial lock-off of the anchors, which did not allow for any lock-off loss due to transfer of load from the jack to the nut. The consequence was that all the anchors were likely to have load at levels significantly less than specified, including the lower row of anchors no longer accessible because buried beneath the finished road level.

As a remedial measure, all accessible anchors were re-tested for acceptability and locked-off at 275kN, 110% of the original design SLS load, in January 2020, thus increasing the average load imposed to the rock face to an average force of 205kN closer to the original design value and equivalent to 1mm of lock off loss. No adverse effects on the viaduct have been recorded to date.

6 CONCLUSIONS

The design of the Stockport Viaduct undercutting provided Network Rail, owner of the asset, with confidence that the Viaduct footings could be undercut by a 70-degress slope to 2.5m depth with works being monitored and contingency strutting implemented between the two footings if ground movements exceeded predictions.

The ground conditions encountered were generally as expected. There was one small wedge failure from unfavourably oriented joints which was addressed quickly by sprayed gunite dentition.

Low anchor stress was identified during monitoring and in turn investigations revealed non-confirmances with the locking-off methodology. It is important to establish what amount of additional stress is required to provide allowance for lock-off losses, especially for short anchors in competant rock where lock-off losses can be very significant. This should be done by immediate lift-off checks to confirm the specified load is locked into each anchor.

The anchor testing was carried out in accordance with BS EN ISO 22477-5:2018 Test Method 1, as per standard UK pratice, which prescribes that the anchor is loaded in steps on one or more load cycles increasing to proof load, with measurement of displacement carried out over a prescribed fixed period at each load step.

ACKNOWLEDGEMENTS

The authors are grateful for the support and collaboration from the main project stakeholders Stockport Council, Graham Construction and Network Rail.

A specific acknowledgement is also made to Jim Martin of Byland Engineering for his expert forensic investigation into the cause of the low anchor stresses and for assisting with a practical solution.

ABSTRACT: The effective design, specification and construction of geotechnical assets or Special Geotechnical Measures (SGMs) are critical to the efficient operation of the National Highways Strategic Road Network (SRN) in England. Given the required performance of the SRN in terms of resilience, reliability, redundancy and recovery it is essential that SGMs are themselves reliable in terms of performance and life; resilient to external conditions such as earthworks deterioration and extraordinary conditions (e.g. climate change). Around 100 different types of SGMs are used on the SRN and the early installations of some SGMs are approaching the end of their design life; the design, specification and application of many of these techniques are based on limited studies. A detailed account of issues identified on the Strategic Road Network (SRN) is given resulting from the inspection of Block Walls of various types and in various settings. The results were used to develop advice on the design, construction, inspection, maintenance and decommissioning of such structures and to make a series of recommendations for their future use. Principle amongst these is that the evidence suggests that when properly designed, specified, constructed and maintained, including an appropriate inspection regime, Gravity block walls can meet the required design life of such SGMs.

RÉSUMÉ: La conception, la spécification et la construction efficaces d'actifs géotechniques ou de mesures géotechniques spéciales (SGM) sont essentielles au fonctionnement efficace du réseau routier stratégique national (SRN) en Angleterre. Compte tenu des performances requises du SRN en termes de résilience, de fiabilité, de redondance et de récupération, il est essentiel que les SGM soient eux-mêmes fiables en termes de performances et de durée de vie ; résistant aux conditions externes telles que la détérioration des terrassements et les conditions extraordinaires (par exemple, le changement climatique). Environ 100 types différents de SGM sont utilisés sur le SRN et les premières installations de certains SGM approchent de la fin de leur durée de vie ; la conception, la spécification et l'application d'un grand nombre de ces techniques reposent sur des études limitées. Un compte rendu détaillé des problèmes identifiés sur le réseau routier stratégique (SRN) est donné à la suite de l'inspection de murs en blocs de divers types et dans divers contextes. Les résultats ont été utilisés pour élaborer des conseils sur la conception, la construction, l'inspection, l'entretien et le démantèlement de ces structures et pour formuler une série de recommandations pour leur utilisation future. Le principe parmi ceux-ci est qu'il n'y a aucune preuve convaincante que lorsqu'ils sont correctement conçus, spécifiés, construits et entretenus, y compris un régime d'inspection approprié, les murs en blocs de gravité ne peuvent pas respecter la durée de vie requise de ces SGM.

Keywords: Geotechnical; asset; retaining; wall; block.

1 INTRODUCTION

This paper provides a brief summary of a study that investigated gravity block walls. Typically, Block Walls are used on the Strategic Road Network (SRN) in England as low-height walls around features such as telecommunication housings and at the base of embankments. However, drystone and mortared stone walls are also prevalent on the network in both free-standing and retaining form.

This work forms part of a wider study (Duffy-Turner et al., 2022a) of the performance of geotechnical asset types, known as Special Geotechnical Measures (SGMs), including block walls (Winter et al., 2022), gabion walls (Duffy-Turner et al, 2022b), counterfort drains (Nettleton et al, 2022), and soil nails (Duffy-Turner et al., 2022c).

An account is given of issues identified from inspections of gravity block walls on the SRN along with issues for their design, construction, maintenance and recommendations for future use.

2 ISSUES IDENTIFIED

A wide variety of issues was identified during the inspection of 10 gravity block walls on the network. These included but were not restricted to the issues described in the following paragraphs.

Deterioration and loss of mortar of the exposed top course (coping) and or the lower courses, most likely due to the effects of salt spray; this often included the complete loss of blocks. Cracking of blocks was also commonly observed (Figure 1).

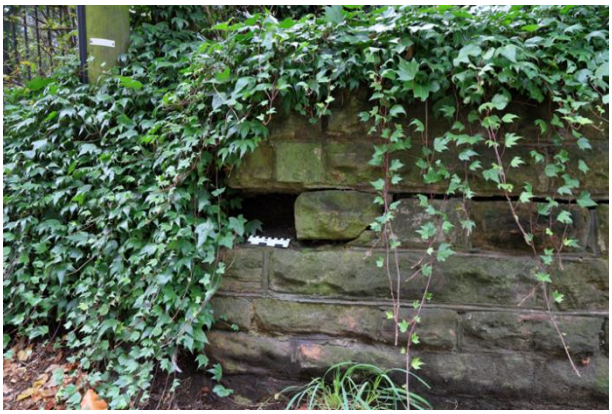

Figure 1. Deterioration of the lower courses of a stone block mortared wall most likely due to salt spray. The deterioration of this wall at this location is through the full height with the loss of block(s) in the central area (A52).

Vehicle damage to the upper free-standing part of a retaining wall was observed (Figure 2).

Figure 2. Upper free-standing part of a dry-stone retaining wall (mortared coping) showing the effects of vehicle impact. The wall below the carriageway retains a height of between 2m and 3m below the road. (A628).

Bulging and leaning were commonly observed, as were sagging and hogging of both modular concrete block (mortar free) and stone (mortared or otherwise) walls (Figure 3).

The provision of weepholes to block walls was relatively uncommon, with seepage taking place through the wall itself, and no instances of an identifiable drainage layer behind the wall were encountered (although this is difficult to establish definitively). Where weepholes were provided, they generally appeared to be working although the washout of gravel particles suggests that construction materials are also being washed out (Figure 4), indicating that there was a lack of a suitable filter/separator in the construction of the wall/drainage. The lack of adequate drainage is a factor that may cause deterioration and subsequent failure and is an area of potential concern that ought to trigger further evaluation of the Block Wall.

Figure 3. Stone block mortared wall showing significant signs of instability: substantial mortar loss, sagging and bowing of the wall and that, in places, has led to substantial misalignment of the individual blocks with the potential for individual blocks, or groups of blocks, to be lost (A303).

Block walls, whether mortar or dry stone, have the potential to fail with blocks falling to the ground surface often from the top course (coping) and the potential to cause injury and blockage of, for example, footpaths causing the public to enter the highway in order to pass. Cracking, bulging, leaning and seepage/lack of drainage provision are indicators of potential failure but do not necessarily indicate that the risk associated with that failure merits intervention. Ownership may also be uncertain.

Evidence of efflorescence was observed at some locations; this was largely at a level considered to be aesthetic issue, with preventative or remedial measures needed only in visually sensitive areas.

Changes to the spatial relationship between walls and the infrastructure can also occur when the asset has been developed around older walls, leading to suboptimal configurations (O'Reilly and Perry, 2009). Some walls thought to have been constructed as free-standing were found to be retaining for at least part of their height, in some instances explaining the absence of weepholes.

Block walls often form the boundary to third party properties and there can be doubt as to the ownership

of the walls. This may in part explain the change in function over time while the build-up of detritus can also form a backfill.

Figure 4. Weepholes (80mm internal diameter at 6m centres) in a 78m long, 0.75m high stone block mortared wall. The gravel particles in front of the wall appear to have been washed out of the weepholes indicating that they are functional but possibly washing out material that forms part of the construction (A30, January 2021).

Notwithstanding the issues outlined above, dry stone walls in particular can be a relatively resilient form of structure.

3 DESIGN

Published design, specification and construction guidance, while limited is summarised by Winter et al. (2022). Key issues include:

- Ensuring that the layout is such as to maximise internal stability, typically stretcher bond, and where that is not possible ensure that vertical joints do not coincide over more than two courses (Haramy et al., 2006).
- That the design takes account of any mechanical interlock.
- Weepholes and an effective drain and filter should be provided to the rear face of the wall allowing water to flow to a suitable outlet. This should be designed in the context of the prevailing surface/ground water conditions.
- That the block materials are considered with respect to their durability. This is particularly the case with stone blocks located in parts of England where weak sandstones and limestones predominate, and competent material may have been in short supply. Argillaceous rocks, and other materials potentially susceptible to weathering, should not be used to construct gravity block walls of any type on the SRN.
- Coping protection may be necessary.
- Where possible block walls should be located so as to minimise the effects of salt spray from de-icing salts as this may cause deterioration in the fabric of the lower parts of the wall.

4 CONSTRUCTION

All blocks and mortar used must maintain integrity in the light of the mechanical and environmental stresses that it might face during its design life. These can include contact stresses in the case of dry-stone walls and the effects of de-icing salts for all forms of wall.

High contact stresses can be caused by incorrect handling during transport and construction such that concentrated loads are generated rather than the blocks being placed square on top of each other, or by subsequent movement of the retained material or deterioration of the block(s).

Drainage provision is essential and must be as detailed in the design. The drainage media must be durable over the design life of the asset with adequate inspection and maintenance built into the plan to manage the asset.

Adequate and competent personnel for construction and supervision are essential for what is often an artisanal form of construction.

Provision should be made for handover inspection and subsequent snagging prior to the removal of any traffic management and the contractor leaving the site.

5 MAINTENANCE

Maintenance (and demolition) of the wall should be considered throughout the design, specification and construction process and plans should be prepared and incorporated into handover documentation.

O'Reilly and Perry (2009) give cost comparisons of various forms of reconstruction and repair techniques for different heights of dry-stone walls and also note that the annual costs of maintenance of such walls are around 0.75% of their replacement cost. While the actual costs date back to around 1995 the relative comparisons are considered to remain valid with those of pressure pointing and soil nailing being around 12% and 50% of replacement structures.

Maintenance of dry stone and many stone block mortared walls must be taken in the context of the history and the natural and cultural heritage of their setting. Amongst the walls inspected during the site visits was a wall retaining an ancient cemetery within the Peak District National Park. It should be clear that a degree of sensitivity and consultation will be required prior to any major maintenance works and

that this will be particularly so if any intrusive repair (e.g. soil nail repair) or reconstruction is considered.

6 CONCLUSIONS AND RECOMMENDATIONS

Different types of wall are not always differentiated in the asset management system, with masonry walls and stone walls all being described as block walls.

The evidence suggests that when properly designed, specified, constructed and maintained, including an appropriate inspection regime, block walls can meet the required design life (120 years) of such SGMs.

Advice in standards and other related documents for Block Walls is clearly limited. Through the course of this work a number of key issues have been identified and these are set out as recommendations for action in the following paragraphs.

Recommendation 1: The design of block walls should take due cognisance of manufacturer's information, where relevant, as well as fundamental design principles.

Recommendation 2: The provision of adequate and appropriate drainage for block walls should be addressed through the design, specification, construction and approval phases.

Recommendation 3: The use of argillaceous rock, or other material susceptible to weathering, to form block walls is not recommended, due to the possibility of rapid deterioration, in particular in locations of high exposure.

Recommendation 4: Contractor acceptance, or self-certification, of block walls is not recommended as part of the findings from the wider work undertaken (Duffy-Turner et al., 2022a).

Recommendation 5: Any inspections for the acceptance of constructed block walls should be undertaken prior to the site becoming fully-operational and while items are visible and remedial measures can be readily implemented; it is recommended that provision for early inspection should be built into the contract.

Recommendation 6: Inspection of SGMs should be certified by a Geotechnical Advisor in accordance with CD 622 .

Recommendation 7: A formal risk-based approach to the inspection and maintenance of block walls should be developed. This would assign values to attributes during assessment to allow prioritisation of actions including maintenance and replacement. Attributes to be considered include but are not limited to, wall type, condition, provision and effectiveness of drainage, proximity to road users; a draft scheme with examples is described by Winter et al. (2022).

Experimental and numerical study on the compaction of granular soils by vibrations

Etude expérimentale et numérique du compactage de sols granulaires par vibrations

M. Wotzlaw*, D. Aubram, F. Rackwitz
Technische/Universität Berlin, Germany

**moritz.wotzlaw@tu-berlin.de*

ABSTRACT: The paper deals with the influence of vibrations, i.e. cyclic excitations with large acceleration amplitudes, on dry granular materials like sand. The inertial stresses induced by the accelerations cause a temporary loss of shear strength as well as a permanent compaction of the material. Although this phenomenon is known for a long time and plays an important role in many geotechnical construction processes like deep vibrocompaction and vibrodriving of piles, only few systematic studies on the fundamental relations exist. The investigations at TU Berlin focus on the relationship between the static and dynamic stress states in the material during vibrations and the achieved compaction. An experimental setup was developed which allowed for the compaction of sand under small effective stresses and large acceleration amplitudes. As the dynamic stresses determining the compaction behaviour vary within the sample, a simple method to evaluate the vertical distribution of void ratio is applied. The results of these tests are presented and a simple model for estimating the compaction based on the stress state and acceleration amplitude is proposed. This model is applied to the results of numerical simulations of deep vibrocompaction, to gain an estimate of the amount of compaction caused by the cyclic accelerations.

RÉSUMÉ: Ce document traite de l'influence des vibrations, c'est-à-dire des excitations cycliques avec de grandes amplitudes d'accélération, sur les matériaux granulaires secs comme le sable. Les contraintes inertielles induites par les accélérations provoquent une perte temporaire de la résistance au cisaillement ainsi qu'un compactage permanent du matériau. Bien que ce phénomène soit connu depuis longtemps et qu'il joue un rôle important dans de nombreux processus de construction géotechnique tels que le vibrocompactage en profondeur et le vibrofonçage de pieux, il n'existe que peu d'études systématiques sur les relations fondamentales. Les recherches menées à l'Université technique de Berlin se concentrent sur la relation entre les états de contrainte statiques et dynamiques dans le matériau pendant les vibrations et le compactage obtenu. Un dispositif expérimental a été mis au point pour permettre le compactage du sable sous de faibles contraintes effectives et de grandes amplitudes d'accélération. Comme les contraintes dynamiques qui déterminent le comportement du compactage varient à l'intérieur de l'échantillon, une méthode simple est appliquée pour évaluer la distribution verticale du taux de vide. Les résultats de ces essais sont présentés et un modèle simple d'estimation du compactage basé sur l'état de contrainte et l'amplitude d'accélération est proposé. Ce modèle est appliqué aux résultats des simulations numériques du vibrocompactage en profondeur, afin d'obtenir une estimation de l'ampleur du compactage causé par les accélérations cycliques.

Keywords: Vibrocompaction; granular soils; cyclic accelerations; experimental tests; numerical simulations.

1 INTRODUCTION

Granular material like sand can be efficiently compacted with the use of vibrations, which we define as alternating deformations of the grain skeleton and sufficiently large acceleration amplitudes. Although the first findings were published early on (Barkan, 1962), the underlying mechanisms are still poorly understood. There have been repeated attempts to investigate the phenomenon (Youd, 1968; Norman-Gregory and Selig, 1989; Bement, 1996; see also Denies, 2014 for an overview) but these have remained isolated and have not led to a systematic theory of vibrocompaction of granular materials. The experimental set-ups of the works mentioned are always comparable: A sample of granular material is placed inside a test container with rigid walls, loaded vertically via a load stamp and vibrated in vertical or horizontal direction using a shaking table. The change of density over time is determined by measuring the settlement of the load stamp.

Irrespective of the exact experimental set-up and the intensity or direction of vibrations applied, the following basic observations were made: Starting from the initial value e_0, the void ratio decreases non-

linearly and asymptotically approaches the limit value e_Γ (also called the equilibrium void ratio, Figure 1 above), which is defined as the minimum void ratio that can be achieved under the given surcharge p_z and non-dimensional acceleration amplitude $\Gamma = a/g$, where a is the acceleration amplitude and g is the acceleration due to gravity. With an increasing value of Γ the equilibrium void ratio e_Γ decreases towards the minimum void ratio achievable for this material by vibrations (Figure 1 below).

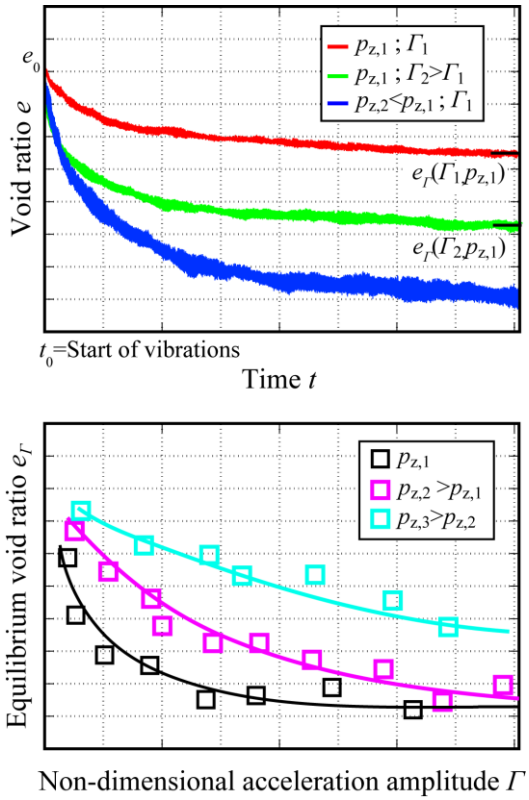

Figure 1. Time history of void ratio during compaction with constant surcharge p_z and dimensionless acceleration amplitude Γ (above). Dependence of the equilibrium void ratio e_Γ on the acceleration amplitude Γ (below).

Obviously the void ratio e_Γ isn't solely dependent on the acceleration amplitude but also the static surcharge p_z. It does not seem reasonable to use Γ as the only non-dimensional number characterising the compaction behaviour, as has been common practice up to now (Youd, 1968; Bement, 1996). Accordingly, a new non-dimensional number is introduced here, which we call the local stress ratio κ. It is defined as the ratio of the dynamic (destabilising) stress amplitude σ_{dyn} to the static (stabilising) stress σ_{stat}. For the specific test conditions applied in this study, it is assumed to take the form:

$$\kappa = \frac{\sigma_{\mathrm{dyn}}}{\sigma_{\mathrm{stat}}} = \frac{\Gamma \cdot g \cdot m/A}{p_z + g \cdot m/A} \qquad (1)$$

where m and A are the sample's mass and sectional area respectively. The dynamically excited mass increases with the depth z of the sample (starting from the sample's top surface), so that κ is a function of z and increases with depth. It will be shown that the dimensionless number controlling densification is κ rather than Γ.

As the stress ratio defined in eq. (1) increases with depth and the equilibrium void ratio depends on κ, one hypothesis is that the distribution of void ratio inside the sample also correlates to the stress ratio, i.e. the density in the lower area of the sample is greater than in the upper area after compaction.

2 EXPERIMENTAL SETUP

The experimental setup depicted in Figure 2 is used for the tests carried out at TU Berlin. Here the sample is placed in a cylindrical container having rigid walls. The surface is straightened and covered by a load stamp. The specimen has a diameter of $d = 80$ mm and initial height h_{ini} ranging from 60 mm to 80 mm, depending on the installed mass and initial density.

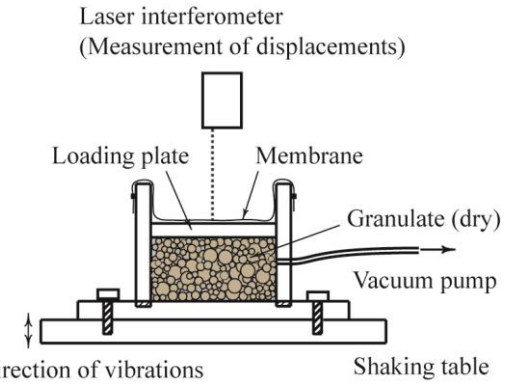

Figure 2. Experimental setup for vibrocompaction tests. The container is cylindric and has an inner diameter of 8 cm.

The container is then sealed by a thin latex membrane, so that an underpressure p_0 can be created inside the sample with the aid of a connected vacuum pump. It follows that the resulting static surcharge is given by $p_z = p_{\mathrm{atm}} - p_0$.

On the one hand this way of load application makes it possible to create a very small static stress level so that even with relatively small accelerations a large value of κ can be achieved. On the other hand, the surcharge itself is not dependent on inertia, as would be the case for example, if the load was applied via weights.

The tested material was a Toyoura sand, with a coefficient of uniformity of $C_{\mathrm{U}} = 1.3$, a minimum/maximum void ratio of $e_{\mathrm{min}} = 0.569$ and $e_{\mathrm{max}} = 0.907$ respectively. After placing the test cell

on a shaking table, it was vibrated at a frequency of 50 Hz in vertical direction, where the acceleration can be regulated by adjusting the displacement amplitude.

In order to determine the local distribution of void ratio and to check on the hypothesis formulated in the introduction, the following simple procedure is applied: After compaction, the sample is removed in layers using a vacuum pump. Height and mass of each layer is measured so that the locally averaged void ratio can be calculated afterwards.

3 EXPERIMENTAL RESULTS

The distributions of the locally averaged void ratios after compaction e_κ over the sample height are shown in Figure 3. For reference an exemplary initial (i.e. pre-compaction) distribution is also shown in black. The average initial void ratio was around 0.9 in all of the tests, which is close to the sand‘s maximum void ratio.

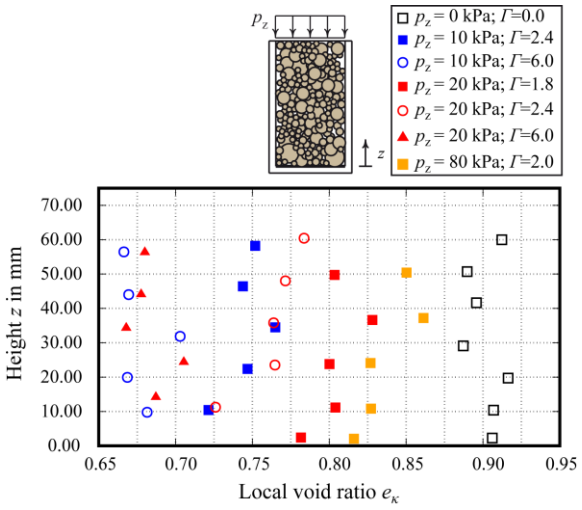

Figure 3. Distribution of void ratios after compaction over the sample height for various combinations of surcharge and acceleration amplitude.

Some already known properties can be identified: The larger the acceleration amplitudes (at constant surcharge), the more the sample is compacted over the entire height. The larger the surcharge, however, the weaker the compaction, given the same or comparable acceleration. There seems to be at least a tendency for the sand to be denser in the lower areas than in the upper areas, although this is not clearly pronounced in all cases. However, this is consistent with the observations by Norman-Gregory and Selig, 1989.

If these test results are plotted over the assumed local dynamic stress ratio κ, a correlation of both quantities is visible (Figure 4). The black curve in Figure 4 is given by equation (2), with the vibratory minimum void ratio $e_\infty = 0.65$, the maximum void ratio $e_{\max} = 0.907$ and a coefficient $\lambda = 0.015$:

$$e(\kappa) = e_\infty + (e_{\max} - e_\infty) \cdot \frac{1}{1+\kappa/\lambda} \qquad (2)$$

4 NUMERICAL SIMULATIONS

We will now demonstrate briefly, how these findings could be used to estimate the compaction of sand due to cyclic accelerations caused by vibroflotation, a well-established method for the compaction of granular (see Kirsch and Kirsch, 2010 for details). For this we use results obtained by simulations with the CEL method. The numerical model is shown in Figure 5.

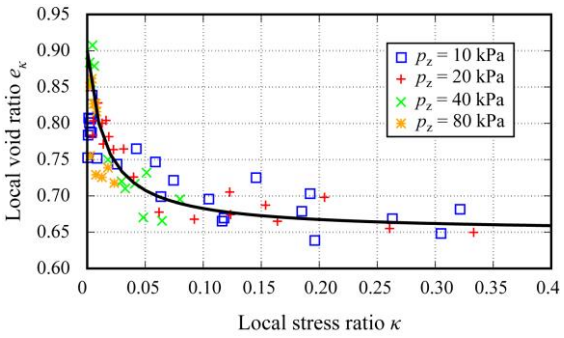

Figure 4. Dependence of the locally averaged void ratio after compaction on the local stress ratio, for which a linear distribution is assumed.

The mechanical soil behaviour is modelled using the hypoplastic constitutive model with intergranular strains (von Wolffersdorff, 1996; Niemunis and Herle, 1997) using the parameters shown in the table in Figure 5. The model and its validation were described in detail by Wotzlaw et al., 2023. It has a height of 30 m and a diameter of 25 m. In our simulations the vibrator is operating at a depth of 11 m below ground level (referring to the vibrator tip). The initial void ratio is given by $e_0 = 0.907$.

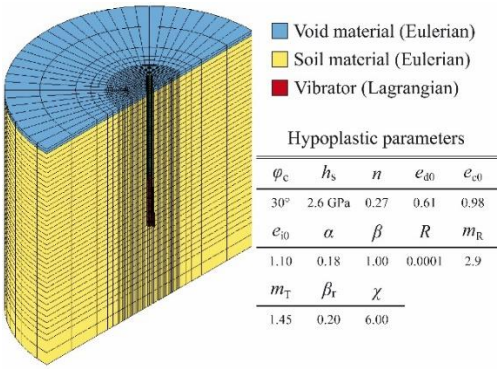

Figure 5. Numerical model and hypoplastic parameters after Herle (1997).

By using this fully fledged CEL model described above, the time history of vertical stress could be evaluated. From this and the local static vertical stress,

a time-averaged local stress ratio has been determined for each finite element in order to apply eq. (2) (Figure 6). In a radial distance of approximately 1 m from the vibrator axis, the stress ratio has a value of up to 0.5 and then quickly decreases in a larger distance to the vibrator. However, as can be seen from Figure 4, the degree of compaction does not increase significantly for stress ratios larger than approximately 0.2.

Accordingly, the distribution of minimum void ratio due to vibrations in Figure 7, which we get solely by applying Eq. (2) on the distribution of average stress ratio, shows that the soil can be compacted efficiently from an initial relative density of $I_D = 0$ to a densities after compaction ranging from $I_D = 0.6$ in a distance of 3 m from the vibrator axis to $I_D = 0.76$ within a radius of 1 m around the vibrator.

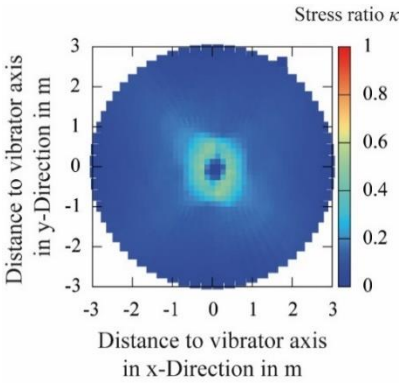

Figure 6. Average local stress ratio in a depth of 9.6 m below ground level caused by vibrocompaction.

5 CONCLUSIONS

We have shown experimentally, that the void ratio after vibrations e_κ depends on the local stress ratio κ inside the vibrated granulate. Further research on this matter has to be performed, especially the influence of the direction of vibration and the effect of vibrations on the shear resistance have to be considered.

We included numerical simulations to show how these findings can be used to estimate the amount of compaction solely by application of the proposed eq. (2). In later works, the effect of simultaneous cyclic shear deformations has to be included. However, even with all simplifications, this example shows that the impact of cyclic accelerations on the relative density of granular soils should be taken into account in numerical simulations. Utilising the dependence on the local stress ratio can be one way of doing so.

Interpretation of ion exchange in soil-bentonite mixtures

Interprétation de l'échange d'ions dans les mélanges sol-bentonite

R. Yu*
Graduate School of Global Environmental Studies, Kyoto University, Kyoto, Japan
A. Takai, T. Kato, T. Katsumi
Graduate School of Global Environmental Studies, Kyoto University, Kyoto, Japan

ABSTRACT: This study investigated the Ca^{2+}-Na^{+} exchange within soil-bentonite (SB) mixtures, commonly employed in the construction of vertical cut-off walls, with a primary focus on the Ca^{2+} sorption and Na^{+} desorption processes. Batch tests were conducted using sodium bentonite, decomposed granite soil, and SB (7.5% mass fraction of bentonite), in $CaCl_2$ solutions with concentrations ranging from 0.5 to 50 mmol/L. The results revealed a significant impact of the water-absorbing swell of bentonite on the volume of the bulk solution, which interfered the calculation of Ca^{2+} sorption. Notably, Na^{+} desorption ceased when the bulk Ca^{2+} concentration exceeded 4 mmol/L, simplifying the development of Ca^{2+}-Na^{+} exchange into Ca^{2+} sorption process. The sorption isotherms of SB, Soil, and bentonite are proportional to their respective bentonite mass fractions. By incorporating parameters related to volume change and sorption isotherms, an average concentration of montmorillonite interlayer space (C_{in}) was proposed. Correlations were founded between C_{in} and the hydraulic conductivity of SB, offering insights into permeability changes based on batch test results.

RÉSUMÉ: Cette étude explore le comportement d'échange Ca^{2+}-Na^{+} dans les mélanges de sol-bentonite (SB) couramment utilisés dans la construction de murs de confinement verticaux. L'accent est mis sur l'sorption du Ca^{2+} et la désorption du Na^{+} dans le mélange SB. Des essais en lots ont été effectués avec de la bentonite sodique, du sol de granite décomposé, et du SB (7,5 % en masse de bentonite), en utilisant des solutions de $CaCl_2$ de 0,5 à 50 mmol/L. Les résultats montrent un impact significatif du gonflement de la bentonite sur le volume de la solution en vrac, influençant le calcul de l'sorption de Ca^{2+}. La désorption du Na^{+} cesse lorsque la concentration en Ca^{2+} dépasse 4 mmol/L, simplifiant le comportement d'échange d'ions en un processus d'sorption de Ca^{2+}. Les isothermes d'sorption du SB, du sol, et de la bentonite sont proportionnelles à leurs fractions massiques respectives de bentonite. En incorporant des paramètres liés au changement de volume et aux isothermes d'sorption, une concentration moyenne de l'espace interlamellaire de montmorillonite (C_{in}) est proposée. Des corrélations sont établies entre C_{in} et les conductivité hydrauliques du SB, offrant des perspectives sur les changements de perméabilité basés sur les résultats des essais en lots.

Keywords: Soil-bentonite; ion-exchange; batch test; sorption; free swell.

1 INTRODUCTION

Soil-bentonite (SB), a mixture of parent soil and sodium bentonite, is widely utilized in constructing vertical cut-off walls because of its exceptional impermeability and self-healing properties (Evans, 1993; Takai et al., 2013) attributed to the added bentonite (Bradshaw & Benson, 2014; Gleason et al., 1997).

The ion exchange of sodium bentonite involves the replacement of Na^{+} within the montmorillonite lattice with other cations from the bulk solution, thereby weakening the barrier performance of bentonite. While previous research has delved into the ion exchange of pure sodium bentonite (Egloffstein, 2001; Whittaker et al., 2019), less attention has been given to the ion exchange behavior of SB, which contains only small quantities of bentonite. Furthermore, challenges persist in assessing material permeability through ion exchange analysis.

Batch test offers an effective means of evaluating ion exchange by subjecting sodium bentonite to multivalent cation solutions (Kaya & Ören, 2005; Meneguin et al., 2017). Existent sorption theories have been found to align well with the characteristics of bentonite when the bulk cation concentration was below 1 g/L. However, its sorption behavior when bulk cation concentrations resembling those found in real-world contaminated leachate (Naveen et al., 2017) is not comprehensively understood.

The aim of this study is to examine the Ca^{2+}-Na^{+} ion exchange behavior of SB and compare it with the behavior in pure bentonite and parent soil. This investigation involves conducting batch tests with pure

2 MATERIALS AND METHODS

2.1 Soil materials

The physical properties of soil materials are listed in Table 1. Decomposed granite soil (Soil), which is a sandy soil widely distributed in the subsurface throughout Japan (Ham et al., 2010), was used as the parent soil. Kunigel V1, one of the sodium bentonites collected in Japan (Komine et al., 2009), was used as the bentonite added to the parent soil.

In order to simulate the SB that have been used in Japan (Takai et al., 2016), moisture content of prepared SB is designed as 29%, and mass fraction of sodium bentonite in SB is controlled at $n_{bent.}$ = 7.5%:

$$n_{bent.} = m_{bent.} / (m_{bent.} + m_{soil}) \quad (1)$$

where m_x (g) represents the dry mass of bentonite or decomposed granite soil.

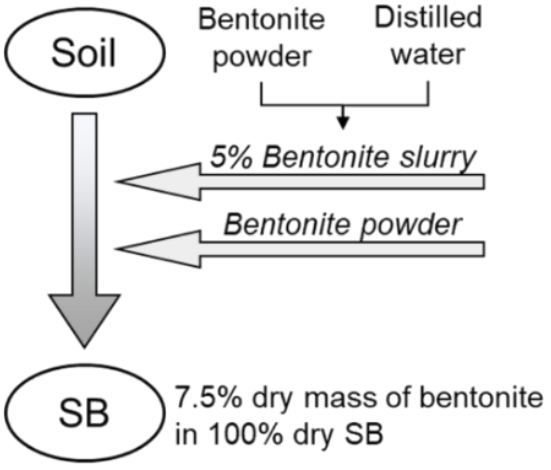

Figure 1. SB mixing procedures.

The procedures of SB preparation is given in Figure 1. The Soil was first passed through 2 mm sieve and then dried by 110 °C oven, while the bentonite powder was air dried with 7.2% initial moisture content, and the 5% bentonite slurry was prepared by mixing bentonite powder with distilled water at a mass ratio of 1:20 for 20 minutes using an aqueous mixer. The slurry was first added into the dried Soil, where the bentonite mass in the slurry was counted in the total $m_{bent.}$. Then, the input of bentonite powder was divided into several times. After all the bentonite powder and water were inputted, the soil mixer will continue to run for 5 minutes to ensure uniform mixing.

2.2 Batch tests

All batch tests were carried out in 250 mL-PP bottles contain 200 mL $CaCl_2$ with different initial concentrations, the initial Ca^{2+} concentrations for each test were listed in Table 2. The solid inputs in bentonite and SB batch systems were designed to have 0.75 ± 0.01 g bentonite, hence ≈12.9±0.1 g SB were placed in SB batch systems, the actual mass of SB input depends on its measured moisture content. And for batch tests of soil, 10 ± 0.1 g were placed in each test.

Table 2. Designed conditions of batch tests.

	Initial Ca^{2+} (mmol/L)									
	0.5	**1**	**5**	**10**	**15**	**20**	**25**	**30**	**40**	**50**
Bentonite	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
Soil	✓	✓	✓	✓		✓	✓			
SB	✓	✓	✓	✓	✓	✓	✓			

After adding the solids, the bottles were secured on an oscillator and agitated at 3.33 Hz for 24 hours. Following agitation, the bottles were left undisturbed for 15 minutes. The solution was then extracted and centrifuged at 3000 rpm for 10 minutes and filtrated through 0.2 μm filter to collect the supernatant for ionic measurement. Each test was triplicated.

The widely known mass conservation for batch system stands as below:

$$q_e = (V_0 C_0 - V_e C_e) / m_s \quad (2)$$

where q_e (mmol/g) is the sorption or desorption amount of specific component at the end of test; V_0 and V_e (L) are the volumes of bulk solution at initial and final states; C_0 and C_e (mmol/L) are the molarities of

specific component in the bulk solution at initial and final states; m_s (g) is the dry mass of solid.

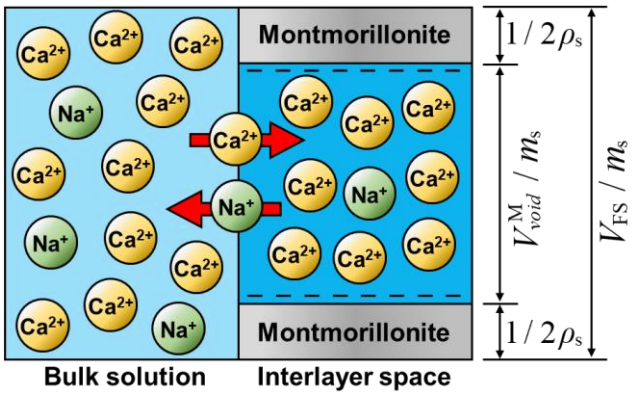

Figure 2. Schematic of montmorillonite unit in bentonite batch system.

Generally, V_0 and V_e are treated as equal. However, in bentonite batch system, the border line between bulk solution and solid particle become ambiguous, the water molecule as well as cations in the solution will be attracted into interlayer space of montmorillonite lattices and be restrained by electrostatic force (Figure 2). In an unfree state, the solution in the interlayer space, strictly speaking, is in a different state than the bulk solution. Therefore, the interlayer space should be eliminated to obtain the volume of bulk solution precisely, the final volume of bulk solution can be calculated by:

$$V_e = V_0 - V_{void}^M + w \cdot m_s / \rho_w = r \cdot V_0 \qquad (3)$$

where V_{void}^M (mL) is the volume of the montmorillonite interlayer in batch system; $w \cdot m_s / \rho_w$ (mL) is the volume of water previously present in the soil; w is gravimetric moisture content. Simplifying V_e as V_0 multiplied by a numerical coefficient r, the mass conservation becomes:

$$q_e = V_0 \cdot (C_0 - r \cdot C_e) / m_s \qquad (4)$$

It has to be noted that in a batch system of bentonite and $CaCl_2$ solution, for Ca^{2+} sorption, the value of q_e is positive, it represents the sum of Ca^{2+} amount that directly contact to the solid particles and those trapped in the interlayer of montmorillonite lattice; and for Na^+ desorption, the value of q_e is negative since $C_0 = 0$, it only represents the Na^+ amount in the bulk solution at the end. According to Eq (4), the diversity of q_e between taking volume change into account or not rises when either the r is not approximately equal to one or the value of C_e is very large, the comparison between sorption/desorption isotherms obtained using coefficient r or not had also been conducted in this study.

2.3 Free swell tests

The free swell tests correspond to ASTM D5890 (2019) were conducted in order to find the volume of interlayer space of montmorillonite under different $CaCl_2$ concentrations. The designed initial Ca^{2+} molarities were consistent with the batch conditions.

The tests were conducted in 100 mL graduated cylinders. Initially, each cylinder was filled with a solution up to 90 mL. Next, 2 g of dry bentonite powder were carefully added without touching the cylinder's walls. The cylinder was then topped up to 100 mL with a solution and left undisturbed for 24 hours. The results were obtained when the bentonite volume reading in the cylinder remained unchanged for 6 hours, at which point the supernatant was collected and the equilibrium concentrations of Na^+ and Ca^{2+} were measured.

The volume of the montmorillonite interlayer space per unit mass of bentonite was calculated by:

$$V_{void}^M / m_s = V_{FS} / m_s - 1/\rho_s \qquad (5)$$

where V_{FS} / m_s (mL/g) is the free swell volume per gram observed from the test; ρ_s (g/cm^3) is the particle density of bentonite.

2.4 Measurement of ionic compositions

The molarities of Ca^{2+} and Na^+ in the supernatants collected from batch tests and free swell tests, and their initial concentrations in every test were measured by an atomic emission spectrometer (SHIMADZU, ICPE-9800). All fluids were collected in 15 mL centrifuge tubes and stored at 4°C previous to the measurement.

3 RESULTS

3.1 Montmorillonite interlayer space

The change of montmorillonite interlayer space of unit mass V_{void}^M / m_s at different Ca^{2+} concentrations obtained from free swell tests according to the Eq (5) are given in Figure 3, the bulk concentrations in the figure are the concentrations when the free swell volumes were read. It can be seen that the V_{void}^M / m_s decrease significantly as the increase of Ca^{2+} molarity in the solution, and the V_{void}^M / m_s at any Ca^{2+} molarity in bulk solution less than 50 mmol/L can be precisely estimated.

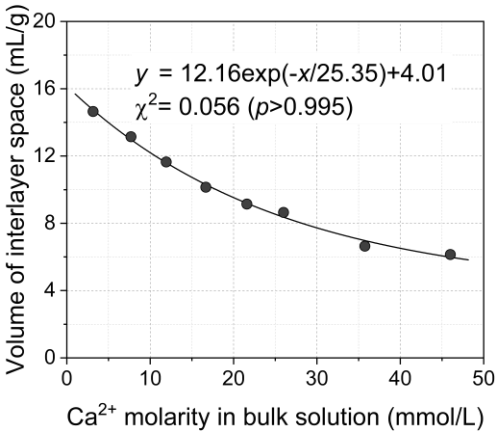

Figure 3. Interlayer space of bentonite in different Ca^{2+} concentrations.

3.2 Sorption and desorption isotherms

All isotherms in this study were plotted with an independent variable of Ca^{2+} molarity in bulk solution, the isotherms obtained without considering the volume change were labelled as Ordinary, while isotherms obtained using Eq (4) were labelled as Modified.

The sorption and desorption isotherms in bentonite and SB batch systems are given in Figure 4, the isotherms in the two systems exhibited same characteristics. For Ca^{2+} sorption, the ordinary isotherms shared a trend of decreasing when the Ca^{2+} concentration in bulk solution exceeded 10 mmol/L while the modified isotherms tended to remain unchanged. The differences between two kinds of isotherms gradually increased with the increase of Ca^{2+} concentration in bulk solution. In Figure 4, when the Ca^{2+} concentration closed to 50 mmol/L, the modified q_e was almost 3 times of the ordinary q_e, meanwhile the estimated interlayer space for 0.75 g bentonite at 50 mmol/L Ca^{2+} was about 3.75 mL, which was only approximately 1.88% of the V_0. Such differences between ordinary isotherms and modified isotherms indicate that when the calculation of bentonite sorption based on mass conservation of batch system was proceeded, the volume changes of bulk solution can be eliminated only when the concentration of bulk solution is very low (at least < 4 mmol/L for Ca^{2+}).

On the other hand, the change of bulk volume did not generate huge diversities in Na^+ desorption isotherms. Recallling Eq (4), when C_0 = 0, the differences between two kinds of isotherms would only depend on the value of r, hence slightly change in bulk volume only have slightly effect to the calculated Na^+ desorption amount. The Na^+ desorption isotherms indicating that the original Na^+ in bentonite were quickly and completely replaced by Ca^{2+} meanwhile the Ca^{2+} sorption were still developing, the development of so-called Ca^{2+}-Na^+ exchange were dominated by the extent of Ca^{2+} sorption when bulk Ca^{2+} exceeded 4 mmol/L. Thus, the binary process of ion exchange in bentonite and SB batch systems could be simplistically described, to a large extent, by single process of Ca^{2+} sorption.

The isotherms in the Soil batch systems are given in Figure 5. Neither Ca^{2+} nor Na^+ had illustrated obvious sorption or desorption, confirmed that decomposed granite soil did not undergo significant ion exchange process, and the isotherms of SB were mostly contributed by the properties of bentonite.

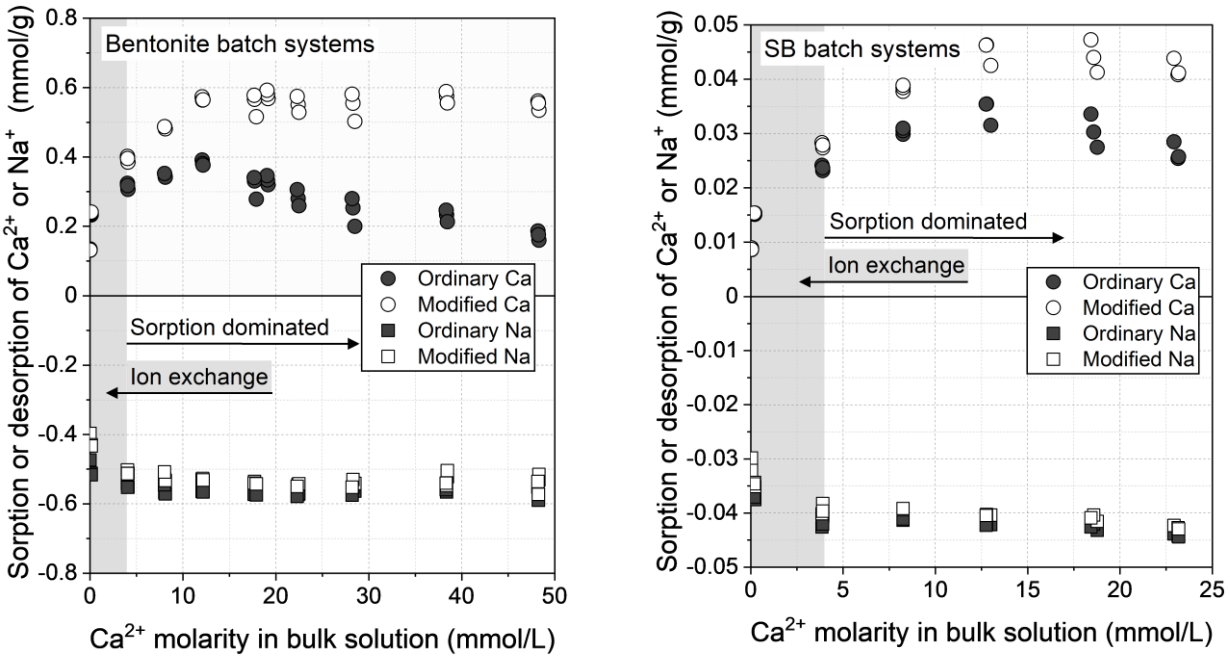

Figure 4. Sorption/desorption isotherms in bentonite (left) and SB (right) batch systems.

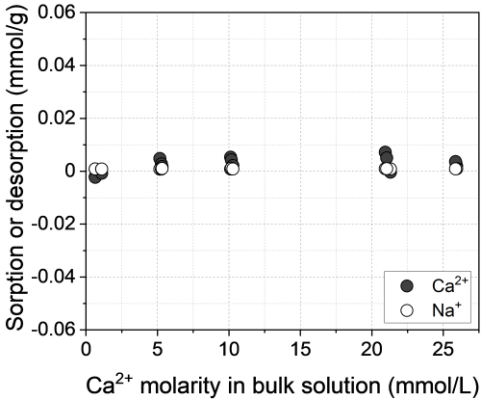

Figure 5. Sorption/desorption isotherms in decomposed granite soil batch systems.

4 DISCUSSION

For the obtained Ca^{2+} sorption isotherms of bentonite, Soil, and SB, quantitative relation based on mass fractions therotically exist as below:

$$q_{\mathrm{SB}} = n_{bent.} \cdot q_{bent.} + (1 - n_{bent.}) \cdot q_{soil} \qquad (6)$$

where q_{sub} is the numerical function of sorption isotherm of specific substance; $n_{bent.}$ = 7.5% in SB mixture, and $q_{soil} = 0$ is approximated. In Figure 6, $q_{bent.}$ was well fitted by Exponential model, and the plots of SB were in line with the calculated q_{SB}, indicating that Soil and bentonite did not interact to each other in batch tests, the Ca^{2+} sorption potential of bentonite can be fully exploited in SB with a 7.5% mass fraction.

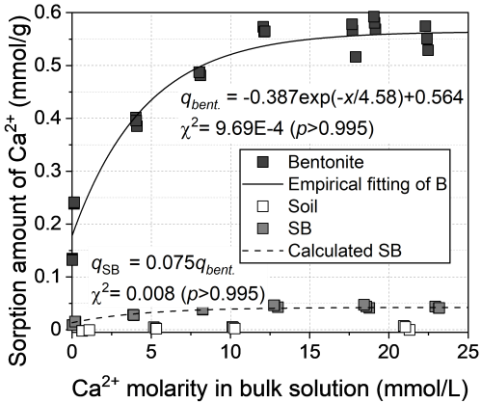

Figure 6. The relation between modified Ca^{2+} sorption isotherms of bentonite, Soil and SB.

Though the ion exchange can be simplfied as Ca^{2+} sorption process, the increase of Ca^{2+} sorption amount were observed converged when bulk Ca^{2+} molarity reached 25 mmol/L, while the permeability of bentonite materials will continue to increase in higher cation molarities (Norris et al., 2018), which has revealed the limitation of using sorption isotherms to estimate permeability changes.

In physical sense, it is the particle surface area and volume of interlayer space that mostly determine the sorption capacity of bentonite (Figure 2). But 1 g bentonite could have different volume of interlayer space under different conditions, which brings insufficiencies to the description of q_e (mmol/g) for bentonite and SB. By considering both the mass and volume, a sufficient description of average molarity in bentonite interlayer space C_{in} is proposed as below:

$$C_{\mathrm{in}} = (q_e / n_{bent.}) / (V_{void}^{\mathrm{M}} / m_s) \qquad (7)$$

where the intensive variable C_{in} (mmol/L) links the results of batch test and the free swell test. Since the scope of C_{in} is only the interlayer space in bentonite, C_{in} is actually independent to the $n_{bent.}$ (q_e is not). The relation between Ca^{2+} molarity in bulk solution and C_{in} is given in Figure 7. C_{in} of Ca^{2+} keeps increasing as bulk concentration and is linearly related to the Ca^{2+} molarity in bulk solution. It can be inferred that the convergence trend of sorption isotherms is limited by the decrease of volume.

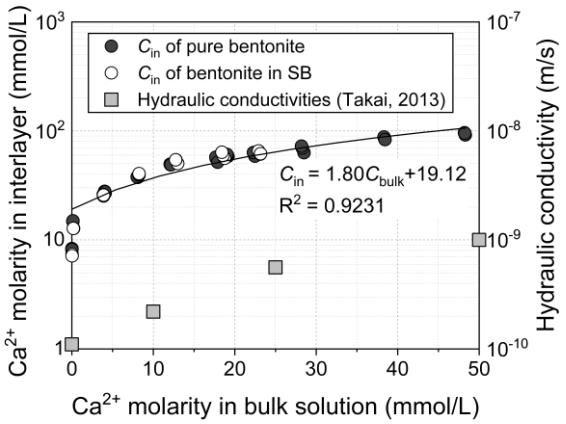

Figure 7. The relations between Ca^{2+} molarity in bulk solution and C_{in} or hydraulic conductivity.

Comparing the C_{in} with hydraulic conductivity of SB prehydrated with $CaCl_2$ solutions, under same concentration range by flexible-wall permeability test (Takai et al., 2013), the increase in hydraulic conductivity was a macroscopic phenomenon that occured simultaneously with the increase of C_{in}. In addition, it is possible to estimate the permeability changes of SB based on the value of C_{in}.

5 CONCLUSIONS

By analysing the results of batch test and the free swell test, the following conclusions were obtained.

(1) In bentonite and SB batch systems, the bulk volume changed as the osmotic swell of bentonite, when bulk Ca^{2+} molarity was closed to 50 mmol/L, the

1.88% of the volume change resulted in an error of nearly 300% in the Ca^{2+} sorption amount.

(2) The developments of Ca^{2+}-Na^{+} exchange process observed in bentonite and SB batch systems were dominated by the extent of Ca^{2+} sorption, when Ca^{2+} bulk concentrations were >4 mmol/L.

(3) The bentonite with 7.5% mass fraction in SB can fully exploit its Ca^{2+} sorption potential as pure bentonite. The measured Ca^{2+} sorption isotherms of bentonite, Soil, and SB are proportional to their respective bentonite mass fractions.

(4) Average molarity in bentonite interlayer space (C_{in}) was proposed, based on the sorption isotherms and results of free swell test. C_{in} was observed to be linearly related to the bulk Ca^{2+} concentration and can be used to estimate the permeability change of SB.

ABSTRACT: This paper reviews previous published articles on structural health monitoring (SHM) of tunnels using distributed fibre optic sensing (DFOS). The installation of DFOS sensors onto curved surfaces in tunnels, such as the transverse cross section of a tunnel, is a major challenge for the effectiveness of SHM of tunnels. The state-of-the-art DFOS sensors installation methods currently used for monitoring surface strains in tunnels are summarized, with emphasis on evaluating the applicability scenario of each method and their advantages and disadvantages.

RÉSUMÉ: Ce document est un recueil d'articles publiés précédemment sur le contrôle de la santé structurelle (SHM) des tunnels au moyen de la détection distribuée par fibre optique (DFOS). L'installation de capteurs DFOS sur des surfaces courbes dans les tunnels, telles que la section transversale d'un tunnel, est un défi majeur pour l'efficacité du SHM des tunnels. Les méthodes d'installation des capteurs DFOS actuellement utilisées pour contrôler les contraintes de surface dans les tunnels sont résumées, en mettant l'accent sur l'évaluation du scénario d'applicabilité de chaque méthode et sur leurs avantages et inconvénients.

Keywords: Distributed fibre optic sensing; tunnel engineering; structural health monitoring.

1 INTRODUCTION

Tunnel engineering has been one of the most vital aspects of underground infrastructure over recent decades, serving an important function in the urban transportation network. By the end of 2020 in China, there were already 16,789 tunnels in operation, with a total length of about 19,630km; 2,746 tunnels under construction, with a total length of about 6,083km; and 6,354 tunnels under planning, with a total length of about 16,255km (Tian et al. 2021). With the increase of construction and service time, tunnel defects are unavoidable (e.g. settlement deformation, lining cracking and tunnel leakage) due to adverse factors such as extreme weather and material deterioration. Recently, distributed fibre optic sensing (DFOS) is emerging as an innovative monitoring tool for measuring continuous strain development by a single fibre optic cable in civil infrastructures (Li et al., 2018). However, DFOS sensors need to be closely attached to the monitored structure so that they can deform simultaneously with the monitored structure and provide accuratemeasurement. Such close attachment can be easily achieved in monitoring flat operational structures such as piles, pipelines, and bridge decks, but it is rarely seen on curved surfaces. The lack of suitable methods for installing DFOS sensors on curved surfaces has been a major obstacle to promoting this innovative technology in tunnel engineering. This paper presents the state-of-the-art methods for installing DFOS sensors on curved surfaces, mainly by comparing the advantages and disadvantages of each method and briefly suggesting improvement measures. It aims to promote the further application of DFOS in tunnel engineering and beyond.

2 EMBEDDED INSTRUMENTATION

Regarding tunnels under construction, DFOS sensors are mainly embedded in the monitored structure, which ensures that DFOS sensors deform simultaneously with the monitored structure by a solid bond, allowing reliable deformation to be transmitted to the sensitive glass fibre core (Monsberger and Lienhart, 2017). Figure 1 shows the typical embedding positions of DFOS sensors.

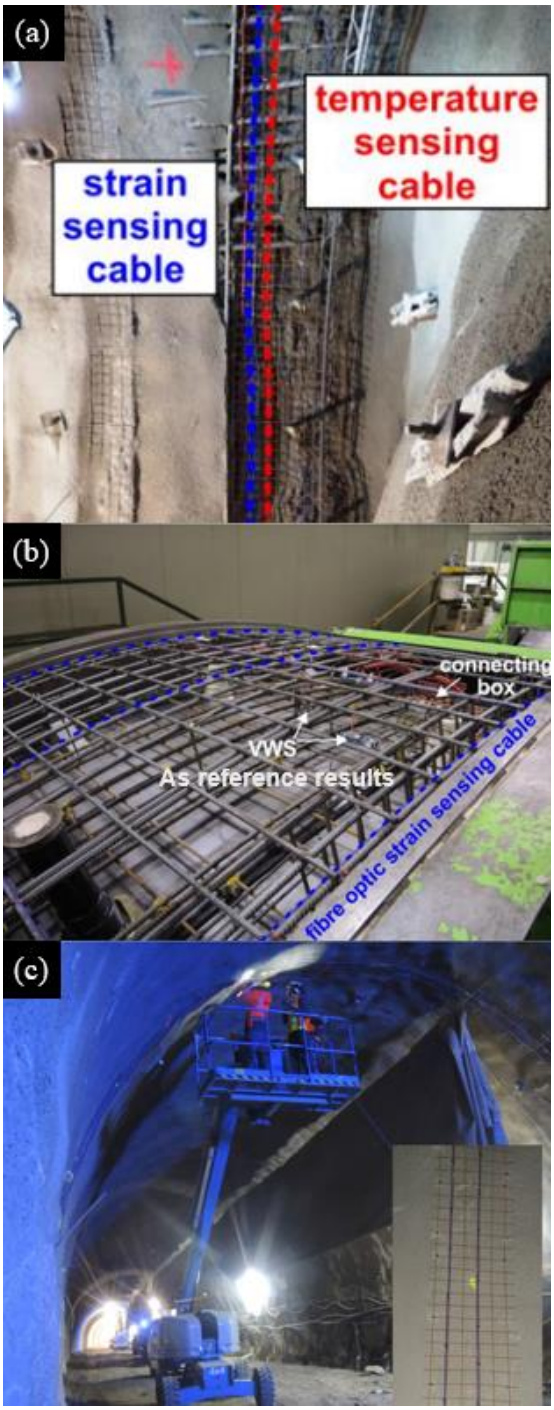

Figure 1. Typical embedding position of DFOS sensors, (a) in shotcrete lining, (b) in tunnel segments and (c) along the shotcrete lining.

Regardless of the tunnel construction methods used (e.g., the New Austrian Tunneling Method (NATM) or prefabricated tunnel segments, as shown in Figure 1(b)), embedding DFOS sensors into the monitored structure in tunnels generally involves two steps:

1) The sensors are first attached directly to the monitored structure at regular intervals (15-20 cm) along the reinforcement bars using some fixing materials, including epoxy resins, eye-bolts, buckles and cable ties.
2) A solid bond between DFOS sensors and the monitored structure is obtained by concrete.

Pre-tension of DFOS sensors has also been shown to be not necessary in a demonstration case reported by Monsberger et al. (2018). A comparative analysis of tunnel lining deformation measurements using vibrating wire sensors (VWS) and non-prestrained DFOS demonstrated that the data obtained from both methodologies exhibited a high degree of congruence in terms of their magnitude and geometric profiles. This finding underscores the reliability and compatibility of non-prestrained DFOS in parallel with traditional vibrating wire sensor measurements for assessing tunnel lining deformations.

For existing tunnels, embedding DFOS sensors directly into the structure at the initial stage is often not possible. In these scenarios, the attachment of DFOS sensors to the cross-section of the tunnel can be achieved via a supplementary structure applied to the tunnel lining, utilizing elements like custom-designed clamps (Muley et al., 2011; Monsberger et al., 2021). After the DFOS sensors installation, additional shotcrete is applied to the area of the secondary structure to ensure a solid bond between the DFOS sensors and the existing tunnel lining. A major limitation of this DFOS sensors installation method is the robustness of DFOS sensors since the DFOS sensors are placed in harsh tunnel construction environment by workers in limited working space. For example, in a NATM construction project, shotcrete is often sprayed onto reinforcement grids under high pressure, the DFOS sensor has to be able to withstand the high pressure and the grid vibrations caused by the high pressure to avoid partial dislodgement of the DFOS sensors from the reinforcement bars. Therefore, DFOS sensors often require additional protective layers and corresponding experimental investigation in the laboratory to examine the influence of site construction on the DFOS robustness and measurement accuracy.

The absence of a requirement for pre-tensioning the DFOS sensors and the ability to accurately track the monitored structural deformations stand as the principal advantages of the embedment instrumentation. However, the construction phase

presents a significant risk of damages the DFOS sensors, resulting post-embedment repairs or replacements changelling without significant intervention in the structure. Consequently, the implementation of supplementary protective measures is advocated to safeguard the integrity of DFOS sensors during installation.

3 SURFACE INSTRUMENTATION

For most existing tunnels, the installation of DFOS sensors on the surface of the monitored structure is more popular due to feasibility, tunnel integrity and serviceablity. The DFOS sensors can be either installed onto tunnel surface using a continuous bonding method or a fixed-point method. Figure 2 summarises the common materials and tools used to attach the DFOS sensors to the surface of the monitored structure.

3.1 Continuous bonding method

In theory, the continuous bonding method shown in Figure 2(a) is the most effective method for attaching the DFOS sensors on the surface of the monitored structure to exploit the continuous strain sensing capacities of DFOS sensors (Sui et al., 2021). Gue et al. (2015) attached the DFOS sensors via continuous gluing to obtain a continuous strain profile along the entire cross section for a cast iron tunnel over a period of 11 months and representative strains of the behaviour of the cast iron ring were measured. However, in order to achieve effective bond between the DFOS sensors and the surface of the monitored structure, a comprehensive treatment of the surface is necessary, including fluting, smoothing, grinding, cleaning, bottoming, sticking, checking etc. These installation techniques severely limit the application of the continuous bonding method. Also, the performance of adhesive (usually a thin layer of epoxy resin) in the long term is vital since the effective contact between the DFOS sensors and the surface of the monitored structure are achieved mainly by the adhesive. According to Gomez et al. (2020), additional protective measures could be taken to avoid possible damage of the DFOS sensors as shown in Figure 2(b).

3.2 Fixed-point method

In many practical situations, a major challenge is that the continuous bonding method can not be used due to the constraints of the construction and service environment. In response to this challenge, the fixed-point method has been advocated. This approach acknowledges the inherent limitation that strain measurements are only representatively for the gauge length. Consequently, rigorous consideration of gauge length is necessary as the computation of deformation hinges on the product of strain and this precisely defined interval length. The hook-and-pulley system shown in Figure 2(c) is currently the most widely reported fixed-point method for installing DFOS sensors (Mohamad et al., 2012). Briefly, the hooks are fixed at different locations on the surface of the monitored structure, with the DFOS sensors passing along the pulleys. Zhu et al. (2022) reported that fixing clamps, designed for installation on tunnel linings through the use of external expansion screws as illustrated in Figure 2(d), are also efficacious in gripping the DFOS snesors. Regardless of the tool used to fix the DFOS sensors to a number of discrete points on the surface of the monitored structure, the DFOS sensors need to be pre-strained to avoid any slack sections. The selected fixation kit should have a suitable curvature to avoid excessive optical signal loss and minimize the distance between the DFOS sensors and the surface of the monitored structure.

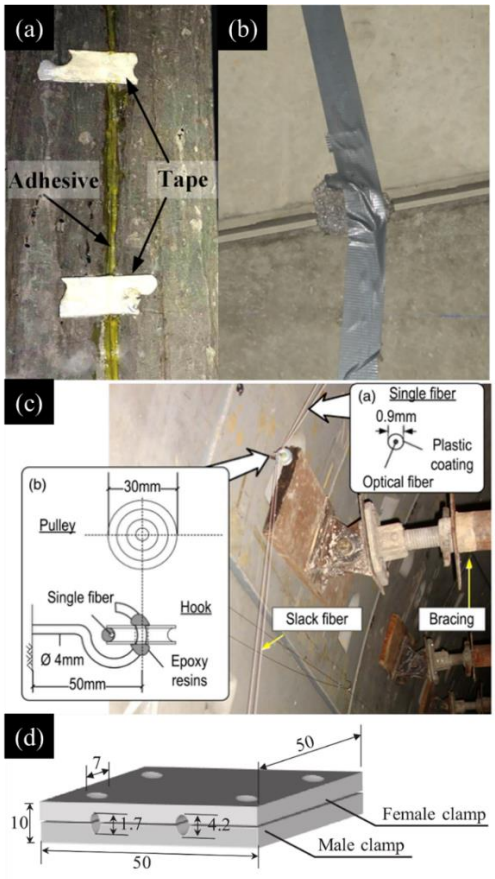

Figure 2. Common materials and tools for attaching the DFOS sensors to the surface of the monitored structure.

Compared with embedded instrumentation, surface instrumentation provides a straightforward and minimally invasive method for structural health

monitoring, offering better flexibility for sensor maintenance, adjustments, and replacements without compromising structural integrity. However, deploying DFOS sensors on the curved surfaces introduces unique challenges, particularly in maintaining consistent contact between the sensors and the curved surfaces, which is crucial for accurate deformation measurement. The complexities introduced by curved surfaces need to be addressed by emphasizing the need for careful method selection, development of innovative attachment solutions and data correction techniques.

4 CONCLUSION

In recent years, a large number of field monitoring projects have been conducted to successfully demonstrate the great potential of DFOS in structural health monitoring. Nevertheless, the capability of DFOS for monitoring structures with curved surface has always been restricted by the reliable DFOS sensor installation method. The present work summarized the DFOS sensors installation method for curved surface, aiming to enhance the applicability of this innovative monitoring technology in tunnel engineering and beyond.

University of Bath, Bath, United Kingdom

**kaa71@bath.ac.uk*

ABSTRACT: Many studies have addressed the embodied carbon of superstructures, however, the carbon footprint of substructures has only been investigated to a limited extent. This study aims to optimize the design of reinforced concrete piles through finding the best combination of concrete design parameters, this is done using a hybrid-optimization algorithm that uses a genetic algorithm to find the optimal pile design. Moreover, the optimization algorithm is used to test the effect of pile geometry on the embodied carbon. Results show that for solid piles, utilizing the optimal design parameters leads to a significant cut in the total embodied carbon compared to common pile designs. However, solid piles proved to be the least efficient environmentally compared to other geometries.

RÉSUMÉ: De nombreuses études se sont penchées sur le carbone incorporé des superstructures, cependant, l'empreinte carbone des infrastructures a été peu étudiée. Cette étude vise à optimiser la conception des pieux en béton armé en trouvant la meilleure combinaison de paramètres de conception du béton, cela est réalisé en utilisant un algorithme d'optimisation hybride qui utilise un algorithme génétique pour trouver la conception optimale du pieu. De plus, l'algorithme d'optimisation est utilisé pour tester l'effet de la géométrie du pieu sur le carbone incorporé. Les résultats montrent que pour les pieux pleins, l'utilisation des paramètres de conception optimaux entraîne une réduction significative du carbone incorporé total par rapport aux conceptions de pieux courantes. Cependant, les pieux pleins se sont avérés être les moins efficaces sur le plan environnemental par rapport à d'autres géométries.

1 INTRODUCTION

Concrete is the most widely used construction material, the pillar of modern infrastructure, and a symbol of human inventiveness. It has played a decisive role in shaping our municipal scenes, from skyscrapers to bridge designs. Yet, behind its long-lasting strength lies a hidden environmental cost and a major threat to our planet (UN report, 2022). As modern societies grapple with the urgent need to mitigate climate change and reduce greenhouse gas emissions, the construction industry is under inspection, and urgent interventions are being taken to cut carbon emissions by 70% by the end of 2030 a milestone towards achieving the net-zero by 2050 (Allwood, J. et al., 2019). Over the past few years, there has been an evolving interest in optimizing the environmental impact of superstructures through introducing new cleaner material-production techniques as well as seeking new structural systems able to resist applied loads utilizing less material and emitting less carbon to the environment (Hawkins et al., 2020). However, researchers have been less devoted to the environmental impact of substructures although foundations are responsible for a considerable share of the total embodied carbon for any structure, including low-rise buildings and lightweight structures such as fences and horizontal structures (Zolotuchin et al., 2018), as well as 14% of the amount of concrete consumed in some of the well-known high-rise landmarks such as Burj Khalifa (Poulos H., 2016). In the United Kingdom, the latest UK FIRES report shows that foundations account for nearly half of the ready-mix concrete consumption and account for 2.5 $MtCO_2e$ emissions annually.

This research focuses mainly on optimizing the environmental impact of reinforced concrete piles, a genetic algorithm optimization method is used to find the optimal pile design parameters as well as testing the effect of pile geometry on its environmental impact. This work is part of a research program that aims at optimizing the design of substructures including building carbon and cost models.

2 METHODOLOGY

2.1 Calculating pile capacities

The structural capacity of a pile N is calculated as shown in equation (1) and according to BS EN 1991-1-1:2008, while equation (2) determines the geotechnical capacity of piles Q_t subjected to compressive loads according to EN 1997-1:2004: The skin friction of tapered piles is calculated using the cavity expansion theory discussed by Khan et al. (2008) and as shown in equation (4).

$$N = 0.4\, f_{ck}\, A_c + 0.75\, f_y\, A_s \quad (1)$$

$$Q_b = q_{soil}.\pi.r_{base}^2 \quad (2)$$

$$Q_s = 2\pi \int_0^L L\,.\,r_i.\tau_s\, d(L) \quad (3)$$

$$\tau_{st} = k_s.k_t.\sigma_v'.tan\delta \quad (4)$$

where:

- A_c and A_s = concrete cross-sectional area and reinforcement steel area.
- f_{ck} and f_y = compressive strength of concrete and yield strength of steel
- Q_t, Q_b, and Q_s = total capacity, base bearing capacity, and shaft friction resistance.
- q_{soil} = soil bearing capacity
- r_i and r_b = pile radius and pile base radius.
- τ_s = pile's surface friction
- δ = the concrete-soil friction angle
- k_s *and* k_t= lateral earth pressure and taper modification coefficients.

2.2 Calculating pile settlement and serviceability limit state

The force-displacement method (t-z method) is used for theoretically calculating the pile's settlement; the pile body is divided into a number of discrete sections with assigned properties, and the pile-soil interaction is modeled using nodal springs with a predefined nonlinear stiffness as calculated by Randolph & Wroth (1978), the nodal stiffness values are then used to form the global stiffness matrix and solve for the pile's settlement as shown in equations (5-7) (Craig and Knappett, 2012):

$$\{F\} = [K_n + K_s] \cdot \{u\} \quad (5)$$

$$\{u\} = [K_n + K_s]^{-1} \cdot \{F\} \quad (6)$$

$$k_s = \frac{G}{r \cdot ln\left(2.5\, L\frac{1-\nu}{r}\right)} \quad (7)$$

where:

- $\{F\}$ and $\{u\}$ = vectors of known axial force and unknown vertical displacements.
- $[K_n]$ and $[K_s]$ = stiffness matrices of pile and soil.
- G and ν = shear modulus and Poisson's ratio of the soil.
- L and r = length and radius of the pile.

The settlement limit is set to match the Eurocode 7 settlement limit of 10% of the pile diameter.

2.3 Calculating the embodied carbon

The embodied carbon at stages A1-A3 is calculated using equation (8) as proposed by Orr et al. (2020): a more detailed study addressing A4 and A5 stages will be published shortly.

$$\sum EC = (m_s)(ECF_s) + (m_c)(ECF_c) \quad (8)$$

where:

- $\sum TEC$ = total embodied carbon (kg)
- m_s = reinforcement steel mass (kg)
- m_c = concrete mass (kg)
- ECF_s = embodied carbon factor for steel (kgCO2e/kg)
- ECF_c = embodied carbon factor for concrete (kgCO2e/kg)

2.4 The optimization algorithm

A genetic-algorithm-based optimization method is used to allocate the optimal values of design parameters; concrete grade (f_{ck}), steel-to-concrete ratio (A_s/A_c) and slenderness ratio and (L/D) corresponding to pile designs with minimal embodied carbon. Afterward, a local minimization function is used to check the genetic algorithm results. Figure 1 summarizes the adopted optimization algorithm. The optimization algorithm is used to fulfill the following research aims:

1. Allocate the optimal dimensions and design parameters for cylindrical solid piles: a cylindrical solid pile is the most popular pile geometry in the industry, however, solid pile designs are barely optimized due to different reasons discussed by Abushama et al. (2023). The algorithm is used to investigate the optimal design parameters for solid piles at different load capacities.
2. Compare different pile geometries: the embodied carbon associated with solid piles, tapered piles, hollow cylindrical piles and hollow tapered piles are all compared at different pile capacities.

Table 1. Soil properties tested by Craig 2012.

Property	Symbol	Value
Unit weight	γ	15 (kN/m^3)
Angle of friction	φ	18^0
Poisson's ratio	ν	0.2
Shear modulus	G	$5000 + 500\,Z$ (kPa)

The soil properties used are as tested by Craig and Knappett (2012) and summarized in Table 1.The tested pile geometries are shown in Figure 2.

3 RESULTS

3.1 Optimizing the embodied carbon of solid piles

Figure 3 shows the optimal values of concrete grade (f_{ckc}) and slenderness ratio $(L/D)_c$ for solid piles of different capacities, the optimal steel-to-concrete ratio was always found to be the minimum allowable ratio set in Eurocode 2 (0.004). It is observed that low-capacity piles prefer very slender piles at high concrete grades, while high-capacity piles prefer stockier piles at lower concrete grades (a large volume of low-grade concrete). These optimization results agree with the basic pile design principles as long thin piles provide higher friction resistance which is favourable in the case of low-capacity piles. However, for high-capacity piles, low-grade concrete provides a bigger concrete volume and consequently higher bearing resistance. Nevertheless, it should be noted that the range of optimal pile slenderness ratios calculated [115-133] is far from industry-common design slenderness ratios [10 - 35] which justifies solid piles not being an optimal solution, therefore, better pile geometries are to be tested.

3.2 Effect of pile geometry on the total embodied carbon

Figure 4 shows the optimal amount of embodied carbon associated with four different pile geometries (solid piles, tapered piles, hollow cylindrical piles, and hollow tapered piles) at different loads. A separate study was performed to find the optimal outer-to-inner diameter ratio (D_i/D_o = 0.87) for hollow-cylindrical piles as well as the optimal pile taper angle ($\alpha = 1.70^0$). Figure 4 shows a significant 77% cut in the total embodied carbon between the common solid piles and the optimal tapered-hollow piles. Moreover, it is observed that optimal hollow-cylindrical piles provide a very good alternative to tapered-hollow piles as hollow-cylindrical piles managed to provide the required pile capacities at 60% less carbon than common solid piles. However, building voids inside piles is a construction concern addressed by a contracting company Keltbray in their latest pile design HIPER Pile (2021).

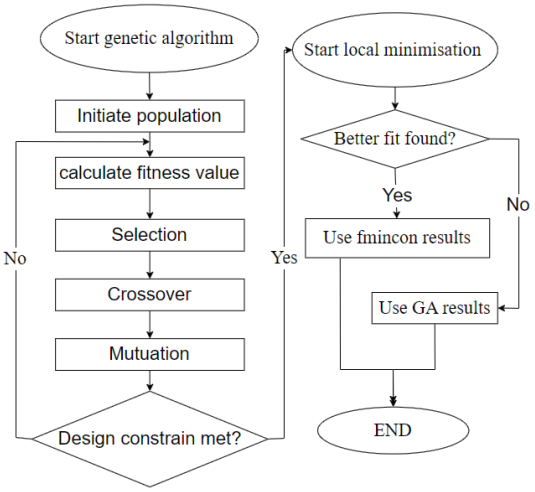

Figure 1. the adopted optimization algorithm.

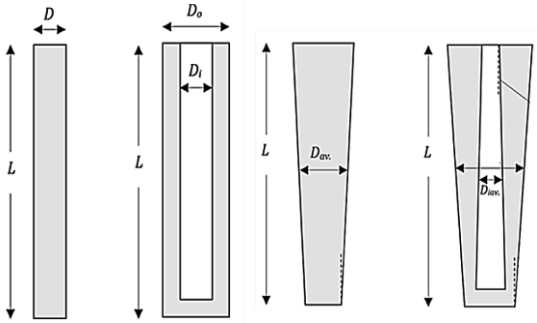

Figure 2. tested pile geometries.

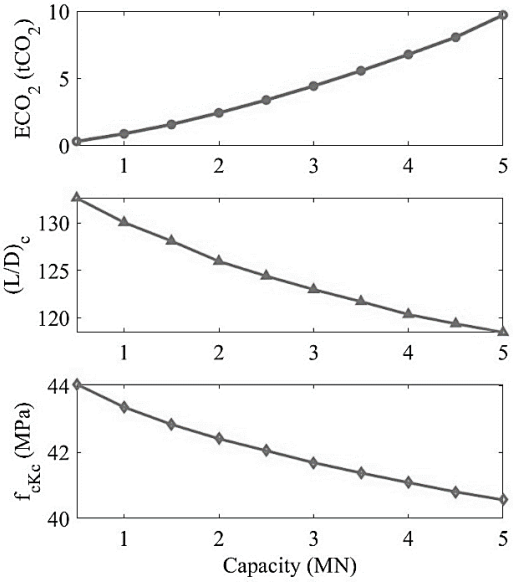

Figure 3. Optimization results for solid piles.

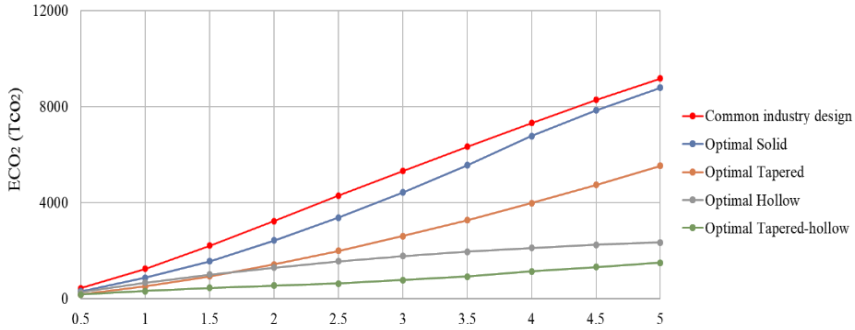

Figure 4. comparing the total embodied carbon for different pile geometries at different load capacities.

4 CONCLUSIONS

To summarize, the environmental impact of reinforced concrete foundations has been barely addressed in the literature. This research introduces a genetic algorithm method that can be used to optimize the design of solid cylindrical piles through calculating the optimal concrete grade, steel-to-reinforcement ratio, and slenderness ratio. Moreover, the algorithm was further used to compare the embodied carbon of different pile geometries at different pile loading capacities, The following are the main concluded points:

- The common solid pile designs are far from optimal as optimal piles acquire higher slenderness ratios than those used in industry.
- Tapered piles with inner voids proved to be the best pile geometry and provided 77% less carbon emissions compared to common solid piles.
- Hollow cylindrical piles provide an adequate solution as they can provide less embodied carbon than solid piles and the adequacy of constructability compared to tapered piles. However, more analysis is needed to quantify the bending capacities of optimal pile designs.
- This research highlights a deficiency in our current pile design standards and policies which should be further covered in more studies.

Long-term horizontal cyclic loading model test results of monopile for offshore wind turbines

Résultats de l'essai sur modèle de chargement horizontal cyclique à long terme d'un monopieu pour éoliennes offshore

C.T. Akdag*, F. Rackwitz
Technische Universität Berlin, Berlin, Germany
**akdag@tu-berlin.de*

ABSTRACT: In this study, a $1g$ model monopile test was conducted under long-term horizontal cyclic loading. The focus of the study is to understand the effect of the number of cycles on the response of the monopile which is mainly used for large $8-9\ MW$ offshore wind turbines OWTs. The monopile was tested in a saturated very dense sand and subjected to a sinusoidal cyclic horizontal load H. The H is approximately 3.5% of the ultimate load capacity H_u. Unidirectional one-way cyclic loading $N = 2{,}000$ with a loading frequency of $f = 0.2\ Hz$ was applied considering the typical frequency range for OWTs. The head of the model pile was equipped with the transducers to obtain the lateral pile head displacement, pile head rotation, and the lateral stiffness evaluation during cyclic loading. The results show that the pile head displacement and rotation accumulation continue to increase with the increase of the number of cycles. In particular, the displacement accumulation during the first few load cycles is clearly larger than the subsequent displacement accumulation. Besides, the lateral secant stiffness k_s decreases with increasing number of loading cycles. The test results indicate that pile head displacement, head rotation, and the lateral stiffness are considerably affected by the number of load cycles.

RÉSUMÉ: Dans cette étude, un essai sur un modèle de monopieu de 1g a été réalisé sous une charge cyclique horizontale à long terme. L'objectif de l'étude est de comprendre l'effet du nombre de cycles sur la réponse du monopieu qui est principalement utilisé pour les grandes éoliennes offshores de $8-9\ MW$. Le monopieu a été testé dans un sable saturé très dense et soumis à une charge horizontale cyclique sinusoïdale H. La H est approximativement 3,5% de la capacité de charge ultime H_u. Une charge cyclique unidirectionnelle $N = 2\ 000$ avec une fréquence de chargement de $f = 0{,}2\ Hz$ a été appliquée en tenant compte de la gamme de fréquence typique des OWT. La tête du pieu modèle a été équipée de transducteurs pour obtenir le déplacement latéral de la tête du pieu, la rotation de la tête du pieu et l'évaluation de la rigidité latérale pendant la charge cyclique. Les résultats montrent que le déplacement de la tête du pieu et l'accumulation de la rotation continuent d'augmenter avec l'augmentation du nombre de cycles. En particulier, l'accumulation de déplacement pendant les premiers cycles de charge est nettement plus importante que l'accumulation de déplacement suivante. En outre, la rigidité latérale sécante k_s diminue avec l'augmentation du nombre de cycles de chargement. Les résultats des essais indiquent que le déplacement de la tête du pieu, la rotation de la tête et la rigidité latérale sont considérablement affectés par le nombre de cycles de charge.

Keywords: Monopile; offshore wind turbines; long-term cyclic loading; 1 g model test.

1 INTRODUCTION

A large number of OWTs with large wind turbines of $8-10\ MW$ rated power are planned to be installed in water depths greater than $40\ m$ over the next few decades (Figure 1). The monopiles, which are the most used foundation type for OWTs, has also been chosen to design OWTs in deeper waters in the current years. The foundations are subjected to large wind and wave loadings with million number of cycles over the duration of OWTs service lifetime in offshore circumstances. It is required to investigate the response of large monopile foundation systems of such OWTs under long-term cyclic loadings.

Several experimental studies have been conducted to understand the behaviour of pile foundation under lateral cyclic loading (Little and Briaud, 1988; Long and Vanneste, 1994; Lin and Liao, 1999). It is stated in almost all investigations that the amplitude and the number of lateral loading cycles have significant influence on the response of pile. The results of 34 cyclic field lateral load tests and 20 full-scale pile lateral cyclic load tests were taken into consideration in the studies of Long and Vanneste (1994) and Lin and Liao (1999), respectively. The researchers indicated that soil-pile stiffness and lateral pile head displacement accumulation are considerably affected

by the number of loading cycles. It should be noted that the cycle number of the considered field tests in these studies are less than 100. A series of centrifuge tests were carried out in dry dense sand under one-way lateral cyclic loading ($20 < N < 50$) in the study of Verdure et al. (2003). The authors stated that secant stiffness under cyclic loading increases slightly with the increase of number of cycles and is obtained 1.5 to 3.0 times larger than the stiffness in monotonic loading condition. It was found that the pile head displacement increases with the increase of cycle number. Similar findings were also reported in the study of Rosquoët et al. (2007). However, the study presented from Rosquoët et al. (2007) was also performed under few loading cycles up to $N = 40$.

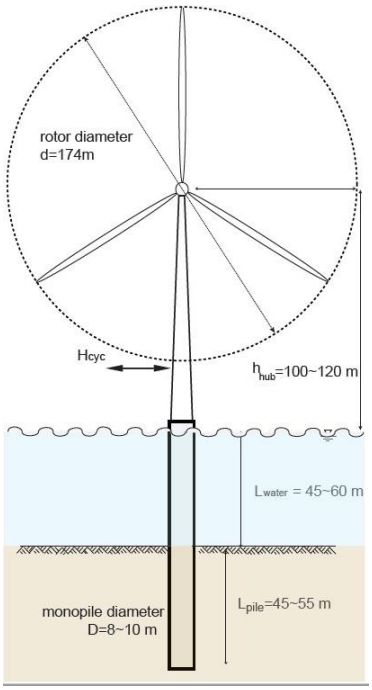

Figure 1. Sketch of a large OWT (8-10 MW).

Model test and field test studies have been implemented on monopiles for OWTs under lateral cyclic loading especially in the last decade. Field test was performed in dense sand with a saturation degree 70% above the ground level under one-way loading up to $N = 5000$ (Li et al., 2015). $1g$ model tests were conducted in saturated loose to dense sand under one-way and two-way cyclic loading between number of cycles $3000 < N < 80{,}000$ (Peralta and Achmus, 2010; Tasan et al., 2011; Nicolai and Ibsen, 2014). The $1g$ tests presented in the study of Nanda et al., (2017) were carried out for open and closed end pile, in dry dense sand under one-way and two-way cyclic loading with $N = 1000$. Centrifuge tests were executed in dry dense sand condition under one-way cyclic loading with $N = 1000$. The results of the above cited investigations on monopile tests in cohesionless soil for OWTs show that the pile head displacement and head rotation accumulation are strongly dependent on the number of cycles, loading type (one-way, two-way), and the amplitude of the cyclic loading.

In this study, the results of the model test are presented. The test was conducted on open-end monopile under unidirectional and one-way lateral loading with N = 2000 number of cycles in saturated very dense sand. The effect of the number of cycles on lateral pile head deformation and rotation accumulation, and lateral stiffness evaluation are investigated and assessed.

2 MODEL TEST

In this investigation, $1g$ model test was conducted to investigate the response of a large OWT with a capacity of $8 - 9\ MW$ under long-term lateral cyclic loading. The large-scale model monopile test was performed for a large OWT supported by a monopile with a large diameter $D = 9\ m$, a diameter-to-wall thickness ratio $D/t = 75$, and an embedded length $L = 50\ m$, and hence an aspect ratio of 5.55. The utilized scaling approach with implemented relations and equations are stated in detail in the study by Akdag and Rackwitz (2023). The testing system involves test pit, subgrade material, loading mechanism, model pile, pile head instrumentation, and lateral load mechanism. The testing system illustration with dimensions are given in Figure 2 and Figure 3.

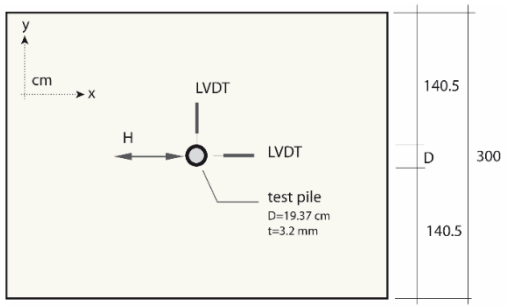

Figure 2. Plan view of 1g model test system.

The large scaled $1g$ model test was conducted on a scaled open-ended steel pile with dimensions of $D = 0.194\ m$, $D/t = 60.53$, and $L = 3.03\ m$.

Poorly graded (SP) “Cottbuser sand” with a grain size among $63\mu m$ and $2\ mm$ was utilized as the subgrade material for the $1g$ model test. It was obtained from the Cottbus area in Germany and the characteristics of the sand is given in the study by (Akdag et al., 2023). The sand was placed in the test pit at its natural moisture content through a repeatable compaction procedure using a vibration plate. First, the sand was placed and compacted to a height equal

to 4 times the pile diameter D to set the soil under the pile. The model monopile was then positioned in the centre of the test pit (Figure 3). Then, sand was located around the pile in layers of 15 cm thickness which are compacted dynamically.

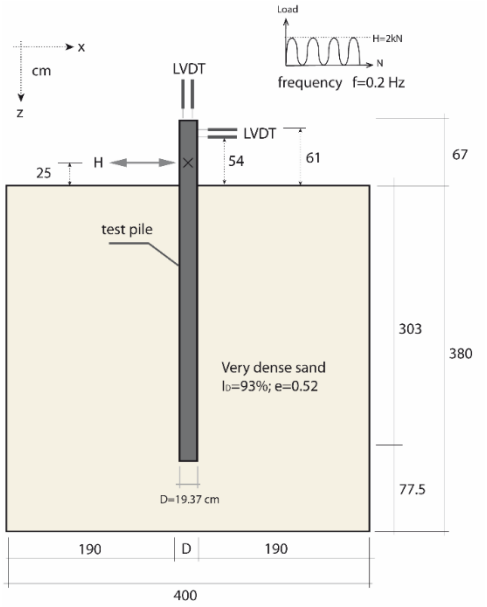

Figure 3. Cross section of model test system.

The average effective unit weight of the sand was found to be $\gamma' = 10.50\ kN/m^3$. The average relative density of the sand was found to be $I_D = 93\%$, which corresponds to very dense sand state. The average void ratio was obtained to be $e = 0.52$. Direct shear test was conducted under normal stresses of $\sigma = 100, 200, and\ 400\ kPa$ to obtain the peak angle of internal friction φ of the sand with a relative density of $I_D = 93$. It was found to be $\varphi = 45.8°$.

During the model test a unidirectional one-way lateral cyclic loading $N = 2000$ was conducted with a constant maximum load value of $H_{max_{cyc}} = 2\ kN$. Applied load amplitude is almost $\xi_b = 3.5\ \%$ of the ultimate load capacity H_{us} of the monopile-soil system in the model test. Two normalised parameters $\xi_b\ and\ \xi_c$ were recommended by LeBlanc et al. (2010) to identify the utilized horizontal cyclic loading characteristics are given in Eq. 1 and Eq. 2.

$$\xi_b = \frac{H_{max}}{H_{us}};\ cyclic\ load\ magnitude \quad (1)$$

$$\xi_c = \frac{H_{min}}{H_{max}};\ cyclic\ load\ ratio \quad (2)$$

Because of one-way cyclic loading application cyclic load ratio is $\xi_c = 0$ in this study.The monotonic ultimate lateral load capacity H_{us} of the model pile was estimated according to the three-dimensional finite element model analysis, which was found to be $H_{us} \cong 60\ kN$ corresponding to the pile head rotation $\theta = 2°$ (Akdag and Rackwitz, 2023).

A load-controlled test was performed in this study, and the horizontal loading mechanism was not fixed to the pile head as shown in Figure 4. Sinusoidal cyclic horizontal loading with a loading frequency of $f = 0.2\ Hz$ was performed considering the typical frequency range for OWTs, as reported in the literature (Lesny and Hinz, 2009; Bhattacharya et al., 2013). The horizontal load was carried out to the pile head at a height $h = 1.30D$ above the sand surface (Figure 3).

Figure 4. Lateral cyclic loading mechanism.

The pile head horizontal displacement accumulation u_x was obtained from the displacement transducers which are instrumented at the pile head in the loading direction. The data recorded from the two transducers oriented in the loading direction were used to obtain the pile head rotation θ accumulation during lateral cyclic loading. Pile lateral stiffness k_s evaluation was found using horizontal load (ΔH) - pile head displacement (Δu) relationship.

3 TEST RESULTS EVALUATION

In this section, the pile head lateral displacement accumulation, pile head rotation accumulation, and pile lateral stiffness evolution are assessed based on the test results.

The accumulation of lateral pile head displacements u_x in the loading direction with maximum $u_{x_{max}}$ and minimum $u_{x_{min}}$ values for increasing numbers of loading cycles up to $N = 2000$ is shown in Figure 5. The test results indicate that the lateral displacement accumulation continues to increase as the number of cycles increases. The

minimum lateral displacement values show the permanent accumulation occurred and increased with the number of loading cycle. Remarkably, $u_{x_{max}}$ accumulation up to $N = 100$ is almost 25% of the maximum pile head accumulations obtained after $N = 2000$.

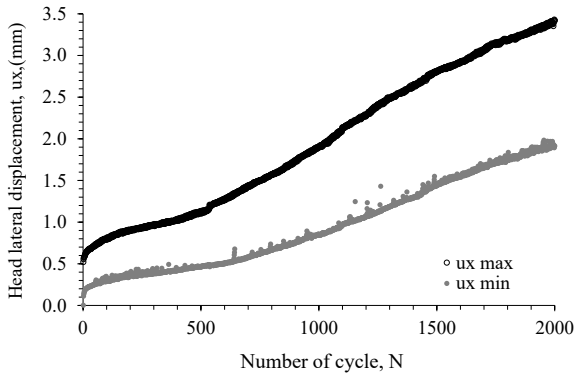

Figure 5. Pile head lateral deformation accumulation.

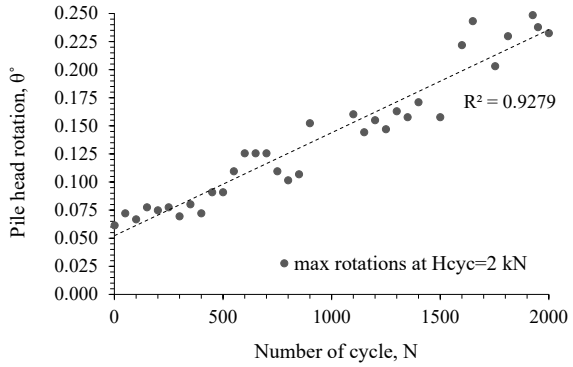

Figure 6. Pile head rotation accumulation.

In Figure 6, the model test results as the pile head rotation accumulation at maximum lateral load level in specific load cycles up to $N = 2000$ is presented. It can be seen from the test results that the accumulation of maximum rotation at $H_{max_{cyc}}$ continues to increase as the number of cycles increases. Notably, the behaviour of the increase in pile head rotation can be evaluated to be linear as shown in the Figure 6. In addition, the maximum rotation reached almost $\theta \cong 0.25°$ after $N = 2000$, which is stated as serviceability limit state SLS according to Det Norske Veritas offshore guideline (DNV, 2018).

The evaluation of pile lateral stiffness during the loading cycles was obtained according to the horizontal load (ΔH) - pile head displacement (Δu) relationship using Eq.3 in Figure 7. The unloading and reloading lateral secant stiffness of the soil-monopile with increasing number of cycles up to $N = 2000$ is given in Figure 8. The test results show that the k_s decreases as the number of load cycles increases. In addition, the rate of decrease in the stiffness alters with increasing N. The rate of reduction in k_s decreased significantly between $N = 1000 - 1400$ with an increasing number of cycles. Subsequently, the change in secant stiffness after the cycles $N = 1400$ is trivial and can be considered almost constant. The stiffness, which reaches an approximately constant value after $N = 1400$, is approximately 3.5 times lower than the stiffness in the initial cycles.

$$k_s = \frac{\Delta H}{\Delta u} \quad (3)$$

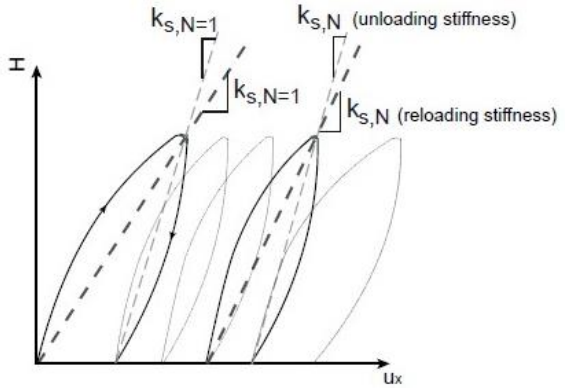

Figure 7. Illustration of secant stiffness determination.

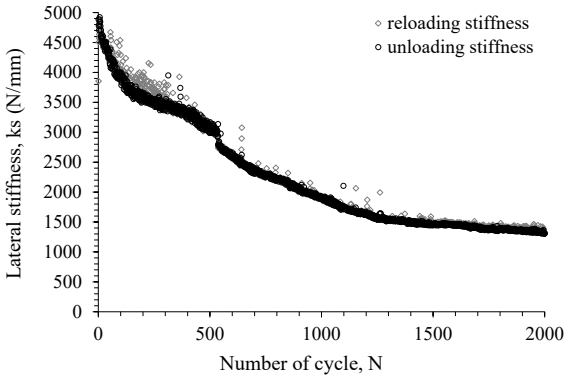

Figure 8. Secant stiffness evaluation.

4 CONCLUSIONS

In this study, the results of the large-scale $1g$ model test is presented. Test was conducted on open-end monopile under unidirectional and one-way lateral loading with N = 2000 number of cycles in saturated very dense sand. The results of the test indicate that the pile head displacement and rotation accumulation continue to increase with the increasing number of cycles. Besides, the lateral secant stiffness k_s decreases with increasing number of loading cycles. Consequently, the test results indicate that pile head displacement, head rotation, and the lateral stiffness are considerably affected by the number of load cycles.

Machine learning to expedite concept monopile design

Apprentissage automatique pour accélérer la conception de monopieux conceptuels

ABSTRACT: Offshore wind turbine generators (WTG)s are typically supported by monopile foundations in shallow water (<50m). The design of monopile foundations is usually conducted using rule-based soil reaction curves (SRC)s in a 1D or 0D model. For the derivation of SRCs, WTG location-specific 3D finite element analysis (FEA) is now typically adopted in industry to ensure optimised foundation design. However, this approach is time consuming to calibrate to new sites and hence not well suited for early-stage structural design and load simulations where thousands of calculations are performed to finalise the offshore wind farm layout. This paper presents a novel approach for early stage monopile design (i.e. concept or pre-FEED), in which a concept design surrogate model was trained on a database of 2000 3D FEA simulations using a machine learning algorithm. The surrogate model provides rapid estimations of monopile design for Natural Frequency Analysis (NFA) and Fatigue Limit State (FLS) conditions, while also intrinsically incorporating the fidelity of the 3D FEA simulations. The surrogate model predicts results close to that of 3D FEA, over 10000 times faster, for layered soil profiles and a wide range of monopile dimensions inside the training space. Published monopile lateral response results from field testing were used to further validate the model. Use of such a tool in practice will speed up the process of preliminary monopile design and load simulations, reducing risks and time for developers, whilst improving site feasibility studies and cost estimates.

RÉSUMÉ: Les générateurs d'éoliennes offshore (WTG) sont généralement soutenus par des fondations monopieux. La conception des fondations monopieux est généralement réalisée à l'aide de courbes de réaction du sol (SRC) basées sur des règles dans un modèle 1D ou 0D. Pour la dérivation des SRC, la FEA 3D spécifique à l'emplacement WTG est désormais généralement adoptée dans l'industrie pour garantir une conception optimisée des fondations. Cependant, cette approche prend du temps à calibrer sur de nouveaux sites et n'est donc pas bien adaptée à la conception structurelle et aux simulations de charges à un stade précoce, où des milliers de calculs sont effectués pour finaliser la configuration du parc éolien offshore. Cet article présente une nouvelle approche de la conception de monopieux à un stade précoce (c'est-à-dire concept ou pré-FEED), dans laquelle un modèle de substitution de conception de concept a été formé sur une base de données de 2000 simulations FEA 3D à l'aide d'un algorithme d'apprentissage automatique. Le modèle de substitution fournit des estimations rapides de la conception de monopieux pour les conditions d'analyse de fréquence naturelle (NFA) et d'état limite de fatigue (FLS), tout en intégrant intrinsèquement la fidélité des simulations FEA 3D. Le modèle de substitution prédit des résultats proches de ceux de la FEA 3D, plus de 10 000 fois plus rapides, pour des profils de sol en couches et une large gamme de dimensions de monopieux à l'intérieur de l'espace d'entraînement. Les résultats publiés de la réponse latérale du monopile du PISA JIP ont été utilisés pour valider davantage le modèle. L'utilisation pratique d'un tel outil accélérera le processus de conception préliminaire du monopieu et de simulations de charge, réduisant ainsi les risques et le temps pour les développeurs, tout en améliorant les études de faisabilité du site et les estimations de coûts.

Keywords: Offshore wind; monopiles; machine learning; concept design; finite element analysis.

1 INTRODUCTION

The offshore wind industry is currently experiencing a period of rapid growth and innovation due to the threat of the climate crisis and the finite supply of fossil fuels. As the scale of wind generating structures grows, impetus to optimise their construction increases. This is especially true for foundations, which can represent up to 30% of the total offshore wind farm (OWF)

CAPEX cost. Monopiles are the most common foundation type for WTGs and are typically used in water depths up to 60m, with diameters up to 12m and length to diameter ratios of 2.5-6. Identifying suitable locations where WTGs can be constructed economically at an early stage in the design process can lead to significant cost and time savings for developers. The approach explored herein, named the Rapid Monopile Design Surrogate (RMDS) tool, employs modern machine learning methods to allow NFA and FLS design assessments at proposed WTG locations to be carried out faster than is currently possible whilst retaining accuracy. The outputs can be easily integrated into established workflows to estimate the optimum monopile dimensions, and subsequently foundation cost, for the given location.

2 BACKGROUND

2.1 Current methods for NFA and FLS design

The monopile diameter and wall thickness, and hence feasibility, is typically driven by the NFA and FLS design; therefore, it is critical this is assessed at the early stage of the project. The current industry practice for early stage NFA and FLS assessments and aeroelastic WTG load simulations uses a combination of 3D FEA and SRCs. However, this is a slow process which is computationally expensive, and can demand a considerable amount of time and expertise to set-up. A macro element 0D model, consisting of a coupled three-spring configuration, is an alternative approach, suitable for early stage design. This simplifies the monopile by replacing it with a lateral spring (K_L), a rotational spring (K_R) and a cross-coupling spring (K_{LR}), where the springs represent the stiffness of the monopile at mudline. Vertical stiffness is generally omitted from calculations as it is large enough that zero displacement can be assumed. The values of the three springs can then be used directly as inputs for calculation of natural frequency and deformation of the monopile in the small displacement zone. To obtain values of each spring, empirical equations have been proposed. Arany (2017) provides a summary of commonly used equations. However, these equations can only be applied to idealised soil conditions and have been shown to lead to overly stiff designs .

2.2 Machine learning models

Few attempts have been made to predict monopile response using ML. Suryasentana (2020) showed that Gaussian Progress regression was effective in predicting *p-y* springs down the length of a monopile.

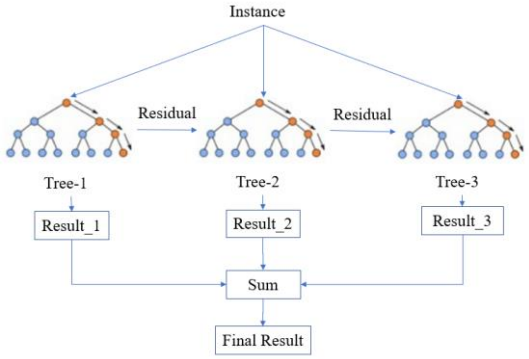

Figure 1. Simplified XGBoost model visualised (Wang et al., 2020).

Suryasentana notes that in their work the dataset was small and specific to one site and therefore, randomised 3D FEA would be a more suitable method to generate a database of monopile responses capable of generalising to a wider variety of soil conditions.

The ML model chosen for this study was the open-source package XGBoost (Chen *et al.* 2016). The algorithm is based on the concept of decision trees; a series of conditions are applied to the inputs of the tree (i.e., is depth greater than 15m?), to improve predictions of an output (Figure 1). XGboost is widely used in datascience due to its scalability and relatively low computational intensity and is increasingly used for regression problems in geotechnical engineering (see Kardani, 2020).

3 METHODOLOGY

3.1 Dataset formulation

The database on which the RMDS tool was trained consisted of results from 2000 FEA simulations with monopile dimensions, loading conditions and soil profiles as outlined in Table 1. These properties were randomly generated at small intervals to reduce the effects of overfitting to input parameters. This process was automated using a python script and employed the commercial FEA software PLAXIS 3D.

Table 1. Parameter space for dataset.

Header	Range	Step
Diameter (m)	6-12	0.25
Embedment length (m)	25-45	1
Lever arm (m)	20-120	1
Initial shear modulus (MPa)	1-350	1
Layer thickness (m)	2-10	1
Poisson's ratio	0.495	Constant
Diameter/pile wall thickness	120	Constant

NFA/FLS calculations are influenced by behaviour in the very small strain region where the behaviour is often close to linear. As a result, the FEA employed a linear elastic soil constitutive model. Two values were extracted from each simulation to train the RMDS tool, these are referred to as the target variables:

$$K_H = \frac{F_x * D}{u_x} \quad (1)$$

$$K_M = \frac{M_y}{\theta_y} \quad (2)$$

Where K_H is the uncoupled lateral stiffness (GN), F_x is the shear at mudline (GN), u_x is the lateral displacement at pile head (m), K_M is the uncoupled rotational stiffness (GNm/rad), M_y is the overturning moment and θ_y (GNm) is the pile rotation at mudline (rad).

Prior to model training, the format of the soil profile was altered to improve resolution and readability for training. This was accomplished by taking values of initial shear modulus (G_{max}) at 30 equally spaced points down the pile length, where each G_{max} value would be an individual input to the ML model.

3.2 Training of machine learning models

The RMDS tool consists of two XGBoost models that were trained using the same 33 input features: diameter, embedment length, lever arm and 30 G_{max} values. For one model K_H was the target variable and for the other it was K_M. The dataset was partitioned so that of the 2000 samples, 80% was used for training and 20% was held out for testing. A grid search was used to return the optimal hyperparameters (these are XGBoost parameters set by the user which govern how the model learns) for both models. It was found that no regularisation hyperparameters were required other than subsampling the data. This is likely because there is very little noise in the database generated by FEA, which is an advantage of using FEA for ML model training.

As a result of training the RMDS tool with different lever arms, the values of each spring in the three spring model can be calculated. This is achieved by solving for each term in the stiffness matrix using two different lever arms:

$$\begin{bmatrix} F_x \\ M_y \end{bmatrix} = \begin{bmatrix} K_L & K_{LR} \\ K_{RL} & K_R \end{bmatrix} \cdot \begin{bmatrix} u_x \\ \theta_y \end{bmatrix} \quad (3)$$

Due to small errors, the cross-coupling terms were not exactly equal, therefore an average of K_{LR} and K_{RL} can be taken as the value of the cross-coupling term.

4 RESULTS

4.1 Model fit

Figure 2 highlights the effectiveness of the RMDS tool in predicting both target variables (uncoupled lateral and uncoupled rotational stiffness) for 20% of the database that was set aside for testing. As shown by the high r^2 value, the variance in the target variables is explained very well by both ML models, and the mean absolute percentage error (MAPE) is very low for both models, most notably the rotational model.

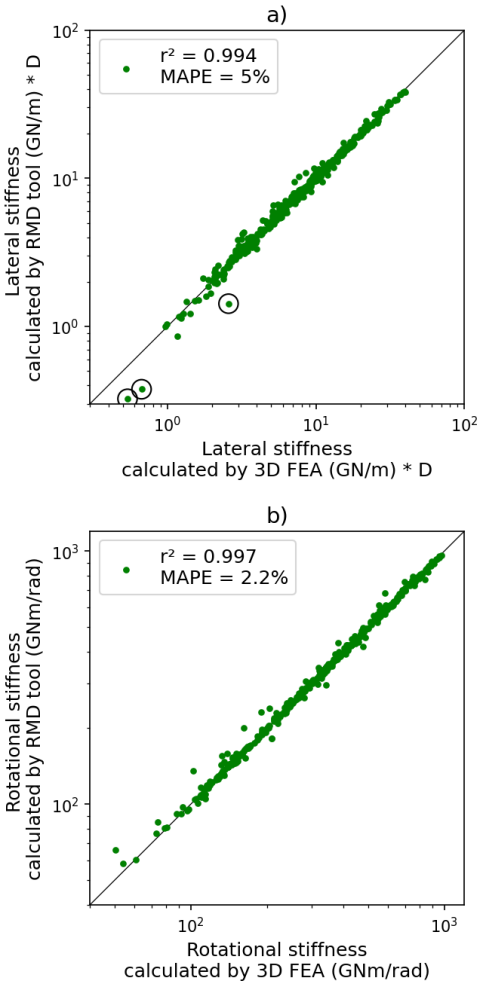

Figure 2. RMDS tool predictions versus 3D FEA predictions for a) uncoupled lateral stiffness and b) uncoupled rotational stiffness. Three poor predictions are circled in a) which corresponded to cases with unrealistic soil profiles.

It was found that the poorest predictions corresponded to an FEA simulation in which the randomised soil profile was unrealistically low. For example the circled points in Figure 2 had a median

G_{max} of 20MPa or lower down the length of the monopile.

The RMDS tool was able to predict both the lateral and rotational stiffness in 0.017 seconds, in comparison to 20 minutes, which is a representative time for the 3D FEA analysis. This highlights the potential time savings of implementing the RMDS tool in concept design. A benefit of the ML approach is that the tool can be continually improved by adding more training data and retraining the model.

4.2 Validation

To further establish the reliability of the RMDS tool, it was compared with 3D finite element calibration analysis conducted within the PISA JIP as presented in Byrne *et al*. (2020), which serves as the basis for industry-standard design methods. Specifically, the RMDS tool was compared to calibration analyses, and design cases for which there was data available and pile diameter and embedment length were within 25% of the corresponding ranges as outlined in Table 1. More details can be found in (Byrne *et al.*, 2020).

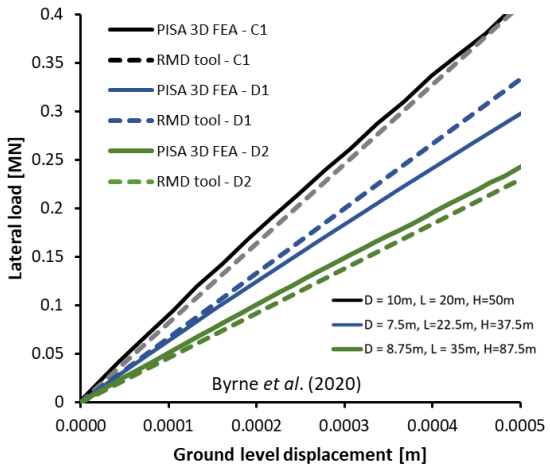

Figure 3. RMDS tool predictions of uncoupled lateral stiffness in the very small strain region, compared to 3D FEA results from PISA calibration analysis C1 and design cases D1 and D2 presented in Byrne et al. (2020).

Generally, very good agreement with the initial lateral stiffness is observed as shown in Figure 3. Therefore, the results provide confidence that the FEA set-up used to create the training database was accurate and that the RMDS tool was able to effectively learn the trends of the database to act as a surrogate FEA model.

5 CONCLUSIONS

The RMDS tool was developed using modern machine learning techniques to act as a surrogate model for 3D FEA, allowing rapid, accurate predictions of monopile stiffness in the very small strain region. This capability could result in significant time and cost savings for concept NFA and FLS assessments. However, unlike 3D FEA, the RMDS tool can only be used within its calibration range and in some instances, may overfit to its input parameters. The demonstrated proof-of-concept tool shows good predictive capabilities on results from well-established published field tests and can be continually improved by retraining the model on new data. This paper has focused on the small strain region, using a simplified linear elastic constitutive model; however, techniques presented in this study could also be used to train ML models for predicting non-linear soil response, using more advanced constitutive models, or predicting *p-y* springs along the length of a monopile.

Raising the standard of flood protection in Hull: the Humber Hull Frontages flood defence scheme

Relever le niveau de protection contre les inondations à Hull: le projet de défense contre les inondations des Humber Hull Frontages

L. Allievi*, A. Willoner
Mott MacDonald, Sheffield, UK
**Lorenzo.Allievi@mottmac.com*

ABSTRACT: The Humber Hull Frontages flood defence scheme reduced the risk of flooding from the Humber estuary for 113,000 properties and it consists of more than seven kilometres of tidal flood defences along the estuary frontage. This paper describes the design of a variety of flood defences in challenging ground conditions, typically comprising deep fill deposits associated with the pre-existing flood defences and with large areas of reclaimed land overlying normally consolidated soft tidal flat deposits. The solutions provided to overcome multiple design and construction constraints due to the current and historical use of the project setting are presented in this paper.

RÉSUMÉ: Le projet de défense contre les inondations des Humber Hull Frontages a réduit le risque d'inondation par l'estuaire de l'Humber pour 113,000 propriétés et il comprend plus de sept kilomètres de défenses contre les inondations maritimes le long du front de mer. Ce document décrit la conception de diverses défenses contre les inondations dans des conditions de sol difficiles, comprenant généralement des dépôts de remblai profonds associés aux défenses contre les inondations préexistantes et de grandes zones de terres récupérées recouvrant des sols alluviaux mous normalement consolidés. Les solutions apportées pour surmonter les multiples contraintes de conception et de construction dues à l'utilisation actuelle et historique du cadre du projet sont présentées dans ce document.

Keywords: Flood defence; soft soil; sheet piles; seepage.

1 INTRODUCTION

The city of Hull lies on the north bank of the Humber Estuary and is protected from tidal flooding by the River Hull Barrier and a combination of raised defences of varying age, condition and height along the Humber Estuary frontage. The objective of the Humber Hull Frontages (HHF) project was to improve the existing tidal flood defences so that they would provide a flood defence for 2040 tidal flood event levels with provision to install future additional defences for 2115 tidal flood event levels.

The £42 million scheme reduced the risk of flooding for 113,000 properties upgrading more than seven kilometres of tidal flood defences, from St Andrew's Quay Retail Park in the west to Victoria Dock Village in the east, as shown in Figure 1.

A wide range of defences were proposed for the scheme, ranging from installation of driven piles, construction of new piled or gravity walls, raising of the existing flood defences and improvement of the existing flood defences.

Figure 1. Plan overview of the Humber Hull Frontages scheme.

This paper focuses on the works at Victoria Pier (Zone 6) and Victoria Dock Village East (Zone 8), where the challenges posed by both historical and current land use had the greatest impact on the design and construction of the flood defences.

2 GROUND CONDITIONS

Like many UK east coast estuaries, the geology of the superficial deposits along the Humber is complex. The wide range of environmental conditions and sea levels has resulted in the deposition of a varied and discontinuous sequence of glacial, fluvioglacial and tidal flat deposits (TFD) consisting of sands, gravels, silts and peats.

A conceptual ground model of the River Hull Barrier, which is also applicable to the HHF project, is depicted in Figure 2.

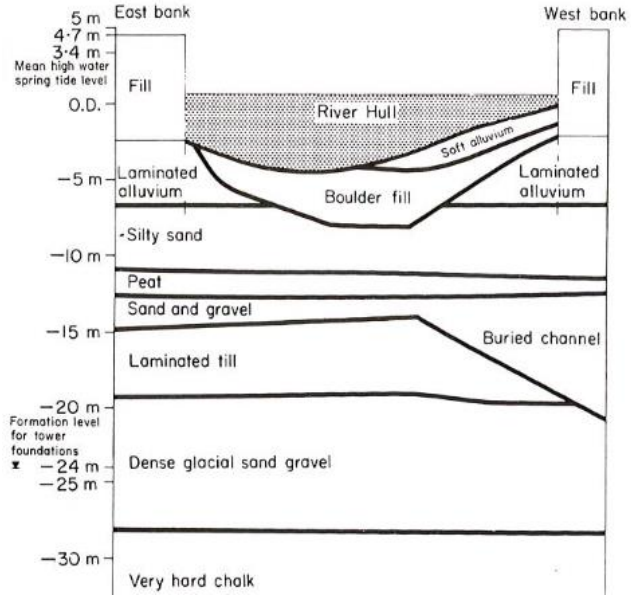

Figure 2. Conceptual ground model of the River Hull Barrier (Fleming et al., 1980).

In general, the ground conditions at the scheme comprise a variable thickness of made ground overlying TFD. Notably, along the Humber frontage vast areas have been reclaimed from the estuary through time and flood defences were built on top of the reclaimed land, resulting in the presence of sections of deep fill, mostly consisting of reworked TFD, overlying a starter layer of gravel to cobble sized chalk. Typically, a 1.0 to 1.5m thick firm to stiff desiccated crust is found at the top of the TFD, where this has not been removed by historical anthropogenic activities. The underlying TFD generally consists of normally consolidated low-strength and low-stiffness silty clay and clayey silt with organic content and peat layers.

The deeper geology comprises mostly glacial till overlying bedrock of the Burnham Chalk Formation from the Upper Cretaceous.

Groundwater associated with the chalk is sub-artesian, with a significant rise noted following the installation of deep boreholes. Groundwater in drift deposits is tidal and is also influenced by the pressure in the Chalk aquifer locally.

3 VICTORIA PIER

Victoria Pier, built in 1825, is a disused ferry terminus named after a Royal visit by Queen Victoria in 1854. The existing structure is a timber pier and jetty, with existing river walls consisting of tied sheet piles.

The new flood defences required complex piling works as the poor condition of the existing tied sheet pile wall indicated minimal residual life to support a new gravity flood wall constructed on the land.

Figure 3. Construction works at Victoria Pier.

Key features and challenges include the following:

- The existing timber pier required partial demolition to fit new sheet piles in front of it.
- The existing sheet piles along the upstream end of the quay wall were inclined at 6 degrees, so the new piles had to be raked to avoid a clash at depth.
- The rake of the new sheet piles had to avoid conflicting with the deep vertical timber piles to the pier.
- The quay wall at the mouth of the River Hull was vertical, so the new sheet-piled wall had to change inclination from raking to vertical. This was also necessary to avoid conflict with the vertical ‘dolphin’ pier to the footbridge.
- New sheet piles had to be installed within 2m of an existing structure, therefore a minimal vibration method was required to install piles.
- Presence of known (and unknown) buried obstructions.
- The ground conditions were highly variable and included very soft organic soils to 22m depth, a buried sand-filled channel and sub-artesian groundwater.
- The site was less than 100m from the location of a 1999 tunnel collapse (Grose et al 2005), which resulted in the largest claim (£50M) ever made under a Contractors ‘all risk’ policy.

- Working through the covid pandemic.

Clearly this was a site that required a comprehensive ground investigation and management of ground risk.

A schematic ground model of this area is shown in Figure 4. The SPTs did not exceed N10 until 22.5m depth in the central area, however adjacent CPT investigation indicated higher soil stiffness and it was likely that the high-water pressures caused piping at the base of the boreholes.

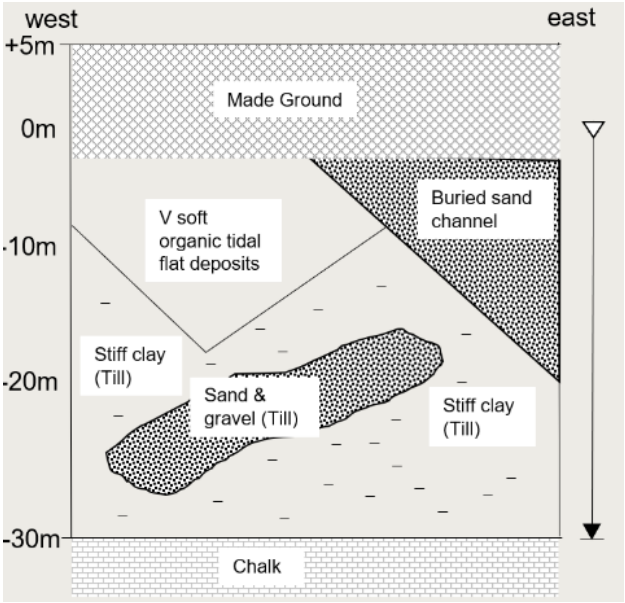

Figure 4. Schematic ground model at Victoria Pier.

Historical records indicated that there would be a high density of buried obstructions. To avoid the need for the installation of ties or anchors to support the sheet piles, the initial proposal was to carry out a wet soil mixing operation to the upper part of the passive wedge, working in 6x6x6m cubic zones during each 'window' of low tide.

Unfortunately, the time required for the regulatory approval process for mixing cement into the mud flats proved to be too long to fit into the programme and the scheme had to revert to an alternative solution. A tied wall was considered lower risk than an anchored wall as the ties could be threaded between and beneath existing timbers and services in open excavations.

Works commenced with the upstream piles, installed at a 3-degree rake 2m in front of the existing wall and 15m in length to avoid conflict with the exiting piles at depth. Although small, the rake on the sheet piles made the design of the wailing beam complex and a double UKB was needed to resist eccentric loading.

Figure 5. Installation of raked piles along the Humber.

As the wall turned the corner from the River Humber to the River Hull, a bespoke triangular pile was installed to transition to vertical piles along the River Hull face. This was vital to enable piles to be pressed rather than driven near existing buildings.

Figure 6. Installation of pressed piles along the River Hull.

As expected, the installation of anchor piles was complex. Some had to be pressed in proximity to a grade II listed toilet block, several were realigned due to obstructions with the tie roads being lengthened, and towards the upstream end of the works, several anchor piles refused at very short depths, potentially due to the original masonry quay wall, and were replaced with a balanced gravity RC wall constructed in open excavation to 3m depth.

4 VICTORIA DOCK VILLAGE EAST

The proposed flood defences at Victoria Village East consisted of a reinforced concrete flood wall up to 1.5m high running at the back of the gardens of the residential properties along the estuary.

The 1856 Ordnance Survey map of Hull shows that the High Water Spring Tide line at Victoria Dock Village East was about 150m to the north of the existing coastline. Land reclamation took place in the second half of the 1800s, consequently, a 7 to 8 metres thick layer of made ground was encountered.

The main challenge for the works in this area was represented by the historical use of the site.

Figure 7. Aerial photograph showing historical timber pond, slipways and shipbuilding yard.

Historical maps and pictures show the presence of the following features:

- a timber pond located to the east of the half tide and outer basins; this basin was then infilled and residential buildings were constructed over it.
- two slipways and a historical tidal dock were located within the area of the proposed works. This was confirmed by an obstruction and locally different ground conditions encountered during the investigation at the location of one of these slipways.
- the area east of Harbour Way used to be a shipbuilding yard, where ships were built on the groynes onto a basic slipway.

The main issue presented by these historical features was related to the potential for seepage paths existing underneath the new flood defences. While the typical infill used for reclaimed land in the area consisted of reworked TFD silty clay or clayey silt, hence with low permeability and low risk of seepage during flood events, the ground investigation confirmed that coarser soil was used to infill these features at a later date than the surrounding area.

Seepage analyses were carried out for the area, considering both the typical ground conditions and ground models specific to the infill recorded at the location of the buried historical features. The analyses showed that if a material with hydraulic conductivity greater than 10^{-5}m/s was encountered below the flood wall foundation level, seepage could have occurred below the walls. Sheet piles for seepage cut-off were therefore installed in the areas where the proposed flood walls encountered permeable infill.

5 CONCLUSIONS

The Humber Hull Frontages scheme provided a high standard of flood protection for 113,000 properties along the estuary of the Humber, in Hull. A wide range of geotechnical works were constructed for the scheme, the majority of which were successfully completed between 2019 and 2021, with the project being officially opened to the public in 2022.

The design and construction of the proposed works faced several challenges, mostly related to the constraints posed by the historical and existing urban context of the works and the onerous ground conditions, comprising a great thickness of made ground and soft TFD.

Two particularly challenging areas of the scheme were Victoria Pier, where the design of the new piled wall had to adapt to the presence of buried obstructions, existing sheet piles and listed structures, and Victoria Dock Village East, which historically was the site of features such as slipways and artificial basins.

A good understanding of the impact of these constraints on the proposed works and flexibility in the design approach, adapting to modifications required during construction, allowed the successful delivery of the scheme.

Influence of spatial variability of ground conditions on energy pile thermal yield

Influence de la variabilité spatiale des conditions du sol sur le rendement thermique des pieux énergétiques

ABSTRACT: Energy piles are a cost-effective alternative to conventional boreholes in shallow geothermal systems as they can lower capital investment while maintaining efficient heat exchanging capability when properly designed. Among a range of parameters that affect the thermal yield of energy piles, ground thermal and hydraulic properties have a decisive influence. Studies on energy pile thermal yield usually consider homogeneous ground conditions, or, to a lesser extent, horizontally layered ground conditions. However, spatial geological heterogeneity exists not only between the soil-stratified layers in the vertical direction but also within each horizontal layer. This study investigates the impact of spatial hydro-geological heterogeneity on heat transfer within the ground. A three-dimensional numerical model is developed to solve for heat transport considering several numerically generated lognormal autocorrelated random fields of ground thermal conductivity and permeability values, transformed from geostatistical random Gaussian distributions based on their statistical distributions. Results show that the assumption of homogeneous ground characteristics has a marginal effect, up to ~6% in energy provision, when the variations in thermal and hydraulic properties are small, making it a pragmatic assumption in such cases. However, the uncertainty in energy yield prediction becomes considerable, in between ~13% to ~25%, for significant ground variability. Moreover, accounting for the variability in hydraulic properties such as the permeability is more detrimental than the thermal conductivity.

RÉSUMÉ: Les pieux énergétiques sont une alternative rentable aux forages conventionnels dans les systèmes géothermiques peu profonds, car ils peuvent réduire l'investissement en capital tout en maintenant une capacité d'échange de chaleur efficace lorsqu'elles sont correctement conçues. Parmi une gamme de paramètres qui influent sur le rendement thermique des pieux énergétiques, les propriétés thermiques et hydrauliques du sol ont une influence décisive. Les études sur le rendement thermique des pieux énergétiques considèrent généralement des conditions homogènes du sol, ou, dans une moindre mesure, des conditions du sol en couches horizontales. Cependant, il existe une hétérogénéité géologique spatiale non seulement entre les couches stratifiées du sol en direction verticale, mais aussi au sein de chaque couche horizontale. Cette étude examine l'impact de l'hétérogénéité hydro-géologique spatiale sur le transfert de chaleur dans le sol. Un modèle numérique tridimensionnel est développé pour résoudre le transport de chaleur en considérant plusieurs champs aléatoires lognormaux autocorrélés numériquement générés de conductivité thermique et perméabilité du sol, transformées à partir de distributions gaussiennes aléatoires géostatistiques basées sur leurs distributions statistiques. Les résultats montrent que l'hypothèse de caractéristiques homogènes du sol a un effet marginal, jusqu'à environ ~6% dans la fourniture d'énergie, lorsque les variations des propriètès thermiques et hydrauliques sont faibles, ce qui en fait une hypothèse pragmatique dans ce cas. Cependant, l'incertitude dans la prédiction du rendement énergétique devient considérable, entre environ ~13% et ~25%, pour une variabilité significative du sol, en particulier à de faibles vitesses d'écoulement des eaux souterraines. Prendre en compte la variabilité des propriétés hydrauliques telles que la perméabilité est plus préjudiciable que la conductivité thermique.

Keywords: Spatial variability; autocorrelated random fields; permeability; thermal conductivity; energy piles.

1 INTRODUCTION

Energy piles are a type of shallow geothermal energy system where the heat exchanger is built into structural pile foundations, to heat and cool buildings through heat exchange with the surrounding soil. Therefore, the energy piles serve a dual purpose: to carry structural load and to harvest energy from the ground. Using pile foundations contributes to a reduction in the high initial costs commonly associated with other

traditional shallow geothermal systems that rely on the drilling of boreholes down to a few hundred meters (Lu and Narsilio, 2019). Shallow geothermal systems rely on the fact that the ground temperature is close to stable throughout the year at depths greater than a few metres from the ground surface, regardless of the air temperature. This makes the ground an efficient medium of heat, such that it can act as both a heat sink and a source (Banks, 2012).

In energy piles, a circulation pump is used to circulate a carrier fluid inside ground heat exchanging (GHE) pipes, attached to the cage of the pile before casting. The carrier fluid enters the heat exchanging pipes, losing or gaining heat via heat exchange with the ground adjacent to the pile, and returns with a lower or higher temperature than at inlet. The heat is then distributed to the building via a ground source heat pump (GSHP).

Optimising the thermal design of energy piles is crucial to their wider adoption. Among the different ground properties that affect the rate of heat exchange, and therefore the system's thermal design, the ground hydrothermal properties (thermal conductivity and permeability) act as primary geological parameters that control ground heat transport rates and thus the thermal yield of energy piles. Energy pile design has been studied extensively with the assumption of homogeneous ground, where average values of ground hydrothermal properties are used. Few studies consider horizontally layered soil, and ground spatial heterogeneity is rarely discussed in the literature, even though conditions vary significantly not only between the soil-stratified layers in the vertical direction but also within each horizontal layer. Using a single average value for the hydrothermal parameters may not always lead to accurate estimation of energy pile thermal yield due to wide ranges in parameter values (Zhao et al., 2022).

Further research is needed to understand the impact of ground heterogeneity on the thermal yield of geothermal energy piles, and to compare it to the widely used assumption of homogeneity. This study investigates the influence of spatial variability in ground thermal and hydrogeological properties (namely, thermal conductivity and permeability) on energy pile thermal yield. To this end, the thermal yield from an energy pile determined using uniform values for the ground properties is compared against that determined from spatially varying properties but with the same mean values. Cases of low-to-high spatial variablity, in terms of coefficient of variation (COV), are considered.

2 METHODOLOGY

In this study, hydrothermal ground heterogeneity is characterised in terms of spatial variability in the ground thermal conductivity, λ [W/ m·K], and the intrinsic permeability κ [m^2], as these are influential energy pile design parameters. The spatial variability of permeability is considered rather than that of hydraulic conductivity as the latter depends not only on the permeability but also the fluid properties such as density and viscosity.

Synthetic 3D autocorrelated random fields for ground thermal conductivity (solid part) and permeability are created using a geostatistical Gaussian randomisation method implemented in the GSTools python library (Müller et al., 2022). A lognormal transformation for the random fields is performed, as it is a preferred option for hydrothermal soil properties distribution since it ranges from zero to infinity. The cross correlation between λ and κ is assumed to be zero, following published findings (Mielke et al., 2010). Figure 1 illustrates a realisation of the random fields.

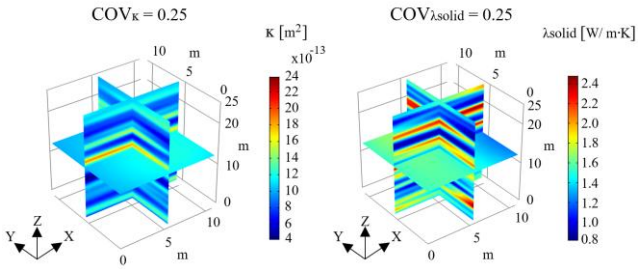

Figure 1. Ground permeability and solid thermal conductivity random field realisations for COV=0.25.

Typical COV values reported in literature are between 0.05 and 0.25 for thermal conductivity, and between 0.25 and 4 for permeability, across a range of materials. Hence, values of $COV_\lambda = 0.25$, and $COV_\kappa =$ (0.25, 0.5, 1, 2, 4) are assumed for the study.

A further important aspect in characterising the spatial variation of ground properties is the scale of fluctuation (SOF) in the horizontal and vertical directions. The SOF describes the distance over which parameters are correlated. In the available literature, the SOF of κ is more widely reported on than that of λ. Therefore, giving the layered nature of the ground, a typical value of horizontal $SOF_h = 10$ m and vertical $SOF_v = 1$ m is adopted for both λ and κ.

The random fields generated are exported as a point cloud and implemented in a 3D numerical model, previously validated by the authors (Alqawasmeh et al., 2024), to solve for conduction-convection heat transfer around energy piles. In the numerical model, λ and κ are assigned to the ground material.

This study assumed characteristics found in the literature typical for a sandy soil: the mean value of permeability is $\mu_\kappa = 1 \times 10^{-12}$ m^2, that of solid thermal conductivity is $\mu_{\lambda solid} = 1.5$ W/ m·K, the porosity $n = 0.4$, and the seepage velocity $v =$ 0.3 m/day. Therefore, the mean effective thermal conductivity is $\mu_\lambda = 1.13$ W/ m·K, given that $\lambda_{fill} = \lambda_{water} = 0.586$ W/ m·K inside voids, following

$$\lambda = (1-n) \cdot \lambda_{solid} + n \cdot \lambda_{fill} \quad (1)$$

The numerical model solves for carrier fluid temperature from inlet to outlet through the GHE. The average fluid temperature, T_{avg}, between inlet and outlet is calculated and compared across the cases considered. In the homogeneous case, i.e., $\kappa = 1 \times 10^{-12}$ m^2, and $\lambda = 1.13$ W/ m·K, T_{avg} is calculated from a single model run. This is compared to the mean value of T_{avg} for the heterogeneous cases, arising from 50 realisations of the random fields, for each case. This number of realisations was found to give a reasonable COV of less than 0.05 for the T_{avg} values, and keeping the pile's energy yield unaffected.

The energy pile considered in this paper is initially designed under the assumption of a homogeneous ground, such that it rejects 1 kW of heat to the ground for three months (cooling), followed by three months of rest (shutting off), before operating again for another three months to extract 1 kW from the ground (heating), followed by another three months of resting, and so on. After that, the design capacity of the energy pile is investigated considering spatial variation in λ and κ, and compared to the 1 kW of the homogeneous case. Figure 2 shows the details of the numerical model setup, boundary conditions in presence of groundwater flow (GWF), and the impeded 4U-loop GHE. The dimensions of the model were chose so as to ensure that boundary effects are negligible.

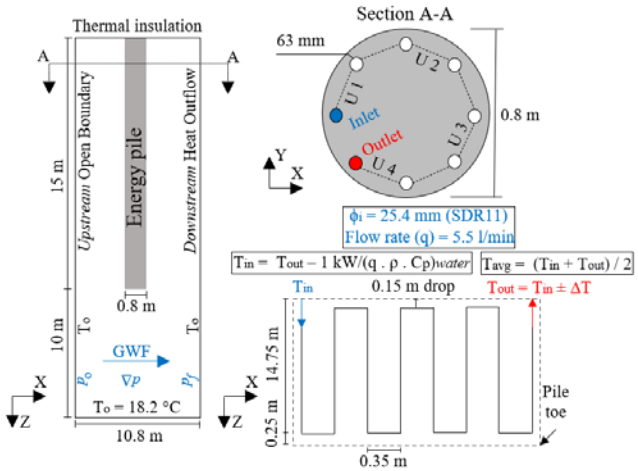

Figure 2. Numerical model setup of the energy pile.

3 RESULTS AND DISCUSSION

The parametric study involves analyses of three different cases:

(i) λ is varying spatially (COV_λ = 0.25) and κ is deterministic (1 x 10^{-12} m^2),

(ii) κ varies spatially (COV_κ = 0.25, 0.5, 1, 2, and 4) and λ is deterministic (1.13 W/ m·K), and

(iii) κ is spatially variable (COV_κ = 0.25, 0.5, 1, 2, and 4) and λ is spatially variable (COV_λ = 0.25).

In all cases, a groundwater flow (Darcy) velocity of 0.3 m/day and ground porosity value of 0.4 are used.

Figure 3 shows the average fluid temperatures resulting from different cases. Each violin plot represents the distribution of the resulting T_{avg} from the 50 realisations, with red dots denoting the mean value of the distribution to be compared with the dashed red line which represents the T_{avg} of the deterministic (homogeneous) case.

Generally, the cases where both permeability and solid thermal conductivity are varied (blue plots) exhibit results very similar to the cases when only the permeability is varied, and the solid thermal conductivity is deterministic (i.e., $COV_{\lambda solid}$ = N/A). This implies that the variability of κ is more influential on the fluid temperature than that of λ. Differences in T_{avg} are evident with increase in variability. For COV_κ values lower than 1, only minor differences arise between the heterogeneous and homogeneous cases, indicating that the assumption of homogeneity can be acceptable in practice for low levels of ground variability. However, when the value of COV_κ is greater than 1, significantly higher values of T_{avg} can be seen compared to that of the homogeneous case. Further, the higher COV_κ, the greater the dispersion of the distribution of the predictions of the thermal yield and, consequently, the lower the probability of getting the deterministic T_{avg} from random realisations.

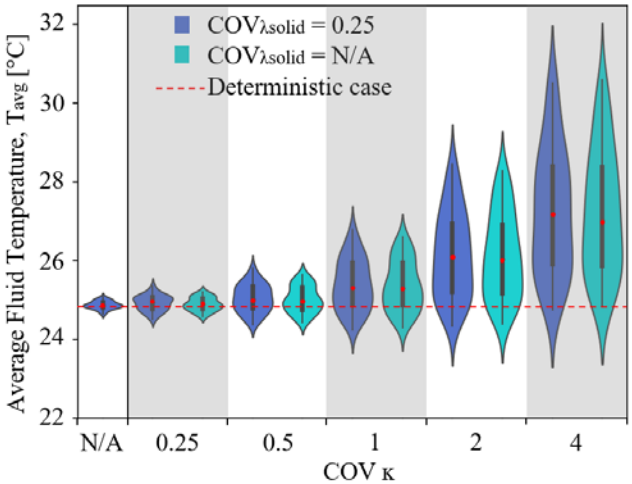

Figure 3. Spatial variability influence on average fluid temperature (each violin plot represents 50 realisations).

Table 1. The difference in energy provision compared to the base thermal load for all considered cases.

	$COV_{\lambda solid}$ = N/A			$COV_{\lambda solid}$ = 0.25		
COV_κ	**$\Delta T^\dagger$ °C**	**ΔEP %**	**Pr %**	**$\Delta T^\dagger$ °C**	**ΔEP %**	**Pr %**
N/A	*Deterministic*			0.03	0.31	6
0.25	0.05	0.52	8	0.05	0.52	12
0.50	0.17	1.80	14	0.20	2.10	18
1.00	0.52	5.40	24	0.55	5.70	24
2.00	1.27	13.20	40	1.29	13.40	38
4.00	2.37	24.70	46	2.40	25.0	46

$^\dagger\Delta T$ is the difference between T_{avg} in the homogeneous (deterministic) ground case and the mean of T_{avg} of 50 realisations for the hetrogeneous ground case realisations.

Table 1 lists the change in average fluid temperature for each of the cases considered, given by the mean over the 50 realisations, compared to that of the homogeneous (deterministic) case. To investigate the influence of the uncertainty associated with the average fluid temperature due to neglect of spatial variability, the expected thermal yield for each case was calculated and the percentage change in energy provision (EP) from the energy pile determined. Finally, the probability (Pr) of the deterministic case overpredicting the thermal yield by ΔEP is quantified.

To illustrate this, Figure 4 shows an example of the difference in the energy provision due to the variation in average fluid temperature for the case when COV_λ = 0.25 and COV_κ = 4. The difference in average fluid temperature within the enclosed area represents the difference in energy provision in this case (i.e., the percentile decrease in the base thermal load, 1 kW cooling/heating, needed to make the solid curves align with the dashed one represents the energy provision difference percentile from the base thermal load).

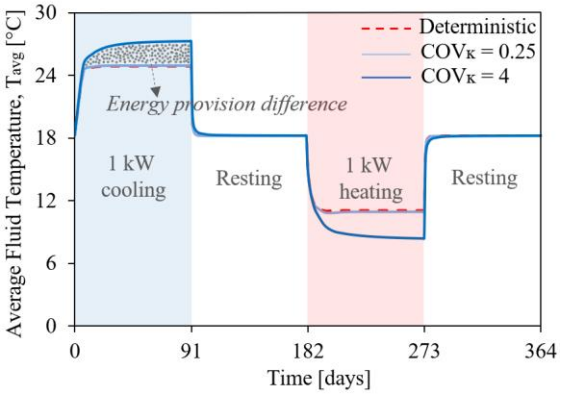

Figure 4. Spatial variability impact on energy provision.

Due to the higher variability that κ can have than λ_{solid}, nearly similar behaviour is exhibited, regardless whether spatial variability of λ_{solid} is considered. This indicates that the spatial variability in permeability is more impactful than that of the thermal conductivity. In addition, when COV_κ is less than 1, the energy provision difference is less than 6%. However, higher ground variability enhances the difference, which can reach up to ~25% when COV_κ=4. Moreover, the chance of getting similar outcomes to the deterministic case out of the random realisations becomes lower with increasing coefficient of variation. In other words, the probability of significant differences in temperature and overpredicting the energy yield becomes higher.

4 CONCLUSION

This study shows that the assumption of homogeneous ground thermal and hydrogeological properties, made in energy pile design, is an appropriate one at low levels of ground heterogeneity, with only a small level of uncertainty in the energy yield exhibited in such cases. However, when ground variability is high, significant variability arises in the calculated average fluid temperature in the energy piles, leading to uncertainty in energy provision of up to ~25% with high chance of occurrence. Further research on the influence of other factors such as seepage velocity and thermal load scheme is encouraged.

Are construction errors in the placement of ground heat exchanging loops in energy piles important to consider?

Les erreurs de construction dans le placement des boucles d'échange de chaleur au sol dans les pieux énergétiques sont-elles importantes à prendre en compte?

ABSTRACT: Shallow geothermal energy is considered as an efficient and sustainable green technology to heat and cool buildings. Incorporating the ground heat exchanging loops (GHEs) inside structural piles, known as energy piles, largely reduces the capital cost. Despite the extensive literature on loops connected in series inside energy piles, optimal distribution or lack of thereof of loops connected in parallel remain largely unexplored. For this purpose, a 3D numerical model has been built to undertake parametric analyses on an energy pile equipped with GHEs connected in parallel. The impact of GHEs misplacement due to construction errors on thermal yield is explored, considering the influence of pile diameter, pile length, pile-to-pile spacing, flow rate, pipe diameter, and ground thermal conductivity. Results show that the GHEs placement generally has a marginal effect of less than 3% on the total thermal yield of the energy pile. However, the heat transfer share between individual loops is highly dependent on its distribution, particularly for certain pile diameters. This may affect maintaining the equilibrium thermal performance. Moreover, in symmetrical loop distributions, an insignificant thermal performance penalisation was observed for a range of separation-to-shank distance ratios from 0.5 to 1.5. While symmetrical and evenly spaced distribution is recommended, the latter result indicates that there is flexibility when installing the GHEs loops, with deviations from design during construction rendering low impacts on overall thermal performance.

RÉSUMÉ: La géothermie superficielle est considérée comme une technologie verte efficace et durable pour chauffer et refroidir les bâtiments. L'intégration des boucles d'échange de chaleur au sol (GHE) à l'intérieur de pieux structurels, appelés pieux énergétiques, réduit considérablement le coût en capital. Malgré la littérature abondante sur les boucles connectées en série à l'intérieur de pieux d'énergie, la distribution optimale ou l'absence de celle-ci des boucles connectées en parallèle restent largement inexplorées. Pour cela, un modèle numérique 3D a été construit pour entreprendre des analyses paramétriques sur une pieu énergétique équipée de GHE connectés en parallèle. L'impact du mauvais positionnement des GHEs en raison d'erreurs de construction sur le rendement thermique est exploré, en tenant compte de l'influence du diamètre du pieu, de la longueur du pieu, de l'espacement pieu à pieu, du débit, du diamètre du tuyau et de la conductivité thermique du sol. Les résultats montrent que le placement des GHE a généralement un effet marginal de moins de 3% sur le rendement thermique total de la pieu énergétique. Cependant, la part du transfert de chaleur entre les boucles individuelles dépend fortement de sa répartition, en particulier pour certains diamètres de pieux. Cela peut affecter le maintien des performances thermiques d'équilibre. De plus, dans les distributions de boucles symétriques, une pénalisation insignifiante des performances thermiques a été observée pour une plage de rapports séparation/distance de tige allant de 0.5 à 1.5. Bien qu'une distribution symétrique et uniformément espacée soit recommandèe, ce dernier résultat indique qu'il existe une flexibilité lors de l'installation des boucles GHE, avec des écarts par rapport à la conception pendant la construction ayant un faible impact sur les performances thermiques globales.

Keywords: Energy piles; loops in parallel; GHEs configuration; GHEs optimisation; GHEs spacing.

1 INTRODUCTION

Energy piles are a sort of shallow geothermal energy system (Brandl, 2006) in which conventional pile foundations are incorporated with high density polyethylene (HDPE) pipes filled with circulating fluid, known as ground heat exchangers (GHEs); therefore, they serve dual purposes: to carry the structural load and to heat and cool buildings.

Nowadays, this green technology has become popular as it contributes to green gas emission reduction due to higher yearly efficiencies than traditional electrical systems (Banks, 2012). A proper design of the GHEs loops within the energy pile is crucial. Wide research studies compared some popular heat exchanger designs to harvest as much energy from the ground as possible, these have been recently reviewed in (Cui et al., 2022). The U-tube loop configuration is widely used due to its simplicity in terms of design, transportation, and construction (Mohamad et al., 2021). Most of the investigated layouts rely on connecting the pipes *in series* to create a longer path for the moving fluid inside the pipes to exchange heat compared to the parallel connection, assuming the performance is the same. However, if faults occur in the serially-connected pipes during their lifetime (such as leakage), this results in the loss of a portion of the geothermal system. In addition, the pumping cost may be greatly different (Banks, 2012).

Some numerical and experimental studies have considered *parallel* loop connection within energy piles and show the importance of accounting for thermal interference between adjacent loops (Park et al., 2022; Cui et al., 2020). Most studies consider an even number of loops, and all of them consider only a symmetrical GHE distribution. However, a design with an odd number of loops can add a zone of potential thermal interferance between two adjacent inlets and outlets (i.e., a colder fluid is running besides a hot fluid). A misplacement of loops from the symmetrical distribution may occur during construction as well. In addition, the optimised distribution of loops in terms of the shank spacing of the same loop and the separation spacing from the adjacent loops is rarely discussed in literature.

This study aims to investigate the thermal performance of a set of energy pile diameters that accommodate three U-tube loops connected in parallel at different placements around the pile perimeter. In addition, the optimal ratio between the separation distance of individual loop legs (shank spacing) and the separation distance of adjacent loops is examined. The study also investigates the impact of various influencing design parameters, including the thermal conductivity of the ground, the length of the pile, the carrier fluid flow rate within the GHEs, the pipe diameter, and the pile-to-pile spacing. The study helps widen the practical design knowledge of such a promising green and sustainable technology.

2 METHODOLOGY

A three-dimensional numerical model, previously validated by the authors (Alqawasmeh et al., 2024), is used to solve for conduction-convection heat transfer. The heat within the wall of the ground heat exchanger, the concrete of the pile body, and the soil mass is mainly transported by conduction. Wherase the heat is transferred by convection through the running carrier fluid inside the GHEs.

Figure 1 shows the energy piles numerical model setup with details of their boundary conditions (a), the considered three U-tube loops (b), and the different placements of one of the loops (L2) around the pile perimeter (c). The misplacement is assumed to likely happen in one loop (e.g., L2). The angle (β) represents the angle that separates the three loops symmetrically, while (α), separates loop L2 and L3. A "*Rotation Factor"* is defined as the ratio of both angles.

The study covers two sets of analyses. The first set is performed on three selected pile diameters (0.5 m, 0.6 m, and 0.7 m), considering site-specific conditions (Arden site) located in Melbourne, Australia. The pile length is 40 m with 5 m of pile-to-pile spacing, representing an isolated pile from a pile array for simplicity and computational cost efficiency. A flow rate of 5.5 l/min running through a 25.4 mm (SDR11) inner pipe diameter is considered for each of the three U-tube loops. The average ground properties of the Arden site are 2.5 W/(m·K) for thermal conductivity, 1,881 kg/m^3 for density, and 1,284 MJ/(m^3·K) for heat capacity (Jensen-Page, 2019).

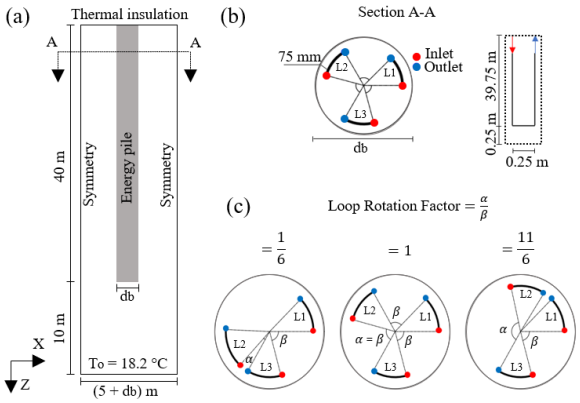

Figure 1. Schematic (not to scale) of: the numerical model setup and boundary conditions (a), three U-loop GHE details (b), and different GHE placements by moving L2 (c).

The inlet temperature entering the system is taken as 32.2°C in cooling mode and 10.7 °C in heating mode follwoing (Kavanaugh , 2008). The system is assumed to operate continuously during 3 months in winter and 3 months in summer and be turned off during the other six months of the year.

The second set of analyses aims to generalise the findings of the site-specific study (Arden site) for 0.5 m pile diameter (where the chance of thermal interference is maximum), taking into account some influential parameters on energy pile thermal performance, including (i) ground thermal conductivity, (ii) pile length, (iii) fluid flow rate, (iv) inner pipe diameter, and (v) pile-to-pile spacing.

3 RESULTS

3.1 The Arden site case

Figure 2 shows the total heat transfer per pile throughout the annual building cooling period for various pile diameters: $P_{0.5m}$, $P_{0.6m}$, and $P_{0.7m}$, Results for the heating period are analogous (not shown).

It is evident that the maximum total heat transfer occurs when the GHEs loops are symmetrically distributed around the pile's circumference ($\alpha/\beta = 1$). Moreover, marginal differences exits for other rotation factors (e.g., for $P_{0.7m}$, the worst-case scenarios at 1/6 and 11/6, results in a heat transfer reduction of ~133 kW h or ~ 2.7% compared to the symmetrical distribution over the annual building cooling period.).

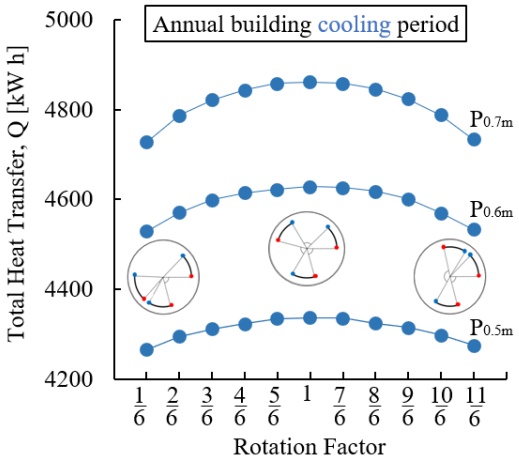

Figure 2. Total heat transfer from all loops for $P_{0.5m}$, $P_{0.6m}$, and $P_{0.7m}$ energy piles for different Rotation Factors, for the three months annual building cooling period.

Moreover, as the pile diameter increases, the separation between loops increases, which decreases the thermal interaction, yielding a higher heat transfer capacity for the same GHEs configuration design.

Furthermore, to examine the individual loops response, Figure 3 depicts the proportionate contribution of each individual loop (L1, L2, and L3) to the total heat transfer. In general, the share of the total heat transfer between loops is nearly equal when loops are symmetrically arranged, but a deviation from this symmetry, potentially arising from human error during construction, can disrupt the total heat transfer share balance between loops. These relatively minor differences increase as the loops' distribution strays further from the symmetrical distribution. The uneven temperature distribution within the pile may induce some thermo-mechanical strains. In the case of the 0.5 m pile's diameter ($P_{0.5m}$), the variation in loop shares, even under symmetrical distribution, reaches up to 2% (~ 30 kW h per pile over the annual building cooling period). This might be attributed to the smaller pile diameter, resulting in reduced separation distance

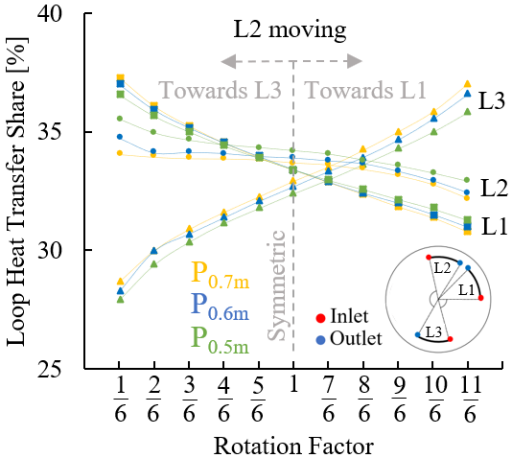

Figure 3. Loop heat transfer share from the total heat transfer for $P_{0.5m}$, $P_{0.6m}$, and $P_{0.7m}$ energy piles for different Rotation Factors of L2.

between individual loops (considering a 25 cm shank spacing between the individual loop's legs), and consequently, higher thermal interference between adjacent loops. However, even for the small pile diameter, the differences are within an acceptable range (less than 5%) as long as the loop distribution does not deviate significantly from symmetry.

From the previous discussion, minor differences in the thermal performance among parallel loops at different relative placements allow for design flexibility and reduce the risk of having significant efficiency decline due to installation uncertainties, although the symmetrical loop distribution is recommended during installation.

The separation distance between loops in a symmetrical arrangement depends on the shank spacing between the legs of individual loops. To further maximise the thermal performance of the energy pile, optimising the shank spacing while all loops are in symmetric distribution is investigated.

Figure 4 shows the total heat transfer considering different separation-to-shank distance ratios (S/K). A similar total heat transfer is achieved for $0.5<S/K<1.5$, suggesting great flexibility in designing the GHEs distribution inside energy piles while maintaining their

thermal performance. Yet, it is still practical to design for an equally spaced arrangement (i.e., S/K = 1).

3.2 Generalised case

To further generalise results, we consider the cases listed in Table 1. Each case focuses on one influencing parameter, with subcase (a) representing the Arden site, and subcases (b) and (c), a smaller or larger value parameter than Arden's (and all others, kept the same).

Results confirm that the highest total heat transfer occurs when the loops are symmetrically distributed (not shown). The maximum differences between loop

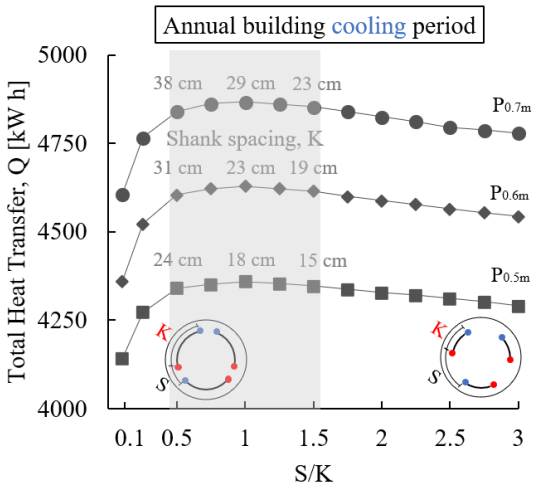

Figure 4. Total heat transfer from all loops for $P_{0.5m}$, $P_{0.6m}$, and $P_{0.7m}$ for different separation-to-shank distance ratios (S/K) over the annual building cooling period.

placements near the symmetry condition ($\alpha/\beta < 3/6$) and in the highly non-symmetric condition ($\alpha/\beta > 10/6$) are summarised in Figure 5.

Table 1. Parametric analysis cases for worst-case $P_{0.5m}$.

Case		Description	Value
1	a	Thermal conductivity (ground) [W/(m·K)]	~ 2.5
	b		1
	c		4
2	a	Pile length [m]	40
	b		15
	c		25
3	a	Fluid flow rate [l/min]	5.5
	b		7.5
	c		10
4	a	Inner pipe diameter [mm]	25.4
	b		12.7
	c		38.1
5	a	Pile spacing [m]	5
	b		2
	c		3.5

4 CONCLUSION

The study demonstrates great flexibility in designing parallel-connected GHEs loops in energy piles and the relatively small impact of misplacing loops during construction. A drop of less than 3% in the overall thermal performance and less than 5% in the total heat transfer share between loops for limited deviations from symmetrical placements has been calculated. Only highly non-symmetric configurations show deviations of ~ 8%. In addition, the marginal drop in thermal performance when the symmetrical separation-to-shank distance ratios range from 0.5 to 1.5 allows for more design flexibility and to increase pile thermal yield by increasing the number of loops.

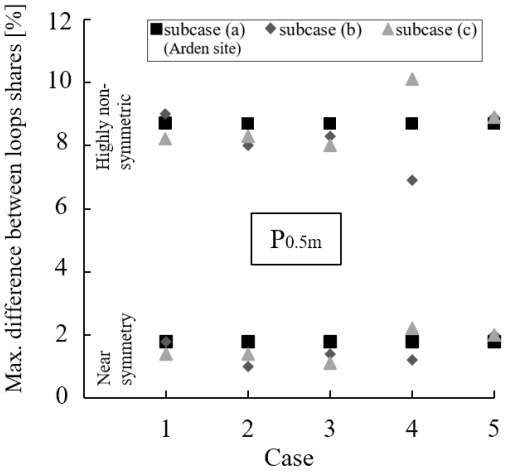

Figure 5. Maximum difference in total heat transfer share between loops for all cases in Table 1 (0.5 m pile diameter).

Installing the loops in a symmetrical and evenly spaced pattern, on the other hand, results in the best overall performance and is thus recommended.

ABSTRACT: In the pursuit of finding a less carbon-intensive binder alternative to cement, an ongoing research project in Norway is investigating the effect on properties of various soft soils when substituting parts of the cement with industrial by-products and biochars. This paper considers how three biochars influence the soil properties of a Norwegian quick clay when acting as the only binder. The practical application would first and foremost be to ease the handling and transportation of excavated quick clay by increasing its remoulded shear strength. The laboratory study determined that the biochar that yielded the lowest shear strength when added alongside cement had the distinctly largest positive influence when added alone. At a quantity of 100 kg/m^3, this particular biochar, made from calcinated sewer sludge, increased the fall cone shear strength of the remoulded clay from an average of 2.3 kPa to 85.0 kPa after 28 days of storage, and to above 100 kPa after 90 days. The follow-up unconfined compression tests only revealed shear strengths of 19.5-31.4 kPa, indicating serious method-dependency. Nevertheless, the calcinated sewer sludge biochar appears as a sustainable binder option to lime and cement when aiming at improving the shear strength of already excavated sensitive soils.

RÉSUMÉ: Dans la recherche d'une alternative de liant moins intensive en carbone que le ciment, un projet de recherche en cours en Norvège étudie l'effet sur les propriétés de divers sols souples lors du remplacement de parties du ciment par des sous-produits industriels et des biochars. Cet article examine comment trois biochars influencent les propriétés du sol d'une argile rapide norvégienne lorsqu'ils agissent comme seul liant. L'application pratique serait principalement de faciliter la manipulation et le transport de l'argile rapide excavée en augmentant sa résistance au cisaillement remaniée. L'étude en laboratoire a déterminé que le biochar qui a donné la plus faible résistance au cisaillement lorsqu'il était ajouté avec du ciment a eu l'influence positive la plus marquée lorsqu'il était ajouté seul. À une quantité de 100 kg/m^3, ce biochar particulier, issu de la calcination des boues d'égout, a augmenté la résistance au cisaillement du cône de chute de l'argile remaniée d'une moyenne de 2,3 kPa à 85,0 kPa après 28 jours de stockage, et à plus de 100 kPa après 90 jours. Les tests de compression non confinée de suivi n'ont révélé que des résistances au cisaillement de 19,5 à 31,4 kPa, indiquant une sérieuse dépendance à la méthode. Néanmoins, le biochar de boues d'égout calcinées apparaît comme une option de liant durable par rapport à la chaux et au ciment lorsqu'on vise à améliorer la résistance au cisaillement des sols sensibles déjà excavés.

Keywords: Quick clay; biochar; remoulded shear strength; fall cone test; unconfined compression test.

1 INTRODUCTION

Quick clays, recognized by their collapsible nature when disturbed or loaded beyond the yield strength, are found in urbanised areas in Scandinavia and Canada, as well as in parts of Russia. Groundworks in these areas typically require the soil to be stabilised, and often the dry deep mixing method is preferred. An ongoing research project in Norway investigates whether various industrial by-products and biochars may replace parts of the lime and cement to reduce the considerable CO_2 impact of the method. To be used in

dry deep mixing, the alternative binders however should not degrade the engineering performance, and at the very least the resulting shear strength should surpass the in-situ undisturbed shear strength. In practice, this excludes several of the alternative binders and limits the amount of lime and cement that may be replaced. However, there are other uses that do not require the same engineering performance. In projects which include excavation of soil, the quick or soft clay above the final excavation level is sometimes mixed with a reduced binder (typically lime and cement) quantity to facilitate easier excavation and transport to a landfill. For these cases, the shear strength is only required to increase to a level where the soil becomes plastic rather than liquid, and easy and safe to handle and transport.

Biochars are materials made from heating organic masses in the absence of oxygen. Contrary to most industrial by-products proposed to be used as alternative binders, biochars sequester carbon that would otherwise have been emitted to the atmosphere. Thus, the use of biochars to stabilise soils can even have a carbon-negative footprint if enough of the cement and/or lime is replaced (Hov et al., 2023). This makes biochars especially interesting as alternative binders.

Findings from unconfined compression tests by Hov et al. (2023) and Ritter et al. (2023a) highlight that the effect of biochars on the strength and stiffness of soft soils depends heavily on the biochar and soil type, as well as on the added cement and biochar quantities (with both having an optimal amount).

Of the in total five tested biochars in the two studies, none were found to give more than a modest strength increase compared to when cement was added alone. Also, two of the biochars were found to have a negative influence. Hov et al. (2023) discussed that the water adsorption ability of the biochars is likely important to the stabilising effect when added alongside cement. While only one biochar was added without cement by Ritter et al. (2023a), none of the four biochars used by Hov et al. (2023) were added without cement. Thus, the knowledge of the individual effect of biochars on the properties of remoulded quick clays is limited.

The described research investigated how three of the biochars used along with cement by Hov et al. (2023) impacted the fall cone shear strength, $s_{u,FC}$, of the tested quick clay when added alone. The study was initiated as a cost- and material-effective way to provide a reference for the cement and biochar stabilised samples as well as to compare the individual effect of the different biochars.

2 METHODOLOGY

2.1 Materials

The soil used was a quick clay from the Norwegian GeoTest Site (NGTS) at Tiller-Flotten, Trondheim, in Norway. The clay from this site was well characterised by L'Heureux et al. (2019) and has previously been used for similar research (e.g. Hov et al., 2022, 2023; Paniagua et al., 2023; Ritter et al., 2022, 2023a). Tube samples from 14-18 m depth were mixed until visually homogenised. The quick clay from this depth has a clay content of around 50-60%, organic content < 1%, water content w = 40-45%, bulk density 18-18.5 kN/m^3, plasticity index I_P between 10-15%, liquidity index I_L around 1.5-2.0, undisturbed shear strength s_u (from unconfined compression and fall cone tests) approximately between 50 and 85 kPa, sensitivity S_t > 30. A stiffness E_{50} of around 2.5 MPa has been measured for this clay (Ritter et al., 2023a).

All three biochars were produced at temperatures around 470-600 °C in a full-scale micro-wave-assisted pyrolysis (MAP) unit with a residence time of ~20 minutes (Hov et al. 2023). The three biochars (BC) originated from: BC1 - demolition wood such as wood panels, furniture etc., containing some metals and glue remains; BC2 - slightly decayed bottom sludge from municipal sewage with around 39wt.% of limestone, $CaCO_3$, added for hygenisation and workability before the sludge was used for biochar production; BC3 - sewage and food waste, with iron chloride ($FeCl_3$) added for flocculation. Before mixing, the biochars were sieved to grain sizes < 1 mm and oven-dried at 100 °C over night. Their respective specific surface areas (SSA) were measured to be 38.5, 54.8 and 51.3 m^2/g by adsorption of gas and calculated according to Brunauer-Emmet-Tellet theory (Hov et al., 2023). In terms of major elements present, determined by X-ray fluorescence, the most notable differences were high contents of CaO ($CaCO_3$) in BC2, and ferric oxide (Fe_2O_3) in BC3 (Hov et al., 2023).

2.2 Sample preparation and lab testing

For the main testing regime in which the shear strength was tested by the fall cone (FC) method, 29 samples were prepared. The quick clay and biochars were mixed by a Kenwood kitchen mixer according to standard Norwegian lime-cement stabilisation lab procedures (NGF, 2012). Seven mixtures were prepared: two of each biochar, with quantities of 50 and 100 kg/m^3, and one without binder. Following the mixing, around 150 g samples were prepared by pouring/scooping the mixtures into small aluminium containers (see Figure 1). The samples were then sealed and left for storage in room temperature (around

20 °C). For each of the biochar-stabilised mixes, four samples were prepared: three to be tested after 28 days of storage, and one to be tested after 90 days. The test regime consisted of calculating water content (NS-EN ISO 17892-1:2014, NS, 2014), performing fall cone shear strength tests in stored undisturbed and remoulded states (Norwegian correlation developed for testing natural soils, NS 8015:1988; NS, 1988), as well as determining the liquid (w_L) and plastic (w_P) limits (NS-EN ISO 17892-12:2018; NS, 2018). The Atterberg limits were only tested after 28 days of storage, on material from two of the prepared FC samples after FC testing.

Because the BC2 gave unexpectedly high fall cone strengths, three 10 cm unconfined compression (UC) samples were prepared with 100 kg/m^3 of BC2 to provide strength and stiffness values directly comparable to those from Hov et al. (2023). They were tested after 14, 28 and 90 days of curing at room temperature, using a strain rate of 3.8% of the height per minute (NS-EN ISO 17892-7:2017; NS, 2017).

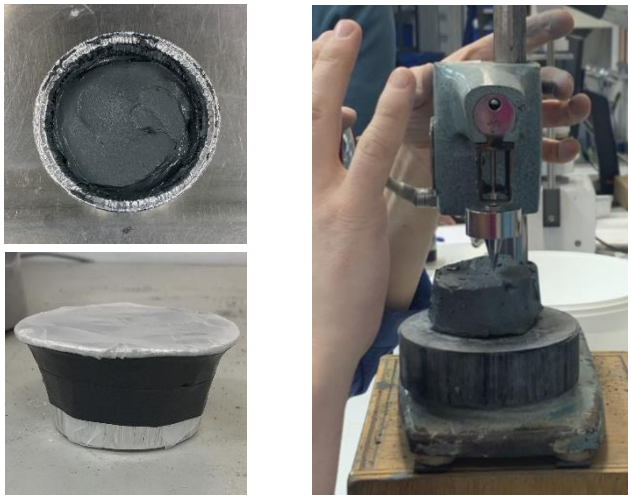

Figure 1. (Upper left) a prepared sample before storage, (lower left) a sealed, prepared sample, and (right) an extracted sample being tested in "undisturbed" state.

3 RESULTS AND DISCUSSION

Figure 2 presents the water contents and liquid and plastic limits. The FC samples with no added binder had a water content varying from 39.6% (1 day) to 37.5% (90 days), indicating that the latter sample might have experienced some drying. For the other samples, this trend was not observed, and the water contents varied insignificantly. The lower water contents when the biochars were added can be explained by the increased dry mass while keeping the amount of water constant. The higher water contents measured for the UC samples can likely be explained by less water being evaporated during mixing and storing.

Considering the Atterberg tests, BC2 had a considerably more prominent effect than BC1 and BC3, both in terms of increasing the liquid (w_L) and plastic (w_P) limits as well as the plasticity index. Although the BC1 and BC3 performed similar, BC1 was the least effective. Even when adding 100 kg/m^3 BC1, the samples still had a water content $w > w_L$.

Figure 3 presents key results from the fall cone (FC) and unconfined compression (UC) tests. Table 1 summarizes all shear strength test results. Every biochar increased the FC shear strengths compared to the non-stabilised remoulded samples. However, BC2 had a greater effect than BC1 and BC3, corresponding with the respective influences on the plasticity. The strength increase caused by BC2 began immediately upon mixing. While all biochars gave a larger strength increase at 100 kg/m^3 than at 50 kg/m^3, the effect was most pronounced for BC2 and BC3, where s_u more than doubled.

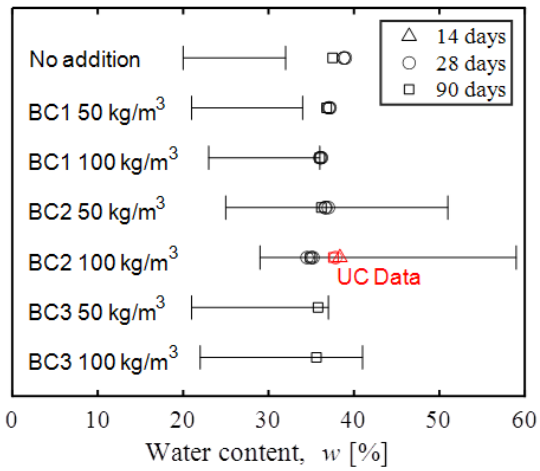

Figure 2. Measurements of w (symbols), and w_P and w_L.

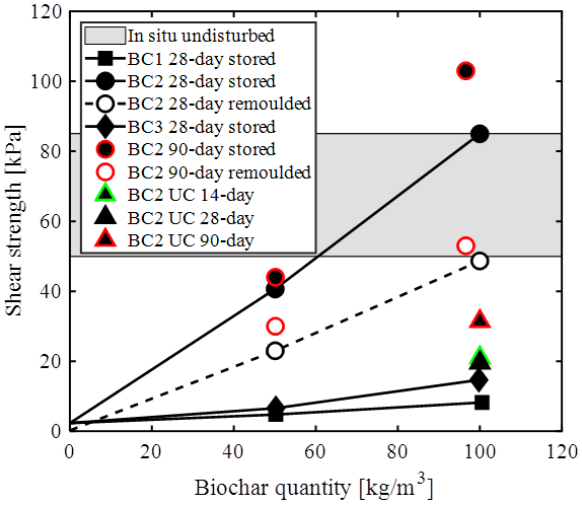

Figure 3. Key shear strength results.

Table 1. Fall cone and unconfined compression test results. Triplicate FC samples were tested after 28 days. All other shear strength results were from one sample/test. Shear strength from UC tests were derived as half the unconfined compression strength (UCS /2).

Binder	Quantity	Fall cone (FC) Stored		After remoulding		Unconfined compression (UC) Stored	
		s_u	St. dev.	s_u	St. dev.	*UCS/2*	*E50*
		28 / 90 days	28 days	28 / 90 days	28 days	14 / 28 / 90 days	14 / 28 / 90 days
[-]	[kg/m3]	[kPa]				[kPa]	
None	-	2.3 / 3.3	0.12	0.2 / 0.6	0.05		
BC1	50	4.8 / 7.7	0.24	1.4 / 3.6	0.24		
	100	8.2 / 15	1.58	2.2 / 7.5	1.58		
BC2	50	40.7 / 44	1.70	23 / 30	1.70		
	100	85 / 103.0	2.83	48.7 / 53	2.83	21 / 19.5 / 31.4	220 / 450 / 1600
BC3	50	6.6 / 15	0.43	3.6 / 9	0.43		
	100	14.7 / 27	1.70	7.9 / 16	1.70		

The reasons why BC2 had a greater effect than the other two biochars have not yet been understood. Some aspects which may explain the observed differences will be discussed in the following.

3.1 Remoulding and time-dependency

Every FC sample experienced a decrease in shear strength upon remoulding. However, all stabilised samples retained a shear strength above the quick clay threshold of 0.5 kPa. As every sample was essentially remoulded upon storing, the reduction indicated a time-dependent strength increase during storing, even for the non-stabilised samples. This thixotropic tendency was also indicated by comparing FC and UC results after 28 and 90 days of storage. Only one sample from each series was tested after 90 days, but the fact that an increase was seen for all series, and that the loss of water content was negligible, strongly implies that there were active processes that increased the strength of the particle structures also after 28 days. How the binders themselves contributed to these processes are difficult to assess based on the results presented herein. It is nevertheless worth noting that percentagewise, both BC1 and BC3 provided a larger increase in stored shear strength from 28 to 90 days than BC2 (83 and 84% vs. 21% for the FC samples, respectively, and 61% for the UC samples). This could indicate that the processes providing the immediate (or short-term) and the time-dependent strength increase are not the same. Alternatively, the processes caused by additions of BC1 and BC3 may have initially been moving slower than when BC2 was added. The stabilising effects of BC2 are further discussed in Section 3.3.

3.2 Fall cone vs. unconfined compression tests

Studies have determined the correlation between unconfined compression tests and fall cone tests to be strongly soil dependent (e.g. Tanaka et al., 2012). From the results presented in this paper, it is also observed that the correlation is distant from 1:1. For example, the average $s_{u,FC}$ of the BC2 100 kg/m^3 samples after 28 days of storage was around 4×*UCS/2*. Part of the discrepancy is likely due to differences in sample preparation, sample size, and test method. Also, the fact that the framework for determining shear strength from fall cone tests was developed for natural soils, and not reconstituted ones, might be part of the explanation.

3.3 Biochar and cement vs. biochar

Not surprisingly, the biochar-stabilised samples exhibited much lower shear strengths than when 50 kg/m^3 of cement was included in the binder mixture (Hov et al., 2023, see Table 2). For BC2-stabilised samples after 28 days of storage, the addition of cement gave approximately a 20-fold increase of *UCS/2* compared to when only the biochar was used (396 kPa vs. around 20 kPa). The stiffness, E_{50}, of the BC2 samples was between 220 – 450 kPa, less than 1/50 of the BC2- and cement samples and less than the in-situ stiffness (2 500 kPa). After 90 days of storage, the *UCS/2* and E_{50} increased to 31.4 kPa and 1 600 kPa respectively which was still below the in-situ values.

Table 2. Extract of results from (Hov et al., 2023). Average shear strength and stiffness values from unconfined compression tests performed after 28 days of storage.

Cement	Biochar	*UCS/2* [kPa]	E_{50} [kPa]
50 kg/m^3	-	460	118 000
50 kg/m^3	100 kg/m^3 BC1	396	102 000
50 kg/m^3	100 kg/m^3 BC2	166	25 000
50 kg/m^3	100 kg/m^3 BC3	217	41 000

Possibly the most surprising finding when comparing the two studies was that BC2 was the least effective biochar when used together with cement but

the most effective one when added alone. It is unclear whether this is related to the biochar properties, such as water retention, or the constituents available for chemical reactions. Considering the latter, it may imply that the chemical compounds in BC2 are more active than those from the other biochars, and that the chemical compounds, or the chemical reactions which they are involved in, may obstruct the curing of the cement. However, Hov et al. (2023) discussed that the BC2 had no cementitous properties, as calcium is only present as calcite ($CaCO_3$) and not calcium oxide (CaO). Microstructural analyses, e.g. with a scanning electron microscope, could provide further insight into the mechanisms involved.

3.4 Implications for the use of the biochars

The calcinated sewer sludge biochar (BC2) notably increased the shear strength and plasticity of the remoulded Tiller-Flotten quick clay. As the strength increase began immediately after mixing in the lab, this biochar could be used as an alternative to lime and cement to stabilise already excavated soft and quick clays. Even at 50 kg/m^3 (or even lower), the instant improvement of the Tiller-Flotten clay would likely be enough to quickly make the clay safe and practical to handle and transport. While the other biochars could in theory also be used for this purpose, a larger quantity of biochar would be required. Further analyses should look at the economic implications due to the actual costs of biochar production.

Recently, the possibility to reuse excavated soils, instead of depositing them at landfills, has gained some attention. For example, an ongoing research project in Norway is investigating whether excavated lime and cement stabilised clays may be utilised as compacted clay liners at landfills (Ånes et al., 2024; Ritter et al., 2023b). In this regard, it could be interesting to explore how clays stabilised with biochars or other alternative binders compare to clays stabilised with lime and cement. If alternative binders are found to be better for this or other purposes, thus increasing the usability of the excavated mass, it could be an incentive for construction projects to rather use such binders to stabilise soft and quick clays after excavation.

4 CONCLUSION

All three biochars had a positive effect on the shear strength of the remoulded quick clay. Additions of 50 and 100 kg/m^3 of BC2 and BC3 stabilised the clay to above the quick clay threshold of $s_{u,\ remoulded} > 0.5$ kPa, as well as $w > w_L$. Samples with BC1 only surpassed the first criterion. BC2 had the distinctly most positive effect and increased the average fall cone shear strength after 28 days of storage from 2.3 kPa to 85 kPa, and *UCS/2* to around 20 kPa.

BC2 seems to be a viable climate-friendly alternative to lime and cement to improve the handling and transportation of quick and soft clays after excavation. The field performance including environmental and economic aspects of using BC2 as an alternative binder to improve remoulded quick clay should be studied further.

The reasons for the superior effects caused by BC2 compared to BC1 and BC3 have not yet been determined. Potential explanations could be a higher water retention capacity of BC2, or that BC2 contains constituents that react chemically when added to clay. However, from the performed chemical and mineralogical analyses by Hov et al. (2023), there are no obvious differences between BC2 and the other biochars to suggest this. Scanning electron microscope should be used to study the microstructure of stabilised samples to help expose the mechanisms.

ACKNOWLEDGEMENTS

This research was funded by Research Council of Norway, grant number 328767 "GOAL – Green soil stabilisation". The authors are especially grateful to Ingrid Peikli, Karl Sigmundstad Halse, and Maria Cansignia at the NGI geotechnical laboratory in Oslo for performing the laboratory tests.

ABSTRACT: To minimize the generation of leachates and thus the contamination of the environment, landfills are usually closed using a cover system which includes a low-permeable hydraulic barrier. For landfills for ordinary and hazardous wastes, a common requirement is that the hydraulic conductivity of this layer must be less than $1x10^{-9}$ m/s. Compacted soil layers with natural dry crust clays have been used for this purpose in Norway. However, these soils are not always available within reasonable transport distances of landfills. An ongoing field-scale pilot test conducted at a landfill site in southern Norway therefore aims to evaluate whether a press filter residue from a soil-washing plant or an excavated cement stabilised clay could be used instead of natural-occurring clays. These two materials are normally considered wastes and currently have no application. Their reuse would therefore contribute to reduce the environmental footprint and the costs associated with their deposition in a landfill. Field results for a 6-month period (May 1st to October 31st, 2023) are presented and discussed in this article. These initial results indicate that the cover made of compacted dry crust clay is the most effective, but that the two alternative materials also fulfil the hydraulic conductivity target of 1×10^{-9} m/s. Overall, field measurements match well characterisation and hydraulic conductivity tests conducted in the laboratory. However, the difference in hydraulic conductivity between the dry crust clay and the reused materials is smaller in the field than in the lab. The environmental aspects regarding the reuse of these materials are yet to be evaluated.

RÉSUMÉ: Afin de minimiser la génération de lixiviats et donc la contamination de l'environnement, les décharges et sites d'enfouissement sont généralement restaurés au moyen d'un système de recouvrement comprenant une couche de faible perméabilité. En Norvège, les installations de stockage de déchets ordinaires et dangereux doivent normalement être recouverts d'une couche d'argile compactée ayant une conductivité hydraulique inférieure à 1×10^{-9} m/s. On emploie souvent des argiles glacio-marines altérées à cette fin, mais les matériaux adéquats ne sont pas toujours disponibles dans un rayon de transport raisonnable des décharges. Un essai pilote est donc en cours sur une décharge du sud de la Norvège afin d'évaluer si un résidu filtré provenant d'une usine de lavage de sols et une argile stabilisée au ciment excavée pourraient être utilisés à la place des argiles conventionnelles. Ces deux matériaux sont généralement considérés comme des déchets et n'ont actuellement aucune autre application. Leur réutilisation permettrait donc de réduire l'empreinte environnementale et les coûts liés à leur entreposage. Cet article présente les résultats de terrain pour une période de 6 mois, du 1er mai au 31 octobre 2023. Ces premiers résultats indiquent que la couverture constituée d'argile est la plus efficace, mais que les deux matériaux recyclés remplissent également le critère 1×10^{-9} m/s. Les résultats de ces essais de terrain confirment bien les caractérisations et tests de perméabilité réalises au laboratoire. Cependant, la différence de perméabilité entre l'argile et les matériaux recyclés est plus faible sur le terrain qu'au laboratoire. Les aspects environnementaux liés à la réutilisation de ces matériaux restent cependant à évaluer.

Keywords: Landfill; final cover; low-permeable barrier; compacted soil; reuse.

1 INTRODUCTION

Reducing the water percolation in a landfill is an important part of minimizing the generation of leachates and thus reduce the risk of contamination of the surrounding environment. Landfills are usually reclaimed using a cover system that includes a low-permeable hydraulic barrier, for example consisting of compacted clayey soil. For landfills for ordinary and hazardous wastes, the environmental authorities in Norway typically require this barrier to have a hydraulic conductivity lower than 1×10^{-9} m/s. This criterion is usually assumed to ensure that the annual percolation does not exceed 20 to 50 mm/yr (Avfall Norge, 2015).

A landfill for inorganic ordinary and hazardous industrial wastes, located in southern Norway, is currently planning its closure. Dry crust clays (DCCs), the weathered upper metres of marine clay deposits, have been used for the construction of a compacted soil layer (called sealing layer in previous associated papers) within the cover system for a closed part of the landfill. However, the availability of DCCs in the region is limited, and the landfill company therefore investigates possible alternative materials for the closure of the last part. Two clayey materials that are normally considered as wastes and deposited as such have been identified as potential alternatives. These include a clayey press filter residue (PFR) from a soil-washing plant, and a cement-stabilised clay (CSC) excavated from a construction site in the region. Several preliminary lab and field studies have, indeed, showed, that these two materials can achieve the target of 1×10^{-9} m/s, provided a sufficient compaction effort is applied (e.g., Kristensen, 2017; Pedroni et al., 2018; Ritter et al., 2023).

A large-scale pilot test is therefore being conducted in the field, complemented by a laboratory characterisation test program, to evaluate the in-situ hydraulic conductivity and properties of these two alternative materials as well as a dry crust clay (DCC). Pilot design and field results are presented in this article.

2 METHODOLOGY

2.1 Materials

Three materials were evaluated in this research: the DCC, the PFR and the CSC. The DCC was obtained from a construction site in Oslo, Norway. The PFR was produced at a soil-washing plant, being the clay- and silt-fractions separated from the coarser fractions of various excavated lightly contaminated sediments. The CSC came from another construction project in Oslo. All three materials have been characterised as part of this study, and earlier by Ritter et al. (2023). The particle size distribution was determined by the falling drop method (NS-EN ISO 17892-4:2016; NS, 2016), water content by loss on drying (NS-EN ISO 17892-1:2014; NS, 2014), compaction properties were determined from the Standard Proctor test (AASHTO T99-10; AASHTO, 2022), consistency limits were evaluated by Atterberg tests (NS-EN ISO 17892-12:2018; NS, 2018), the shear strength was determined from fall cone (NS-EN ISO 17892-6:2017; NS, 2017) and minature vane (ASTM D4648; ASTM, 2016), whereas the hydraulic conductivity was measured in oedometer and triaxial cells (NS-EN ISO 17892-11:2019; NS, 2019). Table 1 summarises the results from these tests. All lab hydraulic conductivities presented herein were measured at 40 kPa, equivalent to the 1.8-2 m overburden the compacted soil layers were subjected to. The entirety of permeability test results are presented by the companion paper by Kim et al. (2024).

Table 1. Hydrogeotechnical properties of tested materials (partly adapted from Kim et al. (2024) and Ritter et al. (2023)). Averages are in parantheses (). DCC = dry crust clay, PFR = press filter residue, CSC = cement stabilised clay.

Parameter	DCC	*PFR*	CSC
Clay content	42-48% (45%)	19-30% (25%)	4.5 – 35% (31%)
Water content	27 – 30% (28%)	31-38% (35%)	23-30% (29%)
Optimum water content	~22-25%	~28-30%	~24-27%
Plasticity index	17 – 22% (20%)	25%	18 – 31% (25%)
Liquid limit	42 – 45% (43%)	53 – 56% (55%)	41 – 65% (53%)
Remoulded shear strength	95 kPa	20 kPa	-
Hydraulic conductivity at 40 kPa	2.4 – 3.0 $\times10^{-10}$ m/s (2.7×10^{-10})	1.0 – 4.9 $\times10^{-9}$ m/s (1.8×10^{-9})	1.9×10^{-7} – 6.2×10^{-10} m/s (4.3×10^{-8})

The used DCC had a clay content of around 45%, a shear strength of around 95 kPa and an average (of 3 oedometer samples) hydraulic conductivity at 40 kPa of 2.7×10^{-10} m/s. The clay content of the PFR varied between 19 and 30%, with an average at 25%. Its shear strength was considerably lower than that of the DCC, with an average of around 20 kPa. Its average hydraulic conductivity (6 oedometer and 2 triaxial samples) was 1.8×10^{-9} m/s. The CSC was characterized by a significant variability of both its geotechnical and hydrogeological properties. For

example, the measured hydraulic conductivity of undisturbed samples from the field (5 oedometer and 2 triaxial samples) was between 6.2×10^{-10} m/s and 1.9×10^{-7} m/s, over 300 times higher.

This heterogeneity may be attributed to the nature of the material, a mixture of cement, cement stabilised clay lumps and non-stabilised natural clay. The various parts were mixed during excavation, handling, and transportation, but seemingly far from homogenised.

2.2 Pilot design, construction and instrumentation

Four test cells were constructed as one continuous final cover about 14 m wide and 35 m long, with a cross-section as shown in Figure 1. A lysimeter, consisting of a permeable gravel placed on top of an impermeable geomembrane with a drain at the bottom, was installed at the base of each cell. All lysimeters were nearly quadratic and varied from about 11.5 m^2 to 14.5 m^2. The percolated water volumes were measured using tipping buckets (Campbell Scientific, 2023). The compacted soil layer was constructed (in three lifts/layers) by laying out the loose materials and compacting with a Cat D6 bulldozer (Caterpillar, 2023). A 13-ton rolling machine was then used to further compact and smoothen the surface of the third lift. The surface of the compacted soil was slightly inclined (approx. 1:16) towards the side of the cells (not towards the neighbouring cell). The compacted soil was covered by a 1.8-2.0 m thick protection layer of crushed limestone against climatic conditions and exterior alterations (freeze/thaw and drying/wetting cycles especially). The four different compacted soil layer designs consisted of (1) the DCC, (2) the PFR, (3) one lift of PFR and two overlying lifts of CSC, and (4) CSC alone.

A tipping bucket and temperature sensor was installed on top of the protection layer to measure the precipitation and air temperature. Teros 12 and 21 sensors (Teros, 2023) and a PT100 temperature sensor were installed at different depths in all cells to monitor temperature, volumetric water content, electrical conductivity, and matric suction. The construction and design of the pilot tests are described in more detail by Ånes et al. (2023).

Daily monitoring data from the 6-month period May 1st to October 31st (2023) were collected and analysed. Measured field percolation was compared with the laboratory characterization conducted on undisturbed samples (Kim et al., 2024).

3 RESULTS

Percolation volumes measured by the tipping buckets were normalised by the lysimeter area and expressed in equivalent millimetres.

The total precipitation during the considered 6-month period was 390 mm. The weather through the period was variable (Figure 2). Only 35 mm of precipitation were recorded in May and June, i.e., 1/5 of the total precipitation for the period. In contrast, July and August were particularly wet with 260 mm in total, while September-October experienced 95 mm. The average temperatures for the three two-month periods were 14.7, 15.9 and 10.9°C, respectively.

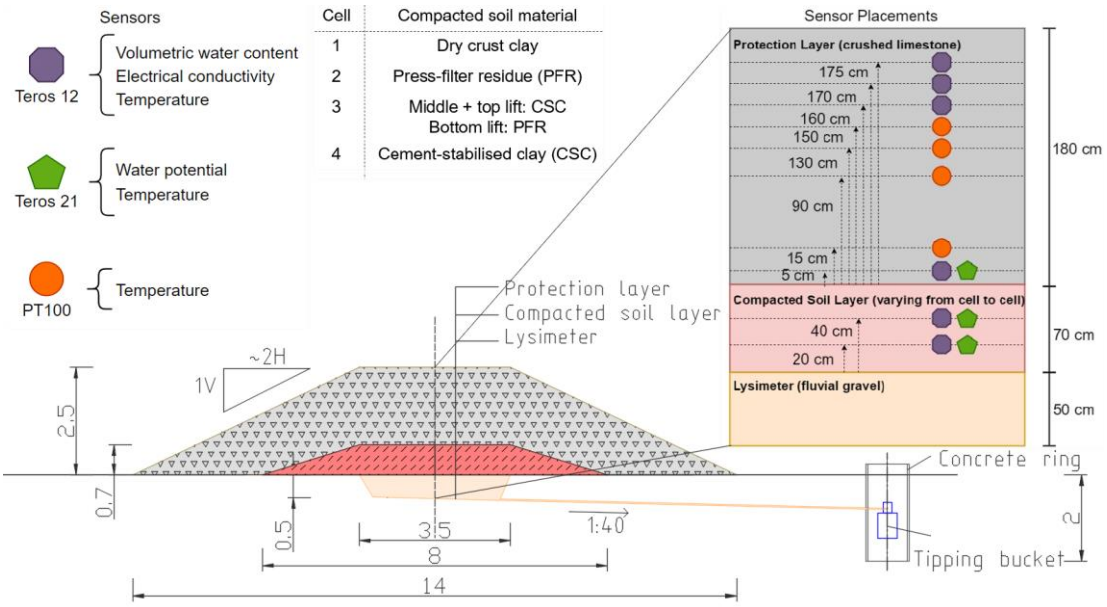

Figure 1. Cross-section drawing of the pilot final cover, including instrumentation. Dimensions for the final cover are in meters. Modified from Ånes et al. (2023).

The percolation through the alternative compacted soil layers (cells 2, 3 and 4) was around 7 mm (1.8% of precipitation), more than 2 times greater than in the cell with DCC (3 mm, 0.8% of precipitation). With an annual precipitation around 1000 mm (2.5 times the recorded precipitation for the monitoring period), the total percolation in cells 2, 3 and 4 was therefore expected to be between 8 and 18 mm/yr, i.e., below the target criteria (Avfall Norge, 2015).

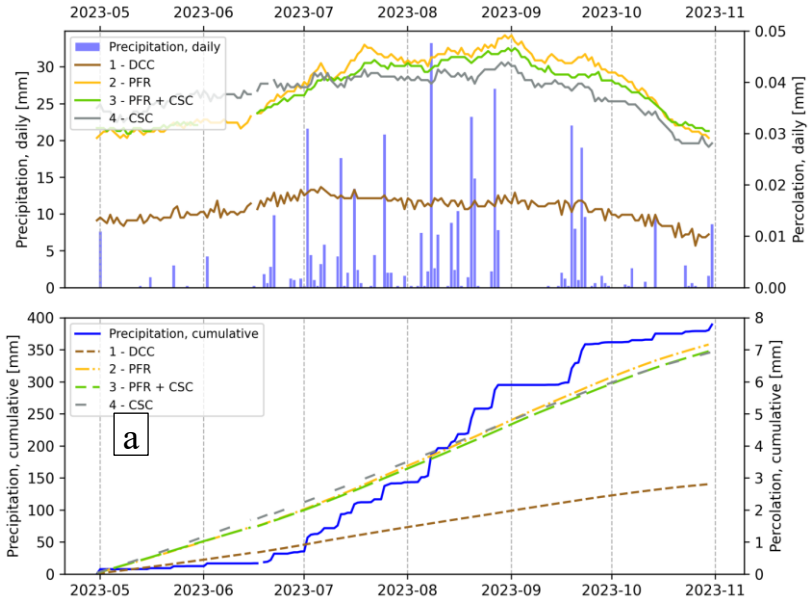

Figure 2. (a) Daily and (b) cumulative percolation and precipitation in each of the instrumented pilot cells from May 1st to October 31st. DCC = Dry crust clay, PFR = Press filter residue, CSC = Cement stabilised clay.

Considering the daily variations (Figure 2a), it may be noted that the effect of precipitation was different for the various compacted soil layers. The percolation through cell 1 plateaued early after the onset of the wet period (beginning of July), whereas the percolation through cell 2 and 3 continued to increase until the end of August when the wet period ended. The percolation in cell 4 varied less than in cell 2 and 3, being higher in the dry period May-June, and lower in July-October. It is not clear what caused this, but differences in material properties and degrees of saturation, and continuous reactions involving cement in the stabilised clay, are possible explanations. Additional tests and analyses are currently ongoing to further investigate potential mechanisms.

The degree of saturation of the compacted soil layers, measured using the water content probes installed in the pilot, was between 85% and 95%. Based on suction measurements, a conservative downward hydraulic gradient of 1 was assumed for all cells, leading to an estimation of the hydraulic conductivity between 2×10^{-10} m/s (cell 1) to around 4×10^{-10} m/s (cell 2-4).

The difference in hydraulic conductivity between the DCC and the PFR and CSC in the pilot was around 2 (towards 3 during the summer and fall), i.e. lower than in the laboratory where the average measured hydraulic conductivity of PFR and CSC were, respectively, 7 and 159 times greater than that of the DCC. The variability of the materials (especially CSC) may at least in part be the cause for these differences between lab and field results. The slightly lower degree of saturation in the field and/or variations in porosity in the laboratory may also be part of the explanation. Further investigations may be required to evaluate if the representativity of the lab samples and their size may be another reason for the observed differences.

4 CONCLUSION

A pilot test has been constructed at a landfill site in Norway to quantify the field-performance of final cover compacted soil layers consisting of various reused clayey soils.

Percolation and precipitation results from May 1st to October 31st showed that all the proposed compacted soil layers had a hydraulic conductivity lower than 1×10^{-9} m/s, and thus satisfied the criteria of hydraulic conductivity for compacted soil layers. The compacted soil layer with dry crust clay had the lowest hydraulic conductivity, which corresponded well with hydraulic conductivity tests conducted in the laboratory (Ritter et al. (2023) and Kim et al. (2024)) as well as with the higher clay content compared to the other materials. The compacted soil layers with the

press filter residues and excavated cement stabilised clay were slightly more permeable than the DCC, but suitable, nevertheless. The hydraulic conductivities of CSC evaluated in the field were notably lower than the lab average, most probably because of the heterogeneity of the materials and scale effects influencing the lab results. Additional lab tests are ongoing to further assess the variations in field and lab, as well as the variation between lab samples of the same material.

ACKNOWLEDGEMENTS

This work was supported by the earthresQue centre for research driven innovation, Rescue of Earth Materials and Wastes in the Circular Economy, partly funded by the Research Council of Norway, project number 310042/F40. The authors thank Taehon Kim, Yusuke Suzuki, Karoline Helen Løvlie and Geir Wold Åsli for all the valuable help with the laboratory work at NGI. Erling Singstad Paulsen, Kristoffer Heian and Ola Paaske Gulbrandsen at the instrumentation group at NGI are also acknowledged for their tedious work with installing sensors as well as facilitating the handling of field data. Lastly, personnel from Kjeldaas entrepreneurs deserve acknowledgement for their skilled and cautious construction of the final cover.

Effect of setback distance of leachate recirculation systems on the slope stability of bioreactor landfills

Effet de la distance de recul des systèmes de recirculation des lixiviats sur la stabilité des pentes des décharges de bioreacteurs

ABSTRACT: The present study investigates the impact of leachate recirculation on stability of landfills by conducting numerical modelling using finite element analysis. The validation of the model was carried out and the results were subsequently compared with the previous literature. The leachate recirculation was simulated using the horizontal trench of 1 m × 1 m. The effect of leachate injection on the pore water pressure and slope stability was examined for heterogeneous and anisotropic waste conditions for various injection pressures and slope configurations. The performance of horizontal trenches with different setback distances varying between 5 m - 50 m for various injection pressures was compared, and their effects on landfill slope stability were evaluated. A setback distance of less than 25 m has a significant impact on landfill stability under high injection pressures, primarily because of the influence of pore water pressure on the slope. The results showed that a factor of safety greater than 1.5 was achieved for the optimum range of setback distance of 30 m - 40 m and was found to be suitable across various injection pressures (49 kPa, 98 kPa,147 kPa, and 196 kPa). The outcomes of the present research would help in better understanding the influence of setback distance of leachate recirculation on slope stability and contribute to the improvement of the design of landfills.

RÉSUMÉ: La présente étude examine l'impact de la recirculation des lixiviats sur la stabilité des décharges en réalisant une modélisation numérique à l'aide de l'analyse par éléments finis. La validation du modèle a été effectuée, et les résultats ont ensuite été comparés avec la littérature précédente. La recirculation des lixiviats a été simulée en utilisant la tranchée horizontale de 1 m × 1 m. L'effet de l'injection de lixiviats sur la pression interstitielle et la stabilité des pentes a été examiné dans des conditions de déchets hétérogènes et anisotropes, pour différentes pressions d'injection et configurations de pentes. La performance des tranchées horizontales avec différentes distances de recul variant de 5 m à 50 m pour différentes pressions d'injection a été comparée, et leurs effets sur la stabilité des pentes de la décharge ont été évalués. Une distance de recul inférieure à 25 m a un impact significatif sur la stabilité de la décharge sous des pressions d'injection élevées, principalement en raison de l'influence de la pression de l'eau interstitielle sur la pente. Les résultats ont montré qu'un facteur de sécurité supérieur à 1,5 a été atteint pour la plage optimale de distance de recul de 30 m à 40 m et s'est avéré adapté à différentes pressions d'injection (49 kPa, 98 kPa, 147 kPa et 196 kPa). Les résultats de la présente recherche contribueront à une meilleure compréhension de l'influence de la distance de recul de la recirculation des lixiviats sur la stabilité des pentes et contribueront à l'amélioration de la conception des décharges.

1 INTRODUCTION

Bioreactor landfills utilize the leachate recirculation mechanism to increase moisture levels, thereby accelerating the biodegradation process and enhancing the stabilization rate of municipal solid waste (MSW). The concept of bioreactor landfills has attracted global interest due to their significant benefits, and they are recognized as an environmentally sustainable approach to waste management (Reddy et al., 2017; Avinash et al., 2023a). Leachate recirculation is facilitated through various leachate recirculation systems (LRS) such as horizontal trenches (HT), drainage blankets, and vertical wells (Reddy et al., 2020; Avinash and Mishra, 2023a). The injection of leachate through HT systems is a preferred choice in new landfills because these can be installed during active landfilling operations without disrupting landfill activities (Avinash et al., 2023b). Leachate injection near the slope has the potential to impact the stability of landfill slopes by leading to the development of excess pore water pressures (PWP). This phenomenon results in a reduction of effective stress, consequently decreasing the shear strength of waste. The failures attributed to excess PWP near

slopes resulting from inadequate leachate operations have been documented in previous studies (Koerner and Soong, 2000). USEPA (2007) recommends a setback distance of 15-30 meters to prevent leachate seepage from side slopes and to ensure the safety of the landfill against slope failure. Giri and Reddy (2014a) investigated the influence of waste anisotropy and heterogeneity under various injection pressures on moisture and PWP distribution within the landfill, as well as its effect on stability. Xu et al. (2012) investigated the impact of pressurized leachate injection on landfill stability under different operational strategies. These include variations in the permeability of MSW with depth, high injection pressures, low permeable cover within the landfill body, and clogging of the leachate extraction system. Based on previous studies, it is evident that the effect of PWP generated from the LRS significantly affects slope stability. Furthermore, limited research is available on the investigation of the setback location for injection in relation to injection pressures and the configuration of landfill slopes.

This study conducts a numerical modelling to investigate the influence of setback distance on the landfill stability. Further, the influence of variation in MSW properties with depth, side slope, and injection pressures were also investigated. The leachate recirculation was performed using a HT system. The optimum setback distance was proposed based on the observations of PWP distribution and its effect on landfill slope.

2 MODELLING

2.1 Landfill Geometry

A two-dimensional numerical analysis was conducted for a 50 m high bioreactor landfill with two landfill configurations (1V:4H, 1V:3H). The landfill model was assumed to be symmetric, and the MSW within the landfill cell was layered with a thickness of 5 m for all ten layers. The landfill widths for the two different slope configurations were 240 m and 190 m, respectively. It was assumed that the leachate collection and removal system (LCRS), which had a thickness of 0.3 m and comprised free-draining granular soil, would be situated at the base of the landfill. In this study, the leachate recirculation was simulated by using a HT of 1 m × 1 m and was assumed to be filled with gravel. The HT system was positioned at a height of one-third of the overall height measured from the landfill surface (Avinash and Mishra, 2023b). The setback distance of the LRS from the slope, which varied from 5 m – 50 m was installed in each numerical simulation.

2.2 Numerical Model

The numerical modelling of landfill stability and leachate infiltration was carried out using GeoStudio to observe the changes in landfill stability and PWP. The infiltration using transient analysis was carried out for a run time of five years in SEEP/W. The boundary conditions type was chosen as hydraulic for landfill modelling. Zero flux was assigned to the landfill bottom, side slope, and top surface to simulate the impermeable boundary. The leachate extraction from LCRS was simulated by using the zero-pressure head. In this study, the Morgenstern-Price method was employed for stability calculations because of its ability to satisfy both force and moment equilibrium conditions of the selected slip surface. Figure 1 shows the bioreactor landfill configuration with boundary conditions for a slope of 1V:3H.

2.3 Input Parameters

The landfilled waste considered for modelling was heterogeneous and anisotropic. The variation in hydraulic conductivity and unit weight with depth was modelled based on relationships proposed in earlier studies, which account for the increase in effective stress caused by overlying MSW layers in simulating the heterogeneous and anisotropic waste (HTAW) conditions (Zekkos et al., 2006; Reddy et al., 2009). These properties of MSW are shown in Figure 1 (Giri and Reddy, 2014b). Unsaturated properties considered for modelling were taken from the previous literature (Breitmeyer and Benson, 2011). The anisotropy of 10, shear strength parameters (friction angle 35°, cohesion 15 kPa), and the properties of the granular material used in LCRS were taken from the previous literature (Xu et al., 2012).

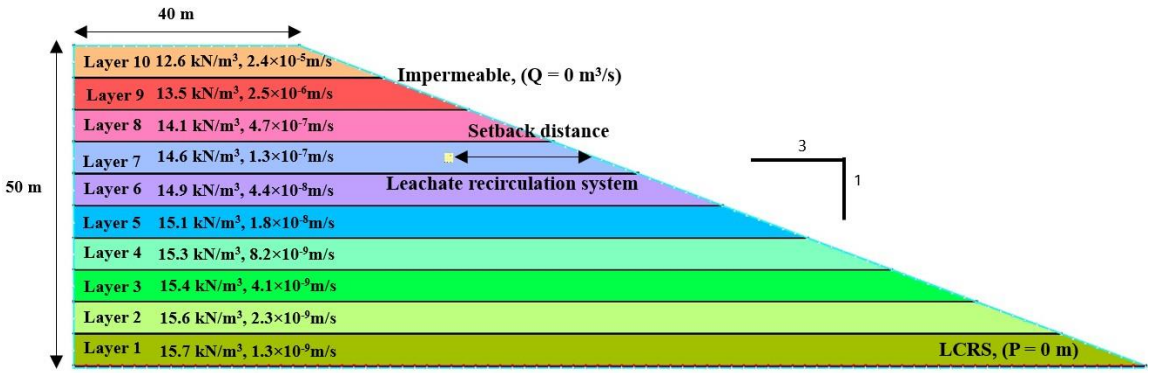

Figure 1. Bioreactor landfill configuration with HT under HTAW conditions.

The pressurized injection was simulated by using water pressure heads ranging from 5 m - 20 m, corresponding to pressures of 49-196 kPa. Table 1 shows the landfill geometry and parameters considered for modelling the leachate recirculation using the HT system.

Table 1. Details of numerical analysis conducted in this study.

Parameter	Value
Slope configuration	1V:3H, 1V:4H
Landfill height (m)	50
Landfill width (m)	190, 240
Setback distance	5-50 m with an interval of 5 m
Injection pressure (kPa)	49, 98, 147, and 196

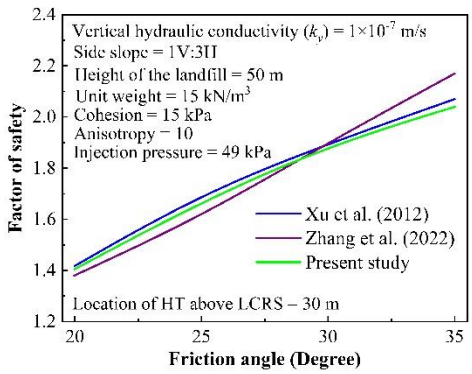

Figure 2. Comparison of FOS for various friction angles of the present study with previous literature.

3 RESULTS

3.1 Validation of Model

The landfill geometry of the numerical model was validated for slope stability under homogeneous anisotropic waste conditions. The leachate injection was conducted using the HT system with an injection pressure of 49 kPa over a 10-year period. The results of factor of safety (FOS) of the present study were compared with the previous studies as shown in Figure 2 (Xu et al., 2012; Zhang et al., 2022). The results were in good agreement with Xu et al. (2012) and a deviation of 6 % with Zhang et al. (2022) was observed due to the difference in computational software and analysis.

3.2 Pore Water Pressure

The monitoring of PWP is an important aspect of bioreactor landfill operations. The magnitude of the injecting pressure varies depending on the type and location of the injecting system. Figure 3 shows the contour of PWP distribution resulting from leachate injection using the HT system.

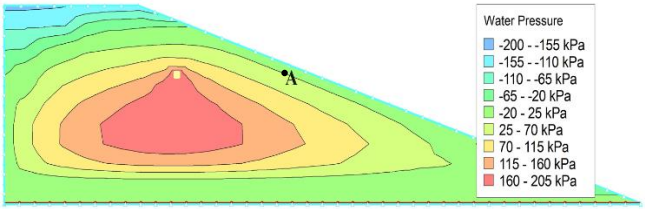

Figure 3. Results of PWP distribution contours due to leachate recirculation.

The observations of PWP were taken at point A, as shown in Figure 3, which is located 5 m from the side slope towards the injection system for all the cases. This location is chosen to monitor the distribution of PWP near the slope in order to safeguard landfill stability and manage lateral seepage effectively for bioreactor landfill operations through pressure control. The maximum PWP was observed at point *A* for the low setback distance of 5 m from the slope and tends to decrease as the setback distance increases. Figure 4 shows the distribution of PWP with time for the different setback distances (10 m, 20 m, 30 m, and 40 m) considered in this study. The PWP distribution observations were found to be nearly the same for both slope configurations. The decrease in PWP as we move away from the injected location is because of the anisotropic nature of the MSW considered in this

study. It was observed that over 85% of the PWP was dissipated upon reaching point *A* for setback distances greater than or equal to 30 m.

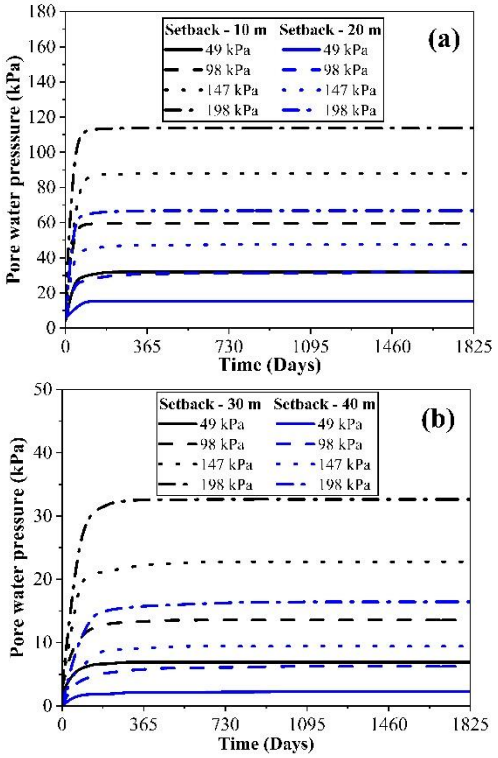

Figure 4. Comparison of PWP with time for various setback distances (a) 10 m and 20 m (b) 30 m and 40 m.

3.3 Slope Stability

Table 2 demonstrates the effect of leachate injection through the HT system on landfill stability by varying the setback distances for all the modelled cases. Figure 5 shows the variation in FOS over time for setback distances of 30 m and 40 m, as they undergo varying injection pressures for various landfill slope configurations. The variation in the stability of landfills is due to changes in the distribution of PWP. The results of this study regarding leachate injection in bioreactor landfills are specifically relevant when the stability design adheres to the safety limit FOS≥1.5, as suggested by Giri and Reddy (2014c) for executing safe landfill operations. The FOS observations in Table 2 indicate that setback distances of 25 m or less are unsuitable for high injection pressures of 147 and 196 kPa, primarily due to the influence of PWP on the slope. However, this influence of PWP decreases with an increase in setback above 25 m, and the recommended safety limit is achieved for any injecting pressure in both slope configurations. The FOS exhibited a notable increase from 0.5 to 1.9, when the setback location was adjusted from 5 m – 50 m, while maintaining an injecting pressure of 196 kPa.

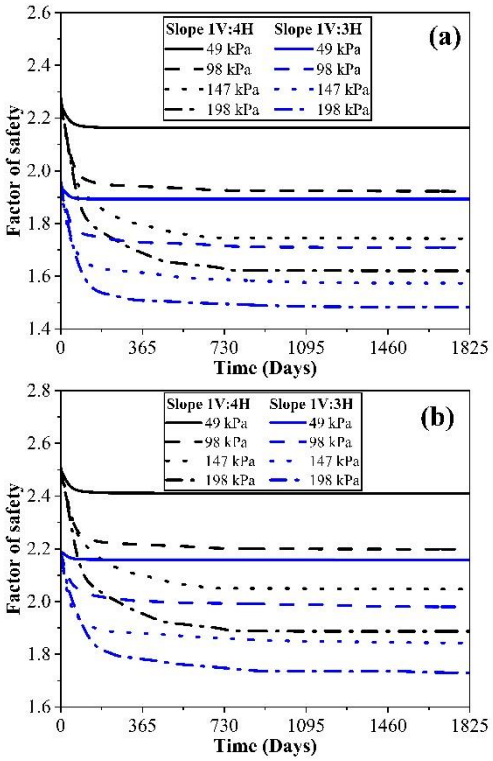

Figure 5. Factor of safety with time (a) setback 30 m (b) setback 40 m.

Therefore, the setback location of injection system proves to be a critical factor in regulating the FOS. The outcomes of the present study suggest that setback distances of 30 m – 40 m are sufficient to carry leachate recirculation in landfill operations.

Table 2. Comparison of FOS for different landfill slope configurations.

Set-back (m)	1V:4H				1V:3H

50	2.6	2.3	2.2	2.0	2.3	2.1	2.0	1.9

4 CONCLUSIONS

In the current study, a numerical modelling was carried out to investigate the impact of PWP on landfill slope stability. The analysis also includes the variations in the side slope configuration and injecting pressures. The conclusions of the present study are as follows.

The PWP in the observed point *A* decreases as the setback distance increases, significantly improving the landfill stability. Furthermore, the slope configuration plays a crucial role in stability, and it is not recommended to provide slopes steeper than 1V:3H. High injecting pressures should not be used for setback distances less than 25 m in leachate recirculation. However, the results of FOS reveal that changing the setback location from 5 m to 50 m enhances the stability of the landfill by 25-75% in relation to the recommended limit, and the required performance is achieved with setbacks greater than or equal to 30 m for all injecting pressures under leachate recirculation. Therefore, this study recommends an optimum setback of 30 m - 40 m for leachate recirculation, making it suitable even for high leachate injecting pressures in conjunction with steep slopes of 1V:3H.

ABSTRACT: This study addresses the effect of saline water on the strength of Pacheco Beach sand, located on the northeast coast of Brazil. Although several studies in the literature deal with the influence of saline water on the behavior of soils in coastal areas, information regarding the behavior of Brazilian coastal sands is scarce, justifying the need for this current research. The study is particularly important for maritime works, such as foundations for offshore wind towers in new exploration potential areas like the northeast coast of Brazil. For this purpose, two samples were collected and subjected to characterization tests and direct shear tests at normal stresses of 50, 100, and 200 kPa. The specimens were saturated with distilled water and saline water for the loose state. The results demonstrate that the presence of salts in water significantly influences the shear strength of sands, as well as the values of friction angles, indicating alterations in the mechanical properties of these soils. In direct shear tests, saturating a sample in saline water resulted in a 6% increase in friction angles compared to samples saturated in distilled water.

RÉSUMÉ: Cette étude aborde l'effet de l'eau salée sur la résistance du sable de la plage de Pacheco, située sur la côte nord-est du Brésil. Bien que plusieurs études dans la littérature traitent de l'influence de l'eau salée sur le comportement des sols dans les zones côtières, les informations concernant le comportement des sables côtiers brésiliens sont rares, justifiant ainsi la nécessité de cette recherche actuelle. L'étude est particulièrement importante pour les travaux maritimes, tels que les fondations des tours éoliennes en mer dans de nouvelles zones à fort potentiel d'exploration comme la côte nord-est du Brésil. Dans ce but, deux échantillons ont été prélevés et soumis à des tests de caractérisation et des tests de cisaillement direct à des contraintes normales de 50, 100 et 200 kPa. Les spécimens ont été saturés d'eau distillée et d'eau salée pour l'état lâche. Les résultats démontrent que la présence de sels dans l'eau influence significativement la résistance au cisaillement des sables, ainsi que les valeurs des angles de frottement, indiquant des altérations dans les propriétés mécaniques de ces sols. Dans les essais de cisaillement direct, la saturation d'un échantillon dans de l'eau salée a entraîné une augmentation de 6% des angles de frottement par rapport aux échantillons saturés dans de l'eau distillée.

Keywords: Coastal soils; saline water; direct shear tests; salinity influence.

1 INTRODUCTION

Knowledge about the variables that can affect soil strength plays an extremely important role in geotechnical engineering. One of the key properties governing structure stability is the soil's shear strength, influenced by several factors, including soil genesis, particle distribution and shape, degree of preconsolidation, saturation level, as well as the nature of the fluid present in the subsurface.

It's worth noting that the water saturation level of soils is subject to constant changes due to seasonal activities, climate variations, and numerous human interventions that can alter the physical, chemical, and mechanical properties of the soil. Studies indicate that the solution's pH strongly influences the geotechnical characteristics of the soil (Osuolale et al., 2012; Sunil, et al., 2006). Rahman and Nahar (2015) demonstrated that the shear strength of sandy soil increases with an increase in the soil's pH value. Moreover, the type and

concentration of the solution affect the soil's shear properties (Naeini and Jahanfar, 2011).

As noted by several studies, the presence of saline solution in the soil increases shear strength (Ajalloeian et al., 2013; Elsawy and Lakhouit, 2020; Geng et al., 2022) and frictional resistance (Geng et al., 2022; Taha and Fall, 2014). However, other studies indicate that this shear strength increases to a certain point and then decreases afterward, as highlighted by Naeini and Jahanfar (2011) and Wilson and Vasudevan (2021).

Regarding the effect of seawater on the consistency limits of clayey soils, there are discrepancies in the literature: Mahasneh (2004) observed an increase in liquid and plastic limits with the use of saline water. However, according to Nguyen et al. (2019), the liquid and plastic limits decrease when the soil is submerged in seawater. Arasan and Yetimoglu (2008) state that high saline concentrations can either reduce or increase the plastic limit depending on the clay classification.

Concerning water salinity, numerous studies analyze the influence of saline solution on soil (Emami Azadi, 2008; Mahasneh, 2004; Tiwari et al., 2005; Yukselen-Aksoy et al., 2008). However, in Brazil, particularly in coastal regions, there is a scarcity of studies addressing this issue, highlighting the need for additional research to fill this knowledge gap.

Therefore, it's observed that the presence of salinity significantly influences the resistance properties and behavior of soils. This factor should be further analyzed, especially concerning coastal, maritime, and offshore structures, which are directly subjected to saline water. Even in these cases, such as in maritime construction projects during the foundation design phase, shear tests are commonly conducted only with distilled water, which may not accurately represent the soil's actual behavior. In this regard, this study investigates the resistance of coastal sand under the influence of saline water compared to distilled water through direct shear tests.

2 MATERIALS AND METHODS

The studied sands were collected from the northeastern coast of Brazil, specifically at Pacheco Beach, in the municipality of Caucaia, Ceará. The tests were conducted on disturbed samples, and for the direct shear tests, the specimens were reconstituted. Initially, characterization tests were performed, determining the maximum and minimum void ratios, X-ray fluorescence, and determining the pH of the saline water (collected from the sea at the same location as the soil collection). It is important to note that distilled water is free from salts and any impurities, with a neutral pH (close to 7), while seawater is naturally saline and composed of various salts.

To study the influence of water salinity, 12 direct shear tests were conducted on two samples of Pacheco soil, PCH1 and PCH2, in their loose state, that is, with void proportions close to the maximum value. Six tests used distilled water, and six used saline water, under normal tensions of 50, 100, and 200 kPa. Additionally, three direct shear tests were performed on PCH2 samples saturated with saline water in the compacted state. In this procedure, the soil sample was previously saturated in either saline (S) or distilled (D) water before being subjected to shear stress under a determined rupture plane, with controlled normal tension. The rupture speed was adjusted to 0.2 mm/min to ensure effective drainage during the shear test.

3 RESULTS AND DISCUSSIONS

3.1 Soil properties

Samples PCH1 and PCH2 are classified as well-graded sand (SW) and well-graded sand with silt (SW-SM), respectively, according to the Unified Soil Classification System (USCS). The particle size distribution curve are presented in Figure 1. The elemental composition of the samples obtained from the X-ray fluorescence test can be verified in Table 1, and the geotechnical characterization is presented in Table 2. The pH of the collected seawater showed a more alkaline content with a value of 7.48.

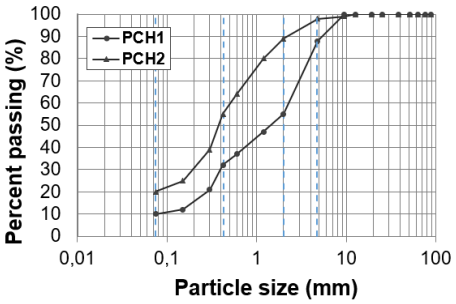

Figure 1. Grain size distribution curves of Pacheco sand (PCH1, PCH2).

3.2 Direct shear test

3.2.1 Saline water effect

In Figures 2(a) and 2(b), the stress-strain curves of shear stress versus horizontal displacement of samples (PCH1 and PCH2, respectively) saturated with saline water and distilled water are compared. It can be observed that sample saturation with saline water resulted in higher shear stresses for both samples and

studied stress levels, supporting the results presented by Tiwari et al. (2005).

Table 1. Mineralogical composition of Pacheco Sands (samples PCH1 and PCH2).

Composition (%)	PCH1	PCH2
Al_2O_3 - Aluminum Oxide	14.89	15.51
SiO_2 – Total Silica	52.55	52.32
dFe_2O_3 – Oxide of iron	2.99	3.78
K_2O - Potash	2.96	3.07
Rb_2O - Rubidium Oxide	1.64	-
SrO - Strontium Oxide	1.12	-
Ta_2O_5 - Tantalum Pentoxide	-	0.96
CaO - Lime	0.89	0.85
TiO_2 – Oxide of Titanium	0.78	0.85
Cl - Chlorine	0.54	0.36
P_2O_5 - Phosphorus Pentoxide	0.4	0.42
ZrO_2 - Zirconium Dioxide	0.17	0.15
MoO_3 - Molybdenum Trioxide	0.21	-

Table 2. Geotechnical properties (PCH1 and PCH2).

		PCH1	PCH2

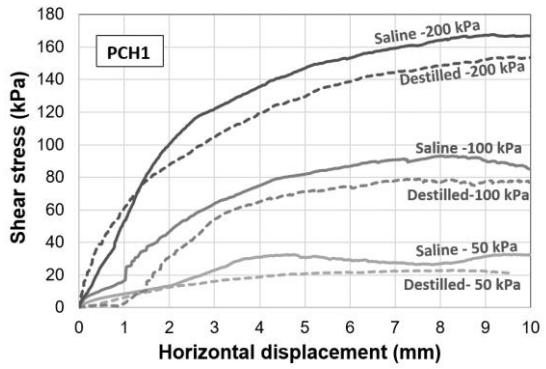
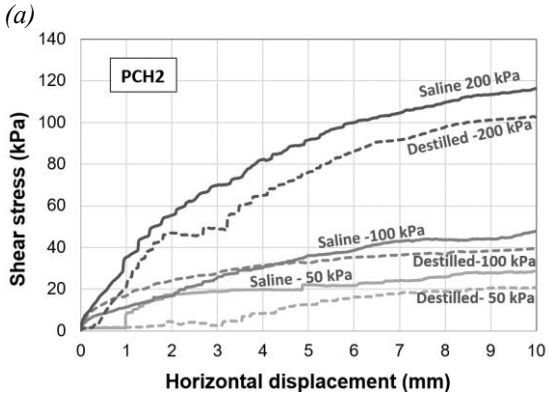
Maximun void ratio ($e_{máx}$)	-	0.78	0.81
Minimun void ratio ($e_{mín}$)	-	0.53	0.52
Specific weigth ($\rho_{mín}$)	g/cm³	1.51	1.51
Specific weigth ($\rho_{máx}$)	g/cm³	1.69	1.8



(a)



(b)

Figure 2. Variation of the shear strength versus horizontal displacement, of samples saturated with saline water and distilled water in the loose state (a) PCH1 (b) PCH2.

In the analysis of the rupture envelopes presented in Figure 3, it is observed that there was no significant variation in the friction angle for the PCH1 sample with the use of saline water. However, for the PCH2 sample saturated with saline water, there was an increase of 6% in the friction angle compared to saturation in distilled water, with values of 31° and 29°, respectively. These results indicate a possible influence of salinity on the shear strength of the soil, which is especially relevant in coastal and maritime works. Furthermore, it is important to highlight that this analysis refers to low normal voltages. It is also observed an increase in the difference in shear stresses between samples saturated with saline water and distilled water as the normal stress increases. Therefore, it is necessary to carry out studies at higher normal stresses to confirm this trend and to evaluate its impact on more sensitive geotechnical applications.

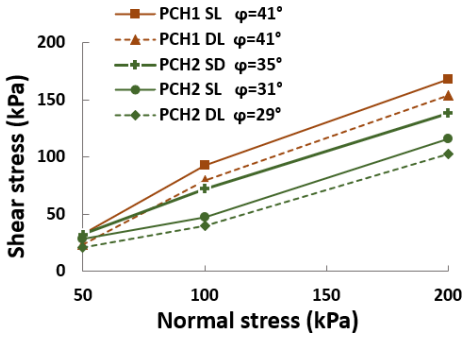


Figure 3. Rupture envelope of samples PCH1 and PCH2 saturated in saline water (S) and distilled water (D) in the loose (L) and dense (D) states.

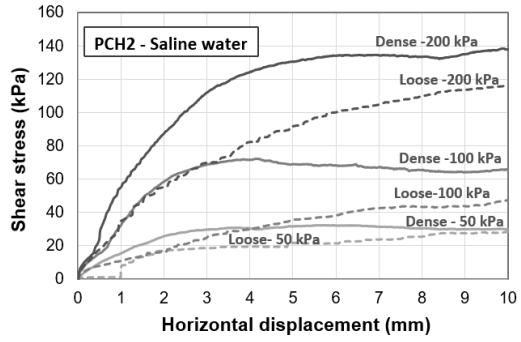
3.2.2 Saline water effect on relative compaction

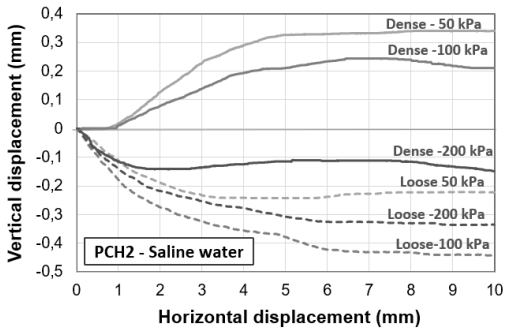
In Figures 4(a) and 4(b), the results of the direct shear test for sample PCH2 saturated in saline water, in loose and compact states, can be observed. It can be seen that for the normal stress of 200 kPa, both the dense and loose states behaved similarly, showing a reduction in vertical displacement. As expected, the most compacted soil exhibited a 13% increase in friction angle compared to the loose soil (Figure 3), with 35° for the dense state and 31° for the loose state.

4 CONCLUSIONS

This study addressed the impact of water salinity on the shear strength properties of the soil, based on direct shear tests. The results revealed an increase in the friction angle of samples saturated in saline water compared to distilled water. Specifically, one of the samples showed a 6% increase in the friction angle when saturated in saline water.



(a)



(b)

Figure 4. Sample PCH2 saturated in saline water in loose and dense states (a) Variation of shear strength versus horizontal displacement, (b) Variation of vertical displacement versus horizontal displacement.

Furthermore, the results point to a greater influence of water salinity at higher normal stresses, which is evidenced by the observed increase in the difference between the shear stresses of samples saturated in saline water and distilled water as the normal stress increases. It is of fundamental importance, however, to conduct more studies under higher normal stress conditions to confirm this trend, especially for coastal and marine geotechnical works.

Thus, it is necessary to carefully consider water salinity in soil behavior, especially when designing geotechnical structures exposed to salt water, aiming to guarantee the safety and durability of these structures in marine environments.

ACKNOWLEDGEMENTS

This study received financial support from the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior – Brasil (CAPES) – through Finance Code 001 – and the Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq). The authors express their sincere appreciation for the generous funding provided by PETROBRAS. Special thanks are also extended to the postgraduate program in the DEHA department at Universidade Federal do Ceará (UFC) for their invaluable support.

Laboratory of Soil Mechanics (LMS), Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

**svetlana.babiy@epfl.ch*

ABSTRACT: One of the major factors controlling behavior of clays is their chemical structure. Active clays in particular are notable for their high-swelling and hydro-isolating properties, which make them valuable in various geotechnical applications, including deep repositories for nuclear waste and landfills. The properties mentioned above arise from the water that is physically attracted to clay particles. This water, often described as "adsorbed" or "physisorbed," can exhibit an ordered structure, greater density, and a distinct dielectric constant compared to water in its bulk liquid form. The attracted water is influenced – among other factors – by salinity of the pore water, degree of saturation, temperature of the waste repositories. The mechanical response of the material, like swelling upon hydration, can be predicted by advanced modelling approach accounting for the physical-chemical interactions between water and clay particles. Such complex multi-physical predictions require precise microstructural investigations, which are critical for understanding the active clays behavior. This work proposes a novel methodology for quantitatively assessing the adsorbed water in active clays using Thermogravimetric Analysis (TGA). Following the proposed methodology, new insights into the types and amounts of water retained at various saturation levels of MX-80 bentonite are provided. These insights can be integrated into mechanical prediction models to enhance their accuracy.

RÉSUMÉ: La structure chimique des argiles est un facteur clé dans la compréhension de leur comportement. Les argiles actives se distinguent par leur capacité à gonfler et à isoler l'eau, ce qui les rend utiles dans diverses applications géotechniques, notamment le stockage souterrain des déchets radioactifs et autre projets d'enfouissement. Ces propriétés sont dues à la forte interaction et attraction entre l'eau et les particules d'argile. Cette eau, qualifiée d'"adsorbée" ou de "physio-absorbée ", possède des caractéristiques différentes de l'eau libre, notamment une structure ordonnée et une densité plus élevée. Les propriétés de l'eau attirée sont notamment influencées par la salinité, le degré de saturation et la température des dépôts de déchets. Une approche de modélisation avancée prenant en compte les interactions physico-chimiques entre l'eau et les particules d'argile permet de prédire le comportement mécanique du matériau. Le développement d'un modèle multi-physique complexe nécessite une étude poussée de la microstructure des argiles, essentielle à la compréhension du comportement des argiles actives. Cette étude propose une nouvelle méthodologie utilisant l'analyse thermogravimétrique (TGA) pour quantifier l'eau adsorbée dans les argiles actives. Elle permet notamment une meilleure quantification de l'eau retenue dans la bentonite MX-80 à différents degrés de saturation, ainsi qu'une caractérisation du type d'eau. Ces informations peuvent être intégrées dans les modèles de prédiction mécanique pour améliorer leur précision.

Keywords: Bentonite; expansive clay; adsorbed water; thermogravimetry.

1 INTRODUCTION

Bentonite is a widely used material in waste disposal, (Laine, Karttunen, 2010). Its favorable properties for waste disposal include swelling and reduced hydraulic permeability upon wetting, preventing the migration of contaminants from waste disposals. Bentonite acts as a "seal" for nuclear waste (Pusch et al. 1998; Laine, Karttunen, 2010).

Presence of salts in the environment affects physicochemical interactions between clay particles and bulk water, leading to changes in hydro-mechanical behavior, such as decreased swelling and increased permeability (Slade, 1991; Likos, 2004; Tester et al, 2016). However, those interactions are not fully understood (Wang et al, 2020).

Understanding water adsorption in clay is vital for assessing changes in mechanical properties. Existing modeling approaches allow predicting hydration isotherms of bentonite by combining different mechanisms connected to types of water adsorbed

(e.g., Wang et al, 2022). Existing experimental assessments of adsorbed water are limited to platelets spacing assessment by X-Ray Powder Diffraction (XRPD) and it is assumed the space between platelets is filled with water. Moreover, XRPD requires fine powders and is unable to detect amorphous structure (such as water or randomly located surface cations) (Cockcroft and Fitch, 2008).

Montmorillonite, a key mineral in bentonite, attracts water in two forms: tightly bonded crystalline hydrates and weakly bonded osmotic hydrates. Mercury Intrusion Porosimetry (MIP) is unable to capture crystalline hydration (e.g. Norrish, 1962), occurring at humidities above 25% (Cases et al, 1992). Additionally, at low humidity levels, most of the surface area remains vacant from water layers.

Thermogravimetric Analysis (TGA) is a technique that allows to obtain the change of mass of a small specimen as a function of temperature (dynamic heating) or time (Tajeddine et al, 2015). Each temperature level corresponds to the energy needed for sublimation/evaporation of certain molecules in the sample (Vieillard, Tajeddine L, 2015). Thus, higher-level bonds removal would be visible at a higher temperature.

In case of clays, similar processes were distinguished to take place in kaolinite, montmorillonite, saponite and other clay minerals during heating from 30°C to 950°C: first step – evaporation of adsorbed water; second one – dehydroxylation – the release of structural OH in the form of water molecules, third – silica phase transformation. It is generally assumed that by the start of dehydroxylation no adsorbed water is left (Vieillard et al, 2016; Saadatkhah et al, 2020, Zeng et al, 2022), however, that assumption remains not proved. Additionally, there is no consensus between authors on the temperature levels when all adsorbed water is removed.

Discrepancies between water retention mechanisms in literature require development of new experimental tools capable of detecting water-clay particle interactions at the nanoscale across different chemo-hydro-mechanical states. These tools are essential for later implementation into accurate modeling approaches.

In the present contribution, a new methodology for quantifying the different types of water retained by active clays is proposed. The proposed methodology involves using thermogravimetric analysis (TGA) on active clay specimens at different hydration stages, as well as using TGA on water samples having the chemical composition of the active clay specimens of interest.

2 MATERIALS AND METHODS

2.1 Tested material

Bentonite MX-80 mixture was obtained by mixing the grains of fractions up to 4 mm with Fuller granulometry distribution. Smectite content of the material is 85%, Specific Surface Area (SSA) is 523m^2/g, specific gravity 2.74 (Seiphoori et al, 2014). Liquid and plastic limits are 544% and 110% respectively. Hygroscopic water content of the resulting mixture under laboratory conditions (imposed total suction 140 MPa, T=25°C) is 5.9%, dry density – 1.3 Mg/m^3.

2.2 Methodology

The proposed methodology involves, after an initial specimen preparation phase, performing TGA on clay and water samples (using the same heating programme for all samples). A comparison of the temperature-water content curves of the clay specimens and of the water specimens reveals the temperature ranges required to remove a certain type of retained water and allows the corresponding water content to be quantified.

2.2.1 Hydration procedure

Bentonite was placed into 3 “Microcells” (cells made of brass able to create constant volume conditions with small openings) for confined hydration in desiccators with the imposed total suction values of 1, 26, 59 MPa (D, C, B states on Figure 1a.) Total suction of bentonite was measured by WP4C dew point chilled-mirror potentiometer (Leong et al, 2003). Total suction value of 1 MPa was measured on fully saturated bentonite (saturation was performed in Microcell in a chamber with water pressure 2.5 MPa for 2 days until no change in water volume in the pump was observed).

2.2.2 Thermogravimetric analysis

Experimental part of TGA consists of 2 sub-parts: testing of bentonite samples and of distilled water (Figure 1b).

Bentonite samples, taken immediately after opening microcells, are put in ceramic crucibles in the heating chamber of a Perkin Elmer TGA 4000 apparatus (Figure 1c). The following heating (for all heating steps the rate is 10°C/min) is adopted: (i) isothermal step for 1 min at 30°C for equilibration; (ii) heating from 30 to 80°C; (iii) isothermal step for 15 min at 80°C; (iv) heating from 80 to 950°C; (v) isothermal step 1 min at 950°C. Bentonite samples included also those oven-dried (105°C) for more than 1 month to ensure the evaporation of all water in the

sample. These long-dried samples are taken as reference state later in the analysis.

Water samples are put into crucibles in a form of a drop using syringe. The initial mass varied from 2mg to 21mg (Figure 1d). The following heating program is adopted: (a) isothermal step for 1 min at 30°C; (b) heating from 30 to 80°C; (c) isothermal step at 80°C; (d) heating from 80 to 150°C.

2.2.3 Accuracy of measurements

The Perkin Elmer TGA 4000 apparatus makes measurements with accuracy of the balance 0.01% (for most of samples 0.005mg), temperature accuracy 0.8°C.

Additionally, the influence of total mass of sample and granulometry on accuracy was measured. Mass of samples influences the first part of the normalized curves (30...450°C) with coefficient of variation 0.53% (standard deviation 0.57%). Granulometry of the sample influences predominantly the part between 600 and 800°C with coefficient of variation 0.42%, standard deviation 0.4%.

2.3 Results analysis

The experimental results are analyzed implementing the following procedure: (i) normalization of all bentonite TGA curves with respect to the final mass; (ii) combination of water evaporation curve with the long-dried sample TGA curve (Figure 1e), representing the change of mass of bentonite without adsorption phenomena; (iii) difference between the actual sample with adsorbed water and the modelled curve. The combined curve is modelled in a way that it has the same water content as the samples in hydration path (Figure 1a), in this way, the only difference between actual and modelled curve is the mass of water bonded to clay platelets. That mass is expressed as the mass of water per unit mass of dry clay on Figure 1f (the normalisation changed to initial mass for interpretation of results).

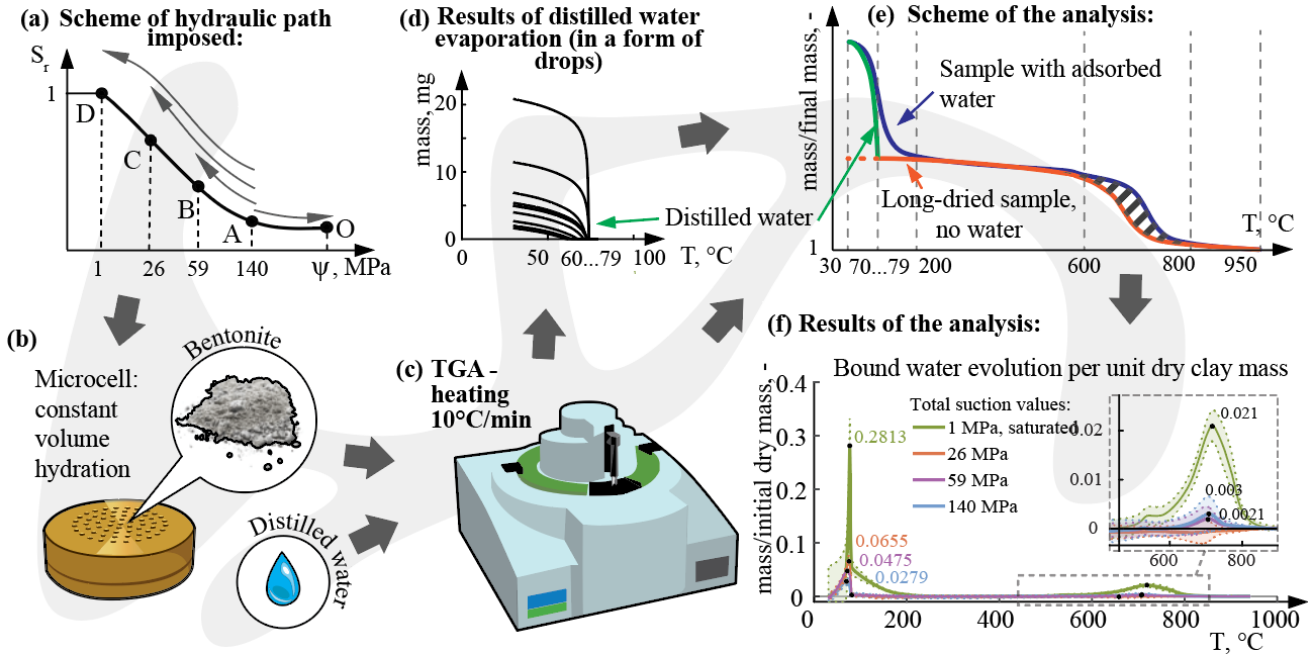

Figure 1. Methodology and results of the present work.

3 RESULTS AND DISCUSSIONS

Figure 1f represents the results of presented methodology. Two main regions could be identified: (i) 30...200°C with sharp peaks at around 80°C and (ii) 600°C...800°C with peaks starting from 0 to 0.021. The first region of the difference represents the water bonded to clay, thus, this region corresponds to adsorbed water (bulk water was removed by difference operation). According to the second region, the states of total suction 26, 59 and 140MPa show peaks of around zero, and the saturated sample has a higher value of 0,021. That fluctuation most probably corresponds to the change of fabric during saturation, as the accuracy evaluation due to granulometry was the highest at similar temperature zone. As samples from the mixture were picked randomly, most probably the variation in grain size and in the amount of water retained by big and small grains resulted in scatter data. Therefore, this methodology should be targeted on the grain size of interest.

Overall, the values of adsorbed water obtained in present analysis is similar to some of the other methodologies (Warr and Berger, 2007 reported half of water stored in adsorbed form). On Figure 2 the interpretation of results is presented in a form of soil water isotherm, representing the water types' amounts change upon hydration (capillary and adsorbed).

4 CONCLUSIONS

In present work a novel thermogravimetric methodology for experimental quantification of adsorbed water was developed for the first time. The advantage of this methodology lies in its reliance on energy-based measurements.

It was found that the adsorbed water and capillary water are present simultaneously and vary upon hydration. The abovementioned water types were quantified and a water isotherm was presented based on the findings. The results were presented as a soil water isotherm.

Investigating foundation damping for OWTs using small strain hardening model calibrated with element scale tests

Étude de l'amortissement des fondations pour les OWT à l'aide d'un modèle d'écrouissage aux petites déformations calibré avec des tests à l'échelle des éléments

M. Barzan*, S. Kasyap, D. Igoe

ABSTRACT: Offshore wind turbines (OWTs) are subjected to cyclic excitations from the environmental and mechanical loads which control the fatigue lifetime of the structural components and can govern the overall design optimisation of the OWT. The growth of OWT size in recent years has led to a greater need to accurately quantify the different sources of damping that significantly influence the dynamic response of offshore wind turbines. Incorporating total damping in integrated numerical analysis will yield more realistic values of structural loads and bending moments which can be used to produce cost effective structural support design for modern size OWTs. One source of damping that is often overlooked is the contribution of the foundation to attenuate the dynamic response through the hysteretic behaviour of the surrounding soil. Thus, this research aims to accurately calculate the global foundation damping for a reference 15 MW OWT through calibrating a constitutive soil model to cyclic triaxial tests, and then implementing full 3D finite element FE analyses to capture the evolution of soil damping with monopile displacement at the mudline level. The small strain hardening soil model (HSsmall) was chosen due to its capability to exhibit non-linearity and stress-strain loops upon load reversals. Time domain free-decay analyses are executed in order to evaluate soil damping through logarithmic-decrement approach.

RÉSUMÉ: Les éoliennes offshore (OWT) sont soumises à des excitations cycliques dues à des charges environnementales et mécaniques qui contrôlent la durée de vie en fatigue des composants structurels et peuvent régir l'optimisation globale de la conception de l'OWT. La croissance de la taille des OWT ces dernières années a conduit à un besoin accru de quantifier avec précision les différentes sources d'amortissement qui influencent de manière significative la réponse dynamique des éoliennes offshore. L'intégration de l'amortissement total dans l'analyse numérique intégrée produira des valeurs plus réalistes des charges structurelles et des moments de flexion qui pourront être utilisées pour produire une conception de support structurel rentable pour les OWT de taille moderne. Une source d'amortissement souvent négligée est la contribution de la fondation à atténuer la réponse dynamique via le comportement hystérétique du sol environnant. Ainsi, cette recherche vise à calculer avec précision l'amortissement global des fondations pour un OWT de référence de 15 MW en calibrant un modèle de sol constitutif pour des essais triaxiaux cycliques, puis en mettant en œuvre des analyses FE par éléments finis 3D complètes pour capturer l'évolution de l'amortissement du sol avec le déplacement du monopile au niveau du sol. niveau de la ligne de boue. Le modèle d'écrouissage aux petites déformations (Hssmall) a été choisi en raison de sa capacité à présenter des boucles de non-linéarité et de contrainte-déformation lors d'inversions de charge. Des analyses de désintégration libre dans le domaine temporel sont exécutées afin d'évaluer l'amortissement du sol par une approche de décrémentation logarithmique.

1 INTRODUCTION

Due to the power production potential offered by offshore wind when compared to its onshore counterpart, this source of renewable energy has become a key technology to help overcome climate change challenges and to create sustainable energy sources for future generations. However, the cost associated with offshore wind development remains a significant issue that restricts its growth. While significant cost reductions in OWTs have been achieved through technological advancements and installations of larger size turbines, further reductions are needed to increase the economic viability of building new wind farms in less favourable conditions. One area that is receiving significant attention within the geotechnical engineering community is optimising the foundation design via understanding the interaction between the foundation

and the wind turbine tower. This is because the cost associated with the foundations can contribute up to 30% of the overall development cost (Bhattacharya, 2019).

OWTs are inherently characterised as flexible structures which are very sensitive to the frequency of the mechanical and environmental applied loads. The behaviour is often determined by carrying dynamic simulations using aeroelastic programs such as FAST. However, the results of these simulations are only valid when the damping contribution of each source is correctly taken into account. The soil-structure interaction affects the eigenmodes and the overall damping ratios, hence, the dynamic amplification that takes place. Several research studies pointed out that integrating foundation damping could lead to reducing the structural demands. Carswell et al., (2015) showed that including the foundation damping as a lumped rotational dashpot at the mudline level reduced the maximum and standard deviation of the mudline moment by 7-9% respectively during storm conditions. Although, the importance of soil damping is recognised in design guidelines such as DNV (2014), there are no standardised procedures for accurate determination.

This research paper aims to calculate foundation damping for the IEA 15 MW (Gaertner et al., 2020) reference wind turbine using 3D FE analysis with a constitutive model that is calibrated to cyclic triaxial results. The results show the global damping ratio against the mudline displacement of the monopile. The novelty of this work lies in the calibration procedure which focuses primarily on the soil element damping while also attempting to properly fit the monotonic tests.

2 METHODOLOGY

The FE numerical analysis is carried out using the software package Plaxis 3D which allows dynamic simulations to be performed. For modelling the soil behaviour, the small strain hardening model (HSsmall) is used and calibrated using the soil test facility that allows recreating common laboratory tests under different scenarios. The damping ratio is determined by displacing the OWT at the RNA level and then removing the load to allow the structure to freely decay and then calculate the damping based on the logarithmic-decrement equation.

The triaxial tests were conducted on sand samples taken from Blessington site in Ireland. The cyclic tests were performed and analysed according to ASTM (D3999).

3 NUMERICAL MODEL

The model mainly consists of beam and plate elements. The monopile is modelled using plate elements while the tower above the mudline is modelled with beam elements. A weightless plate with very large young's modulus is created 1m above mudline (so no soil is in contact with the plate) and is connected to the beam elements to allow the transfer of shear and bending moment between the tower and the foundation. The 3D FE model and its dimensions is shown in Figure 1. Viscous boundaries are activated to prevent wave reflections.

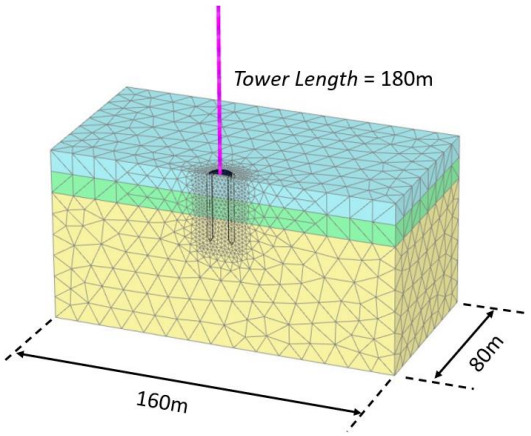

Figure 1. The 3D FE Model.

The mass at the RNA level is represented by modelling a small beam element with an equivalent unit weight. The mesh is generated fine enough to obtain accurate results with reasonable calculation time. The diameter of the monopile is 10m and the embedment depth is 30m. The dimensions of the tower and the mass of the RNA were taken from IEA Wind TCP 37 technical report (Gaertner et al., 2020).

4 SOIL INPUTS

The stratigraphy is divided into three layers. The model parameters are summarised in Table 1 and 2. The relative density of the soil is 60%. The soil is isotopically consolidated to effective confining stresses of 50, 150, and 300 kPa. Parameters that are not mentioned are maintained as the standard values in Plaxis 3D

Table 1. Soil input parameters.

Soil layer	Depth (m)	γ' (kN/m³)	φ' (deg)	ψ (deg)
1	0-10	9.74	46.9	14.9
2	10-20	9.74	43.8	11.0
3	20-80	9.74	39.3	5.4

Table 2. Soil input parameters.

Soil layer	E_{50ref} (kPa)	E_{oedref} (kPa)	E_{urref} (kPa)	G_{oref} (kPa)	$\gamma_{0.7}$ (-)
1	45000	30000	90000	83690	.00020
2	45000	30000	90000	83690	.00036
3	45000	30000	90000	83690	.00057

The two parameters that control damping in the HSsmall soil model are $\gamma_{0.7}$ and the ratio of G_{oref}/E_{urref} which acts as a cutoff. Figure 2 shows the calibrated Plaxis output curves with respect to the triaxial results curve fittings. Since the ratio of G_{oref}/E_{urref} is the same for all three layers, the maximum value of damping remains constant. The damping curves are shifted to the right by increasing $\gamma_{0.7}$ value. The Plaxis outputs match very well with the tests until 0.04% cyclic shear strain. The calibration involved varying the stiffness parameters until the Plaxis output matched the damping ratio and the monotonic test graphs. Figure 3 compares the monotonic response obtained from the laboratory tests and the Plaxis simulations. The monotonic tests were carried out in drained condition in order to find the angle of shearing resistance and the angle of dilation.

The initial stiffness from Plaxis triaxial simulations match well with the laboratory results as can be seen from Figure 3. Furthermore, the peak deviatoric stresses are also very similar which provides further validation for the input values. The axial LVDTs can measure displacements in the small and medium strain range. Thus, the maximum axial strain measured by the LVDTs before reaching their limit is roughly around 3% as shown in figure 3. The tests are further continued to determine the critical angle of shearing resistance which is approximately 35 degrees for the sand used in this research.

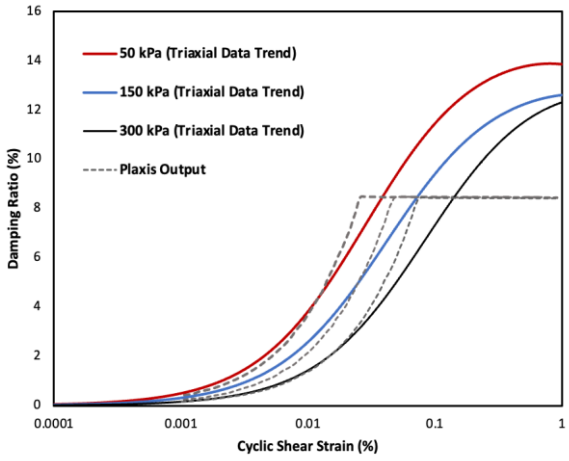

Figure 2. Calibrated damping curves.

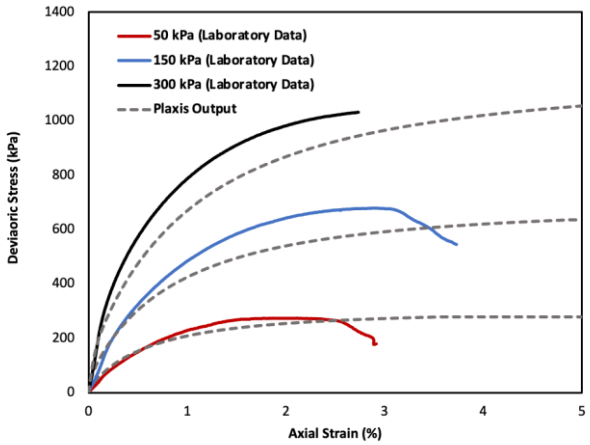

Figure 3. Monotonic triaxial test results and simulations.

5 RESULTS

The free vibration of the tower at the RNA level for different displacements is shown in Figure 4. The following equations are used for calculating the logarithmic decrement ratio (δ) and the damping ratio (ξ):

$$\delta = \frac{1}{n} \cdot ln\left(\frac{A_0}{A_1}\right) \quad (1)$$

$$\xi = \frac{1}{\sqrt{1+\left(\frac{2\pi}{\delta}\right)^2}} \quad (2)$$

where A_0 and A_1 are two successive amplitudes at the RNA level and n is number of cycles apart. The second cycle for each time history is used for the damping calculation. The damping ratio against the mudline translation is shown in Figure 5.

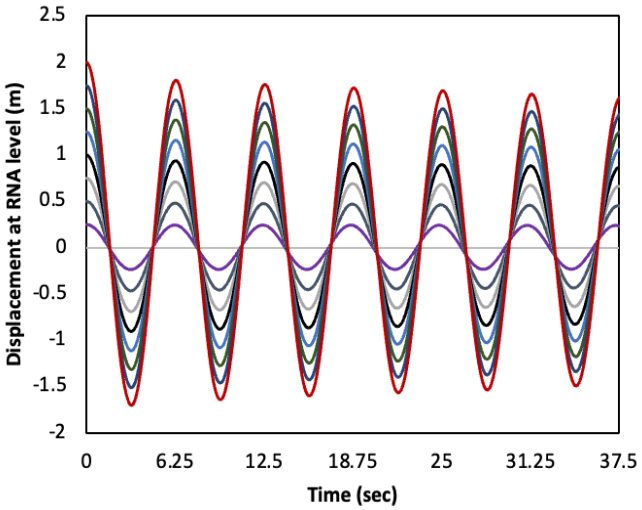

Figure 4. Free vibration of the tower.

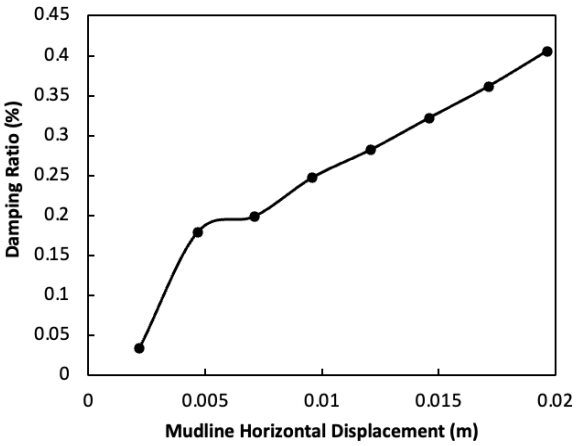

Figure 5. Damping ratio against mudline translation.

Since the 3D FE model contains no other form of damping, the decay of displacements in Figure 4 is only due to the hysteretic behaviour of soil. This has been validated by running the same simulations with a linear elastic soil model and no damping was observed (results not shown here). Figure 5 shows that as the mudline displacement increases, the damping ratio also becomes higher. This is consistent with the behaviour of soil at the element level shown in Figure 2. The damping ratio results obtained in this study falls within the range of ratios (0.15% - 1.5%) determined in previous studies as summarised by Malekjafarian et al., (2021). Several studies (such as Damgaard et al., 2013; Shirzadeh et., 2013; Versteijlen., 2011) back calculated soil damping from the total damping ratio observed during rotor-stop tests on actual OWTs. However, the accuracy of these results depends on whether the damping ratios of the other sources are correctly accounted for and the validity of the assumption of linear combination of different damping sources.

6 CONCLUSION

The primary aim of this paper was to determine the hysteretic foundation damping for the reference IEA 15 MW OWT through carrying out 3D FE analyses and using soil parameters from dynamic triaxial tests. The geometry of the monopile represents the current dimensions employed to support OWTs. The soil was medium-dense and was tested at different mean effective stresses to obtain the variation of damping at different depths. The damping ratio values determined from the FE analyses can be considered reliable and conservative when compared to previous studies and can help design engineers to gain a perspective of the damping ratio that can be expected from the monopile.

Generalized P-y curves for monopile design using the PISA methodology

Courbes P-y généralisées pour la conception de monopieux avec la méthodologie PISA

L. Berenguer Todo Bom*
COWI A/S, Hamburg, Germany

**lbbm@cowi.com*

ABSTRACT: The PISA design model is rapidly becoming the standard methodology for the design of offshore monopile foundations supporting wind turbine structures. The PISA model allows designers to either derive from finite element models (FEM) or use rule-based equations, to obtain normalized parameters. Despite the clear benefits, due to the relatively high computational cost and specialist knowledge required to calibrate advanced constitutive models from specialized soil testing, FEM-based PISA calibrations are only adopted during detailed design stages. On the other hand, the rule-based approach has documented limitations namely in new provinces, for soils with distinct geological histories than those tested as well as in layered soil profiles. Since binding monopile geometry decisions are, however, made at earlier project phases, this presents a dilemma for practising engineers. This paper presents an alternative approach of the P-y curve components of the PISA method. It can used at both early stages of design, to derive the normalized parameters in layered profiles, and at detailed design stage to inform the best-fit procedure of the normalized curves. The input soil profiles may contain both coarse and fine-grained formations, either exhibiting drained or undrained behaviour. The new formulation takes into account physical principles of the soil resistance components, to define the PISA normalized parameters.

RÉSUMÉ: Le modèle de conception PISA est rapidement en train de devenir la méthodologie standard pour la conception des fondations de monopieux offshore supportant des structures d'éoliennes. Le modèle PISA permet aux ingénieurs de dériver à partir de modèles d'éléments finis (FEM) ou d'utiliser des règles pour obtenir des paramètres normalisés. Malgré les avantages clairs, en raison du coût de calcul relativement élevé et des compétences spécialisées nécessaires pour calibrer les modèles constitutifs avancés à partir d'essais de sol spécialisés, les calibrations PISA basées sur les éléments finis sont uniquement adoptées au cours des étapes de conception détaillée. D'autre part, l'approche basée sur des règles a des limites connues, notamment dans les nouvelles géographies, pour les sols ayant une histoire géologique différente de celle des sols testés, ainsi que dans les profils de sol stratifiés. Comme les décisions relatives à la géométrie des monopieux sont prises dès les premières phases du projet, cela pose un dilemme aux ingénieurs en exercice. Cet article présente une approche alternative des composantes de la courbe P-y de la méthode PISA. Elle peut être utilisée à la fois aux premiers stades de la conception, pour dériver les paramètres normalisés dans les profils en couches, et au stade de la conception détaillée pour informer la procédure de meilleur ajustement des courbes normalisées. Les profils de sol utilisés peuvent contenir des formations sableuse ou argileuse, présentant un comportement drainé ou non drainé. La nouvelle formulation prend en compte les principes physiques des composantes de la résistance du sol, pour définir les paramètres normalisés PISA.

Keywords: Offshore engineering; finite element modelling (FEM); monopiles; PISA methodology.

1 INTRODUCTION

The modelling of soil-structure interaction in pile foundations has advanced substantially in the field of offshore geotechnical engineering. The developments to tackle the technical challenges have been driven by a need to improve the existing P-y method approaches and also to integrate additional lateral soil resistance components which became relevant in larger foundation sizes. As monopile diameters increase to ranges beyond the basis of the standard method, designers optimize foundation geometries by adopting the benefits of a larger structure in all resistance components.

For detailed design of offshore monopile foundations, FEM-based methods have become the industry practice, Burd et al. (2020). Due to the complexity, time constraints and high computational costs, however, pile geometry design iterations are not typically performed within FEM software. These rather rely on 1D Beam-in-Elastic Foundation (BEF) simplifications, resorting to soil-structure interaction models consisting of non-linear interaction curves. Moreover, at earlier stages in design, solely the design

of certain positions in the offshore wind farm will be FEM-based, while the remainder rely on extrapolated normalized parameters to define the soil-structure interaction models. For both these cases, normalization methods as well as rule-based parameters to determine the soil interaction curves are required. This paper presents a methodology to derive P-y curves, based on the PISA design model, proposed by Byrne et al. (2017), and supported on soil mechanics principles, to better address the design challenge of monopile foundations.

2 CURRENT METHODS

The traditional design methodologies provided in API RP 2GEO (2014) and DNVGL-ST-0126 (2018), and which can be used for pile foundations subject to lateral loading, were not developed for the large diameter structures currently adopted in the offshore wind industry. The work undertaken by the PISA group aimed to close this gap, as presented in Byrne et al. (2017), and has become the standard design methodology for monopile design. It provides a framework to both include additional lateral components of resistance but mainly a normalization approach to define soil interaction curves in normalized space with a simple mathematical formulation of a conic function. Normalization factors of the P-y curve components, as shown in Table 1, are proposed for both effective and total stress-based soil responses, typically named representative for sand (coarse-grained) and clay (fine-grained) soil materials, respectively.

Table 1. Normalization of P-y curves, Byrne et al. (2017).

Normalized variable	**Clay**	**Sand**
Lateral displacement, $\bar{\boldsymbol{v}}$	$\frac{v}{D}\frac{G_0}{S_u}$	$\frac{v}{D}\frac{G_0}{\sigma'_{vi}}$
Distributed load, $\bar{\boldsymbol{p}}$	$\frac{P}{S_u D}$	$\frac{P}{\sigma'_{vi} D}$

Based on these curve normalization functions and in-situ large diameter pile load testing, Burd et al. (2019) and Byrne et al. (2019) propose a rule-based approach where normalized PISA parameters are defined for both the sand and clay frameworks, respectively. The rule-based approach, however, has been shown to perform poorly namely in new geographies, for soils with distinct geological histories from those tested as well as in layered soil profiles with relevant stiffness contrast, as shown in Burd et al. (2020), among other limitations.

3 MODEL DESCRIPTION

The proposed P-y model approach comprises an improved normalization function for the 'sand framework', a methodology to model the undrained behaviour of sand as well as a soil mechanics'-based analytical approach within the PISA framework.

3.1 Effective stress normalization

The PISA sand framework normalization functions of the p-value solely normalize to the effective stress and pile diameter. This limits its applicability to derive global PISA parameters per unit for sites where the same unit may have distinct strength parameters. More importantly, the normalization does not relate the normalized parameters to other physical quantities. The latter is due to the missing strength parameters and in situ confinement stress definition for it to be compatible with critical state soil mechanics. The proposed modification serves to complement the effective stress normalization, based on Leonards (1962), to normalize by the shear stress as follows:

$$\bar{v} = \frac{v}{D}\frac{G_0\,(1-sin\phi')}{\sigma'_{vi}\,sin\phi'} \quad (1)$$

$$\bar{p} = \frac{P}{D}\frac{(1-sin\phi')}{\sigma'_{vi}\,sin\phi'} \quad (2)$$

where ϕ' is the friction angle. The rule-based formulation in the PISA sand framework also limits its applicability for other sands than those tested in the PISA project. The main parameter selected is ill conceived since relative density (D_r) is not a good indicator of soil behaviour nor of its critical state. Different soils behave differently at the same relative density. Based on the new normalization formulation, a total stress rule-based approach, which is by definition conservative, is defined in Section 3.2. The conservativism of such an approach can be seen by comparing the results of two laterally loaded monopile PLAXIS 3D FE models, in two sand profiles, one adopting effective stress parameters and a second with maximum shear stress, both adopting the Hardening Soil Small-Strain model, according to equations (1) and (2). An additional result for an undrained modelling, adopting the NGI-ADP model, is also shown in Figure 1. The model has a pile diameter of 9m and a pile embedment of 28m. Soil parameters were derived following correlations given in the PLAXIS MoDeTo Manual (2018). The slight difference in secant stiffness is due to limitations on the constitutive model parameter definition when selecting a very low friction angle in PLAXIS. The ultimate capacity is underestimated as expected for

both the total and undrained modelling, since from the constitutive model perspective, this results from the underestimation of the frictional contribution of the resistance during loading as the positive contribution of the increase in horizontal stress is not considered.

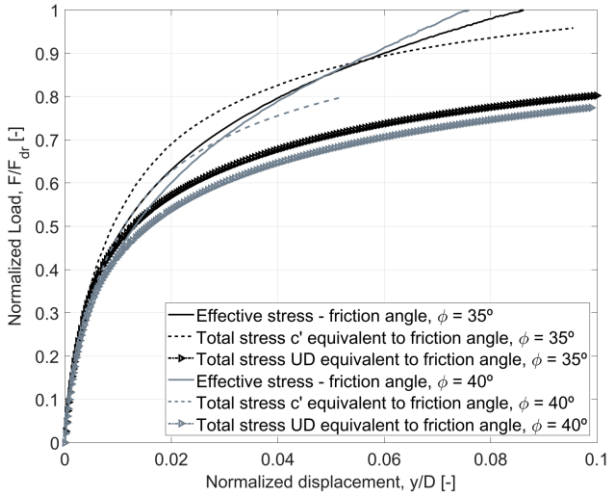

Figure 1. Comparison of 3D FEM effective, total and undrained stress models, where F_{dr} is the effective stress resistance.

3.2 Total stress / Shear stress approach

The sand framework formulation, and its respective rule-based formulation, has been found to be the least representative to be used in design. This is due to several reasons. One of the foremost is the fact that the extreme loading condition of offshore foundations is due to rapid individual loading events, such as wind and waves, for which the soil behaviour may be either undrained or partially drained, rather than fully drained, as is the basis of the PISA formulation. An assessment of the drainage type, using the dimensionless velocity ratio proposed by Finnie and Randolph (1994), indicates that the soil behaviour during the wave impact is not fully drained. Furthermore, the generation of excess pore-pressure will be greater in the vicinity of the pile, which most impacts the soil resistance components.

A pragmatic approach to extend the PISA formulation to an undrained loading of sands is to resort to the total stress approach, i.e., the PISA clay framework, where the undrained shear strength of sands is determined from triaxial extension as:

$$S_{u-sand} = \sigma'_{vi} \cdot \frac{sin\phi' \left(1-A_f+K_0\,A_f\right)}{1-sin\phi'+2\,A_f\,sin\phi'} \qquad (3)$$

where A_f is the Skempton pore-water pressure parameter A at failure. Janbu (1985) defines for triaxial compression tests on saturated soils the dilatancy parameter D as:

$$D = \frac{1}{3} - A_f \qquad (4)$$

where $D = 0$ represents elastic behaviour, $D < 0$ contractive behaviour and $D > 0$ dilatant behaviour. The determination of A_f in sands depends on several factors namely relative density, confinement pressure and loading stress path. This parameter should ideally be determined from constant normal stiffness shear tests or directly from available undrained testing of soil samples. Care should be taken when calibrating from undrained tests since these simulate perfectly rigid boundary conditions. Hence, the increase in effective confinement stress, which in turn increases the shear stress resistance, observed in the laboratory, will not be present in situ. A possible approach to estimate the A_f parameter is through the state parameter ψ, as defined in Jefferies and Been (2006). This parameter can be either directly or indirectly determined from the cone penetration test (CPT). The standard CPT correlations, when inverted, provide a relationship to the commonly derived relative density, shown in Figure 2, for different vertical stress intervals.

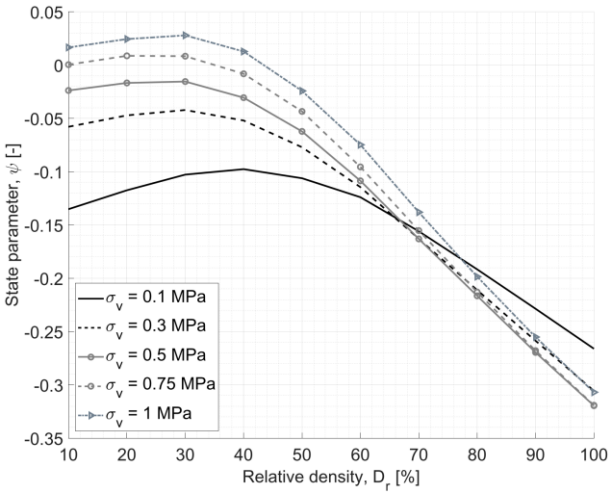

Figure 2. Inverted CPT correlations between D_r and ψ.

This approach implies that the behaviour of sands and parameter usage are in the same context as the undrained shear of clays, which is consistent with critical state soil mechanics' principles. Adopting the formulation given in Wroth (1984), the normalized ratio of both the undrained shear strength of loose sands and clays to the reference level of $\psi = 0.05$ and over-consolidation ratio (OCR) of 1.0, respectively, can be determined, as shown in Figure 3 for the stress path of isotropic triaxial compression. The starting point of both lines is so defined since, as discussed in Jefferies and Been (2006), while the state parameter and over-consolidation are different entities, the

undrained shear strengths of loose sands ($\psi \approx 0.05$) are comparable to normally consolidated clays (OCR=1).

In Figure 3, the red line represents the OCR effect on clay undrained shear strength, given in Wroth (1984), while the black line represents the peak friction angle relation to the state parameter in sands, as given in Jefferies and Been (2006). The different rates of variation are due to the distinct relationship between OCR and ψ to volumetric behaviour of fine- and coarse-grained materials.

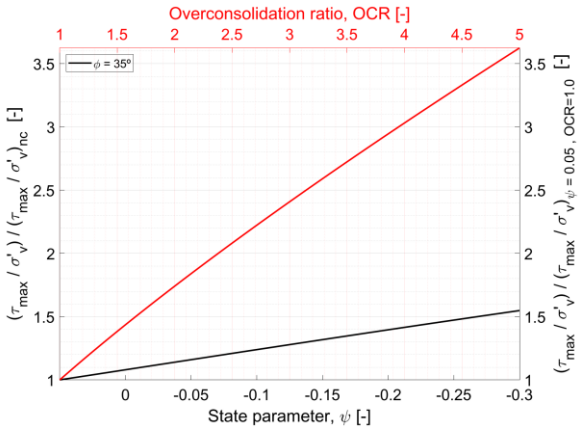

Figure 3. Variation in normalized undrained strength ratio.

This section summarized an analytical approach to determining the undrained shear strength for both fine- and coarse-grained materials for different initial stress conditions and loading histories.

4 RULE-BASED FORMULATION

The proposed formulations in the previous sections are defined based on maximum shear stress, therefore, can be directly incorporated within the PISA clay framework. The normalization functions proposed for the 'clay framework', based on a total stress approach, are simpler and broadly based on analytical solutions. The approach defined results in the normalized P-y PISA parameters ($\bar{p}_u, \bar{v}_{pu}, n_p$ and k_p) having a physical basis from soil mechanics. As shown in the following equations, for example, $\bar{p}_u$ can be seen to be the bearing capacity factor N_p, while k_p is the multiplying factor to G_0, the small-strain shear modulus, to define the initial stiffness of the P-y curve.

$$P_u = \bar{p}_u S_u D\,, \qquad \bar{p}_u = N_p \tag{5}$$

$$k_i = k_p G_0, \qquad k_i = \frac{P_i}{v_i} \tag{6}$$

For both these parameters several analytical solutions exist, such as Jeanjean et al. (2017), Ashford and Juirnarongrit (2003) and Suryasentana and Lehane (2016), respectively, providing a robust rule-based approach for these values. The curvature parameter n_p can be derived from backbone curves such as Darendeli (2001), assuming a shear strain displacement relationship from several simplified approaches summarized in Zhang and Andersen (2017). Finally, the $\bar{v}_{pu}$ parameter can be estimated from rigidity index values at failure, typically varying between 5 to 15% of the ratio of lateral displacement to pile diameter, as per Jeanjean and Zakeri (2023).

5 FINITE ELEMENT ANALYSIS OF P-Y RESPONSE

The comparison between the proposed rule-based method, for both effective and total stress approaches is performed by comparison of the $\bar{p}_u$ and k_p PISA parameters, calibrated to match the P-y curves from the effective stress and undrained load-displacement curves, calculated in FEM presented in Figure 1. The PISA calibration procedure ensures a near perfect match per soil curve extracted which in turn result can replicate the overall pile behaviour. The results obtained are plotted in Figure 4 and Figure 5. Alongside the calibrated PISA parameters, the analytical PISA parameters as per equations (5) and (6) are also plotted for comparison. The rule-based approach is shown to be conservative, both in stiffness and strength, when compared to FEM results. For detailed design stages, multiplication factors, as shown in the right of Figure 4 and Figure 5, can be applied to the formulation to obtain a better match to the FEM model and thereby define global PISA parameters.

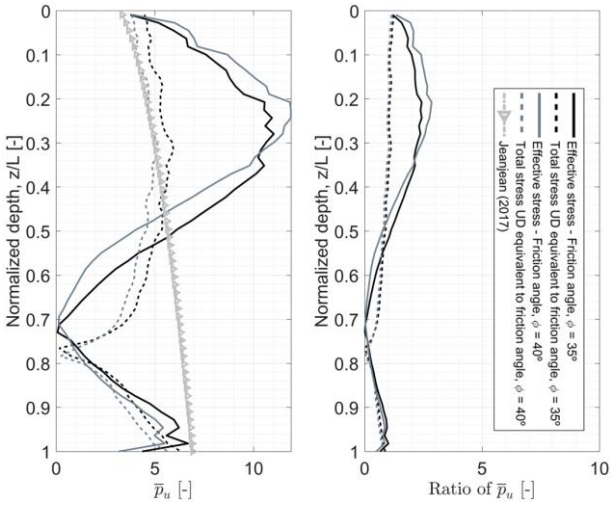

Figure 4. Left - FEM calibrated, analytical $\bar{p}_u$ PISA parameter as given in Eq. (5); Right - ratio between numerical and analytical values.

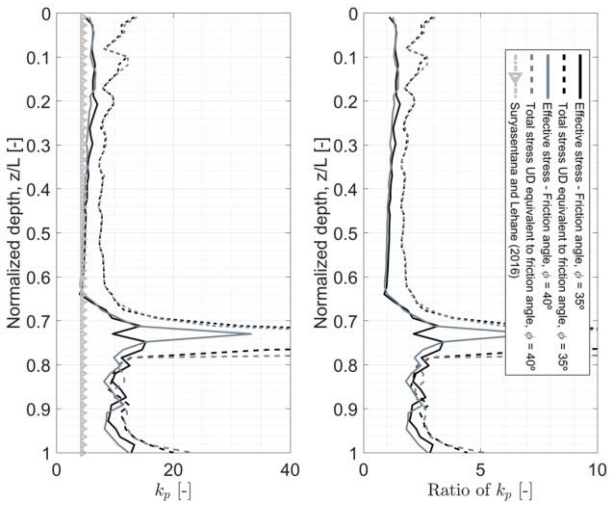

Figure 5. Left - FEM calibrated, analytical k_p PISA parameter as given in Eq. (6); Right - ratio between numerical and analytical values.

6 CONCLUSIONS

The proposed formulation to determine P-y curves for both coarse and fine-grained formations, exhibiting either drained or undrained behaviour has been presented. The method comprises an alternative normalization for coarse-grained materials in the PISA framework and a methodology to determine the failure shear stress of sands under undrained behaviour and a soil mechanics'-based rule-based approach. A comparison to FEM results indicates the rule-based approach proposed to be adequately conservative for early-stage designs.

ABSTRACT: In recent decades, multiple research projects have shown the positive impact of lime treatment on the construction or improvement of hydraulic structures. Both the hydraulic and the mechanical properties of lime-treated soils can be improved allowing for new design techniques and potential resource saving. In July 2015, as part of the DigueELITE project, a full-size experimental levee was built in a meander of the Vidourle River (Gard, France). The structure comprises a first section with a platform and a settling basin at the toe of the slope constructed with silty soil treated with 2% lime, and a second section built with the same soil untreated. As a primary objective, the resistance to external erosion of the lime-treated soil was quantified by performing overflow tests in 2016 and 2017. Then, the monitoring of the durability of the structure treated with lime was carried out. For this latter purpose, a test campaign took place in June 2021; samples were extracted from the core of the structure on the platform in lime-treated soil and characterized. This paper provides a brief description of the experimental levee, the experiments previously carried out, and the procedure implemented to study the geomechanical behavior of the samples extracted. Finally, the results of permeability, UCS, shearing strength, and oedometric compressibility tests, performed 6 years after the construction, are presented, and compared with those acquired just after the construction of the levee on samples prepared in the laboratory and cured for 7 to 28 days.

RÉSUMÉ: Récemment, de multiples projets de recherche ont montré l'impact positif du traitement à la chaux pour la construction ou l'amélioration des ouvrages hydrauliques. L'amélioration des propriétés hydrauliques et mécaniques des sols traités à la chaux, permet d'envisager des nouvelles techniques de conceptions plus économes en ressources. En juillet 2015, dans le cadre du projet DigueELITE une digue expérimentale de taille réelle a été construite dans un méandre du fleuve Vidourle (Gard, France). Le démonstrateur est constitué d'une première section construite avec un limon traité à 2% de chaux et d'une seconde section construite avec le même limon non traité. L'ouvrage comprend aussi une plateforme et un bassin de décantation construits en limon traité. L'objectif premier du projet était de quantifier la résistance à l'érosion externe du sol traité à la chaux à l'aide d'essais de surverse réalisés en 2016 et 2017. Un second sujet d'intérêt concerne le suivi de la durabilité des ouvrages traités à la chaux. A ce titre, une campagne d'essais a eu lieu en juin 2021 et des prélèvements en cœur d'ouvrage ont été réalisés. Ce papier fournit une brève description de la digue et des expérimentations précédemment réalisés puis présente les moyens mis en œuvre pour étudier le comportement géomécanique des échantillons prélevés. Finalement les résultats obtenus en termes de perméabilité, de résistance à la compression simple et au cisaillement, et de compressibilité œdométrique sur le matériau extrait à 6 ans de cure sont présentés et comparés à ceux acquis lors d'une étude antérieure datant de la construction de l'ouvrage et réalisée sur des échantillons préparés en laboratoire et consolidés de 7 à 28 jours.

Keywords: Silty soil; lime; durability; compressive strength; shear strength; permeability.

1 INTRODUCTION

The chemical treatment of soils with lime is a technique widely used on earthworks to improve poor-quality soils containing a clay fraction. The benefits of treating fine silty-clay soils with lime are twofold. Firstly, the addition of lime allows for better control and improves the physical characteristics of the soil and its compaction behaviour during processing, making it much easier to reuse. Secondly, over and above the short-term improvement effect, the addition of lime in sufficient quantity enables the development of improved geotechnical properties compared with untreated soil, particularly in terms of compressive and shear strength (Bell, 1996; Little, 1995). Recent research programs have also demonstrated the positive effects of treating soils for hydraulic structures, thanks to the increased resistance to erosion provided by the treatment, and the adaptation of treatment processes to meet low permeability requirements (Herrier et al., 2012; Nerincx et al., 2018; Herrier et al., 2018). The behaviour of treated soils is widely studied at the laboratory level, but only a few real structures have been monitored years after their construction (Haas et al., 2019, Das et al., 2021; Chabral et al., 2023).

This paper reports the monitoring of the properties of an experimental levee built on a meander of the river Vidourle in France. After a brief presentation of the experimental structure and the initial project, the method for taking and preparing the samples for the laboratory investigation is described. Finally, the results of permeability, UCS, shear strength, and oedometric compressibility tests, performed 6 years after the construction are presented and compared with those acquired on samples prepared and cured in a laboratory for 7 and 28 days.

2 PRESENTATION OF THE EXPERIMENTAL LEVEE

The construction of the experimental levee for the DigueELITE research program was completed in July 2015. Located on the edge of the Vidourle River, the structure is part of the work to improve the network of local levees. With a length of 50 m, a crest height of 3.5 m and a slope of 1.5H/1V, the demonstrator comprises a section of lime-treated soil and a section of untreated soil, and it is shown in Figure 1. The soil used is a locally extracted silt (Plasticity Index = 5), treated in a mobile plant with 2% quicklime. The slopes are not covered with topsoil, so the soil is directly exposed to the environment. The levee concerned by the experiments faces south and is therefore subject to wide temperature variations. The levee is not in direct contact with the Vidourle, which is several meters below; the water table is 2 to 3 meters below the structure.

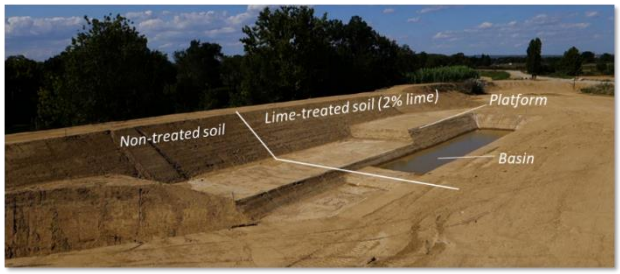

Figure 1. Aerial view of the Vidourle experimental levee. The platform and basin were also made with lime-treated soil and used for overflow test purposes.

This demonstrator was built to conduct overflow tests to quantify and compare the erosion resistance of treated and untreated soil on a real scale. Details of the tests and the overflowing simulator are presented in Bonelli et al. (2018). The project also made it possible to confirm the procedures for using treated soils in the construction of hydraulic structures, which differ from conventional treatment procedures. Thanks to its well-known construction history, the structure can now be used to conduct tests aimed at assessing the durability of the lime treatment solution.

3 SAMPLE COLLECTION AND PREPARATION

In 2021, the external erosion resistance of the treated and untreated soil was assessed using the JET test (Nicaise et al., 2024). This was also an opportunity to take samples from the body of the lime-treated levee on the platform part to assess its geomechanical performance. As for the experimental backfill in Rouen (Saussaye et al., 2020), blocks were extracted with a mechanical shovel using a small bucket to dig two narrow trenches 30 cm wide, 1 m apart from each other. The blocks were then lifted out from the backfill by planting the teeth of a wide bucket in the interlayers identified, with the mechanical shovel overhanging the platform. The extracted pieces were then carefully handled and cut on site using a floor saw to reduce their size and facilitate the handling (Figure 2). The final blocks obtained were approximately 40x40x30 cm in size and showed no visible cracks caused by the handling. After identification, the blocks were sealed in watertight plastic sheets. The material sampled corresponded to layer 6 and layer 7 of the lime-treated silt platform as shown in Figure 3.

The samples for the œdometric tests were obtained by machining the blocks using a milling machine to obtain a diameter of 5 cm and a height of 1.5 cm

(Figure 2). While to carry out direct shear and permeability tests, the samples were obtained by dry coring over a diameter of 10 cm with a height of about 10 cm. For simple compression tests, the same process was implemented, but the ratio length/diameter of the samples varied between 1 and 1.6. The high resistance of the treated soils made them fragile, and the sporadic presence of pebbles did not allow to obtain longer samples with a good yield.

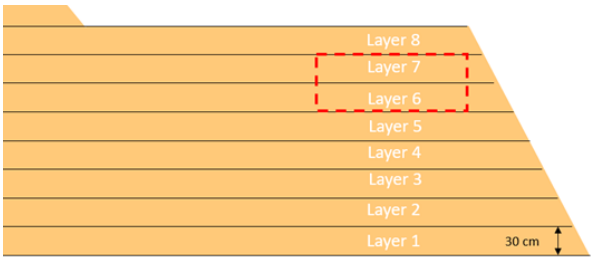

Figure 3. Schematic cross-visualization of the location of layer 6 and layer 7 of the material extracted from the platform in the lime-treated soil.

4 GEOMECHANICAL PROPERTIES AFTER 6 YEARS

4.1 Oedometric compressibility

The œdometric tests were performed by placing the milling-shaped samples between two porous stones in œdometric cells. After a period of saturation in water, loading and unloading tests were carried out in saturated conditions, and the vertical displacement of the samples was measured after stabilization. Ten loading/unloading bearings were applied in the following sequence: 25, 50, 100, 200, 400, 800, 1600 kPa, then 400, 100, and 25 kPa. Three samples from layer 6 were tested in loading up to 800 kPa, and six samples from layer 7 were tested three with loads up to 800 and three with loads up to 1600 kPa. The objective was to verify potential heterogeneities between layers, but also within the same layer.

The results of the compressibility tests are presented in Figure 4 and compared with the results obtained on samples prepared in the laboratory in 2015.

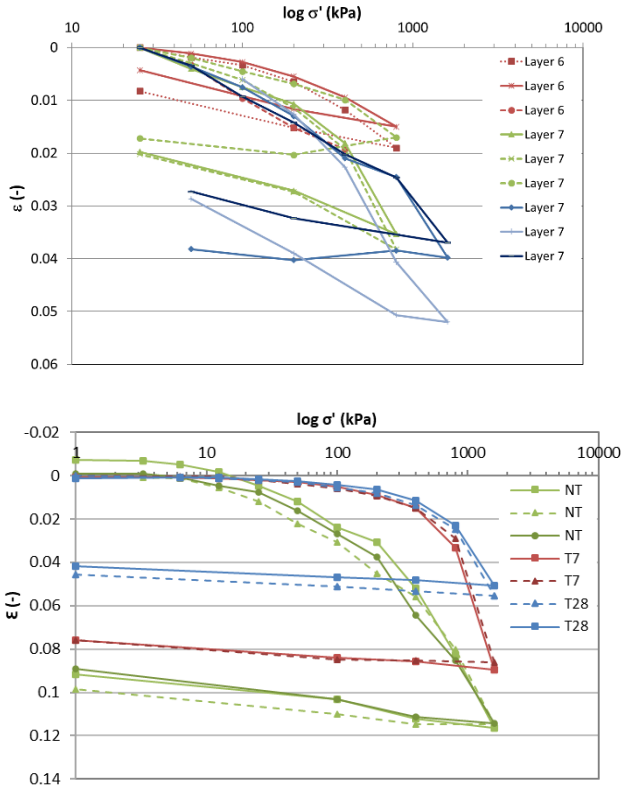

Figure 4. Top: Compression curves of the specimen extracted after 6 years. Bottom: Compression curves of the specimen non-treated (NT) and treated in the laboratory after 7 (T7) and 28 (T28) days of curing.

Table 1 summarizes the various parameters calculated from the compression curves.

Table 1. Parameters measured during the compressibility tests on the samples extracted from the Vidourle levee after 6 years of aging (onsite samples) and compared to values obtained on laboratory samples tested at younger ages.

Study	Soil - Cure	Compressibility index	Swelling index	Pre-consolidation stress σ' (kPa)
This study *(onsite samples)*	Layer 7 (2% treated soil) - 6 years	0.0205	0.0041	> 600
	Layer 6 (2% treated soil) - 6 years	0.0092	0.0040	200 - 600
2015 study *(laboratory samples)*	Untreated soil	0.0415	0.0030	109
	2% treated soil – 7 days	0.0527	0.0016	565
	2% treated soil – 28 days	0.0292	0.0012	503

According to the results, the treated soil, sampled after 6 years of weathering, maintains, or even improves, its compressibility characteristics. Layer 7 shows a compressibility behaviour similar to that of the laboratory-treated soil after 7 and 28 days of curing, significantly improved in comparison with the behaviour of the untreated soil.

A significant difference between layer 6 and layer 7 is observed as layer 6 is less compressible. Furthermore, layer 6's material shows an improved behavior compared to that of the soil tested in the lab at a shorter curing time. Its pre-consolidation stress probably exceeds 600 kPa but remains non-calculable as it is doubtful that the plastic range is reached at 800 kPa. In general, the results obtained within the same layer are close and reproducible.

4.2 Unconfined compressive strength (UCS)

The unconfined compressive strength (UCS) of the samples from both the layers was measured on cylindrical drilled samples. The length/diameter ratio of the samples being systematically lower than 2, a corrective factor on the measured resistance was applied, under the recommendations of the ASTM C42 standard. The tests were carried out at the natural water content, without resaturation; the samples were placed between two horizontal plates and the vertical movement of the upper plate was controlled at a speed of 0.3 mm/min. The vertical deformations were deduced from the measurements of the top plate displacement through two external displacement sensors (LVDT). Table 2 summarizes the corrected UCS values obtained for both layers and compares them to the values obtained on the laboratory samples of the same treated and untreated soil.

Table 2. UCS measured on the samples extracted from the Vidourle levee after 6 years of aging (onsite samples), compared to values obtained on laboratory samples at younger ages.

Study	Curing	UCS (MPa)
This study *(onsite samples)*	Layer 7 – 6 years	0.82
	Layer 6 – 6 years	1.77
2015 study *(laboratory samples)*	Untreated soil	0.21
	7 days	0.32
	28 days	0.39
	60 days	0.44
	90 days	0.53
	180 days	0.73
	365 days	1.20

These results show a similar trend to that already observed; the results are reproducible and relatively homogeneous. Layer 7 displays lower UCS values than layer 6 and comparable with the values obtained for a soil compacted and tested in laboratory after 180 days of cure. Layer 6 exhibits higher strength and stiffness with an improved resistance compared to the one measured on laboratory samples after 1 year, probably reflecting the good development and conservation of pozzolanic reaction products.

4.3 Permeability

Permeability tests were performed on the samples intended for direct shear tests. Samples of 10 cm of diameter and +/- 10 cm of height were wrapped in a latex membrane with two porous stones placed on both free sides. The whole specimen was installed in a confining cell fixing the membrane against the sample. The lower porous stone was connected to a pressure/volume controller to impose pressure and measure the volume of water injected. The upper porous stone was connected to a drainage circuit allowing water to drain to the open air. A pressure of 1 bar (= 100 kPa) was imposed on the base while the pressure at the top of the sample corresponded to the atmospheric pressure.

Table 3 summarizes the permeability coefficients obtained. Overall, the results are reproducible, and the permeability measured is very low for both layers.

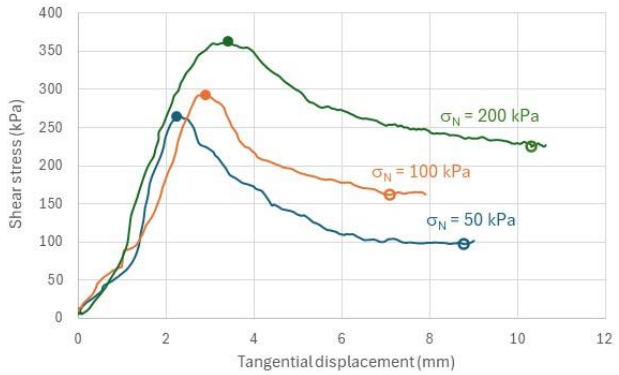
Table 3. Permeability measured on the samples extracted from the Vidourle levee after 6 years of aging.

Soil - Cure	Permeability k (m/s)
Layer 7 (2% treated soil) - 6 years	$1.9.10^{-10}$
	$1.8.10^{-8}$
	4.10^{-9}
Layer 6 (2% treated soil) - 6 years	$1.61.10^{-8}$
	$3.38.10^{-8}$
	$1.06.10^{-8}$
	$2.41.10^{-9}$
	$8.52.10^{-9}$
	$2.99.\ 10^{-9}$

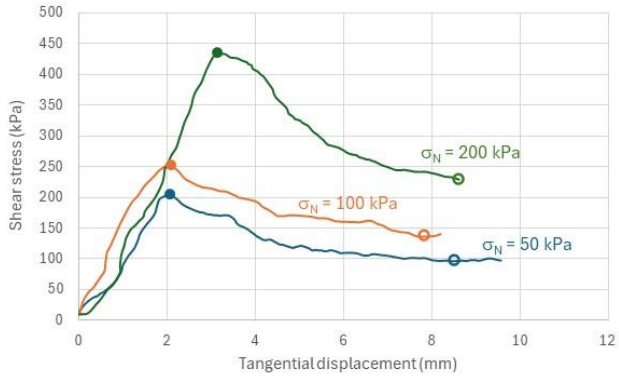
4.4 Shear strength

The same saturated samples that led to the permeability measurements were used to perform direct shear tests under the following normal stresses: 50 kPa, 100 kPa and 200 kPa. The rate of shearing was fixed low enough, at 6 mm/hour, to maintain drained conditions during shearing. According to ASTM D3080, with a coefficient of consolidation of 2E-5 m^2/s (deduced from the permeability and the stiffness), a thickness of specimen of 10 cm and a failure occurring at 3 mm of displacement, the maximum speed should be 9 mm/hour. The evolutions of shear stress versus tangential displacement are reported in Figure 5. The peak state is defined as the maximum

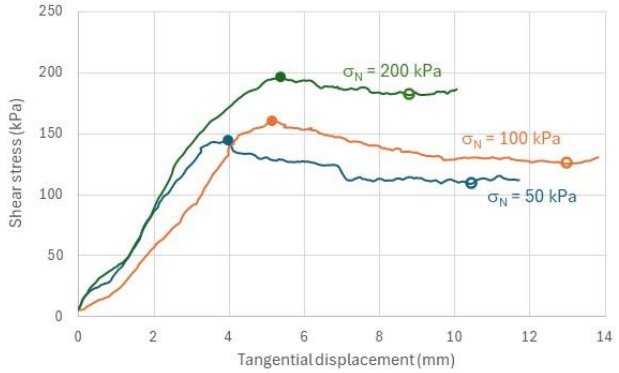
ratio of shear (τ) versus the normal (σ_N) stress, while the residual state corresponds to the minimum of this ratio (τ/σ_N) after passing the peak.



(a)



(b)



(c)

Figure 5. Direct shear tests performed on the specimens extracted after 6 years, at normal stress of 50 kPa, 100 kPa and 200 kPa. (a) 1st series on layer 6, (b) 2nd series on layer 6, (c) series on layer 7. Peak and residual states are reported by full and empty circles, respectively.

The peak and residual cohesion (c) as well as the associated friction angles (ϕ) measured are presented in Table 4. The peak values are compared with those obtained on laboratory samples cured for 7, 14 and 28 days, tested in consolidated undrained triaxial compression.

As for the other geomechanical properties measured, the layer 7 shows lower values than layer 6, with a significant drop in the friction angle. However, in both cases there is a positive change in cohesion which has greatly increased compared to that developed by samples produced and tested in laboratory at younger ages with values multiplied by a factor of 4 to 6. When compared to the natural soil, the treated soil exhibits values 10 to 20 times higher demonstrating a far greater resistance.

5 CONCLUSIONS

The objective of the present study was to carry out a series of geomechanical tests on samples of soil extracted from the Vidourle levee to assess the characteristics and the durability of the lime-treated soil after 6 years of weathering. Based on the results presented above, the following considerations can be drawn:

- the permeability measured on the soil treated with lime is consistently low;
- the soil treated with 2% of lime and then subject to weathering for 6 years has shown to maintain enhanced geomechanical properties if compared to the same natural soil tested in the laboratory (untreated);
- the geomechanical properties of the soil treated with lime tend to increase with the sample depth in the body of the levee;
- the geomechanical properties are significantly improved for the deeper layer (layer 6) demonstrating the positive impact of the pozzolanic reaction in the long term.

The upper layer considered in the study is located at a depth between 30 and 60 cm from the surface. Its position closer to the surface and the fact that the Vidourle levee is subjected to strong variations in temperature and humidity throughout the years, can possibly explain its worse behaviour. Deterioration due to weathering, or a different kinetics of development compared to the deeper material, more protected, could have caused this phenomenon. To verify this hypothesis, an additional monitoring campaign including sampling and testing is planned for 2024 to better investigate this topic.

Table 4. Parameters measured during the shearing tests performed on the samples extracted from the Vidourle levee after 6 years of aging (onsite samples) (from consolidated drained direct shear test) and compared to values obtained on laboratory samples tested at younger ages (from consolidated undrained triaxial tests).

Study	Soil - Cure	Peak resistance		Residual resistance	
		c (kPa)	Φ (°)	c (kPa)	Φ (°)
This study *(onsite samples)*	Layer 7 (2% treated soil) – 6 years	126	18	78	24
	Layer (2% treated soil) – 6 years	157 – 230	32 – 43	54 – 65	36 – 37
2015 study *(laboratory samples)*	Untreated soil	11	33	(residual state not measured from CU triaxial tests)	
	2% treated soil – 7 days	25	48		
	2% treated soil – 14 days	28	46		
	2% treated soil – 28 days	40	42

Solving challenges of operational areas for renewable energy infrastructure

Relever les défis des zones opérationnelles pour les infrastructures d'énergie renouvelable

ABSTRACT: The renewable energy sector requires new infrastructure for development, prefabrication, storage, installation and operation. Most often, the subsoil conditions of the construction facilities, roads and working platforms are characterised by weak clay, organic soil or sand deposals of low density or a combination thereof. The size of loads from e.g. turbine parts, foundation- or tower segments or cranes for installation are challenging. Resulting loads from e.g. low motion vehicles and crane hardstandings are characterised by high deviator-stresses. Anyhow, only limited differential settlements are accepted. To scope with these issues, a wide range of foundation techniques are used as e.g. floating platforms, dynamic compaction, vertical bearing elements or piling. For all techniques, special attention has to be paid on local bearing capacity on the surface, in combination with total and differential settlement. The paper presents a major project on the example of a large nacelle factory, and addressing requirements on working platforms, making use of the combination of different foundation techniques. The geotechnical design by combining analytic models and numerical analysis are presented and discussed.

RÉSUMÉ: Le secteur des énergies renouvelables nécessite de nouvelles infrastructures pour le développement, la préfabrication, le stockage, l'installation et l'exploitation. Le plus souvent, les conditions du sous-sol des installations de construction, des routes et des plates-formes de travail sont caractérisées par des dépôts d'argile faible, de sol organique ou de sable de faible densité, ou par une combinaison de ces éléments. La taille des charges provenant, par exemple, des pièces de l'éolienne, des segments de la fondation ou de la tour, ou des grues pour l'installation, est un défi. Les charges résultant, par exemple, de véhicules à faible mouvement et de grues sont caractérisées par des contraintes de déviation élevées. Quoi qu'il en soit, seuls des tassements différentiels limités sont acceptés. Pour faire face à ces problèmes, un large éventail de techniques de fondation est utilisé, comme par exemple les plates-formes flottantes, le compactage dynamique, les éléments porteurs verticaux ou les pilotis. Pour toutes ces techniques, une attention particulière doit être accordée à la capacité portante locale de la surface, en combinaison avec le tassement total et différentiel. L'article présente des projets majeurs sur l'exemple d'une grande usine de nacelles, et aborde les exigences sur les plates-formes de travail, en utilisant la combinaison de différentes techniques de fondation. La conception géotechnique par la combinaison de modèles analytiques et d'analyses numériques sont présentés et discutés.

Keywords: Working platforms; dynamic soil compaction; geogrids; case study; renewable energy.

1 INTRODUCTION

The south-eastern port area of the city of Cuxhaven in Northern Germany is being planned as the German Offshore Industry Centre, where several production facilities for offshore wind turbines and other components are based. The development of the south-eastern harbour extension was carried out by pumping sands from the North Sea several years ago. Due to the original topography and genesis, the flushing fields in the area of the harbour extension have special geotechnical features. In the tidally influenced area of the river Elbe, there is a soft to pulpy clay layer with widely varying thicknesses on medium-density tidal sands. This is covered by the approximately three metre thick layer of sand, which is loosely to densely compacted (Figure 1).

The eastern area of the harbour extension is used for a production facility for offshore wind turbines. The high stresses of up to 180 kN/m² from the construction and production in combination with low permissible settlements and a subsoil with a 2.0 m to

3.0 m thick layer of clay made special foundation engineering measures unavoidable. Following the evaluation of the ground investigation, the foundation concept envisaged a foundation for the base slab of the production hall, the office and restaurant building, the outbuildings and the circulation areas on a geogrid-reinforced foundation pad over a columnar ground improvement. Despite the high loads in some areas, the client wanted to do without a shallow deep foundation. The highly loaded column foundations, the crane runways and the sprinkler tank were piled.

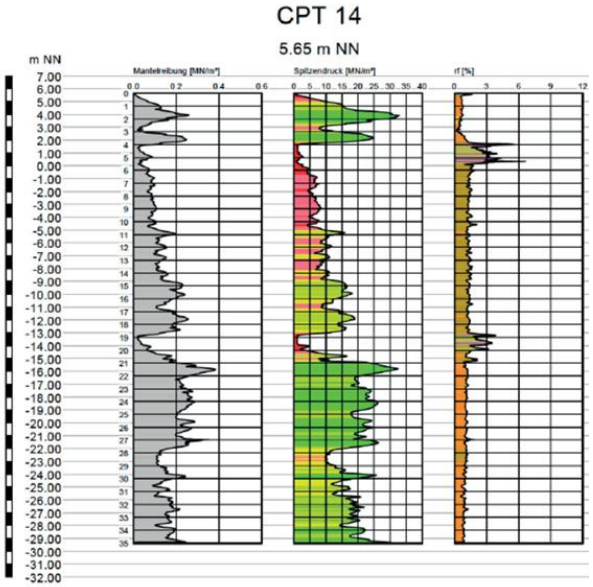

Figure 1. Cone penetration Test Profile, exemplarily.

The columnar soil improvement measure was carried out in the area of the existing access road and the parallel rainwater channel (DN 2,000, GRP material) using vibro-compaction (approx. 200 RSV columns) and in the majority of the area by means of dynamic deep compaction (approx. 5,300 DYNIV® columns) over an area of approx. 130,000 m².

Additional, Cuxhaven is preferred also for monopile production. Monopiles are to be temporarily until they are used in offshore construction. Due to the very large dimensions of the monopiles with diameters of 12 m to 14 m, a length of up to 130 m and a total weight of up to 3,500 tonnes, an economical foundation concept had to be developed for the total available area of just under 330,000 m². In addition to the aforementioned soil conditions of the south-eastern area, the inhomogeneous soil conditions in the area of the formerly approx. 4.00 m deep drainage ditch, which was backfilled in the course of backfilling, required special attention for a floating working area. The surface is to be designed in such a way that it can be driven over by the special transport vehicles for the monopiles.

From a geological perspective, the construction sites are located in the area of Holocene mixed mudflat deposits, which are strongly influenced by their proximity to the water and by the tides. There are Holocene, backfilled sands with a thickness of around 1.70 m to 4.00 m and a very heterogeneous bedding density (very loose to dense).

Below the fill, the subsoil exhibits a typical sequence of Holocene tidal deposits, which can be visualised as follows:

- locally existing lenses of tidal sands with a maximum thickness of 3.50 metres.
- upper clover horizon of varying thickness up to 10.00 m with a soft to stiff consistency. This clay is described as clayey silt with varying degrees of organic content and has low permeability.
- 5.00 m to approx. 17.00 m thick tidal sand layer in loose to medium-dense bedding,
- locally occurring, lower, up to 15.00 m thick clover layer with a soft to stiff consistency,
- From about 18.00 m below ground level, Pleistocene sands in medium-dense to dense compaction.

2 CONSTRUCTION OF NEW PRODUCTION FACILITYS

2.1 Requirements and foundation concept

In total, for the production of wind turbines, an area of 133,000 m² had to be improved. This was divided into six sub-areas, which were differentiated according to their subsequent use. The design load on the individual areas varies significantly between 40 kN/m² and 180 kN/m². Just 60,000 m² of the area is accounted for by the production hall, for which the settlements occurring were to be limited to such an extent that settlement differences incompatible with the structure could be avoided.

The foundation concept envisaged a vertical transfer of the large individual loads in the area of the columns via piles into the Pleistocene layers and a shallow-founded hall base in the other areas. Due to these different foundation systems, large settlement differences were to be expected, which could not be withstood without further geotechnical measures. It was therefore necessary to improve and homogenise the settlement-relevant clays.

In addition to the challenging technical constraints, the time pressure was a decisive factor in

this construction project. For this reason, consolidation using vertical drains and ballast fill, which can be used in similar construction projects, was not an option. As the planned construction period fell between the winter months of November and March, downtimes due to weather conditions had to be minimised.

After a variant test, dynamic intensive compaction with a diameter of over 2.50 m and the addition of foreign material was selected.

As part of a calibration field, a grid dimension of 7.00 m was defined in two phases. This results in a centre distance of 4.95 m. Figure 2 shows the corresponding grid scheme.

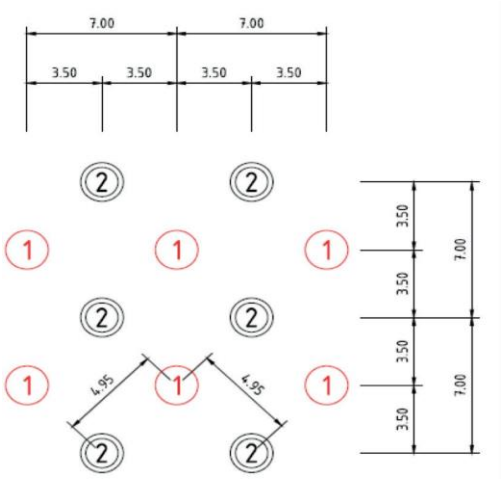

Figure 2. DYNIV® column grid with two offset phases.

Figure 3. Execution of dynamic compaction.

The work sequence provided for the removal of the partially very firm layer of cover sand layer by means of a preliminary excavation and the compaction of the underlying clay with the addition of coarse-grained material. The crater was then backfilled with the pre-excavated material and comparable sand, whereby the installation was carried out in layers. A total of around 5,300 DYNIV® columns were produced, with five machines achieving a peak output of 3,400 m² per day (Figure 3). The amount of material added was adapted to the soil parameters. While between 5 m³ and 10 m³ of crushed stone (base course material with crushed material, 0/32 mm grain size) was usually added to a compaction point, up to 51 m³ of crushed stone was added in areas where high water content was encountered.

2.2 Design of the load distribution layer

In order to ensure optimum load transfer into the compacted columns, a two-layer geogrid-reinforced foundation pad with a total thickness of 75 cm was designed as load and settlement distribution layer. This adaptable, ductile system can compensate for settlement differences resulting from different loads. The design required a long term design yield strength of 1,680 kN/m (per layer) considering creep and installation damage, which could be covered by a biaxial polyester geogrid Secugrid 120/120 Q6 with a short-term strength of 120 kN/m² (md and cmd) to be sufficient to ensure load transfer.

The serviceability verification could not be performed according to EBGEO, as the predefined boundary conditions (significant difference in bedding modulus of rigid column to soft soil > 75) were not met by the DYNIV® columns. Thus, the design was based on the differential equation as provided by Zaeske (2001), documented by Geduhn & Vollmert (2005), taking the column and subsoil stiffness into consideration.

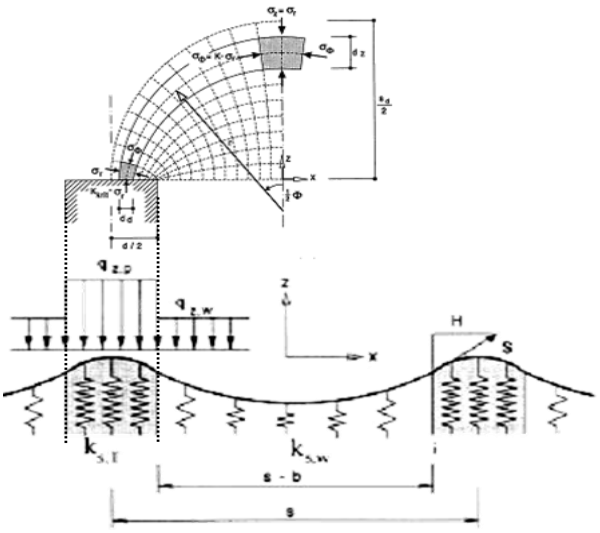

Figure 4. Principle model of the elastic embedded geosysnthetic between vertical bearing elements prone to settlement, arching model according to EBGEO.

Figure 4 shows the model, taking the stiffness of the vertical bearing elements into account. The verification of the static system resulted to a degree

of utilisation of 0.54 << 1.0, thus the ultimate limit state (ULS) was verified.

Beside ULS, the serviceability limit state (SLS) had to be focussed, as the allowable differential settlement was limited to less than 1.5 cm. The finite element method (PLAXIS 2D and PLAXIS 3D) was used, taking into account a linear elastic, ideally plastic model with the Mohr-Coulomb failure criterion. Beside taking into account the long-term design yield stiffness, the calculation of the two biaxial geogrids was carried out with a predefined plasticity limit. For other, more powerful material models, with which more realistic deformation predictions would have been possible, it was not possible to determine further material parameters due to the tight deadlines.

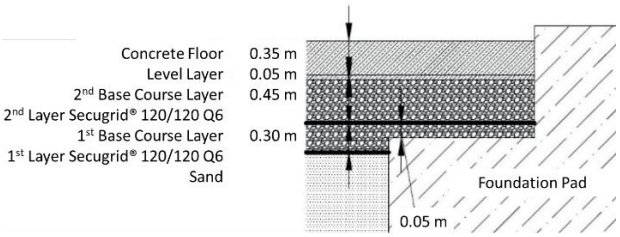

Figure 5. The two-layer, biaxial geogrid in the area of a reinforced concrete foundation (Dr Beuße).

In the area of the hall foundations, the biaxial geogrid layers were arranged as shown in Figure 5, so that notch and shear stresses within the concrete floor are reduced and avoided.

2.3 Installation

Figure 6. Interlocking of base course material and geogrid, compaction with the help of plate compactors (2nd installation level).

During the tender phase, the general contractor had specified Secugrid® 120/120 Q6 from Naue GmbH & Co. KG, as geogrid reinforcement and stabilisation in the first and second layer. Compaction test in a test environment verified the compatibility of the base course material crushed gravel 0/45 mm up to a bearing capacity (plate load test) of 150 MN/m². For this bearing capacity, a compaction of $D_{Pr} \geq 100\,\%$ was verified. The installation guideline required the installation of the base course material by introducing shear forces, so that the geogrid is slightly prestressed and the gravel will be pushed into the open grid structure to ensure proper interlocking of the stiff geogrid structure with the base course grain structure. Figure 6 gives an impression of the interlocking effect.

Figure 7. 1st installation level of the geogrid reinforcement.

The first geogrid layer was laid on the post-compacted sand subgrade (Figure 7). As shown in Figure 8, the second layer of the foundation pad was placed over the individual foundations up to the rising structural elements on a gravel base course.

Figure 8. 2nd installation level of the geogrid reinforcement in the production hall area.

2.4 Safety of construction and transport equipment

The projects in Cuxhaven indicate exemplarily, that weak subsoils covered by relatively thin medium-

dense to dense compacted sandy layers are sensitive to differential settlement. Furthermore, the stability of heavy equipment against ground bearing failure as well as against punching has to be ensured. In some cases, especially in large operational areas for the renewable energy sector as Cuxhaven, extraordinary loads have to be considered from the components itself, or transport vehicles to handle components as e.g. offshore tower segments with dimensions of e.g. 130 m length and 15 m diameter. The dimensions can even exceed the example as given in Figure 9, which represents an equalized load of approx. 110 kPa. Loads like these, demand a special attention to consider weak soil layers even in higher depth, as typically needed for road vehicles.

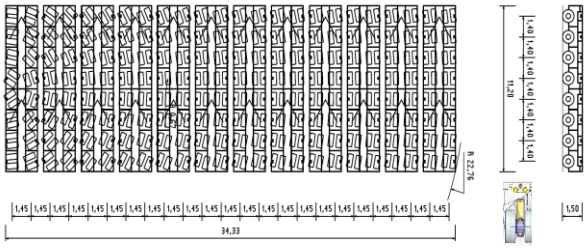

Figure 9. Example of transport vehicle dimensions 34m x 11m with heavy loading up to 120 kPa equalized load.

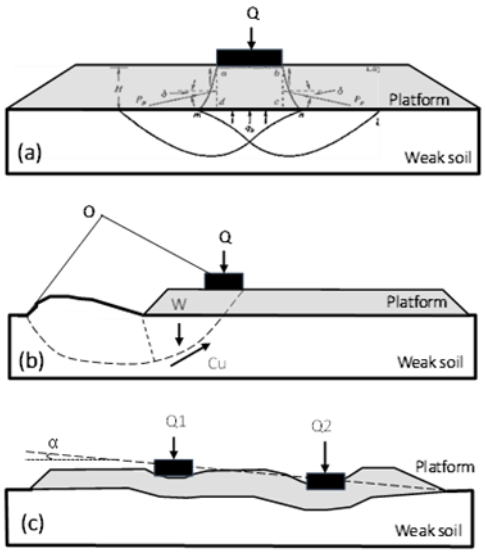

Figure 10. Failure modes to be considered for working platforms as well as for transport devices with large dimensions.

Thus, the punching resistance of the entire structure had to be checked by appropriate measures. Khansari et al. (2023) discussed several aspects of designing operational areas and working platforms, taking thin cover layers and weak subsoil conditions into consideration. Figure 10 outlines the three most relevant aspects, which are considered in design.

Complementing analytical approaches, finite element methods, 2D as well as 3D, allow to calculate the safety level by phi-c-reduction. Therewith, deformation-consistency can be considered more appropriate than using analytical models only. Strain conditions calculated, e.g. on the bottom of asphalt pavements, allow to discuss not only the absolute strain, but also the level of prestressing the system and, comparing with failure strains of asphalt, the tolerance for long term use.

CONCLUSION

Operational areas for renewable energy demand the development of large areas, often placed in locations sensitive to settlements. The presented project has been successfully designed and installed by a combination of soil improvement and stabilized base course layers, reinforced with geogrids of high long term stiffness characteristic. The requirements of the contractor using loads up to 180 kPa could have been met successfully.

Physical models of mechanical root-soil interaction

Modèles physiques de l'interaction mécanique entre les racines et le sol

A. Boiero*, M. Arroyo, E. Romero
Department of Civil and Environmental Engineering, Universitat Politècnica de Catalunya, Barcelona, Spain
**alvaro.boiero@upc.edu*

ABSTRACT: In geotechnical bioengineering, living plant material is used to perform engineering functions. In this context, one of the most complex aspects of the soil-root interaction problem is the interplay between the mechanical reinforcement effect and the hydraulic effect, mediated by suction. Soil-root mechanical interaction has been investigated on 1-g models and at scale, using centrifuge tests. The characteristics of model roots have been explored as well, by means of tensile and direct shear tests, in which the soil-root interface response under different loading conditions was studied. However, in most cases these studies were developed for extreme saturation conditions (dry or fully saturated state). This paper summarizes the advances made so far in the field of physical models applied to the analysis of soil-root interaction, and presents the general characteristics of the models currently under development at the UPC-BarcelonaTECH for the study of soil-root interaction under different saturation conditions, highlighting the advantages and limitations of such experimental methodologies.

RÉSUMÉ: Dans la bio-ingénierie des sols, le matériel végétal vivant est utilisé pour remplir des fonctions d'ingénierie. Dans ce contexte, l'un des aspects les plus complexes du problème de l'interaction sol-racine est l'interaction entre l'effet de renforcement mécanique et l'effet hydraulique, médié par la succion. L'interaction mécanique sol-racine a été étudiée sur des modèles à 1 g et à l'échelle, à l'aide d'essais en centrifugeuse. Les caractéristiques des racines modèles ont également été explorées au moyen d'essais de traction et de cisaillement direct, dans lesquels la réponse de l'interface sol-racine sous différentes conditions de charge a été étudiée. Cependant, dans la plupart des cas, ces études ont été développées pour des conditions de saturation extrêmes (état sec ou complètement saturé). Cet article résume les progrès réalisés jusqu'à présent dans le domaine des modèles physiques appliqués à l'analyse de l'interaction sol-racine, et présente les caractéristiques générales des modèles actuellement en cours de développement à l'UPC-BarcelonaTECH pour l'étude de l'interaction sol-racine dans différentes conditions de saturation, en soulignant les avantages et les limites de ces méthodologies expérimentales.

Keywords: Bioengineering; unsaturated soils; root-soil interaction; interface direct shear tests; 1-g root-soil models.

1 INTRODUCTION

The engineered use of vegetation is referred to as "bioengineering" (Coppin & Richards, 2007; Norris et al., 2008). One of the applications of soil bioengineering is the use of vegetation for slope stabilization. However, although vegetation began to be used for this purpose in ancient times, the formal adoption and development of this technology has been very slow, mainly due to the difficulties faced by engineers when trying to quantify its beneficial effects on slope stability (Coppin & Richards, 2007; Świtała et al., 2018).

The mechanisms of root influence on slope stability can be grouped into hydrological effects and mechanical reinforcement effects (Reubens et al., 2007). From a hydrological point of view, the presence of roots in the soil mass implies a reduction in moisture content do to the evapotranspiration process (which implies an increase in suction), and the generation of macropores during root growth (which results in a greater infiltration capacity). However, it should be noted that these effects occur at different times: the greatest infiltration occur during and immediately after rainfall events, while evapotranspiration predominates between rainfall events. In terms of mechanical reinforcement, it is possible to distinguish three types of root-mediated stabilization mechanisms (see Figure 1): A) *basal reinforcement*, provided by roots crossing a potential failure surface, similar to that provided by an anchor system; B) *lateral reinforcement* provided by the soil-root interface strength when the roots do not reach the failure plane and are located either in the sliding wedge (downstream of the tensile crack) or in the stable part of the ground (above the tensile crack); and C) *soil stiffening* due to the presence of roots in the sliding mass, particularly when there is an interaction between neighboring root systems (Reubens et al.,

2007; Wu et al., 2015; Schwarz et al., 2015; Giadrossich et al., 2017).

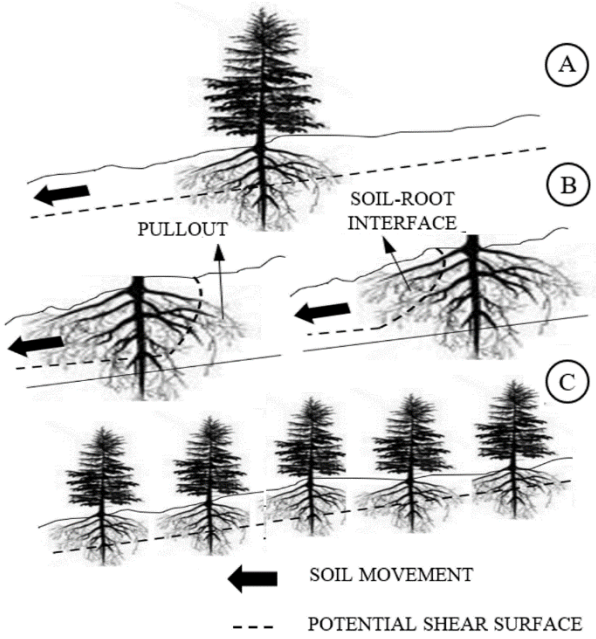

Figure 1. Root stabilization mechanisms: A) basal reinforcement; B) lateral reinforcement; C) stiffening.

Although root systems can penetrate up to 3m into the soil, 80% to 90% of tree roots are concentrated in the upper 0.9m of soil (Coppin & Richards, 2007; Norris et al., 2008). As a consequence, most of soil-root interaction phenomena occur in a low confining stress environment. Thus, during slope failure the unstable soil mass applies a passive pressure or thrust on the wedge soil downstream of the tensile crack and, at the same time, active thrust conditions are generated upstream, when the sliding mass separates from the tensile crack and the soil disaggregates in the form of blocks. This mechanism implies a progressive increase in volume (associated with an increase in void space) and a consequent decrease in total density, leading to a progressive failure.

According to the above, considering that the plant moves together with the sliding mass (because it is rooted in it), when the root system crosses the potential failure surface (Figure 1-A) it will experience displacements that mainly generate bending and predominantly pull-out axial loads. At the same time, lateral roots (Figure 1-B) will mobilize pull-out (when the plant is downstream of the tensile crack) or tensile resistance (when the plant is upstream of the tensile crack), which will depend on the roots themselves and the soil-root interface.

One of the most complex aspects of the soil-root interaction problem is that mechanical reinforcement and hydraulic effects, mediated by suction, interact with each other within a complex root system (Pollen, 2007; Stubbs et al., 2019). This fact seriously complicates purely empirical approaches. However, it must be considered in any soil-roots physical model for an adequate simulation of field conditions.

2 SOIL-ROOT PHYSICAL MODELS

The effects of plant roots on slope stability have been extensively studied over the last 40 years. Early studies on root reinforcement of soil focused on quantifying the mechanical behaviour of roots (O'Loughlin, 1974). In their pioneering work, Wu et al. (1979) studied the increase in shear strength ($\Delta\tau$) provided by a root system using a conventional direct shear test apparatus (63mm square box and 150mm in diameter circular box) to perform drained direct shear tests under constant load conditions (DST_{CNL}), both on natural moisture content and saturated soil-root samples. In addition, measurements of the tensile strength of roots by means a device based on the deformation of a calibrated spring were done.

In the following years, several studies were developed using physical models to analyze the effect of the root morphology and properties, under vertical uprooting stresses and under lateral loads (and moments) associated to wind action. Stokes et al. (1996) conducted a series of 1-g mechanical tests on model young tree root systems made of copper-coated steel wire (1-3 mm thick) and embedded in sand. Each root system was placed in a cylindrical container 300 mm high and 200 mm wide where manually placed damp sand was placed around it. Roots´ anchorage effects were quantified by measuring the pull-out resistance before failure in sand. Operstein & Frydman (2000) developed a simple dead-load application system in which roots were held at each end by specially developed 30 mm in diameter anchor grips, to obtain tensile stress-strain curves for real roots of different plants and diameters. Sonnenberg et al. (2007) performed centrifuge tests applying a scale factor n=15, using a 500x800x500mm height rigid box, with two transparent methacrylate faces. Several sensors were installed in the model: linear variable differential transducers (LVDT), pore pressure transducers (PPT), miniature tensiometers (Ten), and strain gauges attached to woody root analogues. Image processing techniques (Particle-image-velocimetry - PIV) were applied to obtain deformation fields. The model roots were fabricated with lime wood, as a pivoting root structure of L=100mm and A_m=3x3mm^2 size.

Subsequently, some research groups have idealised real root geometries and created artificial roots to assess pull-out strength and quantify the contribution

of roots to slope stabilization. This led to the development of scaled tests using centrifuge (Sonnenberg et al., 2012; Ng et al., 2016; Zhang et al., 2020), 1-g modelling (Zhang et al., 2020), and analysis of the hydromechanical behaviour of rooted soils under partially saturated conditions, both in shear apparatus and in centrifuge (Fraccica et al., 2022; Ng et al., 2016). In general, these investigations corroborate the beneficial effect of roots on slope stability, as well as the influence of the geometry and properties of the soil-root interface at low confining stresses, both under static and earthquake conditions. The importance of the scale factor in 1-g models was also highlighted, in order to consider the effect associated with the lack of confinement on such tests.

Some laboratory and field tests (Leung et al., 2015; Ng et al. 2013) have shown that vegetated soil could retain a suction of up to 10-20kPa within the root zone for rainfall with a return period of less than 10 years. However, most of the above-mentioned research has generally ignored the hydrological effects of evapotranspiration and the resulted induced soil suction.

3 MODELS AT UPC-BARCELONATECH

Computational simulation is now considered as key to accelerating research on soil-root system interaction, as it allows to generalize empirical research findings through virtual models (Stubbs et al., 2019). In relation with this, an experimental programme is under development at UPC-BarcelonaTECH with the following main objectives: a) to document the failure modes of the soil-root system under overturning/pull-out tests in a 1-g physical model, using root analogues; and b) to measure the strength at the soil-real root interface under partial saturated conditions, by means DST_{CNL}. The obtained data will be used in the development of new soil-root interaction simulation tools based on the G-PFEM platform (Geotechnical Particle Finite Element Method; Carbonell et al. 2022).

3.1 Materials

In this research, two soils are being used: a mixture of 70% BR37 quartz sand and 30% UQ12 silt (Material A); and a silty clay from the Agropolis batch, located in Barcelona (Material B). Particle size distributions are shown in Figure 2, while their physical properties are summarised in Table 1.

Two different 3D root analogue models used in previous studies (Liang et al. 2015; Liang & Knappett 2017; Zhang et al., 2020) are considered in this research (Figure 3a): one with a relatively narrow and deep architecture (ND), and another with a wider and shallower architecture (WS). Both models were created from root architecture data obtained from Pinus pinaster trees grown on predominantly sandy soils in France (Danjon & Reubens 2008). Root models will be printed on Acrylonitrile Butadiene Styrene (ABS) plastic, a material that exhibits similar behaviour to that of real roots (Liang et al., 2015).

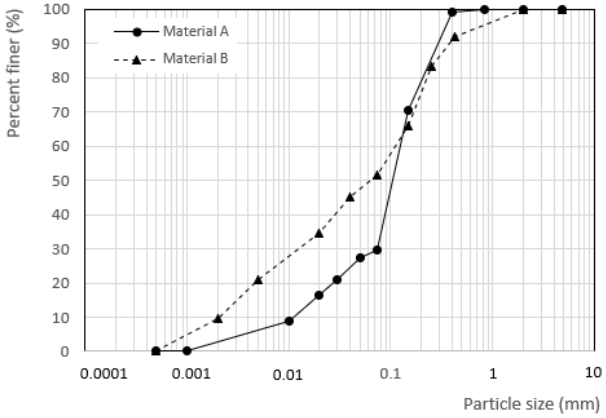

Figure 2. Particle size distribution of materials A and B.

Table 1. Physical properties of materials A and B.

	Material	
	A	**B**
Mean grain size, d_{50} (mm)	0.11	0.07
Density of solids, ρ_s (Mg/m^3)	2.65	2.70
Dry density, ρ_d (Mg/m^3)	1.61	1.80
Maximum void ratio, e_{max}	0.849	-
Minimum void ratio, e_{min}	0.440	-
Plastic limit, PL	NP	16.5
Liquid limit, LL	NP	28.9
Hydraulic conductivity, k_{ws} (m/s)(*)	$5x10^{-6}$	$9x10^{-9}$

(*) Under saturated conditions

Considering a weighted average diameter of the printed root model ($d_{r,\,ave}$) equal to 2 mm, an optimum value of N=20 was selected as scale factor for the tree analogues. Such selection is supported on the rate $d_{r,ave}/d_{50}$ (=17 for material A; =28 for material B), which must be graeter than a minimum threshold of 15 to avoid soil-structure interferences in physical models (Wood, 2004).

For the interface tests in the direct shear apparatus, two types of wood samples were used in order to consider the effect of root´s roughness: a) samples of real roots from Pinus halapencis, obtained in the Collserola mountain range, located near Barcelona (relatively high roughness); and b) samples of a commercial treated pine wood (relatively low roughness).

3.2 Overturning/pull-out tests (1-g model)

According to the failure mechanisms outlined above (see Figure 1), it seems appropriate to assume that the overturnig/pull-out tests allow the analysis of the root extraction scenario from a stable soil, analogous to a surface landslide initiating above the tree line, or to tree uprooting associated with wind action.

A rigid box of dimensions 250x700x400 mm in height, constructed with methacrylate, will be used for 1-g physical models (Figure 3). A 10 mm layer of gravel will be placed on the bottom of the box to facilitate drainage, and a 100 mm layer of BR37 sand on top of it. A 1:20 root model will be installed in the central part of the container, and then the soil will be placed around it by compacting successive layers until reaching void ratios of 0.645 for material A (corresponding to a dry density of 1.61 Mg/m^3) and 0.467 for material B (corresponding to a dry density of 1.80 Mg/m^3). The tests will be performed at variable saturation levels {0-40-70-95}%, which will be reached by ascending saturation from the base of the box, and will be controlled by the installation of a METER Group tensiometer TEROS-31, and several SEN0193 sensors for soil moisture measurement. Readings from these devices will be analysed with the SWCC curve of each material, in order to verify the reached saturation degree.

Subsequently, overturning/pull-out tests will be performed. For the overturning tests, the load will be applied at a point located 60 mm above the surface of the model, through a RS Pro 100N Electric Linear Actuator motor, working at a constant speed of 0.15mm/min (material A) and 0.08mm/min (material B). It will be recorded: i) the load applied on the trunk, by means of a CTCM load cell of 15 kg capacity; and ii) the lateral movement, through a CONTROLS displacement transducer of 25 mm capacity. In the case of pull-out tests, the loading system arrangement will be modified, as illustrated in Figure 3b, and the root of the model will be extracted under the same parameters indicated for the overturnig tests, recording the following: i) the load applied on the top of the trunk; and ii) the vertical displacement. For this, the same sensors mentioned above will be used.

Relative root-soil stiffness ratio is being considered to compensate for the lack of confinement in the 1-g model.

3.3 Soil-root interface tests

When trees are above the tensile crack, as occurs in the case of clearings, riverbanks, or cuts for railroads and roads (Giadrossich et al., 2019), the activated force depends mainly on the friction at the soil-root interface, which can be studied from interface direct shear tests.

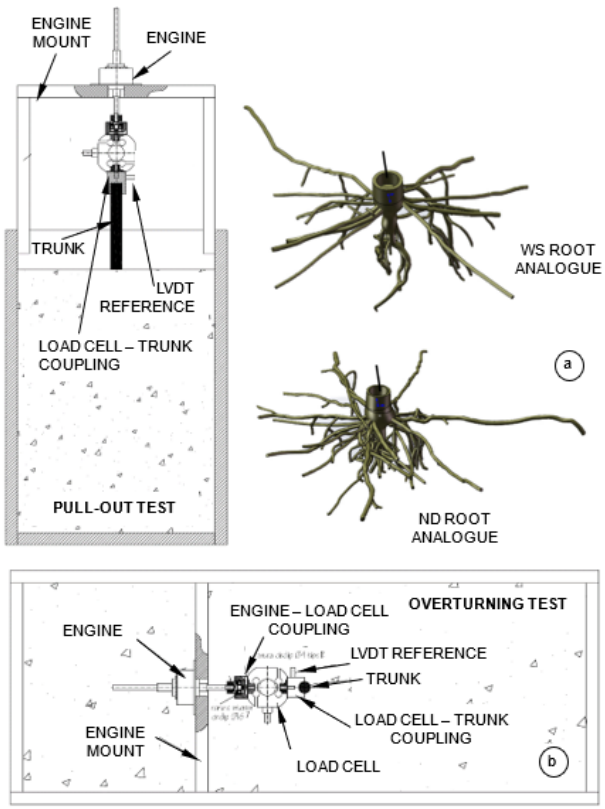

Figure 3. 1-g physical model arrangement: a) root analogues; b) model components.

The research is being conducted on a Wykeham Farrance model 27-WF2160 AUTOSHEAR direct shear machine. The vertical and horizontal displacements in the specimen, and the shear force during the test, are recorded through LVDTs and a 5kN horizontal load cell, using data acquisition software incorporated in the direct shear apparatus. Samples from soils A and B were prepared at the same initial conditions contemplated in the 1-g model. The height of the soil samples was 20mm. For the interface tests, a 14.5mm high and 60x60mm size wood sample was placed in the lower half of the shear box. Then, the soil sample was placed on it. The DST_{CNL} were performed using three initial normal stresses σ_o={7-15-24.5}kPa, on the two types of wood samples mentioned above. The horizontal displacement rate was set at 0.15mm/min (material A) and 0.08mm/min (material B). Figure 4 shows preliminary results obtained in the interface tests on Material A, considering the extension of the Mohr-Coulomb model for partially saturated soils proposed by Fredlund et al. (1978), and the variation of shear strength (τ) as a function of water ratio ($e_\omega=S_{rf}e_f$). This parameter is appropriate as volumetric state variable

because it tends to void ratio (e) under nearly saturated states (Romero & Vaunat, 2000).

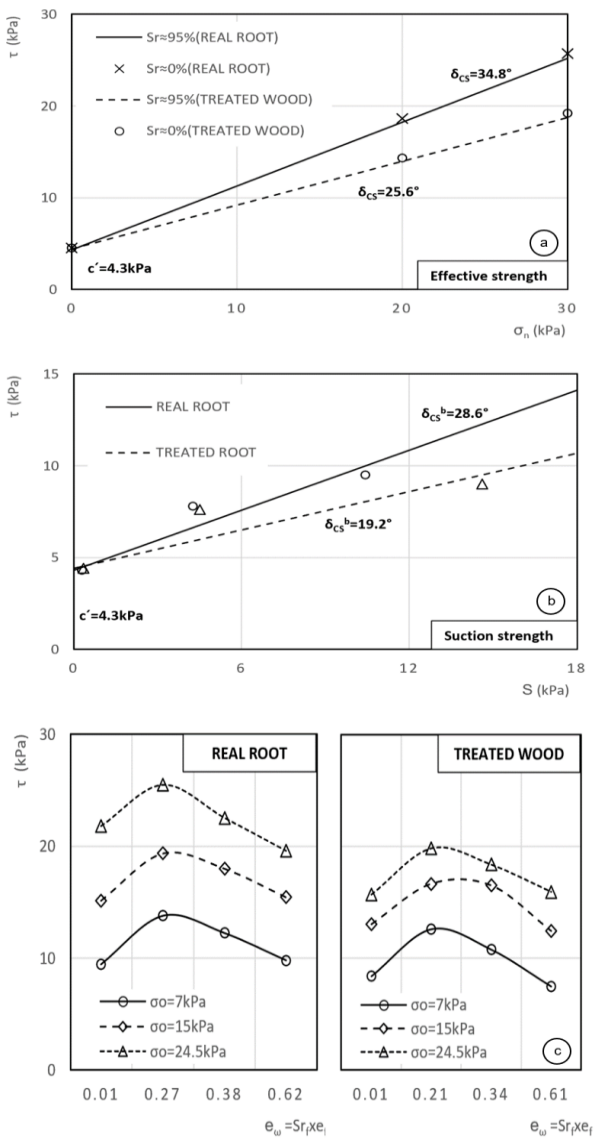

Figure 4. Preliminary results soil-real root interface tests on Material A.

According Figure 4a, from the τ-σ_n graph, the soil-real root (high roughness) effective interface friction angle at the ultimate shear strength is δ_{sc}=34.8º, with an effective soil-root adhesion of 4.3kPa; while the soil-treated wood (low roughness) effective interface friction angle at the ultimate shear strength is δ_{sc}=25.6º, with an effective soil-root adhesion of 4.3kPa. The effect of suction can be seen in Figure 4b. For the real root-soil interface, $\delta_{sc}{}^{b}$=28.6º, while for the treated wood-soil interface, $\delta_{sc}{}^{b}$=19.2º. Finally, from Figure 4c it is evident that for rougher roots, the shear strength at the interface (including the effect of the degree of saturation) is higher than for treated wood, representative of less rough roots.

4 CONCLUSIONS

A review of the physical models used over the last 40 years to study the effect of roots on slope stability, shows the evolution of research from simple root analogues tested in 1-g physical models, to 3D printed root analogous with mechanical properties like those of real roots, employed in 1-g and scaled centrifuge physical models. In addition, direct shear apparatus looks like a useful tool to study the soil-root interface. There is also a trend towards the use of computational simulation in research, as it allows to generalize empirical research findings through virtual models. At the UPC-BarcelonaTECH experimental research is currently underway, which will serve to validate a soil-root interaction simulation tools based on the G-PFEM platform.

ABSTRACT: When pile foundations and the ground around them are thermally-activated as part of a shallow geothermal energy system, new and somewhat complex changes in pile-soil interaction occur. In this paper, the influence of the relative expansion and contraction between the pile and surrounding soil, as expressed via the ratio of the coefficient of thermal expansion (CTE) of the soil to that of the pile, is revisited. Previous steady-state thermo-mechanical analysis by the authors suggested that this may be a very significant parameter especially when the CTE ratio was somewhat greater than 1 but more recent work has shown there are a number of other factors which may work to either mitigate or exacerbate this effect. This paper brings together recent work relating to this effect, to provide guidance on the impact of the form of the thermal loading in time and the initial mobilisation of the pile shaft resistance on when the CTE ratio may be significant in the functioning of thermally-activated pile foundations.

RÉSUMÉ: Lorsque les fondations sur pieux et le sol qui les entoure sont thermiquement activés dans le cadre d'un système d'énergie géothermique peu profond, des changements nouveaux et quelque peu complexes dans l'interaction pieu-sol se produisent. Dans cet article, l'influence de la dilatation et de la contraction relatives entre le pieu et le sol environnant, exprimée par le rapport du coefficient de dilatation thermique (CTE) du sol à celui du pieu, est revisitée. Une précédente analyse thermomécanique en régime permanent par les auteurs a suggéré que cela pouvait être un paramètre très important, mais des travaux plus récents ont montré qu'il existe un certain nombre de d'autres facteurs susceptibles d'atténuer ou d'exacerber cet effet. Cet article rassemble des travaux récents relatifs à cet effet, pour fournir des indications sur l'impact de la forme du chargement thermique dans le temps et la mobilisation initiale de la résistance du fût du pieu lorsque le rapport CTR peut être significatif dans le fonctionnement des fondations sur pieux.

Keywords: Piles; thermal; interactions; safety

1 INTRODUCTION

In order to reduce humanity's reliance on carbon intensive energy and to reduce overall energy demand, many countries are looking to source energy via sustainable technologies. An example of this type of technology are shallow geothermal energy (SGE) systems, which can be used to heat and cool buildings. SGE systems have been widely used since the oil-shocks of the 1970s, especially in North America and Northern Europe and have been demonstrated to reduce environmental impact, have low operational costs and save on primary energy expenditure.

For the implementation of SGE, especially in urban areas, the utilization of the pile foundations as a substitute for borehole heat exchangers, has received increasing attention over the past 20 years, amidst efforts to establish renewable and sustainable, heating and cooling systems within the construction industry. A significant number of experimental studies both in the field and laboratory, supplemented by numerical studies, have been undertaken to examine the technical issues associated with the use of thermally-activated pile foundations (TAPS). When pile foundations and the ground around them are thermally-activated as part of an SGE system, new and somewhat complex changes in pile-soil interaction occur. These effects are

a function of a number of factors, especially the restraint of the pile along its shaft and at the ends, in addition to the thermal characteristics of the soil and pile. In this paper, the influence of the relative expansion and contraction between the pile and surrounding soil, as expressed via the ratio of the linear coefficient of thermal expansion (CTE) of the soil to that of the pile, is examined.

While the CTE of construction materials like steel (11-13 με/K) are well defined, the CTE of concrete is somewhat more variable depending primarily on the mineralogy of the aggregates; e.g. Bonnell & Harper (1951) report values of 6.1-8.5, 8.6-10.4 and 12.2-13.7 με/K for limestone-, granite- and quartzite-based concretes. The CTE of granular soils will also depend largely on the mineralogy of the soil particles with e.g. Bonnell & Harper (1951) reporting values of 4.0- 6.5, 5.4 – 9.0 and 11 – 12.6 με/K for limestone, granite and quartzite aggregates. For concrete piles, in granular soils, the range of values for the CTE ratio is likely to be in the range of 0.5 to 2. In fine-grained soils, the volumetric response to drained thermal loading not only depends on mineralogy but also the over-consolidation ratio. Broadly speaking, in normally and lightly over-consolidated clay, the soil will contract irrecoverably during heating (thermally-induced consolidation) but as the soil becomes over-consolidated, recoverable thermal expansion is observed. In this latter case, indications from experimental data (e.g. Cekerevac & Laloui, 2004) suggest the CTE ratio could be in excess of two.

The potential influence of the CTE ratio in the response of thermally-activated (TA) piles was previously explored by Bodas Freitas et al. (2013), Bourne-Webb et al. (2016) and Bourne-Webb et al. (2019) for a TA pile in a cohesive medium and based on steady state thermal conditions. This suggested a strong effect with the thermal axial stress change becoming increasingly tensile as the CTE ratio increased, as illustrated in Figure 1 where the max. thermal stress in the pile, normalised by the thermal stress in a perfectly restrained pile, is plotted against the pile head thermal movement, normalised by the expansion of a perfectly unrestrained pile.

Rotta Loria & Laloui (2016), illustrated a similar effect when examining the influence of CTE ratio on the interactions between pairs of piles, and Gawecka et al. (2017) found that in back-analysing a TA pile test in over-consolidated London Clay, a CTE ratio of 1.8 was needed to achieve good agreement.

Recognising that steady state thermal conditions or long-periods of sustained thermal loading were not necessarily representative of realistic seasonal thermal loadings, and following the review of cyclic thermal loading of TA piles in Bourne-Webb & Bodas Freitas (2020), further work was undertaken using numerical analysis to explore how balanced periodic thermal loads impact on the behaviour of TA piles and the influence of CTE ratio within this.

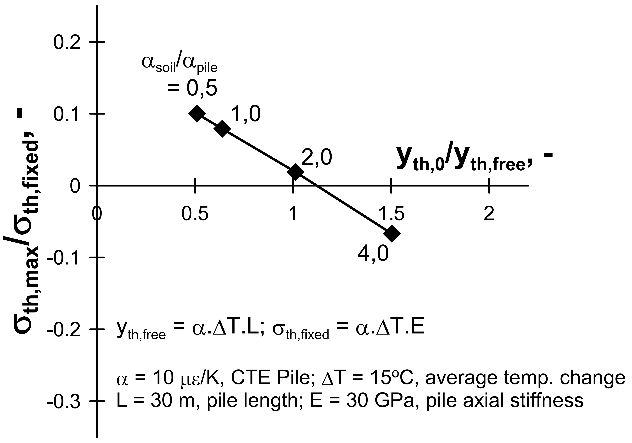

Figure 1. Influence of CTE for a pile in a cohesive medium under thermal steady state conditions (Bourne-Webb et al., 2019)

Bourne-Webb et al. (2022a, 2022b) highlighted how the response of TA piles to cyclic thermal loading was linked to the proportion of the available shaft resistance that was initially mobilised under mechanical loading (quantified by the factor M, the ratio between the shaft resistance mobilised at working load and the ultimate shaft resistance) which was a function of the load itself and pile spacing in groups. Bodas Freitas et al. (2021) modelled the response of a cyclically TA pile in a cohesive medium with the initial shaft mobilisation, M ≅ 50% and 90%, and with varying CTE ratio. In comparison to the steady state case previously examined, it was shown that the effect was much reduced, Figure 2.

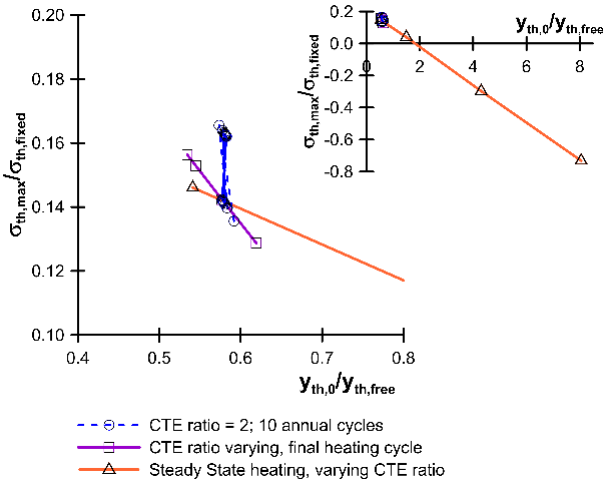

Figure 2. Influence of CTE for a pile in a cohesive medium under transient thermal loading, (Bodas Freitas et al., 2021)

To further explore these results, the work presented herein expands on that in Bourne-Webb et al. (2022a) by examining the role of the CTE ratio in the response of TA piles in granular media at differing levels of initial shaft resistance mobilisation.

2 BASIS FOR ANALYSES

In the axisymmetric finite element analyses presented here, a single reinforced concrete pile with a diameter of 1 m and a length of 30 m was considered, and Figure 3 illustrates the geometry used for the analysis domain. The radius of the model domain was varied between 30 m and 2 m. The reduced radial dimensions permit the behaviour of an infinite pile group to be examined based on a unit cell approach with the pile spacing being equivalent to 2x the radius.

The pile was modelled as a linear elastic material and the soil was modelled as linear elastic-perfectly plastic with a Mohr-Coulomb failure criterion, using the program ABAQUS 2016 (Dassault Systèmes, 2021), with the mechanical and thermal properties outlined in Table 1. The soil stiffness is shown graphically in Figure 3 and averages 129 MPa over the length of the pile.

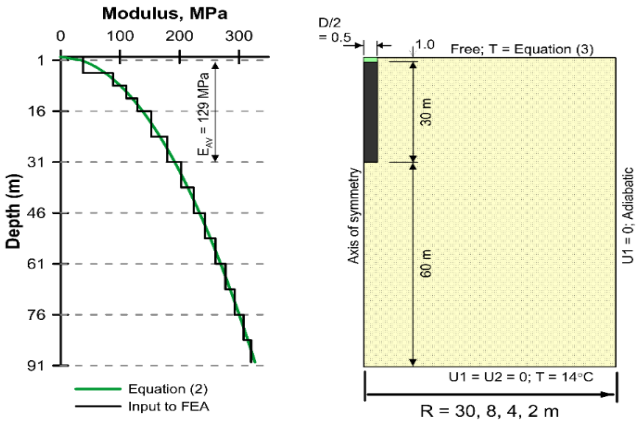

Figure 3. FE Model geometry and soil stiffness variation.

The modelling sequence and temperature boundary conditions were applied as follows: i) the initial stress and temperature fields were established based on the K_0 and T_0 values in Table 1; ii) a periodic temperature function, Eqn. (1) was applied at the ground surface over a period of 10 years, to mimic the initial temperature profile in the near-surface region (T_0 = 14°C, ΔT = 11°C; t is the time in years); iii) The pile was wished-in-place and then mechanically loaded; iv) 10 years of TA pile operation was modelled by applying a temperature change based on Eq. (1) along a line extending over the length of the pile shaft, at a radius of 0.4 m (T_0 = 14°C, ΔT = 12°C). During this period the surface temperature was switched to 23±2°C, to represent the climate-controlled building atop the foundation.

$$T = T_0 + \Delta T.sin[2\pi(t)] \quad (1)$$

Mechanical loads were imposed on in order to generate different levels of initial shaft resistance mobilisation, M which are quoted alongside the respective results in Figures 4 to 6.

3 RESULTS & DISCUSSION

In the following, the results of a parametric analysis utilising the model described in the previous section are presented.

Figure 4 presents the baseline case for an isolated, cyclically TA pile (domain radius, R = 30 m) with a shaft mobilization M = 100% and shows the evolution of thermally-induced pile head settlement, $y_{0,th}$ and axial load, N_{th} for soil:pile CTE ratios of 1:1, 1:2 and 2:1, over 10 years. All start with pile heating, except CTE 1:1c which started with pile cooling. It is apparent that whether the TA starts with heating or cooling only affects the first couple of years, after which the response converges.

In all cases, during the first pile cooling phase, significant additional settlement developed: around 10 mm with CTE ratios of 1:1 and 2:1, after which it is almost stable, and about 20 mm when the CTE ratio was 1:2 (pile expands more than the soil) which continues to exhibit increasing settlement across the 10 years simulated. Thermally-induced axial load changes follow a similar pattern with an initial increase in compression followed by quasi-stable load variations with CTE ratios of 1:1 and 2:1 but a steady increase in load when the CTE ratio was 1:2.

Figure 5 illustrates the effect of cyclic TA for cases where the domain radius is reduced to R = 4 and 2 m, to capture TA pile group effects in an approximate manner. Again, CTE raios of 1:1 (C03, C10), 1:2 (C04, C13) and 2:1 (C07, C37) were considered. With R = 4 m, M remains close to 100% but when R = 2 m, M reduced to about 90%.

Compared to the isolated pile case, a clear reduction in induced thermal movement is seen and the effect of the CTE ratio variation is also progressively eliminated. Broadly speaking, the response is similar to those reported by (Bourne-Webb et al., 2022a). In terms of the thermal load changes, the case where the CTE of the pile is twice that of the soil continues to lead to significant increases (R = 4 m) or much larger amplitude (R = 2 m).

Although not shown here, when the value of M is reduced (moving from a factor of safety on shaft

resistance of 1 to 2 with respect to the mechanical load), the increase in initial stability (reduced M) of the TA pile leads to the thermal ratcheting in R = 4 m cases being eliminated. Again, the main effect of the variation in CTE ratio is in the thermally-induced axial load changes which are smaller than the cases with high initial shaft mobilisation.

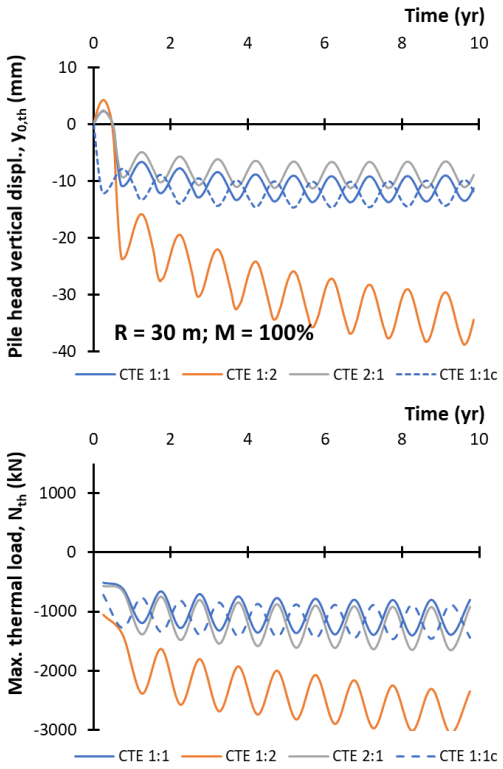

Figure 4. Isolated TA pile (R = 30) with high M.

4 CONCLUSIONS

The work presented in this paper continues to build on the understanding of the response of TA piles: the influence of the geometric layout of the pile(s), mechanical loading and key thermal parameters, i.e. CTE.

While under steady state thermal conditions the CTE has been shown to have a profound effect on pile-soil interactions, when balanced cyclic thermal loading is considered, the resulting effect depends on other factors as discussed above – namely, pile spacing and the initial shaft mobilisation under mechanical loading.

If piles are largely isolated, then care needs to be exercised when cyclic thermal loading is applied on piles with high initial mobilisation of the shaft. More so, if the CTE of the pile is larger than that of the soil.

Depending on the degree of mechanical interaction between piles within a group, which affects the initial shaft mobilisation, the effect of CTE variations in the cyclic thermal response can be reduced or even eliminated.

ABSTRACT: Previous work by the authors reviewed the reported response of full- and small-scale piles in tests in granular soils where they were subject to cyclic thermal loading. In the case of the former, largely stable behaviour has been reported but amongst the latter, the reported response consistently reveals irrecoverable settlement and increase in axial compression stress. This later is reported to be a function of the applied load with greater irrecoverable settlement occurring at lower global factor of safety and has been attributed to a variety of possible mechanisms. A hypothetical mechanism based on the initial mobilisation of the pile shaft resistance was proposed to explain this and then tested by undertaking numerical analysis. This confirmed the stable behaviour of the full-scale piles was likely due to low mobilisation (high margin of safety) with respect to the shaft resistance, while in the small-scale tests, the reverse was true. In this paper, a small-scale test on a thermally-activated pile has been back-analysed. In the test, the mechanical load-displacement behaviour along with the response to three cycles of heating and cooling were reported in sufficient detail to provide a good basis for the analytical work. It is shown that by matching the mechanical response, reasonable agreement between the thermal part of the test and finite element back-analysis can be achieved, and that the agreement can be further improved through calibration of the coefficient of thermal expansion of the pile and soil.

RÉSUMÉ: Des travaux antérieurs des auteurs ont examiné la réponse rapportée des pieux à grande et petite échelle lors d'essais dans des sols granulaires où ils étaient soumis à une charge thermique cyclique. Dans le cas des premiers, un comportement largement stable a été rapporté, mais parmi les seconds, la réponse rapportée révèle systématiquement un tassement irrécupérable et une augmentation de la contrainte de compression axiale. Ce dernier est signalé comme étant une fonction de la charge appliquée avec un tassement irrécupérable plus important se produisant à un facteur de sécurité global inférieur et a été attribué à une variété de mécanismes possibles. Un mécanisme hypothétique basé sur la mobilisation initiale de la résistance du fût du pieu a été proposé pour expliquer cela, puis testé en entreprenant une analyse numérique. Cela a confirmé que le comportement stable des pieux à grande échelle était probablement dû à une faible mobilisation (marge de sécurité élevée) par rapport à la résistance de l'arbre, alors que dans les essais à petite échelle, l'inverse était vrai. Dans cet article, un essai à petite échelle sur un pieu activé thermiquement a été rétro-analysé. Dans le test, le comportement mécanique de charge-déplacement ainsi que la réponse à trois cycles de chauffage et de refroidissement ont été rapportés de manière assez détaillée, fournissant une bonne base pour le travail analytique. Il est démontré qu'en faisant correspondre la réponse mécanique, un accord raisonnable entre la partie thermique de l'essai et la rétro-analyse par éléments finis peut être obtenu, et que l'accord peut être encore amélioré par l'étalonnage du coefficient de dilatation thermique du pieu et du sol.

Keywords: Piles; thermal; interactions; safety.

1 INTRODUCTION

In the last decade, numerous (more than 50) experimental studies examining the response of thermally-activated (TA) piles either at 1-g or in the centrifuge at N-g acceleration have been published. Such testing is promoted as being able to provide valuable insights into the response of geotechnical structures in a more controlled and cost-effective manner than e.g. full-scale tests in the field.

Bourne-Webb et al. (2019) and Bourne-Webb & Bodas Freitas (2020) collated the results for such studies, along with full scale tests on TA piles and found a distinct discrepancy between the reported behaviours, especially with respect to the normalised maximum axial thermal stress response ($\sigma_{th,max}/\sigma_{th,fixed}$

where $\sigma_{th,fixed} = \alpha\Delta T.E$; and α = Pile CTE; ΔT = Temp. change; E = pile stiffness; L = pile length) and the likelihood of the pile head movement ($y_{th,0}$) exceeding the free thermal expansion of the pile ($y_{th,free} = \alpha\Delta T.L$), i.e. $y_{th,0}/y_{th,free} > 1$, Figure 1. Reduced axial thermal stress was attributed to the low confining stress acting in 1-g and the very small thermal displacements generated on the model pile interfaces irrespective of scale, due to the short length of the piles. Pile head movement exceeding $y_{th,free}$ was attributed to effects that led to irrecoverable settlement: namely, reduction of available shaft restraint during cooling and load transfer to the pile base, Figure 2.

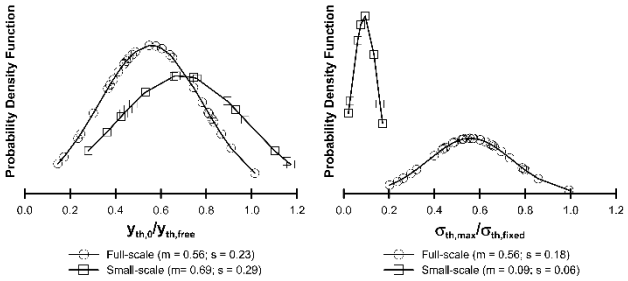

Figure 1. Stress-displacement response of full- and small-scale TA pile tests.

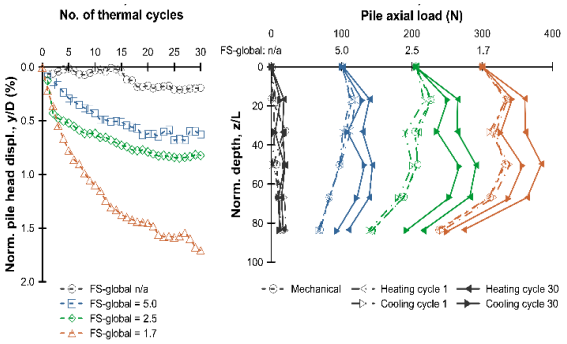

Figure 2. Settlement & axial load response in small-scale cyclically TA pile, Nguyen et al. (2017).

2 BASIS FOR ANALYSES

The model tests used as the basis for this study were those reported by Wang et al. (2016, 2017) in which a single, 104 mm diam., 1.4 m long pile embedded in dry sand was loaded mechanically and then subject to heating and cooling cycles. Specifically, the behaviour of Pile 4 which had a W-shaped heat exchanger tube layout is examined here. In this study, the finite element analysis (FEA) program PLAXIS 2D 2023.1 was employed to undertake the back-analysis of the model test.

The geometry used is based on the physical dimensions of the rectangular test tank which was 1.75 m deep and had plan dimensions of 8 x 8 m^2. While it is possible that the proximity of the lower boundary may have influenced the test results, for this exercise it is not so important as the FEA is replicating the test boundary conditions. The test piles were installed 1 m from the side boundaries and the FEA simplified the geometry to be axisymmetric with a domain radius of 1,0 m (c. 10 pile diameters), Figure 3.

Basic characteristics of the sand used in the testing were reported, along with details of the preparation method and the target initial state: a relative density of about 63%. These details were used to infer suitable parameters to be employed in the back-analysis, Table 1. The stress-dilatancy approach developed by Bolton (1986a, b) was employed to assess the peak angle of shearing resistance that might be applicable in the sand at the very low confining stress in the tank. This suggested a peak angle of shearing resistance of about 40° and thus, a value of φ' = 34° was used in conjunction with an angle of dilation, ψ of 6°, in the FEA. Iwasaki & Tatsuoka (1977) and Mayne (2000) were used to provide an initial estimate for the stiffness parameters, reflecting the confining pressures and level of mobilisation within the model. In the FEA, the Mohr-Coulomb (MC) model available in PLAXIS was employed. These values were then calibrated in order to better reproduce the reported load-displacement of the test piles – primarily through adjusting the soil stiffness and initial stress state.

The thermal and mechanical properties for the model pile were less clearly defined and quoted values in Wang et al. (2016, 2017) appear to be generic rather than model specific, e.g. the quoted coefficient of thermal expansion (CTE) is $10x10^{-6}$ K^{-1} with no mention of their having tested the pile to obtain the value. Likewise, the applicable pile Young's modulus.

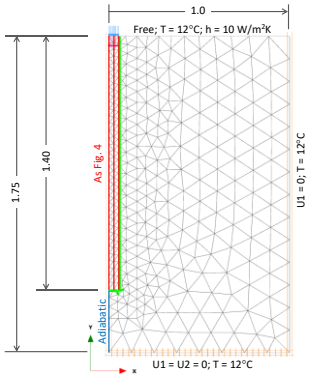

Figure 3. Geometry used in FEA.

Standard mechanical boundary conditions were applied, i.e. fully-fixed on bottom, horizontal fixity on sides and free on the top surface. Regarding temperature boundary conditions, the bottom and outer edge were held constant at 12°C; below the pile, the centreline was set as adiabatic; the surface was set to be convective with a thermal conductance of

10 W/m^2.K and an air-temperature of 12°C. Within the pile, temperatures following the average pile temperaure reported by Wang (2016, 2017) were imposed along lines at x = 0, r/2 and r, where r is the pile radius, Figure 4. This ensured that the pile volume underwent a constant temperature change.

The back-analysis of the model tests was undertaken in two stages: first, the mechanical load-displacement response was evaluated with initial stress, soil shear strength & stiffness parameters calibrated to approximate the response reported by Wang (2016, 2017), then the thermo-mechanical response was evaluated (assuming the above parameters were not affected) with variations in the thermal properties detailed in Section 3. In reproducing the mechanical load-displacement response, the set of parameters finally arrived at included an At-rest Earth Pressure coefficient, K_0 = 1 this is higher than e.g. that given by the Jaky-formula (K_0 = 1-sinφ', Jaky (1948)) but data from Boulon & Foray (1986) show that at low vertical stress, in small scale tests on piles, it is possible to have K_0 values inexcess of 1.0, depending on the density of the soil. So the value used as considered reasonable.

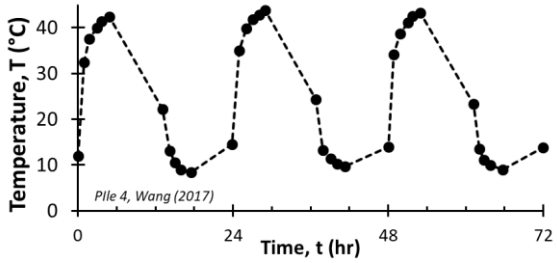

Figure 4. Average pile temperature imposed in FEA, adapted from Wang (2017).

3 RESULTS & DISCUSSION

3.1 Load-displacement response

In Wang et al. (2016, 2017), one model pile was tested in order to define the mechanical behaviour of the pile under axial load. The results were consistent and used to define a working load of 10 kN which was applied to the other test piles before the thermal part of the test was carried out.

After only small alterations in the initiallly assessed soil parameters, acceptable agreement between the reported behaviour and the FEA using both the MC and HS soil models was obtained, Figure 5. This mainly involved, adjustments in the distribution between φ‘ and ψ, and the soil stiffness. From this analysis, it was possible to examine the underlying response which revealed that the available shaft resistance was only a small proportion of the total, around 1,5 to 2 kN, with the remainder derived from the pile base. Thus, a working load of 10 kN, as used by Wang et al. (2016, 2017), implies that the shaft resistance is fully mobilised prior to thermal loading.

3.2 Thermo-mechanical behaviour

Before examining the thermo-mechanical (TM) response, the predicted temperature variation was validated against the radial temperature field reported in Wang (2017). Figure 6 shows this comparison which is very good, confirming that the model is providing an acceptable reproduction of the thermal response. Figure 7 shows the temperature contours for a steady state thermal analysis, to illustrate the effect of the boundary conditions on the temperature field. These fields were the same irrespective of the soil model employed.

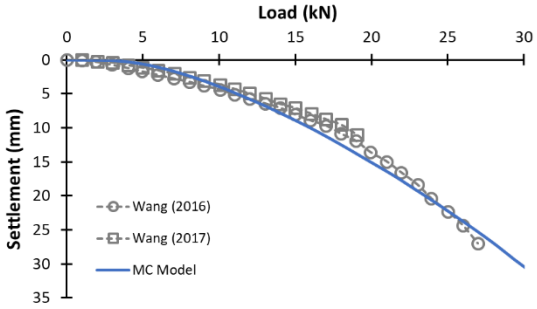

Figure 5. Load-displacement response of model pile as reported in Wang (2016. 2017) and predicted by FEA.

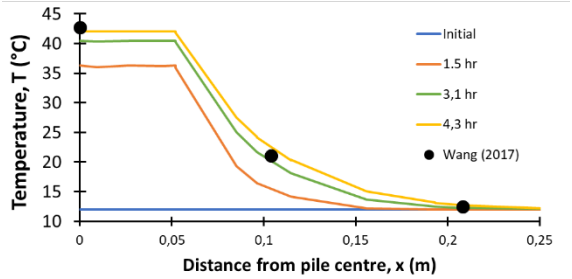

Figure 6. Radial temperature profile at about pile mid-depth, and at the end of first heating stage, reported by Wang (2017) and predicted by FEA.

Having established that the imposed temperature field was acceptable, the thermo-mechanical response was examined via the comparison with reported thermally-induced axial strain (ε_{th}) and stress changes (σ_{th}), and pile head displacement ($y_{0,th}$), and Figure 8 to 10 illustrate the various responses.

Initially, the MC model was employed in conjunction with the CTE of the pile equal to the soil, i.e. 10 x10^{-6} K^{-1}or case "CTE 10/10". First, the axial strain response at a depth of about 0.65 m (0.46L) is compared in Figure 8 and it is apparent that when the

pile CTE is 10 x10^{-6} K^{-1} (cases CTE 10/10 & 10/05), the agreement is very good, irrespective of the soil CTE but using a CTE for the pile of 15 x10^{-6} K^{-1} (case CTE 15/10) overestimates the thermal axial strain. This confirms that the value quoted by Wang et al. (2016, 2017) is reasonable. Also shown is the blocked strain, ε_{blkd} (Eq. 1) obtained in the FEA which are rather small and only a few-percent of $\alpha\Delta T$, confirming a lack of restraint on the shaft;

$$\varepsilon_{blkd} = [\varepsilon_{th} - \alpha(T - T_0)] \quad (1)$$

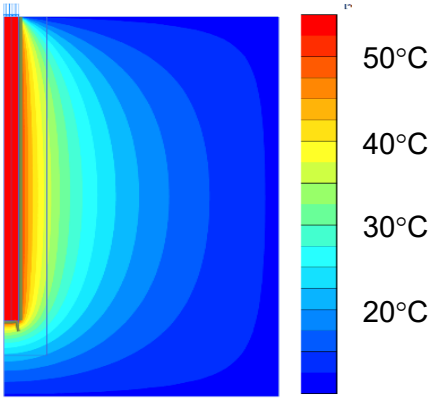

Figure 7. Steady State temperature field for imposed pile temperature of 53 ℃ (ΔT = 41 ℃).

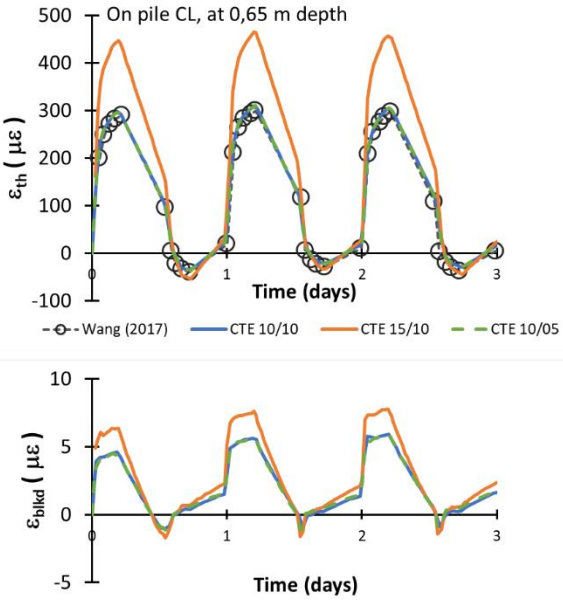

Figure 8. Thermal axial strain reported by Wang et al. (2017) and predicted by FEA using MC soil model.

The associated thermal stress response is shown in Figure 9 where clear discrepancies between the reported values and the FEA can be noted. This belies the good agreement between the reported and back-analysed results presented above. However, given that the thermal stress is evaluated using Eq. (2) in which errors accumulate through each of the experimental input parameters (ε_{th} & T), and the difference inside the square brackets (ε_{blkd}) is small (see Figure 8), large differences can be expected;

$$\sigma_{th} = E[\varepsilon_{th} - \alpha(T - T_0)] \quad (2)$$

To test this further, the 800 to 900 kPa axial stress reported by Wang (2017) implies an axial load of 6.8 to 7.7 kN which is higher than the total available shaft resistance implied by the load test discussed earlier (less than 2 kN). Based on Wang (2016) and other works, the maximum thermal stress will occur a depth of 0.5L to 0.7L. Thus, to generate the axial restraint required, friction equivalent to about 32 kPa and 23 kPa, respectively, would need to be mobilised on the shaft. This is highly unrealistic given the very low confining pressures acting on the pile shaft and based on Eq. (3), implies β = 2.9 – 5.7, values only likely to be found for large-displacement piles in sand;

$$\beta = {}^{q_{s,u}}/_{\bar{\sigma}'_v} \quad (3)$$

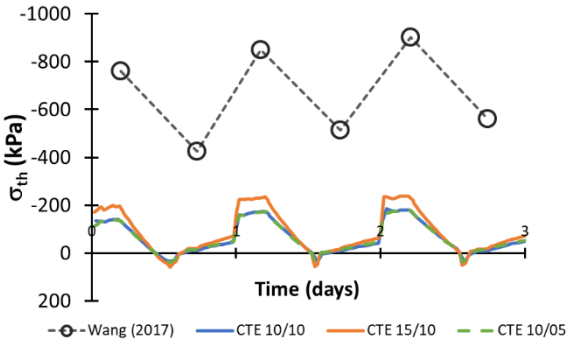

Figure 9. Thermal axial stress response reported by Wang et al. (2017) and predicted by FEA using MC soil model.

The other key parameter in TA pile response is the pile head movement and the reported values are compared with those predicted by the FEA in Figure 10. It is apparent that in terms of $y_{0,th}$, in the first cycle and subsequent heating stages, the agreement is good for case CTE 10/10. However, in the cooling stages, while the behaviour is qualitatively similar, the accumulated settlement diverges from and is less than that reported.

To assess this, a series of analyses were undertaken to investigate how the CTE affected the results. In Figure 10, results from analyses where the CTE of the pile was increased by 50% (CTE 15/10) and where the CTE of the soil was reduced by 50% (CTE 10/05) with respect to the initial values, are also shown. Again, the same pattern of accumulated settlement occurs: increasing the pile CTE improves the agreement with later cycles but at the cost of poor agreement in the

first. Halving the soil CTE only affects the 2nd and 3rd cycles and marginally improves the predicted behaviour. Reducing the soil CTE further improves the match in the cooling cycles but the agreement during heating cycles deteriorates, underpredicting the reported values.

Table 2 and Figure 11 examine the reported thermally-induced pile settlement a little further. Table 2 summarises the incremental pile head movement and temperature change during each temperature change stage, i.e. Initial → H1 → C1 →… Also tabulated is the associated free thermal expansion, $y_{th,free}$ based on the average pile temperature and CTE reported by Wang et al. (2017).

What is clear in Table 2 is that within each cooling cycle, the pile head moves down by an amount approximately equal to $y_{th,free}$, while in the heating stages the pile head moves up and the proportion of $y_{th,free}$ mobilised increases with each heating stage. Figure 11 illustrates schematically what is thought to be happening; when heated the pile expands, reversing the friction in the upper part of the pile and thus, $y_{0,th} < y_{th,free}$. At the base of the pile, the pile expansion leads to downwards movement. When cooled, additional shaft resistance cannot be mobilised, and to maintain equilibrium, the pile base settles some more. After the first cycle, this repeats throughout the test, leading to the thermal ratcheting effect that was reported in Wang et al. (2016, 2017) and predicted by the FEA.

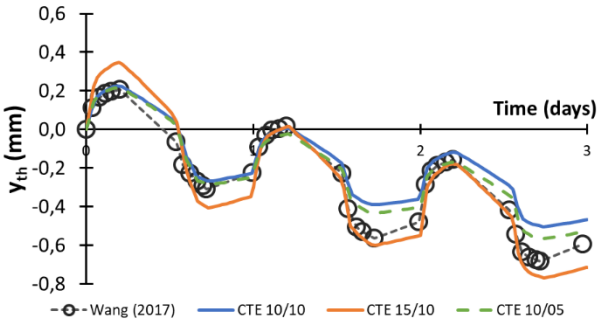

Figure 10. Thermal pile head displacement reported by Wang et al. (2017) and predicted by FEA using MC soil model.

4 CONCLUSIONS

In this work, the behaviour of a small scale thermally-activated pile has been examined using the finite element method, employing two well known and commonly employed soil models. The following points have been demonstrated in this work:

- The mechanical load-displacement of the pile must be reproduced accurately in order to be able to reproduce the correct thermo-mechanical response.
- Good agreement between the test and analysis was found in terms of the thermal axial strains and pile head movements during heating.
- The results diverged in the cooling stages beyond the first cycle. The cause of this is not yet apparent, as e.g., a mechanism involving thermal compaction of the soil adjacent to the pile might improve this comparison but would likely no longer capture the movements during heating.
- The comparison between reported and predicted thermal stress was also poor. This may be due to the low levels of restraint on the pile shaft which means slight errors greatly exaggerate the blocked thermal strain and thus, the thermal stress reported. It is shown that the reported axial stress is likely to be unreliable.

ACKNOWLEDGEMENTS

Climate change impacts on geotechnical infrastructure

Impacts du changement climatique sur les infrastructures géotechniques

C.A. Bridges*
Queensland University of Technology, Brisbane, Australia
**chris.bridges@hdr.qut.edu.au*

ABSTRACT: When undertaking designs for developments and infrastructure, geotechnical engineers now need to account for uncertainty due to climate change. For many years engineers have designed considering historical precedent, such as rare long-term flood events. Now, however, we have to accept these may be more frequent. In other areas climate change may result in periods of long duration drought with less frequent, but higher intensity, rainfall. These effects mean that geotechnical engineers must now consider different conditions which take account of a constantly changing environment over the lifetime of the structure. Geotechnical engineers must also be careful in material selection in order to achieve a required design life when ultimately, the conditions encountered now and are designed for, will change. This paper discusses these issues and how geotechnical engineers can take account of climate change in their designs.

RÉSUMÉ: Lorsqu'ils entreprennent la conception d'aménagements et d'infrastructures, les ingénieurs géotechniques doivent désormais tenir compte de l'incertitude due au changement climatique. Depuis de nombreuses années, les ingénieurs conçoivent en tenant compte des précédents historiques, tels que les rares inondations à long terme. Aujourd'hui, cependant, nous devons accepter que ces phénomènes soient peut-être plus fréquents. Dans d'autres régions, le changement climatique peut entraîner des périodes de sécheresse de longue durée accompagnées de précipitations moins fréquentes mais de plus forte intensité. Ces effets obligent désormais les ingénieurs géotechniques à considérer différentes conditions qui tiennent compte d'un environnement en constante évolution tout au long de la durée de vie de l'ouvrage. Les ingénieurs géotechniciens doivent également être prudents dans la sélection des matériaux afin d'atteindre une durée de vie de conception requise lorsqu'en fin de compte, les conditions rencontrées actuellement et pour lesquelles elles sont conçues changeront. Cet article aborde ces questions et comment les ingénieurs géotechniques peuvent prendre en compte le changement climatique dans leurs conceptions.

Keywords: Climate change; risk.

1 INTRODUCTION

In Queensland, Australia during the winter of 2022 the dry season was anything but dry. In both Queensland and the southern state of New South Wales in 2022 they were areas of flooding and in some cases repetitive flooding. At the time of writing, at the start of the 2023 – 2024 summer we are now seeing the first bush fires in Queensland. With historical global temperature records falling year after year, and weather patterns changing, it must be asked whether the basis of design for a lot of the infrastructure we build today – which is derived from historical precedent - will be relevant over the lifetime of that infrastructure.

With a constantly evolving climate, we need to consider whether our codes, standards and specifications are fit for purpose and ask how this uncertainty is going to be managed in the future.

2 GEOTECHNICAL RISKS

Geotechnical failures typically occur due to a small number of reasons:

- design – the structure is analysed incorrectly, or the design fails to account for the likely ground or loading conditions during the life of the structure
- construction – slopes are cut too steep, ground support may not be installed in time, or the incorrect materials are used
- loading changes – unforeseen changes in loading are not uncommon. Examples include: higher groundwater levels due to extreme rainfall; a new structure applying an additional

load; or, new construction such as excavation in front of a retaining wall
- change of material properties – these could include conditions such as erosion or shrink-swell

How these types of failure are impacted by climate change is discussed in the following sections.

3 CLIMATE IMPACTS AND RISKS

Geotechnical structures are typically sensitive the environment they are in. For example, groundwater levels and surface water flows impact most inground structures and earthworks.

Climate change impacts can be divided into two major groupings:
- precipitation - extreme rain, storm and floods
- increasing temperature - drought and wildfire

However, there are obvious overlaps between the two groupings. For example, hurricanes are caused by elevated sea temperatures and can result in increased precipitation and flooding (due to storm surges).

A summary of potential impacts of climate change on geotechnical structures is provided in Table 1 and examples of impacts on an earth embankment is shown on Figure 1.

3.1 Precipitation

Extreme precipitation is often associated with storms and hurricanes (cyclones) which are of relatively short duration, but high intensity, or from weather systems that continue deposit rain over a number of days or even weeks.

In general, it would be anticipated that increasing precipitation (based on Varallyay, 1990) will result in:
- surface runoff in sloping areas, especially if little or sparse vegetation is present, and the water carrying capacity of the soil is limited
- higher water infiltration and storage, recharging of the groundwater, where water carrying capacity of the soil is not limited

The consequences include an increase in instability of retaining walls and slopes (natural and manmade) which are often observed in the form of landslides (Bracko et al., 2022; The Earthworks Management Task Force, 2021; Toll, 2001).

Increased surface water flows can overwhelm existing drainage systems increasing erosion and making slopes susceptible to infiltration and surficial instability in following rain events. In addition, this could block culverts and undermine structural foundations.

The impact of rising groundwater may also bring naturally occurring sulfates and chlorides from their dry states into solution causing faster deterioration of substructures (Mallick et al., 1989). Alternatively, lowering groundwater tables expose timber piles to aerobic conditions and subject them to biodegradation (Toll et al., 2012).

Short or long-term rises of groundwater can impact foundations and basements reducing bearing capacity, causing uplift or increasing seepage. For retaining walls, increased water pressures will be observed.

3.2 Increasing temperature

Increasing temperatures can influence soils and ground conditions – drying out soils and if long-term can cause a reduction in the groundwater level. In general, it would be anticipated that increasing temperature (based on Varallyay, 1990) will result in:
- decreasing surface runoff, infiltration and recharging of the groundwater, if accompanied by low precipitation
- modification of the extent and depth of permafrost, resulting in increasing groundwater storage and movement

Lower groundwater levels may adversely impact the settlement of structures and increase loads on piles due to negative skin friction (Toll et al., 2012) or through by reducing buoyancy. Areas of karst geology, where the ground is supported by flooded caverns may be severely impacted by lowering groundwater levels resulting in collapse and sinkholes forming (Chen et al., 2021; He et al., 2022; Toll et al., 2012).

In northern latitudes rising temperatures have had the greatest impact on ground conditions. It is typical for settlements in these areas to be built on permafrost - the situation where groundwater near the surface is permanently frozen. As temperatures have increased, whole settlements - and their road accesses - are being flooded due to the recent release of groundwater making the areas marshy or swamp like. Even those areas not as significantly impacted, are facing buildings sinking due to lower bearing capacities. Slopes are also failing due to the release of groundwater.

In Alaska there are long-term concerns about the impact to infrastructure – roads, rail and pipelines – as well as former defence bases where melting permafrost may lead to contamination spread (U.S. Arctic Research Commission Permafrost Task Force, 2003).

Recent examples of hot weather influencing ground conditions are in the UK where the hot weather has resulted in an increase in the number of subsidence claims and have resulted in a number of large-scale coastal rock falls (Menteth, 2022).

Table 1. Summary of potential impacts on geotechnical infrastructure due to climate change (after Bridges, 2023; based on Vardon, 2015).

Climate change feature	Potential impact on geotechnical structure	Potential failure mode
Existing infrastructure		
Increased temperature (incl. fire)	Reduction of vegetation Hydrophobic soil	Erosion, slope stability Erosion
Decreased precipitation (drought)	Soil desiccation Soil shrinkage Reduction of vegetation / soil erosion Lower groundwater level	Piping, internal erosion, slope stability Piping, subsidence Piping, slope stability Overloaded piles, serviceability failure
Increased mean precipitation	Some soil erosion / loss of soil quality Change in water table leading to instability	Erosion, piping Slope stability
Intense precipitation	Significant soil erosion Rapid soil wetting, highly dynamic pore pressure changes potentially Flooding	Piping, slope stability Slope stability Piping, internal erosion, slope stability
Freeze/thaw cycles (incl. reduced permafrost)	Loss of soil structure Expansion of rock joints	Slope stability, bearing capacity, serviceability failure Rockfall
New infrastructure		
Drought	Reduction of moisture content of fill (compaction more difficult) and mixing of fill with water is expensive	Cost, serviceability failure
Increased precipitation / intense precipitation	Collapsing of some fill material due to wetting	Slope stability, serviceability failure

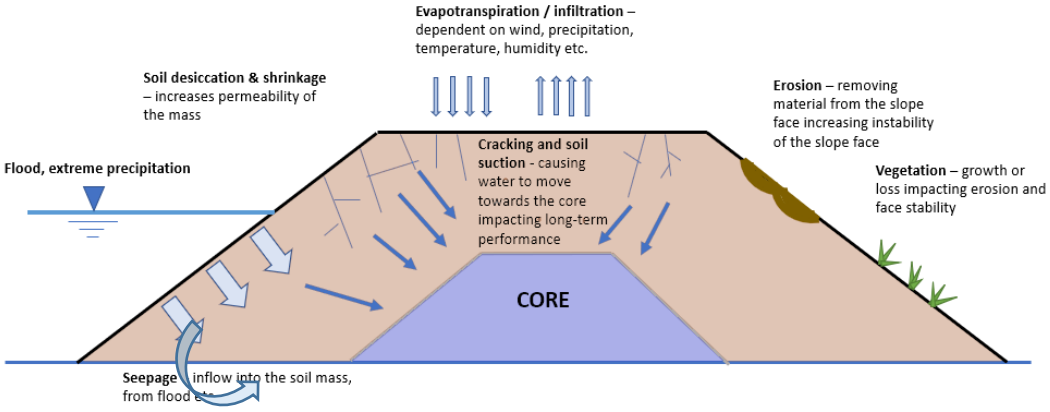

Figure 1. Influence of climate impacts on soil moisture and erosion (NTS) (based on Bridges, 2023; Vardon, 2015).

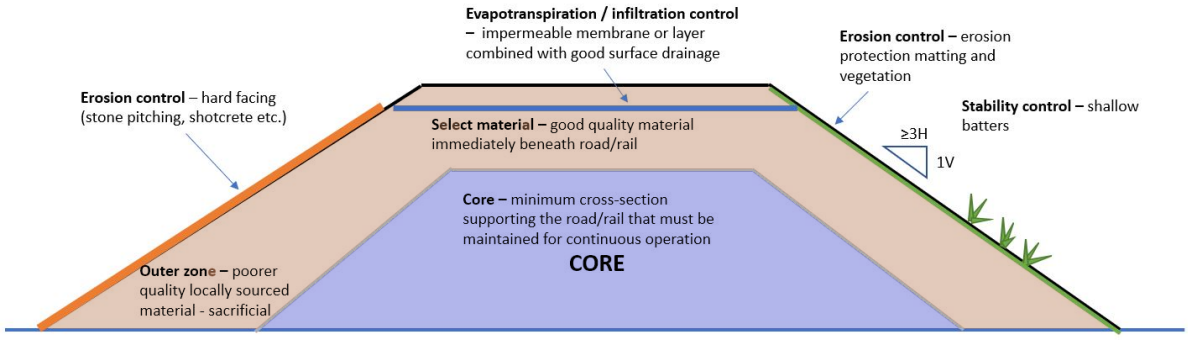

Figure 2. Influence of climate impacts on soil moisture and erosion (NTS) (Bridges, 2023).

Hot, dry conditions can also have an impact on forest or wildfires. Apart from destroying vegetation which can increase erosion, soils become hydrophobic in the period immediately after a fire, which can also increase the susceptibility to erosion (Movasat and Tomac, 2021).

4 ENGINEERED SOLUTIONS

There are a number of solutions that can be adopted to provide long-term performance of geotechnical structures. For example, for embankments some options include (Figure 2):

- wider and shallower embankment shoulders
- soft erosion protection for shallower slope batters and harder protections for steeper batters
- surface and interior drainage
- higher embankment heights to keep the infrastructure above flood levels

For cut slopes erosion protection and surface drainage are primary elements to address, combined with sub-horizontal drains to reduce groundwater levels.

Pile foundation design need to consider additional loads due to rising or falling groundwater levels. It is more difficult to address all the possible scenarios for shallow foundations, such as higher groundwater levels impacting bearing capacity) and this may lead to the adoption of more piled foundations in future.

5 CONCLUSIONS

Codes, standards and specifications are retrospective by nature and climate change impact challenges the geotechnical engineer to develop solutions not based on precedence but to think through the possible environmental conditions their structures will face.

ABSTRACT: There is an increasing need for offshore wind developments and submarine interconnector projects. The selection of the landing area has a major influence in construction techniques, drilling equipment requirements, construction schedule, project risks and costs. Often offshore wind cable landings are under prioritised during the project design until a late stage but are crucial for project viability. This paper illustrates what processes and data are required to select an adequate coastal area for landing using trenchless installation technologies including Horizontal Directional Drilling and Direct Pipe. Once a landfall site has been selected through methodologies such as constraint mapping and BRAG assessments, the site investigation and early-stage design works required to complete a successful project can be scoped and undertaken.

RÉSUMÉ: Le besoin de développer des projets d'éoliennes en mer et d'interconnexions sous-marines va croissant. Or, le choix de la zone d'atterrage exerce une influence majeure sur les techniques de construction, les exigences en matière d'équipement de forage, le calendrier de construction, les risques et les coûts du projet. Souvent, les atterrages de câbles éoliens offshore ne sont pas prioritaires lors de la conception du projet, et ce jusqu'à un stade avancé, mais ils sont cruciaux pour sa viabilité. Cet article illustre les processus et les données nécessaires pour sélectionner une zone côtière adéquate pour l'atterrage à l'aide de technologies d'installation sans tranchée, comme le forage directionnel horizontal et les conduites directes, qui sont discutés. Une fois qu'un site d'atterrage a été sélectionné grâce à des méthodologies de cartographie des contraintes et des risques, l'étude du site et les travaux d'ingénierie préliminaires nécessaires pour mener à bien un projet réussi peuvent être définis et entrepris.

Keywords: Landfall; installation; site selection; HDD; direct pipe; trenchles; subsea cables.

1 INTRODUCTION

There is an increasing need for offshore wind power developments and submarine interconnector projects, which need to connect to the onshore electrical grid system. The selection of the landing area has a major influence in construction techniques, drilling equipment requirements, construction schedule, project risks and costs.

Landfall installation techniques can be categorised into;

1. Surface lay – which may include external protection such as rock bags, cable protection Systems (CPS) etc.
2. Trenched – continual cable burial on to shore e.g., with plough, jet sled. This may include additional onshore techniques such as backhoe etc.
3. Trenchless – Horizontal Directional Drilling (HDD) and Direct Pipe/Micro tunnelling (which this paper focuses on).

This paper summarises what processes and data are required to select an adequate coastal area for landing and the survey and preliminary engineering works required to complete a successful trenchless landfall project, illustrated with examples.

2 TRENCHLESS LANDFALL INSTALLATION TECHNIQUES

For Trenchless landfall installation techniques there are two main methodologies; Direct Pipe and Horizontal Directional Drilling (HDD) which are summarised below.

Direct pipe construction and HDD are two different trenchless techniques used in the installation of

underground pipelines. They each have their own advantages and disadvantages presented in Table 1, and the choice between them depends on various factors such as the specific project requirements, geological conditions, and budget.

2.1 Direct pipe (pipe jacking)

Direct pipe installation encompasses microtunelling (using a microtunnel boring machine, MTBM) and pipe jacking methods benefitting from simultaneous hole creation and pipeline insertion. This is facilitated by direct attachment of the pre-fabricated steel pipeline to the MTBM machine creating a permanently supported bore throughout installation and minimising the risk of collapse, Figure 1.

In contrast to conventional microtunelling, this method is steerable and allows for precise control when creating inclines, slopes and curves across an installation trajectory (Stein, 2005).

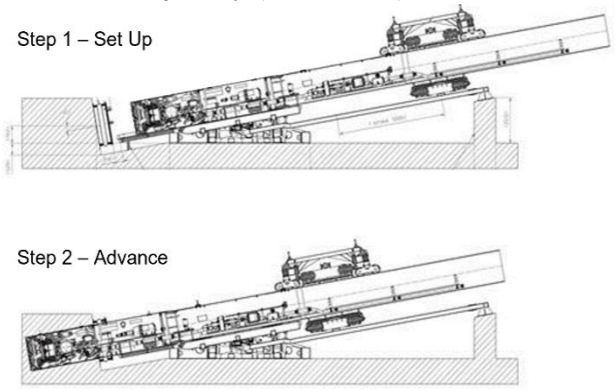

Figure 1. Illustrative direct pipe set-up and advancement (Stockton drilling, 2023).

A small trench may need to be excavated at the punching out point location. The MTBM terminates into the trench and then is remotely disconnected. The microtunnelling machine is then recovered at the exit point, usually by a jack up equipped with a suitable crane. This method is significantly more expensive than conventional microtunnelling and requires a large area to accommodate the jacking and pipe equipment.

2.2 Horizontal Directional Drilling (HDD)

HDD is a trenchless technique using a remotely operated steerable drill head which can accommodate a large range of complex alignments. Pre-construction works include a detailed chainage design of HDD route (entry, exit and trajectory), assessment of drill and pulling requirements, blowout assessments (due to the high drilling fluid pressures used) , duct stresses and cable pull force assessments (Stein, 2005, Willoughby, 2005).

Pipeline and cable installation using HDD comprises a multi-staged approach presented in Figure 2.

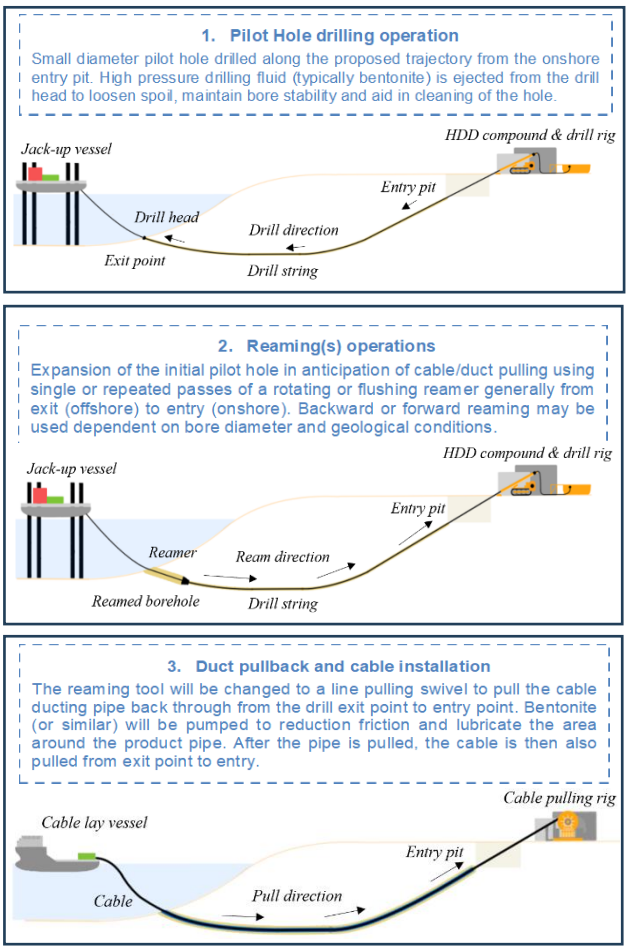

Figure 2. HDD Installation Methodology.

Table 1 summarises considerations of both HDD and Direct Pipe techniques.

Table 1. Installation technique considerations.

Technique	Consideration
HDD	• Need sufficient clearance for operations HDD rig etc. at drill site including access for vehicles etc. • Gravels and fractured rocks are generally not suitable/challenging. • Generally restricted to <2km. • Usually requires deep burial (risk of cable overheating)
Direct Pipe	• Expensive solution as it is requiring tunnelling equipment and recovery. • Need sufficient clearance for operations tunnelling equipment etc. May need personnel to enter duct for maintenance.

2.3 Overall process – concept development

There are varying levels of detail required at each stage. At an early stage a key understanding of project

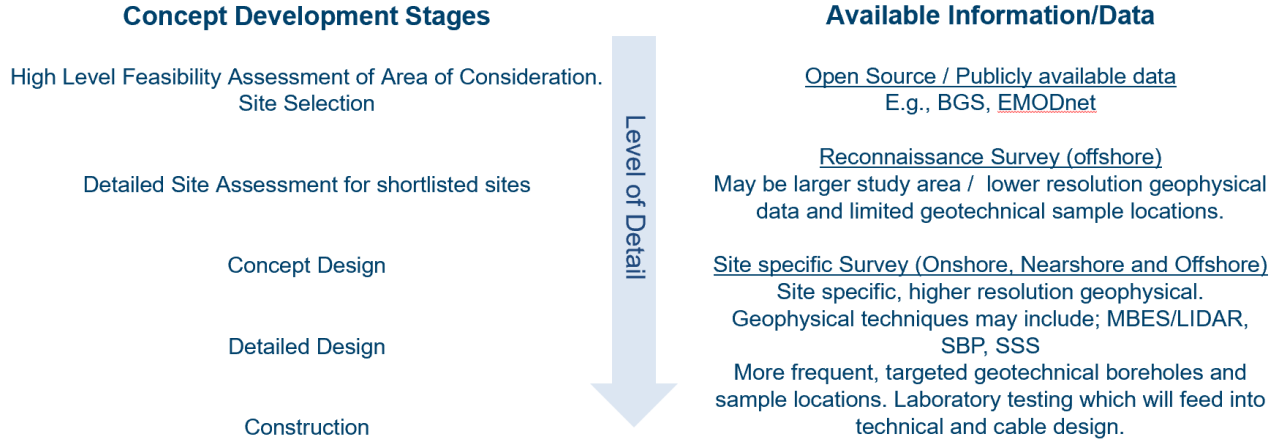

Figure 3. Flow chart presenting Concept Design Development and Associated Available Data.

requirements, risk management and stakeholder engagements is key to a viable landfall selection and a robust concept design. The concept development stages generally follow the sequence presented in Figure 3.

As each stage progresses the required engineering workload increases, as does the available site data. In initial studies such as site selection generally only open-source data and walkover data are available.

The initial studies will aid the survey strategy and inform geotechnical borehole locations. The survey strategy is described in more detail in Section 3.

2.4 Site selection – constraint mapping

The initial site selection is based on numerous factors including onshore grid connection considerations, offshore development distance and site conditions (coastal erosion, environmental constraints, land uses and MetOcean conditions, etc.).

Often the initial landfall location will be defined by the development team and may include a large area(s) which can often be over 5km. The next stage would be to identify specific constraints in the area to define the most appropriate landing points, prior to available site-specific survey data being acquired.

Constraints would be separated into hard constraints which must be avoided, and soft constrains which should be avoided if practicable. Examples of hard constraints may include identified UXO, wrecks, certain land uses, environmental restrictions, etc. Soft Constraints may include certain shallow geology, seabed features etc.

An example of a theoretical landfall selection is shown in Figure 4. Assuming the large study area, there are numerous constraints resulting in only two areas fit for the next stage on the basis of environmental constraints, build up areas and the presente of a fish farm.

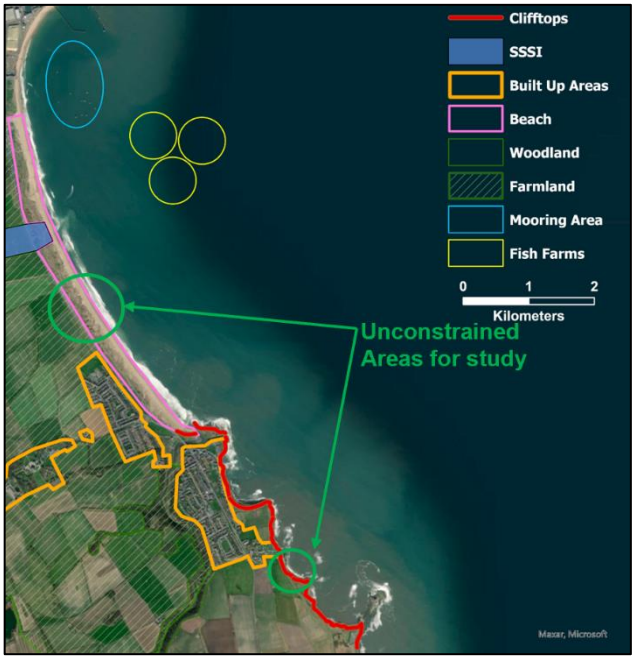

Figure 4. Example of Constraint Identification.

2.4.1 Site Selection – BRAG Assessment

Should there be multiple locations, a further initial study may be undertaken in the form of an optioneering exercise, comparing multiple sites prior to engineering. This may be in the form of a BRAG assessment (black, red, amber, green) where black shows: Significant constraints prohibiting development, red: High potential for the development to be constrained, amber: Intermediate potential for the development to be constrained and green: Low potential for the development to be constrained.

This assessment can include installation techniques in order to shortlist the most suitable installation methodology prior to detailed engineering e.g. should there be a steep cliff present this would rule out trenched methods.

This exercise would generally be undertaken following a constraint mapping exercise compiled from opensource data and prior to detailed engineering.

2.5 Engineering considerations

A series of design checks are required for both Direct Pipe and HDD installation to check feasibility of the design. These are elaborated on below:

1. Settlement Evaluation

Surface settlements are a critical consideration particularly in soft soils when crossing beneath sensitive infrastructure such as railways, roads, underground services, or buildings. Simple analytical tools or FE methods can be used to quantify ground movements above tunnels (O'Rielly & New, 1982, CIRIA, 1996). These are generally classified under two components:

a) Surface (vertical) settlement
b) Resultant horizontal ground movement

Guidance for limiting values of settlement are presented in Eurocode 7 Part 1, Annex H (BSI, 2004) for routine structures. Sensitive infrastructure such as utilities or railways have specific requirements which are set by asset owners and are not covered in general standards.

2. Cable / Duct Pulling Evaluation

Pulling forces are largely dependent on the nature of the HDD/DP trajectories, terrain and cable characteristics. A combination of analytical static pull calculations and specialist software models, such as OrcaFlex (Orcina, 2022) can be used to estimate anticipated pulling forces (Maidla, 1987, Stein, 2005, Willoughby, 2005). This is critical to assess the suitability of the duct and cable in terms of its working load limit and the pulling capacity of plant machinery.

3. Duct Stress Evaluation

Evaluation of duct stresses throughout installation is key to understanding the potential risk of buckling. Curvature of the trajectory, radial stresses from surrounding soils and drill fluids contribute to the overall risk. The right choice of duct material (Steel, HDPE, etc) and internal ballasting helps to combat this issue. The resultant stresses are then compared to the pipes maximum safe bending and tension stress to account for the maximum curvature along the profile (Stein, 2005, Willougby, 2005).

4. Hydrofracture Evaluation

Hydrofracture is the term used to describe fracturing originated from large pressures acting against a borehole wall which exceeds the maximum allowable pressure of the surrounding ground. For HDD, this may occur due to pressurization of the mud slurry within the bore annulus (Bennett et al, 2008).

The maximum allowable pressure is calculated based upon the cavity expansion model (Kuelen, 2001).

5. Thermal Rating Evaluation

Thermal rating of the known site conditions via site investigation and detailed characterisation is crucial to landfall design. Thermal rating is key to deriving the separation distance between cables, burial depths and number of cables required.

2D calculations can be undertaken, however can often be conservative with FE modelling required for complex topography and subsurface conditions. Knowledge of the subsurface, ground water level, thermal conductivity, and ground temperature along the profile are essential to providing a robust evaluation (IEC, 2014, IEC, 2015).

3 SITE INVESTIGATION AND CHARACTERISATION

3.1 Site investigations

Site investigations are crucial to the early-stage design of cable landings. Site investigations need to obtain sufficient information to permit safe and economical design of the duct installation and permanent works, and viability of the cable pulling operations.

Prior to site investigation works, site walk overs are key for early identification of ground, installation and maintanece hazards not easily identifiable from just desk-based studies or historic ground investigation data.

Site investigations are staged into geophysical (non-intrusive) and geotechnical (intrusive) campaigns (BSI, 2020, Eurocode 7, 2012).

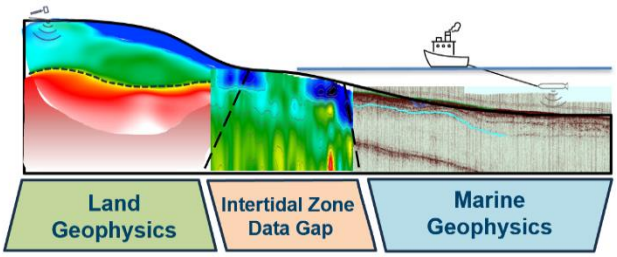

Figure 5. Data acquisition and integration requirements of different landing zones.

1. Geophysical Campaigns (Non-Intrusive)

Geophysical Investigations aim to better understand the ground conditions aiming to profile the shallow subsurface through identifying soil/rock units and geological structure, and allow for identification of seabed features at an early stage.

2. Geotechnical Campaigns (Intrusive)

Geotechnical investigations aim to ground truth the geophysical model and test samples for the design of both the chosen installation methodology as well as the duct and cable itself.

Table 2 presents a summary of common investigation techniques utilised.

Table 2. Summary Table presenting common geophysical and geotechnical investigation techniques.

Location	**Geophysical**	**Geotechnical**
Land	• Seismic Refraction and Reflection • Electrical Resistivity Tomography • Ground Penetrating Radar • LiDAR	• Trial pits • Boreholes • In-situ testing (e.g. geophysical logging, high pressure dilatometer) • Soil and rock laboratory testing
Marine	• Multibeam Echosounder • Sub-Bottom Profiler • Magnetometry • Sidescan Sonar	• Boreholes • Cone Penetration Testing • Vibrocore • In-situ testing (e.g. geophysical logging, high pressure dilatometer) • Soil and rock laboratory testing

Obtaining both geophysical and geotechnical data are sub-divided into three areas: onshore, nearshore and offshore, which maybe undertaken during multiple campaigns.

Often the intertidal region is underprioritised with limited site investigation and characterisation between the land and the marine based survey methods, resulting in a common data gap. This is illustrated in Figure 5. This can be mitigated using established geophysical techniques such as LiDAR, drone magnetometer surveys and geotechnical techniques such as tracked CPT rigs, etc to allow for good data integration between land and marine surveys.

Early-stage site investigation is recommended to confirm open source information or assumptions, and identify ground hazards.

3.2 Site characterisation

Following data acquisition through the required site investigations, early integration of geophysical and geotechnical data is key for a robust site characterisation.

Early construction of a well developed integrated ground model can identify ground hazards which can be mitigated through an adequate conceptual design and planning.

Figure 6 presents an example HDD profile through an integrated ground model. This incorporates site selection, engineering considerations (Section 2.4 and 2.5), and an advanced understanding of the site geological conditions reducing associated installation risk at an early stage.

The trajectory of such drills is designed to specific low angles for launching and punch through (generally between 5-10^0) and high curvature ratios for trayectory changes (in the order of 500m). A minmum level of soil cover is then selected on the basis of blow up risks, cable overheating and more complex geological considerations.

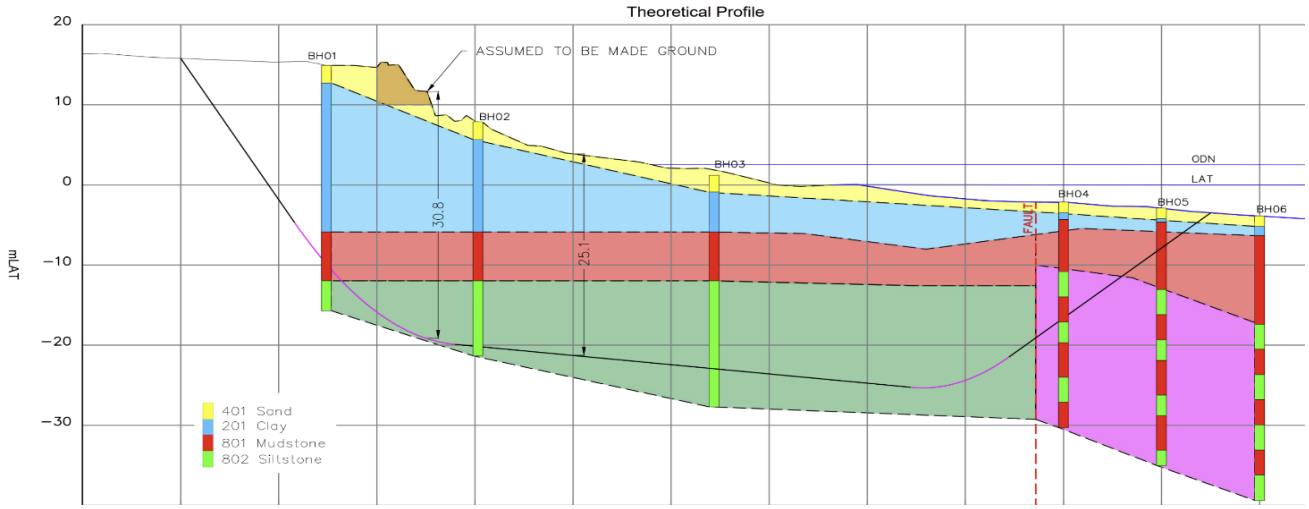

Figure 6. Theoretical HDD Profile Incorporating an Integrated Ground Model.

4 CONCLUSIONS

Landfall selection and concept design are crucial for the project viability of marine cables.

A proactive site selection strategy with good understanding of project requirements, risk management and stakeholder engagements is key to a viable landfall selection and to providing a robust concept design at an early stage.

The identification of a preferred landfall area through methodical constraint mapping and BRAG assessments will inform the possible installation methodologies, allowing for targeted and efficient site investigation stages.

Successful site investigation of trenchless cable landings will, in turn, inform the most adequate design, mitigating ground hazards and reducing installation risks.

Different jacket foundation installation methods for three offshore substations

Différentes méthodes d'installation de fondations de type jacket pour trois sous-stations électriques offshore

A. Cardoso*, J. Leplat, N. Van Damme, S. Raymackers
DEME Offshore, Zwijndrecht, Belgium

**cardoso.alexandra@deme-group.com*

ABSTRACT: Following the world demand for clean energy, the development of Offshore Windfarms (OWF) has been in constant growth with more challenging sites being considered for the construction of these OWF. Three Offshore Substations (OSS) of three different OWF located off the North and West coast of France, are installed on four-legged jackets founded on piles. For each of the OSS, the installation method of the pile foundations was different due to the soil conditions found on site: Rock Socket Drilling (RSD), Drill and Grouted (DG) and Drive-Drill-Drive (DDD). For all the three OSSs a pre-pilling template was deployed on the seabed. For the RSD method, for each pile a casing was oscillated into the seabed. Afterwards the rock socket was drilled to target depth and the casing retrieved after grouting. Then the pile was installed in the socket and the annulus between the pile and socket was grouted. For the DG method, first a pile was driven to the shallowest hard layer. Next a socket was drilled to target depth and the pile inserted. Afterwards, the inserted pile was grouted in the socket and in the driven pile. For the DDD method, first the pile was driven until initial refusal. Then a pilot hole was drilled and afterwards the pile was driven to target depth. In this paper, a more detailed description and challenges of these installation methods are discussed.

RÉSUMÉ: Suite à la demande mondiale d'énergie propre, le développement des parcs éoliens offshore (OWF) n'a cessé de croître et des sites de plus en plus difficiles sont envisagés pour la construction de ces OWF. Trois sous-stations offshore (OSS) pour trois parcs éoliens offshore différents situés au large des côtes nord et ouest de la France ont été installées sur des jackets à quatre pieds fondés sur des pieux. Pour chacun des OSS, la méthode d'installation des fondations sur pieux était différente en raison des conditions de sol rencontrées sur le site Forage de la roche (RSD), Forage et coulis (DG) et battage-forage-battage (DDD). Pour les trois méthodes OSS, un gabarit de préforage a été déployé sur le fond marin. Pour la méthode RSD, un tubage a été oscillé dans le fond marin pour chaque pieu. Ensuite, la cavité rocheuse a été forée jusqu'à la profondeur cible et le tubage a été récupéré après injection de coulis. Le pieu a ensuite été installé dans l'alvéole et l'espace annulaire entre le pieu et l'alvéole a été jointoyé. Pour la méthode DG, un pieu a d'abord été battu jusqu'à la couche dure la moins profonde. Ensuite, une alvéole a été forée jusqu'à la profondeur cible et un deuxième pieu a été inséré. Ensuite, le pieu inséré a été jointoyé dans l'alvéole et le pieu battu. Pour la méthode DDD, le pieu a d'abord été battu jusqu'au refus initial. Ensuite, un trou pilote a été foré et le pieu a été battu jusqu'à la profondeur cible. Dans cet article, une description plus détaillée et les défis de ces méthodes d'installation sont discutés.

Keywords: Pre-pilling; driving; drilling; grouting; offshore.

1 INTRODUCTION

Three Offshore Wind Farms (OWFs) located off the North and West coast of France were planned to be constructed and be commissioned by 2023. For each of these OWFs an offshore substation (OSS) needed to be installed. The OSSs are installed on a four-legged jacket with 26m x 26m footprint, which were founded on four piles. The piles were installed prior to the installation of the jacket (pre-piling) using a piling template deployed on the seabed. The installation method for the piles of each of the OSSs was different and the selection was based on the soil conditions found specifically at the OSS locations: Calcarenite overlying sand (Site 1), sand overlying chalk interbedded with flint layers (Site 2) and sand/clay overlying calcarenite and calcilutite (Site 3). The presence of rock at these sites presented a challenge for the pile installation as the standard/normal installation method (drive only) would not have been able to install the piles at these sites.

The piles were installed using the jack-up platform (JUP) "Sea Installer". A picture of the JUP, at Site 2, is shown in Figure 1.

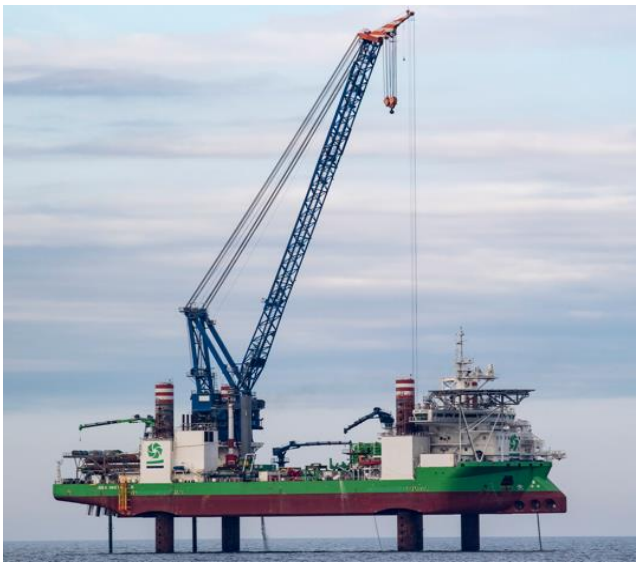

Figure 1. Jack-up platform Sea Installer at Site 2.

2 SOIL CONDITIONS

Rock is present at the three sites. However, the characteristics and depth at which the rock occurs varies between them. The general soil conditions at each of the sites and soil profiles, up to the pile embedment depth, considered for installation assessment, are described below, and depicted in Table 1, 2 and 3.

At Site 1, rock (calcarenite) is found at seabed, with thicknesses around 19m. The rock presents Unconfined Compressive Strength (UCS) values ranging from 2MPa and 24MPa.

Table 1. Soil profile at Site 1.

Stratum Type	Top depth (mbsb*)	Bottom depth (mbsb*)	Range of UCS (MPa)
Calcarenite	0.0	18.8	2.2-24.0

Note: *mbsb – meters below seabed

At Site 2, a thin layer of sand overlies the rock. The rock consists of low to medium density chalk becoming high density with depth. Several flint layers/cobbles were detected within the chalk at different depths below seabed level, the first occurrence being at 13.9mbsb.

Table 2. Soil profile at Site 2.

Stratum Type	Top depth (mbsb*)	Bottom depth (mbsb*)	Range of UCS (MPa)
Sand	0.0	0.4	-
Chalk	0.4	28.5	1.0-4.0

At Site 3, the rock (limestone: calcarenite and calcilutite) is found at around 7mbsb depth overlain by a thin layer of sand and a thick layer of clay.

Table 3. Soil profile at Site 3.

Stratum Type	Top depth (mbsb*)	Bottom depth (mbsb*)	Range of UCS (MPa)
Sand	0.0	0.9	-
Clay	0.9	7.0	-
Calcarenite	7.0	18.8	2.2-24.0
Calcilutite	18.8	21.1	3.5-6.0
Clay	21.1	23.1	-
Calcilutite	23.1	28.9	6.0-9.0
Calcarenite	28.9	31.0	12.0-20.0

The layering considered for these soil profiles, is based on the boreholes performed at the centre of the jacket. The top level of the different stratum types was expected to show some variability between the borehole and the pile locations. Due to this variability, especially for the shallowest flint layer at Site 2 (where driving refusal was expected) and the calcarenite layer at 28.9m depth at Site 3 (where the piles needed to be founded to ensure the pile capacity), contingency measures had to be foreseen to ensure the integrity of the piles (safe driving) and that the piles would reach the necessary embedment depth to obtain the pile design capacity. These measures are explained in Chapters 4.2 and 4.3, respectively.

3 PILE DESIGN

The general pile dimensions for the three sites are given in Table 4, Table 5 and Table 6, respectively.

Table 4. General characteristics of the installed piles at Site 1.

Pile section	Pile length (m)	Pile embedment (mbsb)	Pile diameter (m)	Bottom WT* (mm)
1	9.5	4.5	2.3	80
2	9.5	9.0	2.3	60

*WT – Wall Thickness

Table 5. General characteristics of the installed piles at Site 2.

Pile section	Pile length (m)	Pile embedment (mbsb)	Pile diameter (m)	Bottom WT* (mm)
Driven	16.5	13.5	3.0	75.0
Insert	28.5	28.5	2.4	50.0

Table 6. General characteristics of the installed piles at Site 3.

Pile length (m)	Pile embedment (mbsb)	Pile diameter (m)	Bottom WT* (mm)
35.0	31.0+	3.0	100

Note: + Including 2m contingency length due to variability of the top level of the calcarenite found at 28.9mbsb

4 INSTALLATION METHODS

Based on the soil conditions described in Chapter 2, for the three sites, three pile installation methods were used:

- Site 1 Rock socket drilling (RSD)
- Site 2 Drill and grouted (DG)
- Site 3 Drive-drill-drive (DDD)

Although the installation method was different, all methods used a piling template as a piling guide for placing the jacket piles within tolerances into the ground. One single piling template was custom-made for the projects as the jacket footprints are identical. A picture of the template while being tested is shown in Figure 2.

Figure 2. View of the template used.

The drilling equipment consisted of a Wirth PB 928 for site 1 and LD2500 for sites 2 and 3.

For Sites 2 and 3, adding to the drilling operations, driving operations were necessary as part of the installation method. For that purpose, IQIP impact hammers S-800 and S-2000, for site 2 and 3 respectively, and a follower, were used. A picture of the impact hammer and follower is shown in Figure 3.

4.1 Rock socket drilling – Site 1

Due to the presence of rock at seabed and up to 19mbsb, the installation method chosen for Site 1 was rock socket drilling. This method consisted of deploying the piling template and stabbing a casing in the template sleeve. The casing was then oscillated into the seabed. Afterwards, the drill rig was mounted directly on the top of the casing and the BHA was lowered inside the casing, enabling the rock socket to be drilled to target depth. The drilling methodology is based on the reverse circulation drilling (RCD) process. After drilling operations were completed, the BHA and drill rig were recovered and put back on deck and the casing was cut just above the seabed, leaving the casing shoe (sacrificial) to stabilize the top rock layer. Finally, the pile was lowered into the drilled socket and the annulus between the socket and the pile was grouted. Ultimately, the casing was removed and the template recovered. A view of the drilling set-up (BHA and drill rig) and the oscillator is shown in Figure 4.

Figure 3. Impact hammer and follower.

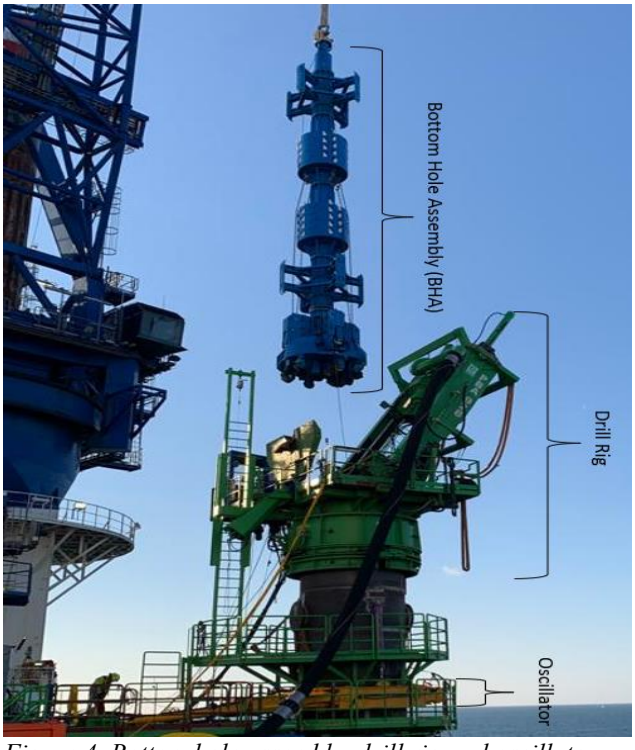

Figure 4. Bottom hole assembly, drill rig and oscillator.

4.2 Drill and grouted – Site 2

Due to the presence of high-density chalk, it was estimated that the pile could not be driven up to target depth. It was also considered that the presence of the flint layers would pose a risk with regards to pile tip damage. Hence, the drill and grouted installation method was chosen.

The drill and grouted method consisted of driving a 3m diameter pile up to the top of the shallowest flint layer (13.9mbsb) with an 800kJ impact hammer. In the case the shallowest flint layer was encountered at depths shallower than the expected 13.9mbsb, and to ensure that the driven pile would have sufficient embedment depth for loads to be transferred from the driven to drilled and grouted casings, a drilling spread was mobilized for a drive-drill-drive contingency. After driving the 3m diameter pile, a casing was stabbed and supported on the template. Then the drill rig was mounted directly on top of the casing and the BHA was lowered inside the casing and a socket was drilled to target depth (the drilling method was the same as for Site 1). Afterwards the BHA and the drill rig were recovered on deck. Finally, the pile was lowered through the driven pile into the drilled socket and the annulus between the socket and the pile and between the insert and driven pile were grouted. At the end, the casing and the piling template were recovered.

4.3 Drive-Drill-Drive – Site 3

At Site 3, due to the presence of rock with UCS values up to 24MPa below 7mbsb depth, it was estimated that the pile could not be driven to target depth with an impact hammer, unless a pilot hole was drilled to reduce the shaft friction and end bearing. Hence the DDD method was considered for this site. The method consisted of driving the pile with a 2000kJ impact hammer through the template sleeve, until refusal (top of calcarenite) occurred. Afterwards a casing was installed, and the drill rig was mounted directly on top of the casing. The BHA was lowered inside the pile and a pilot hole with 80% of the outside diameter of the pile was drilled up to 29mbsb (the drilling method was the same as the one mentioned for Site 1 and Site 2). Then the drill rig was recovered and put back on deck. Afterwards, the pile was driven to target depth with the 2000kJ impact hammer. At the end, the piling template was recovered.

In the case that the stratum required to ensure pile capacity, expected at 29mbsb depth, would be at deeper depths, pile length was increased and a pile cutting spread was mobilized on board. At the end three out of the four piles were cut.

5 PILE DRIVING MONITORING

Hard driving conditions were expected at Sites 2 and 3. The axial stresses on the pile, and particularly at the pile tip, were to be limited to prevent the risk of pile tip damage by means of pile driving monitoring. The instrumentation consisted of two deep-sea underwater accelerometers and four deep-sea underwater strain transducers per pile. Sensors were bolted on the pile external shaft at 5m from the top. All jacket piles on both sites were instrumented.

Monitoring measures the compressive stresses at sensor level. Based on a Safe Tip analysis done prior to installation (defining a safe driving criterion), the stresses at pile tip were estimated. The driving criterion consisted of intervals alert function of a compressive stress limit, taken 80% of the steel yield stress: pre-alert limits (80% of stress limit), alert limits (90% of stress limit) maximum limits (equal to stress limit).

At the sites, the stresses remained below the alert limits which allowed for safe driving operations to take place and mitigate the risk of pile damage.

6 CONCLUSIONS

Soil conditions offshore are becoming more challenging, preventing the use of the “standard” drive only installation method to be used. Also, the fact that there is rock on site does not mean that one method should fit all rock sites. The type of rock, and more particularly the strength and layering encountered at the sites, have a major impact on the method chosen to install the piles.

For the three sites here presented, where rock occurs within the embedment depth of the piles, an active cooperation between designer and installation contractor led to the selection of the optimal design and installation method, that allowed for a safe and economical installation of the piles.

ABSTRACT: Presentation of soil treatment solutions by vibro stone columns and rigid inclusions for the construction of steel storage tanks with references to the defined solutions for this type of structures considering the existing soil conditions, design loads and structural requirements, as well as references to the time and magnitude of the settlements. The main design aspects of steel tank foundations to guarantee permissible settlements were described, remarking the importance of the types of differential settlement to be controlled according to API Standards. Also, some considerations are made regarding the monitoring of those structures either in hydrotest or operation situations.

RÉSUMÉ: Présentation des solutions de traitement des sols par vibro colonnes ballastées et inclusions rigides pour la construction de réservoirs de stockage en acier avec des références aux solutions définies pour ce type de structures en tenant compte des conditions du sol existantes, des charges de conception et des exigences structurelles, ainsi que des références au temps et ampleur des tassements. Les principaux aspects de conception des fondations de réservoirs en acier pour garantir les tassements admissibles ont été décrits, en soulignant l'importance des types de tassements différentiels à contrôler selon les normes API. En outre, certaines considérations sont faites concernant la surveillance de ces structures, que ce soit dans des situations d'essais hydroélectriques ou d'exploitation.

Keywords: Steel tanks; hydrotest; ground improvement; settlements; API Standards.

1 INTRODUCTION

The steel tanks represent one of the most important facilities for industrial developments within the oil and gas sector. In many cases, the construction of their foundations supposes a critical task to achieve the project success. Frequently, the soil conditions impose the need of special works like soil improvement or deep foundation which affect the project schedule, type of tank foundation (e.g.: ring footing, slab foundation), interaction with other facilities (e.g.: pipeline racks) and possibly maintenance tasks for tanks during their life cycle. This paper presents some case studies and key aspects for the tanks analysis and selection of ground treatments.

2 ANALYSIS OF TANK FOUNDATIONS

The analysis of tank foundation should focus on meeting an allowable bearing capacity and appropriate differential settlements, which can cause large damages to the steel structure of tanks. Typically, the analysis is performed considering two different phases of quasi-permanent loading.

Firstly, a hydrotest is carried out by filling up the tank with water to check any leakage or failure of the steel structure. It supposes a preloading to the soil profile, due to afterwards tank should be emptied. Thereafter the piping should be connected to the empty tank. The second loading phase corresponds to the operational loading, imposed by the weight of the storage product in the long term, which have typical densities between 7 to 8,5 kN/m^3. Thus, according to the corresponding standard, different hypothesis and load cases can be considered for loading combination, of wind, seismic, snow, and other special loading.

2.1 Typical tank settlements according to API Standards

The API Standards highlight the following types of settlements to be checked:

Uniform Settlements which represent the uniform descent of the entire tank base. These types of settlements do not suppose a significant risk to the tank structure, and only must be considered to plan the connections between the external pipes and the tank.

Settlements that cause tank to tilt as a rigid body (Rigid body – planar tilt)- which can cause damage to the tank structure. They are generally associated with a failure mechanism due to lack of bearing capacity and/or large differential settlements.

Differential settlements outside the plane of inclination as a rigid body (Out-of-plane settlement), which represent the measured settlements along the tank perimeter. Those settlements are the difference between the settlements corresponding to the possible plane of inclination as a rigid body and the measured settlement in the perimeter. Excessive values of differential settlements on the perimeter would cause significant damage to the structure of the tanks (mainly to the walls of the tank).

Differential settlements in the bottom plate (Bottom plate settlement), which represent the maximum differential settlement under the tank footprint. Usually, the differential settlement between the centre of perimeter of tank bottom-plate.

Figure 1 shows the diagrams that correspond to these types of settlements. Figures 2 shows the methodology indicated by API Standards to evaluate differential settlements along the tank perimeter (Out-of-plane settlements – Appendix B, API 653), indicating the settled location of the tank shell, after rigid body tilt, represented by a cosine wave with respect to its original position in a horizontal plane. In Figure 2 the vertical distances between the irregular curve (measured settlements) and the optimum cosine curve represent the out-of-plane settlement.

The common method to get this cosine curve consists of solving the constants a, b and c, to find the optimum curve of the form: $Elev_{pred} = a + b \cdot \cos(\theta + c)$; where $Elev_{pred}$ is the elevation predicted by the cosine curve at angle θ. The optimum cosine curve is considered the one that fits adequately the measured settlements for $R^2 > 0{,}9$; being $R^2 = (S_{yy} - SSE)/S_{yy}$; where S_{yy} is the sum of the squares of the differences between average measured elevation and the measured elevations, and SSE is the sum of the square of the differences between the measured and predicted elevations. As a reference to be validated by either tank manufacturer or purchaser (or both of them), the allowable out-of-plane can be estimated by Eq. (1) when cosine curve fits the measured curve with $R^2>0{,}9$, otherwise Eq. (2) should be used (Andreani and Carr, 2007; API 653, 2014) and centre of tank settlements can be estimated by Eq. (3):

$$S_{max,ft} = \frac{(L^2 \cdot Y \cdot 11)}{(E \cdot H)} \quad (1)$$

$$S_{max,in} = min\left[K \cdot S_{arc} \cdot \left(\frac{D}{H}\right) \cdot \left(\frac{Y}{E}\right); 4\right] \quad (2)$$

$$W = \left[W_e^2 + \frac{0{,}37 \cdot \sigma_f \cdot D^2}{FS \cdot E}\right]^{0{,}5} \quad (3)$$

where:

$S_{max,ft}$: permissible out-of-plane settlement, in feet
$S_{max,in}$: permissible out-of-plane settlement, in inch
S_{arc}: effective settlement arc (see API 653; Annex B, Section B.2.2.5.1), in feet
W: Deflection or settlement in centre of tank
We: initial camber
FS: Factor of safety (FS ≤ 4 for localized yielding; FS ≤ 2 for severe overstress and possible yielding)
L: length between measurement points, in feet
Y: yield strength of the shell material, in psi
E: Young's modulus of the shell material, in psi
H: tank height, in feet
D: tank diameter, in feet
K: factor estimated according to Table 1

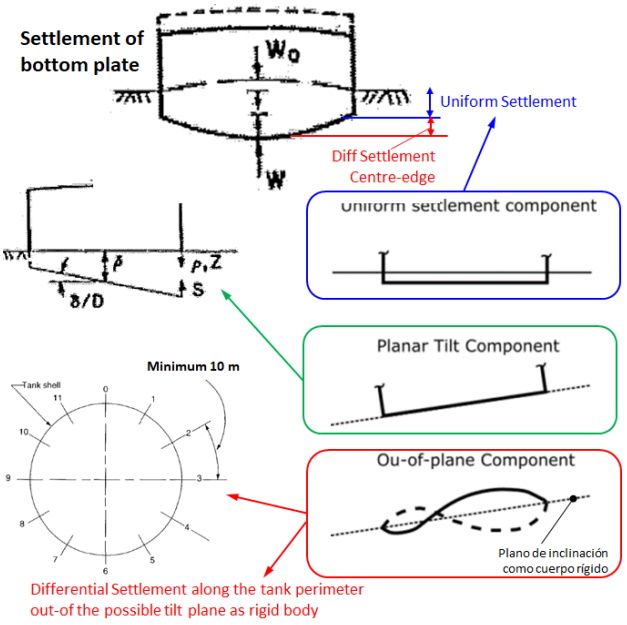

Figure 1. Types of settlement below steel tanks foundation.

Table 1. Factor K for out-of-plane settlement Eq. (2).

Tank Diameter	K, Open Top	K, Fixed Roof
D ≤ 50	28.7	10.5
50 < D ≤ 80	7.8	5.8
80 < D ≤ 120	6.5	3.9
120 < D ≤ 180	4.0	2.3
180 < D ≤ 240	3.6	NA
240 < D ≤ 300	2.4	NA
300 < D	NA	NA

3 CASE STUDY 1: STONE COLUMNS

For the construction of a new terminal of fuel storage tanks in the State of Puebla (Mexico), ground improvement by vibro stone columns was necessary to support the tanks and other facilities.

The soil profile comprises non plastic silts and silty sands below the water table, overlying medium to dense soils beyond 12 m depth. The site location presents high seismicity (Mw=7,2; PGA=0,47g) which suppose high risk of soil liquefaction.

The tanks terminal encompasses 9 fuel storage tanks and 1 fire water tank (Figure 4). The foundation for the structure of all the tanks foresees edge-ring footings of reinforced concrete and granular backfilling inside the ring and right below the tanks).

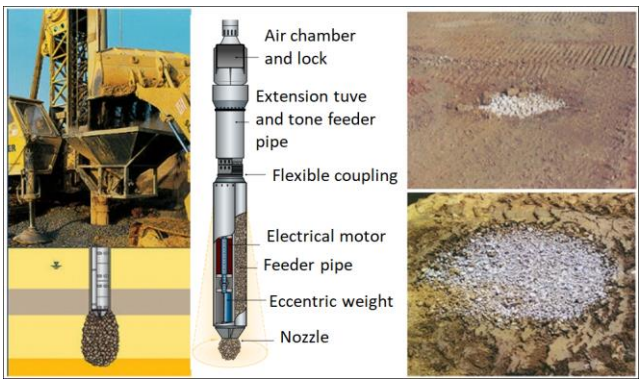

Figure 3. Ground improvement by vibro stone column.

The vibro stone columns installed by deep vibrators have been used successfully in numerous projects since the 1960s to reinforce soft or loose soil with high compressibility, speed up the consolidation process, decrease settlement, increase bearing capacity, and mitigate soil liquefaction. This deep vibro technique has a specific European Standard (EN 14731:2005, Ground treatment by deep vibration). In this project was used the bottom-feed method, which consists of gravel insertion into the ground through a system of tubes attached to a vibrator at the bottom. The whole rod is introduced into the ground aided by lateral displacement, vibration, vertical pull-down force and compressed air. Once the required depth is reached, the tubes stabilize the cavity and allow the gravel feeding. The general motions of deep vibrator compact the gravel by successive lowering and uplifting moves until the column is finished with variable diameter in in the range of 0,6 to 1,0 m depending on the soil stiffness. (Figure 3).

Figure 5 shows a typical borehole with the corrected SPT blow-count with the depth and the factor of safety against soil liquefaction (Boulanger an Idriss 2014) depicting the high risk of liquefaction until 12 to 15 m depth, approximately. Figure 6 shows the foundation details of the tanks, and the stone columns as were installed until 15 to 18 m depth.

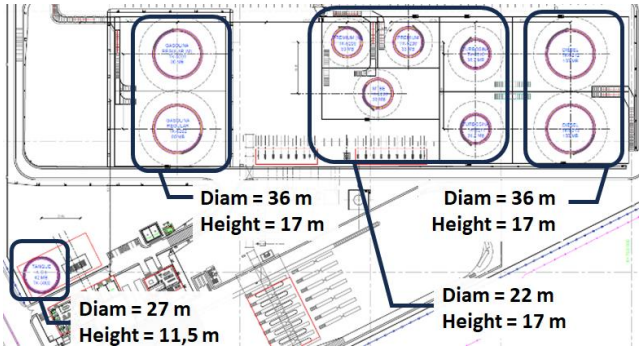

Figure 4. Project layout. Diameter and height of tanks.

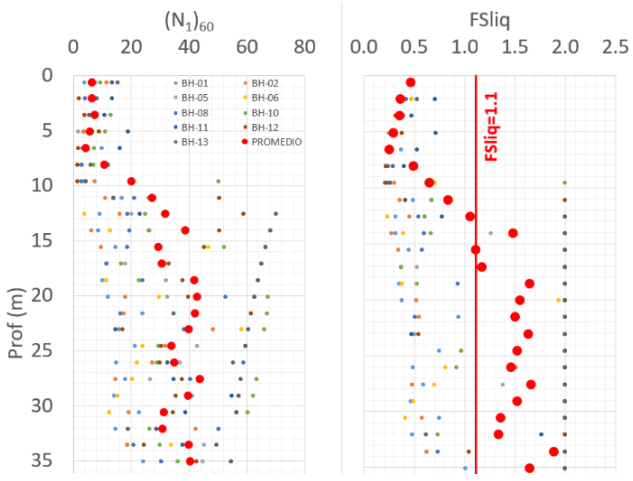

Figure 5. Factor of safety against soil liquefaction.

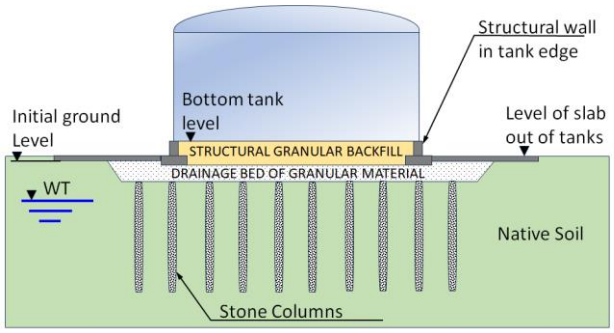

Figure 6. Details of tanks foundation.

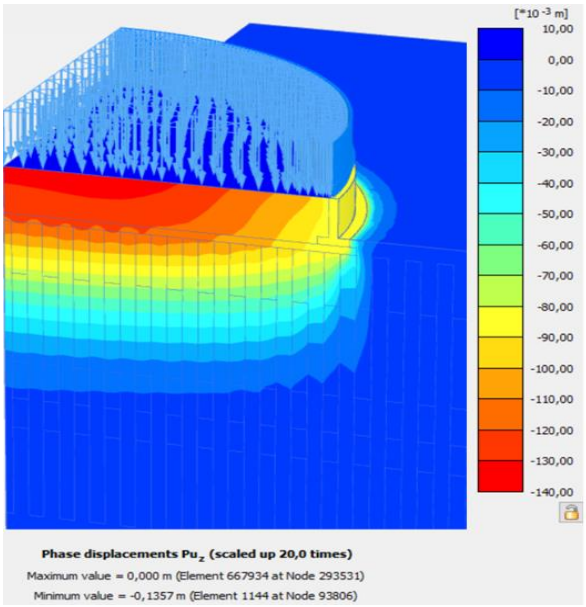

Figure 7. Settlement estimation of tank by FEM analysis.

Figure 7 shows the settlement estimation done by finite element analysis for the hydrotest phase of one of the biggest tanks (diameter of 36 m), resulting a maximum settlement of 13,5 cm in the centre and 9 cm in the perimeter. On the other hand, Figure 8 shows the measured settlements for all the points in the perimeter which match very well the estimated settlements.

Regarding the liquefaction mitigation, Figure 9 shows the results of the pore pressure ratio ($r_u=\Delta u/\sigma'_v$) as a function of depth and earthquake duration. It can be noted that Ru < 0,55, which corresponds to FS>1,1 (Marcuson et al., 1990). In Figure 6 an additional width of ground improvement beyond the rig-wall footing can be noticed to ensure the soil stability against possible liquefaction in the unimproved areas, following the recommendations by JGS (1998).

4 CASE STUDY 2: COMPACTION RIGID INCLUSIONS

Whitin the development of a large industrial project in México, there were built two steel tanks with 85 m in diameter and 15 m height, for fuel storage. The seismic design is characterized by Mw = 6,5 and PGA = 0,19g.

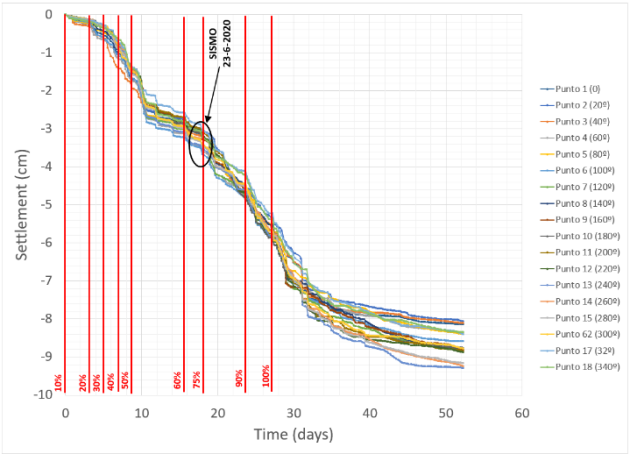

Figure 8. Settlements measured during hydrotest.

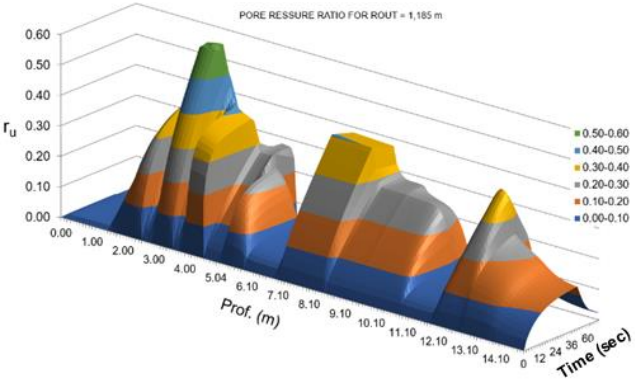

Figure 9. Pore pressure ratio of improved soil.

The soil profile comprises 8 to 12 m of liquefiable sands in the upper layers (qc = 3 to 8 MPa; Ic = 1,6 to 2,1) overlying a very soft clay layer (qc= 1 to 2 MPa; Ic > 3) with 4 to 6 m thickness, and below medium dense sand until 30 m depth was encountered.

After the analysis of the possible solutions, it was adopted as the optimum treatment the ground improvement by Compaction Rigid Inclusions (CRI). This kind of treatment was able to meet the technical requirements which basically were liquefaction mitigation, control of settlement and reaching allowable bearing capacity.

The Compaction Rigid Inclusions (CRI) are performed by means of drillings with full displacement augers (FDA) to avoid massive extraction of soil spoil; once reaching the foreseen depth, the grouting phase initiates by feeding the concrete through the extension tubes coupled to the displacement auger which outflow by the bottom. In those layers which need liquefaction mitigation the grouting is carried out by applying higher pumping pressure until maximum values of 4 to 7 MPa, with the objective to enlarge the column

diameter by displacement process, and this way densify the surrounding soil.

Figure 11 shows a sketch of the adopted solution. In the liquefiable layers until 12 m depth, the CRIs reached an average diameter of 0,6 m, whereas at higher depths there were not liquefiable soils and the mean diameter reach 0,4 m, very similar to the diameter of the drilling auger.

The pattern consists of two overlapped grids of rigid inclusions. The first grid has 2,1 m spacing between columns with compaction grouting process until 12 m. The second grid corresponds to the columns in between the first grid and until the maximum depth of 27 m. In this 2nd grid all the columns have the smallest diameter in the bottom and the highest one in the top where liquefaction needs to be mitigated. So that the column spacing in the top become in 1,5 m, and in the bottom remains of 2,1 m.

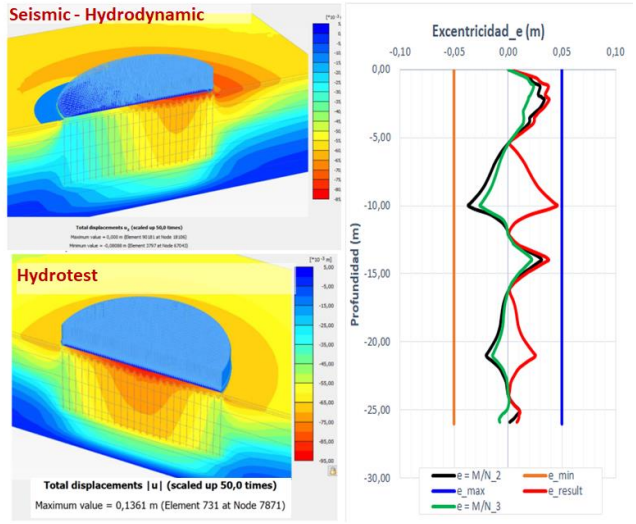

Figure 10. FEM analysis of hydrotest (SLS) and accidental action due to seismic-hydrodynamic loading (ULS).

Figure 11 also shows the pre and post CPTU testing performed in a field trial carried out at the beginning of the treatment. In can be observed the increase of tip resistance by a factor of 2 to 3, that implies improved tip resistances higher than 10 MPa, which meet the required cyclic strength to mitigate the liquefaction.

Figure 10 shows the maximum settlement of 16 cm estimated by FEM analysis of the hydrotest. Figure 10 also shows the results of the seismic-hydrodynamic analysis, that was done by applying the equivalent pseudo-static forces in the bottom of the tanks, which produce vertical stress concentration. The right side of Figure 10 shows the verification of internal forces in rigid inclusions produced by this seismic-hydrodynamic analysis.

5 CASE STUDY 3: RIGID INCLUSIONS

The construction of terminal tanks located in Huelva, south-west of Spain, is developed to facilitate the development of a petrochemical complex.

The soil profile presents predominantly loose to medium dense silty-sand materials until 5 to 7 m depth, overlying a dense gravely sand. The water table was found between 2 and 3 m depth.

The layout includes 8 tanks with 17 m of diameter, and 2 tanks 24 m in diameter. All of them have 28,5 m height and foundation slabs with octagonal configuration and a variable thickness of between 1,4 and 1,0 m. According to the chemical product to be storage, the design load for both hydrotest and operational phases was 287 kPa. Technical requirements foresee differential settlements below 5 mm in 5 m along the perimeter, and 85 mm from centre to edge. Tilt distortion should be below 1/1000, and minimum factor of safety of 3 against bearing capacity. Figure 12 shows an overview of the solution.

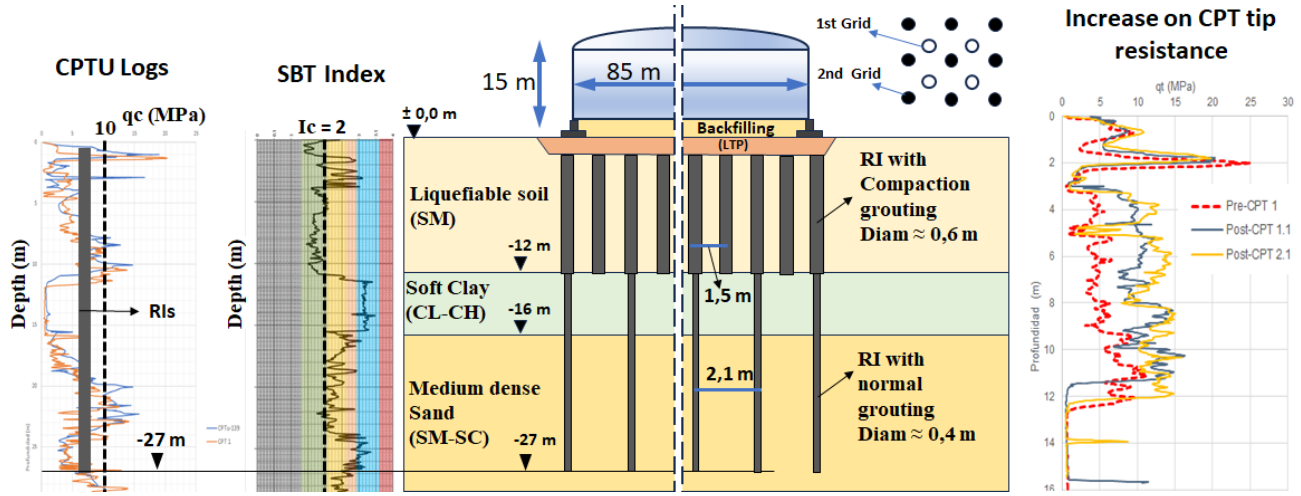

Figure 11. Soil profile, sketch of ground improvement cross section and CPTU verification of liquefaction mitigation.

Figures 13 shows settlement estimation of 5,5 cm in the centre and 3,5 cm in perimeter for the tank of 24 m in diameter. Figure 14 depicts the settlements measured for each loading stage, which match very well the settlement estimation for the last consolidation phase with 100% of loading. Figure 15 shows the analysis of differential settlements measured in the perimeter and the plane of rigid tilt represented by an optimum cosine curve as described in Section 2.1 according to API 653. It was checked an allowable cosine curve to validate the tilt requirement.

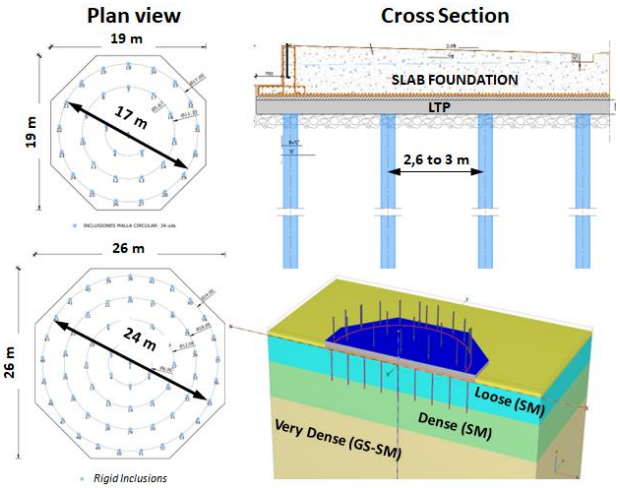

Figure 12. Rigid inclusions solution.

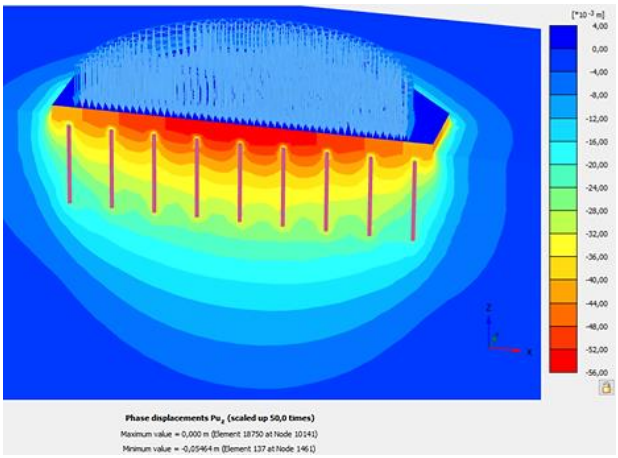

Figure 13. Settlement estimation for tank with 24 m diam.

6 CONCLUSIONS

The main design aspects of steel tank foundations to guarantee permissible settlements were described, remarking the importance of the types of differential settlement to be controlled according to API Standards. As optimal (cost-effective) solutions, it was presented 3 case studies with successfully implementation of ground improvement by vibro stone columns, rigid inclusions, and compaction rigid inclusions. Thus, the presented ground improvement methods demonstrate their capabilities to speed up the consolidation process, decrease settlement, increase bearing capacity, and mitigate soil liquefaction.

Effect of the concentration of the activator on the mechanical properties of the geopolymer stabilized soil

Effet de la concentration de l'activateur sur les propriétés mécaniques du sol stabilisé par géopolymère

D. Chami*, A. Cuccurullo, P. Gerard
Université libre de Bruxelles (ULB), BATir department, Brussels, Belgium
**diana.chami@ulb.be*

ABSTRACT: Geopolymers are the result of a reaction between a precursor (material rich in silica and alumina) and an activator (alkaline solution responsible for the dissolution of the precursor). Optimizing the quantity of activator is crucial to guarantee the strength development of the geopolymer while limiting the use of chemical substances. This study investigates the effect of different concentrations of the activator, in the range from 1 to 12M with a constant precursor content of 10% of the dry mass of the soil, on the mechanical properties of a geopolymer stabilized silty clay soil. A by-product calcium-rich granulated ground blast furnace slag (GGBS) is used as precursor and sodium hydroxide is used as an activator. Cylindrical stabilized samples compacted at the standard proctor optimum moisture content and maximum dry density and cured in sealed conditions for 7, 28, 60 and 90 days are tested for unconfined compressive strength. A set of unstabilized and slag-stabilized samples are manufactured and tested for comparison. First, the results showed that geopolymers can be used efficiently to enhance the strength of the soil. Also, increasing the concentration of the activator do not necessarily increase the strength of the stabilized soil. The optimum compressive strength corresponds to a concentration of 2M.

RÉSUMÉ: Les géopolymères sont le résultat d'une réaction entre un précurseur (matériau riche en silice et alumine) et un activateur (solution alcaline responsable de la dissolution du précurseur). Optimiser la quantité d'activateur est très important pour combiner le développement de la résistance du géopolymère avec un usage limité de substances chimiques. Cette étude analyse l'effet de différentes concentrations de l'activateur, dans la gamme de 1 à 12M avec une teneur constante en précurseur de 10 % de la masse sèche du sol, sur les propriétés mécaniques d'un sol argilo-limoneux stabilisé par géopolymère. Un laitier broyé et granulé de haut fourneau riche en calcium est utilisé comme précurseur et de l'hydroxyde de sodium est utilisé comme activateur. Des échantillons cylindriques stabilisés compactés à la teneur en eau optimale et à la densité sèche maximale standard Proctor scellés pendant 7, 28, 60 et 90 jours de temps de cure sont testés pour leur résistance à la compression simple. Un ensemble d'échantillons non stabilisés et stabilisés par du laitier de haut fourneau (sans activateur) sont fabriqués et testés à des fins de comparaison. Premièrement, les résultats ont montré que les géopolymères peuvent être utilisés efficacement pour améliorer la résistance du sol. De plus, l'augmentation de la concentration de l'activateur n'augmente pas nécessairement la résistance du sol stabilisé. La résistance optimale à la compression correspond à une concentration de 2M.

Keywords: Soil stabilization; geopolymers; mechanical testing.

1 INTRODUCTION

Soil stabilization is of huge importance in civil engineering practice since it aims at improving the physical and mechanical properties of naturally weak soils. While typical soil stabilization techniques involve the use of additives such as lime and cement (Khemissa and Mahamedi, 2014), their production leads to high emissions of CO_2 into the atmosphere. Geopolymer soil stabilization is emerging nowadays to provide a more sustainable alternative. Geopolymers were first introduced in the 1970s to refer to alkali-activated materials (Davidovits, 2002). Geopolymers are synthesized by the dissolution of a precursor (a by-product rich in silica and alumina) by an activator (an alkaline solution) to form a gel that solidifies and hardens. The properties of the geopolymer binder itself were widely studied in the literature while its application for soil stabilization is emerging recently and no standards exist yet to regulate its use.

While the activator is the key component in the geopolymerization reaction and thereafter essential for the strength development of the geopolymer binder, it is the most expensive and non-eco-friendly

component. Hence, finding the optimum concentration of the activator to reach the desired strength without overusing it is very important. Ghadir and Ranjbar (2018) reported that increasing the concentration of the activator from 4 to 12M increases the mechanical strength of volcanic-ash-based geopolymer stabilized clayey soil by around 50%. On the other hand, Cristelo et. al (2012) showed that for a low in calcium fly-ash (class F) based geopolymer stabilized silty sand, an optimum concentration exists, and it depends on the mass ratio of the precursor to the activator. The variation in the conclusions available in the literature can be attributed to the differences in the precursor properties, curing conditions or type of soil. Hence, additional research on the controlling parameters is necessary.

This research focuses on exploring the effect of the concentration of a sodium hydroxide (NaOH) activator on the short and long-term mechanical strength of a ground granulated blast furnace slag (GGBS) based geopolymer-stabilized clayey silt soil. To this end, unconfined compressive strength tests were performed on geopolymer-stabilized soil with varying concentrations of the activator after 7, 28, 60 and 90 days of curing sealed at ambient temperature. Unstabilized and slag-stabilized samples were tested as well for comparison purposes.

2 MATERIALS AND METHODS

2.1 Materials

A clayey silt (CL-ML, according to the Unified Soil Classification System) obtained from Marche-Les-Dames (MLD) region in Belgium was used in the present study. Initially, the MLD soil was oven-dried for 24 hours before being used. The grain size distribution of the soil, showing 93% of fines passing through 75 µm sieve, is presented in Figure 1. The clayey fraction represents 23%, the silty one about 67% and the sandy one about 10%. According to the ASTM D 4318, the liquid limit (LL), plastic limit (PL) and plasticity index (PI) of the soil were measured as 28.4%, 19.6% and 8.8% respectively. The Standard Proctor optimum moisture content (OMC) and the maximum dry density (MDD) of the soil were obtained to be 15.5% and 1.82 g/cm^3 respectively, in accordance with ASTM D 698.

Ground granulated blast furnace slag (GGBS) provided by VVM cement company in Belgium was used as a precursor. All GGBS grains were smaller than 75 µm. It was stored in tightly sealed containers.

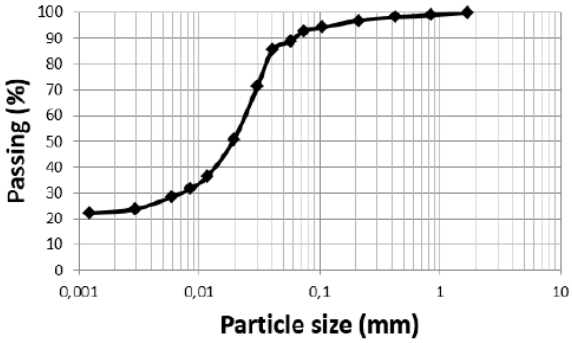

Figure 1. Grain size distribution of the MLD soil.

The chemical compositions obtained from the X-ray fluorescence analysis of the MLD clayey silt and the GGBS are presented in table 1.

As for the activation of the precursor, sodium hydroxide (NaOH) solution was used as the alkali solution. The NaOH solution with the required concentration was prepared in the laboratory by dissolving NaOH pellets with 99% purity in distilled water 24 hours prior to use to enable the release of the hydration heat.

Table 1. Chemical composition of GGBS and MLD soil.

Chemical composition	**Percentage by mass (%)**	
	GGBS	MLD soil
Calcium oxide (CaO)	43.15	0.69
Silicon oxide (SiO_2)	36.27	71.43
Aluminum oxide (Al_2O_3)	10.47	13.89
Magnesium oxide (MgO)	5.98	1.17
Sulphur oxide (SO_3)	1.51	0.02
Potassium oxide (K_2O)	0.67	2.52
Ferric oxide (Fe_2O_3)	0.58	4.27
Titanium oxide (TiO_2)	0.54	0.87
Manganese oxide (Mn_2O_3)	0.29	0.05
Sodium oxide (Na_2O)	0.26	0.77

2.2 Mix proportion and samples preparation

To study the effect of the concentration of the activator on the behavior of the geopolymer stabilized soil, a fixed precursor content of 10% of the dry mass of the soil (MLD) is used with different concentrations of the activator (1, 2, 4, 6, 8, 10 and 12M). To compare, a set of unstabilized soil samples and slag stabilized soil (without activator) samples were tested. For the preparation of the stabilized soil, GGBS and soil were initially mixed under dry conditions for 1 min and a half at low speed in the MATEST mortar mixer to attain uniformity. Then, the NaOH solution of the required concentration (for geopolymer stabilized soil) or distilled water (for slag stabilized soil) was added to the mix and the mixing process continued for 2 more minutes at high speed. NaOH solution or distilled

water is then added to reach the standard Proctor optimum moisture content for the mixture composed of the MLD soil and GGBS. The sample IDs and mix proportions are presented in table 2.

Table 2. Sample IDs and properties.

Sample ID	GGBS (%)	NaOH (M)	MDD (g/cm^3)	OMC (%)
MLD	-	-	1.82	15.5
MLD10	10	-	1.76	17
MLD10M1	10	1	1.76	17
MLD10M2	10	2	1.76	17
MLD10M4	10	4	1.76	17
MLD10M6	10	6	1.76	17
MLD10M8	10	8	1.76	17
MLD10M10	10	10	1.76	17
MLD10M12	10	12	1.76	17

The quantity of the stabilized soil in each sample is obtained based on the MDD of the mixture of the MLD soil and the GGBS. 72 mm height and 36 mm in diameter cylindrical samples were dynamically compacted in three equal layers. After the manual extrusion of the compacted samples from the molds, the soil samples were wrapped in plastic and aluminum films in order to avoid any moisture loss. The samples were cured sealed for 7, 28, 60 and 90 days in at a controlled room temperature of $\pm$ 18 ℃ until the day of testing.

2.3 Experimental procedure

Unconfined compressive strength (UCS) tests were performed on unstabilized and stabilized cylindral samples. During compression, the soil samples were wrapped in an impermeable membrane to avoid altering the composition of the samples during the test. The UCS tests were performed at an axial displacement rate of 0.1 mm/min. Each test continued until the failure surfaces were clearly visible or until an axial strain of 20% was attained.

To ensure consistency and reproducibility, three identical samples, with the same mix proportion and curing time, were tested each time and the average results were reported.

3 RESULTS AND DISCUSSION

Unconfined compressive strength tests on stabilized and unstabilized samples were performed at 7, 28, 60 and 90 days. The results of the UCS tests are shown in Figure 2 where the error bars provide the minimal and maximal strength observed experimentally. The results show a good reproducibility of the experimental data. Overall, regardless of the stabilization technique (slag or geopolymer) and the concentration of the activator, the compressive strength of the stabilized soil increased with the curing time. Although, the variation of the strength between 60 and 90 days is not significant for higher concentrations of activator (4, 6, 8, 10 and 12M). The slag-stabilized soil experienced none to very low strength improvement compared to the unstabilized soil. However, the GGBS-based geopolymer stabilized soil experienced a significant increase in the UCS compared to unstabilized soil even at 7 days.

MLD10M2 specimens reached the highest strength compared to all other concentrations of NaOH. The UCS of MLD10M2 specimens reached 1.4, 2.5, 4.0 and 4.7 MPa at 7, 28, 60 and 90 days respectively compared to 0.13 MPa for the unstabilized soil. The strength development is associated with the dissolution of the silica and alumina ions from the GGBS leading to the formation of a geopolymeric gel

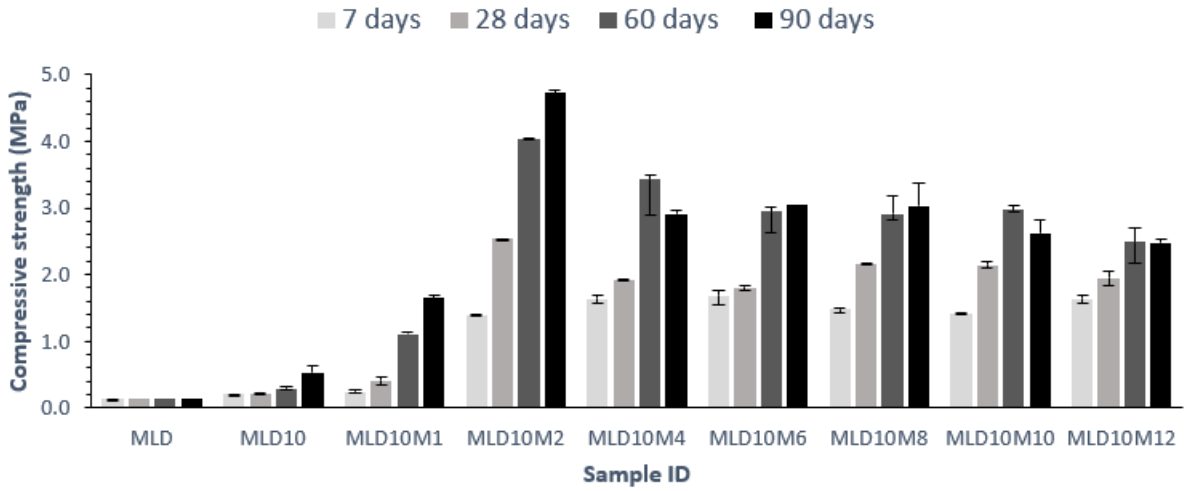

Figure 2. Unconfined compressive strength tests results.

and ultimately hydrated products (Sahoo and Prasad Singh, 2022). However, MLD10M1 attained lower strength increment at all curing times which may be attributed to the lack of alkali in the mixture causing a poor geopolymeric network in the matrix (Sahoo and Prasad Singh, 2022). Furthermore, samples with higher concentrations (4, 6, 8, 10 and 12M) showed lower workability during mixing and difficulties in compaction which may be the cause of the drop in the UCS especially at 60 and 90 days (Cristelo et. al, 2012).

The effect of the curing time on the stress-strain behavior of the geopolymer-stabilized soil with a concentration of 2M during the UCS test is reported in Figure 3. A transition from ductile (for unstabilized soil) to a brittle behavior (for geopolymer-stabilized soil) is observed. This change in behavior can be attributed to the formation of cementitious products that reach their maximum stress level just before experiencing sudden failure (Abdullah et al., 2019). Furthermore, it can be observed that the stiffness of the stabilized soil is independent of the curing time. The Young's modulus of MLD10M2 specimens varies from 190 to 290 MPa with the curing time.

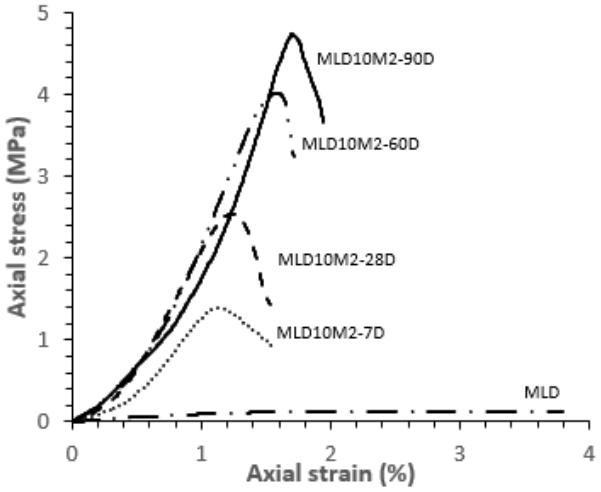

Figure 3. Effect of the curing time on the stress-strain behavior of MLD10M2 samples.

4 CONCLUSION

This study investigated the effect of the concentration of the most expensive geopolymer component (the activator) on the mechanical properties of a GGBS-based geopolymer-stabilized clayey silt soil.

- Geopolymer soil stabilization is an efficient soil stabilization technique. The UCS of the stabilized soil increases with the curing time.
- For a precursor content of 10%, a concentration of 2M of the activator increased the UCS of the soil almost 10 times at short term and 36 times at long term, compared to the unstabilized soil.
- Based on the mechanical strength, a concentration of 2M seems to be an optimum concentration of the activator for a GGBS content of 10%.

In order to better explain the existence of an opitmum activator concentration for the strength development and validate some explanations proposed in this paper (e.g. impact of workability loss at high concentrations), further microstructural analysis such as Scanning Electron Microscopy (SEM) and Mercury Intrusion Porosimetry (MIP) might be of interest.

Improving mechanical performance of soil-bentonite by slag cement addition

Amélioration des performances mécaniques du sol-bentonite par ajout de ciment de laitier

J. Chen*, Y. Masaki, A. Takai, T. Kato, T. Katsumi

ABSTRACT: Soil bentonite (SB) mixtures generally presents inadequate mechanical properties compared to other cutoff wall materials. Since both deformability and a certain level of strength properties need to be achieved for static loads or in situations of dynamic loads, the cement amendment is adopted to improve the engineering performance and ensuring the long-term effectiveness of SB cutoff walls. This study investigated the strength properties and deformation characteristics of soil-bentonite mixtures amended with slag cement using Consolidated-Undrained (CU) triaxial tests. The contents of slag cement powder considered were 25, 50, and 75 kg/m^3. The test results indicate that the undrained shear strength, residual shear strength and effective strength parameters are significantly influenced by the integration of cementation and consolidation. As compared in different cement addition, the 25 kg/m^3 cement amended specimens shows strain-hardening behaviours, 42.7 to 65.1 kPa undrained shear strength in ductile failure mode with no discernible cracks, which signifying plastic deformation with high deformability under triaxial loading. This implies that, although the contents of the slag cement were not so high, such as 25 kg/m^3, the amended soil-bentonite performed high strength and deformability.

RÉSUMÉ: Les mélanges de bentonite du sol (SB) présentent généralement des propriétés mécaniques insuffisantes par rapport aux autres matériaux de mur de séparation. Étant donné que la déformabilité et un certain niveau de propriétés de résistance doivent être atteints pour des charges statiques ou dans des situations de charges dynamiques, l'amendement au ciment est adopté pour améliorer les performances techniques et assurer l'efficacité à long terme des murs de séparation SB. Cette étude a examiné les propriétés de résistance et les caractéristiques de déformation de mélanges sol-bentonite amendés avec du ciment de laitier à l'aide d'essais triaxiaux consolidés-non drainés (CU). Les teneurs en poudre de ciment de laitier considérées étaient de 25, 50 et 75 kg/m^3. Les résultats des tests indiquent que les paramètres de résistance au cisaillement non drainé, de résistance résiduelle au cisaillement et de résistance effective sont significativement influencés par l'intégration de la cimentation et de la consolidation. Comparés à différents ajouts de ciment, les échantillons modifiés au ciment de 25 kg/m^3 présentent des comportements d'écrouissage, une résistance au cisaillement non drainé de 42,7 à 65,1 kPa en mode de rupture ductile sans fissures perceptibles, ce qui signifie une déformation plastique avec une déformabilité élevée sous chargement triaxial. Cela implique que, même si la teneur en ciment de laitier n'était pas si élevée, par exemple 25 kg/m^3, le sol-bentonite amendé présentait une résistance et une déformabilité élevées.

Keywords: Soil-bentonite; slag cement amendment; consolidated-undrained triaxial test; mechanical performance.

1 INTRODUCTION

Soil-bentonite (SB) is widely applied in vertical cutoff walls for preventing the migration of contaminants to the aquifer, owing to extremely low hydraulic conductivity and high deformability (Takai, A. et al., 2016). However, SB exhibits relatively low shear strength, and the effectiveness will be influenced in situations of high hydraulic or seismic loads.

Cementitious additives are often utilized to enhance certain mechanical properties, such as internal friction angle, cohesion coefficient and unconfined compressive strength, of soft soils (Luis, A.L. et al., 2019). The slag cement, as one type of eco-friendly material in cementitious additives, are often applied to improve the engineering properties and ensuring the long-term effectiveness of soft soils. In the application of vertical cutoff walls, it is worthy to investigate the enhanced mechanical performance and the variations in deformability in instances of relatively low content ratio of slag cement. Previous studies evaluated the compressive strength properties coupled with hydraulic performance of soil-cement-bentonite, but the deformation mode as the effect of cement amount was not studied (Ata, A.A., et al, 2015; Huang, X., et al., 2021).

In this paper, a series of Consolidated-Undrained (CU) triaxial tests on soil-bentonite (SB) and soil-bentonite with slag cement (SB-C) was conducted to investigate the variations in residual shear strength properties and effective strength parameters. Moreover, Young's modulus E_0 and secant modulus E_{50}, combining with three typical failure modes were summarised to further investigate the deformation modes and classify the capacities of SB and SB-C to simultaneously maintain both comprehensive shear strength and high deformability.

2 MATERIALS AND METHODS

2.1 Materials

Decomposed granite soil, which is widely distributed in Japan, was selected as the host soil. The bentonite used in this paper was sodium bentonite provided from Kunimine Industries Co., Ltd., Japan. For the cement amendment, the Portland Blast-Furnace Slag Cement was taken as the cement additive. The dry density of the decomposed granite soil, sodium bentonite and slag cement are 2.73, 2.60 and 3.04 g/cm^3, respectively.

2.2 Methods

Before the triaxial test, cylindrical specimens with a height of 100 mm and a diameter of 50 mm were prepared and cured for 7 D. The summary of test scheme has been presented in Table 1.

Table 1. Summary of test scheme.

	Bentonite slurry (L/m^3)	**Bentonite powder (kg/m^3)**	**Slag cement (kg/m^3)**	**Effective confining pressure (kPa)**
C0	350	97.5	0	40, 80, 160
C25			25	
C50			50	
C75			75	

The specimen mixing process of SB-C mixtures can be divided into four steps. Firstly, the bentonite slurry (5% bentonite by weight) was prepared 24 h ahead of time for sufficient hydration. Then, the dry decomposed granite soil was mixed with distilled water and bentonite slurry for 5 mins. The third step was adding the bentonite powder in two batches and mixing for 5 mins respectively. Finally, the slag cement powder was added and mixed for 10 mins. To ensure the homogeneity, the specimens were prepared with the target dry density of 1.30 g/cm^3. After the mixing process, the mixtures were poured into plastic cylinder with vibration to eliminate air voids and bubbles in the specimens. Summary of test scheme The specimens were then sealed immediately with plastic wrap and aluminum foil to minimize possible moisture change and cured at 20 ℃ for 7 days.

To evaluate the mechanical performance of SB and SB-C specimens, a series of consolidated-undrained (CU) triaxial test as per ASTM D4767-11 (ASTM International, 2020) were conducted. The schematic of the triaxial test apparatus is shown in Figure 1.

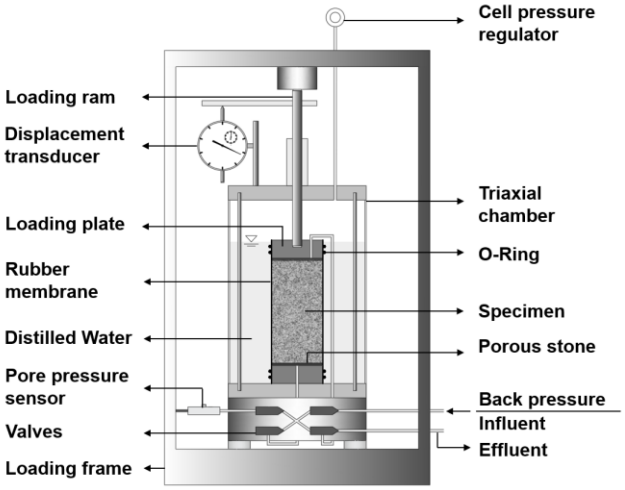

Figure 1. Schematic view of triaxial test apparatus.

For C0 specimens, after the third step of specimen mixing process, the soil-bentonite mixture was poured into a specially manufactured metal cylinder and installed in the triaxial chamber for saturation process. After 7 days curing, the C25/50/75 specimen was dissembled from the plastic cylinder and installed on the apparatus. In CU tests, specimens were saturated under a confining pressure of 10 kPa (i.e., a difference of 10 kPa between cell pressure and back pressure) until the B value is higher than 0.95. The specimens were then consolidated under different isotropic effective confining pressures (i.e., σ_3 =q 40, 80 and 160 kPa) and sheared at an axial strain rate of 0.05 mm/min until reaching approximately 15% axial strain.

3 RESULTS AND DISCUSSION

3.1 Undrained shear strength properties

The results of the undrained shear strength (S_u) and failure axial strain obtained from the triaxial CU test as a function of cement addition under different effective confining pressure are presented in Table 2, where the value of S_u is equal to one half the deviator stress at failure. As according to the ASTM D4767-11 (ASTM International, 2020), the failure of specimen is corresponding to the maximum deviator stress (q_{max}) or deviator stress at 15% axial strain, whichever is the

first obtained during the test. The deviator stress (q) is determined using equation (1),

$$q = \sigma_1' - \sigma_3' \quad (1)$$

where σ_1' is the effective major stress and σ_3' is the effective minor principal stress.

Table 2. Undrained shear strength and failure axial strain.

	40 kPa		80 kPa		160 kPa	
	S_u (kPa)	ε_{peak} (%)	S_u (kPa)	ε_{peak} (%)	S_u (kPa)	ε_{peak} (%)
C0	10.5	15.0	17.5	15.0	30.4	15.0
C25	42.7	15.0	43.2	15.0	65.1	15.0
C50	94.1	13.1	89.6	11.7	117.6	12.6
C75	142.0	7.9	153.9	6.3	190.8	7.4

In Table 2, it can be seen that the value of S_u increases as the cement addtion augments with almost double increment, which suggestes the effect of cementation during curing process. The S_u value of C0 presents over half percent increasing from 10.5 kPa to 17.5 kPa under 40 and 80 kPa effective confining pressure, respectively. As the effective confining pressure rising from 40 kPa to 80 kPa, the value of S_u increases slightly in cement amended cases except for C50 with 4.5 kPa decrease. On the contrary, the S_u value of all the cases pronounce ascending trend when the effective confining pressure doubled from 80 kPa to 160 kPa.

It is indicated that, influenced by cementitious bonding, lower effective confining pressure exerts a reduced impact on the value of S_u. Moreover, all of the C0 and C25 specimens were sheared to S_u at the failure axial strain ε_{peak} of 15%. For C50, the ε_{peak} values were varying from 11.7% to 13.1%, while the ε_{peak} values of C75 were comparatively lower, from 6.3% to 7.4% and 7.9%. Figure 2 shows the variation of residual undrained shear strength (S_r) as the function of cement addtion.

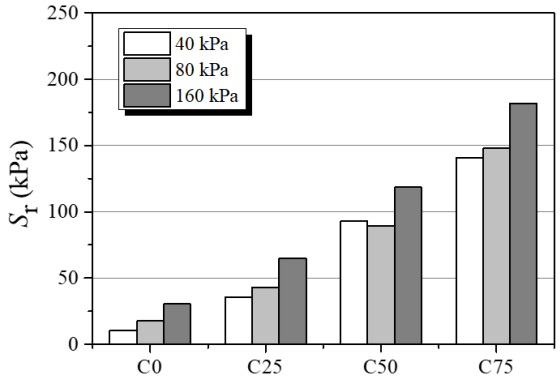

Figure 2. Residual undrained shear strength.

In Figure 2, the S_r is defined as half value of the deviator stress at 15% axial strain. It can be observed that the S_r increases with the increasing of confining pressure at a given cement amount except for the C50. Similar upward variation trend of S_r with the augment of cement addtion can be found, as the variation trend of S_u in Table 2. Moreover, when comparing S_r with S_u, for C0 and C25, the S_r is about the same with S_u. For C50 and C75, the S_r is exceeding 90% on average the S_u, which points to high strength retention characteristics after failure.

3.2 Effective stress path and strength envelope

The results of the effective stress path and strength envelope are plotted in Figure 3. The mean effective stress p' is defined in equation (2):

$$p' = \frac{\sigma_1' + 2\sigma_3'}{3} \quad (2)$$

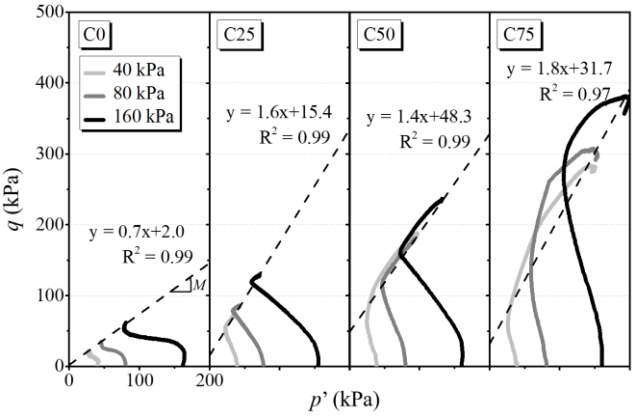

Figure 3. Effective stress path and strength envelope.

In Figure 3, the slope M of linear strength envelopes for SB (C0) and SB-C (C25, C50, C75) specimens were determined to estimate the effective strength parameters (c' and φ'). The relationship between the internal friction angle φ'_{peak} and the parameter M is expressed in equation (3) (Luis, A.L. et al., 2019):

$$M = \frac{6sin\varphi'_{peak}}{3 - sin\varphi'_{peak}} \quad (3)$$

The effective cohesion (c') is determined using equation (4):

$$c' = \frac{c}{M} \quad (4)$$

where the c is the intercept with the q axis of the linear envelopes in Figure 3. The results of c' and φ' are summarized in Table 3.

Table 3. Effective strength parameters (c' /kPa, φ' /°).

C0		C25		C50		C75	
c'	***φ'***	***c'***	***φ'***	***c'***	***φ'***	***c'***	***φ'***
2.0	35.8	15.4	58.2	48.3	55.0	31.7	61.0

As shown in Figure 3, the gradients of these envelopes are similar in SB-C specimens as the φ' were ranging from 55.0° to 61.0°, which represents high shear strength. With low cement amount amended, the φ' of C25 is 58.2 kPa, higher than C50 and close to C75. The c' of C25 is 15.4 kPa, as 2.0 kPa of C0 with high deformability, and over 30 kPa for C50 and C75.

3.3 Elastic moduli and failure modes

To evaluate the deformation mode, the results of Young's modulus E_0 and secant modulus E_{50} (defined at 50% of the peak strength) are illustrated in Figure 4.

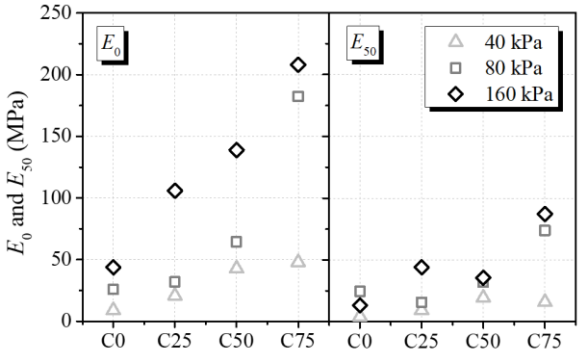

Figure 4. Young's modulus E_0 and secant modulus E_{50}.

It is observed that the moduli (E_0, E_{50}) increase with the augment of cement addition. When comparing the E_0 to E_{50}, it is evident that, the E_{50} is less than 50% of E_0 in all instances. It is noteworthy that this value does not align with that of typical elastic material, which tends to be significantly higher. It is also indicated the propensity for plastic deformation. Moreover, three typical failure modes are summarized in Figure 5.

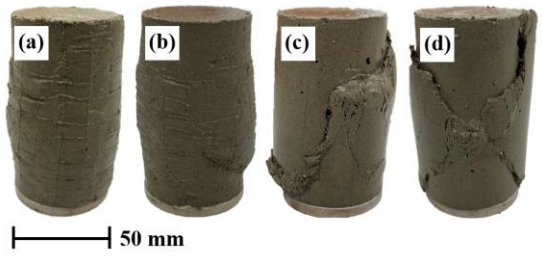

Figure 5. Typical failure modes

Figure 5 (a) was strain-hardening ductile failure in C0 and C25, while (b) presented planar failure in C50 under 40 kPa effective confining pressure. Figure 5 (c) and (d) are planar failure with larger failure angle in C50 specimens, and split failure in all C75 specimens. This point can be explained by the hydration and pozzolanic reactions of cement, which result in the igidity of specimens (Luis, A.L. et al., 2019).

4 CONCLUSIONS

In this paper, the slag cement amended SB-C specimens exhibit diverse mechanical performance.

The results indicate that C25 displays 42.7 to 65.1 kPa undrained shear strength with strain-hardening behaviours. No discernible cracks are observed at ductile failure, signifying plastic deformation with a high degree of deformability when subjected to triaxial loading. Comparing with C25, C0 presents the same failure mode with lower S_u, while planar failure and split failure can be observed in C50 and C75 with excessively higher S_u but lower deformability.

ACKNOWLEDGEMENTS

The authors are grateful for Mr. G. Araki (Raito Kogyo Co., Ltd.) and his colleagues for their great assistance on this research.

ABSTRACT: Excessive copper (Cu) or lead (Pb) in soils can cause serious threats to surrounding environments and human health. In the present work, a modified EK (electrokinetic) reactor was proposed where the single and multiple EICP (enzyme-induced carbonate precipitation) treatments were incorporated into a permeable reactive barrier (PRB) for the first time to remove Cu and Pb metals. Results showed that the EK-PRB technology outperformed the EK technology. The PRB worked with the cathode electrolyte well to reduce the remaining Pb^{2+} by about 35%. The effect of multiple EICP treatments increased the potential of combining Cu^{2+}/Pb^{2+} with CO_3^{2-}, which caused difficulty in performing the electromigration and electroosmosis during the EK remediation. It, however, depressed the focusing effect. The higher cathode pH, induced by the effect of a single EICP treatment, was accompanied by the copper-ammonia complex formation, improving the fraction of Cu^{2+} removed by the cathode electrolyte well. The Pb removal behaved similarly to the Cu removal.

RÉSUMÉ: Un excès de cuivre (Cu) ou de plomb (Pb) dans les sols peut constituer de graves menaces pour l'environnement et la santé humaine. Dans le présent travail, un réacteur EK (électrocinétique) modifié a été proposé dans lequel les traitements EICP (précipitation de carbonate induite par des enzymes) simples et multiples ont été incorporés pour la première fois dans une barrière réactive perméable (PRB) afin d'éliminer les métaux Cu et Pb. Les résultats ont montré que la technologie EK-PRB surpassait la technologie EK. Le PRB a bien fonctionné avec l'électrolyte cathodique pour réduire le Pb^{2+} restant d'environ 35 %. L'effet de plusieurs traitements EICP a augmenté le potentiel de combinaison de Cu^{2+}/Pb^{2+} avec CO_3^{2-}, ce qui a rendu difficile la réalisation de l'électromigration et de l'électroosmose pendant l'assainissement EK. Cependant, cela a diminué l'effet de focalisation. Le pH cathodique plus élevé, induit par l'effet d'un seul traitement EICP, s'est accompagné de la formation d'un complexe cuivre-ammoniac, améliorant la fraction de Cu^{2+} éliminée par le puits d'électrolyte cathodique. L'élimination du Pb s'est comportée de manière similaire à l'élimination du Cu.

Keywords: Electrokinetic remediation; permeable reactive barrier; enzyme-induced carbonate precipitation; loess.

1 INTRODUCTION

The electrokinetic (EK) technology is applied to a variety of contaminated sites due to its good maneuverability (Han et al., 2021). Despite that, the electromigration and electroosmosis require a period of time and their energy consumption may be extremely high to achieve a satisfactory remediation efficiency (Song et al., 2022). Thus, a combination of the EK technology and other technologies may provide a pathway to address the mentioned problems. The enzyme-induced carbonate precipitate (EICP) has drawn great attention as bacterial cultivation is not required prior to catalyzing urea hydrolysis (Sun et al., 2021). Permeable reactive barriers (PRB) are often applied to adsorb heavy metals in water bodies (Ma et al., 2022). The EICP technology may be incorporated into PRB to not only eliminate the discharge of NH_4^+ into surrounding environments but also improve the removal of heavy metals. Despite that, its interplay

with EK process is still unclear. In addition, OH^- can combine with Cu^{2+} or Pb^{2+} to develop the hydroxide precipitation surrounding the cathode, clogging the electroosmosis and electromigration during the EK remediation (Li et al., 2012). The main objectives of this study are to: (1) propose an EK reactor where the multiple EICP treatments are incorporated into PRB, (2) mitigate the focusing effect, and (3) explore the inherent mechanism affecting the removal efficiency.

2 METHODOLOGY

2.1 Electrokinetic reactor

The EK reactor was proposed and applied to the removal of Cu and Pb in the loess soil, as shown in Figure 1. The soil compartment containing five soil sections, namely A1 to A5, was separated from the anode and cathode electrolyte wells using a graphene plate. The Cu- or Pb- contaminated loess was loaded into A1, A2, A4, and A5, respectively, while a PRB was deployed into A3.

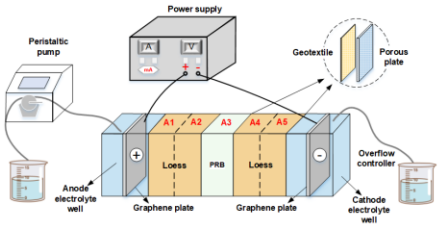

Figure 1. Schematic illustration of electrokinetic reactor.

2.2 Materials

The loess was taken from Jingyang County, Shaanxi Province, China, which is classified as low plasticity clay (CL). Copper nitrate ($Cu(NO_3)_2$) and lead nitrate ($Pb(NO_3)_2$) of analytical pure as a contaminant were applied to prepare Cu- or Pb-contaminated loess. Their concentration was manipulated to 500 mg/kg. In addition, PRB mainly consisted of urea, urease, and chitosan addition. The use of chitosan isolated the urease from Cu^{2+} or Pb^{2+}, preventing its inactivation.

2.3 Experimental design

The experimental design mainly consisted of the control group (CG) and test group-2 (TG-2). CG neglected PRB. TG-2 took PRB into account where the multiple EICP treatments intervened in the EK remediation. The concentration of Cu or Pb was measured in accordance with the Tessier's sequential extraction procedure (Tessier et al., 1979). Five fractions (EXC: Exchangeable state, CAR: Carbonate combination state, OX: Fe-Mn oxides state, ORG: Organic state, RES: Residue state) denoted different species of Cu or Pb.

3 RESULTS

3.1 EK remediation

Figure 2a shows the temporal relationships of electric conductivity applied to Cu removal using the EK technology. In CG test, the changes in electric conductivity fall within a 300 to 2000 μs/cm range. The electric conductivity in A5 goes into a decline at 4 h after the commencement of CG test, which is earlier than A4. Similar phenomena can also be seen in the temporal relationships of electric conductivity applied to Pb removal (see Figure 2b). Figures 2c and 2d show the temporal relationships of pH applied to Cu and Pb removals. As CG test progresses, the difference in pH between the anode and cathode becomes much more significant.

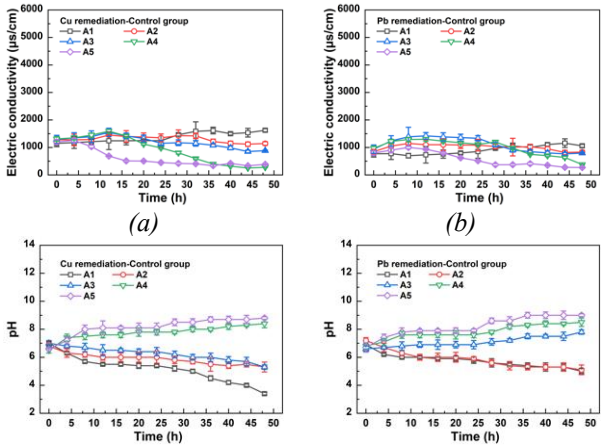

Figure 2. Temporal relationships of: (a) EC applied to Cu removal, (b) EC applied to Pb removal, (c) pH applied to Cu removal, and (d) pH applied to Pb removal.

Figures 3a and 3b show the temporal relationships of cumulative EOF (electroosmotic flow) and electric current applied to Cu and Pb removals. EOF increases very quickly to above 900 mL/h at 15 h for Cu removal and then remains a small change until the end of CG test. The electric current for Cu removal behaves similarly to Pb removal.

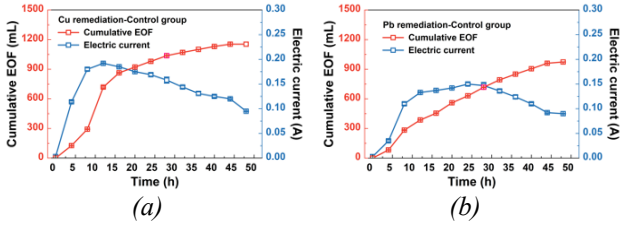

Figure 3. Temporal relationships of cumulative EOF and electric current applied to: (a) Cu removal and (b) Pb removal.

The relationships of removal efficiency versus soil section (A1 to A5) are shown in Figure 4. The removal efficiency decreases in a gentle manner from A1 to A5. The highest removal efficiency of 16% is attained in A1, while the lowest removal efficiency of 2% is attained in A5, most likely because of the hydroxide precipitation in the vicinity of the cathode.

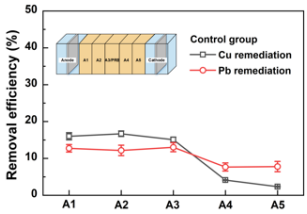

Figure 4. Variations of removal efficiency against soil section.

3.2 EK-PRB remediation considering the effect of multiple EICP treatments

Figure 5 shows the temporal relationships of electric conductivity applied to Cu and Pb removals respectively considering the effect of multiple EICP treatments. The multiple EICP treatments applied to TG-2 test encourage the sequential discharge of NH_4^+ and OH^-. Some of the EC curves lie above those in CG test (see Figures 5a and 5b). In CG test, the difference in pH between the anode and cathode enlarges with time (see Figures 2c and 2d). Here this phenomenon is not as pronounced as that in CG test (see Figures 5c and 5d).

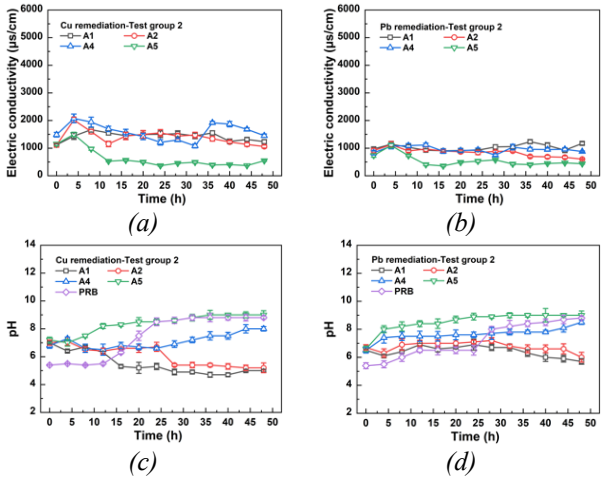

Figure 5. EK remediation (multiple EICP treatments) - Temporal relationships of EC applied to: (a) Cu removal and (b) Pb removal, - Temporal relationships of pH applied to: (c) Cu removal and (d) Pb removal.

Unlike CG test, EOF in TG-2 test starts increasing after a period of time (see Figure 6). The maximum EOF for Cu removal is higher in CG test than in TG-2 test. The maximum EOF for Pb removal is also higher in CG test than in TG-2 test. Although the effect of multiple EICP treatments depresses the focusing phenomenon, it causes a side effect to prevent EOF from going higher. More details would be presented later in this paper.

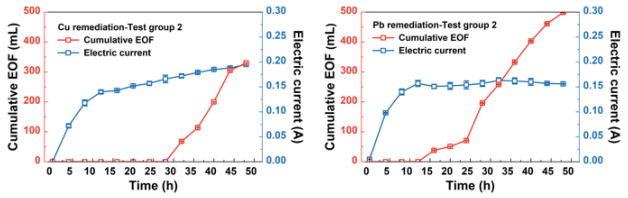

Figure 6. EK remediation (multiple EICP treatments) - Temporal relationships of cumulative EOF and electric current applied to: (a) Cu removal and (b) Pb removal.

The relationships of removal efficiency versus soil section (A1 to A5) are shown in Figure 7. In TG-2 test, the closer the soil section to the cathode, the higher the removal efficiency, meaning that Cu^{2+} or Pb^{2+} can migrate toward the cathode with no difficulty due to the absence of hydroxide precipitation. Despite that, the aforesaid side effect raises up the possibility of combining Cu^{2+} or Pb^{2+} with CO_2^{3-} that is heading toward the anode.

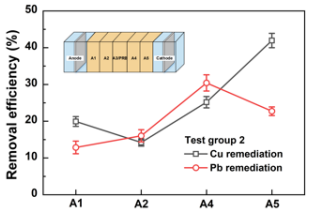

Figure 7. Variations of removal efficiency against soil section.

4 DISCUSSION

Compared to the initial CAR-Cu, CAR-Cu in A1 and A2 in CG test presents a small decrease (see Figure 8), indicating that a part of CAR-Cu desorbs due to exposure to acidic environments in the vicinity of the anode and migrates toward the cathode electrolyte well to achieve their removal (see Figure 9a). CAR-Cu in A4 and A5 in CG test shows a small change compared to the initial CAR-Cu. Alkaline environments around the cathode impede their desorption, causing CAR-Cu in A4 and A5 in CG test to remain nearly the same. In TG-2 test, CAR-Cu in A1 and A2 does not present a further decrease but an increase compared to CAR-Cu in A1 and A2 in TG-1 test (see Figure 8). TG-1 has been omitted herein due to limited space and takes the effect of a single EICP treatment intervenes into account. The effect of multiple EICP treatments increases the possibility of combining Cu^{2+} with CO_3^{2-}

and causes malachite ($Cu_2(OH)_2CO_3$) and azurite ($Cu_3(CO_3)_2(OH)_2$) to precipitate, reducing the fraction of Cu^{2+} removed by PRB (referred to also as the 'side effect'). CAR-Cu in A4 in TG-2 test also presents an increase rather than a further decrease. Since the effect of multiple EICP treatments narrows pH ranges in CG-2 test (see Figure 5), the lower pH of about 8 prevents copper-ammonia complex from developing (Xie et al., 2023), reducing the fraction of Cu^{2+} removed by the cathode electrolyte well. It is worth noting that the fraction of Cu^{2+} removed by the cathode electrolyte well is higher than that removed by PRB (see Figure 9a). In spite that the effect of multiple EICP treatments results in the side effect, it, however, mitigates the focusing effect, improving the fraction of Cu^{2+} removed by the cathode electrolyte well. Pb removal behaves similarly to Cu removal (see Figures 9b and 10).

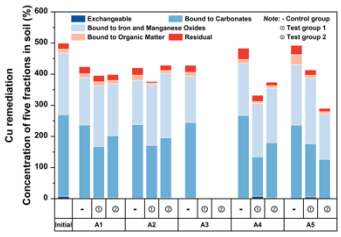

Figure 8. Distributions of five species applied to Cu removal.

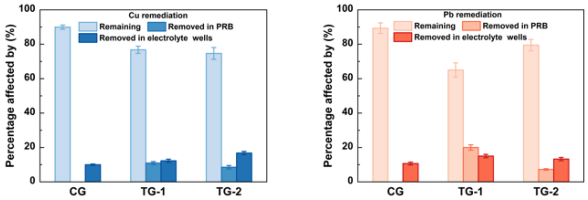

(a) *(b)*

Figure 9. Mass balance calculation: (a) Cu removal and (b) Pb removal.

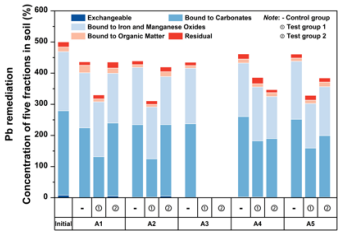

Figure 10. Distributions of five species applied to Pb removal.

5 CONCLUSIONS

Based on the results and discussion, some main conclusions can be drawn as follows:

(a) In this study, the bio-PRB that incorporates the EICP treatment applies to the EK technology as an adsorbent. The EK-PRB technology outperforms the EK technology regarding the Cu and Pb removals.

(b) PRB reduces the remaining Cu^{2+} and Pb^{2+} by 10% and 20% respectively. PRB works with the cathode electrolyte well to reduce the remaining Pb^{2+} by 35%. The above highlights the role of PRB in the EK-PRB technology.

(c) The effect of multiple EICP treatments reduces the fraction of Cu^{2+} or Pb^{2+} removed by PRB. This, in turn, encourages the formation of azurite and malachite precipitation. Due to this reason, only a small number of Cu^{2+} or Pb^{2+} can migrate toward the cathode, reducing the focusing effect. Pb removal behaves similarly to Cu removal, although Pb^{2+} is more willing to combine with CO_3^{2-}.

Waste valorisation in landfill barriers: Opportunities and challenges

Valorisation des déchets en tant que barrières d'étanchéité de décharge: Opportunités et défis

ABSTRACT: Landfill barriers play a fundamental role in environmental protection, mitigating the migration of contaminants into the surrounding environment. This review provides an in-depth analysis of the potential of diverse waste types as substitutes or amendments for conventional landfill liners and covers. Outlined from extensive literature, the study highlights the dual advantage of waste utilization in landfill barriers: conservation of natural resources and waste recycling enhancement. While certain waste products have shown promise due to their improved geotechnical and mechanical characteristics, concerns about the leaching of hazardous contaminants remain paramount. This review evaluates the optimal use of waste in landfill barriers. It emphasizes the necessity of comprehensive chemical and bioassay evaluations to accurately predict long-term leaching behavior and environmental compatibility. Research indicates the prospective utility of waste-derived materials in landfill barrier applications, aligned with environmental sustainability objectives. However, this approach mandates a heightened emphasis on safety, necessitating comprehensive, site-specific evaluations.

RÉSUMÉ: Les barrières d'étanchéité de décharge jouent un rôle fondamental dans la protection de l'environnement, en atténuant la migration des contaminants dans l'environnement environnant. Cette revue fournit une analyse approfondie du potentiel de divers types de déchets en tant que substituts ou amendements pour les revêtements et couvertures de décharge conventionnels. Décrit à partir d'une vaste littérature, l'étude met en évidence le double avantage de l'utilisation des déchets dans les barrières de décharge: la conservation des ressources naturelles et l'amélioration du recyclage des déchets. Bien que certains produits de déchets se soient montrés prometteurs en raison de leurs caractéristiques géotechniques et mécaniques améliorées, les préoccupations concernant la lixiviation des contaminants dangereux restent primordiales. Cette revue évalue l'utilisation optimale des déchets dans les barrières de décharge. Elle souligne la nécessité d'évaluations chimiques et bioessais complètes pour prédire avec précision le comportement de lixiviation à long terme et la compatibilité environnementale. La recherche indique l'utilité prospective des matériaux dérivés des déchets dans les applications de barrière de décharge, alignée avec les objectifs de durabilité environnementale. Cependant, cette approche exige un accent accru sur la sécurité, nécessitant des évaluations complètes et spécifiques au site.

Keywords: Landfill barriers; geotechnical characteristics; recycling.

1 INTRODUCTION

In recent decades, incineration, recycling, and composting have increasingly enhanced solid waste management strategies in contemporary societies. However, landfilling persists as a globally predominant method for waste disposal. A significant portion of industrialized nations, including numerous European Union (EU) member states and the United States of America (US), continue to incorporate landfilling as a fundamental component of their solid waste management systems.

The primary environmental concern with landfilling is the contamination of the surrounding environment due to landfill leachate. To prevent this, engineered landfills are equipped with impermeable multi layered barriers, including a cover and bottom liner systems, which consist of natural geological barriers, technical barriers, and drainage systems. These systems serve to reduce rainfall infiltration, control gas emissions, and protect soil and water contamination.

EU regulations stringently govern landfill specifications, mandating a combination of geological and artificial barriers along with bottom liners from the construction phase till the closure and post-closure phase. It should be mentioned that the affordability and technological feasibility of such landfill lining technologies is often beyond the reach of low-income

countries. Consequently, a diverse range of alternative materials, both natural and waste-derived, have gained attention as potential substitutes.

The application of waste materials in landfill linings is believed to have economic benefits. It conserves natural resources and conforms to essential international environmental policies that emphasize waste reduction, the reuse of materials, and recycling efforts. Moreover, incorporating waste materials can potentially enhance liner characteristics and performance. However, the application of these unconventional materials is not without controversy.

Despite extensive research on the use of wastes material in landfill barrier construction, results still present poorly definitive conclusions on the suitability of each waste material for such applications. Therefore, this paper provides a comparative analysis of various waste materials suggested in literature publications for use in engineered hydraulic barriers within landfills. It discusses the geotechnical (Figure 1) and hydraulic conductivity (k)properties (Table 1), advantages, and disadvantages of these materials, with a focus on environmental protection issues, adhering to international global regulatory norms and guidelines.

2 RED MUD

In waste management, the application of Red Mud, a byproduct of alumina extraction from bauxite, has garnered significant interest for its potential in environmental remediation, particularly as a liner material for landfills. Several studies, demonstrated the Red Mud's efficacy in reducing contaminants like iron (Fe), sulphate (SO_4), cooper (Cu), Zinc (Zn), and bacteria in leachate (Duchesne and Doye, 2005; Çoruh and Ergun, 2010). Field investigation conducted by Ujaczki *et al.*, (2016) evaluated the use of red mud-soil mixtures as potential additives for landfill cover layers. Using a comprehensive set of chemical, biological, and ecotoxicity metrics, it was concluded that these mixtures could be safely used in poor-quality subsoils at concentrations up to 20% by weight without causing ecological toxicity. Based on these findings, red mud-soil mixtures were advocated to be incorporated into the surface layers of landfill cover systems.

Kalkan (2006) found that red mud improves the density and strength of compacted clay liners while reducing their expansibility and permeability (k<10-9m/s). Rubinos et al. (2015, 2016, 2017) studied red mud in landfill liners, examining its geotechnical qualities, low permeability, chemical stability, and environmental safety. They also noted its ability to capture mercury from leachates. Their findings show that red mud has a low permeability (10-9 m/s), high friction angle (38°), and cohesion (79.5 kPa), enhancing shear resistance on slopes. However, organic solvents and acids affect its properties, suggesting the need for more research on its chemical and environmental effects.

Nonetheless, the studies also highlighted that desiccation significantly affect red mud's permeability, raising concerns about its direct application in landfill cover systems. Panda et al., (2017) highlighted that red mud bioneutralization using microbial action with various carbohydrate sources could improve its geotechnical properties. While red mud's resistance to chemical attack and contaminant retention are notable, concerns about its alkalinity, the need for effluent management, and the potential release of radionuclides and trace metals under varying conditions necessitate careful consideration (Rubinos and Barral, 2013; Hegedűs et al., 2016). Field validation red mud liners remains essential. Given these factors, the use of red mud liners might be best suited for industrial or mining waste landfills. While red mud shows promise as a landfill liner material, its application should be carefully evaluated, considering its narrow operational range, potential environmental impacts, and the need for effective effluent management.

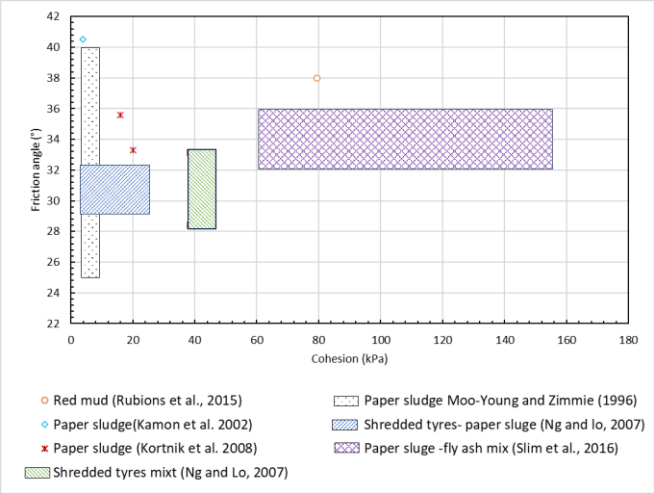

Figure 1. Shear parameter of wastes studied in the review.

3 PAPER SLUDGE

In recent decades, the utilization of waste materials from the paper industry, particularly paper sludges, gathered considerable consideration in the context of sustainable landfill engineering. These by-products, often described as paper sludge, have been increasingly recognized as viable alternatives to traditional clays for the construction of landfill liners.

Table 1. Waste material characteristics and its hydraulic Conductivity.

Material	Hydraulic Conductivity	Advantages	Limitation	Reference
Red Mud	9 x 10^{-10} to 5.13 x 10^{-10} m/s	- Good for reducing contaminants like Fe, SO4, Cu, Zn, and bacteria. - Enhances geotechnical properties when used in clay liners. - Can withstand shear forces on landfill slopes.	-Susceptible to desiccation affecting permeability. -Concerns about alkalinity, need for effluent management, and potential release of radionuclides and trace metals.	Rubinos et al. (2015); Panda et al. (2017)
Paper Sludge	3.4 x 10^{-10} to 5.3 x 10^{-8} m/s	- Effective as hydraulic barriers due to low *k*. - Contains organic fibers enhancing cohesion and friction angle. -Environmental compatibility confirmed for landfill applications.	-Susceptibility to desiccation and freeze-thaw cycles. - Requires high *w* during compaction.	Moo-Young and Zimmie (1996); Kamon et al. (2002); Kraus et al. (1997); Kortnik et al. (2008)
Paper Sludge - Wood Ash	5.0 x 10^{-9} m/s	-Potential enhancement of geotechnical properties.	-Requires further study for comprehensive understanding.	Kortnik et al. (2008)
Shredded Tyres - Paper Sludge	4.15 x 10^{-9} m/s	- Improves shear strength. - High ability of Pb retardation.	-Potential increase in *k*. -Variable concentrations of heavy metals in leachates.	Ng and Lo (2007)
Shredded Tyres Mixture	4.01 x 10^{-7} to 1.0 x 10^{-10} m/s	-Reduces dry density and compressive strength beneficially. -Enhances contaminant sorption capacity.	-May lead to an undesirable elevation in *k*.	Ng and Lo (2007)
Cement Kiln Dust - Black Cotton Soil	1.0 x 10^{-8} to 1.5 x 10^{-10} m/s	-Elevates maximum dry density and reduces optimum *w*. -Improves vertical strain and unconfined compressive strength.	-Concerns about caustic nature and potential leachates containing harmful compounds.	Oriola and Moses (2011)
Cement Kiln Dust - Lateritic Soil	9 x 10^{-9} to <1.0 x 10^{-10} m/s	-Reduction in plasticity index and vertical strain. -Notable increase in unconfined compressive strength.	-Concerns about caustic nature and potential leachates containing harmful compounds.	Amadi and Ebermu (2013)

Investigations identified the potential of paper sludge to achieve a state of low *k*, thereby serving effectively as hydraulic barriers (Rubinos and Spagnoli, 2018).Moo-Young and Zimmie, (1996) investigated the geotechnical characteristics of various paper mill sludges, revealing their high water content (*w*: 150 – 250%), plasticity index (77–191), and compressibility. These studies highlighted the impact of *w* on the compaction and hydraulic properties of paper sludge, noting the trade-off between water content and hydraulic performance although the shear strength varied based on the contents of organic matter and the fibres. However, challenges such as the susceptibility of the paper sludge to desiccation and freeze-thaw cycles, which can significantly influence its *k*, were also identified.

Further laboratory and field investigations focused on the long-term efficiency of paper sludge as an hydraulic barrier layer in landfill covers by Kraus *et al.*, (1997) and Moo-Young and Zimmie, (1997), demonstrated that paper sludge could maintain acceptable hydraulic barrier properties over extended periods ($k < 10^{-9}$ m/s). Kamon *et al.*, (2002), confirmed these results by conducting a comprehensive assessment of paper sludge for landfill cover applications, emphasizing its potential to maintain low *k* under a large range of *w* (50–200%) and for 10 years, and its high friction angle (40.5˚) and cohesion of 3.9 kPa due to the presence of organic fibres.

The environmental compatibility of paper sludge has been the subject of studies by Boni *et al.* (2004) that have evaluated the leaching potential of heavy metals from paper sludge, finding concentrations to be within acceptable environmental thresholds. Zule *et al.* (2007) and Kortnik *et al.* (2008) extended these analyses to include chemical and biodegradability assessments, further validating the environmental suitability of paper sludge for landfill applications.

Studies by Slim *et al.*, (2016), have experimented with paper sludge mixtures and, incorporating class C fly ash to enhance their geotechnical properties while maintaining low *k*. These studies suggest that with appropriate modification, paper sludge could serve as an effective component in alternative landfill liner designs.

Paper sludge appears to be a viable option for landfill barrier construction as its primary benefits include its suitable *k* and geotechnical characteristics, which have been verified in operating municipal solid waste landfills across the United States, Finland,

Canada, and Japan. It`s considered relatively safe regarding the leaching of trace metals (Rubinos and Spagnoli, 2018). However, its significant vulnerability to drying out and freeze-thaw cycles presents a notable drawback.

4 CEMENT KILN DUST

Cement kiln dust, a fine, alkaline material by-product captured through electrostatic precipitators during cement clinker manufacture, has been increasingly investigated for its potential as a soil stabilization agent, particularly in the construction of waste containment barriers(Kunal, et al., 2012). Research conducted by Mohamed (2002) in which cement kiln dust was utilized at an optimal ratio of 6% in soil barriers formulation specifically for hazardous waste in arid environments, led to a significant reduction in k, to below 10^{-9} m/s, and simultaneously improved the soil's shear strength. Parallel findings were reported by Oriola and Moses, (2011), who examined the effects of integrating 4 –16% cement kiln dust (by dry weight) into "black cotton" expansive soils. The research indicated that cement kiln dust generally elevates the maximum dry density and reduces the optimum w. Soils with 4–12% cement kiln dust content achieved satisfactory k levels below 10^{-9} m/s. However, it was noted that the 4% cement kiln dust concentration was particularly effective in improving soil k, while higher cement kiln dust proportions tended to be counterproductive. Additionally, significant improvements in vertical strain and unconfined compressive strength were observed, surpassing 200 kN/m^2, for up to 16% cement kiln dust treatment. This enhancement is attributed to the pozzolanic properties of cement kiln dust.

Amadi and Eberemu, (2013) extended this research to compacted lateritic soils derived residually, stabilized with up to 16% cement kiln dust. They reported a reduction in plasticity index (from 20 to 30%) and maximum unit weight, alongside a decrease in vertical strain (consistently below 4%) and a notable increase in unconfined compressive strength with rising cement kiln dust content. Osinubi *et al.* (2015) outlined the optimal zone for cement kiln dust cured lateritic soil, specifying 10% cement kiln dust content, prepared with w ranging between 13.5 and 21.3%, and compacted using British Standard Heavy (BSH) energy.

Collectively, these studies advocate for the potential application of cement kiln dust as a soil stabilizer in the construction of waste containment barriers, especially considering its geotechnical properties and influence on k. However, it is crucial to address concerns regarding the potential environmental hazards posed by cement kiln dust leachates, which may contain harmful compounds and exhibit a caustic nature. Hence, a definitive assessment of cement kiln dust's suitability for such applications necessitates a detailed understanding of these environmental implications.

5 SHREDDED TYRES

The integration of shredded tyres in landfill hydraulic barriers, either alone or in conjunction with natural soil or other waste materials, has been the focus of numerous research. Al-Tabbaa and Aravinthan, (1998) examined the engineering and leaching attributes of compacted clay mixed with up to 20% shredded tyres. The findings indicated that the addition of shredded tyres resulted in reduced dry density, unconfined compressive strength, and k. Natural clay-shredded tyres mixtures with varying percentages and particle sizes when permeated with different liquids such as paraffin, acidic water, and distilled water, exhibited interesting adhering dynamics between shredded tyres and clay. The study found that k increased when permeated with water or acidic water, but decreased significantly when permeated with paraffin by more than 50 times, attributed to the absorption by tyre particles and their consequent swelling (up to 600 kPa). This property was seen as beneficial, as it mitigated the negative impact of organic chemicals with low dielectric constants on clays. However, the leaching tests indicated variable concentrations of heavy metals, necessitating site-specific assessments.

Ng and Lo (2007) adopted a different approach by creating a combination of waste tyre aggregates with paper sludge for use as daily landfill covers. The research demonstrated that the mixed paste, being significantly lighter and less permeable than conventional soil covers, improved shear strength. Additionally, the paste displayed a high ability of Pb retardation (retardation factor D = 19.0–59.0), suggesting its effectiveness as a landfill cover system (Ng and Lo, 2010).

A study focusing on the geotechnical characteristics of sand-bentonite mixtures reinforced with tyre chips (5 - 15%) for a potential use as liner material, revealed a reduction in maximum dry density from 1.69 to 1.76 g/cm³ with an increase in tire content from 0% to 15% (Mukherjee and Mishra, 2017). Up to 10% tyre content the consolidation coefficient exhibited a slight decrease, but then rose to 0.110 with further addition (15%). The optimum water content remained largely stable at approximately 16%. Additionally, the swelling index improved across all tire content levels (from 0.023 to 0.089), attributable to the tires elastic properties. The inclusion of tire

material positively influenced the unconfined compressive strength, as evidenced by a growth in the Improvement factor. This enhancement was also seen in the cohesion (from 28.4 kPa to 49.1 kPa) up to 10% tire content, and in the friction angle (from 27.3° to 33.1°) for all tire contents. These findings suggest that the integration of tire chips into soil base can significantly reduce the probability of failure. Despite improving the shear strength, the addition of tyre chips adversely affected hydraulic conductivity, necessitating careful consideration of the tyre content to maintain desired permeability values.

Overall, these studies collectively indicate that shredded tyres can be an effective reinforcement additive for clay liners, mitigating issues like cracking due to desiccation and enhancing contaminant sorption capacity. Conversely, concerns regarding increased *k* and potential leaching of contaminants from the tyres remain.

6 COMPARATIVE CONCLUSION

The examination of the previously mentioned waste materials demonstrates that a significant proportion exhibit technical attributes appropriate for the landfill barriers. Nonetheless, it is imperative to acknowledge that every distinct waste type possesses unique properties, and its deployment offers both benefits and drawbacks relative to conventional materials employed in landfill liners and covers. These considerations predominantly pertain to geotechnical and hydraulic efficacy, economic implications, and environmental safety concerns.

Bauxite residue (red mud) is characterized by a suite of beneficial properties for application as a liner, predominantly due to its robust mechanical resistance, considerable capacity of acid neutralization, resilience to chemical degradation, and notably, its superior adsorption capabilities for a large spectrum of contaminants, comprising toxic trace metalloids, organic chemicals, phosphorus, and bacteria. Conversely, its limitations are marked by a restricted range of acceptable *k*, vulnerability to desiccation, inherently caustic nature, the presence of radionuclides and trace metalloids, its alkalinity leaching and its sensitivity to desiccation. These factors necessitate a cautious approach, recommending the use of red mud primarily for reactive bottom liners in industrial or mining wastes landfills.

Pulp and paper mill sludges present viable options for landfill cover system, attributed to their low *k*, acceptable slope stability, and controlled metal leaching during landfilling operations. The primary challenges associated with paper sludge include the necessity for high *w* during compaction and the risk of biodegradation. However, the most critical limitation of paper sludge is its heightened susceptibility to desiccation and freeze-thaw cycles and oxidative and microbiological degradation. This characteristic strongly suggests the implementation of a protective top layer to mitigate the risk of structural compromise due to cracking.

Cement Kiln Dust is beneficial as a conditioner for clays or clayey soils, enhancing the geotechnical properties, density, and vertical settlement properties of barrier materials. However, limitations exist in the permissible proportions of in the mixture, and its occasional adverse impact on k presents technical challenges. The most notable concerns with Cement Kiln dust use are its acidic properties and its leachate hazardous materials.

End-of-life shredded tires demonstrate functional efficacy in reinforcing liners, attributable to their swelling and elastic characteristics. The incorporation of such materials enhances the geotechnical characteristics and contaminant retention capabilities of the natural barriers. Significantly, their incorporation mitigate the detrimental effects of low dielectric constant organic chemicals on clays. However, this approach is not without weaknesses, as it may lead to an undesirable elevation in hydraulic conductivity and an increased risk of contaminant leaching.

The utilization of waste in engineering landfill barriers offers common advantages, such as reducing landfill space and environmental impacts, decreasing costs, and enhancing waste recycling rates. However, there is a necessity for more comprehensive research on the chemical compatibility and environmental impact of these wastes, particularly regarding their contaminant leaching characteristics.

ABSTRACT: Chalk is a type of porous rock formed from cemented calcite grains. It is widely found in areas across the UK, and is present beneath the North Sea where offshore wind turbines are being installed. Large piles are often driven into chalk to support these turbines. However, the installation process can cause the intact rock below the pile to crush, creating a putty-like material with different mechanical properties from the original rock. This unpredictability has made it difficult to design piles that are appropriate for use in chalk. This paper presents two approaches to modelling open-ended pile installation in chalk. The first approach is based on the Discrete Element Method (DEM), which represents the rock as separate particles bonded together. A new contact model is proposed for highly porous rocks. The second approach uses the Geotechnical Particle Finite Element Method (GPFEM), which has been adapted to account for the large displacements and nonlinearities of the problem. With GPFEM the coupled hydromechanical effects developing during pile installation are investigated using a robust and mesh-independent implementation of an elasto-plastic constitutive model at large strains. With DEM the micromechanical features of pile plugging are explored and the mechanisms behind radial stress distributions inside and outside the plug are unveiled. Although both approaches have their challenges, they have been successful in modelling pile installation experiments at model scale. This offers the potential for a closer examination and improved understanding of the mechanisms underlying open-ended pile installation in chalk.

RÉSUMÉ: La craie est un type de roche poreuse formée de grains de calcite cimentés. Elle est largement répandue au Royaume-Uni et se trouve sous la mer du Nord, où des éoliennes offshore sont installées. De grands pieux sont souvent enfoncés dans la craie pour soutenir ces éoliennes. Cependant, le processus d'installation peut entraîner l'écrasement de la roche intacte située sous le pieu, créant ainsi un matériau semblable à du mastic dont les propriétés mécaniques sont différentes de celles de la roche d'origine. Cette imprévisibilité a rendu difficile la conception de pieux adaptés à une utilisation dans la craie. Cet article présente deux approches pour modéliser l'installation de pieux ouverts dans la craie. La première approche est basée sur la méthode des éléments discrets (DEM), qui représente la roche comme des particules séparées liées entre elles. Un nouveau modèle de contact est proposé pour les roches très poreuses. La seconde approche utilise la méthode des éléments finis à particules géotechniques (GPFEM), qui a été adaptée pour tenir compte des grands déplacements et des non-linéarités du problème. Avec la GPFEM, les effets hydromécaniques couplés qui se développent pendant l'installation des pieux sont étudiés en utilisant une implémentation robuste et indépendante du maillage d'un modèle constitutif élasto-plastique à grandes déformations. Avec le DEM, les caractéristiques micromécaniques du colmatage des pieux sont explorées et les mécanismes qui sous-tendent les distributions radiales des contraintes à l'intérieur et à l'extérieur du colmatage sont dévoilés. Bien que les deux approches présentent des difficultés, elles ont permis de modéliser avec succès des expériences d'installation de pieux à l'échelle du modèle.

Keywords: Displacement piles; DEM; GPFEM; Chalk.

1 INTRODUCTION

Designing foundations in soft, cemented porous rocks presents a significant challenge due to the material's complex mechanical behaviour. Upon loading soft rocks may crush and collapse and, if saturated, consequent pore water pressure build up would further reduce the effective stress. Material behaviour would then change from stiff elastic to a non-linear irreversible soil-like one, characterised by completely different hydraulic properties. Whilst for low levels of loading, an elastic response may facilitate design, the insertion of a rigid body like a steel pile will definitively remould the rock (Buckley et al., 2017) and therefore suffer from the above-mentioned consequences. Small scale physical modelling in soft

rocks has revealed that the damage process is completely different when comparing a closed-ended cone shaped pile with an open-ended tubular one (Alvarez-Borges et al., 2018). For this reason, the post-installation stress field will change depending on the geometry of the penetrating object. To incorporate installation effects, current practice for pile design in soft rocks is moving towards cone penetration test (CPT) methods (Jardine et al., 2023) where radial stress profiles around open-ended piles pushed into soft rocks are inferred from the CPT response.

In recent years, several numerical methods able to overcome difficulties related to large deformations and various types of non-linearities (e.g. material, contact) have been developed. On one side, the Discrete Element Method (DEM), often used to investigate elemental soil behaviour, has been shown to be an appropriate tool that with reasonable computational power can be used to simulate boundary value problems (BVPs). Several boundary value problems including pile penetration (Cerfontaine et al., 2023; Ciantia et al., 2019) and screw piles (Sharif et al., 2021) have been investigated using the DEM.

On the other hand, amongst various continuum approaches (CEL, MPM, SPH), the Geo-Particle Finite Element Method (GPFEM) has been shown to be able to manage large deformations and address the complexities of nonlinear soil behaviour (Carbonell et al., 2022). GPFEM has been shown to be suitable to investigate CPT installation and interpretation in structured ground (Oliynyk et al., 2021). Thanks to its robust large deformation hydro-mechanically-coupled formulation it was used to study installation problems in chalk in partially drained conditions (Previtali et al., 2023).

Both DEM and GPFEM have advantages and disadvantages. For example, whilst DEM only requires calibration of simple physical parameters to capture soil behaviour quite realistically at the macroscale, it is computationally demanding, particularly if hydro-mechanical problems need to be modelled. In contrast, continuum approaches were developed from the outset to solve BVPs, but strongly depend on the ability of the constitutive relationship used to accurately simulate soil behaviour. In this work DEM and GPFEM are used to investigate the installation process of an open-ended pile in a soft rock. Reference experimental data by Alvarez-Borges et al. (2018) that used X-ray tomography will be used as a validation dataset.

2 NUMERICAL FRAMEWORKS

2.1 DEM for highly porous rocks

The behaviour of rocks has been historically modelled in DEM by introducing cohesive bonds through the Bonded Particle Method (BPM) (Potyondy & Cundall, 2004). Zheng et al. (2023) recently developed a bond-softening damage model able to capture the complex pressure dependent behaviour of weakly cemented porous rocks. Such a contact model, which is used in this study, is defined within the macro-element framework characterized by a generalized force-displacement failure envelop:

$$f = \left|\frac{\tilde{M}}{\bar{M}}\right|^{1.001} + \left(\frac{N}{\bar{N}}\right)^2 + \left(\frac{V}{\bar{V}}\right)^4 \left[1 - \left(\frac{N}{\bar{N}}\right)^2\right]^{-1} - 1 \quad (1)$$

The behaviour in the (i) normal (N), (ii) tangential (V) and (iii) bending direction ($\tilde{M}$) is linear elastic within the yield surface, according to Euler beam theory. The overbar symbols $\bar{M}, \bar{N}$ and $\bar{V}$ represent the size of the yield surface on a given axis and are function of the bond tensile (σ_{t0}), compressive (σ_{c0}) and shear (τ_0) strength. Unlike in the BPM, the bond does not instantaneously fail once the combined load reaches the yield surface but starts accumulating damage. This damage variable (D_d) then affects the size of the yield surface modifying σ_0 and τ_0 through plastic softening. D_d depends on the irreversible displacements in the normal u_n^p and tangential u_s^p direction and the irreversible rotation θ_b^p:

$$D_d = 1 - e^{-\left(\frac{\left|u_n^p\right|}{u_n^c} + \frac{u_s^p}{u_s^c} + \frac{\theta_b^p}{\theta_b^c}\right)} \quad (2)$$

Table 1. Chalk DEM parameters (see. Zheng et al. (2023)).

Parameter	Value	Parameter	Value
$\bar{E}^*[GPa]$	1.7	θ_b^c[rad]	6e^{-3}
$\bar{\kappa}^*[-]$	5	$\sigma_{c0}[MPa]$	50
$u_n^c[m]$	2e^{-5}	$\sigma_{t0}[MPa]$	1
$u_s^c[m]$	2e^{-5}	$\tau_0[MPa]$	2

2.2 GPFEM of structured soils

The GPFEM is based on a standard FEM framework that, through continuous remeshing, mitigates mesh distortion issues. The efficiency of the numerical approach lies in the use of low-order triangular elements which simplify the remeshing process. To avoid interlocking issue, a mixed formulation is used. The constitutive model used in this work is an extension of Modified Cam Clay to incorporate bonding (Monforte et al., 2019). In addition to the standard preconsolidation pressure of the unbonded material p_s, an extra internal variable related to the

tensile strength of the rock (p_t) is used to account for bonding. The shape of yield surface is controlled by M_f while $M_g$controlles the plastic flow. The hardening internal variables evolve with deviatoric and volumetric plastic strains. $\rho_{s,t}$ and $\xi_{s,t}$ are constitutive model parameters controlling the rate of hardening and softening. The material parameters listed in Table 1 and 2 were calibrated against a combination of literature data and element tests on Saint Nicholas at Wade (SNW) chalk (Riccio et al., 2023). Refer to Previtali et al, (2023) for further details.

Table 2. Constitutive model parameters for chalk.

Parameter	Value	Parameter	Value
$\boldsymbol{e_0}$ [−]	0.83	p_{s_0} $[kPa]$	3000
$\boldsymbol{\rho'}$ $[\boldsymbol{Mgm^{-3}}]$	1.4	p_{t_0} $[kPa]$	200
$\boldsymbol{\nu}$ [−]	0.12	E $[GPa]$	1
$\boldsymbol{\rho_s}$ [−]	19	ρ_t [−]	15
$\boldsymbol{\xi_s}$ [−]	0.5	ξ_t [−]	0.5
$\boldsymbol{M_f}$ [−]	1.0	M_g [−]	1.2

3 MODEL PILE SIMULATIONS

Figure 1 shows the numerical model reproducing the experimental set up for the model pile installation tests in SNW chalk by Alvarez-Borges et al. (2018). In the experiment a tubular pile with external diameter of 8 mm and wall thickness of 1 mm was jacked to a depth of 2 cm in a cylinder of diameter 100 mm and length of 120 mm. The axisymmetric simplification of the geometry along with some geometrical quantities are represented in Figure 1. The figure also shows the DEM and GPFEM numerical model initial conditions.

Axisymmetric conditions for DEM models are extremely challenging due to the particles on the symmetry axis and therefore a 3D model is used. The rock domain is generated using the periodic cell replication method PCRM (Ciantia et al., 2018) . It consists of a combination of different techniques aimed at speeding up large DEM models generation. To reduce the computational burden, the PSD of destructured chalk was upscaled by a factor of 2.1 near the pile (<0.6D) increasing to a factor of 4.8 at 2.5D. Considering that the damage model is framed to be scale independent the scaling used does not affect the calibrated parameters (Zheng et al. 2023). The maximum and minimum particle size was 0.18 mm and 0.066 mm, respectively, with a d50 of 0.116 mm. To limit scale effects on potential plugging behavior (Cerfontaine et al., 2023), this scaling value was chosen to provide a sufficient number of particles in contact with the pile whilst keeping the computational burden manageable. Pile wall thickness (t_w) to d50 ratio is 4.0.

To mitigate computational load and prevent boundary effects, the edges of the DEM domain are coupled with a Finite Difference Model (FDM). Additional details on DEM-FDM model coupling are available in Zheng et al. (2023). Given the significant stiffness contrast between the pile and the rock, the pile representation is simplified by using a rigid, non-deformable wall and the installation force is obtained as the sum of the vertical contact forces.

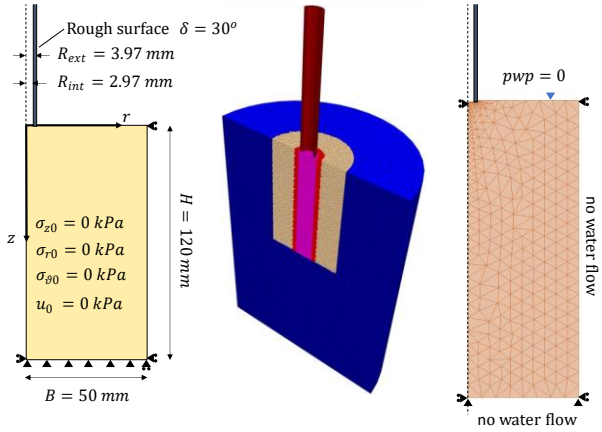

Figure 1. (left) Model pile tests experimental setup by Alvarez-Borges et al. (2018) along with geometrical quantities and snapshots of the discrete (middle) and continuum (right) numerical model initial states.

The GPFEM model generation is much simpler as initial conditions can be directly assigned as for classic FE models. Moreover, axisymmetric conditions are easily modelled with continuum methods and are hence here used. Although the experiments were performed pushing the pile slow enough to attain drained conditions, the simulations were carried out using a coupled hydro-mechanically formulation. As with the DEM model, the pile is simplified as a perfectly rigid wall and the installation force is measured as the sum of the contact forces. Boundary conditions are represented in Figure 1.

4 RESULTS AND DISCUSSION

Figure 2a compares the experimental results against the load displacement curve predicted by the two numerical models. The general trend is very similar although the GPFEM simulation seems to underpredict the penetration force. There are several reasons for such discrepancy. These include for example, the constitutive model softening parameters or the approximation of the flat tip with a curved geometry to avoid the sharp corners. Figure 2b shows contours of the radial stresses close to the pile tip. Whilst the continuum and discrete model results appear very similar a more quantitative comparison would be required for a proper comparison.

5 CONCLUSIONS

Two different numerical approaches, namely the DEM and GPFEM have been used to simulate open- ended pile installation in a soft chalk. Both procedures were able to overcome the difficulties associated with large displacements, large strains as well as geometrical, material and contact nonlinearities. The good agreement between the two methods and the experimental data indicates that both approaches are adequate for the investigation of open-ended pile installation in chalk.

Initial design and testing of a new site investigation tool for the direct determination of *p-y* soil reaction curves: ROBOCONE

Conception initiale et expérimentation d'un nouveau dispositif d'investigation de site pour la détermination directe des courbes de réaction du sol *p-y*: ROBOCONE

ABSTRACT: This paper presents the initial design, specification, testing and calibration of a new site investigation tool aiming to provide direct characterisation of the '*p-y*' soil reaction curves. This tool, developed within the ROBOCONE project consists of a dedicated '*p-y*' module to be attached behind the cone of a conventional CPT. The proposed module is capable of horizontal translation with respect to the CPT rod, imposing kinematic conditions different from those of the conventional pressuremeter and dilatometer, and fully resembling those of a miniature laterally loaded pile. Beyond the main design features and performance specification of this innovative module, this paper presents some initial preliminary tests to investigate the capability and output of the device in addition to its sensor calibration. Initial testing has been performed in a miniature calibration chamber. It is shown that the module can be used to apply both monotonic and complex displacement-loading histories, while obtaining the expected shape of soil reaction. The potential for implementation in 'whole-life' geotechnical design approaches will be discussed, however development of the theoretical framework for the full interpretation of the module results is outside the scope of this paper.

RÉSUMÉ: Cet article présente la conception initiale, les spécifications, les essais et l'étalonnage d'un nouvel outil d'investigation de site visant à fournir une caractérisation directe des courbes de réaction du sol "*p-y*". Cet outil, développé dans le cadre du projet ROBOCONE, consiste en un module "*p-y*" destiné à être installé derrière le cône d'un CPT conventionnel. Le système proposé est capable de subir un mouvement latéral par rapport à la tige du CPT, imposant des conditions cinématiques différentes de celles du pressiomètre et du dilatomètre conventionnels, et ressemblant totalement à celles d'un pieu miniature soumis à une charge latérale. Au-delà des principales caractéristiques de conception et des spécifications de performance de ce dispositif innovant, cet article présentera les premiers essais visant à étudier la capacité et le rendement de l'appareil, ainsi que l'étalonnage de ses capteurs. Les premiers essais ont été réalisés dans une chambre d'étalonnage miniature. Il sera démontré que le module peut être utilisé pour appliquer des séquences de force-déplacement monotones et complexes, tout en obtenant la réaction attendue du sol. Le potentiel de mise en œuvre dans les approches de conception géotechnique "tout au long de la vie" sera discuté, mais le développement du cadre théorique pour l'interprétation complète des résultats du module n'entre pas dans le cadre de cet article.

Keywords: ROBOCONE; site; investigation; tool; offshore.

1 ROBOCONE: CONTEXT AND OPPORTUNITY

To meet future net zero carbon emission targets by 2050, global installed offshore wind capacity must be increased by a factor of ~5 over the next 25 years (GWEC, 2023). This acceleration of offshore wind deployment requires a compression of typical project timelines (HMG, 2022). A key stage which could be streamlined is the typically lengthy and expensive site investigation where soil samples are obtained and returned to shore for determination of geotechnical

parameters via laboratory testing. An alternative approach could utilise specifically designed in-situ soil testing procedures to generate these parameters earlier in the project cycle, speeding up the design process.

Recent developments in both robotic and sensing technologies offer techniques that could improve the speed, and also the quality of the site investigation stage supporting advanced 'whole-life' design of ocean structures over a complete strain range (Gourvenec, 2020; Mayne, 2001; White, 2022).

The ROBOCONE project presented in this paper introduces an innovative new device with the capability of smart in-situ soil testing, aiming to improve the efficiency and quality of offshore geotechnical design and other applications.

2 THE ROBOCONE PROJECT

2.1 Overview

The ROBOCONE research project is a collaboration between the University of Bristol, University of Southampton and Trinity College Dublin. The aim of the ROBOCONE project is to develop an intelligent robotic tool which upon insertion within the ground, can mimic the loading histories experienced by soil elements around geotechnical infrastructure. The device is designed to fit behind a standard 15cm^2 cone penetrometer, consisting of three modules, each capable of smart and controlled probing of the soil in three different active sensing directions (vertical, horizontal and torsional) demonstrated in Figure 1 (Creasey et al, 2023). The device aims to infer soil mechanical characteristics over an entire strain range relevant to design through the application of whole life stress paths, an example of which is also shown in Figure 1. The current focus of the project has been to develop the *p-y* module, capable of horizontal translation described in the next section.

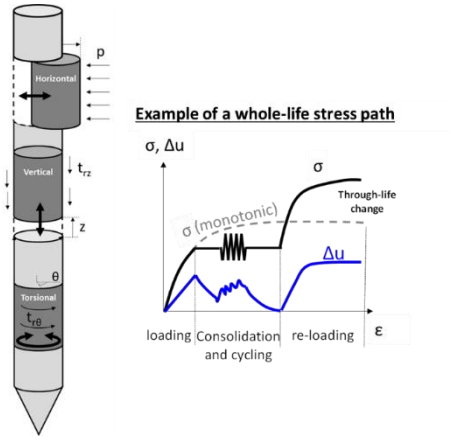

Figure 1. The ROBOCONE device and an example of a whole-life stress path that can be applied to the soil.

2.2 The *p-y* module

The ROBOCONE *p-y* module, is a cylindrical section of cone with the ability to translate horizontally within soil as highlighted by Figure 2a. The module translation aims to mimic the force and displacement history imposed by a laterally loaded pile element, so that the in-situ measured response can be scaled for pile design or used to determine soil constitutive parameters. An initial concept design for an aluminium prototype of the *p-y* module has been built at the University of Bristol (Figure 2b) with design specifications shown in Table 1. The device is capable of horizontal translation through an internal straight-line mechanism that converts vertical to horizontal linear motion driven via a motorised lead screw actuator fitted within the shaft above the module.

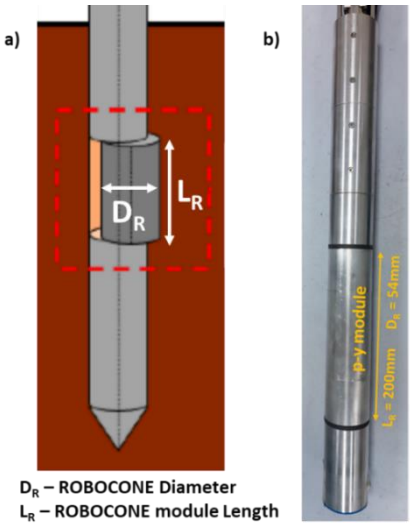

Figure 2. The ROBOCONE p-y module: (a) schematic; (b) initial aluminium prototype.

Table 1. Initial ROBOCONE p-y module specification.

Module diameter	54 mm
Module height	200 mm
Horizontal displacement range	0-13 mm
Displacement resolution	< 0.1 μm
Force capacity	~ 5-6 kN

The module is designed to fit within an enlarged section of cone with diameter 54 mm compared to the standard 44 mm cone penetrometer, enabling the housing of components of the internal mechanism, miniature sensors and cables. This enlarged section, occasionally included on a standard cone penetrometer acts as a friction reducer during soil penetration, easing resistance on the remaining cone length to be pushed to greater depths.

3 INITIAL *P-Y* MODULE TESTING

3.1 Bench verification and testing

Prior to testing the *p-y* module within soil, correct functioning of the device has been checked to ensure accuracy and reliability of both force and displacement measurements.

Measuring the total force acting on the module face as it displaces has been a challenge during the device development. All points of contact between the internal mechanism used to push the module must be connected to the shell via a load cell, so that all the load required to displace the module is measured. Figure 3 shows the method used to check the load cell configuration within the device. A central portion of the *p-y* module is placed in a loading frame and displaced up and down against an external load cell. The force measured by the external cell is then compared to the combined force measured by two internal load cells connecting the two points of contact between the internal mechanism and the outer shell. Comparison between external and internal load shows very good accuracy during both loading and unloading stages (Figure 4), a feature which was repeatable and not present in early design attempts due to the development of friction and unforeseen parallel contact points within the system, shown by the grey lines in Figure 4.

Due to space limitations only the vertical displacement imposed by the electrical motor could be measured through an LVDT placed inside the ROBOCONE. Therefore, a calibration process has been carried out to convert the vertical displacement of inner mechanism to the horizontal module translation, leading to a repeatable conversion factor of 2.52 as shown in Figure 5.

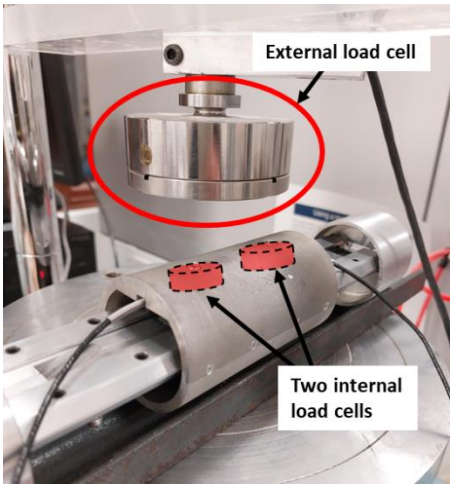

Figure 3. Test configuration for load cell investigation within the ROBCONE p-y module.

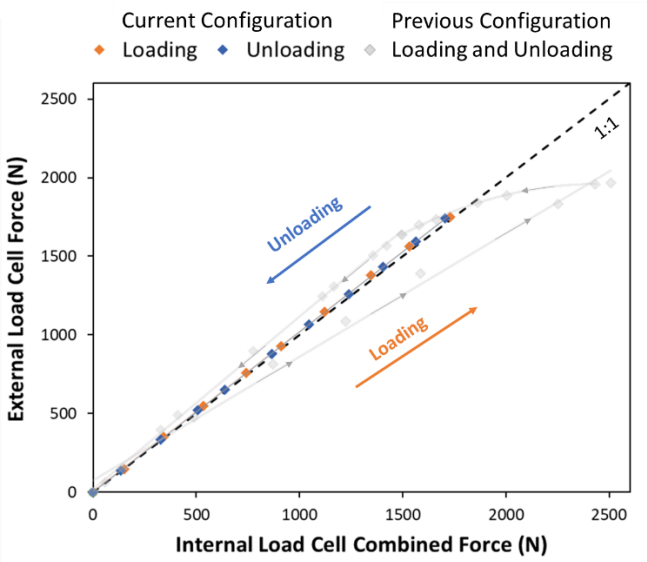

Figure 4. Comparison of external and internal load cell measurements.

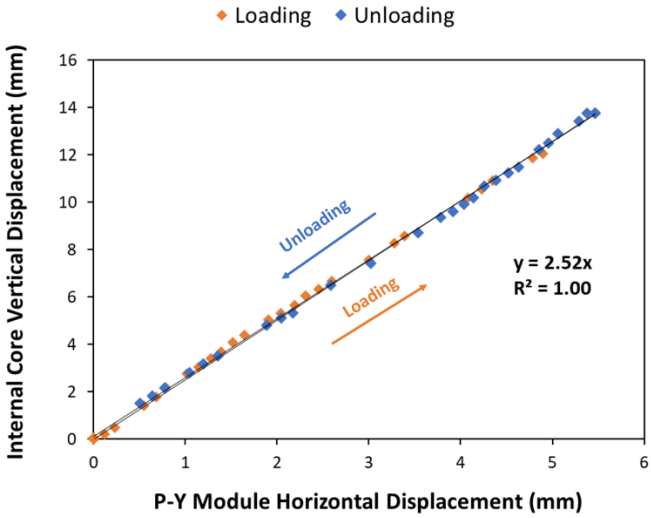

Figure 5. Comparison of vertical core displacement and horizontal p-y module displacement.

3.2 Calibration chamber testing

To investigate the capability and output of the ROBOCONE *p-y* module, initial small-scale tests have been conducted within a calibration chamber (Figure 6).

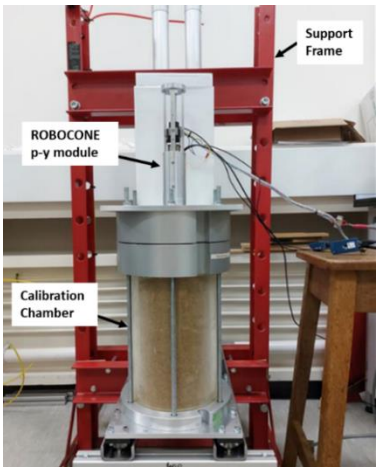

Figure 6. Initial small-scale testing of p-y module within a calibration chamber.

Within the chamber, the *p-y* module was displaced in dry Redhill sand (D_{50} = 0.17mm) with different vertical stresses applied. Varying load and unload loops were trialled and measurements of lateral force on the module face and lateral displacement were recorded. A typical force-displacement curve obtained is shown in Figure 7, where the module was displaced with two unload-reload loops during loading. The data shows load-displacement trends as expected and demonstrates the system capability to apply complex load histories.

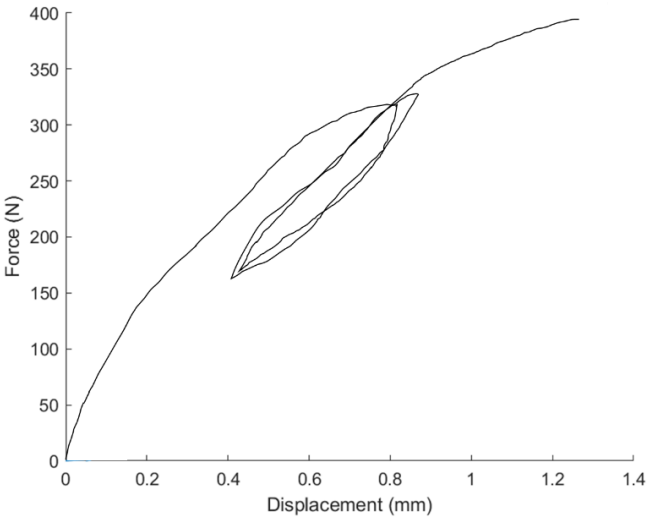

Figure 7. A typical force-displacement curve obtained within Redhill sand.

During testing, an assessment of the device's mechanical operation showed that the internal mechanism successfully transferred force to displace the module within sands and the sealing effectively prevented ingress of small dry sand particles.

4 CONCLUSIONS

Within the context of offshore wind design, the opportunity for an intelligent robotic site investigation tool has been highlighted. The initial design and specification of a horizontal (*p-y*) modular section of ROBOCONE has been presented, alongside preliminary bench verification and chamber tests in sand that validate its ability to impose complex stress paths and obtain force-displacement curves. It is essential that these tests are carried forward using a fully developed device with a larger range of soil types to obtain 'whole-life' soil reaction curves, supporting the advanced design of complex infrastructure.

ABSTRACT: The proposed note presents the results of an experimental activity aiming at studying the hydraulic and mechanical behaviour of a Finnish sensitive soil treated by fly ash and lime. A laboratory testing program was carried out both on treated and untreated soil; soil-binders samples were prepared by wet mixing of the components and by Standard Proctor compaction. Hydraulic conductivity tests were carried out in flexible wall permeameters; the compressibility was studied by incremental load oedometric tests. The results have shown a general increase of the hydraulic conductivity and a significant reduction in compressibility after binders addition; the extent of modification of soil properties was observed to depend upon the compaction water content of the soil. The soil treatment is generally economically convenient if compared to disposal in waste landfills, which would represent the only alternative for the soil type of concern. In addition, if a by-product such as fly-ash is able to act as effective binder in the mixture, this surely constitutes a promising perspective in terms of sustainability in the field of earthen structures.

RÉSUMÉ: La note proposée présente les résultats d'une activité expérimentale visant à étudier le comportement hydraulique et mécanique d'un sol finlandais sensible traité aux cendres volantes et à la chaux. Un programme d'essais en laboratoire a été réalisé sur du sol traité et non traité. Les échantillons de sol modifié aux liants ont été préparés par mélange humide des composants et compactage Standard Proctor. Les tests de conductivité hydraulique ont été réalisés avec des perméamètres à parois flexibles; la compressibilité a été étudiée par des essais oedométriques à charges incrémentales. Les résultats ont montré une augmentation générale de la conductivité hydraulique et une réduction significative de la compressibilité après l'ajout de liants; les degré de modification des propriétés du sol a été différent en fonction de la teneur initiale en eau du sol. Généralement, le traitement du sol est économiquement avantageux par rapport à la mise en décharge, qui représenterait la seule solution alternative pour le type de sol concerné. De plus, si un sous-produit tel que la cendre volante est capable d'agir comme liant efficace dans le mélange, cela constitue sûrement une perspective prometteuse en termes de soutenabilité dans le domaine des constructions en terre.

Keywords: Soil reuse; sensitive soils; stabilization.

1 INTRODUCTION

Fostered by the objectives of the recent European Green Deal, global societies share the target of implementing reuse practices and search for innovative technical solutions to reduce overall waste generation thus limiting landfilling and carbon emissions. Environmental geotechnics, in particular the field of ground improvement techniques, can surely contribute to reach these goals allowing for the reuse of treated excavated soils in earthen structures.

Several studies (e.g. Blengini et al., 2010) indicate that the re-use of excavated soils and rocks saves up to 14 kg CO_2 per ton and 250 MJ/ton of non-renewable energy as transport, landfilling and collection from quarries are reduced. Soil stabilization allows for the reuse of excavated soil by treating it with different additives. If the binder used in the mixture is a by-product from industrial processes, this will additionally contribute to the sustainability goal.

1.1 Soil stabilization by lime

Lime is nowadays commonly used as binder for clayey soil stabilization. In addition to the need of extracting limestone for lime production, the process itself causes the emission of 1006.5 kg CO_2/ton of lime (Zhang et al., 2019). On the other hand, its potentiality is well known and testing standards and construction procedures have been fully finalized (e.g., Di Sante et al., 2014; Beetham et al., 2014).

When treating a clayey soil with lime, cation exchange reaction firstly develops (and consequent aggregation of clayey particles) and then lime reacts with silica and alumina producing long-term pozzolanic products (reaction fostered by high pH environment).

The treatment improves the mechanical characteristics of a soil (increase in strength and reduction in compressibility), whereas, hydraulic conductivity usually increases taking into account the compaction water content effect (Bhattacharia et al, 2003; Bellezza et al.,2006; Di Sante et al., 2016).

1.2 By-products for soil stabilization

Developing a strategy to employ production scraps as binding agents for soil stabilization unquestionably constitutes a significant stride within the context of sustainable methodologies. By-products currently studied for soil stabilization include rice husk ash, mushroom waste, wet olive pomace, marble powder, ground granulated blast furnace slag or fly ash (Devi et al., 2020). The latter develops cementitious products if alkali activated with hydroxides acting as strong bases in the soil-binders-water system (Costa et al., 2023). The high alkaline environment fosters the dissolution of silicates and aluminates coming both from the ash and from the clay fraction of the soil, thus cementation reactions.

1.3 Soft sensitive soils

Soft sensitive clays can be found in the coastal areas of Scandinavia, as well as in some part of North America and Asia. The high compressibility, low undrained shear strength and high sensitivity shown by these soils make the geotechnical design often rather challenging. The degree of sensitivity is expressed by the ratio between the undrained shear strength of an undisturbed specimen and the strength of the same specimen at the same water content but in a remoulded condition (Torrance, 1974; Rosenqvuist, 1953; Bjerrum, 1954). The essential factors for development of high sensitivities can be divided into depositional and post-depositional factors (Torrance 1974). Of depositional factors most important is inter-particle flocculation, which is necessary to create open structure high water content sediments. Most of these clays are deposited in marine to brackish environment, where the ions in salty water reduce the repulsive forces between the soil particles allowing flocculation. In fresh water similar response may be due to sufficiently high concentrates of calcium. Out of post depositional factors the one having most impact is leaching. When the salinity decreases the open structure remains, but repulsive forces between the soil particles increase, reducing the liquid limit and remolded shear strength. Such high sensitivity clays with a remoulded shear strength below 0.5 kPa are often classified as quick clays.

Soft sensitive clay deposits are mainly located along the coastal regions of southern Finland. Inland, various local conditions manifest, such as the presence of intermediate soils like clayey silt or silt. While these soils might arise from similar geological processes, they exhibit distinct mechanical behaviors and mineral compositions.

In the present note, experimental results on soil-lime-fly ash mixtures are presented, focusing on hydraulic conductivity and compressibility. Results are discussed also in comparison with those of the untreated compacted soil. The present work is the result of an established research cooperation between Università Politecnica delle Marche, Ancona – Italy and Tampere University, Tampere – Finland.

2 MATERIALS AND TEST METHODS

2.1 Materials

The studied soil is a clayey silt of low plasticity, characterized by a medium-high sensitivity (Sensitivity index=31.4 - Rankka et al., 2004) taken from the Kouvola site in the southern part of Finland, 135 km east of Helsinki. It is worth highlighting that the remoulded strength of the soil is equal to5 kPa, higher than the usual values registered for sensitive clays (<1 kPa). Soil characteristics are summarized in Table 1.

Table 1. Soil properties(ICL=Initial Consumption of ime).

Property	Value	STANDARD
sand (%)	22	ASTM D422-63(07)
fine (%)	78	ASTM D422-63(07)
clay (<2μm,%)	24	ASTM D422-63(07)
Liquid Limit (%)	28	CEN ISO/TS17892-12
Plasticity Index (%)	16	ASTM D4318-05
ICL - %CaO	3	ASTM C977-00
CEC (meq/100g)	8.6	CUR n.33 EUBA2002
Specific surf. (m^2/g)	77	CUR n.33 EUBA2002

The X-Ray diffraction spectrum (Philips diffractometer, PW1730 X-ray generator, PW 1050/70 goniometer and CuK radiation) is displayed in Figure 1: the main mineralogical components include Quartz, Albite, Muscovite, Chlinochlore (chlorite group), Amphibole and Sanidine (potassium Feldspar).

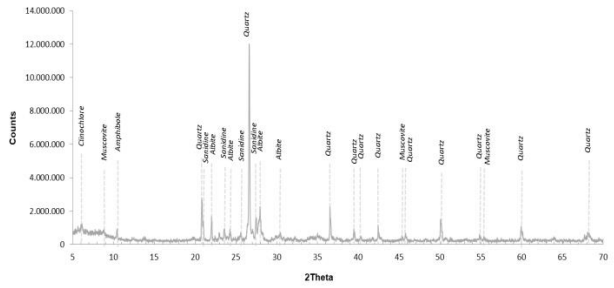

Figure 1. X-Ray diffraction spectrum of the soil.

The amounts of sulphate and organic matter are 0.01% and 1.31% by dry mass of soil, respectively. The studied soil fully matches the requirements for the suitability for lime treatment.

The lime used (QL) is a fine calcic quicklime, classified as CL80-Q dp (UNI EN 459-1).

The Fly Ash (FA) is a high pozzolanic fly ash (supplied by General Admixtures SpA). Its unit weight is 2200 kg/m^3. Microstructural and chemical investigation was performed on the FA by means of SEM observations and Energy Dispersive X-Ray Spectroscopy, EDS (FESEMSUPRA40–ZEISS), after air dewatering of samples and their gilding (by an Emitech K550 sputter coater). SEM image of spheroidal particles of the FA is displayed in Figure 2. EDS highlighted the presence of 45% Silicon, 23% Aluminum, 10% Iron, 10% Calcium, 4% Potassium and 7% other components (% by weight, excluding Oxygen).

The X-Ray diffraction spectrum highlights the presence of silicon dioxide (quartz), calcium oxide and mullite ($Al_{4.56}$ $Si_{1.44}$ $O_{9.72}$) as main components.

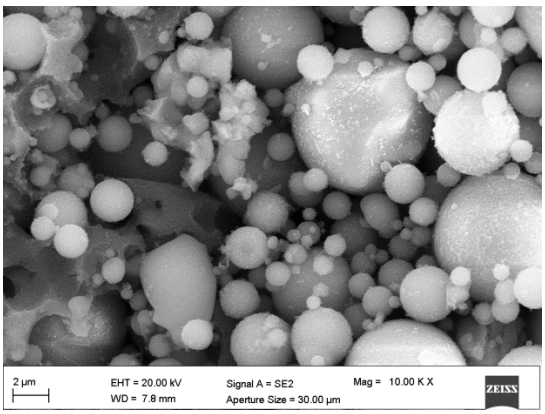

Figure 2. SEM images of the FA (Magnification:2000x).

2.2 Test methods

All the specimens for the laboratory geotechnical tests were prepared by crumbling the air dried soil (to 2 mm in size), adding the amount of water necessary to reach the desired moisture content, then mixing binders and soil at the wet state (as usually done in the field) until a uniform distribution was achieved. The only exception was done for the soil at w_{Nat}, for which lime was added "as is". The soil mixtures was then compacted according to the Standard Proctor procedure (ASTM D698-12) in one layer, obtaining samples of 101 mm in diameter and 40 mm in height. The samples were then cured in sealed plastic containers at a temperature of 20±1°C.

One-dimensional incremental load consolidation tests (ASTM D24345-11) were performed on specimens after 7 days of curing.

Permeability tests (ASTM D5084-10) were carried out in flexible walls permeameters at 35 kPa of effective confining stress with tap water as permeant. The tests on the treated specimens were carried out for 20 days of curing.

Also pH trend with time is monitored by daily measuring pH in the slurry of the mixture of concern (20g of dry soil+2%FA+2%QL+100ml of distilled water).

3 RESULTS AND DISCUSSION

In order to set the mix design for the experimental program, being the ICL value equal to 3% by dry weight of soil (Table 1) and given that ICL+1-2% is usually the promising value to be tested in lab phase of lime stabilization studies, a total amount of 4% of binders was fixed. Aim of the present research work is to test the efficacy of the use of by products as binders for soil stabilization. For this reason soil was treated with 2% of FA combined with 2% of QL. The latter has the double function of acting both as a stabilizer and as activator of the FA.

The first important experimental results is that the soil lost its sensitive behaviour once treated.

3.1 Compaction

Compaction curves of the untreated soil and of soil treated with binders are shown in Figure 3.

Binders addition slightly reduces the optimum water content from 20% to 19%. In Figure 3 it is possible to identify in 14-23% the range of water contents able to guarantee a sufficiently high dry unit weight (considered higher than 95% of the γ_{dmax}, as reported in most of technical specifications for construction works).

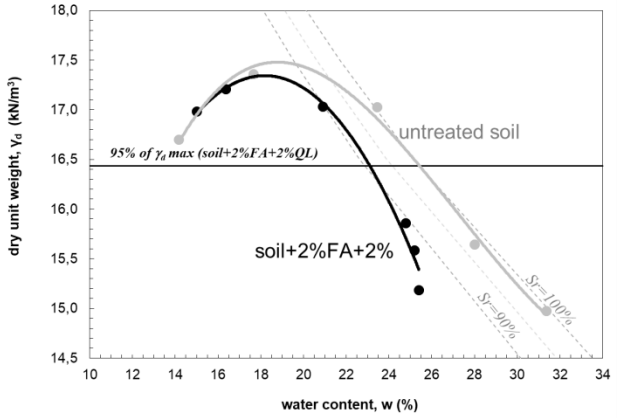

Figure 3. Proctor compaction curves of treated and untreated soil.

It is worth noticing that binder addition systematically reduces of 2-4 percent points the water content mainly due to CaO hydration process (oxide coming from both QL and FA).

3.2 Compressibility

Figure 4 shows the results of the one-dimensional compression tests performed starting from 7 days of curing on specimens of soil-FA-QL mixtures and of untreated soil, both compacted at w_{Nat}.

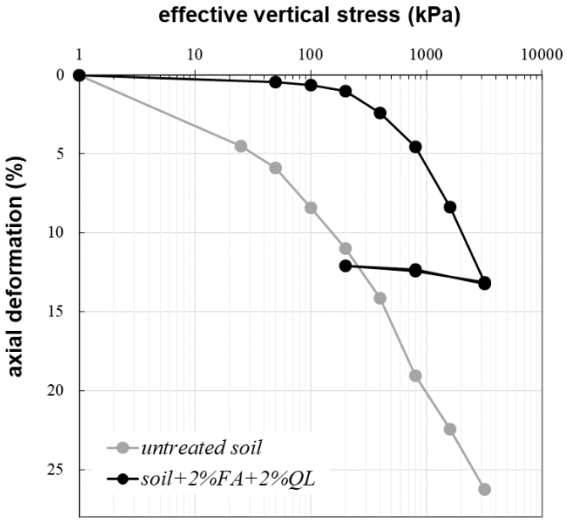

Figure 4. Compressibility curves of the untreated soil: and treated with 2%FA+2%QL (7days of curing).

The significant reduction in compressibility caused by binders addition is evident. In particular, at the range of 50-100 kPa of effective vertical stress (typical values for designing of earthworks, e.g. road embankments) axial deformation of the treated specimen is almost 10 times lower than that of the untreated compacted soil (8% deformation at 100kPa). When the vertical confining stress is increased, the untreated soil showed a maximum axial deformation of 26% that is reduced to 13% after FA+QL addition. The yield stress of the treated soil is 200 kPa while it is not possible to identify any yeld stress for the untreated compacted soil.

3.3 Hydraulic conductivity

Hydraulic conductivity values, k, are shown in Figure 5 as a function of the curing time. An increase in k values due to binders addition is evident when comparing data for treated and untreated soil compacted at w_{Nat} (grey and black circles in Figure 5). This increase is probably due to the aggregation of clay particles after cation exchange reaction. For the sample compacted at w=18% (w=15% after binder addition) k values (blak diamonds in Figure 5) are 2 order of magnitude higher than those of the treated sample compacted at w_{Nat}.

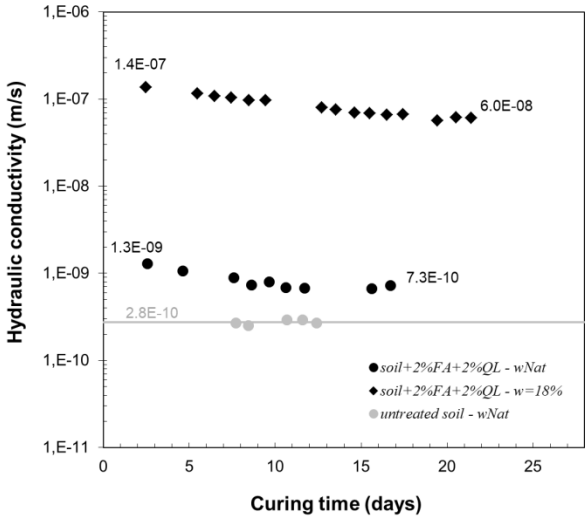

Figure 5. Hydraulic conductivity of treated and untreated compacted samples.

In addition, the treated samples show significant decreasing trend with curing (k values attained after 14 days of curing is half of the initial k). This trend is typically caused by gel form of pozzolanic products that partially fill the inter-aggregate porosity resulting from cation exchange (Beetham et al., 2014). Pozzolanic products are formed due to both hydration of fly ash and reaction of calcium ions supplied by lime and silicates and aluminates from clay fraction of the soil.

Measurements of pH of slurry of the mixture soil+2%FA+2%QL (Figure 6) corroborates this findings showing a continuously decreasing trend. In fact, in pozzolanic reactions, each calcium ion reacting with SiO_2 links 2 hydroxil ions thus causing the decrease in pH values.

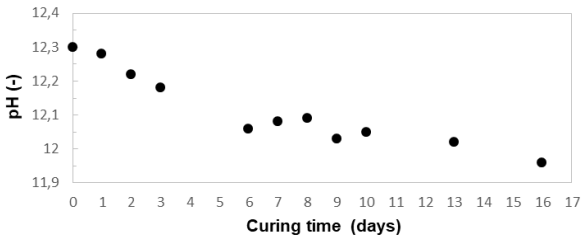

Figure 6. pH values - slurry of soil+2%FA+2%QL.

4 CONCLUSIONS

The combined use of fly ash and lime demonstrated to be a sustainable solution for the stabilization of the Finnish soil of concern. In particular, for the considered soil-fly ash-lime mixture, a general increase in hydraulic conductivity due to the addition of binders is observed. Permeability turns out to be very sensitive to a reduction in water content showing an increase of 2 orders of magnitude. Pozzolanic reaction development contributes to reduce the permeability in the long term (within 1 order of magnitude). Compressibility is significantly reduced 7 days after the treatment.

The soil treatment is generally economically convenient if compared to disposal in waste landfills, which would represent the only alternative for the soil type of concern. In addition, if a by-product such as fly-ash is able to act as effective binder in the mixture, this surely constitutes a promising perspective in terms of sustainability in the field of earthen structures.

The present work represent a preliminary feasibility study that should be completed with micro-structural investigation, strength tests and an in-situ test-pad.

ABSTRACT: Flood events caused by the collapse of water-retaining earthworks are recognized as one of the most impactful natural disasters, affecting both urban and rural environment, as well as society and economy. The understanding of the peculiarities of different failure mechanisms is crucial for explaining the causes of breaching and assessing the safety of both new and existing earth infrastructures, under different hydraulic loading scenarios. This paper investigates the potential instability of the landside slope induced by high uplift pressures beneath the toe of a river embankment. This complex failure mechanism is largely influenced by the stratigraphy of the foundation soil and it might occur when embankment is constructed on alluvial plains with silty or clayey blankets overlying sandy soil strata, which act as preferential flow channel between the water basin and the landside. Results of a numerical predictive study carried out with the finite element method (FEM) on an unsaturated river embankment model, characterized by this peculiar subsoil layout, are presented and discussed. The impact of different thickness of the fine-grained layer on the potential failure mechanism has been evaluated, showing that this mainly affects the onset time of failure and the hydrometric level associated with its triggering. The analyses here presented provided fundamental insights for the design of a physical model test in a centrifuge.

RÉSUMÉ: Les inondations provoquées par l'effondrement des ouvrages de retenue d'eau sont parmi les catastrophes naturelles les plus dévastatrices, affectant tant les milieux urbains que ruraux, ainsi que la société et l'économie. Comprendre les divers mécanismes de défaillance est crucial pour expliquer les ruptures et évaluer la sûreté des infrastructures existantes et nouvelles, en tenant compte des conditions hydrauliques changeantes. Cet article se penche sur l'instabilité potentielle des talus terrestres, déclenchée par des pressions de soulèvement sous le pied d'une digue fluviale. Ce mécanisme complexe est largement influencé par la stratigraphie du sol de fondation et survient souvent lorsque la digue est érigée sur des plaines alluviales, avec des couches limoneuses ou argileuses recouvrant des strates de sol sableux, servant de voies de circulation privilégiées entre le bassin hydrographique et le talus. Les résultats d'une étude numérique utilisant la méthode des éléments finis sur un modèle de digue non saturée sont présentés, fournissant des orientations essentielles pour la conception de tests en centrifugeuse. L'impact de différentes épaisseurs de la couche de grains fins sur le mécanisme de défaillance est évalué, démontrant que l'épaisseur influe principalement sur le moment et le niveau de déclenchement de la défaillance. Ces analyses sont cruciales pour la conception de tests en centrifugeuse afin d'étudier les phénomènes physiques à petite échelle.

Keywords: River embankments; FEM numerical modelling; uplift pressure.

1 INTRODUCTION

Due to its profound impacts on the population, communication infrastructures, and economic and productive fabric, hydrogeological instability associated with the collapse of water-retaining earth structures constitutes a relevant issue for European countries. Therefore, identifying the main factors that adversely affect river embankment stability and trigger failure conditions is of particular concern for researchers and geotechnical engineers and represents a fundamental step for the optimal design and assessment of this critical infrastructure.

River embankment failure, defined as the inability to prevent the inundation of the area surrounding a watercourse, may occur due to various hydraulic and structural causes, such as overtopping, seepage flow through the embankment body and foundation layers, internal and external erosion, macro-instabilities of the slopes, scour and liquefaction (Van et al., 2022). Among macro-instabilities, it is possible to distinguish two mechanisms induced by the development of uplift pressures underneath the toe of the embankment that might lead to collapse: *(i)* backward erosion piping, involving the erosion and transportation of sand particles from the aquifer underlying a water-retaining structure, driven by underseepage forces; *(ii)* instability of the external slope of the embankment, due to a localized reduction in soil shear strength within the foundation.

This paper focuses on the second mechanism, which might occur when the subsoil is characterized by a shallow soft fine-grained layer, overlying a highly permeable sandy one, directly connected with the river and acting as a preferential channel between the reservoir and landside. In particular, if the water level increases, high pore water pressures can build up at the interface between the fine-grained and sandy layers, exceeding the overburden stress of the blanket on the landside. This circumstance may result in localized toe uplift and, simultaneously, favour the progression of a slip surface in the embankment body, resulting in a potential collapse, as evidenced in ICOLD (2013).

Despite the increasing occurrences of river embankment failures, there is a shortage of well-documented case studies of embankment collapse triggered by pore pressure build-up at the toe, with the exception of notable investigations carried out on some specific events. These include the embankment failure at Dartfort Lock (UK) in 1953, attributed by Cooling and Marsland (1953) to fine fissuring, as consequence of the abnormally high tides, which caused the development of high pore-water pressure in the underlying permeable sandy gravel layer. In the same year, a flood embankment collapsed at Crayford Marshes, on the south side of the River Thames, due to excessive pressures beneath the stratum of peaty clay alluvium, leading to slope instability of the outward face. In the Netherlands, the collapses of Wolpherense and Streefkerk river embankments in 1981 and 1984, respectively, have been also attributed to uplift pressures (Van et al., 2005), as well as the instability of a segment of the Adige river embankment near to San Floriano (Italy) in 1981, as reported by Amabile et al. (2020). In 2013 an embankment failure near Breitenhagen (Germany), was triggered by a localized weakness of the soil and to unexpected high water pressures, due a connection between a pond on the riverside of the earth structure and the aquifer (Kool et al., 2021).

To shed light on this complex failure mechanism, fully coupled flow-deformation analyses have been carried out using the software PLAXIS 2D (2021), on a river embankment model, subjected to a simulated river stage increment. The earthwork is characterized by an unsaturated silty sand embankment, supported by a fine-grained foundation overlying a sandy aquifer. Parametric analyses have been conducted by varying the thickness of the clayey silt foundation layer to explore its influence on the onset time of failure and to predict the critical hydraulic head, able to trigger the embankment failure. The results of the simulations are presented and discussed hereafter.

These findings provided crucial insights for the design of a centrifuge model test, executed at the Istituto Sperimentale Modelli Geotecnici - ISMGEO (Bergamo, Italy). To this aim, numerical simulations have been performed by considering the reduced physical model dimensions, to replicate the stress states expected during all the stages of the experiment. Further seepage and stability analyses were carried out at the prototype scale using various software on the same river embankment model and the outcomes of these studies are detailed in Girardi et al. (2023).

2 NUMERICAL MODELLING

2.1 Geometry and materials

The geometry of the river embankment numerically analysed is shown in Figure 1, along with control points for displacements. It refers to a small-scale physical model. In centrifuge modelling the geometrical similitude (Garnier et al., 2007) is expressed by Eq. (1):

$$L_m/L_p = 1/N \quad (1)$$

where N is the scale factor for acceleration (i.e. $a_m=N\,a_p$), L_m and L_p are characteristic lengths of model and prototype, respectively. In the present case the model acceleration, a_m, has been assumed equal to 50 times the gravity. The embankment body is characterized by a height of 150 mm, a 60 mm wide crown and slopes inclination of 1H:1V and 1H:1.5V for the riverside and the landside, respectively (Figure 1). The model has been numerically discretized with 4864 fifteen-triangular elements, with an average element size of 0.01 m. The foundation consists of a clayey silt deposit underlying a sandy layer, which extends beyond the landside toe and is hydraulically connected to the water basin on the riverside.

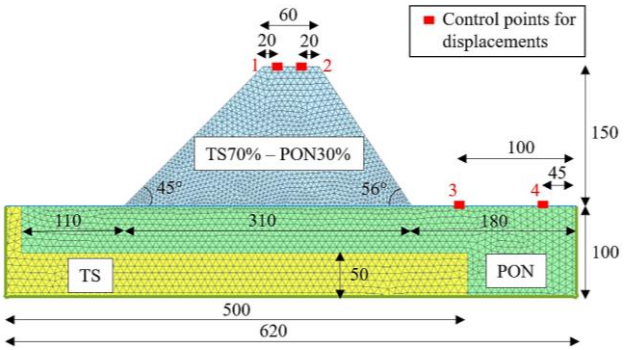

Figure 1. Geometry of the embankment section numerically analysed (in the case of 2.5 m-thick PON layer) in PLAXIS 2D - length unit at the model scale (in mm).

The filling material selected for the embankment body, typically constituted by a heterogeneous mix of sands and silts, is a compacted mixture of 70% by weight of Ticino Sand (TS, a uniform, coarse to medium, clean sand) and 30% of Pontida Clay (PON, a sandy clayey silt), while for the upper layer of the subsoil, which frequently consists of clayey and silty strata, deposited in a floodplain environment, a homogeneous consolidated layer of PON is considered. For the aquifer a compacted TS layer has been adopted. The main index and physical properties of the three materials can be found in Fioravante and Giretti (2016) and Ventini et al. (2021). The optimum moisture content (w = 8.8%) and dry density (γ_d = 20.60 kN/m^3), determined using the Standard Proctor compaction energy, are taken as reference for the initial state (at 1g, i.e. before centrifuge acceleration) of the TS70% - PON30% mixture, while a pre-overburden vertical effective stress of 800 kPa has been considered for the PON layer. A relative density equal to 80%, with a water content of 5%, has been assumed to define the initial conditions of the TS layer.

2.2 Mechanical and hydraulic soil properties

The mechanical behaviour of the materials is modelled with the hardening soil (HS) constitutive model, developed by Duncan and Chang (1970) under the framework of the plasticity theory. Soil strength and stiffness parameters, calibrated based on specific laboratory procedures - extensively discussed in Ventini et al. (2021) - and assumed as input in the finite element analyses, are listed in Table 1.

Table 1. Mechanical properties of the embankment and foundation units, according to HS constitutive models.

Soil		TS	TS70%-PON30%	PON
E	-	0.644	0.314	0.440
k_{sat}	m/s	$3.45\cdot10^{-5}$	$1.23\cdot10^{-7}$	$4.34\cdot10^{-9}$
γ_{dry}	kN/m^3	15.89	20.36	18.85
γ_{sat}	kN/m^3	20.00	22.30	21.09
N	-	0.256	0.233	0.200
c'	kPa	0.1	5.0	4.0
φ'	°	41	46	33
$E_{50,\,ref}$	kPa	19800	22000	6000
$E_{oed,\,ref}$	kPa	14143	15000	4500
$E_{ur\,ref}$	kPa	59400	60000	20000
m	-	0.5	0.5	1.0
$K_{0,NC}$	-	0.344	0.287	0.455
OCR	-	1.0	1.0	6.9
POP	kPa	0	0	800

Hydraulic and retention properties of the mixture and PON, accurately estimated from constant head permeability tests, evaporation tests and high-range psychrometric measurements (Dodaro, 2023) are listed in Table 2, together with the saturated hydraulic conductivity of TS. The non-hysteretic van Genuchten (1980) model was adopted for the fitting of the experimental data, through the parameters g_n, g_a, g_l. It is noted that the constitutive model adopted is able to take into account the influence of suction on soil shear strength, nevertheless, the dependence of compression index, C_c, on suction and the phenomena of wetting collapse, that distinguish the behaviour of unsaturated soils, are neglected.

Table 2. Hydraulic and retention parameters considered for the fully coupled flow-deformation analyses.

Unit	k_{sat} (m/s)	S_{res} (-)	S_{sat} (-)	g_n (-)	g_a (1/m)	g_l (-)
TS 70% - PON 30%	$1.23\cdot10^{-7}$	0.057	1.000	1.240	0.821	-3.350
PON	$4.34\cdot10^{-9}$	0.000	1.000	1.455	0.070	-0.584
TS	$3{,}45\cdot10^{-5}$	-	-	-	-	-

2.3 Initial, boundary conditions and calculation stages

Imposing realistic initial conditions in terms of pore water pressure distributions is a crucial aspect when conducting transient seepage analyses of water-retaining earth structures. In the present numerical

study, a uniform value of matric suction of about 5 kPa has been initially assigned to the embankment, to reproduce the physical model preparation state. In addition, an initial water head of 0.03 m (1.5 m at the prototype scale) has been applied for the time required to attain the equilibrium of pore water pressures in the whole model and to lead the aquifer to a saturated state (Figure 4a). Regarding boundary conditions, since the model is expected to be contained in a rigid steel box, in the FE analysis, the bottom horizontal, right, and left vertical sides of the subsoil are assumed to be impermeable, with fully and horizontally fixed constraints, respectively. A zero head hydraulic condition has been assigned to the top surface of the foundation on the landside, to simulate a water outlet zone. Furthermore, to model the interaction between the foundation soil and the container walls and to account for potential flow channels, three interface elements have been included. These last are characterized by a stiffness equal to the Young modulus of the steel and a hydraulic conductivity of 10^{-5} m/s. The progressive drying of the model due to evapo-transpiration phenomena has been neglected.

To replicate the centrifuge test plot, the following five calculation stages were considered: *I*) generation of initial stresses; *II*) construction of embankment; *III*) acceleration to the target; *IV*) self-weight equilibrium; *V*) river level rise. Details concerning each phase are reported hereafter and a scheme is provided in Figure 2. Vertical and horizontal effective stress-fields have been initialized in *phase I* with the '*K0 procedure*' (PLAXIS 2D, 2021). To generate the preconsolidation stress state of the foundation strata at 1g, during the initial phase of the simulation, only the foundation layer has been activated and a pre-overburden pressure (POP) of 800 kPa has been imposed. During *phase II*, the 1g embankment construction has been simulated by means of an elastic-plastic deformation analysis ('*Plastic analysis' in* PLAXIS), in which the foundation is modelled as an undrained material, thus, excess pore water pressures have been calculated. The *'spin-up'* of the model, characterized by the gradual increase in the angular speed of centrifuge has been simulated through '*Consolidation analyses'*, by setting two different multiplier factors (*ΣM weight* equal to 24.3 and 50.6 g), uniformly applied on the whole numerical model, thus neglecting the distortion of the centrifugal field (*phase III*). Then, *'Fully coupled flow-deformation analyses'* have been carried out to simulate the dissipation of excess pore water pressure, resulting from the increase in the angular speed (*self-weight equilibrium stage, phase IV*) and to investigate the triggering of the failure mechanism caused by the rising of the water level (*flooding stage, phase V*) and the subsequent increase in the pore water pressure beneath the toe of the embankment. To identify the critical hydraulic head which would likely trigger a toe uplift mechanism, a time-dependent hydrometric condition, has been imposed on the riverside of the embankment (Figure 2). Each water level was incrementally reached at a rate of about 14 mm/min and maintained for a period of 30 minutes, corresponding to about 50 days at the prototype scale, according to centrifuge scaling laws (Garnier et al., 2007), to guarantee the establishment of a steady-state flow regime within the embankment body at each step (Figure 3). The parametric study has been conducted by varying the fine-grained layer thickness, among 0.04 m, 0.05 m, and 0.06 m, while maintaining a constant dimension for the foundation (0.1 m). Consequently, the thickness of the sandy layer was adjusted accordingly.

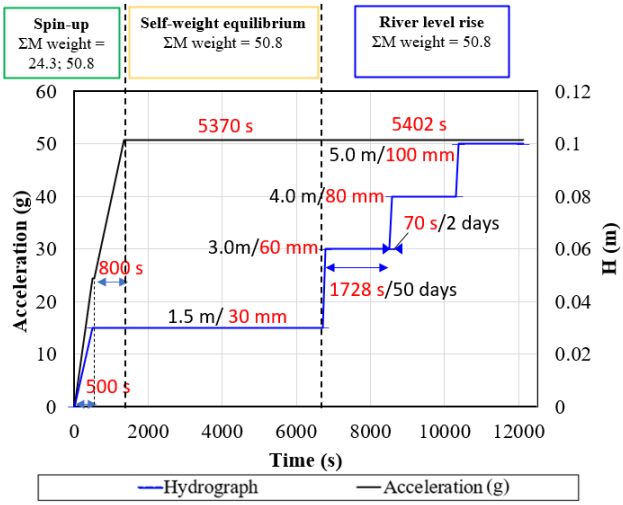

Figure 2. Time histories of the acceleration and water levels applied during the stages of the test (in red at the model scale and in black at the prototype scale) and calculation phases.

3 RESULTS AND DISCUSSION

Figure 3 shows FE numerical results, considering a 0.05 m-thick PON layer (2.5 m at the prototype scale) with reference to three significant time steps: a) at the beginning of the flooding stage (H = 0.03 m); b) at the end of the persistence of the first river stage; c) in correspondence of the triggering of the failure mechanism, occurred at H* = 0.073 m (3.65 m at the prototype scale). Following the first water level increment, a sudden increase of pore water pressures occurs in the aquifer. Then, the water level persistence leads to a progressive saturation of the lower part of the embankment body and, simultaneously, to a gradual rise in pore pressures, even in the fine-grained layer. The total deviatoric strains, initially extremely low and concentrated at the interface between PON

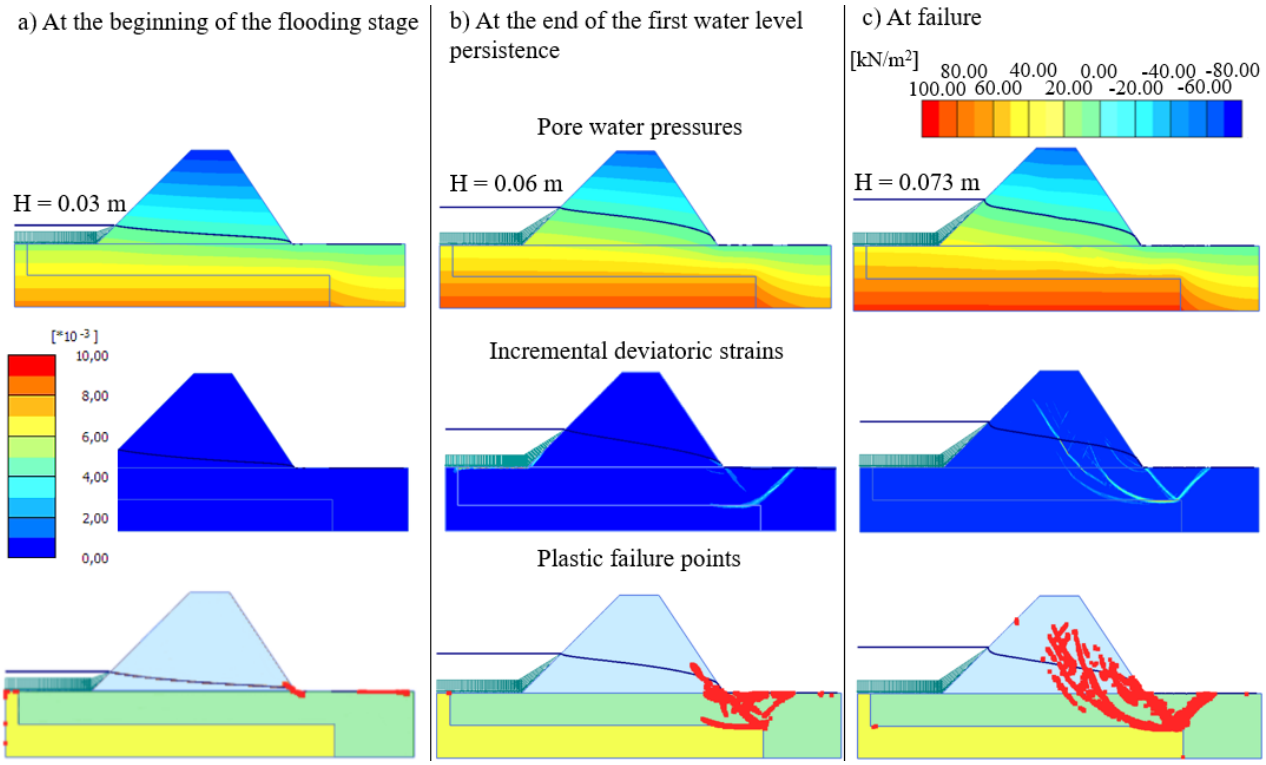

Figure 3. Pore pressures, total deviatoric strains and plastic failure points at different stages during FE analysis, considering a PON layer thickness of 0.05 m. Isoline increment = 10 kPa, phreatic surface in blue line.

and TS, gradually increase, as the phreatic surface advances within the earthfill. This progression is accompanied by a contextual decrease in vertical effective stresses in the PON layer, highlighting the shape of an instabile wedge and of potential slip surfaces within the embankment body, on the landside. Even the number of plastic failure points dramatically increase, as the hydrometric level rises to 0.073 m, suggesting a significant weakening of the embankment section, especially in correspondence of the landside toe, ultimately resulting in the collapse of the earth structure. Figure 4 reports the vertical displacement, u_y, calculated at the nodes highlighted in Figure 1, throughout all stages of the analysis conducted with the 0.05 m-thick PON layer. During the centrifuge spin-up and the self-weight equilibrium stage, a gradual ground settlement associated with the consolidation of the PON layer was observed at nodes 1 and 2, located on the crest of the embankment. The settlement tendency diminished during the persistance of the first river stage, while at the critical head H*, displacements approached a vertical asymptote, evidencing the collapse of the embankment. After an initial settlement, during the second increment in water level, the ground surface on the landside began to ascend, with node 3 experiencing a higher rate of rise than node 4, indicating the occurrence of an uplift phenomenon near the toe of the embankment.

The correlation between the thickness of the PON layer and the critical hydrometric level for the three stratigraphy investigated is notably apparent in Figure 5. In particular, the 0.04 m thick PON layer reaches a critical condition towards the end of the first water level persistence. Conversely, for thicknesses of 0.05 m and 0.06 m, the critical hydraulic heads, H*, are higher, i.e., 0.073 m (3.65 m at the prototype scale) and 0.08 m (4.0 m at the prototype scale), respectively. The foundation stratigraphy also influences the timing of failure onset. As the thickness of the PON layer increases, the time to reach conditions of potential instability also rises, as clearly highlighted by the trend depicted in red in Figure 5. Pore pressures changes and deformations detected in the FE analyses, suggest an appropriate layout for the monitoring sensors.

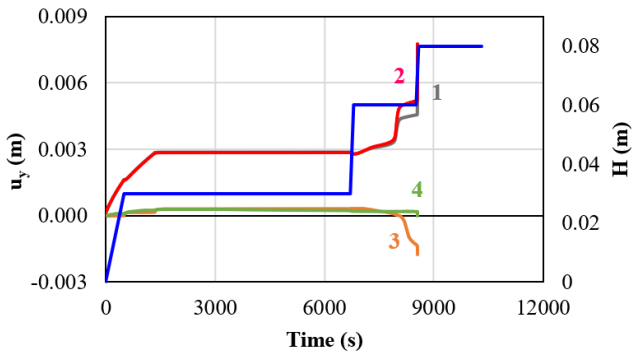

Figure 4. Vertical displacement calculated during the FE analysis on the crest of the embankment (1-2) and on the ground level on the landside (3-4). Settlements correspond to positive displacements.

This layout should include tensiometers within the embankment body; pore pressure transducers in the foundation soils, concentrated at the interface between the the fine-grained and sandy layer, and displacement sensors positioned on the crest, the outward face and near the toe of the embankment.

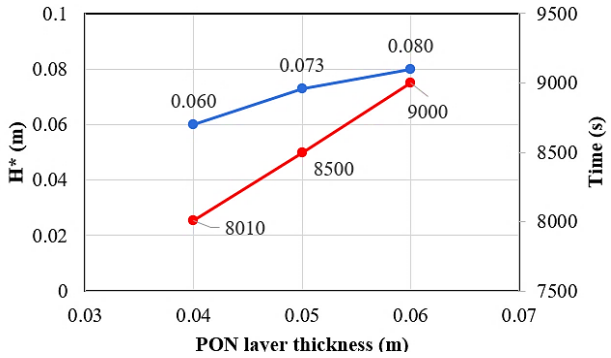

Figure 5. Effect of the PON thickness on the critical hydrometric level H (in blue) and on the time of failure onset (in red).*

4 CONCLUSIONS

This paper presents and discusses the results of a numerical study carried out to investigate a failure mechanism for river embankments caused by uplift pressures beneath the toe. The main aim was to support the design of a centrifuge test. The study examines the influence of different foundation stratigraphy on the timing of failure and the hydrometric level associated to the collapse of the earthwork. In particular, as the thickness of the PON layer increases, the critical water level rises, and collapse occurs after a longer persistence of the flood event. Additionally, recommendations regarding an appropriate instrumentation layout for the centrifuge test were provided based on the outcomes of Finite Element Method (FEM) analyses.

ACKNOWLEDGEMENTS

The Authors would like to acknowledge the financial support from MIUR (RedReef - PRIN 2017, Grant agreement 2017YPMBWJ). We would also like to thank Prof. Claudio Mancuso, our friend and colleague and tireless PI of this project, who recently passed away.

ABSTRACT: Tensar International Limited was subcontracted by Arcadis Setec COWI (ASC) DJV working for Eiffage Kier Ferrovial BAM (EKFB) JV delivering the design and construction of Britain's High Speed Rail Main Works Civils Contract C23, to carry out the design of the load bearing bridge abutments and wing walls that will support an overbridge over Network Rail tracks at Station Road. The original concept design comprised reinforced concrete (RC) bridge abutments and L-Shaped wing walls, all founded on piled foundations. The alternative design replaced the piled RC bridge abutments and wing walls with polymer geogrid reinforced soil bridge abutments and wing walls founded on shallow foundations. Coffey Geotechnics Ltd subsequently partnered with Tensar to undertake a comparative assessment of a reinforced soil wall system against the original piled RC retaining system. This paper presents the technical solution eventually adopted by EKFB and a comparison of the embodied carbon related to the two design options. The carbon emissions compared in this assessment includes the embodied carbon at the factory gate for the main materials and carbon emissions associated with transportation, on-site construction activities and waste disposal. The paper also presents cost savings from adopting the alternative retaining system both in design and construction.

RÉSUMÉ: Tensar International Limited a été sous-traité par Arcadis Setec COWI (ASC) DJV travaillant pour le groupement d'Eiffage Kier Ferrovial BAM (EKFB), pour la conception et la construction du contrat civil C23 des principaux travaux ferroviaires à grande vitesse britanniques, pour réaliser la conception des supports de charge. Les culées du pont et les murs en aile qui soutiendront un pont supérieur au-dessus des voies du Network Rail à Station Road. Le concept original comprenait des culées de pont en béton armé (BA) et des murs d'aile en forme de L fondés sur des fondations sur pieux. La conception alternative a remplacé les culées de pont sur pieux RC et les murs en aile par des culées de pont en sol renforcé de géogrille polymère et des murs en aile fondés sur des fondations peu profondes. Coffey Geotechnics Ltd s'est ensuite associée à Tensar pour entreprendre une évaluation comparative du système de murs en sol renforcé par rapport au système de soutènement RC sur pieux d'origine. Cet article présente la solution technique finalement adoptée par l'EKFB et une comparaison du carbone incorporé lié aux deux options de conception. Les émissions de carbone comparées dans cette évaluation incluent le carbone incorporé à la sortie de l'usine pour les principaux matériaux et les émissions de carbone associées au transport, aux activités de construction sur site et à l'élimination des déchets. Le document présente également les économies de coûts résultant de l'adoption du système de retenue alternatif, tant au niveau de la conception que de la construction.

Keywords: Reinforced soil; sustainability; carbon; bridge abutments; high speed rail.

1 INTRODUCTION AND BACKGROUND

The High Speed Two (HS2) project is a High-Speed Railway Line currently under construction in the UK. Phase 1 of HS2 runs between London and Birmingham across the English Midlands. This scope is part of the HS2 Main Works Civils Contract C23, awarded to Eiffage Keir Ferrovial Bam (EKFB) JV in partnership with the design JV of Arcadis Setec COWI (ASC).

Station Road, which joins the village of Quainton to the A41 in Buckinghamshire is to be realigned to the northwest of its current location. The bridge currently carrying Station Road (Quainton Road Overbridge, MCJ2/184A) over the Marylebone to Claydon Junction (MCJ) is to be replaced to provide access to the Buckinghamshire Railway Centre (BRC) and car park.

Two new overbridges, and associated earthworks, are required to cross over the HS2 supporting earthworks and the existing Aylesbury Link Railway (MCJ) which is being replaced as part of the HS2 works. As the route is used to transport locomotives to the BRC on low-loaders, all new structures must be designed to accommodate SV100 loading. Fiddlers Field Road and Quainton Road will also be realigned.

2 DESIGN PHILOSOPHY AND DEVELOPMENT

The original scheme design of the new Station Road National Rail Overbridge comprised prestressed concrete u-beam deck fully integral with reinforced concrete (RC) abutments and wingwalls, founded on RC piles, in keeping with HS2's design philosophy of minimising maintenance over the structure design life. In order to comply with the highway alignment requirements, the bridge was skewed at 36.8 degrees.

A value engineering exercise was carried out to reduce cost and programme and improve the sustainability performance of the structure. The piled RC abutments and wingwalls were replaced with polymer geogrid reinforced soil bridge abutments and wing walls parallel to the Network Rail track and supported on shallow foundations. The original RC load bearing bridge abutments replaced with bank seats sat on top of the reinforced earth retaining wall fill.

2.1 Reinforced concrete structure

A piled solution was proposed for the structure to manage the magniture of settlement expected due to the presence of a thick deposit of firm to very stiff clay of the Oxford Clay Formation.

Each abutment was founded on a group of 8no. 1050mm diameter RC piles of 23m length. The pile caps measured 14m in length by 7.2m in width and were 1.5m deep. The abutment walls measured 14m in length by 7.2m in height. The abutment wall thickness was 2.3m

Wingwalls either side of the bridge abutments were also proposed to be founded on two rows of 1050mm diameter piles measuring 20m in length, totalling 39 piles for both sides. The wingwalls varied from 12.8m to 17.7m.in length to suit the approach embankment earthworks, accounting for the skew of the structure. The wingwall pile caps measured 1.5m in depth in 5m in width. The wingwall stem was trapezoidal in shape, with a minimum width of 300mm at the top and a 7degree slope on the back of the wall. The width of the bottom of the stem varied along the length of the structure.

The total volume of concrete required to construct the abutments, wingwalls and piles was 1,885m^3.

2.2 Reinforced soil load bearing bridge abutments and wing walls

Tensar was appointed in April 2020 to carry out the detailed design of the reinforced soil structures proposed to support Station Road Network Rail Overbridge. Reinforced soil retaining walls with near vertical faces were chosen as the preferable to form the bridge abutments and adjoining wingwalls to minimise the bridge span.

The Tensar*tech*® TW3 geogrid reinforced soil retaining wall system was used to create the near vertical face (1° incline). The system comprises four major components, namely the concrete modular face block, the HDPE uniaxial geogrid, the polymeric mechanical block connector and high quality, granularreinforced fill material.

The facing units are produced in an automated factory process in the UK using a semi-dry concrete mix with a minimum crushing strength at 28 days of 40 MPa.

The uniaxially orientated high-density polyethylene (HDPE) geogrids are produced in the UK and are subjected to all internationally recognised standards such as ISO and ASTM. The geogrids carry the European CE registration and the independent HAPAS (ex-British Board of Agrément (BBA)) certification.

The mechanical polymeric connectors are also made of HDPE to provide a high level of load transfer at the grid-block connection whilst allowing the transfer of horizontal shear loads between adjacent blocks. The shape and feature of these connectors is designed specifically for the system, is durable in all conditions and provides high efficiency connection strength.

The shear strength properties for the various soil types used for design are as shown in the table 1 below.

Table 1. Design parameters for reinforced soil wall.

Soil Type	ϕ' (°)	c' (kPa)	γ' (kN/m^3)
Reinforced Fill type 6I*[1]	42	0	20
Retained fill 6N	38	0	20
Foundation Treatment Fill Class 1A	38	0	20

*[1] Series 600 of Highways Works Specification in the UK & Maximum particle size not more than 75 mm, Percentage by mass passing 63 micron sieve (0.075 mm) less than 15%, Uniformity Coefficient – higher than 10, pH value of reinforced fill between 4-12

An added advantage of the modular block retaining system was that the individual component parts of the system listed above could be easily transported to the site seperately. In addition, the individual components are all dry laid so no curing time or formwork is necessary, minising construction programme.

2.3 Design Method

Reinforced soil modular block walls have been constructed internationally for more than 35 years. In the UK, reinforced soil structures used in bridge applications are designed in accordance with BS8006-1:2010+A1:2016. Retaining wall structures designed in accordance with this standard, incorporating polymeric geogrids, are classified as 'extensible' reinforcement and utilize a tie-back wedge design method.

Internal stability comprises two fundamental checks: failure against rupture and failure against pull-out of geogrid or adherence check. Internal stability provides the geogrid strengths and spacing that are required for a stable design.

In accordance to BS8006, an additional internal stability check was also carried out to make sure that the geogrids will not strain more than 1% under the sustained working load that they will be subjected to over their 120 year design life.

2.4 External Stability & Shallow Foundation Design

Tensar, in collaboration with Geofem Limited, developed the foundational designs of the reinforced soil abutment and wing walls for Station Road National Rail Overbridge. A two-dimensional (2D) plane strain finite element analysis (FEA) was performed using Plaxis 2D Version 22, capitalizing on the uniform geometry of the abutment and wing walls. This approach facilitated the simultaneous evaluation of potential failure modes and prediction of foundation settlement.

The modelling work aligns with the protocols set out in published papers (Lees, 2016), ensuring the adopted methods adhere to recognised industry standards.

A division of the Oxford Clay at 74.7mAOD introduced varied strength and stiffness characteristics. Boundary constraints minimized boundary effects, and groundwater levels were set at the formation level. Initial findings pointed to potential sliding, bearing failures under undrained conditions, and bearing failures in drained conditions without ground modifications. For an optimal safety margin, we implemented the following measures:

- Foundation soil replacement with Class 1A $\varphi'=38°$ and $\gamma=20kN/m^3$ material, 3.7m in depth.
- Geogrid Reinforcement length of 10m and 7.8m for the abutment and wing walls, respectively.

Fill materials adhered to the standardised Linear Elastic Perfectly Plastic (Mohr-Coulomb) constitutive models. The FEA model integrated Geogrid specifications from Tensar, accounting for the material's long-term resilience. Load assessments incorporated the fill material's self-weight density and mechanical properties FEA modelling unfolded over several phases, each contemplating diverse loading and soil scenarios for a thorough evaluation. Adjustments in soil and fill strengths were predicated on foundation soil drainage conditions, with strategies ranging from stepwise reduction to equilibrium attainment without discernible failure routes. Drained ULS (with partial factors applied only on the loads in the drained case) assessments for both structures yielded a safety factor (via shear strength reduction) exceeding 1.25 (Figure 1). Figure 2 depicts the wing wall's slip surface. For undrained ULS, partial factors modified the soil parameters, with the model converging smoothly (safety factor > 1.0). Post-construction predictions include a wall displacement of approximately 12mm, a bankseat shift close to 13mm, horizontally, vertically of ~28mm shown in Figure 3, and a peak geogrid tensile axial force of around 20kN/m in any SLS analysis. Notably, an

average additional post-construction tensile strain of 0.12% is anticipated in the lowermost geogrid layer due to prolonged foundation consolidation, remaining within accepted boundaries.

3 CARBON CALCULATIONS

3.1 Background

The Climate Change Act 2008 committed the UK to an 80% reduction in carbon emissions by 2050, compared to 1990 levels and in 2019 this was updated to 100% reduction (Institute for Government, 2020). This made the UK the first major economy to set legally binding carbon budgets which require emissions, including those from transport, to be Net Zero by 2050. This commitment is supported by HS2's Environmental Sustainability Vision and Net Zero Carbon Plan and EKFB's target to reduce carbon emissions by 50%.

The call to measure and reduce carbon dioxide emissions comes from two directions: regulatory and commercial. Regulatory pressures arise from government drives to reduce greenhouse gas emissions in the UK and commercial pressures arise from increased client demand for information to demonstrate steps taken to limit carbon emissions.

Following the change in the design of Station Road Network Rail Overbridge, a comparison of the carbon emissions arising from the construction of RC bridge abutments and wing walls supported on piled foundations against polymer geogrid reinforced soil bridge abutments and wing walls founded on shallow foundations, was undertaken.

For the purpose of this paper, only the carbon emissions of the major elements of the wall construction have been considered, it does not take into account other things that may be included in a life cycle assessment such as storage, on site movements, removals and land use change.

3.2 System Boundaries

It is important when communicating carbon dioxide emissions that the boundaries of the calculation are known. Comparison of carbon dioxide emissions for different products can only be made if they are based within a similar set of boundaries.

This approach is in line with EKFB's Carbon Management Plan and based on PAS 2050:2011 (BSI, 2011) and BS EN 17472:2022 (BSI, 2022) and considers cradle to end of construction. The boundaries cover 'Product' module stages: 'Raw Material Supply' (A1); 'Transport'; (A2) and 'Manufacturing' (A3). It also considers 'Construction Process' module stages: 'Transport' (A4); and 'Construction Installation' (A5). The 'Use' and 'End of Life' module stages have not been considered in the calculations. Emissions have been calculated separately for the 'Product' stages (A1 to A3), 'Transport' stage (A4), and 'Construction Installation' stage (A5), and are then combined for assessment and comparison.

3.3 Process

Process maps were derived for each structural option detailing the requirements of each stage in the process. For the 'Product' modules this included manufacturing/production of the wall components including, geogrids, modular blocks and connectors, concrete, reinforcing steel and aggregate. The 'Construction Process' modules included transport of all the components (by a variety of vehicles either by train or road) and the construction elements included, but were not limited to, boring of piles, excavation of foundation, pouring of concrete for the piles, pile cap, walls, levelling pad and bankseat and placement and compaction of aggregate for the different fill types (i.e. Class 1A, 6I1 and 6N).

3.4 Collecting Data

A combination of primary and secondary data sources was used in the calculations, with primary data sources such as design drawings, details of specific transport vehicles and Environmental Product Declarations (EPDs) from manufacturers being the preferred option. Emission factors that convert activity data into carbon emissions were typically from secondary sources including the Inventory of Carbon and Energy database (Circular Ecology, 2019) and UK Government GHG Conversion Factors 2023.

3.5 Calculating the Emissions

Total CO_2 equivalent emissions to the end of construction were calculated for both bridge supports. The RC wall option was not considered at detailed design, therefore, assumptions have been made on the material quantities based on reasonable engineering judgement and typical construction practices. The concrete bankseat has been included in the Reinforced Soil wall calculations to ensure a comparable design up to the level of the bridge bearings. It is assumed that the deck construction and its ancillaries would be the same in both cases, therefore this has been omitted from the carbon emission calculation.

3.6 Results

The potential reductions in carbon dioxide equivalent emissions available by constructing a Reinforced Soil wall in comparison to a RC wall have been calculated and are shown in Figure 4.

The total calculated carbon emissions for the Reinforced Soil wall are 663 tCO2e of which 58% is in the 'Products', 35% in the 'Transport' and 7% in the 'Construction Installation'. For the RC wall there is 2,002 tCO2e of which 91% is the embodied carbon in the 'Products', 6% in the 'Transport' and 3% in the 'Construction Installation'.

The direct comparison between these two equivalent structures demonstrates that the Reinforced Soil design contributes a 66% carbon saving in comparison to the RC design.

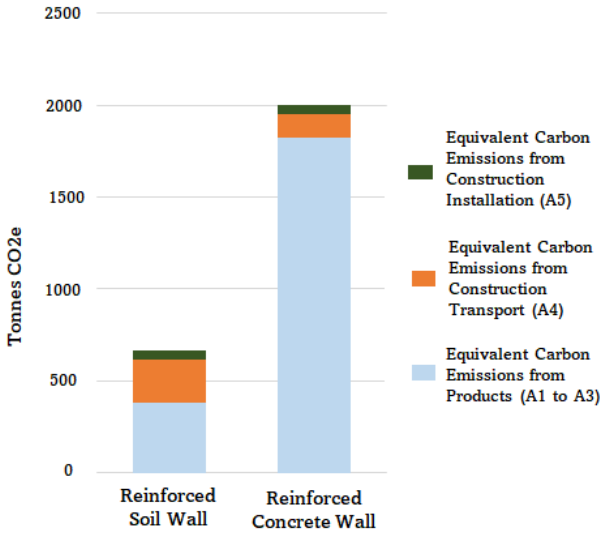

Figure 4. A comparison of the equivalent carbon emissions in both the Reinforced Soil Wall and Reinforced Concrete Wall.

3.7 Discussion

The majority of the embodied carbon in the RC wall comes from the concrete (842 tCO2e) and steel (898 tCO2e) making up 95% of the 'Product' emissions with only 5% coming from the structural fill element (85 tCO2e). Both concrete and steel production are very carbon-intensive with steel being the largest industrial source of CO_2 emissions in the UK (E&T, 2021) and cement being the largest single industrial emitter of CO_2 emissions globally (Ellis et al, 2019). These high value CO_2 emissions for concrete and steel also contribute to the Reinforced Soil wall results with the concrete reinforced bankseat comprising 36% of the embodied carbon within the 'Products' for a component which makes up only 2% of the overall volume. The remaining CO_2 emissions attributed to the embodied carbon in the 'Products' for the Reinforced Soil wall include 21% in the Reinforced Fill, 20% in the Class 1A foundation, 2% in the Class 6N behind the bankseat and 21% combined from the geogrid, modular blocks and connectors.

The CO_2 emissions calculated for 'Transport' were higher for the Reinforced Soil wall (230 tCO2e) due to the movement of a larger amount of aggregate required for the construction of the 3.7m deep foundation. Material is to be sourced from UK quarries up to 295km away from site.

The CO2 emissions for 'Construction Installation' were similar for both wall options with the Reinforced Soil wall being slightly higher at 49 tCO2e compared to 48 tCO2e for the RC wall. For the RC wall the majority of the emissions relating to construction came from the boring of 1,148 linear metres of 1050mm diameter piles. This equated to 95% of the carbon emissions in the 'Construction Installation'.

For the Reinforced Soil wall, the majority of the emissions relating to construction came from the disposal of the excavated soils for the foundation. This equated to 93% of the carbon emissions in the 'Construction Installation'. In both cases the carbon emissions generated by construction activities are small in comparison to the carbon in the 'Products' and 'Transport'.

4 COST COMPARISON

The direct comparison between the two equivalent structures demonstrates that the Reinforced Soil bridge abutment option resulted in savings of the order of 35% in comparison with the Reinforced Concrete bridge abutment supported on piled foundation.

5 CONCLUSIONS

Within the last 40+ years, polymeric geogrid reinforced structures have become established as reliable alternatives to conventional reinforced concrete structures and have been successfully used in high-risk applications like bridge abutments. This paper, through a direct comparison between two equivalent structures, has proven that a Reinforced Soil design contributes up to 66% savings in carbon in comparison with a Reinforced Concrete design, when assessing emissions from cradle to end of construction, and savings in cost of the order of 35%. Additionally, significant extra savings will be achieved in programme, personnel and plant movements.

In conclusion, in this project, by replacing the traditional RC bridge abutment construction solution with polymer geogrid-reinforced soil wall alternative, a robust, cost and carbon effective solution was provided, while championing HS2's legacy as one of the world's most sustainable high speed rail network.

A laboratory study of freeze-thaw effects on hydraulic conductivity of kaolin-sand mixtures

Une étude en laboratoire des effets du gel-dégel sur la conductivité hydraulique des mélanges kaolin-sable

ABSTRACT: Freeze-thaw effects on subgrade soils are of relevance to geotechnical and pavement engineering given the potential for increased road construction in colder regions due to climate change. The freezing and thawing cycles can result in changes to some soil parameters, therefore, for design processes, there is a need to characterize such progressive changes. This paper gives an overview of a laboratory experimental campaign on fine-grained soil and clay-sand mixture soil samples under multiple freezing and thawing cycles. The effects of freezing and thawing conditioning processes on the hydraulic and properties of tested soil samples were investigated. The experimental observations were used to develop transformation models for fine-grained soil and soil mixtures tested.

RÉSUMÉ: Les effets gel-dégel sur les sols de fondation sont importants pour l'ingénierie géotechniques et des chaussées, étant donné le potentiel d'augmentation du volume des routes dans les régions plus froides en raison du changement climatique. Les cycles de gel-dégel peuvent entraîner des modifications de certains paramètres du sol. Par conséquent, dans les processus de conception, il est nécessaire de caractériser ces changements progressifs. Cet article donne un aperçu d'une campagne expérimentale d'essais en laboratoire sur des échantillons de sol à grains fins et de mélanges argile-sable sous plusieurs cycles de gel et de dégel. Les effets d'application de ces cycles sur les propriétés de conductivité hydraulique des échantillons de sol testés ont été étudiés. Les observations expérimentales ont été utilisées pour développer des modèles de transformation pour les sols à grains fins et les mélanges de sols testés.

Keywords: Freeze-thaw effects; soil mixtures; hydraulic conductivity.

1 INTRODUCTION

Hydraulic conductivity (k) is used in many aspects of geotechnical engineering to understand the flow of fluids through soils and has been the subject of much geotechnical research (e.g. Chapuis, 2012). Freeze thaw effects have been reported in various studies showing some effect on intrinsic soil parameters (e.g. Benson and Othman, 1993; Othman and Benson, 1993; Feng et al. 2023).

For many geotechnical applications, including road construction, soils are found as a mixture comprising coarse and fine-grained materials and this can affect k values (e.g. Sivapullaiah et al. 2000). Various forms of empirical equations linking k to soil void ratio (e_s) (e.g. Nagaraj et al. 1993; Sivapullaiah et al. 2000; Vardanega et al. 2017; Feng and Vardanega, 2019) have been reported for fine-grained soils.

The important study of Sivapullaiah et al. (2000) compared k data for different percentages of Bentonite mixed with different sand and silt materials. Sivapullaiah et al. (2000) showed a log(k) versus e_s fitting for the datasets studied: in this paper this assumption will be tested for Kaolin-Leighton Buzzard Sand (K-LB) mixtures subjected to various numbers of freeze-thaw cycles (FTC). This paper will study the influence of FTC on the k function.

2 SAMPLE PREPARATION & TESTING

The kaolin sample preparation followed the procedure outlined in Feng (2022) and Feng et al. (2023). Reconstituted kaolin samples were prepared in a floating cylinder type consolidometer. The samples were then subjected to incrementally to the following vertical pressures, 30 kPa, 60 kPa, 120 kPa and 180 kPa. The first three pressures were continuously applied for 48 hours, and the final pressure for 120 hours. The samples were then allowed to swell for 48

hours after the consolidation phase. The extruded soil samples were sliced horizontally and then cut into oedometer samples of approximately 20mm in height and 75 mm in diameter. These samples had a pre-conditioned e_s of around 1.30. Further details on this testing are detailed in Feng (2022) and Feng et al. (2023).

In this paper, data from tests on Kaolin-sand mixtures are presented. The sand used in the mixtures was Leighton Buzzard Sand with: the sieve sizes through which ten percent (and fifty percent) of the material would pass are (D_{10}) of 1.28mm and (D_{50}) of 1.5mm respectively; coefficient of uniformity (C_U) of 1.26; coefficient of curvature (C_Z) of 0.97. The Kaolin-sand mixture samples were prepared using a moist tamping method to minimize the potential nonuniformity and inhomogeneity of the mixtures. The Kaolin was mixed with water, and then sand was added to form a mixture consisting of 50% kaolin and 50% sand (by mass) with an initial water content of 35%. The soil mixtures were then tamped in the oedometer cell to a pre-conditioned e_s of around 0.56.

The conditioning process was similar to the procedure described in the recent paper of Feng et al. (2023). In summary, samples were saturated with de-ionized water in the oedometer cell for 24 hours, then frozen at a temperature set at -20°C in a freezer. After 24 hours of freezing, the oedometer cells were then allowed to thaw with access to water in a bucket at room temperature (approximately 20°C) for 24 hours. After applying FTC, the specimens were placed in an oedometer cell and consolidated under vertical stresses of approximately 50 kPa, 110 kPa, 220 kPa, 440 kPa, and 110 kPa applied incrementally (following BSI 1990). The k values were found by the 'square root of time fitting method' (Taylor, 1948).

3 ANALYSIS RESULTS

3.1 Selection of empirical function

Figures 1 to 8 show the hydraulic conductivity (k) versus (e_s) data for both the pure kaolin data from Feng (2022) and Feng et al. (2023) and the new data for Kaolin-Leighton Buzzard (KL-B) sand mixtures fitted with various empirical functions. The statistical measures: number of data-points (n), coefficient of determination (R^2), standard error (SE) and p-value of the correlation (cf. Paradine and Rivett 1953) are also shown on the Figures 1 to 8.

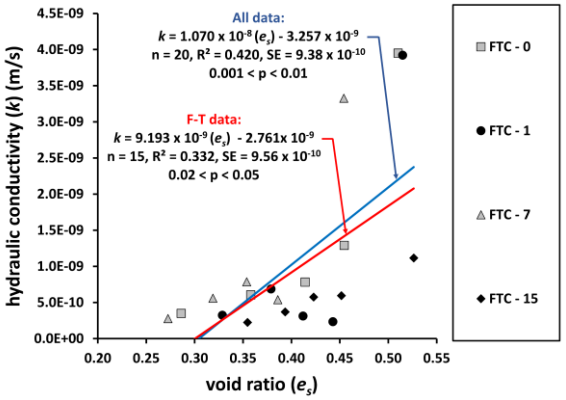

Figure 1. k versus e_s for the studied K-LB mixes.

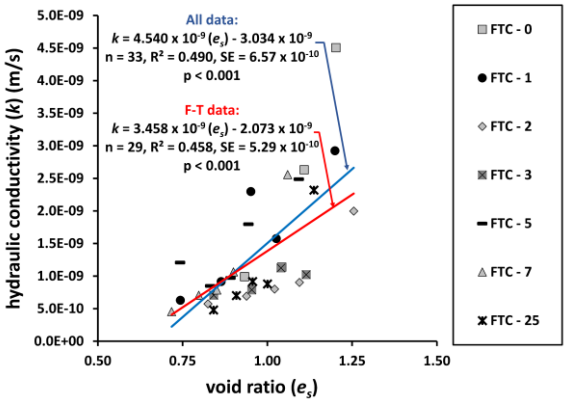

Figure 2. k versus e_s for the studied kaolin tests.

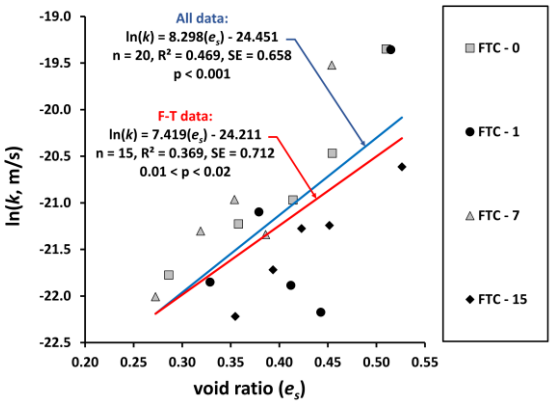

Figure 3. ln(k) versus e_s for the studied K-LB mixes.

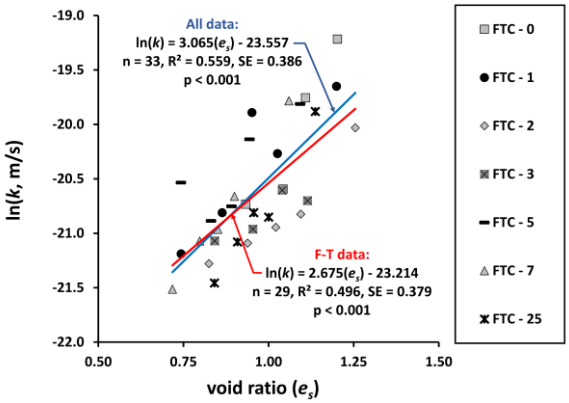

Figure 4. ln(k) versus e_s for the studied kaolin tests.

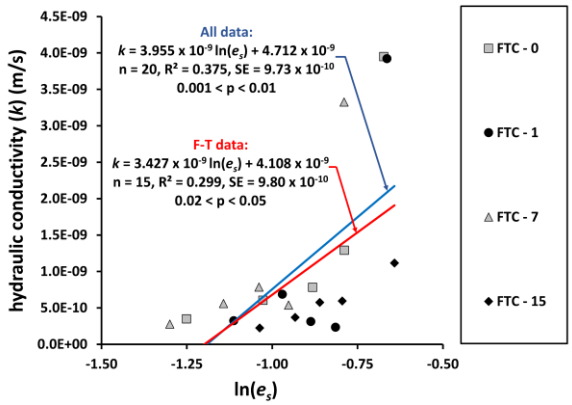

Figure 5. k versus ln(e_s) for the studied K-LB mixes.

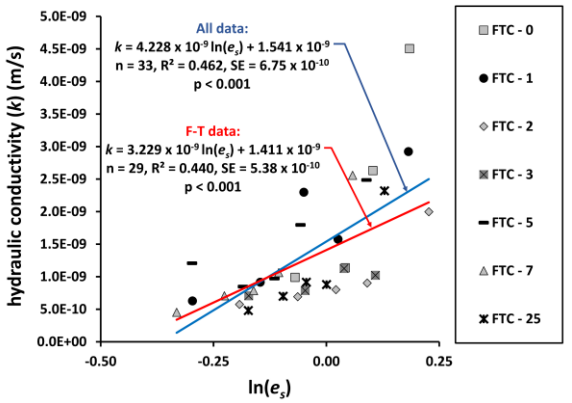

Figure 6. k versus ln(e_s) for the studied kaolin tests.

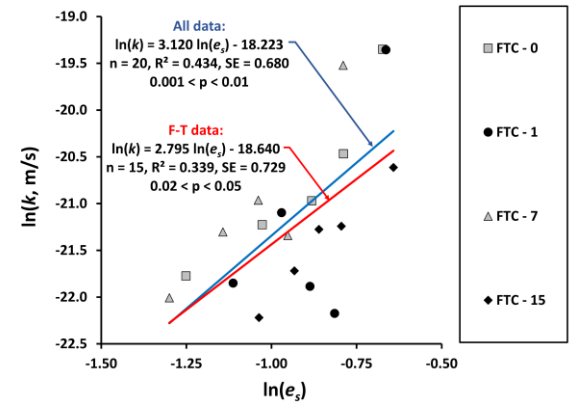

Figure 7. ln(k) versus ln(e_s) for the studied K-LB mixes.

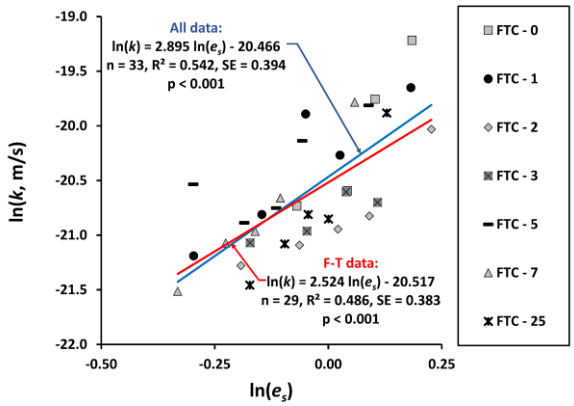

Figure 8. ln(k) versus ln(e_s) for the studied kaolin tests.

Figures 1 and 2 show a linear fitting to the K-LB mixtures and the pure kaolin tests series. The linear fittings considering only samples with FT conditioning give similar trends as the combined datasets albeit with consistently lower R^2 values. The correlations shown on Figures 1 and 2 have $R^2 = 0.420$ ($0.001 < p < 0.01$) (K-LB) and $R^2 = 0.490$ ($p < 0.001$) (Kaolin). Figures 3 and 4 show a semi-log fitting to the K-LB mixtures ($\ln(k)$ vs. e_s) and the pure kaolin tests series. The correlations shown on Figures 3 and 4 have $R^2 = 0.469$ ($p < 0.001$) (K-LB) and $R^2 = 0.559$ ($p < 0.001$) (Kaolin). Figures 5 and 6 also show a semi-log fitting to the K-LB mixtures (k vs. $\ln(e_s)$) and the pure kaolin tests series. The correlations shown on Figures 5 and 6 have $R^2 = 0.375$ ($0.001 < p < 0.01$) (K-LB) and $R^2 = 0.462$ ($p < 0.001$) (Kaolin). Figures 7 and 8 present a log-log fitting to the K-LB mixtures ($\ln(k)$ vs. $\ln(e_s)$) and the pure kaolin tests series. The correlations shown on Figures 7 and 8 have $R^2 = 0.434$ ($0.001 < p < 0.01$) (K-LB) and $R^2 = 0.542$ ($p < 0.001$) (Kaolin).

3.2 $\ln(k) - e_s$ equation

The best fitting was obtained for both kaolin and kaolin-sand data sets (see Figures 1 to 8) was the $\ln(k)$ versus (e_s) fitting of the form shown as Eq. (1) (see also Sivapullaiah et al. 2000) which can be rearranged to Eq. (2):

$$\ln(k) = \alpha(e_s) - \beta \quad (1)$$

$$k = e^{-\beta} e^{\alpha e_s} \quad (2)$$

where α and β are fitting parameters. For the K-LB data series (Figure 3):

$$\ln(k) = 8.298(e_s) - 24.451 \quad (3)$$
$$[n = 20, R^2 = 0.469, SE = 0.658, p < 0.001]$$

For Eq. 3 the R^2 value indicates that 46.9% of the variation in $\ln(k)$ can be explained by e_s (cf. Montgomery et al. 2004, p.273). Eq. 3 can further be rearranged to the following format:

$$k = 2.405 \times 10^{-11} e^{8.298 e_s} \quad (4)$$

For the kaolin data series (Figure 4):

$$\ln(k) = 3.065(e_s) - 23.557 \quad (5)$$
$$[n = 33, R^2 = 0.559, SE = 0.386, p < 0.001]$$

For Eq. 5 the R^2 value quoted means that 55.9% of the variation in $\ln(k)$ can be explained by e_s. Eq. 5 can be rearranged to:

$$k = 5.879 \times 10^{-11} e^{3.065 e_s} \quad (6)$$

3.3 Freeze-thaw effect

Table 1 shows the fitted α values for Kaolin samples with 0% and 50% sand after various numbers of FTC. The α parameter increases consistently with the addition of sand. A decrease in α is seen when comparing the 'All data' to the 'FTC samples' dataset. The small sizes of single FTC value datasets (e.g. 1 FTC, 2 FTC etc) are not sufficient to establish if the α values are influenced by the number of FTC.

Table 1. α-values for data series from this study.

Mixture	0% Sand		50% Sand	
	α	n	α	n
All data	3.065	33	8.298	20
FTC samples	2.675	29	7.418	15
0 FTC	5.973	4	10.14	5
1 FTC	3.348	5	10.86	5
2 FTC	2.820	5		
3 FTC	1.641	4		
5 FTC	2.657	5		
7 FTC	5.006	5	12.21	5
15 FTC			9.022	5
25 FTC	5.137	5		

4 SUMMARY AND CONCLUSIONS

This paper has presented some new k data of Kaolin-sand mixtures. The new data has been compared with k tests on kaolin reported in Feng et al. (2023). A semi-log function was found to be the best fit to the data studied in this paper. The α value increases considerably with the addition of 50% sand to kaolin, compared to the tests on pure kaolin. However, the effect of the number of FTC was not detected in this study.

Sustainable erosion control in geotechnical structures – case study

Contrôle écologique de l'érosion dans les structures géotechniques - étude de cas

A. Ferreira*, J. Sousa, J. Dias, A. Neves
Ascendi IGI, Porto, Portugal

**aferreira@ascendi.pt*

ABSTRACT: Bearing in mind that surface erosion is one of the most recurrent pathologies in geotechnical structures, and its occurrence has become more and more common with greater structural consequences due to climate change, Ascendi has worked to find more sustainable and innovative solutions to prevent and resolve this type of pathology using bioengineering methodologies. The solution presented, in this case study, is limited to the projection of a mixture with a specific formulation, with species of reticulated root, appropriate to the active and adjusted to the geographical location, not requiring the previous existence or application of a layer of vegetable soil. The embankment slope under analysis, located at PK 201+000 of the A13 was presumably composed by silty sand intercalations of black schist (slate) and quartz-feldespar brown schist soils from excavations carried out near the site, very susceptible to erosion, and difficult to stabilize with the application of hydroseeder with vegetable soil. The traditional solution for this pathology would resort to filling the eroded strata with rock material. This new approach reduces the consumption of materials, water and fuels, preserving existing ecosystems and favoring biodiversity through the application of native species. The creation of a uniform vegetation cover on the slope face and the establishment of the reticulated roots allow a stabilization of the slope and increased resilience to Natural Hazard.

RÉSUMÉ: Sachant que l'érosion de surface est l'une des pathologies les plus récurrentes dans les structures géotechniques, et que son occurrence est devenue de plus en plus courante avec des conséquences structurelles plus importantes en raison du changement climatique, Ascendi s'est efforcé de trouver des solutions plus durables et innovantes pour prévenir et résoudre ce type de pathologie en utilisant des méthodologies de bio-ingénierie. La solution présentée, dans cette étude de cas, se limite à la projection d'un mélange avec une formulation spécifique, avec des espèces de racines réticulées, appropriées à l'actif et adaptées à la situation géographique, ne nécessitant pas l'existence préalable ou l'application d'une couche de sol végétal. Le talus analysé, situé au PK 201+000 de A13, était vraisemblablement constitué de phyllites grises et de métagraviers brunâtres provenant d'excavations réalisées à proximité du site, très sensibles à l'érosion et difficiles à stabiliser par l'application d'un hydroseeder avec un sol végétal. La solution traditionnelle pour cette pathologie consisterait à remplir les strates érodées avec du matériel rocheux. Cette nouvelle approche réduit la consommation de matériaux, d'eau et de combustibles, tout en préservant les écosystèmes existants et en favorisant la biodiversité grâce à l'utilisation d'espèces indigènes. La création d'une couverture végétale uniforme sur la face de la pente et l'établissement de racines réticulées permettent une stabilisation de la pente et une résilience accrue aux risques naturels.

Keywords: Geotechnical structures; erosion; sustainability; bioengineering; natural hazard.

1 INTRODUCTION

Nowadays, as result of climate change, there is a greater frequency of very high and concentrated rainfall in short periods of time. These phenomena, usually associated with other factors (quality of geotechnical materials, slope geometries that are not in line with the geology, insufficient drainage systems, construction problems, among others), can lead to serious pathologies in geotechnical structures and ultimately to instabilisation and rupture phenomena.

Ascendi, aware of this fact, has researched, studied, and implemented more sustainable solutions from an ecological point of view, that allow pathologies to be resolved and increase the resilience of its assets against Natural Hazards.

This document presents a practical case study in which a sustainable solution was implemented using bioengineering to correct and mitigate the surface erosion phenomena observed.

2 TRADITIONAL VS SUSTAINABLE SOLUTION

To treat or prevent this type of pathology, there are different solutions which can be implemented, all with a set of advantages and disadvantages.

To treat pathologies related to surface erosion, the most common and traditional solution is often to fill these surfaces with stone material.

Figure 1 shows an example of a traditional solution, where the surface ravine was repaired by using rockfill.

Figure 1. Example of a traditional solution - repaired by using rockfill.

Although it is a very effective and easy-to-implement solution, promoting stabilization of the geotechnical structure and increasing resistance to erosion phenomena, it has a number of disadvantages in environmental terms when compared to other more sustainable solutions, such as hydro-sowing.

Solutions using stone material generally require more labor and mechanical resources, and consume more non-renewable natural resources such as water, energy and fossil fuels. As a result, they have a higher economic and environmental cost and more negative impacts on the ecosystem. Other solutions can be considered, such as:

- Application of geotextile for erosion control;
- Surface coating;
- Construction of containment barriers;
- Reinforcement of the drainage system
- Slope re-profiling

As less traditional but more sustainable solutions, Chemical Stabilisation and the application of hydro-sowing can also be considered.

Figure 2 shows an example of the implementation of a sustainable solution, where the surface was treated by applying a hydro-sowing.

Figure 2. Example of a sustainable solution – applying hydro-sowing.

3 CASE STUDY

The slope that is the subject of this study was built in 2013, with a slope gradient of 1.0V:1.5H and a total height of 52.0 metres. It was initially built with 3 benches, and in 2022 it was supplemented with a backfill with two more benches.

The material that makes up the embankment comes from excavations carried out to build a short-distance overpass and is highly susceptible to erosion due to its composition.

The body of the embankment was built according to Elsamex (2021) and the Detailed Design with black and dark grey phyllites, with a very variable state of alteration (from decomposed to moderately altered) and a generally high state of fracture; reddish-brown, greyish, black and greenish-grey shales, sometimes with quartz fillets, sometimes with oxidised fractures and clay fillings, with a very variable state of alteration (from decomposed to moderately altered) and a generally high state of fracture; dark grey metagrauvaques with a generally high state of alteration and fracture.

In 2016, the first longitudinal cracks were seen in the embankment pavement. In 2020, several pathologies were observed on the same slope. Pathologies related to the displacements and instability phenomena observed in the structures. In order to guarantee the stability of the structure and stop the instability phenomena, a new support slope was built at the foot of the embankment.

After the construction of the new reinforcement earth structure, which was completed in February 2023, a landscape integration and surface protection

solution - hydro-sowing - was studied with the aim of protecting the embankment against surface erosion agents. This will act as a preventative measure, avoiding the occurrence of future pathologies associated with erosion phenomena, promoting the growth of native vegetation, biodiversity and the preservation of ecosystems. This solution also adds value in economic terms and is more environmentally sustainable.

Hydro-sowing is a landscaping and protection technique that consists of spreading a mixture of seeds, fertiliser, mulch, fixatives and water on the surface. All these materials are mixed and applied according to set proportions. This mechanical process makes it possible to firmly fix the seeds and create a favourable environment for germination in the most adverse weather conditions and on poor, hard-to-reach land.

The hydro-sowing system implemented is adapted to the region, considering soil conditions and water availability. A mixture of 90 per cent herbaceous plants (grasses and legumes) and 10 per cent shrubs was considered.

The mix will thus be made up of grasses, whose fasciculate roots actively contribute to fixing the soil, legumes that will act as green manure and a portion of shrubs that will make up the stable and permanent autochthonous scrub communities.

The composition of the hydro-sowing is as follows:

- Grasses and Legumes 35g/m2 (90% of the total seed mixture)
  - 55% Lolium multiflorum;
  - 18% Lolium perenne;
  - 10% Brisa maxima;
  - 10% Festuca arundinácea;
  - 5% Dactilis glomerata;
  - 1% Trifolium repens;
  - 1% Vicia spp.
- Shrubs 3,5g/m2 (10% of the total seed mixture)
  - 50% Lavandula stoechas;
  - 40% Ulex. Sp.;
  - 10% Caluna vulgaris.

The study considered two solutions:

A. Solution adopted for the two lower levels:
   a. Covering the areas with a layer of vegetable soil;
   b. Application of hydro-sowing as described above.

Figure 3 shows the application of solution A during phase b.

Figure 3. Solution A - Application of the hydro-sowing (December 2022).

Figure 4 shows the evolution of the solution A.

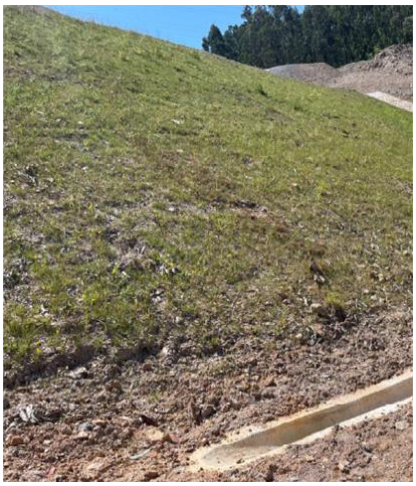

Figure 4. Evolution of Solution A.

B. Solution adopted in the upper level:
   a. Scarifying the surface;
   b. Application of hydro-sowing as described above.

Figure 5 shows the application of solution B during phase b.

Figure 5. Solution B - Application of the hydro-sowing (March 2023).

Figure 6 shows the evolution of the solution B.

Figure 6. Evolution of Solution B.

The two solutions were adopted, A - with a layer of vegetable soil and B - without the soil layer, to compare the results of both. As the entire landfill was made using material from the same geological formation, it is possible to compare the results obtained. Solution A achieved a better uniformity of vegetation cover, but only one growing cycle has been completed so it is too early to reach any final conclusions. It is also necessary to take into account the time difference between the application of both solutions (3 months).

Figure 7 shows the record in December 2023.

Figure 7. Results of the hydro-sowing application (December 2023).

4 CONCLUSIONS

The case study, for both solutions presented in the previous point, proved to be effective in controlling surface erosion on embankment slopes.

The application of a layer of vegetable soil can be an advantage in the early stages of vegetation growth. The advantages or disadvantages in later stages are still being analyzed. We're expecting that solution B might be the most attractive overall, and at a lower cost.

This type of solution - the application of hydro-sowers - with species and formulation studied for the location of the geotechnical structure to be treated, is a more sustainable natural engineering solution that stands out:

- Less consumption of non-renewable natural resources;
- Control of invasive species by using native species;
- Lower water and energy consumption compared to traditional solutions using stone and/or blankets;
- Less consumption of fossil fuels;
- Promotion of biodiversity;
- Greater landscape integration;

All these indicators encourage the preservation of ecosystems. This solution mitigates the surface erosion of geotechnical structures, helping to increase resilience to Natural Harazds.

As future challenges, we intend to extend the methodologies to other Embankment and Excavation Slopes with other geotechnical formations and geographical locations within the Ascendi network.

Enhancement of soil mechanical properties with biopolymers

Amélioration des propriétés mécaniques des sols avec des biopolymères

ABSTRACT: The utilization of biopolymers in geotechnical engineering to enhance soil properties has garnered significant interest owing to their environmentally friendly, biodegradable, and sustainable characteristics. Various biopolymers, including chitosan, alginate, pectin, cellulose, and starch, have been explored for soil improvement purposes. Notably, guar and xanthan gums have emerged as prominent biopolymers for soil stabilization applications. The primary objective of employing biopolymers is to augment mechanical properties such as shear strength, stability, and permeability of soils. Evaluations of treated soils have consistently demonstrated the effectiveness of guar gum and xanthan gum in enhancing soil behavior, rendering them suitable for diverse geotechnical applications. Moreover, they represent a sustainable and eco-friendly alternative to conventional chemical and mechanical soil improvement techniques, which may entail adverse environmental consequences. In the research, several laboratory tests, including Atterberg limits, Proctor, and direct shear tests, were conducted on Hungarian soils treated with guar and xanthan gums to observe their mechanical behavior after treatment. Specifically focusing on uniformly graded sandy soil, the research delves into shear test parameters discussion and microscopic visualizations depicting the bonds between guar and xanthan gums and the sand particles.

RÉSUMÉ: L'utilisation de biopolymères dans l'ingénierie géotechnique pour améliorer les propriétés des sols a suscité un grand intérêt en raison de leurs caractéristiques écologiques, biodégradables et durables. Divers biopolymères, dont le chitosane, l'alginate, la pectine, la cellulose et l'amidon, ont été étudiés à des fins d'amélioration des sols. Les gommes de guar et de xanthane se sont notamment imposées comme des biopolymères de premier plan pour les applications de stabilisation des sols. L'objectif premier de l'utilisation des biopolymères est d'augmenter les propriétés mécaniques telles que la résistance au cisaillement, la stabilité et la perméabilité des sols. Les évaluations des sols traités ont constamment démontré l'efficacité de la gomme guar et de la gomme xanthane dans l'amélioration du comportement des sols, ce qui les rend appropriés pour diverses applications géotechniques. En outre, elles représentent une alternative durable et écologique aux techniques conventionnelles d'amélioration chimique et mécanique des sols, qui peuvent entraîner des conséquences néfastes sur l'environnement. Dans la recherche actuelle, plusieurs tests de laboratoire, y compris les limites d'Atterberg, les tests Proctor et les tests de cisaillement direct, ont été effectués sur des sols hongrois traités avec des gommes de guar et de xanthane afin d'élucider leur comportement mécanique. En se concentrant spécifiquement sur les sols sableux à granulométrie uniforme, la recherche examine les résultats des tests de cisaillement et les visualisations microscopiques décrivant les liens formés entre les gommes de guar et de xanthane et les particules de sable.

Keywords: Biopolymers; soil stabilization; shear strength; stability; permeability.

1 INTRODUCTION

Over time, several approaches have been developed to enhance the geotechnical characteristics of soil. These include chemical stabilization, dewatering, natural and synthetic soil reinforcement, and the provision of drains.

The type of soil, the project's requirements, the budget, the available expertise, and other considerations all play a role in the technique selection. One of the most often used methods for improving the quality of the ground is the use of different admixtures and additives to change the properties of the soil. But there's also reason for considerable concern over how this stabilizing method affects the soil ecosystem.

When it comes to improving the strength of soil, chemical techniques that include adding cementitious additives, such as cement, lime, etc., work incredibly well, but they also permanently change the soil's environment. Furthermore, throughout the cement product's production process, significant greenhouse gasses such as carbon dioxide are released (Chang et al., 2016)

The use of cement and lime is often seen as less ecologically benign than the use of industrial by-products. Industrial by-products are fundamentally more sustainable because they constitute a beneficial

reuse application that is an alternative to landfilling or another comparable by-product disposal. Because of the high Ca $(OH)_2$ concentration of the stabilizer, traditional additive stabilization typically elevates soil pH following treatment, which may have negative environmental impacts such as affecting groundwater quality or limiting vegetation growth. Traditionally treated soils are also overly brittle, which can have an impact on the performance and stability of structures (Chang et al., 2015).

The review of existing literature has shown that numerous studies have explored the use of gum and xanthan gum to stabilize soil across various soil types, yielding promising outcomes. For instance, Chang et al. (2015) observed that the inclusion of guar gum enhanced soil aggregate stability and mitigated soil erosion, while Mendonça et al. (2021) noted that xanthan gum improved the rheological properties and resistance to erosion in silty clay soil. Both studies focused on assessing the impact of biopolymers on the geotechnical characteristics of loess soil. Jiang (2022) discovered that injecting guar gum significantly elevated the unconfined compressive strength of loess soil while decreasing its permeability. Similarly, xanthan gum was found to enhance the elastic modulus and shear strength of loess soil, with its effectiveness being linked to the concentration used.

In a laboratory trial, the addition of 0.2% guar gum led to a notable increase of up to 50% in the unconfined compressive strength of loess soil compared to untreated soil (Bagheri, 2023). Another study revealed that incorporating 0.2% xanthan gum resulted in substantial enhancements of up to 180% in elastic modulus and 77% in shear strength of loess soil (Jiang, 2022). It's important to note that the precise improvements in soil properties depend on various factors such as soil type and concentration of biopolymer, and curing duration, thus these effects may differ across different soils and biopolymers. Further research is necessary to fully grasp the impacts of biopolymer treatment on soil properties and to validate its efficacy in improving soil mechanical properties.

Biopolymers are naturally occurring polymers with remarkable tensile strength that are non-toxic and biodegradable. Because of potential cost savings, low environmental impact, non-toxicity, and non-secondary pollution, biopolymers are acknowledged as a viable alternative to traditional chemical polymers (Aminpour and O'Kelly, 2015).

2 MATERIALS

2.1 Soil

The soil was obtained from a construction site in Göd, Hungary originated from a mine of Dűne Szektor Kft. (October 2022).

It is greyish-black in color and does not contain any organic content.

The grain size distribution curve of the soil as measured by hydrometer and sieve tests and following the ASTM D, 2487-06 ASTM International (2021), indicates that the soil is a uniformly graded sand, as shown in Figure 1. The percentages of different soil components are presented in Table 1 and the grading characteristics of the soil are shown in Table 2.

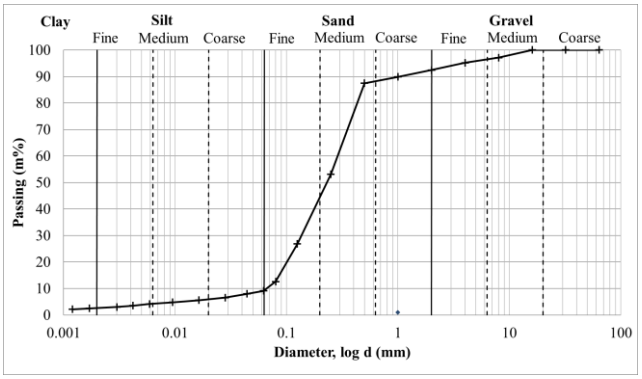

Figure 1. Grain size distribution curve of sand.

Table 1. Soil composition.

Soil Fractions m (%)	
Gravel K(Gr)	7.57%
Sand H(Sa)	83.17%
Silt I(Si)	6.63%
Clay A(Cl)	2.63%

Table 2. Grading characteristics of the soil.

Soil characteristics			
D90	1.059 mm	Cu	4.50
D60	0.300 mm	Cc	0.98
D30	0.140 mm	w	1.3%
D10	0.067 mm	γ_s	2.65 kN/m^3

2.2 Guar Gum (GG)

Guar gum, scientifically identified as Cyamopsis tetragonolobus, is a natural biopolymer obtained from the endosperm polysaccharide of guar seeds, classified within the Leguminosae family, and categorized as a seed gum. Its composition comprises D-galactose and D-mannose polymers in a 1:2 ratio (Sujatha and Saisree, 2019).

Upon complete hydration, guar gum transforms a thixotropic, viscous, colloidal dispersion. The borate ions inherent in guar gum serve as cross-linking agents, facilitating the formation of cohesive and thick gels.

2.3 Xanthan Gum (XG)

Xanthan gum is a polysaccharide that is extensively used as a food additive and rheology adjuster; it is generated by the Xanthomonas campestris bacteria by fermentation of glucose or sucrose. Xanthan gum's ($C_{35}H_{49}O_{29}$) fundamental chemical structure is a linear linked b-D glucose backbone with a trisaccharide side chain on every other glucose. Using hydrogen bonds, the trisaccharide side chain is aligned with the backbone, providing stability and overall shape.

3 METHODS

3.1 Sample preparation

The soil samples are oven-dried at 100 °C to 110 °C for 24 h. The guar gum and xanthan gum-treated soil samples are prepared by adopting the dry mixing procedure. Initially, the biopolymer in powder form is mixed with the required amount of soil at percentages of 0.5% and 1% by weight of the soil.

The biopolymer powder is mixed thoroughly with the soil sample in a plastic bag to be sure that the fine particles of powder won't be wasted in the air, and then the required water amount is added. In this experiment, the optimum water content was added for the mixing, which is 9.5% of the total mass of the dry mixture. With the first contact of the biopolymer with water, the galactose, and the mannose present in the biopolymer hydrate at a faster rate by absorbing the water rapidly, and the soil becomes coated with the biopolymer.

3.2 Experimental investigation

3.2.1 Microscopic observations

The interaction of sand with the biopolymer was investigated microscopically using a transmitted illumination optical microscope (Olympus BH2 PLM Asbestos Polarizing Microscope) see Figure 2.

This Olympus BH2 microscope is equipped with a binocular head featuring a pair of CWHK 10x eyepieces, with one eyepiece incorporating a crossline reticle. The Bertrand lens module includes a rotating analyzer and is furnished with a 530 nm wave plate.

The nosepiece, offering four positions, is fitted with D Plan PO objectives of 10x, 20x, 40x, and a Central Stop Dispersion 10x A PO objective. The stage is capable of 360-degree rotation and is accompanied by a set of stage clips. Additionally, the flip-out condenser is complemented by an attached rotating polarizer (Microscope central, 2023).

For this research, samples were prepared in small portions immediately and observed by the microscope. The two types of biopolymers were observed independently to analyze their microscopic structure, then mixed dry with sand particles, Finally, some water drops were added to the mix to visualize the created bonds between the powders and the sand grains.

Figure 2. Olympus BH2 PLM Asbestos Polarizing Digital Microscope.

3.2.2 Shear box test

After finishing the preparation of the sample and where homogeneity was achieved, the direct shear test was conducted using the machine in Figure 3.

Figure 3. Direct shear test (The Laboratory of Geotechnics and Engineering Geology at BME University, Hungary).

This test is among the most frequent and simple methods to determine the shear strength of soils. It was

performed on five specimens with 5 different mixtures: an untreated sandy sample and four treated samples with the ratios, respectively: 0.5%GG, 1%GG, 0.5%XG, and 1%XG. The amount of water was specified to be the optimum water content, which is 9.5%. The shear tests were done with three loading points each (50, 100, and 150 kPa) to get enough outputs to compare.

The setting inputs of the shear box test are resumed in Table 3.

Table 3. Direct shear box parameters used in geotechnical engineering laboratory (BME university).

Consolidated	yes	

4 DISCUSSION

The preference for guar gum and xanthan gum as stabilizing agents was driven by their natural abundance and sustainable characteristics, leading to enduring positive impacts. Extensive experimental tests were carried out to investigate the feasibility of utilizing these biopolymers for enhancing the geotechnical characteristics of soil, and the findings from these tests are detailed in the study.

4.1 Microscope

According to the results obtained using the Olympus microscope at different magnifications, the granules displayed an interesting diversity of morphologies ranging from oval, spherical, and polygonal to irregular forms depending on the type of the utilized biopolymer. In this phase of research, the Olympus microscope provided a simple visualization of the GG and XG powders on a bigger scale which also allowed us to compare the shapes and forms of these biopolymers, see Figures 4 and 5.

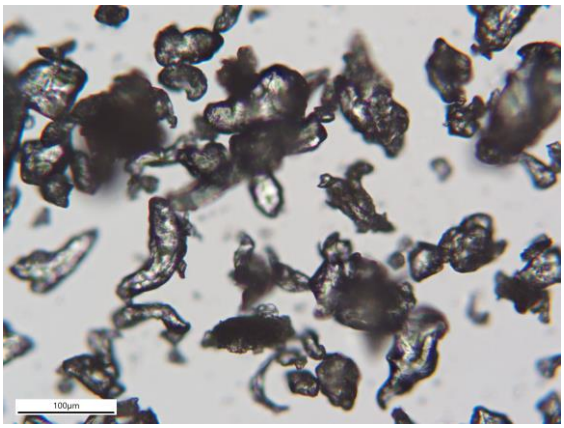

Figure 4. Guar gum at 200X magnification.

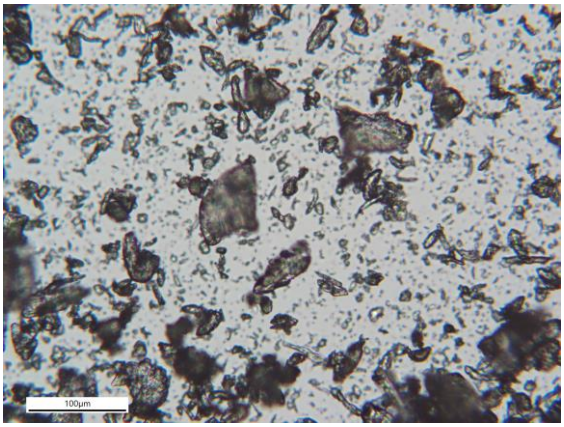

Figure 5. Xanthan gum at 200X magnification.

For instance, at the same 200X magnification, it is clear that GG has bigger particles than the XG particles, they are more fine and dense, it is also shown that the particle quantity of XG is more than the one of GG, as a result, it was mostly the reason why it works more with granular soils proving the results found by previous literature (Bagheri, 2023; Chang et al., 2015). However, GG was proved more efficient with cohesive soils (Bagriacik et al., 2021). Under the microscope, the raw soil in this study—which is sand—also revealed an intriguing shape with shades of brown and yellow colors. Refer to Figure 6.

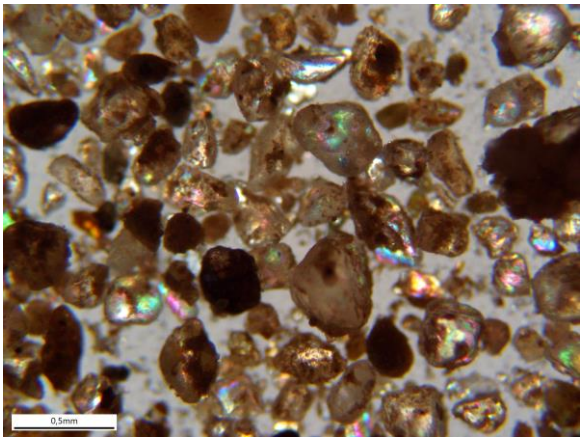

Figure 6. Sand sample with 40X magnification.

Observing the behavior of the soil in dry form with the two different powders and the entire mixture after adding water was the most fascinating aspect. It was shown by the microscopic magnification that the hydrogen linkages formed the instantaneous bonds between the biopolymer grains and soil crystals.

The water filled the voids, and the powder created a coating on the sand particles, the white-colored shapes are the gel-like structure created by water plus powder.

Figures 7 and 8 show both dry and wet mixtures of soil with GG and XG biopolymers at 40X magnification.

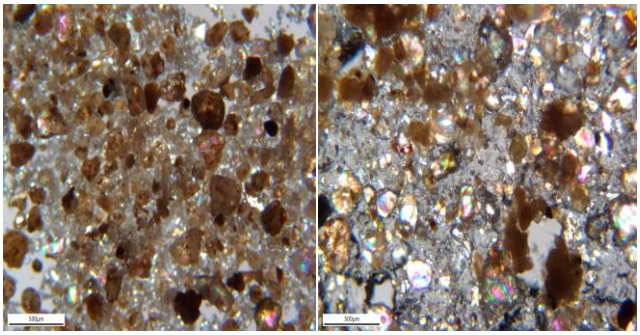

Figure 7. Dry (left) and wet(right) mixtures of soil with GG at 40X magnification.

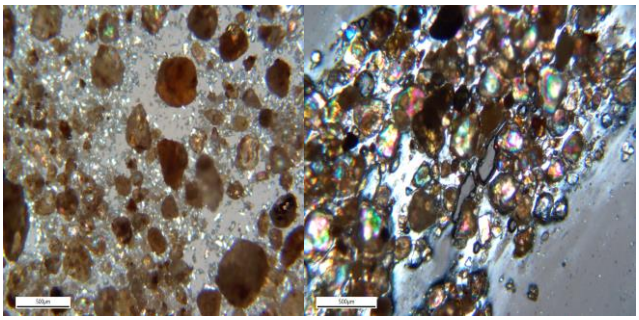

Figure 8. Dry (left) and wet(right) mixtures of soil with XG at 40X magnification.

4.2 Shear test

The initial soil exhibits a friction angle with a peak value of 33° and 0 kPa cohesion, characteristic of sandy soil. Subsequent treatment with Guar Gum (GG) and Xanthan Gum (XG) at varying ratios results in notable changes in soil properties. Simultaneously, cohesion experiences substantial improvement, with the peak value reaching 18.4 kPa, after being initially cohesionless, this result was achieved with just a 0.5% addition of GG. A parallel evolution is observed with a 1% addition of the same powder.

On the other hand, XG-treated sand demonstrates significant improvements in cohesion, exceeding the GG, results are shown in Table 4. This observation is consistent with current literature findings (Chang et al., 2020), indicating that XG is more commonly employed for granular soils, such as the soil under investigation in the present research.

Biopolymers like guar gum and xanthan gum can act as lubricants between soil particles, reducing inter-particle friction. This lubricating effect can lead to a slight decrease in friction angle as the soil particles experience less resistance to sliding past each other. However, this decrease is typically minimal compared to the increase in cohesion. The addition of biopolymers may also influence the arrangement of soil particles. The formation of a cohesive matrix can promote closer packing of particles, leading to improved interlocking and a slight reduction in friction angle.

Table 4. Shear Test results.

	Friction angle (°)		Cohesion (kPa)	
(%)	**Peak**	**Residual**	**Peak**	**Residual**
0.5% GG	23.5	26.5	18.4	6.9
1% GG	26	27	9.8	6.4
0.5% XG	27.5	25	18.4	16.6
1% XG	28.5	27	11.9	11.4

5 CONCLUSIONS

The research delves into an examination of guar gum and xanthan gum biopolymers concerning the stabilization of sand soil, aiming to enhance geotechnical properties while preserving mineral compositions. The findings reveal observable modifications in geotechnical properties with the addition of 0.5% and 1% concentrations of both guar gum and xanthan gum. This study provides valuable insights into the underlying mechanisms of stabilization between biopolymers and soil, as uncovered through various laboratory tests, including meticulous microscopic investigations.

Key conclusions drawn from the study highlight a change in the behavior of the granular soil;

- In Xanthan-treated granular soil, the enhanced strength primarily arises from the formation of the Xanthan matrix on the soil's surface and within voids. This matrix notably contributes to the increased shear strength of the soil.
- When water, guar gum, or xanthan gum is added to improve sandy soil, cohesion increases due to enhanced particle bonding facilitated by these substances. This results in higher overall shear strength. However, the friction angle may remain steady or increase slightly due to changes in particle arrangement and interlocking.
- Determining the optimal dosage of biopolymers is crucial and contingent on specific purposes,

such as stabilization, enhancing dam permeability, or improving the plasticity of a given soil.

Future studies aimed at precisely quantifying the use of xanthan and guar gum in soil stabilization would significantly enhance our understanding of stabilization mechanisms and improve overall process efficacy. Embracing these microbial enhancers opens avenues for altering biopolymer stabilization and modifying soil characteristics in ways not achievable with conventional stabilizers like cement.

Experimental study on the elasticity modulus of RCA–RTW mixtures

Étude expérimentale du module d'élasticité des mélanges RCA–RTW

K. Gabryś*, W. Sas
Water Centre WULS, Warsaw University of Life Sciences – WULS, Warsaw, Poland
**katarzyna_gabrys@sggw.edu.pl*

ABSTRACT: The present study aims to show the possibility of soft rubber tire waste (RTW) application in rigid recycled concrete aggregate (RCA) by evaluating the mechanical properties of the large concrete aggregates with a grain diameter size up to 4.0 mm mixed with small ground rubber with diameter 0–2 mm, with weight percentages between 0 and 50%. The paper presents the results of drained monotonic triaxial tests on compacted RCA–RTW mixtures. The test results prove that the inclusion of rubber in the RCA significantly reduces the elastic modulus (*E*). From the perspective of the utilization of the studied material in road construction, a less rigid (stiff) material is obtained.

RÉSUMÉ: La présente étude vise à démontrer la possibilité d'utiliser des déchets de pneus en caoutchouc mou (RTW) dans des agrégats rigides de béton recyclé (RCA) en évaluant les propriétés mécaniques de gros agrégats de béton d'un diamètre de grain allant jusqu'à 4,0 mm mélangés à du petit caoutchouc broyé d'un diamètre de 0 à 2 mm, avec des pourcentages de poids compris entre 0 et 50%. L'article présente les résultats d'essais triaxiaux monotones drainés sur des mélanges compactés RCA–RTW. Les résultats des essais prouvent que l'inclusion de caoutchouc dans le RCA réduit de manière significative le module d'élasticité (*E*). Du point de vue de l'utilisation du matériau étudié dans la construction routière, on obtient un matériau moins rigide.

Keywords: Mechanical properties; anthropogenic soil; recycled concrete aggregate; rubber waste.

1 INTRODUCTION

The primary goal of the solid waste management system is to protect public health, safety, and welfare effectively. Recycled materials are mostly used for non-structural applications. However, a large number of industrial and municipal waste can be used in the construction industry. The sustainable management of tire rubber waste is a major challenge for industry and the public sector. This is due to the following reason: landfill disposal of scrap tires is legally prohibited in all countries due to the negative environmental impact (Al-Rkaby, 2019).

Given this problem, various academic research studies are proposing to investigate the feasibility of the re-use of this waste through reliable and viable long-term solutions (Benjelloun et al., 2021). Examples may include road engineers who tried incorporating tire rubber into asphalt pavements (Carlson and Zhu, 1999). The desirable properties of rubber waste in geostructures over geomaterials include compressibility, lightness, high thermal insulation, and good durability (Saberian et al., 2018). Many experiments using triaxial and direct shear tests have been carried out so far to understand the strength properties of tire shreds, tire chips, and their mixtures with sand. Notable among these is a study by Rao and Dutta (2006) who found that mixtures of sand with 20% of tire chips could be a potential material for highway and embankment construction, due to the improved load-bearing characteristics compared to sand only. Earlier research by Ghazavi (2004) indicates that the addition of 10 to 20% rubber to the sand is optimal for the highest friction angle, with these rubber materials alone giving a friction angle of 31°. Other previous studies demonstrated that scrap tire particles ranging in size from 50 to 100 mm give the highest shear strength parameters (Moo-Young et al., 2003). Wu et al., (1997) performed triaxial tests on pure tire chips including rubber powder, and reported that rubber waste improved shear strength and internal friction angle in blends. The value of Young's modulus varied from 420 to 840 kPa.

More recent studies carried out by e.g. Bali Reddy et al. (2016) indicate that shear strength increases with increasing rubber shred content up to 30–40% by weight and then decreases. Similar observations were made by Tiwari et al. (2017) who showed that shear strength increased to an optimum value of 25% of the

volume and weight of the rubber aggregates and then decreased above 25%. Even more recent studies, such as the work of Balaban et al. (2019) reduce this optimum level of rubber waste in the mix to 20%, when an improvement in mix strength can be observed. A summary of previous work on sand reinforcement by adding crushed rubber can be found in the work of (Benjelloun et al., 2021).

The authors have explored the effect of the addition of waste rubber on the strength parameters, using different waste materials, i.e. fine recycled concrete (particles ≤ 2 mm) (Gabryś et al., 2021). The research was part of an ongoing extensive program of experimental trials carried out at the Warsaw University of Life Sciences (WULS), Poland, and at the Vytautas Magnus University Agriculture Academy (VMU), Lithuania. According to the triaxial tests conducted, the largest improvement in shear strength occurred for the mixture with 10% recycled tire waste (RTW).

It is also important to note that, among other rubber properties, the modulus of elasticity (E) has a significant effect on the mechanical behavior of soil–rubber compounds (Aksoy et al., 2021). The results of laboratory tests on this parameter of granular rubber–sand mixture, in addition to the previously mentioned work by Wu et al., (1997), can be found, e.g., in the research of Guler and Enunlu (2009). The inclusion of rubber waste in the sand was found to reduce the E–modulus significantly.

Regarding the state of the art discussed above, this work aims to study the mechanical behavior, particularly the elasticity modulus of compacted anthropogenic soil modified with recycled tire waste (RTW). This research focuses on the use of man-made soil material–recycled concrete aggregate (RCA), which in its unbound state can be placed as a subbase in road structures.

2 MATERIALS AND METHODS

The materials used in this work are recycled concrete aggregate (RCA) and rubber aggregates from waste car tires (RTW), their characteristics are summarized below.

2.1 RCA

The RCA adopted in the present study was the reference material in many of the authors' previous research (e.g. Gabryś et al., 2023). The physical characteristics of this RCA were determined in our laboratory (Table 1). The RCA belongs to the category of gravel with sand (saGr), according to PN-EN ISO 14688-1:2018-05, with uniform and spherical grains after crushing. The RCA has an average grain size of D_{50}=2.0 mm; the void ratio can vary between e_{min}=0.201 and e_{max}=0.405, and the specific density of the grains is ρ_s=2.17 g/cm^3. The particle size distribution curve of this RCA, together with its image after grinding and mixing, is presented in Figure 1. From Figure 1 it can be seen that the RCA is a non-uniformly well-graded coarse material. This classification was obtained by estimating the uniformity (C_U) and curvature (C_C) coefficients.

Table 1. Physical characteristics of used recycled concrete aggregate and recycled rubber aggregate.

Materials Under Study	RCA	RTW
D_{10} (mm)	0.25	0.68
D_{30} (mm)	1.00	0.84
D_{50} (mm)	2.00	1.00
D_{60} (mm)	2.30	1.10
C_U (/)	9.20	1.62
C_C (/)	1.74	0.94
ρ_s (g/cm^3)	2.17	1.19
$\rho_{d,\,min}$ (g/cm^3)	1.545	0.464
$\rho_{d,\,max}$ (g/cm^3)	1.735	0.565

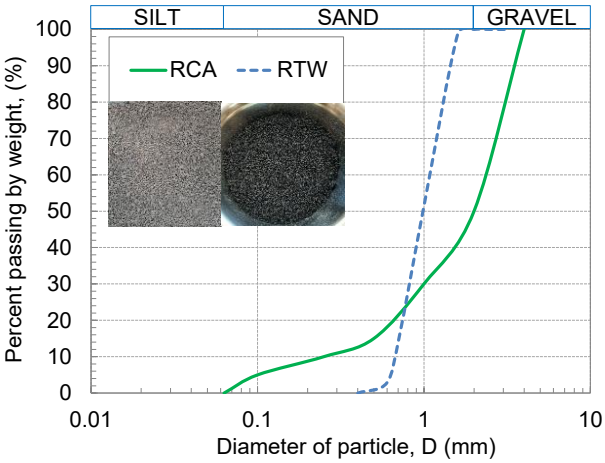

Figure 1. Particle size distribution of testing materials and their images.

2.2 RTW

The ground rubber used in this study is a by-product of the scrap tire shredding process. Rubber particles were sieved to obtain a uniform size. The rubber material is angular and irregularly shaped and has a diameter varying from 0.5 to 2 mm with an average diameter of D_{50}=1.0 mm. The specific density of the rubber grains is 1.19 g/cm^{3,} which falls within the range of values given by, e.g., Akbulut et al. (2007). The determined maximum and minimum values of the

void ratio are e_{max}=1.565 and e_{min}=1.106. The particle size distribution curve of the RTW is shown in Figure 1, whereas the basic parameters of tire waste are presented in Table 1. The values of the coefficients C_U and C_C indicate rubber materials with uniform granulation. No amounts of textile parts or steel strapping were found in this rubber additive. The applied rubber waste is not harmful to human health, and has a stable composition, posing no risk during storage and transport (according to the manufacturer), with a positive health assessment.

2.3 Mixtures preparation and testing procedure

In this study, a triaxial apparatus is used to perform all standard isotropic CD triaxial tests on samples with different mixing ratios of the RCA and RTW. The testing program is summarized in Table 2. A total of 9 samples, consisting of ground rubber tires and recycled concrete aggregate, mixed in a ratio of 0:100, 25:75, and 50:50 by weight, are employed in laboratory tests. Generally, the volumetric proportion of the geotechnical mixture controls the mechanical behavior of the mix. Thus, the mixing ratios by volume (a_v) of the RTW and the RCA are tabulated in Table 2. The a_v values were calculated based on the volume of particles for each mix as follows (Youwai and Bergado, 2003):

$$a_v = \frac{1}{\frac{G_{RTW}}{R_m}\left[\frac{(100-R_m)}{G_{RCA}}+\frac{R_m}{G_{RTW}}\right]} \quad (1)$$

where R_m is the mixing ratio by dry weight of the RTW in the mixture (%), G_{RTW} is the specific gravity of the RTW, and G_{RCA} is the specific gravity of the RCA. An isotropic confining pressure is applied at three different values, 90, 180, and 270 kPa, to cover the range of stresses in applications such as road construction or off-road lightweight fill used in embankment construction.

A standard triaxial cell is used in a temperature-controlled room, capable of handling samples 70 mm in diameter and 140 mm in height (Figure 2). It was important to avoid any segregation when preparing the mixtures that could affect the results obtained. Therefore, to obtain a reasonably uniform, non-segregated mixture, special care is taken to mix the RCA and RTW thoroughly from the beginning to the point of pouring into the mold. After mixing the appropriate amount of dry crushed concrete aggregates and rubber aggregates, the specimens are carefully constructed in five layers using undercompaction (Ladd, 1978). Every layer is subsequently tamped using a metal rod tamper providing a relative density between 70 and 80%. To ensure a uniform compaction energy in each layer, the number of blows per layer varies from 21 blows for the first layer to 25 for the fifth layer.

Figure 2. Triaxial apparatus available at WULS.

After each compound is set up in the triaxial cell with the vacuum pressure (~10 kPa), the chamber is filled with de-aired water, and the saturation process is carried out by applying different values of back pressure while keeping a constant initial effective stress of 50 kPa until obtaining a Skempton's *B*-value greater than 0.93. Thereafter, every mixture is isotropically consolidated by increasing the effective confining pressure to the appropriate value according to Table 2. At the end of consolidation, the axial load is increased at a constant axial strain rate until failure occurs. A controlled shear rate of 0.033 mm/min is applied during testing.

3 RESULTS

This section presents the results and analysis of the mechanical properties of the RCA–RTW mixtures from triaxial consolidation and drainage (TXCD) tests, where the shear of the specimens follows a standard path, i.e. with a constant chamber pressure and increasing vertical stress. In this article, the authors focus primarily on the analysis of the elastic modulus (alternatively elasticity modulus or Young's modulus).

During the standard triaxial shear stage, when the total confining stress is held constant, Young's modulus is usually calculated from the equation:

$$E = \frac{\Delta q}{\Delta \varepsilon_v} \quad (2)$$

where Δq is the deviatoric stress increment, and $\Delta \varepsilon_v$ is the vertical (axial) strain increment. All soil moduli can be calculated as secant or tangent, similar to Young's modulus. In Figure 3, schemes for

determining the secant (E_S) and tangent (E_t) modulus at two selected points X and Y are presented, from stress–strain curve measured in drained monotonic triaxial tests. The authors are particularly interested in two characteristic moduli, namely E_0 and E_{50}. E_0 is the initial (maximum) stiffness value in the very small strain range (< 10^{-5}). E_{50} is evaluated as secant stiffness for the interval between deviatoric stress q = 0 and q = $q_{failure}/2$ (Wichtmann et al., 2017).

Table 2. Summary of the testing program.

No	Designations	Mixing ratio		Preshear mean stress (kPa)	Preshear dry unit weight (kPa)	Preshear void ratio (/)
		RTW: RCA by weight (%)	RTW by volume (%)			
1	MIX1_A	0:100	0	90	16.68	0.30
2	MIX1_B	0:100	0	180	16.68	0.30
3	MIX1_C	0:100	0	270	16.68	0.30
4	MIX2_A	25:75	0.38	90	11.71	0.85
5	MIX2_B	25:75	0.38	180	11.85	0.83
6	MIX2_C	25:75	0.38	270	11.90	0.82
7	MIX3_A	50:50	0.65	90	9.35	1.32
8	MIX3_B	50:50	0.65	180	9.36	1.32
9	MIX3_C	50:50	0.65	270	9.38	1.31

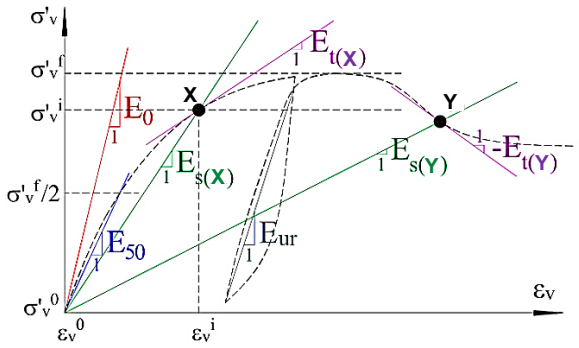

Figure 3. Evaluation of elastic modulus based on stress–strain characteristics (Wichtmann et al., 2017).

The stress–strain relationships of the anthropogenic soil–ground rubber compounds at different mix ratios are plotted in Figures 4–6. For mixtures with rubber waste (MIX2 and MIX3), the relationships between q and ε_S are relatively linear when the distortional strain is less than 15% for MIX 2 (Figure 5) and 20% for MIX 3 (Figure 6). Despite the high deformability of the ground rubber particles used, it is possible to obtain a failure in the mixes with rubber. It can be observed that the distortional strain magnitude increases with increasing rubber waste content in the specimen. In contrast, by comparing Figures 5 and 6, ca. 20% decrease of the deviatoric stress (e.g. from ~ 645 kPa to ~ 434 kPa for MIX2_C and MIX3_C, respectively) with increasing RTW content is evident.

Overall, the deformation characteristics of the studied RCA–RTW blends are quite similar to the pure RCA. Regarding the RCA, the peak strength (up to even ~ 860 kPa) develops at distortional strains ε_S=3.33, 2.76, and 2.53% for the confining stress at 90, 180, and 270 kPa, respectively. It can be seen that adding 25% rubber to the RCA results in an average 16% increase in distortional strains.

Based on the results in Table 3, the shear strength of the non-reinforced RCA and RCA–RTW mixes increases significantly with increasing normal stress, and the shear strength of the mix is greater at higher normal stresses. This increase is due to the modification of the microstructure of the blends, which produces an improvement in the contacts between the particles, namely the friction angle.

The results obtained have been attempted to compare with the mechanical properties of pure rubber waste found in the literature, see e.g. Guler and Enunlu (2009). In the case of pure rubber specimens, no internal friction angle can be determined, as the rubber shows no signs of yield, even when approaching 20% strain. Consequently, the E_S modulus can be only defined from the slope of the stress–strain curve, which is more and less straight.

Regarding the elastic moduli, the RCA containing 25 and 50% of RTW are characterized by moduli E_0 averaging between 80 and 113 MPa lower and E_{50} averaging around 64–66 MPa lower in comparison to Young's modulus E_0 and E_{50} of the pure RCA. Among all tested mixtures, the largest stiffness values are recorded for crushed concrete.

In Table 3, there are also the assumed values of E_{50} (designated as $E_{assum.}$) representing the arithmetic average of the three values obtained for a given mixture. The comparison between $E_{assum.}$ and the

E–moduli of pure rubber waste indicate that the RTW has over 90% less stiffness than the RCA. Moreover, for the blend with a mixing ratio of 50:50, the influence of the confining stress on Young's modulus is rather negligible. For the mixes MIX3_A, B, and C very similar values of E_0 and E_{50} are derived.

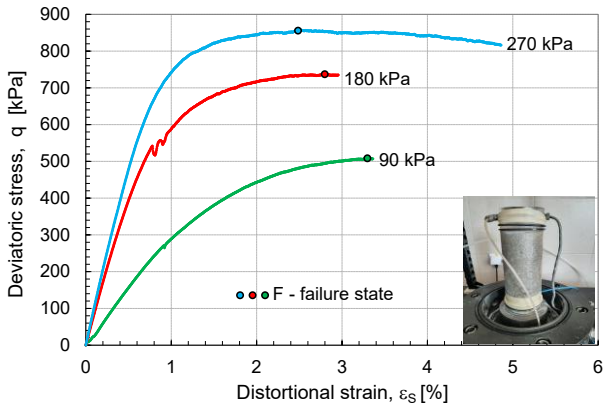

Figure 4. Deviatoric stress curves of the RCA–RTW mixtures: MIX1 (RTW=0% by weight).

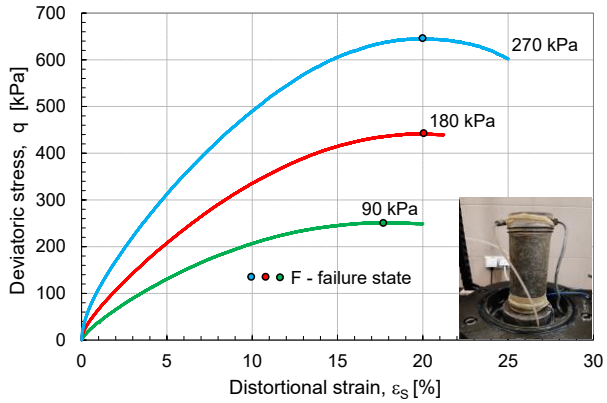

Figure 5. Deviatoric stress curves of the RCA–RTW mixtures: MIX2 (RTW=25% by weight).

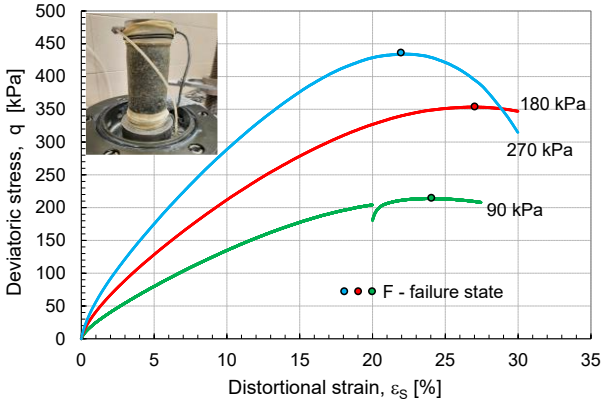

Figure 6. Deviatoric stress curves of the RCA–RTW mixtures: MIX3 (RTW=50% by weight).

4 CONCLUSIONS

The introduction of new or alternative (recycled waste) materials in geotechnical engineering applications may have many various benefits, but a proper understanding of their geomechanical properties is essential to correctly evaluate their performance. Because of the above, this article attempts to verify selected mechanical parameters of recycled concrete aggregate blended with recycled rubber inclusions.

The results obtained in this study can be summarized as follows. The friction angle and shear stress at the failure of the RCA-RTW mixtures generally decrease with increasing rubber content. As is the case of gravelly soils, and conversely to sandy soils, the addition of rubber does not enhance the strength of the RCA. Available experimental data demonstrate that the rubber-reinforced RCA has the *E*–moduli lower in comparison with the pure RCA. This reduces the possibility of using the tested mixes

Table 3. Summary of selected mechanical properties of the tested RCA–RTW mixtures.

in road construction, where the stiffness of the material seems to be a key value. Finally, as the rubber itself is characterized by the elasticity modulus ca. 70 times lower than that of the RCA, the applicability of this material is expanding. The addition of rubber to the RCA thus creates opportunities for the potential use of such mixtures as a barrier to absorb pressure waves caused by earthquakes.

ABSTRACT: Over the past decade, the offshore wind industry has evolved with significant technological advances. These have been driven by the need for offshore wind energy to provide cost-competitive renewable energy. The economics of offshore wind necessitates lean and efficient designs and nowhere is this more prevalent than in anchors for floating wind turbines. This paper examines the impact of geotechnical spatial variability on the installation of suction caisson anchors for floating offshore wind turbines (FOWTs). Monte Carlo simulations are used to examine the probability of failure of the suction caissons to reach its target depth during installation.

RÉSUMÉ: Au cours de la dernière décennie, l'industrie éolienne offshore a évolué grâce à des avancées technologiques significatives. Celles-ci ont été motivées par la nécessité de l'énergie éolienne offshore pour fournir une énergie renouvelable à un coût compétitif. L'aspect économique de l'éolien offshore nécessite des conceptions simples et efficaces, et cela n'est nulle part plus répandu que dans les ancrages des éoliennes flottantes. Cet article examine l'impact de la variabilité spatiale géotechnique sur l'installation d'ancrages à caissons à succion pour les éoliennes offshore flottantes (FOWT). Les simulations Monte Carlo sont utilisées pour examiner la probabilité de défaillance des caissons d'aspiration pour atteindre leur profondeur cible lors de l'installation.

Keywords: Suction caisson anchor; offshore geotechnics; suction installation; floating offshore wind turbine; Monte-Carlo simulations.

1 INTRODUCTION

The offshore wind sector has undergone significant advancements in recent years, and there is now particular focus on the development of floating offshore wind turbines (FOWTs) for deep water. Better understanding of the uncertainty in their design, can help reduce the cost of suction caisson anchors (SCAs) for FOWTs. One aspect of uncertainty can be related to geotechnical variability and the complexity of the soil across a wind farm site. Moreover, the high costs associated with offshore geotechnical surveys can lead to overly cautious SCA designs, primarily due to the lack of detailed, site-specific geotechnical data. This paper aims to outline an approach for addressing this issue using Monte-Carlo simulations to examine the probability of failure to achieve the target penetration of a SCA during installation.

2 SUCTION CAISSON INSTALLATION DESIGN

The installation of a SCA takes places over two stages: (1) touchdown and self-weight penetration followed by (2) suction penetration. The penetration resistance, R, of a SCA can be calculated using two standard approaches: the bearing capacity (alpha/beta) or Cone

Penetration Test (CPT) based approach. This paper will focus on the latter.

Penetration resistance is determined using equation 1 (DNV, 2017):

$$R = A_p k_p q_{c,L} + A_{si} \int k_f q_{c,z} dz + A_{so} \int k_f q_{c,z} dz \quad (1)$$

where A_p (m^2) is the anchor skirt tip area, k_p(-) is an empirical coefficient relating the CPT tip resistance to the unit-end bearing resistance, $q_{c,L}$is the CPT cone tip resistance at the anchor embedded length, L (m), A_{si} (m) is the caisson inner perimeter, k_f (-) is an empirical coefficient relating the CPT tip resistance to the unit skin friction resistance, $q_{c,z}$ is the CPT cone tip resistance at depth z (m) and A_{so}(m) is the caisson outer perimeter.

3 ANALYSIS INPUTS

A simple suction caisson anchor model was developed to assess the probability of failure during installation due to geotechnical variability in the soil. A diameter of 10m, skirt wall thickness of 50mm and a range of lengths from 10-20m (in 1m increments) were assumed for the anchor geometry. To estimate the anchor weight, padeye dimensions of 1m x 1m with a thickness equal to twice the wall thickness of the skirt were assumed. The thickness of the top plate was assumed equal to that of the padeye. To maintain model simplicity, the mass contributions of internal or external stiffeners were omitted.

3.1 Maximum installation force

The maximum available installation force was defined as the sum of the force due to the maximum pump pressure and the weight of the caisson for each length considered. The maximum pump pressure was assumed to be 500kPa, or 5bar, and was transformed to a force by multiplying it across the area of the anchor lid. The weight of the caisson was computed by multiplying the sum of the volume of the skirt, top plate and padeye by the submerged density of steel, taken to be 6,850 kg/m^3.

3.2 Soil parameters

In the calculation of penetration resistance, this study adopted a lognormal distribution of the k_p and k_f parameters to account for the model uncertainty in these empirical coefficients. The mean and 95th percentile parameters of the resulting lognormal distributions were adopted as the 'Most probable' and 'Highest expected' values, respectively, as reported in DNV (2017) and shown in Table 1.

Table 1. Values of k_f and k_p for SAND from (DNV, 2017).

Coefficient	Most Probable (R_{prob})	Highest Expected (R_{max})
k_f	0.001	0.003
k_p	0.3	0.6

Firstly, the underlying normal distribution parameters, mean and standard deviation, were derived, and these were exponentiated to obtain a lognormal distribution dataset. The standard deviation (SD) of the lognormal distribution can be determined from equation 2:

$$SD = \sqrt{(e^{\sigma^2} - 1)(e^{2\mu + \sigma^2})} \quad (2)$$

where σ and μ are the standard deviation and mean of the underlying normal distribution, respectively. The lognormal distribution had a standard deviation of 0.0639 for k_p and 0.000344 for k_f.

For each Monte Carlo realisation, a unique value for k_p and k_f was sampled from a lognormal distribution of 10,000 values. Local seepage effects in sand during installation were ignored.

3.3 Monte-Carlo simulation inputs

In the study, geotechnical spatial variability was examined using spatially varying CPT cone resistance profiles, generated using the random field approach. The method used to develop these profiles is outlined in Igoe and Reale (2023). A summary of the procedure is provided in this section.

The CPT profiles were assumed to be normally distributed, and the random field was defined using three parameters: mean, standard deviation, and scale of fluctuation (θ). At first a mean CPT profile is derived to which noise can then be added. The mean CPT cone resistance profile, $\bar{q}_t$ (corrected for pore pressure effects), was derived based on a constant relative density of 70% using correlations proposed by Kulhawy and Mayne (1990). A scale of fluctuation value of θ = 5m was assumed in this analysis. Using the Markov correlation structure, a correlation matrix can be developed from equation 3:

$$\rho(\tau_j) = exp\left(\frac{-2|\tau_j|}{\theta}\right) \quad (3)$$

where j = 0, 1,…, n-1 with n being the number of data points, $\tau_j = j\Delta\tau$ is the lag distance between the two data points and ρ is the correlation matrix. Given that

the correlation matrix is positive definite, it can be decomposed into upper (L^T) and lower (L) triangular forms via Cholesky decomposition:

$$\rho = LL^T \quad (4)$$

Subsequently, the spatially correlation normal random field, G, is derived by multiplying the lower triangular matrix with a matrix of independent normal random numbers with a mean of zero and a standard deviation of one, denoted as U, as per equation 5:

$$G = LU \quad (5)$$

Finally, by adjusting the normal random field, G, using the mean and standard deviation, stochastic CPT profiles are produced using equation 6:

$$q_t = \bar{q}_t + \sigma G \quad (6)$$

For the corrected cone resistance in this paper, a coefficient of variation of 30% was assumed meaning $\sigma = 0.3\bar{q}_t$.

4 RESULTS AND DISCUSSION

Firstly, an acceptable probability of failure (p_f) was defined at 5%. 10,000 CPT profiles were developed to represent the geotechnical variability across a site. The result of this analysis is shown in Figure 1.

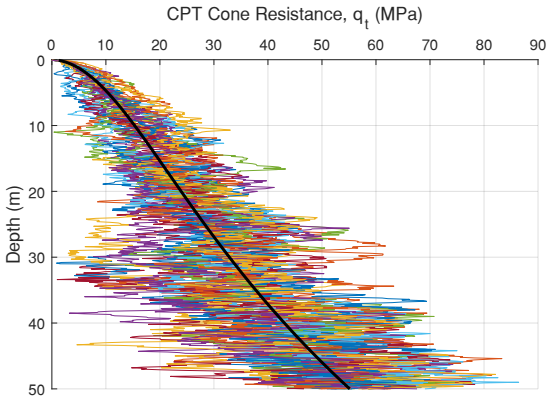

Figure 1. Cone resistance versus depth below seabed (mean profile represented by black line).

For each CPT profile, values of kf and kp were sampled from their distribution and the penetation resistance of the SCA was computed using equation 1. No uncertainty in the geometrical properties of the caisson was considered. Figure 2 shows the total soil installation resistance of the anchor with respect to depth below seabed for a range of pile embedded lengths. The weight of the anchor (black line), maximum installation force including self weight (red line) and total resistance using the mean CPT profile and 'Most probable' (dashed blue line) and 'Highest expected' (dashed black line) k_f and k_p parameters are also included in Figure 2.

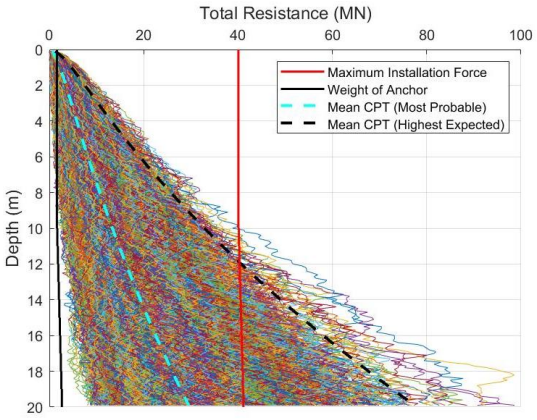

Figure 2. Total installation resistance versus depth below seabed.

Figure 3 shows a box plot of the total resistances across for a range of anchor lengths from 10 – 20m. The mean is shown as a horizontal red line across the centre of each box, with the top and bottom of each box representing +/- one standard deviation from this mean. The whiskers extending from the box show the minimum and maximum values of total resistance at each anchor length. The horizontal stepped green line above each box represents the maximum installation force for that anchor length.

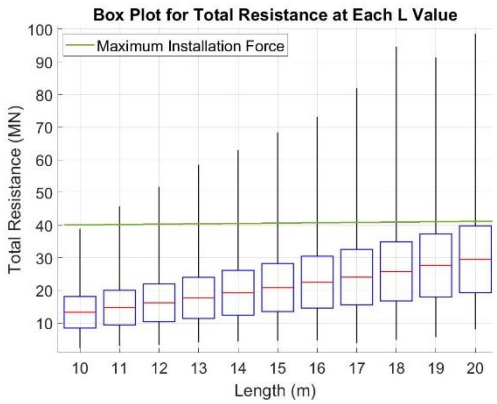

Figure 3. Box plot of total resistance for each anchor length.

The probability of failure in this paper is estimated using Monte-Carlo simulation. The failure criterion was defined using the inequality shown in equation 7:

$$R > maximum\ installation\ force \quad (7)$$

This failure included any instance up to and including the length increment, as the anchor may fail

during installation prior to reaching the target penetration depth.

The probability of failure across all CPT profiles for each length can be determined as N_f/N where N_f is the number of realisations which fail and N is the total number of realisations. A sensitivity analysis was conducted to confirm that 10,000 realisations was adequate to maintain a stable probability of failure for each iteration. Figure 5 shows this analysis for each increment in length. A summary of the maximum installation force and percentage failure for each anchor length is provided in Table 2.

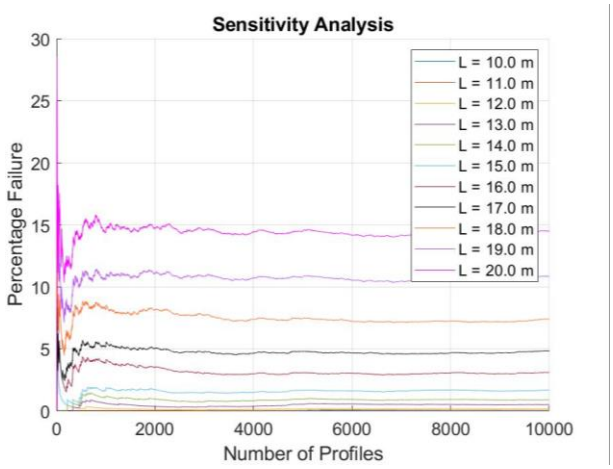

Figure 5. Sensitivity analysis for each anchor length, L.

Table 2. Summary of results.

Length (m)	Maximum Installation Force (MN)	Percentage Failure (%)	Mean Resistance (MN)
10	40.08	0.00	13.30
11	40.18	0.07	14.72

20	41.13	14.47	29.52

5 CONCLUSIONS

This paper explores the potential impact of geotechnical spatial variability on the installation of suction caisson anchors for floating offshore wind turbines. The probability of failure of a range of anchor lengths was investigated using Monte-Carlo simulation with 10,000 realisations. This paper presented an approach to the preliminary installation design of suction caisson anchors from CPT data to account for site-specific variations in ground conditions. This study has shown that Monte-Carlo simulations can be used effectively to enhance quantitative understanding of the impact of geotechnical variability on the suction installation failure/success rate. This work will be developed to incorporate the in-place capacity of an anchor to include an estimation of the site-specific operational probability of failure of suction caisson anchors.

ABSTRACT: Offshore wind farms have been attracting the attention of both researchers and practitioners over the past few decades, due to the growing interest in renewable energy. The choice of a particular foundation, which depends on several factors such as the mechanical properties of soil, depth to bedrock and bathymetry, may influence the overall wind farm cost by up to about 20%. Monopiles are the most used foundation system in the market, whose design can be further refined with advanced numerical analyses, provided that input parameters are properly calibrated. This paper shows the main results of a nonlinear static analysis of a monopile subjected to a horizontal load and embedded in a layered deposit. The analysis was performed using a 3D Finite Element model, where the foundation was represented with *plate* elements, and the soil mechanical behaviour was described with advanced constitutive models. The obtained pushover curves are shown and discussed, from which a reference design condition was selected. Then, the bending moment profile was obtained following three approaches, listed in a descending order of complexity: (1) integration of the stresses at the soil-*plate* interface; (2) derivation of the monopile rotation profile of the *plate* elements; (3) direct output from a *dummy beam* element located at the centreline of the monopile. It is shown that the *dummy beam* provides results in good agreement with those from the other two approaches, suggesting that it may be successfully adopted in practice to speed up the post-processing in the design of monopiles. The methodology presented in this paper would be useful for industrial projects.

RÉSUMÉ: Le développement des parcs éoliens en mer s'est accéléré au cours des dernières décennies grâce aux politiques publiques en matière d'environnement. Les monopieux sont le type de fondation le plus courant. Leur optimisation nécessite des modèles numériques avancés. Cet article présente les principaux résultats de la modélisation par éléments finis 3D d'un monopieu soumis à une charge horizontale. Dans cet exemple, le monopieux est installé dans un sol stratifié composé d'argile et de sable. Les résultats sont présentés en termes de déplacement et rotation du pieu sous l'effet du chargement latéral. L'évolution du moment de flexion le long du pieu est extrait de trois manières différentes: (1) par intégration des efforts à l'interface sol-pieu; (2) par dérivation du profil de rotation calculé à partir du déplacement des éléments coques qui modélisent le pieu; (3) à l'aide d'une poutre fictive modélisée au centre du pieu et qui permet de faciliter l'extraction des résultats. Cet exemple montre que les trois approches mènent à des résultats équivalents. Cela suggère que l'utilisation d'une poutre fictive peut être adoptée afin de faciliter et accélérer la modélisation des monopieux.

Keywords: Offshore wind turbines; monopiles; pushover analysis; 3D Finite Element model; *dummy beam.*

1 INTRODUCTION

Wind energy has emerged as a promising alternative energy source over the last few decades, to fill the world's energy supply and overcome some of the key issues associated with traditional fossil fuels, such as global warming. Particularly in Europe, offshore wind energy shows immense potential thanks to the presence of substantial portions of sea that are ideally suited for the construction of offshore wind farms (OWFs). Thanks to advancements in technology, OWFs have become profitable enough, despite their high construction costs, which depend not only on governmental subsidies, but also on private support. Most of the OWFs budget is allocated to foundation design, construction, and installation. Despite other solutions being under development, monopiles are still the most used type of substructure.

In this paper, the main preliminary results of a nonlinear static (*i.e.*, pushover) analysis of a monopile embedded in a layered deposit are presented. The analyses were carried out with the Finite Element (FE) code *Plaxis 3D* (Bentley, 2023a), considering advanced constitutive models, capable of capturing the nonlinear and irreversible behaviour of the soil. The

results of the analyses are first given in terms of force-displacement and force-rotation curves, together with the bending moment profile developed in the monopile. The latter was computed following three approaches, namely: (1) integration of the stresses at the soil-*plate* interface; (2) derivation of the rotation profile obtained from the *plate* elements representing the monopile; (3) extraction of direct output from a *dummy beam* element located at the centreline of the monopile. It is shown that the *dummy beam* provides results in good agreement with the other two strategies, which may suggest adopting it in the practice to speed up the post-processing step in the design of monopiles.

2 PROBLEM DEFINITION

Figure 1 shows the soil profile considered in the study, together with the geometry of the monopile. The soil profile is composed of two units, namely a clayey and a sandy layer. The layer thickness is equal to 5.2 m for the clay layer and 9.3 m for the sand layer. The water table is located 0.6 m below ground level.

The monopile is a hollow steel pile with an outer diameter $D = 2.0$ m, a wall thickness $t = 0.035$ m, a length $L = 11$ m ($L/D = 5.5$), and an embedment depth $H = 10.0$ m. Although the above dimensions are slightly smaller than those typically adopted for monopiles, they were considered in the numerical study for ease of numerical runs.

3 3D FINITE ELEMENT MODELLING

The Finite Element Analysis (FEA) was performed using the *Plaxis 3D* software to simulate the monotonic test under undrained conditions with a horizontal load applied atop the monopile, with a level arm $e = 0.5$ m with reference to the ground surface.

The mechanical clay behaviour was modelled using the *NGI-ADP* constitutive model (Grimstad *et al.*, 2012), while the sand was simulated using the *HS-small* (*HSS*) model (Benz *et al.*, 2009). The *NGI-ADP* constitutive model has been tailored to model the undrained behaviour of clays, matching both the undrained shear strength and strains at failure for three different stress paths *i.e.*, Active (s_u^A), Direct Simple Shear (s_u^{DSS}), and Passive (s_u^P). The *HSS* model is simple to calibrate and yet capable of capturing the key soil behaviour for the problem under consideration, such as a good representation of the stiffness at small strains and the non-linear stiffness behaviour with increasing strain.

The monopile was modelled using linear elastic, homogeneous and isotropic 6-node triangular *plate* elements with five degrees of freedom per node and quadratic shape functions, characterised by a wall thickness 0.035 m, a unit weight $\gamma = 78.5$ kN/m^3, a Young's modulus $E = 199.2$ GPa, and a Poisson's ratio $\nu = 0.3$. The modulus is slightly lower than that of steel, as a consequence of the code interpreting the input diameter as a centreline diameter: hence, the Young's modulus was corrected so that the bending stiffness *EI* remained unaffected.

The behaviour of the interface within the soil-monopile zone was modelled with linearly elastic-perfectly plastic *interface* elements, whose coefficient of reduction of the shear strength was equal to $R_{inter} = 0.7$ along the shaft and to $R_{inter} = 1.0$ at the base. The FE model consisted of 18117 elements, extending by 40 m along the *y*-axis and by 16 m along the *x*-axis (Figure 2), corresponding to $20 \cdot D$ and $16 \cdot D/2$, while the depth of the model was equal to 14.5 m. These model dimensions resulted from a preliminary sensitivity analysis, which showed that the boundaries did not affect the results when horizontal loads are applied atop the monopile. Also, they are in agreement with previous analyses performed on caisson foundations and onshore wind turbines under seismic loading (Gaudio *et al.*, 2016; 2023).

In the analysis, the monopile was applied a horizontal force at the top, along the *y*-direction: therefore, half of the domain was only modelled, due to the symmetry of the problem.

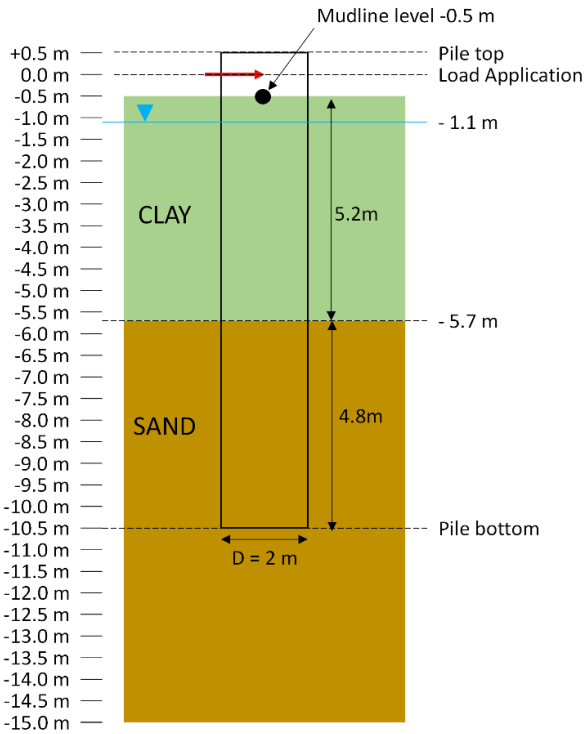

Figure 1. Soil profile and monopile geometry.

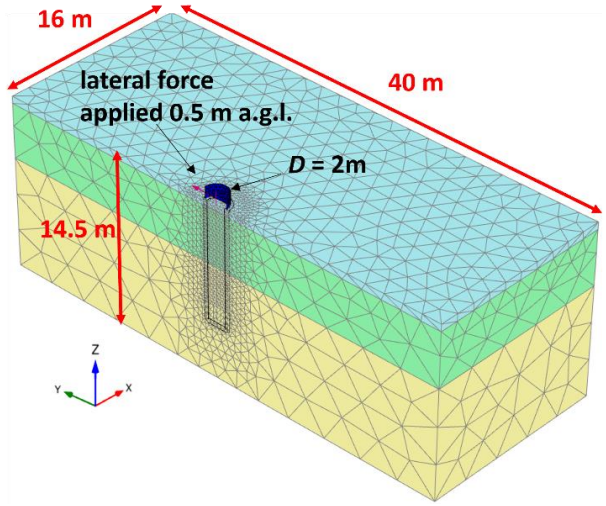

Figure 2. 3D Finite Element model adopted in the study.

3.1 Constitutive model soil parameters

The soil parameters of the constitutive models adopted in the FE analysis are listed in Table 1 and 2 for the *NGI-ADP* and the *HSS* models, respectively, which are representative of the mechanical behaviour of the clayey and sandy layers.

Table 1. NGI-ADP parameters for the clay layer.

4 PUSHOVER CURVES

The results obtained from the nonlinear static analysis are discussed in this paragraph, which was performed as a *Plastic* calculation in Plaxis 3D. The monotonic response of the monopile is presented in Figure 3 in terms of the lateral load against the horizontal pile displacement and rotation of the monopile at the mudline level (see Figure 1).

As expected, the non-linear behaviour of the soil-monopile system was triggered from low levels of horizontal displacement. The displacement $y = D/10 = 0.20$ m is also marked in Figure 3, which was taken as a reference design condition for the assessment of the bending moment acting into the monopile, to compare against the yield moment, M_y, as discussed in the following section. The horizontal load $H_{0.1D} = 3076$ kN was computed for this design condition, which corresponded to a rotation $\theta = 1.49°$.

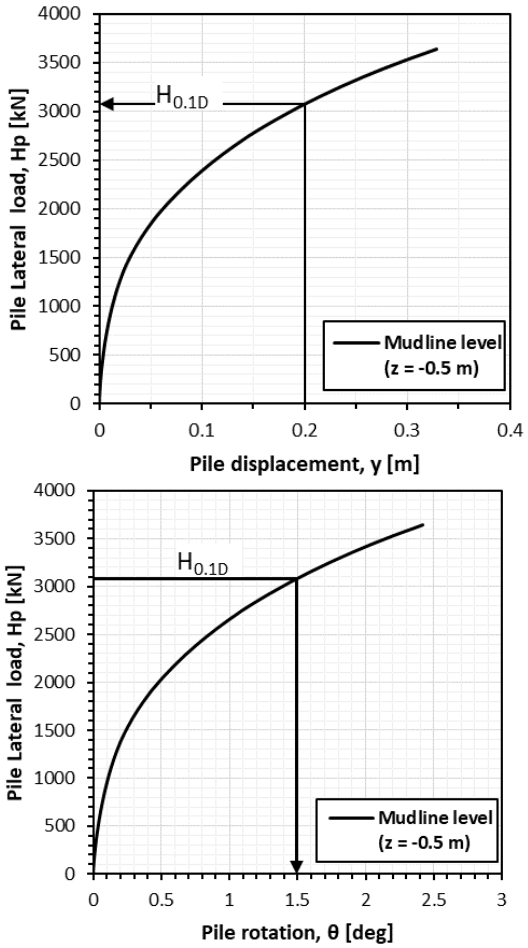

Figure 3. Monotonic pile response at the mudline level.

5 BENDING MOMENT PROFILES

The structural checks of the foundation were made by comparing the maximum bending moment

experienced by the monopile for the reference design condition mentioned above. To this end, the bending moment profile was first evaluated, following three different approaches, such as: (1) integration of the stresses at the soil-*plate* interface; (2) derivation of the rotation profile of the *plate* elements simulating the monopile; and (3) extraction of a direct output from the *dummy beam* element located at the centreline of the monopile.

The results obtained with the three approaches are compared in the next sections, after introducing them in a descending order of complexity.

5.1 Stress integration at the soil-*plate* interface

The bending moment profile was first calculated from the integration of stresses acting at the soil-*plate* interface as below:

$$M_{i,s} = H_p \times e + \int_0^{z_i} \left[p(z) \times \Delta z \right] \cdot dz + \int_0^{z_i} m(z) \cdot dz \quad (1)$$

where subscript i represents a depth counter (i = 1 m, 0.5 m, 0,…,-10.5 m), H_p is the lateral force applied atop the monopile, e = 0.5 m is the distance between the lateral load and the mudline level, $p(z)$ and $m(z)$ are the distributed lateral reaction and moment applied by the soil to the monopile, respectively, and Δz = 0.5 m is the depth interval selected for integration (Figure 4). The distributed lateral reaction $p(z)$ was computed from the integration of the interface forces along the y-direction, while the distributed moment, $m(z)$, was obtained from the integration of forces along the z-direction, multiplied by the respective lever arm $y = D/2$ = 1 m:

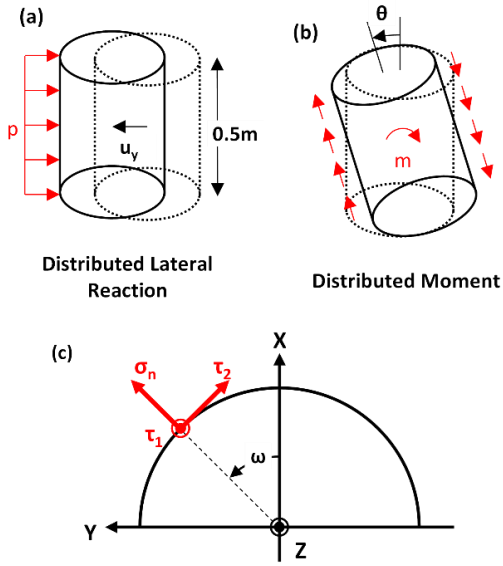

Figure 4. Distributed (a) lateral load p(z) and (b) moment m(z); (c) local coordinate system.

$$p(z) = \frac{\int_{z-\Delta z/2}^{z+\Delta z/2} F_y(z) \cdot dz}{\Delta z} \quad (2)$$

$$m(z) = \frac{\int_{z-\Delta z/2}^{z+\Delta z/2} F_z(z) \times y \cdot dz}{\Delta z} \quad (3)$$

where F_y and F_z are the forces along the y and z-direction, respectively.

Only stresses in local coordinates are accessible rather than forces F_y and F_z in the FE analysis, where σ_n is the stress normal to the interface, while τ_1 and τ_2 are the vertical and horizontal tangential stresses, respectively (Figure 4). The stresses were translated into forces as in eqs. (4) and (5) below, for every stress point, *i.e.*, for a given pair of coordinates, x and y, element area, A, and integration weight, w (Bentley, 2023b):

$$F_y(z) = w \cdot A \cdot \left[\sigma_n(z) \sin\omega - \tau_2(z) \cos\omega \right] \quad (4)$$

$$F_z(z) = w \cdot A \cdot \tau_1(z) \quad (5)$$

5.2 Derivative of rotations of *plate* elements

The bending moment profile was also calculated from the *plate* elements representing the monopile. To this end, the steps reported below were followed, starting from the vertical displacement of the two ends of the plates, whose sign convention is depicted in Figure 5:

- extraction of the back and front vertical displacement of the plate, $u_{z,i}^{front}$ and $u_{z,i}^{back}$, respectively;
- calculation of the pile rotation, θ_i, at the ith depth (i = 1 m, 0.5 m, 0,…,-10.5 m) as:

$$\theta_i = \tan^{-1}\left(\frac{u_{z,i}^{back} - u_{z,i}^{front}}{D} \right) \quad (6)$$

- computation of the bending moment at the ith depth (i = 1 m, 0.5 m, 0,…,-10.5 m), $M_{i,p}$, from the derivative of the pile rotation with depth (*i.e.*, curvature), where EI represents the bending stiffness of the monopile (E = Young's modulus, I = moment of inertia around the vertical axis) as:

$$M_{i,p} = EI \cdot \frac{d \tan\theta_i}{dz} = EI \cdot \left(\frac{\theta_i - \theta_{i+1}}{z_i - z_{i+1}} \right) \quad (7)$$

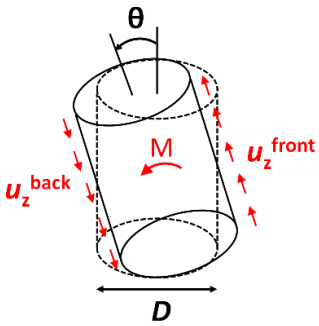

Figure 5. Calculation of the bending moment from plate elements.

5.3 Direct output from the *dummy beam*

Finally, the bending moment profile of the monopile was also obtained from a *dummy beam*, which was introduced at the centreline of the monopile. It is worth noting that this approach has already been routinely followed for excavation wall simulations in 2D conditions, when using continuum elements to model the wall and postprocessing the wall bending moments (Lam, 2018).

The stiffness of the *dummy beam* was selected to be low (*i.e.*, $E_{real}/E_{dummy} \approx 1000$) in order to not affect the results, as this beam was only used as a trick to avoid either integrating stresses acting along the shaft of the monopile or differentiating the *plate* rotation profile. Therefore, a Young's modulus $E_{dummy} = 210$ MPa was assigned to the *dummy beam* element, since the "real" Young's modulus of the monopile was the one of steel, $E_{real} = 199.2$ GPa (see § 3). As for the moment of inertia of the dummy beam, only half of the monopile inertia was considered thanks to the symmetry of the problem, *i.e.*, for the original diameter $D = 2$ m, the moment of inertia of the *dummy beam* was $I = 1/2 \cdot \pi/64 \cdot [D^4 - (D - 2t)^4] = 0.05216$ m^4. The bending moment profile was then extracted as follows:

$$M_{i,b} = \frac{(EI)_{real}}{(EI)_{dummy}} \times M_{dummy,i} = 1897 \times M_{dummy,i} \quad (8)$$

5.4 Comparison of bending moments profiles

A comparison of the bending moment profiles obtained with the three strategies above is made in Figure 6. The bending moments were computed for the design at the reference condition of a horizontal displacement $y = D/10 = 0.20$ m at mudline level. In the figure, the bending moment at yield, $M_y = 33.9$ MN·m, is also plotted.

From Figure 6 it is evident that the three solutions provide quite similar results, both in terms of the bending moment profile and its maximum value. In

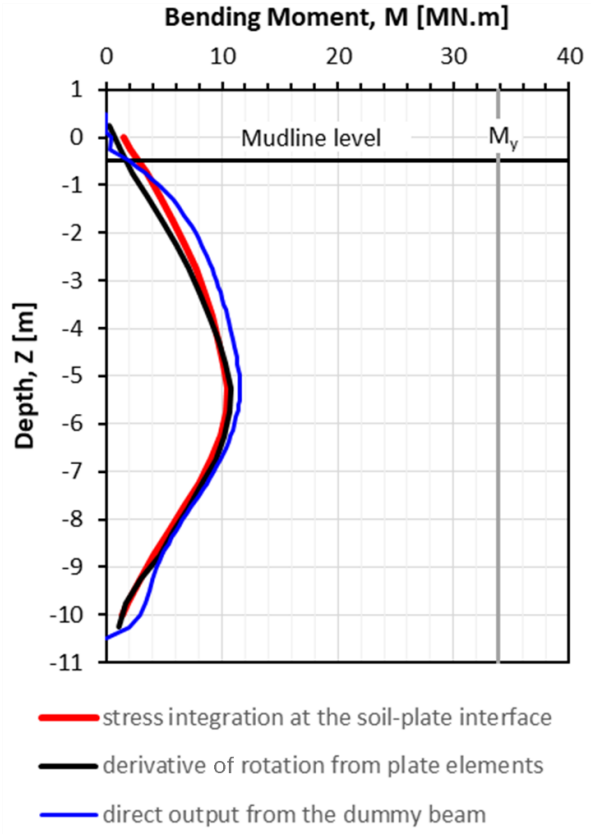

Figure 6. Bending moment profiles along the monopile computed with the three approaches adopted in the study.

particular, it is shown that the maximum bending moment from the stress integration (red line) was equal to $M_{max,\,s} = 10.4$ MN·m, while the one from the derivative of the monopile rotation (black) was equal to $M_{max,\,p} = 10.8$ MN·m, with negligible deviation of about 4.0%. As for the profile from the *dummy beam* (blue), the peak bending moment is equal to about $M_{max,\,b} = 11.5$ MN·m, which corresponded to an overestimation of 1.1 MN·m (~ 9.6%) and 0.7 MN·m (~ 6.1%) from the maximum values obtained from the stress integration and the derivative of rotations from the plate elements, respectively. This result shows that the *dummy beam* provides results in a good agreement with the other two strategies, which may suggest adopting it in the practice in the design of monopiles. Based on project experience of the Authors, the best method to derive the bending moment profile was the derivative of rotation from *plate* element method. The results above are summarised in Table 3.

Table 3. Summary of maximum bending moments (MN·m).

Approach	**Value [MN·m]**	***Comparison with the dummy beam***
stress integration	10.4	– 9.6%
rotation derivative	10.8	– 6.1%
dummy beam	11.5	/

6 CONCLUSIONS

The market of offshore wind turbines has been expanding over the last decades due to climate change, thereby increasing focus on the design of the foundation system, which can represent up to about 20% of the cost of the entire wind farm. Innovative solutions and design methods have therefore been sought to reduce costs of the foundation system.

In this paper, the results of a 3D Finite Element pushover analysis conducted on a monopile embedded in a layered deposit have been presented. In the analyses, the monopile was simulated through *plate* elements and subject to a horizontal force applied to the top of the foundation. The resulting force-displacement and force-rotation pushover curves have been first shown and discussed to detect a reference design condition for the monopile, corresponding to a horizontal displacement at the mudline level equal to one tenth of the outer diameter.

Then, the bending moment profile developed in the monopile has been computed. For the design condition, three different approaches have been used to determine this profile which include the integration of the stresses at the soil-*plate* interface, the derivation of the rotation profile obtained from the *plate* elements representing the monopile, and the extraction of direct output from a *dummy beam* located at the centreline of the monopile. It has been shown that the *dummy beam* provides results in good agreement with the other two strategies, which may suggest adopting it in the practice to speed up the post-processing step in the design of monopiles. It is worth noting that the Timoshenko's beam theory has been adopted in this study, which means that the beam deflection comes both from bending and shearing. This is expected to be well representative of the real behaviour for the monopile at hand. A discussion on the pitfalls of the deterministic approach followed for the *dummy beam* is given in Beck and Silva Jr. (2011).

The capability of 3D Finite Element models of capturing the main features of the soil-monopile behaviour under consideration would always involve a level of uncertainty. It is recommended that these models and results are validated using field-test results or case histories from existing literature.

Technical solutions for reducing CO_2 footprint in MSE wall constructions

Solutions techniques permettant de réduire l'empreinte carbone des murs en terre armée

A. Grandclerc*, T. Joussellin
Terre Armée, Rueil-Malmaison, France

**anais.grandclerc@terre-armee.com*

ABSTRACT: Today, the construction industry represents 6 to 8% of total GWP emission worldwide (Lee and Romero, 2023). Actions have been taken for several years to reduce these emissions, but progress is still being made to reach the global greenhouse gas emission reduction targets. MSE walls are mainly composed of a facing made of concrete or welded mesh panels with a backfill reinforced by metallic or geosynthetic elements. They are one of the least CO_2 intensive earth retaining structures. This article deals with the proposal of technical solutions to reduce each component's carbon footprint of a MSE wall (facing, reinforcement, backfill) and to estimate the CO_2 emission reduction at the construction project level (calculations based on a specific and real construction project). Concerning the concrete panels, the replacement of ordinary Portland concrete by low carbon concrete is a key parameter in the reduction of CO_2 emissions of the construction of a MSE wall (estimation of CO_2 emission reduction between 15% and 30% on the total CO_2 emission for this project). Regarding the backfill reinforcement, using geosynthetic reinforcement instead of steel reinforcement is also a way to reduce CO_2 emissions. Indeed, steel reinforcement accounts for around 20% of total CO_2 emissions for this project, while geosynthetic reinforcement accounts for around 5%. Finally, regarding backfill, its carbon impact represents about 45% of this project's overall CO_2 emissions, considering the materials and their transportation. Thus, using recycled materials as backfill or marginal backfill to reduce transportation distance are essential.

RÉSUMÉ: De nos jours, l'industrie de la construction représente 6 à 8% des émissions mondiales de GES (Lee and Romero, 2023). Des actions ont été entreprises depuis plusieurs années pour réduire ces émissions, mais des efforts doivent encore être fournis pour atteindre les objectifs de réduction des émissions de gaz à effet de serre. Les murs en terre armée sont composés de panneaux en béton ou en treillis soudé et d'un remblai renforcé par des éléments métalliques ou géosynthétiques. Ils sont l'un des ouvrages de soutènement à l'empreinte carbone la plus réduite. Cet article porte sur la proposition de solutions permettant de réduire l'impact de chaque élément constituant un mur en terre armée (parement, renforcement, remblais) et d'estimer la réduction d'émission de CO_2 à l'échelle d'un réel projet de construction. Concernant les panneaux en béton, le remplacement des bétons à base de ciment Portland par des bétons bas carbones est un paramètre clé dans la réduction de l'empreinte carbone d'un mur en terre armée (réduction comprise entre 15 et 30% sur l'émission totale de CO_2 du projet). Par ailleurs, l'utilisation de bandes en géosynthétiques à la place des renforcements métalliques pour le remblai est aussi une solution pour réduire l'impact carbone des projets. En effet, les renforcements métalliques représentent 20% des émissions totales du projet, tandis que les renforcements en géosynthétiques représentent uniquement 5%. Concernant le remblai, son impact représente environ 45% des émissions carbones totales. Ainsi, il est essentiel d'utiliser des matériaux recyclés comme remblais et de réduire les distances de transport.

Keywords: Carbon footprint; MSE wall; low-carbon solutions.

1 INTRODUCTION

Progress is still being made to reach the global greenhouse gas emission reduction targets in the construction industry which represents 6 to 8% of total GWP emission worldwide (Lee and Romero, 2023).

MSE wall (Reinforced Earth® wall) components are divided into three parts (Figure 1):

- Facing made of concrete reinforced by steel or welded mesh panels.
- Backfill
- Steel or geosynthetic reinforcements for the backfill.

MSE walls are one of the least CO_2 intensive earth retaining structures.

For this study, a real construction project is considered. The carbon footprint of the components used in the project but also the transportation from the

plants to the construction site, are calculated. A scheme of MSE wall is presented in Figure 2.

In the following, the CO_2 emissions associated with this construction project will be calculated, and then alternatives will be proposed with technical solutions that emit less CO_2.

Figure 1. Description of MSE wall.

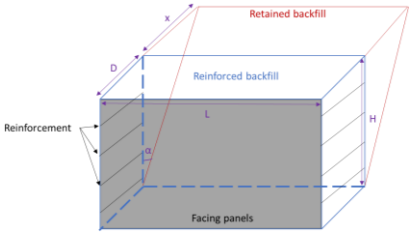

Figure 2. Schematic representation of MSE wall.

2 DESCRIPTION OF THE MSE WALL CONSIDERED FOR THIS STUDY

The construction project considered for this study is a MSE wall composed of reinforced concrete panels as facing, geosynthetic straps as reinforcements of the backfill and backfill.

In this study, the manufacturing of the components, and the transportation of components from the factories to the construction site are considered. The quantities used for this project are presented in Table 1 and in Table 2 and are calculated for 1 m² of wall. The weights of reinforced backfill and retained backfill are calculated from geometrical dimensions of the wall section (Figure 2). The emission factors used to calculate the carbon footprint of this project are presented in Table 3.

Table 1. Geometrical dimensions of the wall and quantity of material for 1 m² of wall.

Designation	Quantity
Surface considered	1 m²
Average height	4 m
Average depth	5 m
Steel reinforcement ratio of the panels	5 kg/m²
% of recycled steel for the panel reinforcement	99%
Total length of backfill reinforcements	14 linear meters
Weight of reinforced backfill	7.5 t
Weight of retained backfill	3 t

Table 2. Transportation of materials from the plants to the construction site.

Materials	Type of transportation	Distance (km)
Facing panels	Truck	150
Geosynthetic reinforcements	Truck	500
Backfill	Truck	20

Table 3. Emission factors used in this study.

Materials	Emission factors	Unit	Database
Concrete	300	$kgCO_2e/m^3$	Exegy solutions, 2022
First cast steel in concrete	1.99	$kgCO_2e/kg$	ICE Database V3, 2019
Recycled steel in concrete	0.565	$kgCO_2e/kg$	EcoInvent v3.10, 2023
Geosynthetic reinforcements	0.30	$kgCO_2e/lm$	EPD GeoStrap, 2021
Backfill	4	$kgCO_2e/t$	Base carbone (V22), 2023
Steel straps (galvanized steel)	2.67	$kgCO_2e/kg$	LCI study, 2021

The result obtained for this construction project is equal to **99 $kgCO_2e$ for 1 m² of MSE wall**.

CO_2 footprints of components (manufacturing and transportation of components to the construction site) of MSE wall are broken down as follows (Figure 3):

- 47% for concrete reinforced by steel panels.
- 4% for reinforcement of backfill.
- 49% for backfill itself.

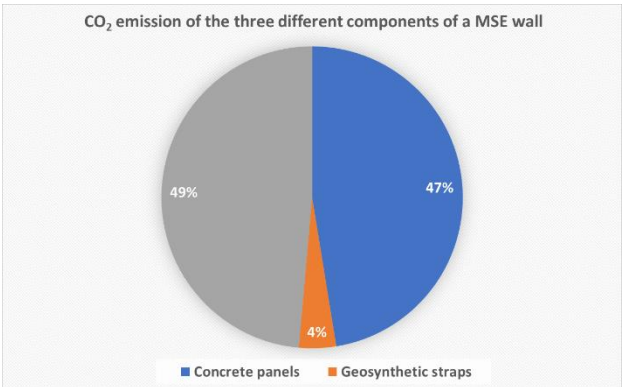

Figure 3. Breakdown of CO_2 emission of a MSE wall specific project.

3 TECHNICAL SOLUTIONS TO REDUCE CARBON FOOTPRINT

3.1 Facing panels

In this part, the impact of using low carbon concrete is studied. Three categories of low carbon concretes are defined in terms of emission factors for concrete with a compressive class strength between C35/45 to C45/55 (MPa), which is the most common strength classes used for concrete panels in MSE applications (Table 4). The emission factors are extracted from Exegy solutions, 2023.

Table 4. Emission factors for three low carbon concrete categories according to Exegy solutions, 2023.

Category	Emission factors minimum	Emission factors maximum	Unit
Classic concrete	240	-	$kgCO_2e/m^3$
Low carbon concrete	175	240	$kgCO_2e/m^3$
Very low carbon concrete	120	175	$kgCO_2e/m^3$
Ultra-low carbon concrete	-	120	$kgCO_2e/m^3$

The impact of using low carbon, very low carbon and ultra-low carbon categories on total CO_2 emission of a MSE wall is proposed in Table 5.

Table 5. Impact of using low carbon concretes on the CO_2 emission of a MSE construction project.

Category	Emission factors ($kgCO_2/m^3$)	Total CO_2 emission ($kgCO_2e$) for 1m² of MSE wall
Classic concrete	300	99.35
Low carbon concrete	200	85.35
Very low carbon concrete	150	78.35
Ultra-low carbon concrete	100	71.35

The use of low-carbon concrete reduces the carbon footprint of the entire structure by 14% for low carbon concrete, 21% for very low carbon concrete and 28% for ultra-low carbon concrete.

3.2 Reinforcements of backfill

In this part, the impact of using steel straps with 50% of recycled steel instead of geosynthetic straps is studied. The results are presented in Table 6.

Table 6. Impact of using steel straps instead of geosynthetic straps on the CO_2 emission of a MSE construction project.

Type of reinforcement	Emission factors ($kgCO_2/kg$)	Total CO_2 emission ($kgCO_2e$) for 1m² of MSE wall
Steel straps (50% recycled)	1,62*	109.16
Geosynthetic straps	3,3**	99.35

** from steel with 50% recycled, from [EcoInvent v3.1, 2014].*
***from [EPD GeoStrap, 2021].*

The use of geosynthetic straps reduces the carbon footprint of the entire structure by 9% compared to the use of steel strips with 50% of recycled steel.

3.3 Backfill

This section examines the CO_2 footprint impact of the distance of transportation for the backfill.

As mentionned in section 2, backfill represents 49% on the total CO_2 emission of the specific MSE wall construction project considered in this study and 15% of the CO_2 emission from the backfill is occupied by the transportation to the construction site.

Table 7 presents the study of the impact of transportation distance on the CO_2 footprint of the structure.

Table 7. Impact of transportation distance of backfill on the CO_2 emission of a MSE construction project.

Distance of backfill transportation (km)	Total CO_2 emission ($kgCO_2e$) for 1m² of MSE wall
20	99.35
50	108.75

It is important to use a fill material from the closest possible source to the construction site, as increasing the transportation distance from 20 to 50 km increases the project's CO_2 emissions by 8.6%.

4 CONCLUSIONS

The three alternatives proposed have a significant impact on the total CO_2 footprint of a MSE wall. Indeed, the calculation of the carbon footprint of a project with the most polluting assumptions (steel straps, conventional concrete for the panels, 50 km for the transportation of the backfill) results in a total CO_2 emission of 118.56 $kgCO_2e$, while for a project with the least polluting assumptions (geosynthetic straps, Ultra-low-carbon concrete, and 20 km for the transportation of the backfill), the total emission is equal to 71.35 $kgCO_2e$. Using low carbon concretes

seems a key parameter to reduce CO_2 emission of this type of construction.

This study demonstrates that feasible solutions can significantly reduce the carbon emissions of a MSE wall.

Other alternatives exist, such as increasing the amount of recycled steel in steel strips or replacing the steel reinforcement in panels with glass or basalt fibers reinforcement or using recycled materials such as crushed concrete as backfill.

ABSTRACT: Many authors working on soil permeability put forward the proportionality of its value with the term $e^3/(1+e)$, where e is the void ratio. Others working on soils having a sandy-silty-clayey matrix, consider that the natural logarithm of their permeability is proportional to e. These two relations are very different. The link between them will be presented. Then, the way to calculate the soil permeability through that of the 0-400µ fraction will be detailed.

RÉSUMÉ: De nombreux auteurs travaillant sur la perméabilité des sols avancent que leurs perméabilités est proportionnelle au terme $e^3/(1+e)$, où e est leur indice des vides. D'autres travaillant sur des sols à matrice sablo-limono-argileuse considèrent que le logarithme décimal de leurs perméabilités est proportionnel à e. Ces relations sont très différentes. Le lien qui les relie est présenté. Puis sera détaillée la manière de calculer la perméabilité du sol au travers de celle de la fraction 0-400µ.

Keywords: Soil permeability; void index; liquidity limit; plasticity index; volume-specific area.

1 INTRODUCTION

When working on soil permeability k, geotechnical engineers use relationships linking its value to void ratio e. Chapuis, for example propose its proportionality to the term $e^3/(1+e)$ and Tavenas put forward a linear relationship between the natural logarithm of k and e.

In order to make the comparison possible between the two relationships, a general geotechnical framework is at first proposed in order to classify the type of soil we are working on. Then, the importance of the notion of the equivalent vertical stress σ'_{eq} will be presented. Comparing the correlation for 0-400µm soils due to Terzaghi between compressibility index Cc and the liquidity limit wl to the relationship in a oedometer test between Cc and the vertical pressures σ'_1 and $\sigma'_{7,5}$ explaining water-contents equal to liquidity limit and 7,5% will be deduced the value of $\log\sigma'_{7,5.}$ Then, still in an oedometer test diagram, we will develop a relationship between void ratio at a vertical pressure of σ'_{eq} defined in paragraph 3 and a relationship between soil dry density and liquidity limit and $\sigma_{eq.}$. It will then imply a linear relationship between $\log(e^3/(1+e))$ and e for 0-400µm soils. For 0-D soils, a difficulty will remain, that is the evaluation of the volume-specific surface as proposed by Chapuis and appearing in the general relationship giving k. Will then be presented improved ways compared with those suggested by Chapuis and Locat,soil permeability being deduced from the assesmnent of the permeability of the 0-400µ fraction.

2 PROPOSED GENERAL GEOTECHNICAL FRAMEWORK.

We work on soils having a 0-D particle size distribution curve, D being the lowest diameter of the

maximum particle size. The passing value at 400µ is written %400µ.
It is then important to distinguish those where D is equal to or less than 400µm, and when D is greater than 400µm, those for which 400µ-D grains are scattered in the 0-400µ matrix and those where they are in contact. When scattered, then a consolidation process explais their density. In both cases, we can notice that soil permeability of the 0-D soil is the permeability of the 0-400µ fraction, adjusted by the surface of the 0-400µ fraction passed through by the waterflow:

$$k_{0\text{-}D} = \%400\mu(\gamma_{d0\text{-}D}/\gamma_{0\text{-}400\mu})\, k_{0\text{-}400\mu} \quad (1)$$

Secondly, the dry density of the total soil $\gamma_{d0\text{-}D}$, of the 0-400µ fraction $\gamma_{d0\text{-}400\mu}$and of the grains γ_s are linked in both cases by the relationship:

$$1/\gamma_{d0\text{-}D} = \%400\mu / \gamma_{d0\text{-}400\mu} + (1\text{-}\%400\mu)/\gamma_s \quad (2)$$

For 0-400µm soils, grains 400µ-D scattered, they are generated by a consolidation process, through a first loading at a preconsolidation pressure σ'_p followed by an unloading at σ'_{v0} kPa, vertical effective pressure. The soils are supposed not to be cemented. They don't include organic matters and are not saline. Their sensitivity St is lower than 4.

3 EQUIVALENT VERTICAL PRESSURE

The equivalent pressure σ'_{eq} is the vertical pressure that would lead through a normally consolidated process to the same soil void ratio than that due to the loading and unloading process. Its value is linked to σ'_p and σ'_{V0} through the relationship:

$$\sigma'_{eq} = \sigma'^{(Cs/Cc)}_{vo}\, \sigma'^{((Cc-Cs)/Cs)}_{p} \quad (3)$$

Cc compression index and *Cs* recompression index, measured by an oedometer test, then for *D* less than 3,2mm.

4 DRY DENSITY, LIQUIDITY LIMIT AND EQUIVALENT VERTICAL PRESSURE

For 0-400µm soils, one correlation is well known between Cc compressibility index and liquidity limit wl due to Terzaghi:
Cc = 0,009 (wl - 10) that can be written with little difference:

$$Cc = 0{,}0085(wl - 7{,}5),\ wl \text{ in } \% \quad (4)$$

Looking at an oedometer diagram, we can write:

$$Cc = \gamma_s/\gamma_w\ (wl - 7{,}5)/100/\log(\sigma'_{7,5}/\sigma'_1) \quad (5)$$

where σ'_1 and $\sigma'_{7,5}$ are vertical effective stresses leading to void ratios corresponding to a saturated water content equal to liquid limit and to 7,5%, γ_s and γ_w being grains and water density.

Comparing (4) with (5), it appears that for $\log\sigma'_1=1$ corresponding to σ'_1 = 10 kPa, then $\log\sigma'_{7,5}$ = 4,2. We can then write, using the second relationship hereafter:

$$Cc = \gamma_s/\gamma_w\ (wnoc - 7{,}5)/100/\ (\log\sigma'_{7,5} - \log\sigma'_{eq}) \quad (6)$$

$$\gamma_w/\gamma d = \gamma_w/\gamma_s + 0{,}075 + 0{,}00315(wl-7{,}5)(4{,}2-\log\sigma'_{eq}) \quad (7)$$

or, with σ'_{eq} in kPa:

$$eoc = \gamma_s/\gamma_w\ (0{,}075 + 0{,}00315(wl-7{,}5)(4{,}2-\log\sigma'_{eq})) \quad (8)$$

or:

$$eoc = 0{,}20 + 0{,}0085\ (wl-7{,}5)\ (4{,}2-\log\sigma'_{eq}) \quad (9)$$

For 0-D soils, we will have to make a correction on γ_d through relationship (2).

5 GENERAL RELATIONSHIP GIVING k

For a water at a temperature of 10 degrees Celsius, Kozeny and Carman general equation giving k in m/s is:

$$k = 1{,}5\ 10^{-6}\ (1/vssa)^2\ e^3/\ (1+e) \quad (10)$$

where vssa is the volume-specific surface area (m^{-1}), calculated through the gradation curve as proposed by Chapuis and Locat, and developed in paragraph 7.

For a water at a temperature t, k given by (9) must be multiplied by the expression:

$$\alpha = 0{,}737 + 0{,}025\ t + 0{,}00016\ t^2 \quad (11)$$

due to the water dynamic viscosity variation with temperature. In Martinique island, for a water at 30 degrees, k must be multiplied by 1,63.

6 CALCULATION OF log(e^3/(1+e)) AS A FUNCTION OF wl AND e FOR 0-400µ SOILS

Through relationship (9), we calculate values of e for varying values of σ'_{eq} and liquid limit wl. Then we calculate log (e^3/(1+e)) and compare its value to e.

The results are summarized in Table 1.

Table 1. values of e for varying values of σ'eq and liquid limit wl.

wl	σ'eq kPa	50	100	150	200
0,20	E	0,46	0,43	0,41	0,40
	log(e^3/(1+e))	-1,16	-1,24	-1,30	-1,33
0,40	e	0,89	0,81	0,76	0,72
	log(e^3/(1+e))	-0,43	-0,53	-0,60	-0,66
0,60	e	1,32	1,18	1,10	1,05
	log(e^3/(1+e))	-0,007	-0,12	-0,19	-0,25
0,80	e	1.74	1.56	1.45	1.37
	log(e^3/(1+e))	0,28	0,17	0,09	0,03
1,00	e	2,17	1,93	1,79	1,69
	log(e^3/(1+e))	0,51	0,39	0,31	0,26

Looking at the values displayed in Table 1 and shown in Figure 1, it appears that they obey to the general relationship:

$$log(e^3/(1+e)) = A + Be \qquad (12)$$

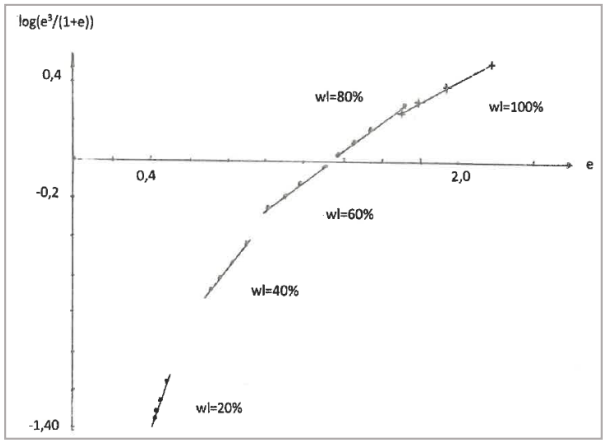

Figure 1. Relations between log (e^3/(1+e)) and e.

Table 2. Values of A and B

wl	0,20	0,40	0,60	0,80	1,00
A	-2,444	-1,658	-1,200	-0,884	-0,638
B	2,762	1,382	0,907	0,710	0,528

It appears that A and B are hyperbolic functions of wl, as shown by Figure 2:

$$A = - 0,706/ (wl + 0,0883) \qquad (13)$$

$$B = 0,529/ (wl – 0,009) \qquad (14)$$

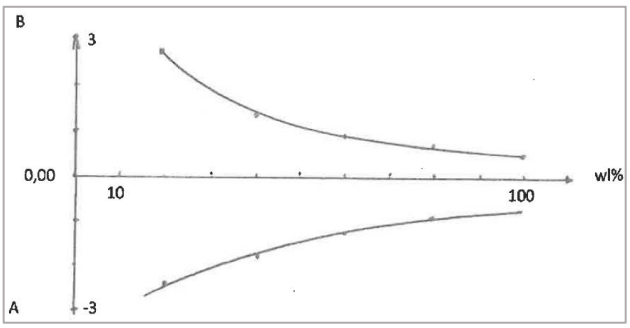

Figure 2. Values of A and B function of wl.

Then taking the natural logarithm of each member, relationship (10) becomes:

$$logk = 6,176 - 2log\ vssa + log(e^3/(1+e)) \qquad (15)$$

and using expressions (12), (13) et (14):

$$logk=6,176-0,706/(wl+0,0883)-2logvssa+0,529e/(wl-0,009) \qquad (16)$$

In the proposed framework of thinking, it appears that the natural logarithm of permeability is indeed a linear function of void ratio e for 0-400µm soils.

7 CHAPUIS AND LOCAT CALCULATION OF VSSA

We need to have the soil particle size distribution and the soil dry density $\gamma d_{0\text{-}D}$. We will use relationships (1) and (10),and for the latter vssa and e are those of the 0-400µ fraction.

7.1 Soils having a non-plastic matrix, PI of the 0-400µ fraction being less than 10.

Chapuis and Legaré (1992), suggest to calculate vssa through the grain size curve, and the expression:

$$vssa = 6\ \Sigma\ (Pnod_i – Pnod_{(i+1)})/(d_{(i+1)} \qquad (17)$$

($Pnod_i$ – $Pnod_{(i+1)}$) is the difference between the percentage by weight smaller than size d_i and that larger than next size $d_{(i+1)}$, vssa unit being m2/m3. The grain size curves always have a minimum measurable particle size dmin. In the method of Chapuis and Legaré, an equivalent size deq must be defined for all particles smaller than dmin through the expression:

$$deq^2 = dmin^2/3 \qquad (18)$$

the percentage in weight dedicated to deq being the difference between 100% and the percentage value

corresponding to dmin. Secondly (figure 3), in the fine size zone, the grain size distribution has to be modified to follow a minimum slope of 20% (Chapuis).

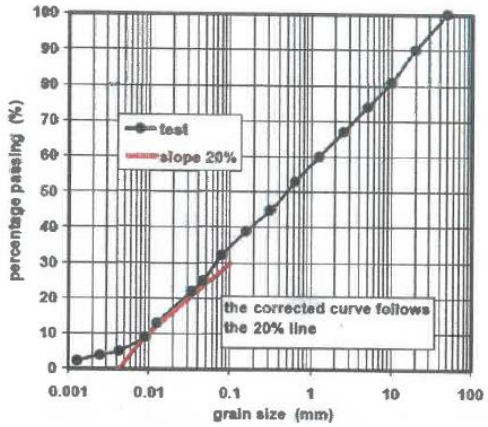

Figure 3. Chapuis proposed modification if slope flatter than 20%.

The assessment of vssa is made on the 0-400µ fraction. The void index is that of the 0-400µ fraction, equal to the void index of the 0-D soil,divided by the volume of the 0-400µ grains:

$$e_{0\text{-}400\mu} = (\gamma_s/\gamma_{dO\text{-}D} - 1)/(\%400\mu\ \gamma d_{0\text{-}D}/\gamma_s) \quad (19)$$

7.2 Soils having a plasticity index of the 0-400µ fraction greater than 10.

The mssa value is that of the 0-400µ fraction calculated through Locat (1984) proposals. Chapuis gives on Figure 4, Locat correlation between mass specific surface area and percentage smaller than 2µm. Based on this suggestion, we propose the underlying correlation:

$$mssa \text{ in } m^2/kg = 10^3(5+1.2\ PI) \quad PI \text{ in } \% \quad (20)$$

We know (Gress) that:

$$PI = -4(1-\%2\mu) + 4.5\ \%2\mu\ VB2\mu \quad (21)$$

VB2µ being the methylene blue value of the 0-2µ fraction.

(20) can then be expressed as:

$$mssa = 10^3\ (0.2 + \%2\mu\ (4.8 + 5.4\ VB2\mu)) \text{ in } m^2/kg \quad (22)$$

Figure N°4 gives the link between mssa value of the 0-400µ fraction , the passing at 2µ and the blue methylene value of the 0-2µ fraction VB 2µ.

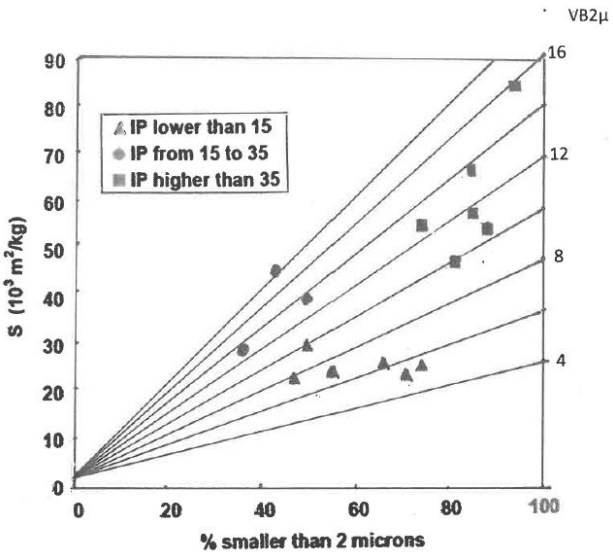

Figure 4. Locat highlighted by VB2µ values.

The link between vssa and mssa is given by:

$$vssa = \rho_s\ mssa,\ \rho_s \text{ given in kg/m}^3 \quad (22)$$

8 CONCLUSIONS

The reason why the natural logarithm of permeability is a linear function of void ratio for 0-400µ soils has been explained.

Furthermore, ways to estimate the soil permeability have been given in order to calculate the permeability of all 0-D soils through Kozeny- Carman expression, through that of the 0-400µ fraction.

All these proposals are valid in the general framework of working, we have detailed. Difficulties will still be due to the quality of the samples on which we will measure dry densities and determine grain size curves.

Theoretical assessment of the advective-diffusive transport of contaminants through landfill composite liners

Évaluation théorique du transport advectif-diffusif de contaminants permis les barrières composites des décharges

N. Guarena*, A. Dominijanni, M. Manassero
Polytechnic University of Turin, Turin, Italy

**nicolo.guarena@polito.it*

ABSTRACT: Composite liners consisting of a geomembrane, placed over a low-permeability clay layer, are used throughout the world for the lining of waste disposal facilities, with the aim to prevent the groundwater quality from being compromised, and an unacceptable risk for the human health and the environment from occurring. Despite the importance of developing a rational approach to calculate the contaminant transport rate through composite liners, for both the design of new landfills and the risk assessment of the existing ones, limited attention has been paid so far to the derivation of analytical, numerical, or hybrid analytical-numerical solutions, which can help designers assess the containment performance of lining systems. After an overview of the simplified calculation approaches that are currently adopted for the performance-based design of composite liners, a novel theoretical framework is presented in this paper, which allows the advective-diffusive transport of inorganic contaminants to be modelled considering imperfect contact conditions between the geomembrane and the underlying clay layer.

RÉSUMÉ: Les barrières composites constituées d'une géomembrane, placée sur une couche d'argile à faible perméabilité, sont utilisés dans le monde pour l'isolement des installations de stockage des déchets, pour éviter que la qualité des eaux souterraines ne soit pas compromise et ne présente pas un risque inacceptable pour la santé et l'environnement. Malgré l'importance de développer une approche rationnelle pour calculer le taux de transport des contaminants permis les barrières composites, pour la conception de nouvelles décharges et pour l'évaluation des risques des décharges existantes, une attention limitée a été accordée jusqu'à présent à l'élaboration de solutions analytiques, numériques ou hybrides analytiques-numériques, qui peuvent aider les ingénieurs à évaluer les performances de confinement des systèmes d'isolement. Après un aperçu des approches de calcul simplifiées actuellement adoptées pour la conception basée sur les performances des barrières composites, un nouveau cadre théorique est présenté dans cet article, qui permet de modéliser le transport advectif-diffusif des contaminants inorganiques en considérant des conditions de contact imparfaites entre la géomembrane et la couche d'argile sous-jacente.

Keywords: Contaminant transport; geosynthetics; landfills; performance-based design; risk assessment.

1 INTRODUCTION

Composite liners that include a high-density polyethylene (HDPE) geomembrane (GM), placed over a compacted clay liner (CCL), are prescribed throughout the world for the bottom lining systems of waste disposal facilities, with the goal of minimising the migration of contaminants from the waste fill to the surrounding environment (Giroud and Cazzuffi, 1989). Furthermore, the use of alternative lining systems, such as those in which the CCL is replaced with a geosynthetic clay liner (GCL), is permitted in most regulations, provided that equivalency with the prescribed composite liner is demonstrated on the basis of a selected performance criterion. The most widely adopted approach is to assume that equivalency is demonstrated if the steady-state advective travel time through the proposed alternative liner is lower than that through the prescribed liner, but this approach fails to recognise that diffusion is a significant, if not the dominant, contaminant transport mechanism within low-permeability clay liners (Manassero and Shackelford, 1994; Foose et al., 2002; Shackelford, 2014). For such a reason, the performance criteria that account for the combined effect of advection and diffusion on contaminant transport, under either steady-state or transient-state conditions, are preferable over the advective travel time criterion (Shackelford, 1990; Manassero et al., 2000; Katsumi et al., 2001; Rowe and Brachman, 2004).

Although several analytical, numerical, and empirical solutions have been developed, since the pioneering study of Giroud and Bonaparte (1989), to calculate the liquid flux through landfill composite liners, relatively few studies have been aimed at quantifying the advective-diffusive transport of contaminants in the presence of defects in the GM layer (e.g., defective seams between adjacent panels, punctures caused by sharp materials beneath and above the GM, and tensile failures induced by the landfilling operations). The latter issue is particularly relevant in the case of inorganic compounds, which, unlike many organic compounds, do not readily diffuse through intact portions of the GM and, therefore, their transport should be recognised as a three-dimensional (3D) process that involves migration through the GM defects, through the interfacial zone between the GM and the underlying low-permeability mineral layer and, finally, through the mineral layer itself, via a combination of advection and diffusion.

A simplified approach to model the advective-diffusive transport of inorganic contaminants through composite liners was proposed by Katsumi et al. (2001), who identified an equivalent one-dimensional (1D) system for which analytical solutions to the contaminant breakthrough time and mass flux exist. This approach, which has since been implemented in a number of analytical studies that have dealt with the performance-based design of landfill lining systems, allows both steady-state (Foose, 2010; Guarena et al., 2020; Dominijanni and Manassero, 2021; Dominijanni et al., 2021) and transient-state contaminant transport analyses (Foose et al., 2001; Kandris and Pantazidou, 2012; Dominijanni et al., 2023) to be carried out using typical spreadsheet applications and hand-held calculators. Despite being particularly attractive because of its versatility, the Katsumi et al. (2001) approach is not devoid of drawbacks, the most serious of which can probably be ascribed to neglecting the mass conservation condition for the solute phase. The objective of this paper is thus to illustrate a novel theoretical framework, which has recently been developed by Guarena et al. (2023) with the aim of covering the aforementioned modelling gap.

2 THEORETICAL FRAMEWORK

The theoretical framework outlined herein has been developed under the assumption that inorganic contaminants preferentially migrate through holes that are located in correspondence to the wrinkles of the GM layer, rather than through holes that occur in flat areas. Therefore, only the case of a damaged wrinkle of width $2b_w$ is referred to in this paper, which is perfectly analogous to the case of a cut, tear, or defective seam of width $2b_w$ occurring in a flat area of the GM if the liquid and contaminant transport rates are not controlled by the size of the actual holes in the wrinkle (Figure 1). Moreover, if the length of the defect, L_w, is much greater than its width (i.e., defect of uniform width and infinite length), the liquid and contaminant transport analyses can be treated as two-dimensional problems (Touze-Foltz et al., 1999; Giroud and Touze-Foltz, 2005).

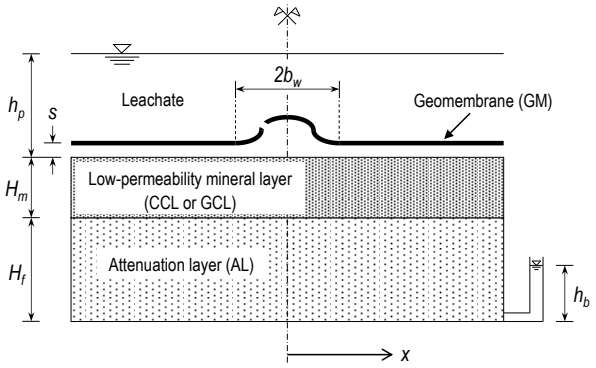

Figure 1. Reference scheme for the liquid and contaminant transport analyses through a composite liner with a defect of uniform width and infinite length in the GM layer and imperfect contact conditions between the GM and the low-permeability mineral layer (not to scale).

2.1 Katsumi et al. (2001) approach

The approach that was proposed by Katsumi et al. (2001), with the aim of providing a simple calculation tool to analyse the transport of inorganic contaminants through composite liners when the leachate flow is at steady state, consists in computing an equivalent area, A_e, which conducts the same (total) leachate flow rate as the considered defect for the same hydraulic head drop across the composite liner. If Rowe's (1998) analytical model for non-interacting defects of uniform width and infinite length is adopted to assess the leachate flow rate, the equivalent area is expressed as follows:

$$A_e = 2b_w L_w \left(1 + \frac{1}{\alpha b_w}\right) \tag{1}$$

The α parameter that appears in Equation 1 can be interpreted as the exponential decay constant of the hydraulic head beneath the GM, and is given by:

$$\alpha = \sqrt{\frac{k_s}{\left(H_f + H_m\right)\theta_h}} \tag{2}$$

where θ_h is the hydraulic transmissivity of the interfacial zone between the GM and the low-permeability mineral layer, and k_s is the equivalent hydraulic conductivity corresponding to the low-permeability mineral layer (saturated hydraulic conductivity k_m) and the attenuation layer (AL) (saturated hydraulic conductivity k_f):

$$k_s = \frac{H_f + H_m}{\frac{H_f}{k_f} + \frac{H_m}{k_m}} \tag{3}$$

Once the equivalent area has been computed, the contaminant mass flow rate through the GM defect, J_e, can be obtained as the product of A_e and the contaminant mass flux, which in turn is calculated according to the existing analytical solutions to the partial differential equation that governs the 1D solute transport through multi-layerd barriers via advection, diffusion, sorption, and degradation. When steady-state conditions are achieved for both the liquid and solute transport, the dimensionless contaminant mass flow rate through the GM defect, J_e^*, which is defined as the ratio of J_e to the advective component of the mass flow rate occurring below the defect, is given by:

$$J_e^* = \left(1 + \frac{1}{\alpha b_w}\right) \frac{\exp(P_L) - \chi_b}{\exp(P_L) - 1} \tag{4}$$

where P_L is the Péclet number and χ_b is the ratio of the contaminant concentration at the bottom of the composite liner to that in the leachate drainage layer.

The Péclet number can be assessed as follows:

$$P_L = \frac{i_s k_s}{\Lambda} \tag{5}$$

where i_s is the maximum mean hydraulic gradient through the low-permeability mineral layer and the attenuation layer, and Λ is the equivalent diffusivity:

$$i_s = 1 + \frac{h_p - h_b}{H_f + H_m} \tag{6}$$

$$\Lambda = \frac{1}{\frac{H_f}{n_f D_f^*} + \frac{H_m}{n_m D_m^*}} \tag{7}$$

being n_m and n_f the porosities of the low-permeability mineral layer and the attenuation layer, respectively, and D_m^* and D_f^* the effective diffusion coefficients of the low-permeability mineral layer and the attenuation layer, respectively, which are obtained as the product of the apparent tortuosity factor, τ (< 1), and the free-solution diffusion coefficient of the contaminant, $D_{s,0}$.

2.2 Guarena et al. (2023) approach

According to the theoretical framework which has recently been developed by Guarena et al. (2023), the 3D advective-diffusive transport of inorganic contaminants within the composite liner is conceptualised as a horizontal flow along the interface between the GM and the low-permeability mineral layer and then a vertical flow in the low-permeability mineral layer, in a similar way to the reference scheme that was considered by Rowe (1998) and Touze-Foltz et al. (1999, 2001) with a view to approximating the actual leachate flow network under imperfect contact conditions at the GM/CCL or GM/GCL interface.

If steady-state conditions are achieved for both the liquid and solute transport, the contaminant concentration profile beneath the GM satisfies the following homogeneous, second-order, linear ordinary differential equation with non-constant coefficients:

$$\frac{\mathrm{d}^2\chi}{\mathrm{d}\xi^2} - \frac{\Theta}{\exp(\xi)}\frac{\mathrm{d}\chi}{\mathrm{d}\xi} + \\ - \frac{\Theta}{\exp(\xi)\left[\exp\left(\frac{P_L}{\exp(\xi)}\right) - 1\right]}(\chi - \chi_b) = 0 \tag{8}$$

which has to be solved for $0 \le \xi < +\infty$ in conjunction with the following set of boundary conditions:

$$\begin{cases} \chi(0) = 1 \\ \lim\limits_{\xi \to +\infty} \dfrac{\mathrm{d}\chi}{\mathrm{d}\xi}(\xi) = 0 \end{cases} \tag{9}$$

In Equation 8, χ is the ratio of the contaminant concentration beneath the GM to that in the leachate drainage layer, ξ is the dimensionless distance from the GM defect, $\xi = \alpha(x - b_w)$, and Θ is the transmissivity number, which is a measure of the relative importance of advection compared to diffusion through the GM/CCL or GM/GCL interface:

$$\Theta = \frac{i_s \theta_h (H_f + H_m)}{\theta_d} \tag{10}$$

where θ_d the diffusive transmissivity of the interface.

Once the steady-state contaminant concentration profile beneath the GM has been determined, the

dimensionless contaminant mass flow rate through the GM defect, J_s^*, is given by:

$$J_s^* = \frac{\exp(P_L) - \chi_b}{\exp(P_L) - 1} + \frac{1}{\alpha b_w}\left[1 - \frac{1}{\Theta}\frac{d\chi}{d\xi}(\xi = 0)\right] \quad (11)$$

3 EXAMPLE ANALYSIS

With the aim of quantifying the error in the predicted steady-state contaminant mass flow rate, due to the use of the Katsumi et al. (2001) approach relative to the novel theoretical framework outlined in this paper, and referred to as the Guarena et al. (2023) approach, the lining system described in Table 1 has been considered herein. Such lining system comprises, from top to bottom, a GM, a 1-cm-thick GCL, and a 4-m-thick AL. Cadmium (Cd^{2+}) has been selected to represent the inorganic leachate constituent of interest ($D_{s,0}$ = $7.17 \cdot 10^{-10}$ m^2/s), and the half-width of the GM defect, b_w, has been assumed equal to 0.1 m. The GM-GCL interface has been assigned a value of the hydraulic transmissivity ($\theta_h = 3.5 \cdot 10^{-11}$ m^2/s), which is consistent with the range of variation measured through laboratory-scale experiments (Rowe and Brachman, 2004).

Table 1. Properties of the layers comprising the landfill composite liner, which is referred to for the purposes of the example analysis.

	AL	GCL	
n	0.3	0.69	(-)
τ	0.25	0.31	(-)
k	$1 \cdot 10^{-7}$	$1 \cdot 10^{-11}$	(m/s)

Perfect flushing boundary conditions have been adopted at the base of the composite liner (i.e., $\chi_b = 0$), while the diffusive transmissivity of the GM-GCL interface, in the absence of experimental studies devoted to its measurement, can be tentatively estimated as follows:

$$\theta_d = D_{s,0} s \quad (12)$$

where s is the thickness of the GM/GCL interface, which in turn can be related to θ_h, if Newton's viscosity law for the flow between two parallel plates applies to the transmissive layer (Giroud and Bonaparte, 1989):

$$s = \sqrt[3]{\frac{12\theta_h \mu_w}{\gamma_w}} \quad (13)$$

being γ_w (10 kN/m^3) and μ_w (10^{-6} kPa·s) the unit weight and viscosity of water, respectively.

According to Equation 12, the θ_d parameter varies between $1 \cdot 10^{-15}$ and $1 \cdot 10^{-14}$ m^3/s, and the associated range of variation of the transmissivity number can be assessed through Equation 10 as a function of the hydraulic gradient. As shown in Figure 2a, even when diffusion represents the dominant transport mechanism within the multi-layered soil profile (i.e., $P_L \ll 1$), contaminant transport through the GM/GCL interface may be controlled by advection due to the high values of the transmissivity number (i.e., $\Theta \gg 1$) corresponding to the estimated values of the diffusive transmissivity.

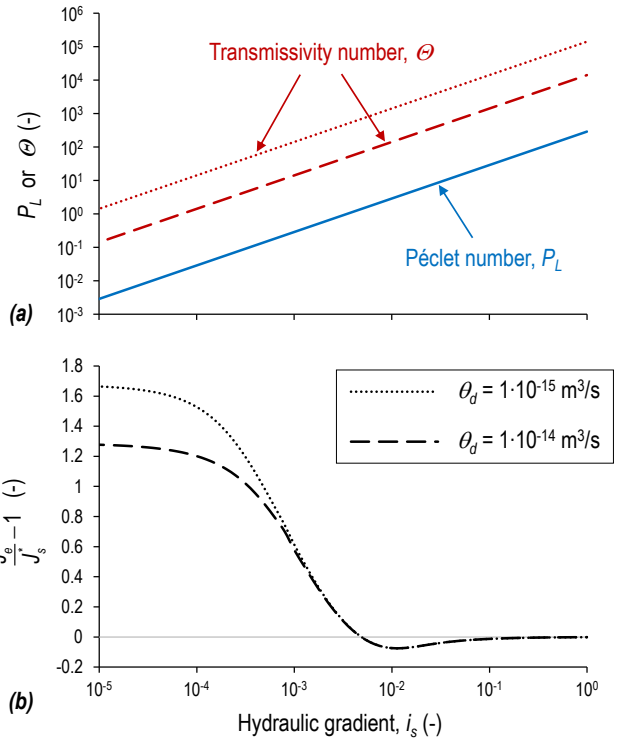

Figure 2. Results of the example calculation: (a) Péclet and transmissivity numbers as a function of the hydraulic gradient across the composite liner, and (b) error in the predicted contaminant mass flow rate due to the use of the Katsumi et al. (2001) approach.

The error in the predicted steady-state contaminant mass flow rate, which is associated with the use of the Katsumi et al. (2001) approach, can be finally assessed for the considered range of variation of both the hydraulic gradient and the diffusive transmissivity. Equations 4 and 11 have been used to calculate J_e^* and J_s^*, respectively, the latter of which has been determined after solving numerically Equation 8 according to the finite difference method.

As shown in Figure 2b, two asymptotic conditions clearly emerge from the example analysis:

- at the highest hydraulic gradients ($i_s > 10^{-2}$), when advection dominates over diffusion through both the multi-layered soil profile ($P_L \gg 1$) and the GM/GCL interface ($\Theta \gg 1$), the Katsumi et al. (2001) approach leads to a prediction of the contaminant mass flow rate that can be regarded as the rigorous one from the mass conservation condition viewpoint, for both the liquid and solute phases;
- at the lowest hydraulic gradients ($i_s < 10^{-3}$), when the importance of diffusion is comparable to ($\Theta \sim 1$) or greater than ($P_L \ll 1$) that of advection through the GM/GCL interface and the multi-layered soil profile, respectively, neglecting the mass conservation condition for the solute phase causes an error, whose magnitude depends to a large extent on the diffusive transmissivity of the GM/GCL interface.

4 CONCLUSIONS

An original theoretical framework has recently been developed by Guarena et al. (2023) to calculate the steady-state mass flow rate of inorganic contaminants through landfill composite liners, which are made up of a GM overlying a low-permeability mineral layer. The transport of both the liquid and the solute has been assumed to only occur through GM defects of uniform width and infinite length (e.g., holed wrinkles and defective seams), with the additional restriction that all the soil layers maintain fully-saturated conditions. The migration pathway within the lining system has been conceptualised as a horizontal flow along the interfacial zone between the GM and the underlying mineral layer, and then as a vertical flow in the mineral layer itself, as in the reference scheme considered by Rowe (1998) and Touze-Foltz et al. (1999, 2001) for the calculation of the leachate flow rate. The theoretical framework developed by Guarena et al. (2023) can thus be interpreted as an attempt to take a step forward with respect to the simplified calculation approach, which was originally conceived by Katsumi et al. (2001) and is routinely being used for the performance-based design of landfill lining systems.

The error associated with the use of the simplified calculation approach proposed by Katsumi et al. (2001) has been quantified in the present paper with the aid of an example analysis. In the case of purely advective transport, the latter approach has been proven to be consistent with the mass conservation condition for both the solvent and solute phases, while satisfaction of the mass conservation condition for the solute phase is no longer guaranteed when diffusion represents the main transport mechanism, leading to an error that greatly depends on the diffusive properties of the interface between the GM and the mineral layer.

Further research is recommended on the aspects dealt with in the present paper. From a theoretical viewpoint, solutions to the contaminant mass flow rate should be developed for shapes of the geomembrane defects (e.g., circular holes in a flat GM), boundary conditions (e.g., parallel interacting damaged wrinkles), transport properties of the soil layers (e.g., change in the degree of saturation for positive suction heads), and chemical types (e.g., organic contaminants diffusing through intact GMs) that differ from the working hypotheses of this study. From an experimental viewpoint, the laboratory investigation of the relative role of advection and diffusion in the transport of contaminants through the GM/CCL and GM/GCL interfaces is of the utmost importance. Finally, it would be advisable to validate the outlined theoretical framework through comparison of the model predictions with actual field measurements, e.g., the contaminant concentration in the secondary leachate collection system of a double composite liner.

ABSTRACT: The mechanical behaviour of soils under non-isothermal conditions is a crucial factor in the analysis and design of energy geostructures. To investigate this behaviour, thermal direct shear tests were conducted in this study within the practical operational temperature range (8-45°C) of energy geostructures. Normal stress was applied in the range of 100 and 400 kPa. Within the scope of the study, continuous heating and cooling was adopted as thermal loading protocol and therefore, the effect of creep was not examined. Furthermore, the impact of soil type on the temperature-dependent shear strength parameters of soils was investigated. Results show that hardening behaviour was observed for normally consolidated (NC) clays while there was no change in the behaviour of sand. There was an increase in apparent cohesion for both heating and cooling episodes. Angle of friction remained unchanged for sand during tests while in NC clays lower friction angle is observed at higher temperatures. Obtained experimental results are reported and used to discuss the practical implication of the dependency of soil strength parameters on temperature in design and performance of energy geostructures.

RÉSUMÉ: Le comportement mécanique des sols dans des conditions non isothermes est un facteur crucial dans l'analyse et la conception des géostructures énergétiques. Pour étudier ce comportement, des essais de cisaillement thermique direct ont été réalisés dans cette étude dans la plage de température opérationnelle pratique (8 à 45 °C) des géostructures énergétiques. Une contrainte normale a été appliquée dans la plage de 100 à 400 kPa. Dans le cadre de l'étude, un chauffage et un refroidissement continus ont été adoptés comme protocole de chargement thermique et donc, l'effet du fluage n'a pas été examiné. De plus, l'impact du type de sol sur les paramètres de résistance au cisaillement dépendant de la température du sol a été étudié. Les résultats montrent qu'un comportement de durcissement a été observé pour les argiles normalement consolidées (NC) tandis qu'il n'y a eu aucun changement dans le comportement du sable. Il y a eu une augmentation de la cohésion apparente pour à la fois les épisodes de chauffage et de refroidissement. L'angle de frottement est resté inchangé pour le sable pendant les tests, tandis que dans les argiles NC, un angle de frottement plus bas est observé à des températures plus élevées. Les résultats expérimentaux obtenus sont rapportés et utilisés pour discuter de l'implication pratique de la dépendance des paramètres de résistance du sol à la température dans la conception et les performances.

Keywords: Shear strength; temperature; silica sand; normally consolidated clay.

1 INTRODUCTION

The impact of thermal influences on soil shear strength has been a subject of exploration over several years (Laloui et al. 2014, Maghsoodi et al. 2020, Laloui & Sutman 2021). Investigations into the shear strength of clay soils have yielded varied results, without a definitive consensus on the precise effect. Some studies suggest that higher temperatures can enhance the shear strength of clays (Graham et al. 2001, Abuel-Naga et al. 2007), while others indicate a decrease in strength at elevated temperatures (Chiu 1996, Maghsoodi et al. 2020). In contrast, assessments of temperature changes on sand's shear strength parameters reveal an independence of interface shear strength from temperature (Di Donna et al. 2015, Vasilescu et al. 2019, Maghsoodi et al. 2020, Laloui & Sutman 2021).

This study aimed to gain a deeper comprehension of temperature-dependent soil strength parameters by conducting thermal direct shear tests on both sand and clay soils.

2 TESTING PROCEDURE

2.1 Tested materials

In the present study, thermal direct shear tests were conducted for both sand (silica sand) and clay (Polwhite-E type kaolin). Physical properties of the silica sand are shown in Table 1. The soil classification for the sand used in the tests is SP according to the Unified Soil Classification System (USCS).

Table 1. Silica sand properties.

Property	Value
D_{50} (mm)	0.140
C_u	1.596
C_c	0.906
AFS (Average Fineness Number)	99.53

Polwhite-E type kaolin is a non-active temperature-sensitive clay and classified as CH according to USCS. Corresponding properties are shown in Table 2. Water content for the tested kaolin clay was 30%.

Table 2. Clayey soil properties.

Property	Value
Specific Gravity (G_s)	2.61
LL (%)	50.71
PI (%)	18.67
w_{opt} (%)	26.8
Maximum dry unit weight ($\gamma_{d,max}$ kN/m^3)	13.94

2.2 Experimental set-up

The experiments for silica sand and kaolin clay were conducted with different direct shear devices. Thermal direct shear device shown in Figure 1 was used for the silica sand, while a modified standard direct shear device was used for the kaolin clay, as show in Figure 2 (Hashemi et al., 2022). Shear box dimensions for the silica sand and kaolin clay are 100x100x20 mm and 60x60x20 mm, respectively.

Figure 1. Thermal direct shear device used for silica sand.

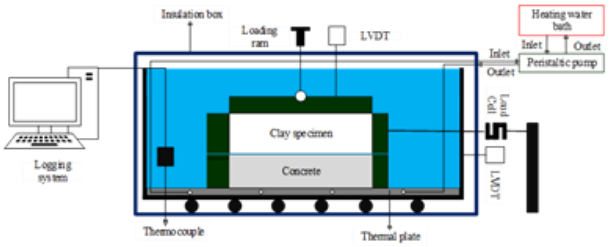

Figure 2. Thermal direct shear device used for kaolin clay.

2.3 Thermal loading protocol

In this experimental study, the loading path applied for the silica sand before shearing is shown in Figure 3. Sand samples initially loosely placed in the shear box with the pouring method. The dry density of the sand placed in the shear box was set to be the same for each test and 14.52 kN/m^3. Next, specimens were immersed in distilled water at a temperature of 24°C to ensure complete saturation. Subsequently, consolidation was carried out at normal stress levels of 100 and 400 kPa in the corresponding paths of A-B and A-C, respectively. Prior to initiating the shearing process, thermal loading was applied to selected samples. For both normal stress conditions, the samples were subjected to thermal loading at temperatures of 8°C (path B-D and C-F) and 45°C (path B-E and C-G). The samples experienced a temperature variation of 15°C within a span of approximately 30 minutes, corresponding to 0.5°C/min heating and cooling rate. Since the thermal loading was rapid, the sample was kept at constant temperature for 3 hours after reaching the designated temperature to allow for the dissipation of any excess pore water pressure that may occur, although it is not very likely. Upon achieving the desired temperature and the associated deformation, the shearing phase was initiated. Since silica sand is a granular soil, the shearing rate was determined as 0.5 mm/min based on the standards (ASTM,1998).

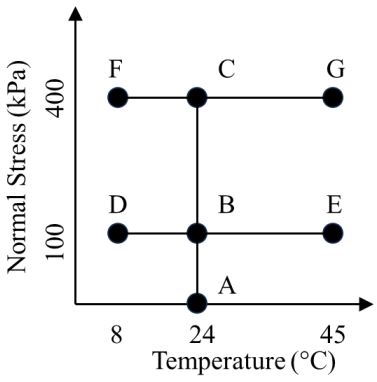

Figure 3. Loading paths.

Kaolin clay samples were subjected to the same thermo-mechanical (TM) paths as those shown in

Figure 3. The kaolin samples were immersed in distilled water for at least 48 hours at a temperature of 24°C. This immersion period ensured a degree of saturation exceeding 95% before testing commenced. To confirm this, a series of separate immersion and saturation degree tests were conducted beforehand on multiple samples. The mixture was stored in an airtight container for a minimum of three days to achieve moisture equilibrium (Ravera et al., 2020). Subsequently, the soil was statically compacted within the shear box. This involved applying a gradual and variable static force via a piston in the strain-controlled press until the target void ratio was reached.

The water level was maintained above the samples throughout the testing period. Next, the samples were consolidated to the desired mechanical load (100 or 400 kPa). Unlike silica sand samples, the heating/cooling rate was limited to 3°C/hr to maintain drained conditions (Hashemi and Sutman, 2023). Once the desired temperature and associated deformation were stable, the shearing phase was initiated at a rate of 0.005 mm/min to ensure drained shearing (Di Donna et al., 2016; Hashemi et al., 2022).

3 EXPERIMENTAL RESULTS

3.1 Silica sand

The outcomes derived from experimental investigations on silica sand are shown in Figures 4-6. In all tests conducted at three different temperatures and under two different normal stresses, shear stress increased as the horizontal displacement increased. Maximum shear strength did not change with temperature and was found to be a function of normal stress. As shown in Figure 4, soil contracted at low horizontal displacement and then, it exhibited a dilative behaviour. Angle of friction is obtained as 34° and it is independent of temperature.

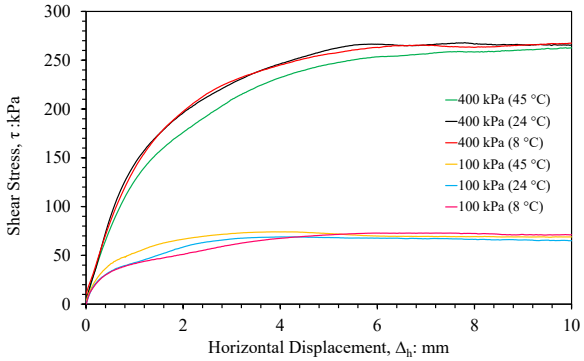

Figure 4. Experimental results on sand: shear stress versus horizontal displacement.

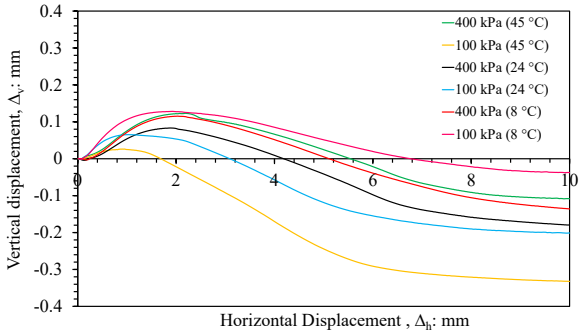

Figure 5. Experimental results on sand: vertical displacement versus horizontal displacement.

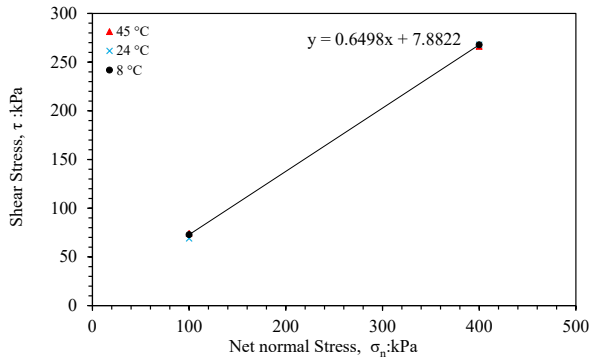

Figure 6. Failure envelope of sand.

3.2 Kaolin clay

Figures 7 and 8 show the results of direct shear tests on kaolin clay, with respect to shear stress and vertical displacement evolution with horizontal displacement. At the low normal stress of 100 kPa, heating and cooling induced insignificant changes in the shear strength of the sample. However, by increasing the normal stress to 400 kPa, the heated sample showed lower shear strength than the interfaces either cooled or sheared at room temperature. This suggests that the impact of thermal loading on shear strength is governed by normal stress, at least for the clay tested in this study (Hashemi et al. 2023).

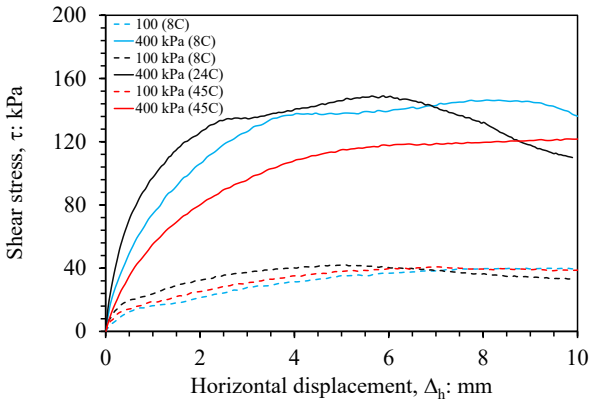

Figure 7. Experimental results on clay: shear stress versus horizontal displacement.

Temperature also has a significant impact on the volumetric behaviour of the clay during shearing. As shown in Figure 7, the thermally loaded samples showed a less contractive behaviour during the shearing stage, regardless of the normal load. This behaviour can be attributed to thermal deformation of the samples prior to shearing, with cooled and heated samples experiencing an elastic or plastic contraction, respectively (Hashemi and Sutman, 2022).

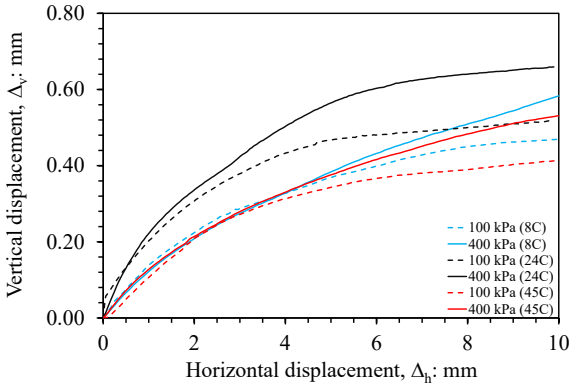

Figure 8. Experimental results on clay: vertical displacement versus horizontal displacement.

Figure 8 presents the failure envelopes at varying temperature, revealing a downward shift towards lower shear stresses upon heating. While a higher cohesion and an identical friction angle are determined upon cooling, a higher cohesion is coupled with a lower friction angle for the heated samples. For the kaolin samples studied here, the relationship between thermal loading and strength parameters is summarised in Table 3.

Table 3. Shear strength parameters of kaolin clay (c_a: cohesion; φ: interface friction angle).

Temperature (°C)	c_a (kPa)	φ (°)

4 DISCUSSIONS

Results from the tests on silica sand indicate strong consistency in terms of shear stress with respect to horizontal displacement. However, the consistency for vertical displacement versus horizontal displacement is not as evident. Vertical displacement is correlated with the volume of the sheared zone, which can vary for each test. A linear function can be successfully employed to establish a correlation between shear strength and normal stress, which facilitates the determination of the friction angle. These findings highlight the reliability of the obtained results.

According to obtained results, the effect of temperature on silica sand strength and angle of friction is almost negligible, which was also shown by previous research (Di Donna et al. 2015, Vasilescu et al. 2019, Maghsoodi et al. 2020, Laloui & Sutman 2021). Upon achieving larger horizontal displacements, residual shear strength remained unchanged.

The effect of temperature on the friction angle of soils is generally insignificant. However, for cohesive soils tested at high temperatures, the friction angle can either increase or decrease, depending on the specific soil and the testing conditions (Di Donna et al. 2015, Maghsoodi et al. 2020). In the current study on kaolin clay, plastic thermal deformation in response to heating and ensured drained shearing caused by a low heating rate are likely the main reasons for the observed temperature effects on friction angle, which might be absent in other studies (Hashemi et al., 2023).

To understand the effect of temperature on cohesion, it is important to study the mechanisms that contribute to cohesion in non-isothermal conditions. Two main mechanisms that determine cohesion force are solid-solid and liquid-mediated contacts (Bhushan, 2003). In this study, both mechanisms contributed to higher cohesion at higher temperatures caused by increased number of contacts due to thermal contraction and higher viscous force, respectively (Li et al., 2019; Hashemi et al., 2022).

5 CONCLUSIONS

In this study, the impact of soil type on the temperature dependent shear strength parameters of soils was investigated through thermal direct shear tests. To achieve this, tests were conducted on both sandy and clayey soils under two different normal stresses (100 and 400 kPa) at various temperatures (8, 24 and 45 °C). It was observed that the effect of temperature on the shear strength of sand was negligible in the applied temperature range. At large horizontal displacements, the residual shear strength did not change.

This study also investigated the effect of temperature on the shear strength of normally consolidated (NC) clay. The results showed that heating NC clay leads to a decrease in shear strength, which is more pronounced at higher normal loads. Cooling, on the other hand, does not have a significant effect on shear strength. The decrease in shear strength upon heating is attributed to the plastic contraction of the soil. For the NC clay, the plastic contraction due to heating and the elastic contraction due to cooling resulted in less contractive behaviour during shearing and contributed to a lower friction angle at higher temperatures and higher cohesion at both low and high temperatures.

ABSTRACT: Some soils are not suitable to support the application of loads or to be used for embankment construction due to their low strength and/or high deformability. However, with proper treatment, these soils can improve their geotechnical properties to fulfil the requirements needed for this use. Building on or with problematic soils usually requires the use of traditional stabilizers like lime and cement which drives up construction and environmental costs. Alternatives have been studied to avoid or reduce these costs associated with soil improvement. Marble dust or Limestone powder obtained as waste from cutting and polishing activities of the natural stone industry has shown great potential in stabilizing expansive soils. Nevertheless, the effect of limestone waste on the properties of the mixed soil depends on the characteristics of the natural soil. In this work, the effect of limestone powder has been studied on three types of clayey soils to evaluate the geotechnical properties of the mixed soil and their relation to some properties of the natural soil such as grain size, plasticity and calcium carbonate content. Preliminary results show that as the addition of limestone powder waste to clayey soils can increase the unconfined compressive strength and the CBR index, reducing the swelling potential of the soil. The level of improvement depends on the type of soil, being influenced by its grain size distribution and mineralogy, although a clear match between parameters has not been obtained.

RÉSUMÉ: Certains sols ne sont pas adaptés pour supporter l'application de charges ou pour être utilisés dans la construction de remblais en raison de leur faible résistance et/ou de leur grande déformabilité. Cependant, avec un traitement approprié, ces sols peuvent améliorer leurs propriétés géotechniques pour répondre aux exigences nécessaires à cette utilisation. Construire sur des sols problématiques ou avec eux nécessite généralement l'utilisation de stabilisateurs traditionnels tels que la chaux et le ciment, ce qui augmente les coûts de construction et environnementaux. Des alternatives ont été étudiées pour éviter ou réduire ces coûts liés à l'amélioration des sols. La poudre de calcaire obtenue en tant que déchet des activités de découpe et de polissage de l'industrie de la pierre naturelle a montré un grand potentiel dans la stabilisation des sols expansifs. Néanmoins, l'effet des déchets de calcaire sur les propriétés du sol mélangé dépend des caractéristiques du sol naturel. Dans ce travail, l'effet de la poudre de calcaire a été étudié sur trois types de sols argileux pour évaluer les propriétés géotechniques du sol mélangé et leur relation avec certaines propriétés du sol naturel telles que la granulométrie, la plasticité et la teneur en carbonate de calcium. Les résultats préliminaires montrent que l'ajout de déchets de poudre de calcaire aux sols argileux peut augmenter la résistance à la compression non confinée et l'indice CBR, réduisant le potentiel de gonflement du sol. Le niveau d'amélioration dépend du type de sol et est influencé par sa distribution granulométrique et sa minéralogie, bien qu'il n'y ait pas de correspondance claire entre les paramètres.

1 INTRODUCTION

The strength and deformability of a soils are crucial for the suitability of a material in construction. Expansive soils, not meeting the required quality standards in embankment construction, often undergo treatments to improve their geotechnical properties (Chu et al., 2009; Mitchell, 1981), resulting in increased construction costs and energy consumption in the production of hydraulic binders (Sharma et al., 2018).

Alternatives have been investigated to reduce soil improvement costs using industrial byproducts (Kar, 2021; Uma Maguesvari et al., 2023)

On the other hand, mining activity continues to grow due to its economic utility. Spain is one of the leading producers of natural large amounts of waste stone (Trio Maseda and Guillermo Ortuño, 2018). Approximately 25% of a marble block becomes slurry (Kuoribo and Mahmoud, 2022; Saygili, 2015), and another 15% becomes solid waste (Founti et al., 2010). Limestone dust (LD), being inert and non-biodegradable, is often disposed of in landfills without treatment (Aukour and Al-Qinna, 2008), causing negative environmental impacts (Çınar and Kar, 2018).

Limestone dust could serve as a stabilizing agent in road embankments (Thirumalai et al., 2017). Jassim et al., (2022) found that the plasticity index decreased by approximately 22% with increased limestone dust content. Cabalar and Omar, (2023) demonstrated that the unconfined compressive strength (UCS) of a silty specimen with 30% of limestone dust reached 500 kN/m^2, twice the UCS without limestone dust. Additionally, an increase in the CBR index was observed with 17% limestone dust in a clayey soil (Niraj and Sharma, 2023).

2 MATERIALS AND METHODS

To perform the tests, ornamental rock residue and three types of clayey soils were used.

2.1 Soil

The clayey soil was extracted from the localities of Novelda (S1), Almería (S2), and Fortuna (S3), all of which are located in sutheast Spain. The properties of the materials are detailed in Table 1. Sample S1 is classified as low-plasticity silty clay. Sample S2 is classified as low to medium-plasticity clay. Sample S3 is classified as medium to high-plastic clay.

2.2 Limestone dust

The limestone dust (LD) residue was collected from the landfill of a natural stone factory located west of the province of Alicante. The calcium carbonate content in the limestone powder samples was 90.9%.

3 METHODOLOGY

3.1 Sample preparation

The clayey soil and the residue were prepared by crushing them with a rubber mallet without breaking the particles, and placed in an oven at a temperature of 50º C until a constant weight, and a homogeneous mixture was prepared. Standard Proctor tests were used to obtain the optimum moisture content and maximum dry density for specimens with and without limestone dust. Once the optimum moisture content was defined, test specimens were prepared for further testing with the optimum moisture content and the compaction energy of the Standard Proctor.

3.2 Free swelling test

Three specimens with a diameter of 50 mm and a thickness of 25 mm were manufactured. Each clayey soil sample has its corresponding specimen with added residue, prepared with the respective optimum moisture content for each type of soil, and soil mixed with limestone dust. The determination of swelling of a specimen was carried out on an oedometer bench following Spanish regulations (AENOR, 1996).

3.3 Unconfined compressive strength

The specimens for the Unconfined compressive strength (UCS) test were manufactured with a diameter of 50 mm and a height of 100 mm using compaction energy according to the standard Proctor method. The maximum axial stress that a cylindrical specimen can withstand before its failure is defined as the UCS This test was conducted in accordance with Spanish regulations (AENOR, 1993).

3.4 CBR index

To determine the California bearing ratio (CBR) index, tests were conducted following the relevant standard (AENOR, 1995). The manufactured specimens underwent a four-day curing period in a humidity and temperature-controlled chamber (>95% RH and 20 ± 2º C).

4 RESULTS

4.1 Atterberg limits

The liquid limit (LL) of each sample is shown in Figure 1. There is a significant reduction in the liquid limits of the Novelda (S1) and Fortuna (S3) samples; however, the LL remains approximately constant in the case of the Almería sample (S2) after adding limestone dust (LD).

4.2 Free swelling

The results of the free swelling potential for the prepared samples, natural soil (NS) and natural soil with limestone dust (NS+LD) by adding 20% of the residue weight of dry soil are shown in Figure 2. The free swelling of the samples decreased when limestone dust was added.

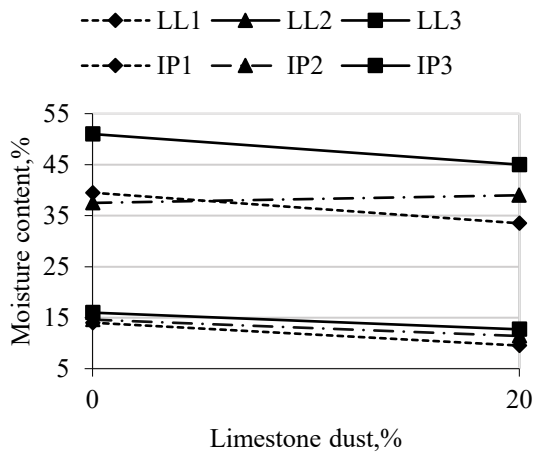

Figure 1. Liquid limit of samples containing limestone dust.

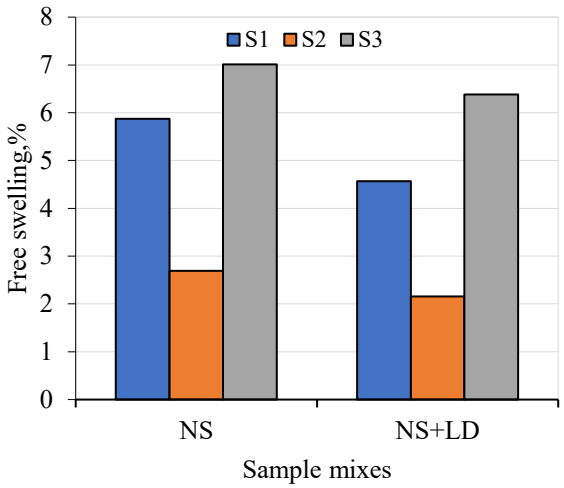

Figure 2. Free swelling of clay samples with limestone dust.

4.3 Unconfined compressive strength

The unconfined compressive strength of the analysed samples without the addition of residue can be seen in Figure 3. The results of the specimens with 20% limestone dust are shown in Figure 4. The strength of the specimens increased to a greater extent with the clay from Almería (S2). Nevertheless, the limestone dust did not have a positive effect on the Fortuna soil (S3).

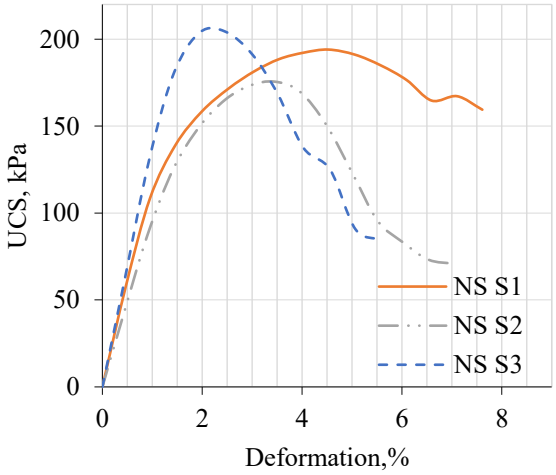

Figure 3. Unconfined compressive strength of natural soil (NS).

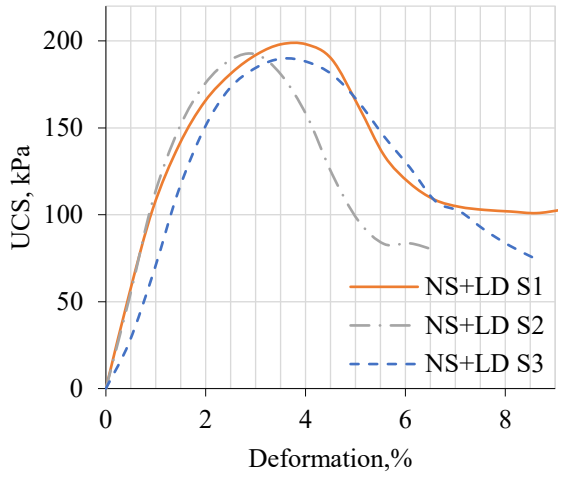

Figure 4. Unconfined compressive strength of natural soil (NS) with limestone dust (LD) of each clay sample.

4.4 California bearing ratio

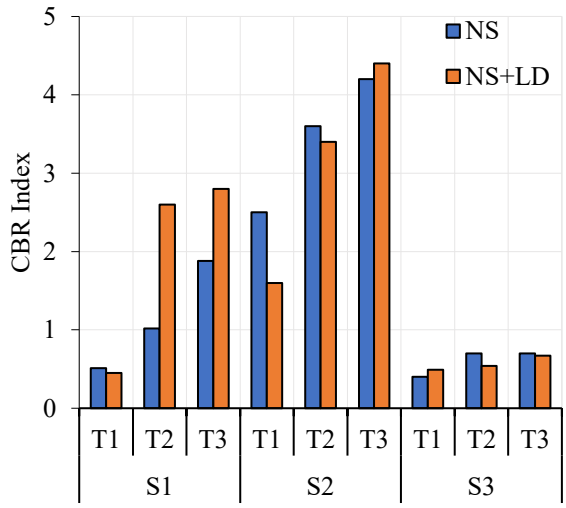

Figure 5. CBR index of the samples with and without LD.

The California bearing ratio (CBR) index was obtained using the normal Proctor energy, and the results are shown in Figure 5. The ornamental rock dust has not had a positive effect on the Fortuna soil (S3). The greatest increase in the CBR index occurred in the soil from the Novelda (S1) locality.

5 DISCUSSION

The results obtained show, in the first instance, positive effects when adding the limestone waste to the natural soils. Nevertheless, the effect was different for the three soils. A decrease in the consistency limits is observed for soils S1 and S3, however, it remains approximately constant for S2. In the case of sample S3, the reduction in the consistency limits would imply a change in position on the Casagrande chart, shifting from an MH-OH classification to ML-OL. Ali et al., (2014) obtained a similar result by reducing the LL by 12% and changing the classification of their samples from CH to CL.

Swelling is reduced with the addition of limestone residue, similar to the results obtained by Ali et al., (2014). A reduction in free swelling is observed in all three types of clayey soils, with a greater effect on the Novelda soil (S1) and Fortuna soil (S3), with a decrease of 23% and 20%, respectively. The Almería soil (S2) experienced a 9% reduction compared to the maximum swelling obtained.

The UCS results do not show a general tendency. The UCS of sample S2 increased by 7.5% compared to the maximum obtained for the natural soil. However, the UCS of soil S3 decreased slightly. Chore et al., (2023) reported an increase of the UCS of a clayey soil when adding marble powder. Similar results to those obtained by Ahirwar and Chore (2021), although in this case the maximum UCS was obtained for a 15% addition of limestone dust, decreasing the UCS when adding 20%. The UCS obtained when adding LD could depend not only on the type of soil but also on the final LD content. As it looks like there is a threshold of LD addition, after this threshold the UCS could decrease.

Regarding the CBR, soils S1 and S2 showed an increase in the CBR index. Being S1 the soil which showed the greatest gain. Similar results were obtained by Niraj and Sarma (2023) after adding 17% of limestone dust, although a decrease was observed when adding 21%. This could mean that the optimal limestone powder content may fall within this range. The greatest improvement observed for soil S1 when adding limestone powder waste could be related to the lowest content of carbonates observed on this soil before adding the limestone powder waste.

6 CONCLUSIONS

Different improvement has been observed by adding limestone dust to three different clayey soils. This could be due to the different chemical compositions of the three soils. Limestone dust is primarily composed of carbonates. However, the carbonate content in Soils S1, S2 and S3 is different. On the other hand, the content of silicon oxide and aluminum oxide is higher in soil type S1. The relationship between the chemical compounds of each soil and the improvement of their properties is not entirely clear. The addition of limestone dust to clayey soils reduces the free swelling and improves the consistency of the clays. The improvements are quite remarkable in the CBR index. In general, in most of the test conducted,

improvements are observed, both in strength and in expansiveness.

ABSTRACT: The increasing construction activity along the shoreline of the Stockholm region has intensified the use of existing quay structures. The geotechnical stability is a major issue for the condition assessment of the quays and normally requires geotechnical rehabilitation to retain the usage. However, such methods can entail a large carbon footprint, which needs to be considered in the preliminary design phases. This paper presents a systematic evaluation of five geotechnical remediation methods at an early design stage to facilitate the selection of an appropriate method. The methods are applied to a quay with insufficient stability to reach a target safety factor. The climate impact for each method was evaluated through a life cycle assessment (LCA) based on data from environmental product declarations (EPD). The result shows that the method with the lowest climate impact is the support berm, and the one with the highest is the piled embankment with steel piles. The paper also discusses uncertainties regarding the methods' applicability in real-life conditions, the impact of later life-cycle stages, and the influence of cost on the choice of remediation.

RÉSUMÉ: L'activité croissante de construction le long du littoral de la région de Stockholm a intensifié l'utilisation des structures de quai existantes. La stabilité géotechnique est un problème majeur pour l'évaluation de l'état des quais et nécessite généralement une remédiation géotechnique pour maintenir leur utilisation. Cependant, de telles méthodes peuvent entraîner une empreinte carbone importante, qui doit être prise en compte dès les phases de conception préliminaire. Cet article présente une évaluation systématique de cinq méthodes de remédiation géotechnique à un stade précoce de la conception pour faciliter le choix d'une méthode appropriée. Les méthodes sont appliquées à un quai dont la stabilité est insuffisante pour atteindre un facteur de sécurité cible. L'impact climatique de chaque méthode a été évalué à travers une analyse de cycle de vie (ACV) basée sur des données provenant de déclarations environnementales de produits (EPD). Les résultats montrent que la méthode ayant l'impact climatique le plus faible est la berme de support, tandis que celle ayant le plus élevé est le remblai en pieux avec des pieux en acier. L'article aborde également les incertitudes concernant l'applicabilité des méthodes dans des conditions réelles, l'impact des étapes ultérieures du cycle de vie et l'influence des coûts sur le choix de la remédiation.

Keywords: Quay structure; slope stability; climate impact; life-cycle assessment.

1 INTRODUCTION

The increasing construction activity along Stockholm's coastal areas has intensified the use of the existing quays. Different and more extensive land use with higher loads requires a re-examination of the bearing capacity, and the geotechnical total stability can be a significant issue. Geotechnical rehabilitation methods can be used in cases where renovation is required. These methods often entail a large climate impact, which therefore should be included in the early design phase.

One method for assessing climate impact is through a life cycle assessment (LCA). LCA in geotechnical engineering is a relatively new field with limited research conducted and there is no standardized

framework for the implementation (Samuelsson et al., 2021; Song et al., 2020; Das et al., 2018, Maas et al., 2011).

Consequently, there exists a need to investigate how climate impact, with an LCA, can be included and facilitate the selection of remediation methods for quay renovations. The aim of the paper is to provide a systematic evaluation of remediation methods through the assessment of climate impact at an early design stage to facilitate the selection of an appropriate method.

2 METHOD

A case study has been carried out where five geotechnical rehabilitation methods have been applied to a clay slope with a gravity-wall quay structure. The rehabilitation methods have been compared through a total stability analysis performed in the LE-program GeoStudio SLOPE/W.

The calculation process is shown in Figure 1, with an initial total factor ($SF_{initial}$) of the slope, in this case SF=1.0. With each rehabilitation method, the goal was to achieve a final sufficient safety factor (SF_{target}) to evaluate the quantities of materials needed. The target safety factor was 1.5, for undrained analysis, and 1.3, for combined analysis.

The climate impact of the different methods has subsequently been evaluated through a life cycle analysis (LCA) based on climate data from environmental product declarations (EPD) and the material quantities. The climate data originates from *Klimatkalkyl*, a tool developed by The Swedish Transport Administration. The LCA was limited to include only the product stage of the life cycle (A1-A3) which includes raw material supply, transport, and manufacturing. Input data for the general slope and quay was based on Munkbrokajen in Stockholm (see Figure 2). Input data and characteristic values are shown in Table 1.

In addition to the case study, a sensitivity analysis was carried out to investigate the impact of slope inclination and undrained clay shear strength on the results. For the slope, steeper inclinations of 30° and 40° were implemented, as well as varying undrained shear strengths 15, 18, 22 and 25 kPa.

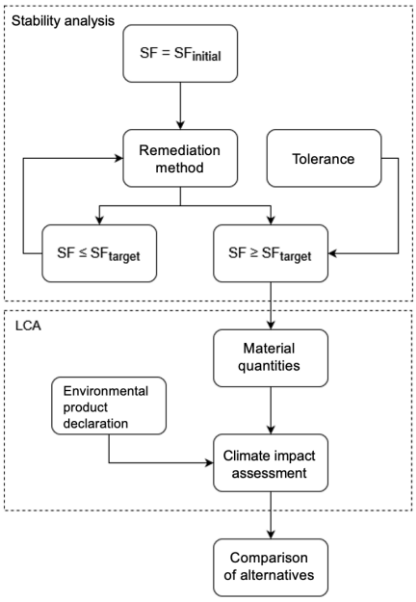

Figure 1. The working process.

Table 1. Input data for soil layers.

Material	γ [kN/m³]	ϕ [°]	c_u [kPa]
Gravel fill	18	33	(18)
Clay	17	(30)	20+1.5 kPa/m*
Sand/Gravel	21	35	-
Gravity wall	24	-	-
Wooden piles	17	-	$9 \times c_{u,clay}$

*Increasing undrained shear strength with depth.

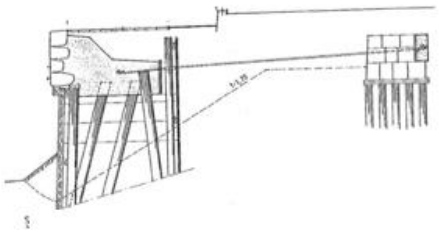

Figure 2. Munkbrokajen in central Stockholm.

2.1 Rehabilitation methods

The case study has included stability analysis of the following methods.

2.1.1 Ground improvement

Ground improvement with lime-cement columns aims to increase the strength of the soil volume under the fill. The emission factor was weighted where a 50/50 distribution was assumed of cement and lime, the amount of mixing 90 kg/m^3 and a coverage rate in the soil of 50%. The cement was adopted to be of the CEM II type.

2.1.2 Lightweight fill

Lightweight fill increases the slope stability by decreasing the weight on the slope and therefore

decreasing the driving force. The lightweight fill consists of expanded cellular plastic with a density of 30 kg/m^3. The friction angle was assumed to be 33°, the same as the original fill.

2.1.3 Support berm

The support berm increases the resisting moment and therefore the overall stability (see Figure 3). It consists of crystalline uncompacted rock fill with a weight of 20 kN/m^3 and a friction angle of 45°. The rock fill was assumed to be collected from a project nearby, whereby a limited amount of processing is required.

2.1.4 Piled embankment

The piled embankment aims to decrease the destabilizing force in the slope by countering the traffic load and the load from the filling. Two cases are examined, one with concrete piles and another with steel piles. The piled embankment is constructed of 13.5 m long piles with concrete pile caps and a load-distributing layer (see also Figure 4). The reinforced concrete piles have a diameter of 235 mm while the steel piles are of the type RD 170/10 filled with unreinforced concrete. The concrete pile caps have the dimensions 1.6 x 1.6 x 0.5 m and are reinforced with a quantity of 200 kg/m^3.

2.1.5 Sheet pile wall

The sheet pile wall is installed in front of the gravity wall structure and back-anchored to a 5 m retaining wall (see also Figure 5). The area between the gravity wall and the sheet pile wall is filled with soil fill. The sheet pile is made of structural steel of the type LX, PU16 with a density of 7850 kg/m^3. The wale band is assumed to consist of two UPE 330 beams.

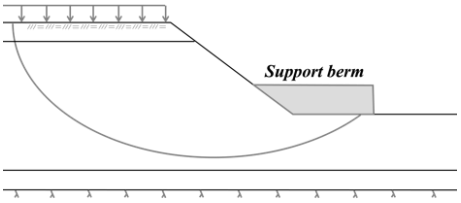

Figure 3. Cross-section of the support berm structure.

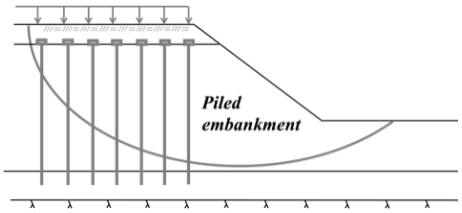

Figure 4. Cross-section of the piled embankment.

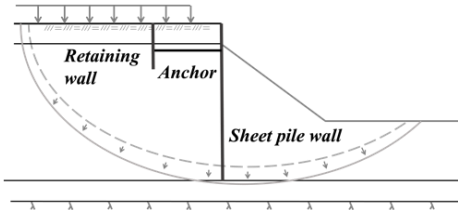

Figure 5. Cross-section of the sheet pile wall structure.

3 RESULTS

The result from the assessment of the total climate impact for each remediation method is shown in Table 2 and Figure 6. The piled embankment with steel piles gives the largest emission of greenhouse gases and thus the largest impact on the climate in the product stage of the life cycle. Furthermore, the sheet pile wall, the lime-cement columns, and the piled embankment with concrete piles result in a similar climate impact value. The light-weight fill has the second lowest climate impact of all the methods, regardless of its relatively high emission factor. The support berm with the largest volume is ultimately the method with the lowest climate impact.

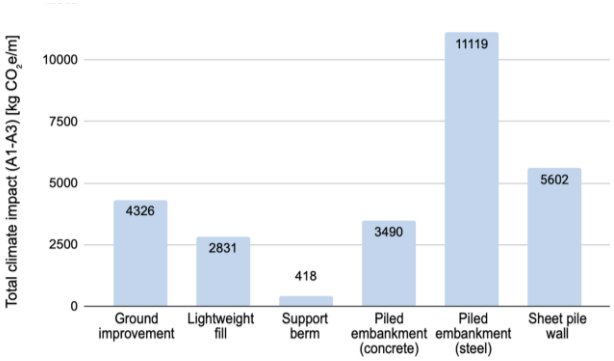

Figure 6. Calculated total climate impact for each method.

Table 2. Climate impact assessment for each method. The emission factor is expressed either per mass or length unit.

Method	Material	Length [m]	Mass [kg/m]	Volume [m^3/m]	Emission factor /kg [kg CO_2e/kg]	Emission factor /m [kg CO_2e/m/m]	Total climate impact [kg CO_2e/m]	
Ground improvement	Lime-cement columns	*a*=50%	3915	43.5	1.1	-	4326	**4326**
Lightweight fill	EPS	-	1191	39.7	2.4	-	2823	**2831**
	Geotextile	22.3	5.8	-	1.4	-	8.3	
Support berm	Rock fill	-	1045540	52.3	0.004	-	418	**418**
Piled embankment (concrete)	Conc. piles (SP1, 7pc)	13.5	-	0.06	-	26.3	1184	**3490**
	Pile caps (7pc)	1.6	-	1.28	-	430.7	2297	
	Geotextile	23	5.98	-	1.4	-	8.6	
Piled embankment (steel)	Steel piles (SP1, 10pc)	13.5	-	-	-	93.0	7172	**11119**
	Pile caps (10pc)	1.6	-	1.28	-	430.7	3938	
	Geotextile	23	5.98	-	1.4	-	8.6	
Sheet pile wall	Sheet pile	15	-	-	-	268.4	4026	**5602**
	Ret. sheet pile	5	-	-	-	268.4	1342	
	Wale beam	-	53.2	-	2.2	-	234.1	
	Anchor (cc=3)	18	0.1	0.007	2.2	-	0.1	
	Soil fill	-	18360	10.2	0.0003	-	0.003	

3.1 Sensitivity analysis

With steeper slope inclinations, several of the rehabilitation methods are not applicable. The support berm and the sheet pile wall can be used in slopes with steeper inclinations. The sheet pile wall is dependent on the depth of the clay layer rather than the inclination of the slope.

Assessing the sensitivity of the undrained shear strength value the lightweight fill, lime-cement columns, and the piled embankment are not applicable at a shear strength of 15 kPa or lower due to a non-sufficient safety factor. The impact from the sheet pile wall and the piled embankment with concrete remains constant with varying shear strengths. This results in a shift in the relative ranking of some of the different methods, which otherwise have a relatively constant relation to one another (see Figure 7).

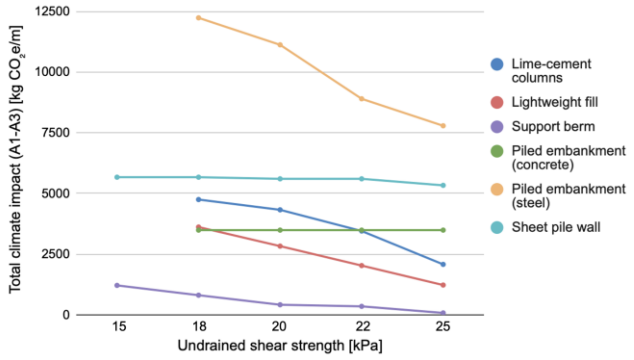

Figure 7. Climate impact with varying undrained shear strength for the clay.

4 DISCUSSION AND CONCLUSIONS

The results clearly show, as expected, that the support berm has the lowest climate impact, while the piled embankment with steel piles has the highest impact. It should be noted that the support berm's low climate impact comes from its low emission factor due to the assumption that it is a by-product. This is consistent with other studies by Song et al. (2021) and Samuelsson et al. (2023). The result for the lime-cement columns will be different in the future with the development of fossil-free steel or alternative materials such as cement kiln dust (CKD) or blast furnace slag.

For a more comprehensive result, the practical feasibility of each method and additional climate data should be included. Additional climate data combined with a project-specific study could lead to the inclusion of additional life cycle stages. The result of the support berm can, e.g., be significantly affected by the inclusion of the production due to its large weight, therefore requiring more transportation.

In addition, it can also be important to consider whether all the methods are practically feasible or how they can be combined to optimize the usage of materials. The analysis shows that with steeper slopes and lower strength in the clay, the methods aiming to reduce the driving moment or change the soil properties are generally not applicable in this case.

When deciding which alternative to choose, other factors can also influence the choice, where financial cost can be a crucial factor. Therefore, it is suggested to complement the LCA with a life cycle cost analysis (LCCA), preferably considering the uncertainties in the final assessment of the remediation method.

Despite these limitations, it can be considered sufficient to achieve the goal of evaluating the climate impact of the measures at an early design stage.

Large-scale soil bio-cementation: insights into homogeneity, quality control, and waste handling

Sur l'effet des paramètres et des techniques d'injection pour obtenir une bio-amélioration homogène des sols: aperçus d'une expérience à grande échelle

R. Harran, D. Terzis, M. Büyüklü*, L. Laloui
Laboratory of Soil Mechanics/ Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland
**merih.buyuklu@epfl.ch*

ABSTRACT: This paper deals with challenges in large-scale soil bio-cementation. Introducing a novel treatment strategy with ex-situ hydrolysis in a 1000 L bioreactor, the study employs a state-of-the-art installation to inject hydrolyzed solutions into a 40 m^2 area of 0–4 mm sand. A comprehensive multilevel quality control system monitors chemical and hydraulic processes across cycles, resulting in reaction efficiencies exceeding 80%. The paper discusses the gradual increase in pressure at the injection inlet, correlating with higher calcification levels. Findings indicate improved resistance in zones with higher injection pressure, demonstrating the efficacy of ex-situ bio-cementation. The study also explores the mechanical improvements, suggesting comparable results to traditional in-situ methods. Additionally, the paper addresses the monitoring of microbially induced calcium precipitation (MICP) at the geotechnical scale, highlighting the issue of residual ammonium reaching absorbed quantities of 4 mol/L.

RÉSUMÉ: Cet article traite des défis liés à la bio-cimentation des sols à grande échelle. Introduisant une nouvelle stratégie de traitement avec l'hydrolyse ex-situ dans un bioréacteur de 1000 L, l'étude utilise une installation de pointe pour injecter des solutions hydrolysées dans une zone de 40 m2 de sable de 0 à 4 mm. Un système complet de contrôle de la qualité à plusieurs niveaux surveille les processus chimiques et hydrauliques à travers les cycles, aboutissant à des efficacités de réaction dépassant 80%. L'article discute de l'augmentation graduelle de la pression à l'entrée de l'injection, corrélée à des niveaux de calcification plus élevés. Les résultats indiquent une résistance améliorée dans les zones avec une pression d'injection plus élevée, démontrant l'efficacité de la bio-cimentation ex-situ. L'étude explore également les améliorations mécaniques, suggérant des résultats comparables aux méthodes traditionnelles in-situ. De plus, l'article aborde le suivi de la précipitation calcique induite par les micro-organismes (MICP) à l'échelle géotechnique, mettant en lumière le problème de l'ammonium résiduel atteignant des quantités absorbées de 4 mol/L.

Keywords: MICP; upscaling; quality control; dynamic penetrometer; field testing.

1 INTRODUCTION

Nearly two decades since its inception, Microbially Induced Calcium Carbonate Precipitation (MICP) has gained attention as a sustainable alternative for ground improvement. Utilizing urease-bearing microorganisms, urea hydrolysis induces carbonate ion creation, leading to solid calcium carbonate precipitation. This biochemical process enhances soil properties, impacting permeability, stiffness, compressibility, and shear strength. The technique has been explored in controlled setups and natural environments, addressing diverse geotechnical challenges (Terzis & Laloui, 2019).

2 MATERIALS & METHODS

To validate the ex-situ treatment strategy, a bench-scale campaign was conducted. Sand columns, representing the tank's porosity, underwent treatment with hydrolyzed and calcium-rich solutions. Analysis of liquid samples assessed precipitation efficiency through calculations involving influent and effluent reactant concentrations. The laboratory-scale investigation provided insights into the chemical efficiency of the treatment strategy, microstructural comparisons, and its potential for improving soil mechanics.

A reinforced concrete container, 8.0 m × 10.0 m × 2.5 m, was constructed with two compartments for repeated experiments (Harran et al., 2022).

Figure 1. Testing set-up.

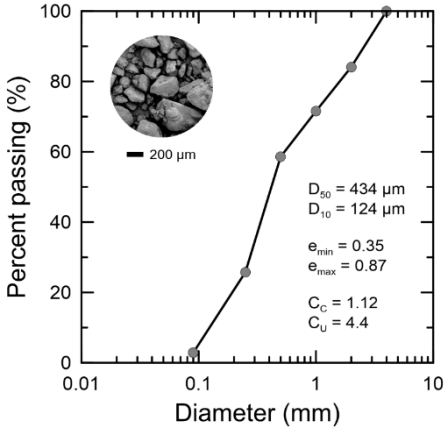

Figure 2. Particle size distribution and properties of the chosen sand.

Unlike previous impermeable setups, this design incorporated draining tubes in the tank's bottom, preventing reactant accumulation. This setup allowed control over water table levels, simulating real environmental conditions. Eight injection wells (Figure 1) per compartment facilitated the bio-cementation protocol's implementation. The design prioritized preventing ammonium leaching and maximizing liquid circulation.

Both compartments were filled with 0–4 mm sand from the Catellani quarry (Switzerland), exhibiting a diverse grain size distribution and composed of 70% quartz and 30% natural carbonate minerals. The sand is labelled SP according to ASTM D2487 but still covers a range of contents from fine (2.9% < 0.1 mm diameter) to coarse (15.9% > 2 mm diameter). (Figure 2). The bio-cementation protocol involved 11 days of successive cycles injecting hydrolyzed carbonate solution followed by immediate cementation solution injection. Sporosarcina pasteurii was used for urea hydrolysis, and both solutions were prepared in 1000 L batches.(Table 1) The protocol aimed for full pore volume coverage, and drainage tubes simulated a draining bottom surface, collecting effluents for monitoring. This setup enabled control over injection pressure and offered insights into the bio-cementation process.

In-situ testing utilized an instrumented dynamic penetrometer (Panda, Solsolution) across treated and untreated sand volumes. Tests at various locations, chosen for spatial heterogeneity representation, assessed the bio-cementation effect on cone tip resistance. The results provided a detailed understanding of the treatment‘s impact on the soil‘s mechanical properties.

Mechanical performance assessment involved Unconfined Compressive Strength (UCS) tests on lab-treated samples. The samples were compared to conventionally bio-cemented ones. Testing included controlled axial strain rates and subsequent determination of calcium carbonate contents, offering insights into the treatment‘s impact on mechanical behavior.

Samples from both laboratory and large-scale experiments underwent Scanning Electron Microscopy (SEM) for textural and geometrical characterization of the precipitated calcium carbonate. This microscopic analysis provided visual insights into the structure and morphology of the cemented material.

Table 1. Treatment solution constituents.

	Bioreactor Solution (BS)	Cementation Solution (CS)
Peptone (kg/m^3)	1	-
Lyophilized bacteria (L/m^3)	1	-
Urea (kg/m^3)	50	-
Calcium chloride (kg/m^3)	-	200

3 RESULTS

The precipitation efficiencies were computed based on the excess reactant species found in each injection cycle, using either calcium or TIC excess. For each injection cycle, two effluent samples were taken. Remarkably, high completion rates exceeding 70% were achieved with reaction times as short as 4 hours between injections. The effluent predominantly exhibited a richness in calcium in five out of eight injection cycles.

The use of pre-hydrolyzed urea played a pivotal role in this efficiency, as calcium carbonate precipitated immediately upon the contact of BS and CS solutions. This process demonstrated comparable efficiency to conventional Microbially Induced Calcium Carbonate Precipitation (MICP). Notably, it boasted faster precipitation times and the advantage of

introducing a solution into the ground with known characteristics, concentrations, and stability.

UCS (Figure 3) values increased with rising bond contents, reaching as high as 2.1 Mpa for 10% $CaCO_3$. Young's modulus (E) varied between 180 Mpa and 480 Mpa, increasing with higher bond content. Despite some observed scattering associated with the measured heterogeneity in gravimetric contents within the same sand column, the results were consistent. Generally, higher $CaCO_3$ contents resulted in a brittle response, characterized by distinctive peak strength followed by sharp softening.

SEM observations of precipitates formed in liquid batches after mixing the ex-situ BS and CS solutions are provided in Figure 4. The crystals exhibited a typical rhombohedral calcite morphology, reaching a size of 20 µm when precipitated without a sand matrix.

When ammonium concentrations exceed the water's natural self-purification capacity, it triggers various environmental concerns, notably eutrophication. Eutrophication, in turn, leads to the decline of aquatic life, such as fish, degradation of water quality, and disturbance of biodiversity. Therefore, it is crucial to monitor and mitigate ammonium concentrations arising from the bio-cementation process, to maintain them below acceptable thresholds. The recirculation of ammonium, combined with the levels produced with every new hydrolyzed batch, led to an increase in influent NH4+ concentrations throughout the treatment, as illustrated in Figure 5. At the end of the 20,800 L treatment, the effluent NH4+ concentration stabilized at around 1 mol/L.

Considering the average NH4+ concentration in the 11 cycles, accounting for dilution, the residual recorded ammonium aligned with the theoretical value. This suggests that to bring NH4+ within acceptable limits, substantial volumes and pumping times are needed in large-scale projects. The potential retention of NH4+ on soil particles and dissolution in groundwater observed in previous literature works further underscores the challenges associated with NH4+ elimination through MICP-induced ureolysis.
Hence, the study postulates that byproduct extraction from treatment solutions prior to injection into the ground using ex-situ hydrolysis remains a promising alternative. This approach aims to enable NH4+ elimination and minimize operational constraints, ultimately producing soil admixtures or grouts for bio-cementation that align with environmental norms.The results of dynamic penetrometer tests revealed varying heterogeneity in the treated section. Figure 6 presents a typical penetrogram result with a discrepancy at a depth of 1.2m attibuted to the well‘s outlet.

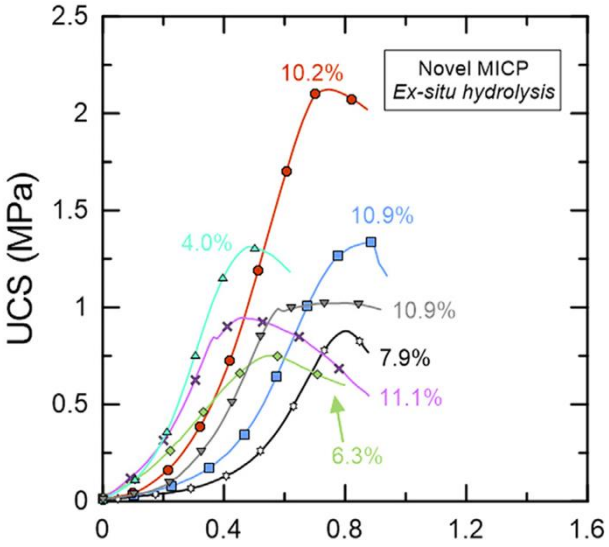

Figure 3. UCS determination on samples produced using ex-sity hydrolysis.

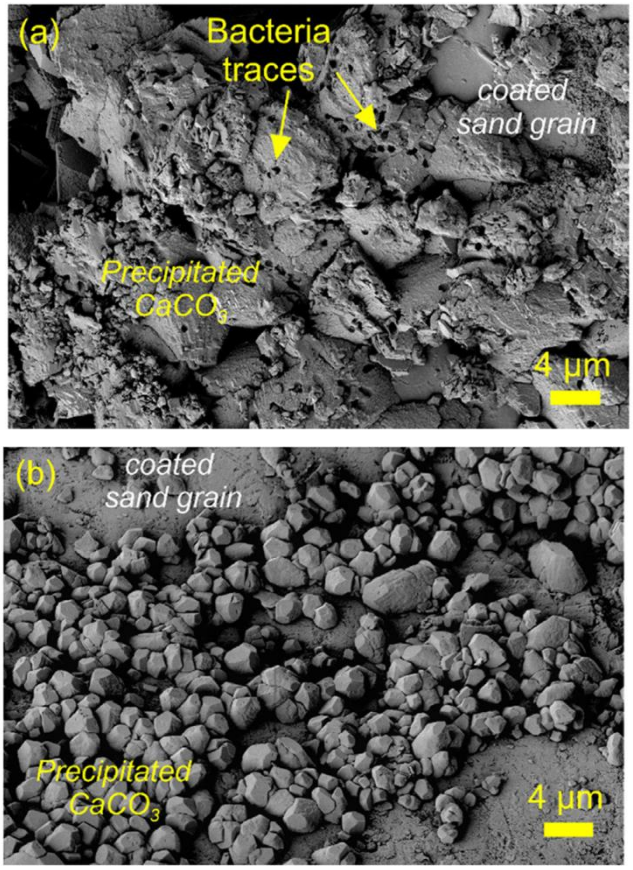

Figure 4. SEM observations of calcium carbonate precipitated on the surface of sand grains using (a) traditional MICP with in-situ hydrolysis and (b) novel MICP with ex-situ hydrolysis.

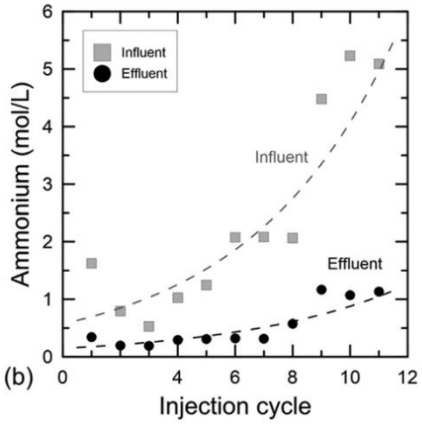

Figure 5. NH4+ concentrations during recirculation of enriched treatment batches.

All tests in the untreated compartment demonstrated overall homogeneity in cone resistance (qd) across depth, with values ranging between 0.5 and 1 MPa. A follow-up experiment using a slited pipe, i.e. without outlets every 50cm across the well‘s depth, yielded more homogenous results (Figure 7).

4 CONCLUSIONS

The ex-situ hydrolysis approach demonstrated high precipitation efficiencies and comparable mechanical properties to traditional MICP. The microscopic analysis revealed changes in mineralization processes at the pore scale. Chemical monitoring confirmed the efficiency of the precipitation reaction, with implications for the treatment of residual ammonium. The dynamic penetrometer campaign provided spatial insights into the effectiveness of bio-cementation, highlighting areas of significant improvement. Overall, the study contributes to bridging laboratory advancements with large-scale implementation of bio-cementation, providing a comprehensive multi-level quality monitoring system for real-world applications.

ABSTRACT: The dimensioning of underground extra-high voltage direct current (HVDC) power lines, requires detailed knowledge of the ground and its thermal conductivity. For this purpose, a laboratory test using transient methods with the needle probe, to determine reproducible values of the thermal conductivity of soils was developed for the construction of the 700 km long SuedLink underground power line in Germany. The unique approach of this test not only yielded precise thermal conductivity measurements but also allowed for the depiction of the thermal conductivity to water content relationship, covering the entire range from saturated to oven-dried soil states. This allows site specific groundwater conditions to be considered during the design. Additionally, the gravel content of the soil was also taken into account.The results of the thermal conductivity tests of the soil samples form the basis of the thermal ground model which governs the thermal design of HVDC underground cables. The thermal design is crucial for optimising the spacing between cables in order to minimise the project costs and the environmental impact. In this paper the process from laboratory testing to the creation and analysis of the thermal ground model is presented. Furthermore, insights into the thermal design of HVDC cables are provided focussing on horizontal directional drilling (HDD) methods.

RÉSUMÉ: Le dimensionnement des lignes électriques souterraines à courant continu à haute tension (HVDC) nécessite une connaissance détaillée du sol et de sa conductivité thermique. À cet effet, un test en laboratoire utilisant des méthodes transitoires avec une sonde à aiguille, pour déterminer des valeurs reproductibles de la conductivité thermique des sols, a été développé pour la construction de la ligne électrique souterraine SuedLink de 700 km de long en Allemagne. L'approche unique de ce test a non seulement permis d'obtenir des mesures précises de la conductivité thermique, mais a également permis de représenter la relation entre la conductivité thermique et la teneur en eau, couvrant toute la gamme des états du sol, de saturé à séché au four. Cela permet de prendre en compte les conditions spécifiques au site en ce qui concerne les niveaux d'eau souterraine lors de la conception. De plus, la teneur en gravier du sol a également été prise en compte. Les résultats des tests de conductivité thermique des échantillons de sol constituent la base du modèle thermique du sol qui régit la conception thermique des câbles souterrains HVDC. La conception thermique est cruciale pour optimiser l'espacement entre les câbles afin de minimiser les coûts du projet et l'impact environnemental. Dans cet article, le processus allant des tests en laboratoire à la création et à l'analyse du modèle thermique du sol est présenté. De plus, des informations sur la conception thermique des câbles HVDC sont fournies en mettant l'accent sur les méthodes de forage directionnel horizontal (HDD).

Keywords: Soil thermal conductivity; underground cables; extra-high voltage direct current; water content; renewable energy.

1 INTRODUCTION

In line with the Renewable Energy Sources Act (BMWK, 2021), all electricity in Germany should be carbon-neutral by no later than 2050. The extra-high voltage direct current (HVDC) underground cable project SuedLink will contribute to this goal by making

it possible to transmit wind energy from the northern parts to the southern parts of the country.

Most of the 700 km route of the SuedLink power line consists of the so-called trunk-line where four HVDC cables will be installed underground at various distances to one another, see Figure 1. This will be done by means of open excavations as well as using trenchless construction techniques (such as HDD) along significant lengths of the project.

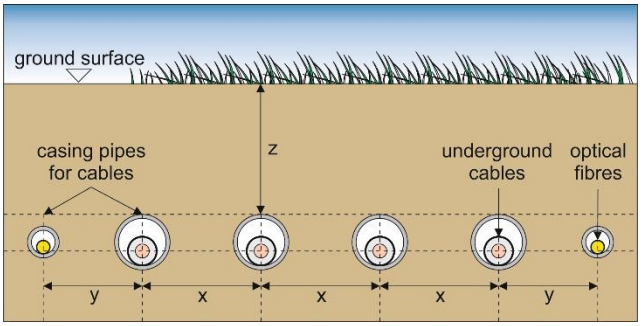

Figure 1. Sketch of HVDC underground cables constructed using HDD.

Some of the electrical energy transported along the cables is converted to heat energy due to the resistance of the cables. As each of the HVDC cables emits a certain amount of heat, they need to be spaced sufficiently far apart from one another in order to avoid overheating and thereby reducing their performance. This is why the thermal conductivity (TC) of the ground plays a crucial role in the thermal design of underground HVDC cables.

As part of the SuedLink project a novel method for determining the water content dependant TC of soils was developed and applied. The results of these tests were used to develop thermal ground models which formed the basis of the thermal design of the HVDC cables.

Different methodologies can be applied in order to determine the TC of soils as explained by Banks (2012). Typically, these fall into either the category of employing the steady state solution to Fourier's law in several variants or by using a transient method. In laboratory settings, steady-state methods entail subjecting a specimen to unidirectional heat flow. The power input and temperature difference across the specimen are then measured once a steady state is achieved. Transient methods require the application of heat to the specimen, with subsequent monitoring of temperature changes throughout a specified duration.

Clarke et al. (2008) described a steady state test method for TC of soils where heat is applied to one end and assumed to have one-directional flow, since the sample is insulated radially and at the base. Low et al. (2017) performed an error analysis on the Clarke et al. (2008) setup by performing physical laboratory tests and then comparing these to a finite element model of the tests. Low et al. (2017) conclude that significant radial heat losses occur through the sides of the thermal cell which significantly impacts the calculated TC. Low et al. (2017) proceed to recommend using transient testing techniques. Furthermore Schedel et al. (2019) argue that a valid measurement of the TC on a partially saturated material, using steady state methods, is also not possible. This is because the displacement of the water content along the temperature gradient, due to uneven heat distribution, can also lead to significant inaccuracies.

Other literature on TC of soils is typically found in the context of ground source heat pumps or energy foundations. Here the thermal response test to determine the effective TC along the length of a borehole is described in Banks (2012) and VDI 4640 (2010). However, the results of these tests are applied in the design of ground source heat pump systems and are not directly applicable for determining the TC of specific soil samples and their representative layers. VDI 4640 (2010) does, however, provide typical values of thermal conductivities for various soil types at different water contents which can be useful as indicative values to use during a pre-design.

Currently no standard exists for determining the characteristic TC value of soils in the field or in the laboratory using transient test methods. Only the configuration of the needle probe and the subsequent measurement to determine the TC are described in standards ASTM D5334:22a and IEEE Std 442-2017. With the participation of numerous experts, the processes of sampling, sample transport and measuring across various water contents up to evaluation were developed into a project specification, which has been adopted by the four major energy grid operators in Germany.

2 THERMAL CONDUCTIVITY (TC) TEST

In the SuedLink project, the investigation of thermal properties of soils is carried out on samples taken during the ground investigation. The TC of a soil is highly dependent on its water content as well as the degree of compaction. The latter is adjusted to the in-situ density when samples are prepared for TC measurements. The water content of soils is subject to natural (seasonal, land use) and operational (drying due to heat radiation of cables) changes. To take this into account, the samples are dried out in the laboratory over a defined period of time, starting from the saturated state and ending in the oven-dried state. During this drying process the TC is continuously measured and recorded. The results of the laboratory

tests yield a relationship between TC and water content for a specified density. In contrast to only having measurements at single points, this continuous measurement allows the entire process to be partially automated, thus avoiding external influences and providing very detailed data on the TC.

2.1 Test setup

In the laboratory test the sample is air dried, from an initially saturated state, in an open topped cylinder. During this drying period, the TC is measured using the needle probe method, as per ASTM D5334:22a, while simultaneously measuring the water content gravimetrically. The basic procedure of this continuous TC measurement and the use of 50 mm high cylindrical soil samples is based on investigations by Markert (2012) and Drefke et al. (2017) and further adapted by Stegner et al. (2017).

Figure 2 shows the experimental set-up for the continuous measurement of TC and water content on a cylindrical soil sample.

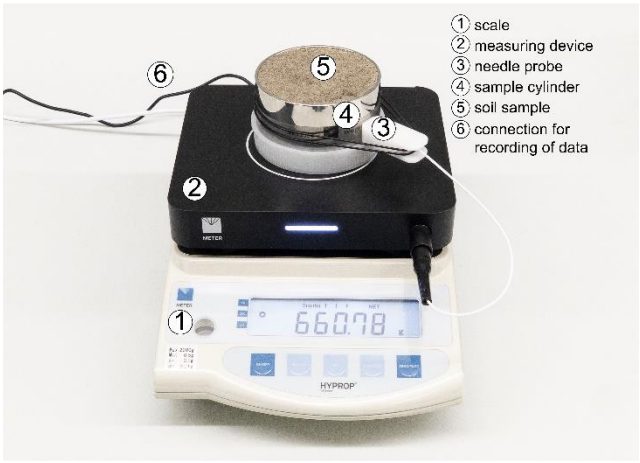

Figure 2. Experimental setup for continuous measurement of TC and water content of a cylindrical soil sample, adapted from METER Group AG (2021).

The laboratory test is carried out with standardised 250 cm³ steel cylinders (inner diameter = 80 mm; height = 50 mm). Three openings are arranged at 120° to each other along the middle of the cylinder. One of these is used to insert the needle probe into the soil sample.

In the SuedLink project, the TR-3 Inline needle probe from METER Group AG with a length of 70 mm and a diameter of 2.4 mm is used. The needle probe complies with the specifications of the relevant electrical engineering standards (ASTM D5334:22a; IEEE Std 442-2017).

For determining the relationship between TC and water content, the VARIOS measuring system (Meter Group AG) was further developed in cooperation with the manufacturer and the laboratory based on the measurement specification provided by the client. The special feature of this measuring system is the fully automated continuous measurement and recording of the TC data using the line source test method (ASTM D5334:22a) and the water content via weighing. The samples remain in position on the scales during the entire test procedure, so that disturbances during sample handling and thus falsification of measurement results can be ruled out.

2.2 Sample extraction and preparation

Both disturbed and undisturbed samples can be used for the laboratory test to determine the TC. In the case of high coarse grain contents, disturbed samples are preferred to undisturbed samples, as these allow the so called “oversize grains” (d > 6.3 mm) to be separated during sample preparation. This may be necessary if the insertion of the needle probe into the soil samples is hindered by these oversize grains.

If the samples from the ground investigation are mostly gravel free, it is favourable to take undisturbed soil samples by means of modified stainless-steel liners, specifically intended for the TC tests (see Figure 2). Undisturbed soil samples have the in-situ density and thus reflect the natural state more accurately than disturbed soil samples which are subsequently packed. It is therefore favourable to use undisturbed soil samples, since the TC of a soil is dependent on the density.

In the case of disturbed samples (bucket samples), first the water content of the soil is determined and, if necessary, oversized granular material is separated. By knowing the water content as well as the natural density of the soil, the sample can be installed into the cylinder as close as possible to the in-situ conditions. If no density information is known, the sample is compacted to a density that matches the packing density or consistency as per DIN 4220:2020-11 (2020). In the case of undisturbed samples, no special preparation is necessary before carrying out the test, as these samples are already in a near to in-situ state.

In the next step, the entire sample is covered by a filter paper and permeable caps on both sides and then saturated in a water bath for at least 30 hours.

2.3 Testing

After saturation, the needle probe is inserted and fixed in one of the three lateral openings. The test is started once the sample with the needle probe and the TC measuring device are placed on the scale and connected to the needle probe.

The system automatically measures the TC of the sample at intervals of 60 minutes. Simultaneously the

corresponding weight of the experimental set-up, i.e., the continuous weight loss, is recorded via the scales. The exact water content at each measurement can only be assigned after the sample is oven dried at the end of the test. Both the sample preparation and the measurements are carried out at constant room temperatures under controlled laboratory conditions.

Normally the test would be terminated once the sample has reached a constant mass. However, depending on the soil type, this could take between a few days up to weeks. A termination criterion of 8 days from start of test, has proven to be sufficient to record the water content relevant for HVDC cable dimensioning. The sample is then dried in an oven at 65 °C for 48 hours. After cooling in a desiccator, the so-called "oven-dried" TC is measured. Hereby the theoretically possible driest condition of the soil directly around the cables is simulated. Finally, the sample is dried at 105 °C in order to assign the corresponding water contents and dry density to the recorded sample weight measurements. The procedure described above is represented in the flow chart in Figure 3.

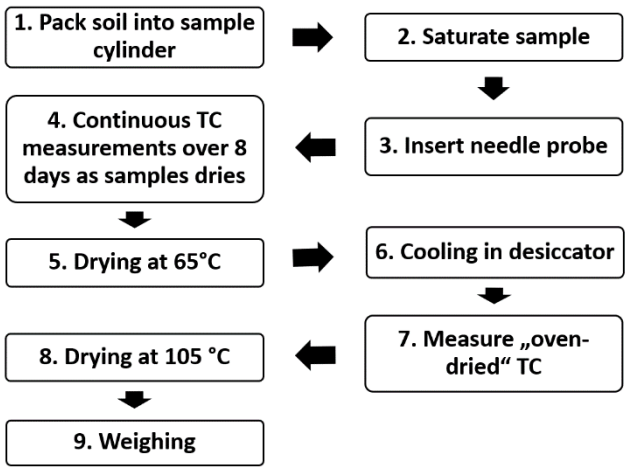

Figure 3. Laboratory test procedure for determining soil TC.

3 THERMAL CONDUCTIVITY RESULTS

3.1 Raw Data

A laboratory test result of the TC to water content of a sand sample is shown in Figure 4. The (almost) fully saturated sample has a volumetric water content of about 47% with a corresponding TC of approximately 1.5 W/(m·K). As drying progresses, the TC decreases to about 0.9 W/(m·K) at a volumetric water content of about 15%. This range is recorded during the continuous measurements of 8 days. In this case the "oven-dried" TC was determined to be approximately 0.35 W/(m·K) at a volumetric water content of 2%.

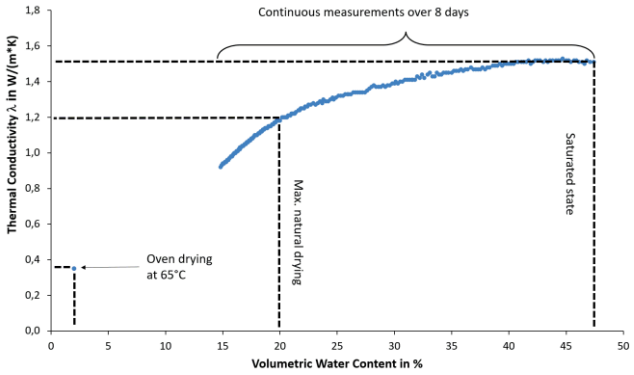

Figure 4. Exemplary TC test result of a sand sample measured from complete saturation to oven drying.

The above example clearly illustrates the tendency of the TC to decrease as drying progresses. At low water contents further drying by evaporation takes longer than at high water contents, which is why the 8-day cut-off criteria was defined. The gap between the oven dried reading and the last reading after 8 days can be bridged with sufficient precision by linear interpolation.

Generally, the TC decreases as the soil dries out. However, occasionally cohesive soils show an increase in TC with increased drying over a certain period of time. This observation correlates with a shrinkage observed in these samples during the initial phase of heating and subsequent drying-out (Laloui, 2001).

3.2 Evaluation of raw data

To ensure a uniform evaluation and a minimisation of human errors of the TC laboratory results within the SuedLink project, the geo-data management software GeODin was used, for which a specific TC-plug-in was developed by Fugro GmbH.

For the evaluation, all relevant subsoil data, such as stratigraphic logs, information on the TC samples, and so on need to be entered into GeODin. The software imports and reads the raw data of the TC test results. The GeODin plug-in corrects the discrepancy that arises from the non-measurement of the oversize grains during the TC tests, by geometric means (Woodside & Messmer, 1961; Farouki, 1986). This is done because rocks have a higher TC than soils, which is why the oversize grains fraction that was separated before the test (see section 2.2) has a positive influence on the overall TC of a stratigraphic soil layer. In addition to this the relevant water contents and corresponding thermal conductivities of the soil are determined by the plug-in. This whole process is semi-automated.

In the next step of the evaluation, the measurement gap between the continuous measurement and the "oven dried" TC (see Figure 4) is closed by linear interpolation.

In a further evaluation step, the TC value of the minimum natural water content is determined. This is based on the results of site-dependent, multi-year water balance models. In the example in Figure 4, the minimum natural water content is 20% which corresponds to a TC of approx. 1.2 W/(m·K), as per Figure 4. Under certain conditions, it can also be necessary to apply a water content that accounts for technically induced drying. Ultimately the evaluation of the TC test with the GeODin-TC-Plugin yields the TC associated with the typical drying of the soils (saturated, natural drying/damp, technically induced cable drying, oven-dry) for each sample.

4 THERMAL GROUND MODEL AND DESIGN

For the thermal design of the cable above groundwater, the relevant thermal conductivities are comprised of a pair of TC values corresponding to the water content of the soil in its natural state and the soil dried by the cable. Below groundwater the TC corresponding to the saturated water content of a soil is adopted. For each sample these thermal conductivities are integrated into a thermal ground model where areas of comparable thermal properties (thermal zones) are defined. An example of a thermal ground model is displayed in Figure 5.

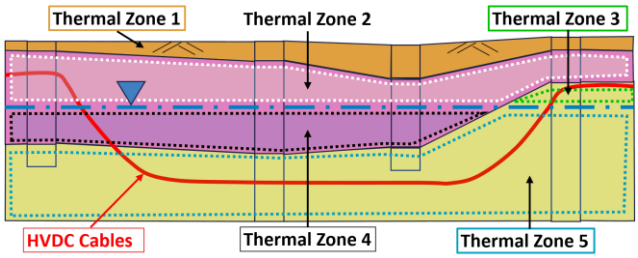

Figure 5. Example of a thermal ground model with demarcated thermal zones.

Within a soil layer, different thermal conductivities due to different water contents can become relevant for the design. For example, when a soil layer extends from above the water table to below the water table. This is why, for example, the thermal zone 2 is differentiated from the thermal zone 4 in Figure 5. The lowest groundwater level expected over the lifetime of the cable must always be used during design.

The closer the cables are laid to each other, the greater their mutual thermal influence. The maximum operating temperature of 70 °C in the cable conductor limits the minimum centre-to-centre spacing between the cables for a given cable type and local thermal soil properties. In the thermal design the minimum centre-to-centre spacing is calculated iteratively as a function of the depth of the cable.

The thermal design calculations are performed by means of Finite Element modelling for stratified ground using a two-layer model according to the Cigre Study Committee 21 (1992). The primary input parameters for the thermal design calculations are the TC value-pairs.

The results of these calculations were developed into a set of tables for the SuedLink project that cover the vast majority of cases encountered when performing a thermal design. This not only stream-lined, but also created a transparent and reproducible designs. Specific cases that were not covered by the tables had to be calculated individually.

At the same installation depth, changes in soil type and water content can result in large differences in the required cable spacing, which can in some cases differ by a factor of four.

The detailed TC investiagtions have led to signficant optimisations in cable-spacing, as can be seen by the following example. Conventionally a very conservative TC-Pair corresponding to the „damp“ and „cable-dried“ water contents, of 1 W/(m*K) and 0.4 W/(m*K), is assumed. At 8 m cable depth this would lead to a required cable spacing of approximately 27 m along the trunk-line. Comparing this to a true TC-Pair of 1 W/(m*K) and 1 W/(m*K), which has often proved to be the case for various soils, a cable spacing of only 9 m is required.

For the thermal design, various boundary conditions such as heat-emitting underground cables (from third parties), pipelines and topographic changes in ground level need to be carefully considered.

Various technical solutions can be adopted and considered in the design in order to reduce the required spacing between the cables installed by means of trenchless construction. This included improving the TC in the area of the cable by filling the casing pipes with a conductive material such as a gel or water. Alternatively, the standard casing pipe diameter (280 mm) was increased and also filled with a conductive material. In certain cases, the construction tolerance for the HDD was reduced.

5 CONCLUSIONS

The partially automated testing and evaluation processes described here has been established and used on over 6000 soil samples in the SuedLink project. The creation and understanding of the thermal ground model require detailed evaluation with corresponding expertise due to complex stratigraphy’s as well as various external boundary conditions. Similarly, a

good understanding of soil thermal conductivity principles, in the context of HVDC cables, are essential for an efficient design.

Looking forward, European energy grid operators envision the development of a comprehensive database incorporating the soil TC test results from the SuedLink project. Coupled with pedotransfer functions, this database would streamline ground exploration for future underground cable projects, contributing to more efficient and cost-effective designs.

ABSTRACT: The PS logger is a low frequency dipole-based sonic logging probe which is used widely to measure P- and S- wave velocities of earth materials. It is of particular interest to offshore environments where the latter can be used to derive the small-strain stiffness G_{max}, an important measurement in offshore construction. The method relies on the indirect excitation of the borehole via a dipole pressure wave excited in the borehole fluid, allowing shear wave velocity (V_s) to be measured in both fast and slow formations. In this study, the theoretical basis for the PS logger is presented, alongside the results of recent field projects which provide answers to key questions regarding the viability of the tool for a range of situations, and to the interpretation of results for widely ranging ground conditions. These include a comparison of results from both uncased (open) and cased boreholes, and from a wide range of ground velocities ($V_s \approx$ 220m/s to 3760m/s), and for varying borehole sizes. Full waveform analysis of time-series data is undertaken and underlines the need for consideration of theoretical principles in data interpretation. Ultimately, the results demonstrate the wide applicability of the tool beyond the geotechnical limits of traditional logging tools, which is attributed largely to the low frequency nature of the PS logger.

RÉSUMÉ: Le système PS Logger est une sonde de diagraphie sonique utilisant un émetteur basse fréquence de type dipôle, utilisée pour générer et mesurer les vitesses des ondes de compression P et de cisaillement S dans les sols. La sonde est particulièrement intéressante dans la conception de structures offshore où elle peut être utilisée pour calculer le module de cisaillement G_{max}, qui est une mesure majeure dans ce domaine. La méthode repose sur l'émission d'une onde de compression dans le fluide qui au contact de la paroi du forage génère une onde flexurale permettant de mesurer la vitesse de l'onde de cisaillement (Vs) dans les formations rapides mais surtout dans les formations lentes. Dans cette étude, le principe théorique de fonctionnement de l'outil PS logger est présenté, ainsi que les résultats de chantiers récents qui éclairent sur les capacités de l'outil dans différentes situations et montrent des résultats dans des conditions de sol très variés. Également présentés: - une comparaison des résultats en forages non tubés (ouverts) et tubés, - des mesures dans une gamme très large de vitesses de terrain (Vs ≈ 220 m/s à 3760 m/s) et dans différents diamètres de forage. Une analyse complète des trains d'ondes a été réalisée utilisant l'ensemble des principes théoriques régissant la propagation des ondes P et S dans les sols. En conclusion, les résultats présentés démontrent la large applicabilité de l'outil PS Logger et ses capacités bien supérieures aux outils de diagraphie traditionnels de type FWS grâce à son système d'émission dipolaire flexural.

1 SONIC LOGGING

Sonic logging methods are used to obtain velocity data in boreholes with depths ranging from a few metres to several kilometres. Variations exist on logger configurations, which have evolved to overcome problems including measurement in slow formations and poor measurement resolution (Close et al., 2009). The propagation velocities of body waves in a medium are a complex function of several factors, including density, porosity, and mineralogy (Rafavich, 1984). Sonic logs utilise acoustic sources operating within a frequency spectrum, exciting waves in the surrounding formation of wavelength λ (m) determined by Eqn. 1, where f (Hz) is excitation frequency within the source spectrum, and V (m/s) is the velocity of the wave:

$$V = f\lambda \quad (1)$$

Traditional monopole tools use critical refraction of compressional (P) and shear (S) waves to measure velocities, causing symmetric borehole displacement (Figure 1.a), but are impeded by the fact that shear refraction is not possible in slow formations. Dipole tools overcome this issue by generation of the flexural

(bending) mode (Figure 1.b), which, at sufficiently low source frequencies travels at the formation shear velocity (but technically constituting a surface mode) (Close et al., 2009).

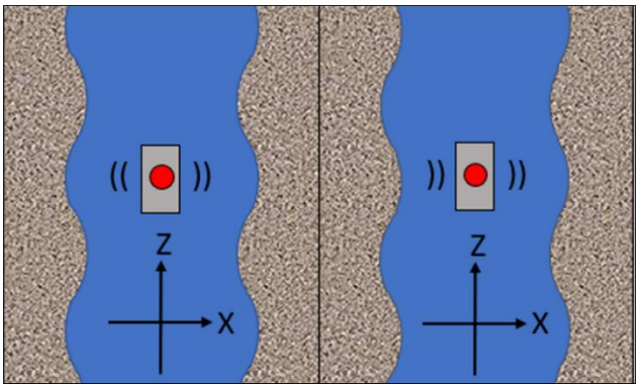

Figure 1. Side view of fundamental borehole movement resulting from (a) monopole; (b) dipole forces.

1.1 PS Logger

The principal features of the PS logger (a suspension-type logger) are a dipole hammer source, separated from two receivers by acoustic damping tubes. The hammer source constitutes a solenoid-operated shuttle housed within a steel cylinder. Firing causes the shuttle to strike the inner surface of the steel cylinder, indirectly exciting the borehole fluid, exciting both P and S_f (flexural) waves along the borehole in both fast and slow formations (Robertson Geo, 2023). Measurements are made in two horizontal directions (left and right), producing flexural modes 180˚ out of phase. The source centre frequency is approx. 1.5kHz.

As the hammer strikes the cylinder, a momentary imbalance in push/pull action between the struck/ opposite sides causes bulging (Figure 2a), creating a monopole in the fluid, exciting P and Stoneley waves. As the opposite side reacts, a pressure doublet is set up, such that a pressure increase in the fluid on one side of the cylinder is matched by a pressure decrease in the fluid on the other side (Figure 2b), exciting the flexural mode, generating dipole P waves and flexural waves. The PS logger is fitted with hydrophones and geophones, which are configured to measure P and S_f (flexural) wave velocities, respectively.

In this paper, widely ranging ground conditions are considered, in order to evaluate the viability of the PS for diverse geotechnical conditions. The particular focus is on measurement of shear wave velocities, generally harder to resolve than compressional waves.

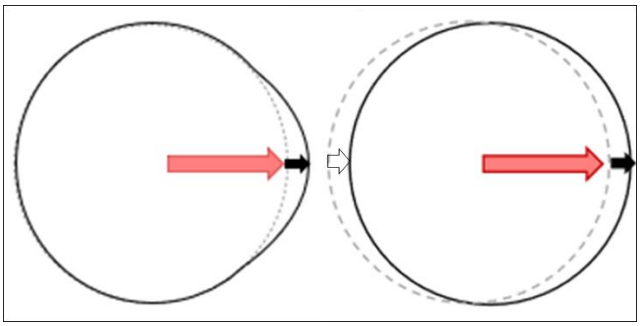

Figure 2. Planar view of steel cylinder primary displacement modes. (a) Bulging caused by initial imbalance; (b) flexural mode displacement.

2 CASE STUDIES

Anonymised Robertson Geo archives provided the data for the following case studies, allowing the following geotechnical scenarios to be investigated. Recorded waveforms were obtained using the geophone receivers.

2.1 Open (uncased) versus cased borehole

A 146mm diameter borehole was drilled and PS logging undertaken along a 17m profile, at 0.5m intervals, whilst the borehole was open (uncased).

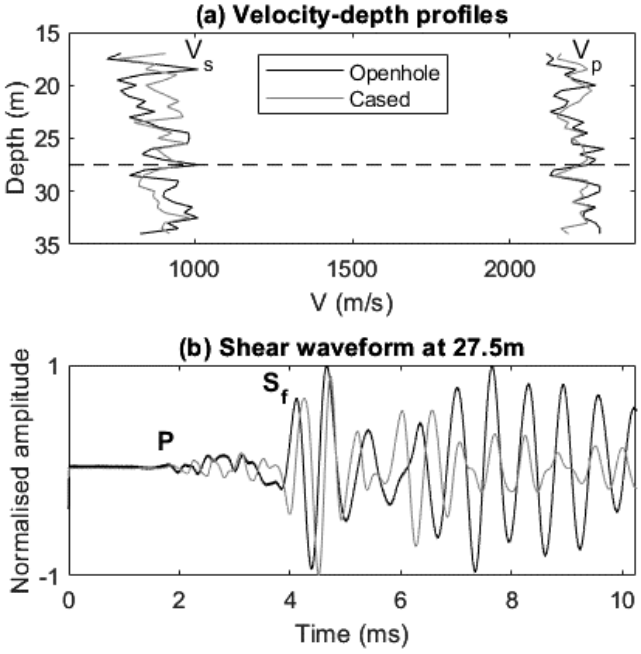

Figure 3. Openhole versus PVC cased borehole comparison. (a) Velocity-depth profile averaged from right and left hammer shot results (V_s obtained from geophone channels, V_p from hydrophone channels); (b) Geophone-recorded waveforms (data from right hammer shot only). "P" and "S_f" indicate the arrival of compressional and flexural waves, respectively.

The PS logger was removed and the borehole lined with PVC casing, reducing the diameter to 90mm, and the measurements repeated with the casing in place. Figure 3. shows reasonable agreement between datasets, summarising relative differences in Table 1.

Table 1. Summary of openhole versus cased (PVC-lined) borehole comparison.

Velocity type	Min. diff (%)*	Max. diff (%)*	Mean diff (%)*
V_p	0.0	5.4	1.6
V_s	0.0	21.6	8.1

*Calculated with respect to openhole data. Describes absolute difference.

2.2 Varying formation velocity

Waveforms pertaining to the extremes of shear velocities were obtained from the data archives, describing very slow shear velocities of 223m/s and 3759m/s respectively. In the slow formation, both P and S_f waves are observed on both near and far receivers, whilst in the fast formation, only S_f waves are observed (Figure 4).

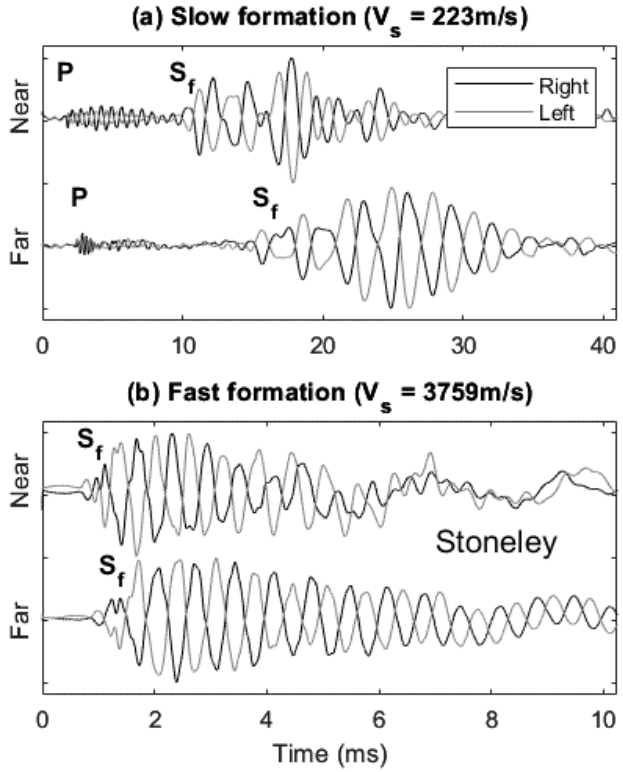

Figure 4. Geophone-recorded waveforms for (a) slow; (b) fast formations. Data from both right and left hammer shots are shown, illustrating clear reversals of amplitudes. Note, different time axes reflect different sampling rates. "P" and "S_f" indicate the arrival of compressional and flexural waves, respectively. Calculated Poisson's ratio for the slow formation waveform is 0.49.

2.3 Borehole size

Waveforms pertaining to the extremes of industry borehole sizes were obtained from the data archives describing borehole diameters of 250mm (large), 146mm (medium) and 76mm (small). Figure 5 demonstrates that in all three cases, clear waveforms have been obtained, resolving both P and S arrivals.

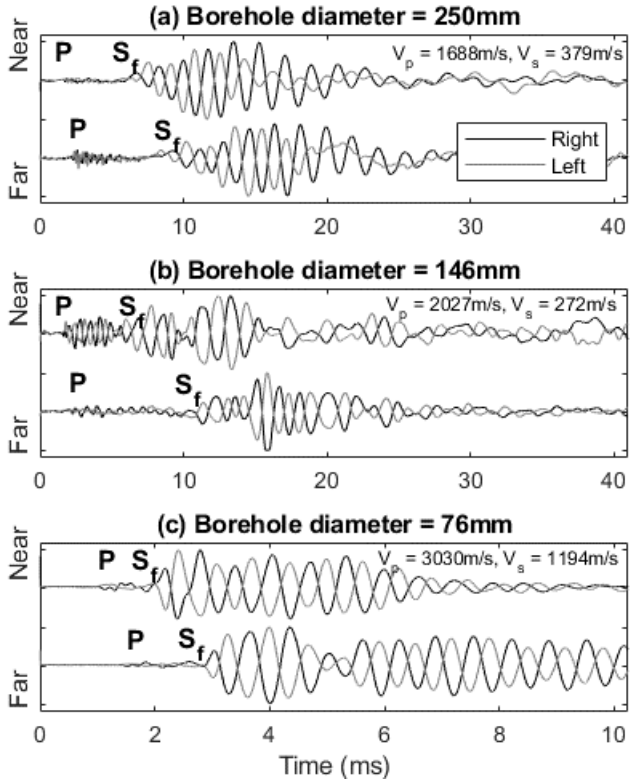

Figure 5. Geophone-recorded waveforms for (a) large, (b) medium and (c) small borehole diameters. Data from both right and left hammer shots are shown, illustrating clear reversals of amplitudes. Note, different time axes reflect different sampling rates. "P" and "S_f" indicate the arrival of compressional and flexural waves, respectively. Poisson's ratios are 0.47 (a), 0.49 (b) and 0.41(c).

3 DISCUSSION

Generally, the PS logger is recommended for use in uncased boreholes, however, manufacturers do provide specifications for casing installation and grouting such that the tool should operate regardless (Robertson Geo, 2023). Figure 3.a shows velocity-depth profiles of a borehole with and without PVC casing, where V_p values are in strong agreement, and V_s sees deviations of up to 21.6%. It should be noted that the two datasets were obtained one month apart, such that ground conditions may have changed, affecting measured velocities, and it is possible that the installation of the casing may have disturbed the borehole. According to Eqn. 1, the wavelength of P

waves will be greater than that of the flexural waves (as compressional waves arrive first) for a source centre frequency of 1.5kHz, therefore, it is reasonable to consider that they would be less affected by near-borehole disturbance, however, there is still good agreement between V_s profiles (mean diff. 8.1%).

One principal issue of traditional monopole tools is that they cannot refract a shear wave in slow formations (Schmitt, 1988). Figure 4 shows a comparison of waveforms recorded using the geophone channels ("S-channels") in slow and fast formations, where the flexural mode has allowed shear wave velocity to be inferred in the slow formation. In the fast formation, a refracted S wave will also be present, and indistinguishable from the flexural arrival. Time axes demonstrate the requirement for different sampling rates, and show that in the fast formation, the P arrival cannot be observed, which usually only appears in slow formations. In Figure 4b, a low frequency oscillation is present, in phase between right and left hammer shot traces, likely to be a Stoneley wave generated by the monopole component of the logger.

Under ideal conditions, the same material would be tested for varying borehole diameters, however, because the borehole diameter is largely dictated by the formation material (larger boreholes in softer, slower formations) and client constraints and specifications, this is usually only possible using modelling techniques (e.g., Wang et al., 2022). Figure 5 shows waveforms from three slow formations (V_s < 1500m/s) where full waveforms have been successfully obtained in boreholes with diameters ranging from 76mm to 250mm. A general consideration of any invasive measurement method is disturbance to the material. For borehole logging, the ratio of the wavelength to the borehole diameter is considered key in determining the degree of disturbance but is difficult to quantify. Kurkjian (1986) cites a minimum ratio of 10, however, in Wang et al. (2022), simulated experiments demonstrated that at sufficiently low source frequencies, the borehole size has relatively little influence on the radiated acoustic. Because of its relatively low operating frequency, the required wavelength to borehole diameter ratio to avoid borehole effects is likely to be considerably lower than 10, however, greater understanding of the ratio effects would be beneficial.

Since the development of dipole-based logging tools which generate the flexural mode, the problem of measurement of shear velocities in slow formations has been overcome, however, many tools operate at relatively high frequencies, where dispersion correction is required (Cheng, 2015) if source frequencies exceed a cutoff value estimated to be 3.5kHz (Schmitt, 1988). With a source centre frequency of 1.5kHz, observed flexural arrivals can be assumed to travel at the formation shear velocity.

4 SUMMARY AND CONCLUSIONS

The PS logger is most often used in offshore geotechnics applications, where measured shear velocities are combined with density info (samples or log data) to derive the small-strain stiffness (G_{max}) important for offshore wind turbine construction. In such situations, formations are usually slow (e.g. unconsolidated sands) and boreholes are uncased with typical diameters of 150mm. The PS logger can successfully be deployed in geotechnical scenarios beyond these conditions, overcoming some of the problems of traditional tools including measurement in slow formations and avoiding the need for dispersion correction, rendering it highly versatile in its applicability. Although it has successfully been deployed in large boreholes, borehole effects may be important; more research is needed to fully understand these implications on seismic velocity estimates.

Impact of soil parameters on cyclic pull-out capacity of offshore screw anchors

Impact des paramètres du sol sur la capacité d'arrachement cyclique des vis d'ancrage offshore

C.F. Ho, A.P. Dyson, A. Tolooiyan*
Computational Engineering for Sustainability Lab (CES-Lab), School of Engineering, University of Tasmania, Hobart, 7005, Australia

ABSTRACT: This paper presents a comparison of the cyclic behaviour of offshore screw anchors for various soils using the Simplified UnDrained Cyclic Accumulation Model (UDCAM-S). In producing the required stress-strain contours for UDCAM-S, a new correction procedure proposed in previous research with reference to a database of Drammen clay is followed and performed on Gulf of Mexico clay, the results of which are compared with the physical soil test results of the same clay. Stress-strain contours are also constructed for a Kaolin clay following the same procedure. Thereafter, modelling of the screw anchor is performed using the finite element method to investigate its pull-out capacity under cyclic tension, for each of the selected clays. Based on a chosen failure criterion, the bearing capacity is determined and normalised. According to the stress-displacement curves of the simulated screw anchor for each given clay, the validity of the correction procedure is investigated by comparing the corrected and experimental test results, and the effects of plasticity index are assessed to determine the associated impact on the anchor cyclic behaviour.

RÉSUMÉ: Cet article présente une comparaison du comportement cyclique des ancrages à vis offshore pour divers sols grâce à l'utilisation du modèle d'accumulation cyclique simplifié non drainé (UDCAM-S). Lors de la production des contours contrainte-déformation requis pour UDCAM-S, une nouvelle procédure de correction proposée dans des recherches antérieures en référence à une base de données d'argile de Drammen est suivie et réalisée sur l'argile du Golfe du Mexique, dont les résultats sont comparés avec le sol physique. Résultats des tests de la même argile. Des contours contrainte-déformation sont également construits pour une argile Kaolin en suivant la même procédure. Par la suite, une modélisation de la cheville à vis est réalisée par la méthode des éléments finis afin d'étudier sa capacité d'arrachement sous tension cyclique, pour chacune des argiles sélectionnées. Sur la base d'un critère de rupture choisi, la capacité portante sous contrainte de rupture est déterminée et normalisée. Selon les courbes contrainte-déplacement de la vis d'ancrage simulée pour chaque argile donnée, la validité de la procédure de correction est étudiée en comparant les résultats des tests corrigés et expérimentaux, et les effets de l'indice de plasticité sont évalués pour déterminer l'impact du cycle sur le comportement de l'ancrage.

Keywords: Screw anchors; cyclic behaviour; UDCAM; clay; plasticity index.

1 INTRODUCTION

Offshore screw anchors are becoming more common in offshore energy production because of their obvious advantages due to the low costs of installation. These ground anchor systems are often fixed to the seabed, which is saturated. In the case of offshore clays, for example, their behaviour is assumed to be undrained (Andersen, 2015), because the excess pore water pressures are not able to dissipate with the fast progression of load cycles. Cyclic shear stresses trigger the accumulation of pore pressure due to the compressive behaviour of the clay in shearing (Rasch, 2016).

To better understand the behaviour of such clays, a cyclic constitutive soil model named the Simplified UnDrained Cyclic Accumulation Model (UDCAM-S) is used in this project. While UnDrained Cyclic Accumulation Model (UDCAM) requires less modelling time due to its ability to model soil cyclic degradation without modelling individual cycles, UDCAM-S is a simplified model that can put the sophisticated UDCAM into practical applications (Rasch, 2016). In the modelling of this research, UDCAM-S serves as the constitutive model using the Finite Element Method (FEM).

The equivalent number of cycles at failure (N_{eq}) is determined by pore pressure accumulation or strain

accumulation (Andersen, 2015). To obtain the necessary input clay parameters for UDCAM-S, the results of relevant cyclic tests such as Direct Simple Shear (DSS), Triaxial Compression (TXC), and Triaxial Extension (TXE) are required.

To compare the effects of different clay parameters on the cyclic behaviour of offshore screw anchors, this project presents several offshore clays for comparison based on the differences in plasticity index (I_p) and undrained shear strength (s_u), with reference to a procedure proposed by Andersen et al. (2023) for establishing cyclic parameters for clays from a database of Drammen clay.

2 DATA SOURCE

Three offshore clays are chosen for comparison, namely Drammen clay, Kaolin clay, and Gulf of Mexico (GoM) clay, which have different values of I_p and s_u. Drammen clay is treated as the principal clay given the calibration procedure (Andersen et al. 2023) is largely based on the database of stress-strain contours of Drammen clay, which were determined using a procedure that assumed the pore pressure at the start of each load cycle was equal to that at the end of the previous cycle (Andersen, 2015). Cyclic DSS test results of GoM clay are available from a previous study (Liedtke et al., 2019), allowing comparison with the calibration procedure.

Table 1 gives a summary of the properties of the selected clays in this research. Drammen clay has the lowest I_p, given by Andersen et al. (1988, 2023). GoM clay has the largest I_p, given by Liedtke et al. (2019). The I_p and s_u^C values of Kaolin clay are based on previous simple shear test results (Huang B. et al., 2023) and research (Zografou, 2018), respectively.

Table 1. Properties of the selection of offshore clays.

Clay	I_p	Undrained compressive shear strength (s_u^C, kPa)
Drammen	27	126.5
Kaolin	34	30.0
GoM	47	31.2

3 METHODOLOGY

The numerical simulations were performed using the FEM with PLAXIS 2D (Bentley Systems, 2021). As for the other two clays in comparison with Drammen clay, some extra steps are taken to determine their corresponding stress-strain contours for UDCAM-S.

The procedure to develop relevant soil contours for UDCAM-S (Andersen et al., 2023) is specified below.

- Determine the equivalent over-consolidation ratio (OCR) of the specified clay for Drammen clay given the measured normalised monotonic DSS strength, using the SHANSEP equation:

$$\frac{(\frac{s_{uD}}{\sigma'_{ref}})_{OC}}{(\frac{s_{uD}}{\sigma'_{ref}})_{NC}} = OCR^m \quad (1)$$

  where s_{uD}/σ'_{ref} is the normalised monotonic DSS strength and m is a laboratory test-specific constant.
- From the database of Drammen clay contour diagrams for OCR of 1, 4 and 40 (Andersen et al., 1988), determine which of the three values is the closest to the previously determined equivalent OCR.
- Correct the Drammen clay contour diagrams using the correction factor calculated below:

$$F_{I_p} = 0.41 * \frac{{I_p}^{0.224}}{27^{0.224}} \quad (2)$$

  where, F_{Ip} is the plasticity index correction factor, and I_p is the plasticity index of the specified clay.
  The correction is performed by dividing the shear strains on the vertical axis of the contour diagrams by the correction factor.

To identify the impact of clay properties on the cyclic behaviour of offshore screw anchors, an axisymmetric FEM model has been developed in PLAXIS 2D to simulate the cyclic pull-out behaviour of a 3-helix screw anchor in each of the selected offshore clays.

Figure 1(a) shows the geometry of the offshore screw anchor, in which B is the helical diameter (equal for all helices), D is the shaft length from the top helix to the top of the anchor, t is the thickness of each helix (equal for all helices), S is the spacing between helices (equal for all helices), d is the shaft diameter, y is the distance from the bottom of the bottom helix to the bottom of the anchor. Figure 1(b) presents the geometry of the axisymmetric FEM model in PLAXIS 2D. The simulated screw anchor has a helix diameter of 0.5 m and a shaft length of 2 m.

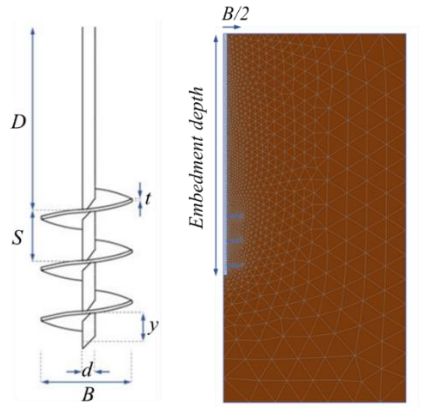

Figure 1. (a)Screw anchor geometry; (b)model geometry.

4 RESULTS

4.1 Stress-strain contours

Using Equation 1, the closest OCR value of Drammen clay for both GoM and Kaolin clays is 1, which is the reference OCR for this research and determines the corresponding stress-strain contours of Drammen clay in the database for the subsequent correction.

Comparison of stress-strain contour diagrams between Drammen and the other two offshore clays is given in Figure 2. The presented stress-strain contours correspond to an N_{eq} of 10, assuming an isotropic soil behaviour.

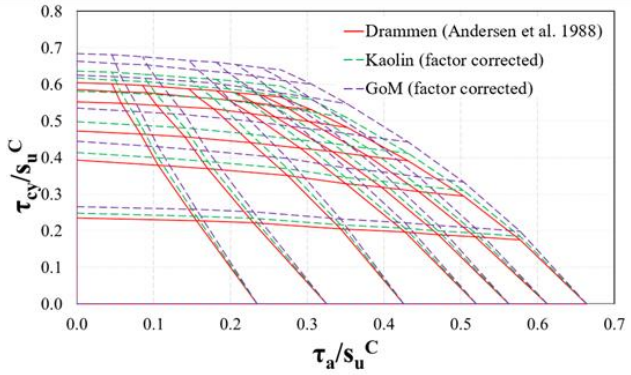

Figure 2. comparison of stress-strain contours between Drammen clay and factor corrected clays.

The original contour diagrams in the database have the average and cyclic shear stresses normalised by undrained DSS shear strength (s_u^{DSS}) (Andersen et al. 1988). In PLAXIS 2D, shear stresses are normalised by undrained compressive shear strength (s_u^{C}) for the cyclic accumulation calculations in UDCAM-S. Therefore, the original contour diagrams from the data base have to be converted for modelling in PLAXIS 2D. According to the laboratory test results, the ratio of s_u^{DSS} to s_u^{C} is 0.664, which has been applied when constructing stress-strain contours of Drammen clay.

The correction procedure proposed by Andersen et al. (2023) only applies the correction on the vertical axis of the stress-strain contours, which is the cyclic shear stress normalised by s_u^{C}. An alternative approach is specified in the procedure to perform the correction by applying two other factors on the derived stress-strain curves from the contours. In this research, however, correction has been performed using the correction factor in Equation 2 only. As I_p increases, the horizontal contour lines are shifted upwards, dragging the vertical contour lines slightly rightwards.

Since cyclic soil test results are available for GoM clay (Liedtke et al. 2019), the experimental stress-strain contours are provided with the factor corrected contours in Figure 3. Similarly, the original contour diagrams are based on cyclic DSS tests and the shear stresses normalised by s_u^{DSS}. Given the monotonic DSS and triaxial test results on GoM clay, the ratio of s_u^{DSS} to s_u^{C} is 0.8774, which has been applied when constructing the stress-strain contours of GoM clay (from cyclic DSS tests) in Figure 3.

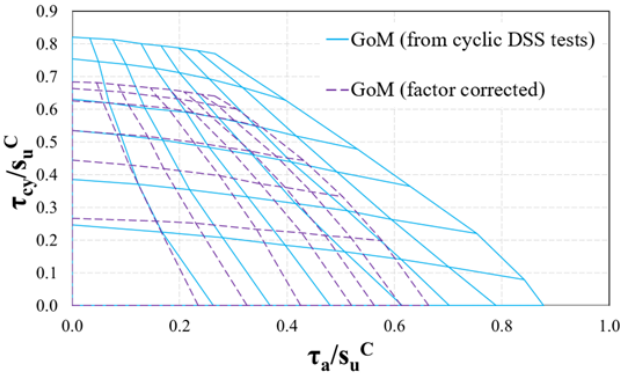

Figure 3. comparison of stress-strain contours between GoM clay based on cyclic DSS tests and factor corrected GoM clay.

As shown in Figure 3, there are obvious differences between the two sets of contours of GoM clay ranging from 10% to 25%.

One possible reason for such differences is that the corrected stress-strain contours of GoM clay are corrected with F_{Ip} given in Equation 2 only. As mentioned previously, the alternative correction approach using two other factors is not adopted in this research. Although there is this alternative option, it is applied to the derived stress-strain curves or calculated load-displacement curves. As a result, the stress-strain contours will still not reflect any differences directly, even if the alternative approach has been used instead.

Another possible explanation for the differences in contours in Figure 3 is that the determined ratio of s_u^{DSS} to s_u^{C} of 0.8774 is based on the trendlines drawn on the corresponding normalised shear strength scatter plots with an assumed ratio of vertical consolidation stress

to atmospheric pressure of 1. Considering that the trendlines cannot fully represent the scattered data points, the calculated ratio of s_u^{DSS} to s_u^C is, therefore not totally accurate.

4.2 FEM simulations

The stress-strain contours for each of the selected clays are inputed into PLAXIS 2D for modelling the cyclic uplift behaviour of the simulated screw anchor. The "total analysis" of UDCAM-S deals with ultimate limit state calculations for bearing capacity (Rasch, 2016) and is thus considered in this research.

With force captured at the displacement (s) corresponding to 10% of the helix diameter (B), the bearing capacity ($q_{0.1}$) is calculated by dividing the force by the helix area, then normalised by undrained compressive shear strength. As seen in Figure 4, the normalised stress (q/s_u^C) curves of the simulated screw anchor in each of the four cases only have minimal differences. Considering only the factor corrected clays and Drammen clay, the slope of the normalised stress curve is the greatest for GoM clay and the smallest for Drammen clay, with Kaolin in the middle, at displacements below 2% of the helical diameter. This is in line with the order of their I_p values, suggesting that the stiffness of the clay increases with increasing I_p.

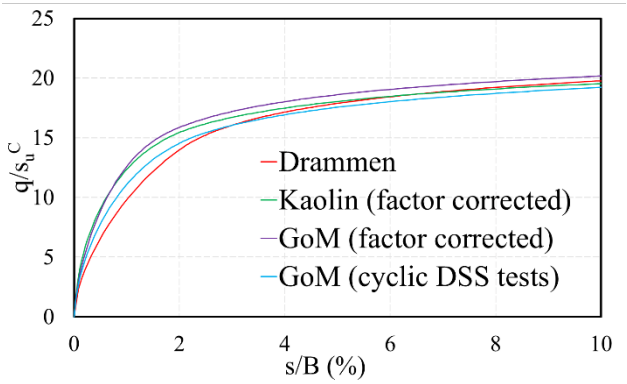

Figure 4. stress-displacement curves of the simulated screw anchor in each of the three offshore clays.

Comparing the actual values of normalised bearing capacity for the factor corrected GoM clay and the GoM clay from cyclic DSS test results in Table 2, it can be seen that $q_{0.1}/s_u^C$ for these two cases differs by 4.8%. Although there are large differences in their stress-strain contours, the small difference in normalised bearing capacity suggests that the correction procedure proposed above is applicable, producing comparable results with the same clay based on cyclic soil test results.

Table 2. Normalised bearing capacity in each of the offshore clays.

Clay	$q_{0.1}/s_u^C$
Drammen	19.77
Kaolin (factor corrected)	19.54
GoM (factor corrected)	20.19
GoM (cyclic DSS tests)	19.22

5 CONCLUSION

The results of the FEM simulation suggest that the clay stiffness increases with increasing I_p, and that the correction approach can produce results comparable with those based on experimental soil test results.

Improving soil dry compaction by adding granular material

Amélioration du compactage à sec en ajoutant du gravier

Y. Hocini*, A. Medjnoun, R. Bahar
Faculty of Civil Engineering, LEEGO / University of Sciences and Technology Houari Boumediene, Bab Ezzouar, Algiers, Algeria

*yhocini@usthb.dz

ABSTRACT: In the arid and semi-arid zones, where about eighty percent of Algeria is covered, the earthworks are more difficult because of the rarity of water sources and their transportation which is commonly expensive. Increasing compaction energy was suggested in previous research as the best solution to compensate for the lack of water. This paper is an experimental study carried out in the laboratory on fine-grain soil. It consists of compacting soil with optimal water content and low water content. To improve the maximum dry densities and the California bearing ratio values at low water content, this work also shows that it's necessary to add coarse materials, such as gravel, to the fine-grained soil, in order to improve the values of compaction characteristics at low water content. The obtained results showed that it's possible to reach the maximum normal and modified dry densities at low water content. And, the existence of optimal gravel content refers to optimal compaction behavior.

RÉSUMÉ : Dans les zones arides et semi-arides, qui couvrent environ quatre-vingts pour cent du territoire algérien, les travaux de terrassement sont plus difficiles en raison de la rareté des sources d'eau et de leur transport généralement coûteux. L'augmentation de l'énergie de compactage a été suggérée dans des recherches antérieures comme la meilleure solution pour compenser le manque d'eau. Cet article est une étude expérimentale réalisée en laboratoire sur les sols fins. Il consiste à mesurer la compacité d'un sol avec une teneur en eau optimale et faible teneur en eau. Pour améliorer les densités sèches maximales et l'indice portant californien à faible teneur en eau. Ce travail montre également qu'il est nécessaire d'ajouter des matériaux grossiers, tels que le gravier, au sol fin, afin d'améliorer la compacité à faible teneur en eau. Les résultats obtenus ont montré qu'il est possible d'atteindre les densités sèches maximales normales et modifiées à faible teneur en eau. Ils montrent aussi l'existence d'une teneur en gravier optimale qui fait référence à un compactage optimal.

Keywords: Dry compaction; fine grained soil; low water content; maximum dry density; gravel material.

1 INTRODUCTION

The development of southern regions in Algeria requires the construction of numerous road infrastructures to develop its economy. However, this latter is very expensive given the extremely severe climatic conditions, the difficulty of reusing local materials, and the non-availability of water sources and transportation. This research aims to improve soil compacity by addition granular material on arid soils at their low natural water content. This solution is considered widely economic and environmental, owing to the fact of preserving water sources and avoiding high water transportation costs.

According to literatures, various materials have been added to different soils such as lime; cement, fly ash (Kolias, et al 2005) , (Ige and Ajamu 2015) ; stone dust (Suresh et al, 2009.) (Mishra.S et al 2019) , etc...(Al-naje et Al-Taie 2020).

However not so many researchers investigated the improvement of the soil's geotechnical properties at the dry side of the compaction curves. In general, compaction at the dry side of the optimum, exhibit higher CBR values than those of soil compacted on the wet side of optimum.

In order to improve the geotechnical characteristics of lateritic fine soil different percentages of crushed granite were added. It appears that the optimal water content decreased. The soaked CBR values increased from 14 to 37% with the addition of 20 to 30% (Mbengue et al. 2022).

Marginal base soil was stabilized mechanically by the addition of gravels with sand or crushed stones with sand. It appears that The CBR values were improved by the addition of gravel from 15% to 20%; and for crushed stones from 12% to 15%. (Zumrawi 2012)

I.Goual et al 2012, tested compaction and bearing capacity of tuff and quarry dust mixture showed that OMC decreases and MDD increase. The bearing capacity indexes showed the existence of an optimal

mixture formulation, equivalent to 30% to 40%, respectively for the immediate indices and after 4 days of soaking.

The present work aims to improve soil compaction at low water content through a series of laboratory tests (proctor and CBR tests). At first, the influence of the low water content is studied on silty-sand soil, the effect of the addition of grained material on the silty sands in terms of the impact of compaction at low water content, maximum dry density (MDD), and CBR test are also studied in the second part of this work.

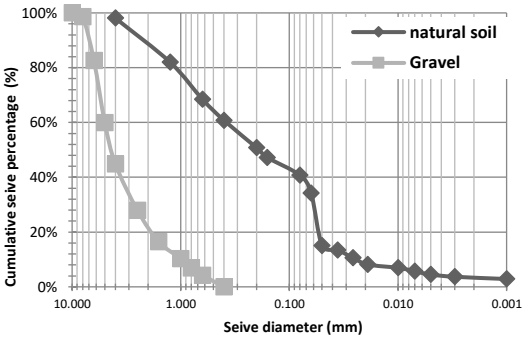

Figure 1. Sieve analysis curve of the studied soil and gravel.

2 MATERIALS AND METHODS

2.1 Methods

The studied soil went through several laboratory tests like sieve analysis (NF P094-056 and NF P094-057), Atterberg's limits (NF P094-051), specific gravity (G). The compaction parameters are also determined according the French standards for both standard and modified proctor test (NF P94-AFNOR).

The soil specimens were compacted using a proctor and CBR mold with the modified compaction energy. Each specimen was compacted in five layers ; 56 blows per layer, with a hammer of4,5 kg. The CBR test was also determined immediately after the compaction process to evaluate the immediate Californian bearing index. The classification of the used soil is done according to the Unified Soil Classification System (USCS).

2.2 Materials

The chosen soil is similar to that of the Algerian desert in the aim to better evaluate the behavior of dry compaction at lower water content. This soil was extracted from Jijel by *SOALKA Company* in the northern east of Algeria.

The gravel material was chosen from a local supplier according to its granular classes (0/3) and (3/8) and its angular shape. The sieve analysis for both natural soil and gravel are presented in Figure 1.

The soil physical parameters and the gravel properties are presented in the Table 1.

The process of adding the different amounts of gravel in order to study the effect of its addition on the dry density and the CBR Index was done by a path of 5% to the natural soil by dry weight.

3 RESULS AND DISCUSSIONS

3.1 Soil characterization

The results of soil physical properties are shown in Table 1. The used soil contained 38,2% of silts and 43,3% of sand with small amounts of clay and gravel (Figure 1). A plasticity index of 11,25 % and 39,80% for the liquid limit. The soil was classified according to the USCS standards as fine well-graded silty sand. Whereas the crushed gravel used in this study was classified as well graded clean gravel.

Table1. Soil and gravel physical properties.

Parameter	soil	Gravel
Specific gravity	2,65	2,7
Gravel (%)	15,4	78
Sand (%)	43,3	15,2
Silt (%)	38,2	6.8
Clay (%)	3,1	-
Uniformity coefficient (Cu)	15,38	5
Coefficient gradation (Cc)	0,34	1,8
BMV	0,53	-
Natural moisture content (%)	7,83%	-
Liquid Limit LL (%)	39,80%	-
Plasticity Limit PL (%)	28,55%	-
Plasticity Index PI (%)	11,25%	-

3.2 Effect of water content on dry density and CBR index

The results of Figure **2** present the soil's dry density versus moisture content for standard and modified proctor test. The lower dry density is obtained for the standard proctor energy at low and optimum water content, whereas; the maximum dry density is obtained for the modified proctor energy at the optimum water content.

The maximum dry density increases from 16.7 to 18.80 KN/m^3 respectively with a decrease of water content from 15.85% to 11.50% in standard and modified compaction energy test.

The growth of the maximum dry density is negligible (12%) and relative to the decrease of the optimal moisture content of about 15 %. The compaction process helps the soil particles to rearrange closely resulting in a reduction in air voids existing in the soil.

The complete compaction curves shape of studied fine soil is irregular and similar to those studied by (Ellis,1980) and (Faure et Fiès, 1972), and it's particularly for the dry compaction side. The figure also shows that it is possible to achieve a dry compaction test with high values of maximum dry density (>15%) for low water content at 2% and 4% of water.

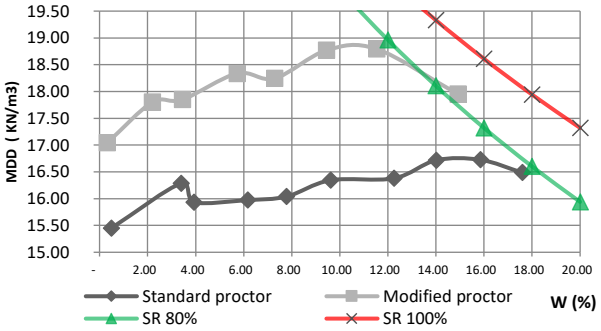

Figure 2. Soil compaction curve for standard and modified proctor test.

The compacted soil samples are submitted immediately to the CBR test, the CBR values are shown in Figure 3.

The maximum value of CBR index was noticed for the optimal water content and it is about 35.

At 4% of water content an acceptable value of CBR (24,40) was also noticed. This value is approximately near to that of optimum water content about 30% but relative to a reduction of 65% in water content.

At 2 % the CBR value is lower than the recorded values at OMC and W= 4%. This decrease is due to the low hydration of studied soil as observed.

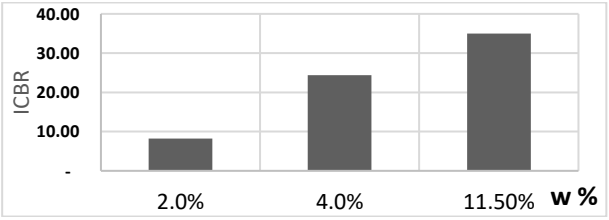

Figure 3. CBR index evolution as function as water content.

3.3 Effect of gravel addition on soil compaction parameters

Since the tested theory of the dry compaction process had satisfactory results on dry density and CBR values, another compaction tests are examined at 4% of water content by adding various amount of gravel to the natural soil by dry weight (5%, 15%, 20%, and 25%). The effect of gravel addition on the soil's dry density is shown in Figure 4.

It was noticed that even though the low moisture content (4%), the MDD values of 18.38 KN/m^3 and 18.6 KN/m^3; respectively for 20% and 25% of gravel addition were closely higher or the same of that obtained at the optimum water content with no additives (18.47 kN/m^3). Owing to the gravel angular shape and its large particles that interlocks the soil fine particles increasing its compactness and density (Mustafa 2018).

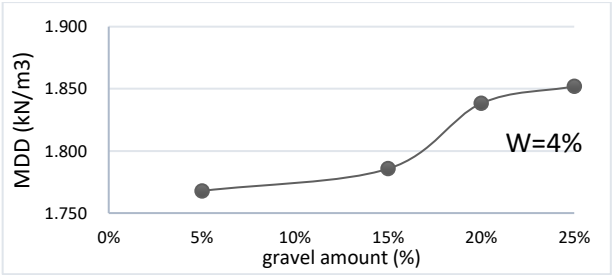

Figure 4. The evolution of maximum dry density at 4% of water content as function as gravel content.

These results are confirmed by the results of the bearing capacity tests represented in Figure 5.

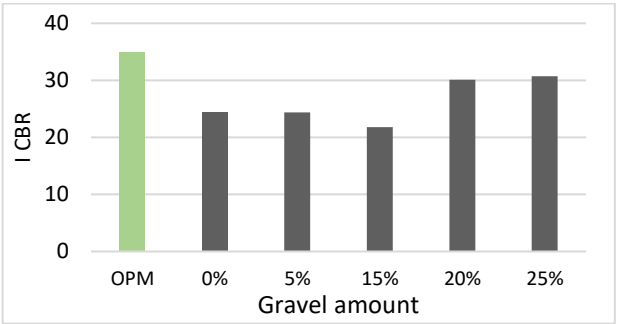

Figure 5. The evolution of CBR index at 4% of water content as function as gravel content.

The Figure 5 shows interesting results considering the low water content. It can be seen that a slight difference in the CBR values was measured between the optimal moisture content and low moisture content at 4% with no addition. In contrast, the gravel addition to the soil allowed obtaining high CBR values when adding 20% and 25% of gravel reaching a peak value of 30.12 And 30,70 respectively.

According to figures 4 and 5, it can be considered that the amount of **25%** of gravel addition as an optimal gravel content. This optimal amount strengthens the soil structure by providing a more rigid and stable structure, that contributes to improve the soil's bearing capacity. This may be due to the gravel high density.

4 CONCLUSIONS

The present study shows that soil compaction at low water content reduce its bearing capacity and dry density. To overcome this, reduce, the soil is treated with gravel. The results showed a significant increase of the CBR Index and of the maximum dry density more than the one obtained at Optimum moisture content.

However, the present compaction results need a complementary study as the Unconfined Compressive Strength UCS to confirm the satisfactory results of the CBR values of the studied soil at 4%of water content.

ABSTRACT: Due to long spells of droughts, embankments can desiccate. Dikes constructed of high plasticity clays can crack. These cracks can be detected by visual inspection, site investigation, or geoelectric resistivity. We aimed to identify areas with geoelectric measurements that are desiccated and vulnerable to fissuring. To better understand the cracks' cause, geophysical measurements and traditional geotechnical investigations were carried out on a dike section where cracks on the paved crest were already visible. A soil moisture monitoring system was already installed at one of the investigated sections. Geophysical measurements can identify large areas of desiccated embankment slopes, while geotechnical drillings and sensors can only be at point locations. Geophysical measurements can only be used to identify desiccated areas if it is known that the investigated embankment is relatively homogeneous. Electric resistivity and moisture content correlation were done based on the field measurements.

RÉSUMÉ: En raison de longues périodes de sécheresse, les digues peuvent se dessécher. Les digues construites avec des argiles à haute plasticité peuvent se fissurer. Ces fentes de dessiccation peuvent être détectées par une inspection visuelle, une étude du site ou par résistivité géoélectrique. Dont l´objectif d´identifier les zones vulnérables aux risques de desséchement, des mesure géoélectriques ont été prélever. Pour mieux comprendre ce phénomène, l´étude geoélectrique a été couple par une études géotechniques traditionnelles sur un tronçon de digue où des fissures sur la crête pavée étaient déjà visibles. Un système de surveillance de l'humidité du sol avait déjà été installé sur l'une des sections étudiées. Les mesures géophysiques permettent d`acquérir une identification continue sur la totalité de la surface de zone étudier, alors que l´identification des forages et des capteurs n´est que ponctuels. L'approche géophysique ne peut être utiliser pour identifier les zones à risque de dessiccation que dans les cas où le talus étudier est relativement homogènes. La corrélation de la résistivité électrique et de la teneur en eau a été effectuée sur la base des mesures de terrain.

Keywords: Dikes; geophysics; high plasticity clays; soil moisture sensors; shrink-swell behaviour.

1 INTRODUCTION

Flood protection embankments, also known as dikes, are built to protect floodplains and the population of their areas along rivers and lakes from inundation. In Hungary, dikes along the Tisza River and its tributaries are mainly constructed from locally available cohesive materials such as silt and clay (Illés and Nagy, 2022). Most of them were built before the development of modern soil mechanics in the middle of the 19th century (Nagy 2006). At that time, construction standards were more permissive than today, and materials available near the site were utilised. Historical methods, namely cross transportation, were used as the primary construction mode (Dyer et al., 2009). The material was extracted from ditches at the waterfront and then piled onto the dike. The soil was moderately or not compacted at all.

Wide-spread cracking has been identified on the dikes of the Great Hungarian Plain, along the Tisza and its tributary rivers (Szepessy 1991; Lazányi and Horváth 1997). The same phenomena have been identified in North England (Dyer et al. 2009).

The desiccation of clay (and fine-grained) layers in lake and river beds has been studied since the middle of the 20th century (Neal 1968; Walker 1986).

The desiccation and cracking of these high plasticity and mainly high montmorillonite content

earthworks are triggered by long spells of droughts as a consequence of climate change.

2 METHODS

2.1 Location

The examined dike section is located on the Szolnok-floodplain, north of Szolnok, Great Hungarian Plain (Figure 1). The surface of the area is covered by Holocene sediments (silt and clay) transported by the Zagyva and Tisza rivers from the North Hungarian Mountain range.

The site was selected based on a dike crest pavement survey (Illés and Nagy, 2022) and on-site visits. The nationwide study aimed to identify the natural and human causes of the dike pavement fissure and deterioration (Illés 2023). The cracks on the pavement and the grass slopes indicate that clays susceptible to volume change are present.

Figure 1. Location of the water retention monitoring system in the dike.

2.2 Dike materials

The dike, according to ISO 14688-2:2017, is constructed of high plasticity clays ($w_L = 56.1\%$ and $I_p = 33.7\%$), while the subsoil under the dike has higher Atterberg limits ($w_L = 70.5\%$ and $I_p = 43.8\%$). The dike contains considerable fine content ($Si > 50\%$ and $Cl > 20\%$) based on the grain size distribution measurements (ISO 17892-4:2016).

The shrinkage limit, according to Krabbe's empirical relationship from 1958 (Schultze and Muhs 1967):

$$w_s = w_L - 1.25 \cdot I_P \qquad (1)$$

Based on the equation for the dike and the subsoil the shrinkage limits are 14 % and 16% respectively.

2.2.1 Unsaturated soil properties

Dikes saturate during flooding until the seepage line, or the upper parts of the cross-section after heavy showers. Apart from these events most of the dike section is unsaturated. The measurements presented by Illés and Antal (2022) support this statement, however under the paved crest the dike is almost constantly saturated. The volumetric behaviour of compacted unsaturated soils is particularly complex due to the co-existence of three different phases: solid, liquid and air (Kieu and Mahler 2018). It is influenced by soil suctions. Laboratory and in-situ soil suction measurements are conducted and compared to better understand the state of the dike (Illés and Antal 2022).

2.3 Monitoring system

It is essential to monitor soil moisture content to determine the health state of an embankment (Utili et al. 2015). An established method is to create a water content profile from disturbed samples when signs of shrinkage cracks are visible on an embankment (Nagy and Illés 2016). However, we aimed to continuously monitor a flood protection embankment's water content at as many points as possible.

2.3.1 Sensors

The monitoring system is composed of 17 sensors: 14 TEROS 11 soil moisture sensors, 3 TEROS 21 water potential sensors and 3 ZL6 data loggers, all supplied by METER Group. The instruments are located at Doba (North of Szolnok city), section 87+620 and installed in 4 borings; flood side slope, flood side of the crest, crest axis, and at the protected side charging bench (see Figure 2.). The soil moisture sensor (TEROS 11) has a range of 0.00 – 0.70 m^3/m^3 volumetric water content (METER Group, Inc. 2018a), while the water potential sensor (TEROS 21) has a range of −5 to −100,000 kPa (METER Group, Inc. 2018b). Both instruments are equipped with thermocouple, measuring temperature; their detailed data sheets are available in the manuals.

The installation procedure and the initial results are described by Illés and Antal (2022).

2.4 Geophysical measurements

In-situ electric resistivity tomography (ERT) measurements are a useful tool for engineers to assess the soil properties along a section and not just from drilling. It can be used to identify soil water deficit (Chrétien et al. 2014), to detect desiccation cracking (Nagy et al. 2008; Sentenac and Zielinski 2009; Jones et al. 2014) and the presence of dispersive clays (Nagy et al. 2021). We aimed to identify the areas with different moisture content and, if present the location, of possible cracks.

Multielectrode site geophysical measurements were conducted in the cross-section of the monitoring

system, and in other two cross-sections before and after it. Furthermore, the dike was examined in three longitudinal sections, on the flood side. Altogether a total length of 535 m was measured with a 0,5 m electrode arrangement. Three longitudinal (90 m) and three cross-sections (55 m).

Resistivity (P) measurements by the ERT and soil moisture measurements by the sensors can be related by using the Waxman and Smits (1968) model:

$$Pws = \frac{a}{\varphi^m {S_r}^n}\left(\frac{1}{\rho_w} + \frac{BQ_v}{S_r}\right)^{-1} \qquad (2)$$

where S_r is the degree of saturation, φ is the porosity, a is the tortuosity factor, m is the cementation, while n is the saturation exponent, ρ_w is the pore water density, B is the average ionic mobility, Q_v is the cation concentration per unit pore volume in (meq/cm^3). The material density (ρ_s) and dry density (ρ_d) of the samples are measured. The void ratio ($e = \rho_s/\rho_d - 1$), and the porosity ($\varphi = 1 - \rho_d/\rho_s$) are calculated. The void ratio are used for the calculation of the saturation (S_r).

3 RESULTS AND DISCUSSION

Temperature and soil moisture distribution of the examined cross-section is presented along resistivity measurements in Figure 2. High resistivity areas on the flood and protected side are matched by areas of low water content. The dike crest is paved, it acts as a seal. A stretch of high moisture content can be found under the dike crest. The installation depth of the soil moisture sensors was limited by the installation tool, provided by the manufacturer. From the resistivity map it can be seen that the core of the dike has a homogenous resistivity indicating a stable water content.

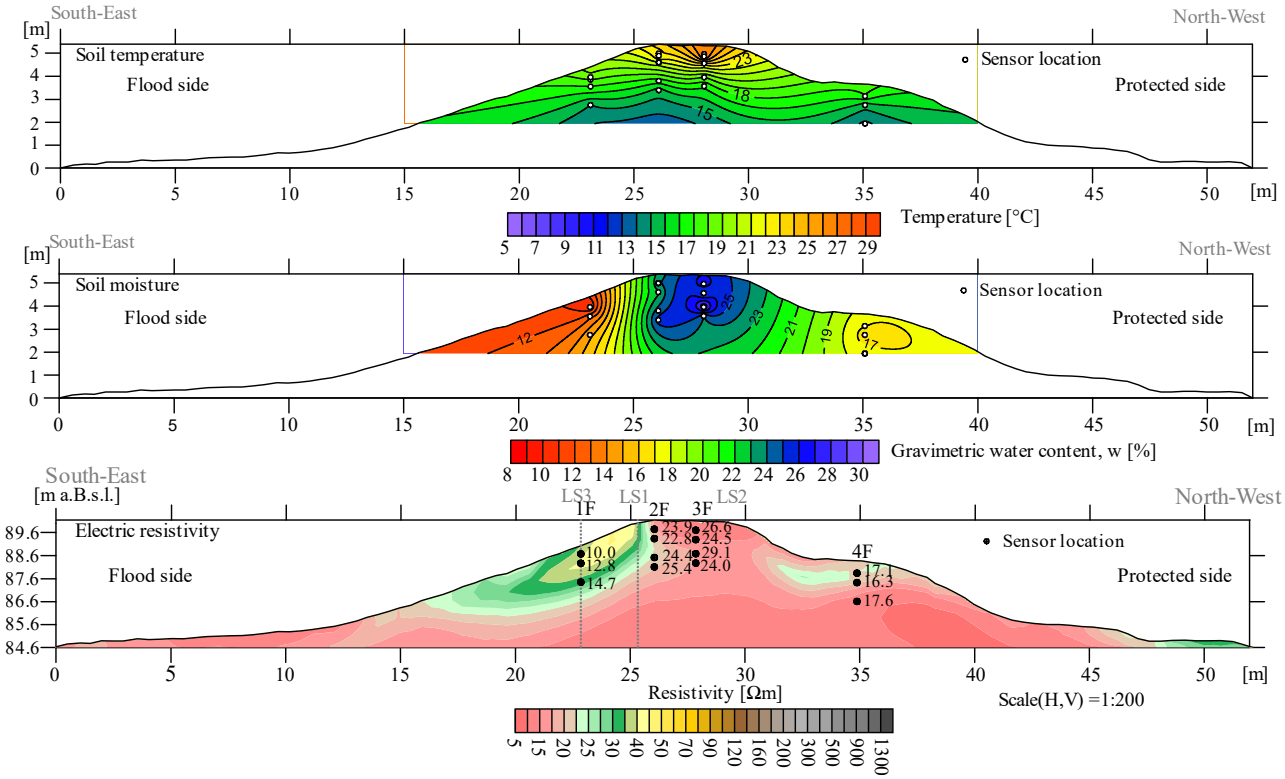

Figure 2. Dike cross-section; soil temperature and moisture distribution, resistivity measurement.

The data of the soil moisture sensors and electric resistivity measurements are pared (same location and time), to analyse the connection in between them.

The Waxman-Smits model was fitted on these measurements (see Figure 3). The used parameters are summarised in Table 1. The cation exchange capacity (CEC) value is based on a literature review. Csillag et al. (1995), measured 39.0 meq/100g near the Hungarian town Szolnok. Furthermore, Yilmaz (2004) proposed a connection between liquid limit and cation exchange capacity; the proposed equation resulted in a similar value, somewhat higher. In general, clays have a higher CEC value than 30 meq/100g.

Table 1. Waxmann-Smith parameters.

Parameters		Value	Notes	Units
Tortuosity factor	α	2.56	Fitted	-
Cementation exponent	m	2.82	Fitted	-
Saturation exponent	n	1.58	Fitted	-
Pore water resistivity,	P_w	14.00	Estimated	Ωm
Pore water density,	ρ_w	1.00		g/cm^2
Solid density,	ρ_s	2.70		g/cm^3
Average ionic mobility	B	2.00	Estimated	(Sm^{-1}) cm^3/meq
Cation exchange capacity,	C	39.00	Estimated	meq/100g

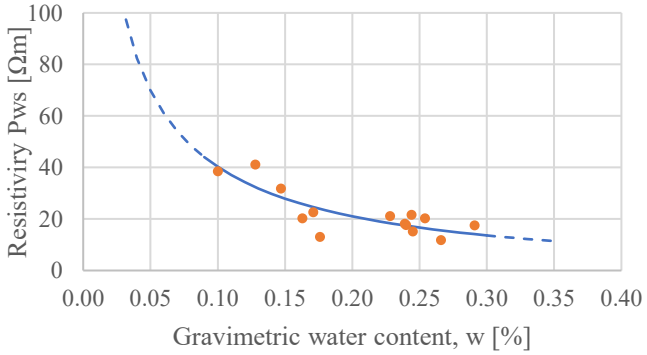

Figure 3. Waxman-Smits model, correlation of in-situ resistivity measurements versus gravimetric moisture content.

As only the in-situ measurements were used (soil with natural water content), we could not capture the whole phenomena, the exponential increase of resistivity with the decrease of soil moisture content.

Glendinning et al. (2014) used laboratory resistivity and gravimetric moisture content measurements to fit the Waxman-Smits model. The gained curve was used to calculate the volumetric water content distribution of the test embankment at the times of the ERT resistivity measurements.

The resistivity measurements of this conference paper (5-120 Ωm) and Glendinning et al. (2014) (10-150 Ωm) are in the same range, the two major differences are; i) the embankment at Tisza river is paved, due to it the moisture content is relatively high under the crest, ii) the slopes desiccate to much deeper extent in Hungary, due to the more severe droughts.

4 CONCLUSIONS

Electric resistivity tomography is a useful tool to distinguish areas with different moisture content. It can be applied to identify stretches with considerable moisture deficit, on dike slopes or just on the open field. For different kinds of soils, resistivity moisture content calibrations are needed to be able to use geophysical measurements on their own. In our case, with 0,5 m electrode distribution the cracks were not visible on the sections. However, areas with high resistivity indicate a highly unsaturated state (pores mainly filled with air) and an area with a possible hairline crack system. The results were correlated with the Waxman-Smits model, indicating reasonable agreement.

ABSTRACT: This study examines the saturated water permeability using samples of loose and dense 2-fraction coarse sand mixtures. Besides the non-normalised entropy variables, some additional parameters like void ratio or relative density are used to characterize the pore sizes. Two variable pairs the (Cu and d10) and the non-normalised entropy variables (ΔS and S0) are found to have similar role, to describe the mean and the maximum controlling pore diameter sizes, resp.

RÉSUMÉ: Cette étude examine la perméabilité à l'eau saturée à l'aide d'échantillons de mélanges de sable grossier à 2 fractions lâches et denses. Outre les variables d'entropie non normalisées, certains paramètres supplémentaires tels que la densité (trouve important) sont utilisés pour caractériser la taille des pores. Deux variables paires (Cu et d10) and d'entropie non normalisées (ΔS et S_0) ont similaire role pour decrire la moyenne et maximum de contrôle diameter des pore, resp.

Keywords: Grading entropy; saturated permeability; coarse sand; model fitting; specific surface area; harmonic mean.

1 INTRODUCTION

A study has been started within the context of a large research project related to the various physical model parameters of granular matter as a function of the grading curve (Imre et al., 2021, 2022, 2023).

The space of the grading curves with N fractions is isomorphic to the space of the unit-sided simplex with dimension N-1 (Imre et al., 2014). The image of the simplex by the entropy map is the 2-dimensional grading entropy diagram. Instead of the interpolation over the simplex based on j^{N-1} interpolation points (j in each coordinate direction), the interpolation is made on the grading entropy diagram, using about 2j such points where the entropy map is unique (eg., on the image points of mean grading curves).

This paper is related to the saturated water permeability prediction in terms of the grading curve. A model discrimination was started to be made. The models contained traditional and new diameter type variables (the specific surface variables, the d_{10} and C_u, the grading entropy parameters), the void ratio and the relative density as a new parameter. According to the results, without the density parameters no acceptably good fit was attainable. Moreover, an acceptably good fit needed both mean pore size and maximum pore size related parameters.

2 MATERIALS AND METHODS

2.1 New permeability variables

The base entropy S_o and its normalised form, A, are defined by Lőrincz (Lőrincz,1986; Singh, 2014) as:

$$S_o = \sum_{i=1}^{N} x_i S_{oi} \text{ and } A = \frac{S_o - S_{o\min}}{S_{o\max} - S_{o\min}} \quad (1)$$

where x_i is the relative frequency of fraction i, $S_{0i} = i$ is the ith fraction entropy (see Table 1), and N is the number of fractions. The entropy increment ΔS:

$$\Delta S = -\frac{1}{\ln 2}\sum_{i=1}^{N} x_i \ln x_i \text{ and } B = \frac{\Delta S}{\ln(N)} \quad (2)$$

The harmonic mean diameter (being similar to d_{10}) and the specific surface area per volume are related to the mean pore size (Imre et al., 2014):

$$d_h = \frac{1}{\sum_{i=1}^{N} \frac{x_i}{d_i}} \text{ and } S_{sv} = 6/[(1+e)d_h] \quad (3)$$

The tested density variables were the void ratio e and the relative density $R_d = (e_{max} - e)/(e_{max} - e_{min})$.

2.2 Data

In this paper, an existing granular database (Imre et al., 2021, Figure 1a) is started to be extended onto the coarse sand range of granular soils. The four fractions: 0.25 – 0.50 mm, 0.5 – 1.0 mm, 1.0 – 2.0 mm and 2.0 – 4.0 mm, are illustrated in Figure 1b.

Constant head permeability tests were made on the samples comprising 15 finite fractal 2-fraction mixtures, with two different sample preparation methods to obtain loose densities (15 samples) and dense densities (45 samples, 3 repetitions).

In Figure 1c, the maximum void ratios were assessed from earlier research of Lőrincz (1986) with different sand materials but the same composition, e_{min} was computed from e_{max}/e_{min} (Imre et al., 2011).

2.3 Regression models

The equations for k_{sat} were as follows, extending the approach of Feng et al. (Feng et al., 2019):

$$k = \exp(C_3)\Delta S^{C_1} S_0^{C_2} \quad (4)$$

$$k = \exp(C_4)\Delta S^{C_1} S_0^{C_2} e^{C_3} \quad (5)$$

$$k = \exp(C_4)\Delta S^{C_1} S_0^{C_2} p^{C_3} \quad (6)$$

where C_1,C_2, C_3 and C_4 are model parameters to be identified, p can be the relative density, specific surface area per unit volume or other variable. The grading entropy parameter pair was interchanged by d_{10} and C_u, the Ren and Santamarina (2017) equation:

$$k = \frac{e^{C_1}}{(S_{sv})^2} \quad (7)$$

where S_{sv} is the specific surface area per unit volume of the soil (mm^{-1}), parameter C_1 is identified.

Table 1. Definition and properties of fraction j.

j	**1**	**23**	**24**
Limits in d_0	1 to 2	2^{22} to 2^{23}	2^{23} to 2^{24}
S_{0j} *[-]*	1	23	24

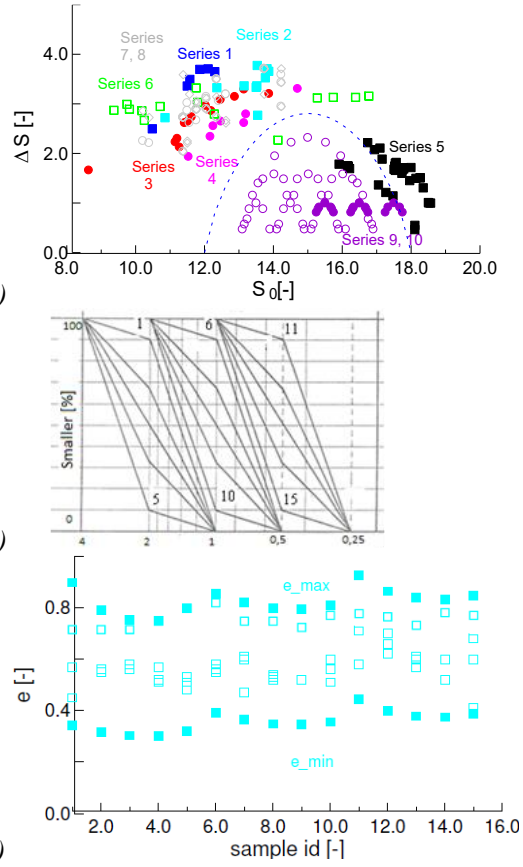

Figure 1. (a) Series 9 in the database (i.e. new samples 1 to 15) in purple closed symbol. Blue, light blue, red, pink, green, black, purple open: old series 1, 2, 3, 4, 5, 6, and planned mixtures, resp. (b) Particle size distributions of the 2-fraction fractal mixtures in Series 9. (c) void ratio for 15 mixtures in terms of id number, shown in Figure 1(b).

3 RESULTS

The k_{sat} of the 15 optimal 2-fraction soil mixtures with finite fractal gradings was between about 0.01 to 1 cm/s. The data were separated considerably for loose and dense samples in terms of specific surface area per volume (Figure 2a) or d_{10} relations.

In contrast, the measured data did not separate within series when the relative density or when the Ren and Santamarina variable (Figures 2b, c) were used. Since one sample was tested at a low relative density value, and three samples were tested at higher relative density values, the repetition of the former could reduce the difference, some further data are needed.

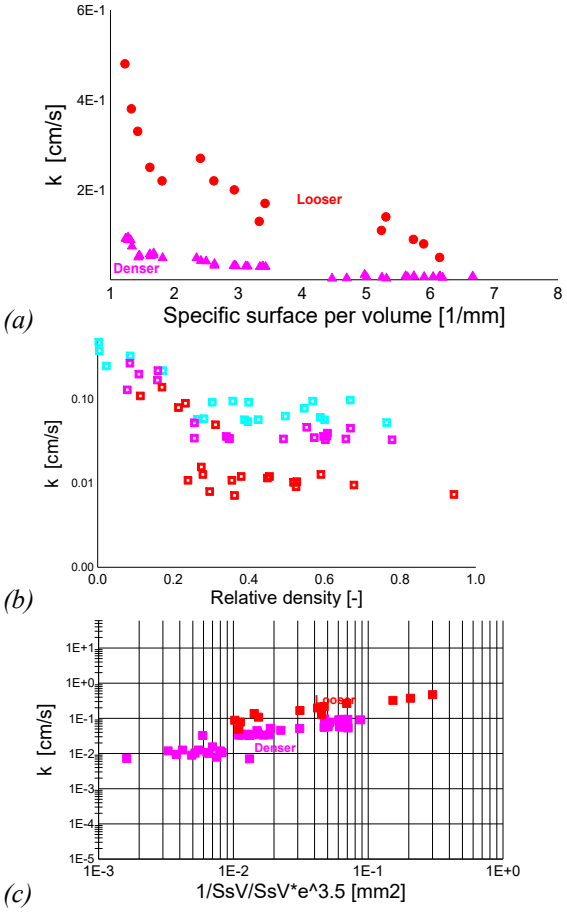

Figure 2. Permeability in terms of (a) specific surface per unit volume and (b) relative density, (c) Ren and Santamarina variable. Colours in (b): sub-series 1, 2 and 3 in turquoise, pink, and red, respectively.

The parameters of the empirical equations were determined using the Gauss Normal Equations approach (Press et al., 2007). The results of the Least-Squares fitting process was evaluated through the coefficient of determination value (R^2) – expressing what fraction of the variance is explained.

Referring to Table 2, by using only entropy parameters for the 2-fraction soils with small C_u, the R^2 is not satisfactory having identical gradings with different density. When additional density parameters were considered (i.e. void ratio e, relative density R_d) the models showed higher values of R^2. The highest values of R^2 were found with the relative density, this result need confirmation with new data.

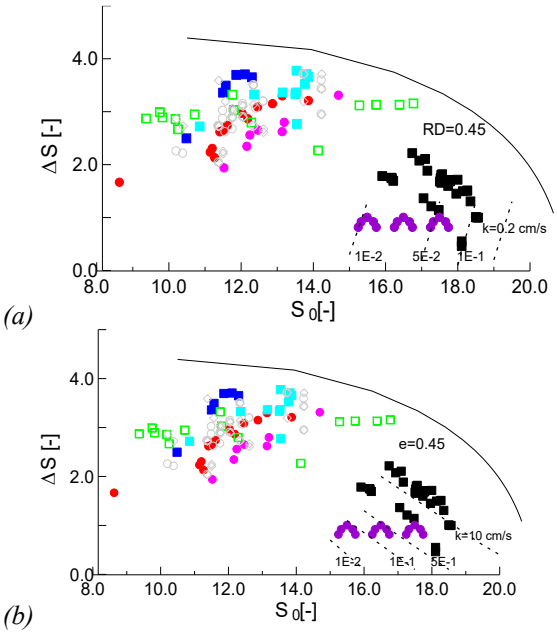

Figure 3. Approximate constant permeability level lines in the edge of diagram (a) assuming constant void ratio e, (b) constant relative density R_d. The shape of the level lines is finalized once series 5 data are completed with R_d.

Table 2. 2-fraction mixtures with R^2 values.

Variable	R^2
Entropy parameters, relative density	0.8847
d_{10}, C_u and relative density	0.8733
d_{10}, C_u with specific surface area	0.7709
Entropy parameters with void ratio, e	0.7701
Entropy parameters, S_{sv}	0.7476
Ren and Santamarina, 2017	0.7362
Entropy parameters only	< 0.5

Approximate k-level lines for series 9 were constructed in the non-normalised diagram using the identified parameters by fixing the R_d and the e values. The constant void ratio and the constant relative density R_d level lines qualitatively differed (Figure 3).

4 DISCUSSION

The grading entropy parameter pair was interchanged by pair d_{10} and C_u, (the latter were suggested by Nagy, 2011), and the fit had a similar R^2 as in the case of the grading entropy coordinates.

These parameter pairs were compared by using a series of mean grading curves (Imre et al., 2022). The mean C_u - ΔS relation (Figure 4) is not unique, having two close branches: in $0<A<2/3$ and $1>A>2/3$ (see more in Imre et al., 2022). The base entropy S_o or A has a unique relation with d_{10} (Figure 5). These relations may explain the similar results in Table 2.

The identified exponent of e was greater than 2 in in every empirical equation and for the other parts of

the database (Figure 1(a), Imre et al., 2021). The relative density was established from the ratio of e_{max}/e_{min} (Imre et al., 2011, Kabai, 1974) and the e_{max} data of Lőrincz (1986).

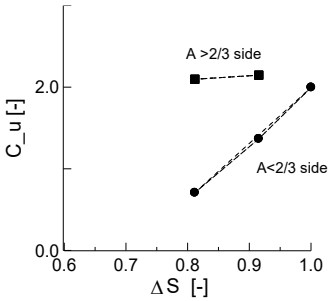

Figure 4. The relation of $C_u \Delta S$, N= 2, all tested data.

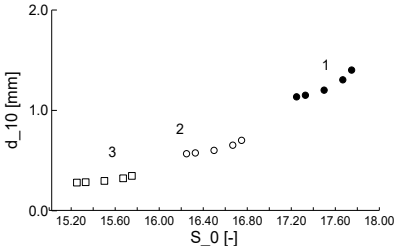

Figure 5. The relation of d_{10} and S_o, N= 2, all tested data.

The e_{max} at fixed A is decreasing with increasing fraction diameter range (since larger fractions have wider diameter range allowing a denser configuration). The void ratio is not related to the maximum pore channel size, being important in describing the k_{sat}. besides the mean pore size.

5 CONCLUSION

Theoretically, to assess for k_{sat}, the relevant problem is to assess the mean and the maximum controlling diameters of the pore channels (Imre et al., 2008).

The permeability variables can be divided into various groups and are either related to the mean controlling pore size variables (Imre et al., 2014) as d_{10}, d_h, S_{sA}, S_0, or to the maximum controlling pore size variables as C_u and ΔS, scaled by the relative density or the void ratio or the $e/(1+e)$ porosity term.

The result of the model fitting was acceptable in case of the tested 2-fraction coarse sands (identical composition, different densities) if one variable from each class was included. The best density parameter was the relative density.

The statement is supported by the facts that the S_0, ΔS and the d_{10}, C_u pairs were similar in mean grading curves relations, moreover these pairs were interchangeable in the equations. Further measurements and research are suggested, e.g., on the role of the the relative density.

ABSTRACT: The research project GeoSustained, funded by the Portuguese Foundation for Science and Technology (PTDC/ECI-CON/1866/2021), aims to study sustainable solutions for using shallow geothermal systems for buildings and infrastructure acclimatization. Lisbon Municipality is a partner in the consortium, playing a particularly important role in the implementation and regulation of the mandatory elements for installing the system. For this purpose, a working group was created to collaborate with the responsible entities, namely Direção-Geral de Energia e Geologia (DGEG, a public energy and geology institution). Two priorities were established: (1) definition of the best practices for the implementation of shallow geothermal solutions; (2) development of a guide with the flow to implement the systems licensing procedure. This information will be integrated into the Municipal Regulation for Urbanization and Construction in Lisbon (Regulamento Municipal para a Urbanização e Edificação de Lisboa). It is also expected that the collaboration with DGEG will contribute to improve the implementation of this type of solution at a national level, being a critical approach to more sustainable and resilient cities to climate change.

RÉSUMÉ: Le projet de recherche GeoSustained, financé par la Fondation Portugaise pour la Science et la Technologie (PTDC/ECI-CON/1866/2021), vise à étudier des solutions durables pour l'utilisation de systèmes géothermiques peu profonds pour l'acclimatation des bâtiments et des infrastructures. La municipalité de Lisbonne est un partenaire du consortium, jouant un rôle particulièrement pertinent dans la mise en œuvre et la régulation de ce type de système à l'échelle locale. À cette fin, un groupe de travail a été créé pour collaborer avec les entités compétentes, à savoir la Direção-Geral de Energia e Geologia (DGEG, une institution publique d'énergie et de géologie). Trois priorités ont été établies: (1) définition des meilleures pratiques pour la mise en œuvre de solutions géothermiques peu profondes; (2) élaboration d'un guide avec le flux à adopter pour permettre la licence de ces systèmes. Ces informations seront intégrées dans le Règlement Municipal pour l'Urbanisation et la Construction de Lisbonne (Regulamento Municipal para a Urbanização e Edificação de Lisboa). Il est également prévu que la collaboration avec la DGEG contribuera à améliorer la mise en œuvre de ce type de solution au niveau national, étant une approche critique pour des villes plus durables et résilientes face au changement climatique.

Keywords: GeoSustained project; sustainable urban acclimatization; climate resilient cities; geothermal potential map.

1 INTRODUCTION

The GeoSustained project (CML, 2023), "Sustainability assessment of shallow geothermal systems for Lisbon. Characterization studies of the city soils thermal and thermomechanical behavior" is funded by the Portuguese Foundation for Science and Technology (FCT). Laboratório Nacional de Engenharia Civil (LNEC) leds the Consortium and Lisbon Municipality (CML), Universidade de Aveiro (UA), and Agência de Energia e Ambiente de Lisboa, Lisboa E-NOVA are partners. The GeoSustained project has two general objectives:

- To understand the thermal and thermomechanical behavior of geological formations in Lisbon through in situ and laboratory tests and mathematical modeling.
- To evaluate and contribute to the sustainability of shallow geothermal systems, considering Lisbon's geological and climatic characteristics.

This project is aligned with three Sustainable Development Goals (United Nations, 2015):

Goal 7: Affordable and Clean Energy – Ensure access to affordable, reliable, sustainable, and modern energy for all. Characterizing the thermal conductivity of Lisbon's geological formations will contribute for using shallow geothermal resources in the city, or others with similar soils and weather conditions, making it easier and more accessible for project developers to carry out feasibility studies.

Goal 9: Industry, Innovation, and Infrastructure – build resilient infrastructure, promote inclusive and sustainable industrialization, and foster innovation. Thermomechanical characterization of Lisbon's soils will increase the knowledge about their behavior and how temperature affects it, particularly their strength and deformability. In addition, buildings that use shallow geothermal systems are less energy dependent infrastructures and, therefore, more resilient.

Goal 13: Climate Action – take urgent actions to combat climate change and its impacts. Shallow geothermal is a clean energy source of great importance in reducing greenhouse gas emissions and, consequently, in combating climate change.

2 APPROACH

Lisbon Municipality, as the organization in charge of managing the city of Lisbon and a partner of the GeoSustained Project, has a fundamental role in encouraging and regulating the implementation of geothermal systems. To achieve that, three significant outputs must be considered:

1. Standards for the use of shallow geothermal resources in an urban context: a guide is being developed with relevant information to encourage and simplify the evaluation of the feasibility to use geothermal resources, namely a regulatory document, references for real estate developers interested in using these systems, and information on the prospecting work to be carried out, including relevant tests.

2. Procedural workflow and licensing documents: a working group has been set up, which includes technicians of the GeoSustained project and technicians from Direção-Geral de Energia e Geologia (Directorate-General for Energy and Geology). This group's mission is to develop a guide with the procedural workflow to be adopted to simplify the licensing of these operations and a list of instructional elements to be presented by those that need to develop an urban licensing procedure. This information will soon be included in Regulamento Municipal para a Urbanização e Edificação de Lisboa (Lisbon Municipal Regulations for Urbanization and Building).

3. Geothermal Potential Map: this dynamic map will be a decision-support tool integrated into the Lisbon Geotechnical Map, making it possible to identify the shallow geothermal systems potential. The geothermal potential map is a critical output for increasing the implementation of shallow geothermal systems in Lisbon, and it is the main topic covered in this paper.

3 GEOTHERMAL POTENTIAL MAP

The Geothermal Potential Map will indicate, for each area in the city, the differences in the potential for exploiting the geothermal resource in depth, considering factors such as geology, thermal conductivity, the existence of water in-depth, and also subsoil occupation, a fundamental aspect in a densely urbanized area such as Lisbon (Figure 1). The purpose of this map is to support the preliminary assessment of the viability of shallow geothermal systems for new buildings and urban rehabilitation in Lisbon. The possibility for project developers and planners to conduct this quick assessment by consulting the geothermal potential map will incentivize them to consider using this clean energy resource in their projects.

Figure 1. Considered components of the Lisbon Geothermal Potential Map.

The Geothermal Potential Map is made up of different components that complement each other:

Three-dimensional modeling of geological formations of Lisbon: this task is being carried out using RockWorks software. It is based on the information available on the 1:10,000 scale geological

map and Lisbon Municipality's GeoSIG platform. This platform gathers geotechnical data obtained from boreholes in Lisbon and currently includes more than 13,000 entries. This information will allow the geometry of Lisbon's geological formations to be modeled at depth.

Determination of the thermal conductivity of the modeled geological formations: this task is underway and is based on a three-scale approach (Figure 2): macroscale, in which thermal conductivity values are obtained from the literature; mesoscale, in which conductivity values measured in local geological formations are used and whose values are extrapolated to other points where the geothermal potential is to be assessed; microscale, with conductivity values measured directly on representative samples of the site to be evaluated.

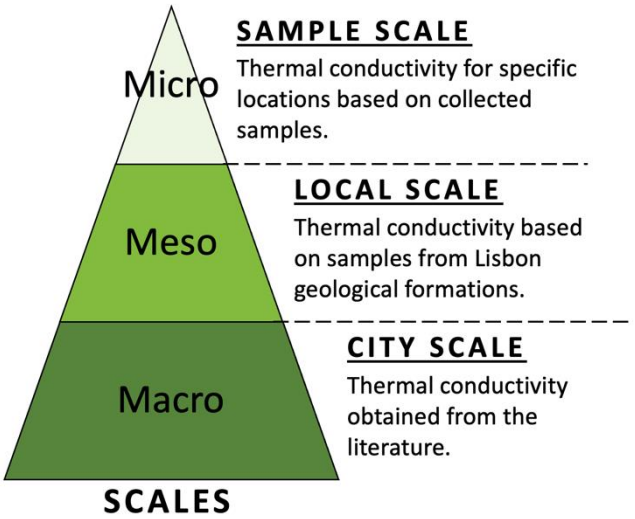

Figure 2. Three-scale approach to obtain thermal conductivity values for the Lisbon Geothermal Potential Map.

In the macroscale approach, Vieira *et al.* (2023) compiled thermal conductivity values for soils and rocks like the ones in Lisbon, allowing cartography to be drawn up on the scale of the municipality. This work assigned minimum and maximum thermal conductivity values and recommended estimates to the formations, which were grouped into ten systems based on their lithostratigraphy and mineralogy. The result was represented in a distribution of surface values (Inácio *et al.*, 2023). At this stage, parameters as compaction and water saturation were not considered.

At the microscale, where the information is being refined, the actual thermal and thermomechanical characteristics of samples collected in the project's scope are considered. Three boreholes were made in three different locations within the municipality to reach the microscale, aiming to intercept most of the Lisbon's geological formations (Figure 3).

A 65 m deep borehole was drilled in Parque da Quinta das Conchas e dos Lilases, in which 8 m of alluvium and 57 m of Lower Miocene formations were intersected. The second borehole was drilled at the Lisbon Municipality's Sewage Brigades, where is intended to install a shallow geothermal system for climatization and water heating in the framework of a rehabilitation process. An 80 m borehole was drilled at this site, in which 15 m of alluvium and 60 m of Middle Miocene formations were intersected. Finally, the third borehole was drilled at Doca de Pedrouços, next to the future "Hub do Mar" complex, where the feasibility of using shallow geothermal systems is also being studied. A 50 m borehole was drilled at this site, in which 38 m of alluvium and 12 m of the Complexo Vulcânico de Lisboa (Lisbon Volcanic Complex) were intersected. Undeformed samples were also collected at these sites and are being analyzed in laboratory to determine the thermal and thermomechanical characteristics of these formations. In addition, temperature and thermal conductivity measuring sensors were installed along the drilled depths (every 5 m) to detect seasonal and in-depth temperature variations.

Finally, to gather more information on the characteristics of Lisbon geological formations, a sampling plan is also being carried out on construction sites that are underway in the municipality, whether carried out by private or public entities, namely in the context of Plano Geral de Drenagem de Lisboa (Lisbon Drainage Master Plan). The aim is to cover possible data gaps on geological formations that were not intercepted in the boreholes. The samples will be submitted to the same tests as the ones collected in the boreholes.

The mesoscale approach will be possible considering the modeled geology, as well as the tests, carried out on the samples collected as part of the project, consisting of extrapolating the conductivity values obtained for the locations of these same formations elsewhere in the city, considering the local conditions in which these formations are present, namely depth, compaction, and saturation. Regarding water levels, existing data on the GeoSIG platform will be considered, which will also be complemented with data from Lisbon Municipality on the existence of underground structures that could influence water circulation, which has been updated through ModSub 3D Project.

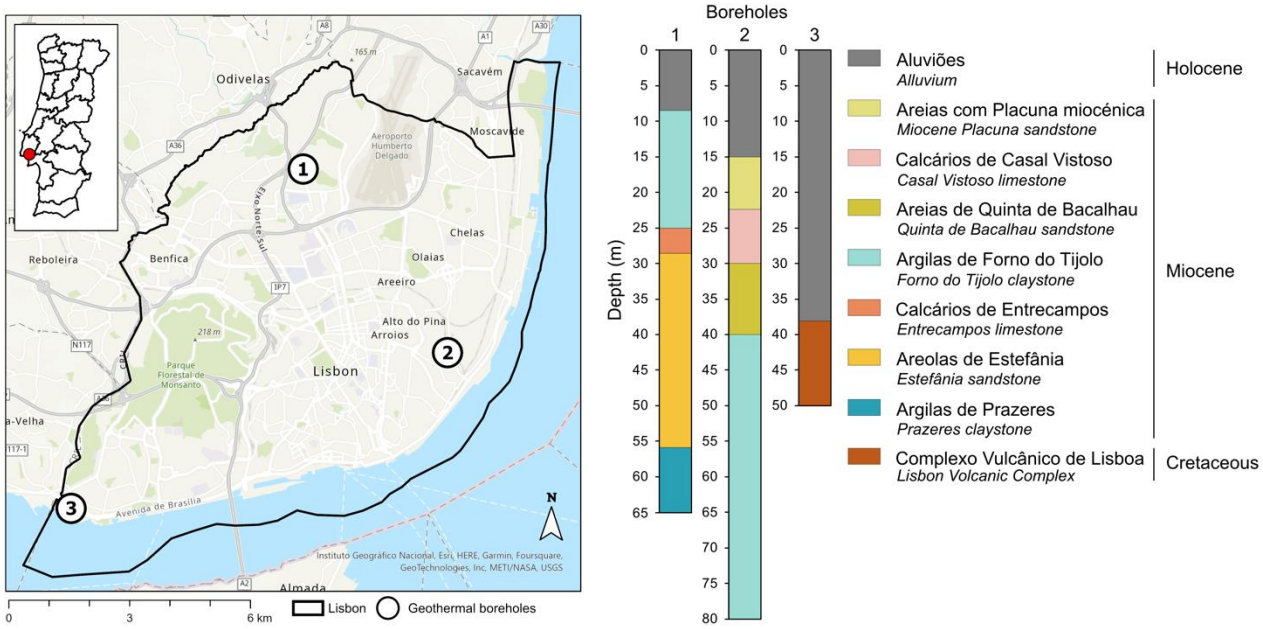

Figure 3. Location and geological logs of the boreholes performed in the scope of the GeoSustained Project.

4. CONCLUSION

The GeoSustained Project is actively contributing to increasing the use of shallow geothermal resources in Lisbon, namely through the Geothermal Potential Map. This map is currently being drawn up, and a preliminary version has already been presented on a macroscale approach with superficial information. Transposing this information in depth will be the next step, as well as assessing the potential of the Lisbon geological formations based on samples collected as part of this project. At the same time, the work being done on writing a guide to good practices and establishing regulations for projects using geothermal energy will, in the short term, make its application in a real context much simpler and faster.

Finally, the work carried out under this project can be extrapolated to other municipalities, being Lisbon a pilot city for defining the best approaches to increase the use of geothermal energy in Portugal. DGEG is also a strategic partner that will enable similar strategies to be implemented at a national level, and this approach is aligned with the best practices ongoing in other European countries.

ABSTRACT: Evaluation of pile driving feasibility in weak carbonate rocks such as calcarenite requires an estimation of the penetration resistance. Results from an experimental programme are presented during which open-ended model pipe piles were jacked into large intact calcarenite blocks. The failure mechanisms at the pile toe and shaft were characterized. A significant feature of the penetration resistance was its oscillations with trough values as low as 10% of the peak values. Heterogeneity of the block was ruled out as a possible cause of the oscillations after a careful examination. Such behaviour was attributed to repeated calcarenite failures inside the pipe after some incremental penetrations of the pipe. The failure mechanism was confirmed by observing that disk-like fragments were generated inside the pile. At the outer pile-calcarenite interface, a region of crushed material formed. Contributions of pipe shaft and toe annulus to the jacking resistance were evaluated.

RÉSUMÉ: Évaluation de la faisabilité du battage de pieux dans des roches carbonatées faibles telles que la calcarénite nécessite une estimation de la résistance à la pénétration. Les résultats d'un programme expérimental sont présentés au cours duquel des pieux modèles à extrémité ouverte ont été introduits par vérinage dans de grands blocs de calcarénite intacts. Les mécanismes de rupture au niveau de la base du pieu et de son fût ont été caractérisés. Une caractéristique significative de la résistance à la pénétration était ses oscillations avec des valeurs de creux aussi basses que 10% des valeurs de crête. L'hétérogénéité du bloc a été exclue comme possible cause des oscillations après un examen attentif. Un tel comportement a été attribué à des ruptures répétées de la calcarénite à l'intérieur du pieu après quelques pénétrations incrémentales du pieu. Le mécanisme de rupture a été confirmé en observant que des fragments en forme de disque étaient générés à l'intérieur du pieu. À l'interface externe pieu-calcarénite, une région de matériau concassé s'est formée. Les contributions du fût du pieu et de l'anneau de la base à la résistance au vérinage ont été évaluées.

Keywords: Pile driving; weak rocks; open-ended model pipe piles.

1 INTRODUCTION

Recent developments in the domain of renewable energy have led the industry to go offshore on the continental shelf where winds are stronger and steadier for harnessing green energy. One of the challenges in this new environment is the presence of soft carbonate rocks. Pipe piles may have to be driven through hard layers to ensure lateral stability at the design depth. Pile piles must survive the installation process. Wide discrepancies have been reported in the description of cemented carbonate deposits. The term “calcarenite” is often used in the literature to describe cemented carbonate formations (Le Tirant and Nauroy, 1994).

Several studies investigated the shaft and base response of pipe piles in cemented formations through model tests (Jafari et al., 2019; Holeyman, 2017; Montargès, 1988; Settgast, 1980). Results from an experimental programme are presented during which model pipe piles were jacked into calcarenite blocks to investigate jacking resistance and failure mechanisms at the pile toe and shaft.

2 SPECIMEN PREPARATION

Model pipe piles were jacked into four calcarenite blocks extracted from Saint-Maximin Quarries in France. The calcarenite is locally referred to as “Roche Douce” or “Roche Saint Leu”. The supplier was Ouachée et Corpechot. Mechanical properties are listed in Table 1. Information regarding microstructure

of similar materials can be found elsewhere (Baud et al., 2017; Stavropoulou et al., 2021). It consists of calcite (60%) and quartz (40%) embedded into a calcite matrix and frequent fossils. Each block was an octagonal prism with the diameter of the inscribed cylinder equal to 0.45m, a height of 0.5m, and a mass of about 137kg. Each block was confined with a steel tube of an outer diameter (D_o) of 508mm and a wall thickness (t) of 7.9mm. The gap between the calcarenite block and the confining steel tube was filled with non-shrinking grout.

Table 1. Mechanical properties of the calcarenite (Bosco and Vander Elst, 2018).

	Units	Mean (SD*)
Bulk density	kg/m^3	1772 (45)
Particle density	kg/m^3	2692 (9)
Uniaxial compressive strength (σ_{ci})	MPa	6.8 (1.7)
Splitting tensile strength	MPa	1 (0.2)
Elastic modulus	GPa	7.2 (1.3)
Porosity	%	39
Poisson's ratio	-	0.22 (0.04)
Shear modulus	GPa	2.9

*SD: Standard deviation.

Five jacking tests of model piles with diameter D_o and length L were conducted at various locations as shown in Figure 1c. For tests with shallow penetration depth on one face (face 1), the block was turned upside down and another test was conducted on the intact face (face 2). Information regarding pile geometries, test locations, and the final penetration depth for each test are listed in Table 2.

Table 2. Description of the model pipes and jacking tests.

Model Pile	D_o [mm]	L [mm]	Block	Face	Location	Final depth [mm]
P4	60	200	B	2	W	137
P5	60	200	B	2	C	158
P6	60	200	A	1	S	157
P8	110	300	E	1	N	171
P9	110	300	D	1	S	242

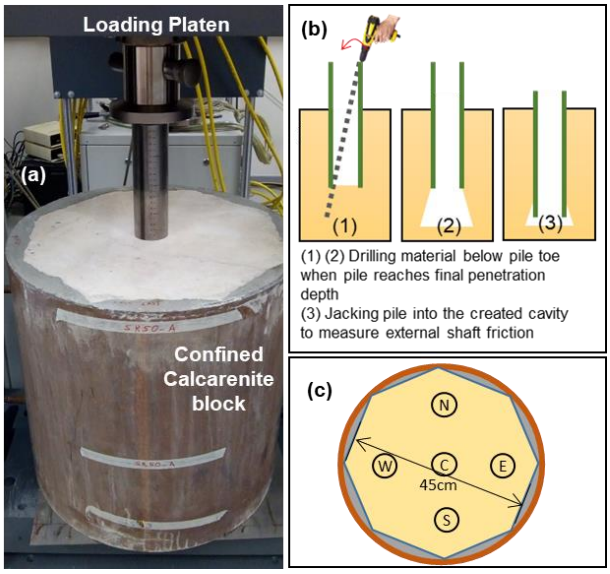

Figure 1. (a) Typical test configurations for P5 (b) procedure for measuring shaft resistance at the end of the test (c) possible locations on a block for conducting jacking tests.

3 TEST PROCEDURE

In the jacking tests, to avoid development of resistance due to the material accumulating inside the pipe (plug), the pipe was regularly emptied at penetration intervals of about 20mm for the 60mm piles and 35mm for the 110mm piles. Large calcarenite fragments (Figure 2) were recovered by hand or with a drill bit. The remaining fines and smaller fragments were vacuum cleaned from the inside the model piles.

After each pipe had been jacked to the desired depth, a cavity was created at the base of the model piles with a hand drill (Figure 1b). Then the pipe head was further jacked downwards to measure the external friction on pipe wall (Figure 1b). Later, the model pile was filled with non-shrinking grout.

Figure 2. Disk-like fragments recovered from P4.

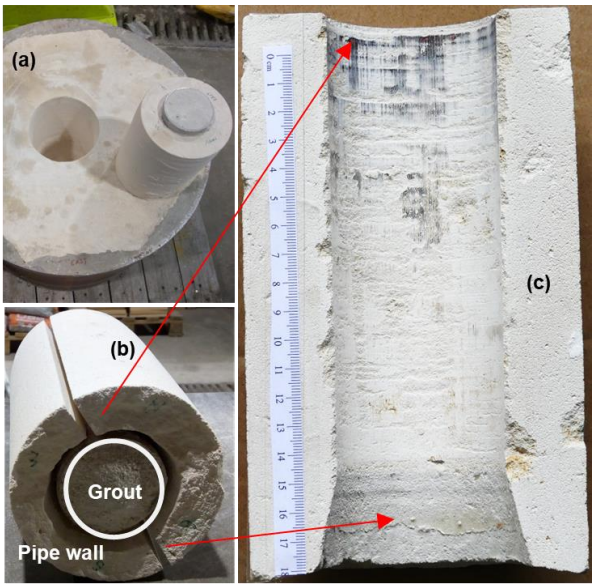

Figure 3. (a) Model pile (P5) filled with hardened grout cored out of the block (b) core sawn longitudinally to the remove the pipe (c) half of the core showing the pipe-calcarenite interface.

To analyse the interface of pipe and calcarenite, the pipe and the adjacent calcarenite for P5 was cored out with the aid of a concrete coring bit (Figure 3a). The core was cut longitudinally to detach the pipe from the interface. One half of the core showing the pipe-calcarenite interface can be seen in Figure 3c. The other half was placed inside gypsum to preserve the interface. It was then sawn transversally to see the pipe calcarenite interface as shown in Figure 4. Test setup is shown in Figure 1a. The pile head was axially jacked downwards via strokes of 1mm followed by unloading to below 500N. The velocity was 0.3 mm/min during loading. The force-displacement curve of P4 is shown in Figure 5. The unloading-reloading cycles are removed for visual clarity. Further details on the results and tests can be found in (Jafari, 2021; Jafari et al., 2019).

4 RESISTANCE MECHANISM

The force-displacement curves of all model piles exhibited an increasing trend with considerable variations (see e.g., Figure 5). The applied force can decrease down to 10% of the peak values. The Force-displacement curve in Figure 5 exhibits a constant linear part at the end beyond a depth of 137mm. This part is due to the removal of the calcarenite at the pile toe, which leaves only the shaft resisting the pile downward movement. Knowing the shaft skin friction at the end of the test, one can reasonably argue that increasing trend of the applied force is due to the increasing skin resistance with further pile penetration.

As the cause of the oscillations, the heterogeneity of the calcarenite was ruled out after a careful examination of the blocks did not reveal any signs of stratification.

Similarly, sudden reductions followed by build-up of the applied forces were reported during penetration of model pipe piles in sand (Paikowsky,1990). This behaviour was attributed to the destruction of arches inside the plug. In our experiments, the plug was regularly removed. The only remaining component of jacking resistance, which can be responsible for the oscillations is the annulus resistance. This is confirmed by the failure mechanism at the pile base.

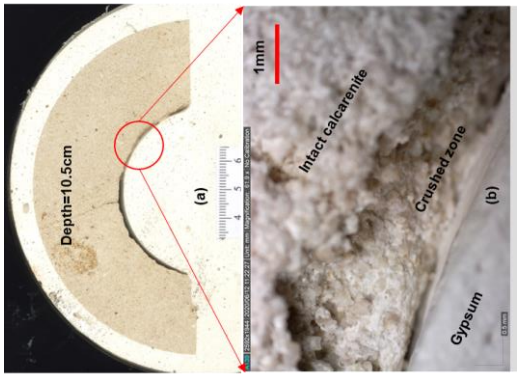

Figure 4. (a) Transversal cross section of pipe-calcarenite interface for P5 (b) close-up showing crushed region adjacent to external pile wall.

4.1 Failure mechanism at pile base and shaft

During the tests, it was observed that pile penetration into the calcarenite block generated disk-like calcarenite fragments popping up inside the pipe. Figure 2 shows the fragments recovered for P4. The jacking resistance decreased significantly upon formation of a disk-like fragment inside the pipe. Jafari et al. (2019) reported similar Behaviour. This process will be hereafter referred to as "chipping". The annulus resistance depended on the "chipping type" at the pile toe. In general, the chipping type was either "full chipping" (Figure 2d) or "partial chipping" (Figure 2abc). In full chipping, a full disk-like calcarenite fragment is created inside the pipe after a peak is reached. The penetration resistance was highest prior to full chipping.

Failure patterns at the external shaft of model piles can be seen in Figure 4. A crushed compressed zone was seen to form around the pipe wall as seen in transversal cross-sections (Figure 4). The thickness of the crushed zone is almost equal to the pipe wall thickness. With help of an air blow gun, some of the crushed material could be blown away so that the extent of the crushed zone could be assessed.

The chipping mechanism can be expected to

influence the thickness of the crushed zone around the model pile (Figure 4). The pipe penetration results in the volumetric compression of the calcarenite at the pipe tip. The compressed region consists of compacted finely crushed calcarenite forming a doughnut-shape. Intuitively, it could be expected that the radius of the circular cross section of this doughnut increases with penetration depth until some critical embedment d_{crit} is reached. At that point, chipping occurs allowing the pipe to cut through the doughnut and to leave a region of dense fine material at the external and internal faces of the pipe. This process repeats itself with further penetration. The compacted crushed region has a maximum thickness (hence maximum normal stress) at a depth when chipping occurs. At that depth, the calcarenite tends to stick to pipe (leaving a dent on calcarenite interface) when one separates the pipe and calcarenite as seen in Figure 3c.

4.2 Periodicity of oscillations in jacking resistance

To understand the frequency content each resistance curve (F_0) was decomposed as follows:

1. F_0 was de-trended by fitting a fifth order polynomial to find $F_{detrended}$ (Figure 6a)
2. Low frequency content (F_{smooth}) is obtained by smoothing $F_{detrended}$ with a moving average filter (Figure 6b).
3. High frequency oscillations (F_{oscill}) were obtained as $F_{oscill}=F_{detrended}-F_{smooth}$ (Figure 6b)
4. Scalograms of both high and low frequency contents were constructed (Figure 6b-c).

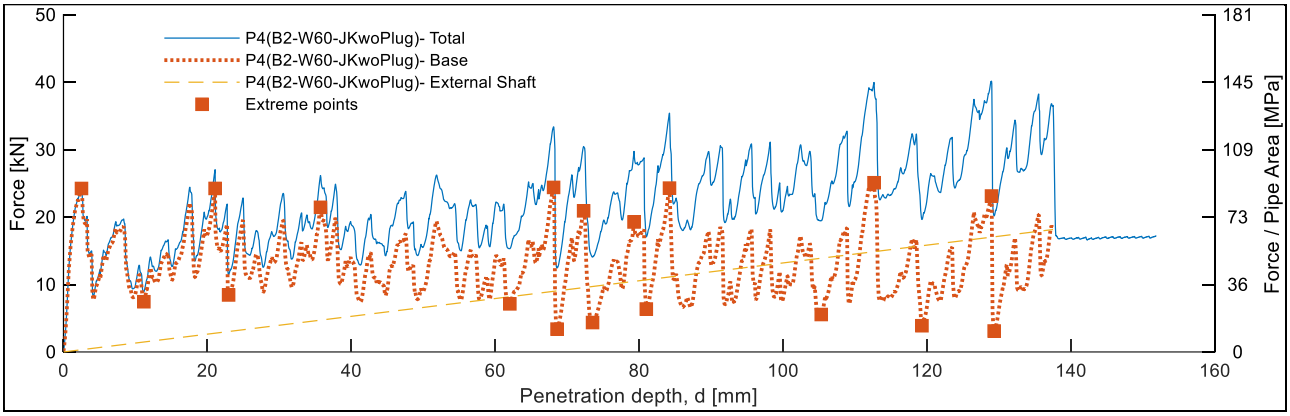

Figure 5. Typical force-displacement curves for test P4 with the estimated shaft and annulus components.

The peaks in the F_{smooth} curve corresponded to when full chipping occurred in the tests. On the other hand, the peaks in the F_{oscill} corresponded to when partial chipping occurred.

From the scalograms, it was found out that on average:

- The high frequency component has a period of 4mm for the 60mm-piles while it has a period of 8mm for the 110mm-piles. These periods are about $0.07D_o$.
- The low frequency content has a period of 12mm for the 60mm-piles while it has a period of 27mm for the 110mm-piles. These periods are about $0.23D_o$.

The period of the low and high frequency components of the signals from 110mm-piles is about two times that of the 60mm-piles. These results indicate that the resistance oscillations depend on the pile diameter rather than the pile wall thickness in contrast to what was reported by Jafari et al. (2019).

4.3 Shaft resistance

External shaft resistance at the end of the tests was measured by jacking the pipe into a cavity created below the pipe tip (Section 4). Assuming a linear increase of shaft resistance with penetration depth (Figure 5), one can compute an average shear stress τ_{ave} on the pipe outside wall. τ_{ave} is 440 kPa and 405 kPa for the 60mm and 110mm piles, respectively. These values are about 6% of σ_{ci}.

These values are consistent with laboratory experiments by ARGEMA (Association de Recherche en GEotechnique MArine) in which small piles were *driven* in limestone with 5MPa< σ_{ci} <25MPa. Skin friction values were between 7 to 9 percent of σ_{ci}. In addition, pullout tests of driven piles in cemented carbonate formations exhibited skin friction values reaching 300 kPa in formations with σ_{ci} ranging from 3.5 to 5MPa according to Le Tirant and Nauroy (1994). High shaft friction values seem to be typical of model pipe piles installed in carbonate rocks. These results may be used combined with the investigation of rock-steel interfaces after Ziogos et al. (2023) to

better understand the skin friction of crushed calcarenite and the model steel pipe pile.

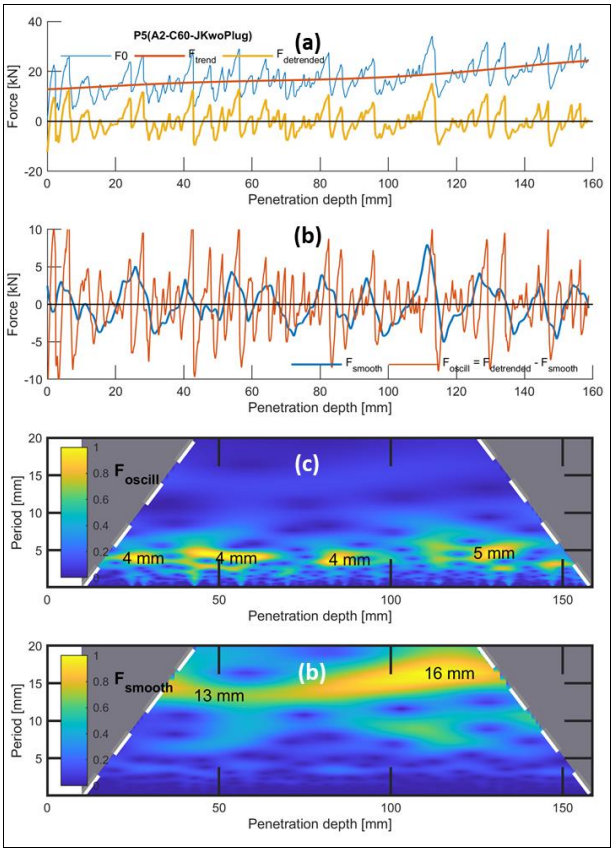

Figure 6. (a) De-trending of penetration resistance for P5 (b) decomposition of detrended curve into high frequency and low frequency curves (c) (d) scalograms of Foscill and Fsmooth.

4.4 Annulus resistance

By subtracting the shaft resistance from the total jacking resistance, one can obtain the annulus resistance. The estimated annulus resistance falls in a band of peak and residual values (Figure 5). For the peaks with the highest prominence, full chipping occurred (Section 4.1). The *findpeaks* function of Matlab® was used to identify all the peaks and troughs of a curve with a prominence equal to 30% of the maximum annulus resistance. This criterion proved relatively effective in capturing the peaks and troughs associated with full chipping as seen in Figure 5. Mean peak annulus stress of all the model piles is 85MPa = $12.5\sigma_{ci}$ while mean residual annulus stress is 23MPa = $3.4\sigma_{ci}$. No discernible scale effects were observed between the annulus capacity of the 60mm and 110mm model piles. The estimated residual annulus stress is close to upper bound suggestion by Le Tirant and Nauroy (1994), which is the minimum of $4.5\sigma_{ci}$ and 12 MPa. The authors (Jafari, 2021; Jafari et al., 2019) investigated numerically the bearing capacity of open-ended pipe piles in intact rock. The annulus bearing capacity did not depend on the D_o/t for the common ranges in practice ($D_o/t < 100$). With increasing embedment depth, a maximum annulus capacity q_b was approached. A fit to those numerical results leads to an annulus bearing capacity of $11.8\sigma_{ci}$. This value is in good agreement with the mean peak stress of the jacked model pile which is $12.5\sigma_{ci}$. Prediction of the residual bearing capacity in terms of the intrinsic properties of the medium is an area open to further research.

5 CONCLUSIONS

Model pipe piles were jacked into relatively large blocks of a reference calcarenite. The model piles were jacked down to 1.5 to 2.5 times pipe diameter. Penetration resistance was measured. During jacking, the material accumulating inside the pipe was removed at regular intervals. The total jacking resistance was split into annulus and shaft resistance components. Annulus resistance exhibited important oscillations, which was attributed to calcarenite chipping mechanisms inside the pipe. The period of the oscillations depended on the pile diameter rather than pile wall thickness. At the pile-calcarenite interface, a region of compacted crushed material formed over a thickness of the order of that of the pipe wall.

ACKNOWLEDGEMENTS

Calcarenite samples used for penetration testing were graciously supplied by EDF Renouvelables, thanks to Ms. Elisabeth Palix. Contributions from members of LEMSC laboratory in particular Ms. Catherine Doneux, who facilitated the experiments are also appreciated.

RÉSUMÉ: Le projet des tunnels de drainage « Monsanto-Santa Apolonia » (TMSA) et « Chelas-Beato » (TCB) vise en priorité à maitriser les inondations qui se produisent en plusieurs endroits de la ville de Lisbonne. Le marché attribué en Conception-Réalisation au groupement Mota-Engil – Spie Batignolles International (constructeurs), Spie Batignolles Génie Civil – LCW – Aqualogus (concepteurs) comprend la construction des deux tunnels - le TMSA de 4,4 km de longueur, et le TCB de 1,1 km. Il comprend également la réalisation des travaux de dérivation des ruisseaux canalisés en amont des tunnels, de trois chambres d'interception du réseau existant avec les puits de chute associés et les ouvrages de décharge dans le Tage. Le TMSA recoupera deux grands ensembles géologiques, de longueur équivalente. En partie nord-ouest, le tunnel recoupera des calcaires crétacés et les tufs et basaltes du complexe volcanique de Lisbonne. En partie Sud-Est le tunnel recoupera des terrains sablo-argileux compacts à indurés, de la série du Miocène de Lisbonne, Le TCB recoupe uniquement les couches supérieures du Miocène. Les ouvrages de décharge seront réalisés dans des remblais de remodelage des rives du Tage. Le contexte urbain du TMSA est très dense sur les deux tiers sud-est du tracé, avec le croisement de trois lignes de métro sous une faible couverture et le passage sous des quartiers anciens d'une grande valeur architecturale. Le contexte urbain du TCB est moins dense mais comprend le passage sous deux voies ferrées importantes.

ABSTRACT: The «Monsanto-Santa Apolonia» (TMSA) and «Chelas-Beato» (TCB) Drainage Tunnels Project is aimed primarily at controlling flooding in several areas of the city of Lisbon. The design & build contract attributed to the joint-venture Mota-Engil – Spie Batignolles International (builder), Spie Batignolles Génie Civil – LCW – Aqualogus (designer) includes the achievement of the two tunnels - TMSA of 4,4 km long and TCB of 1,1 km. It also includes the work of capturing the canalized streams upstream of the tunnels, three interception chambers of the existing network with the associated shafts and works of the outlets in the Tagus. The TMSA will intersect two large geological units of equivalent length. In the northwest part, the tunnel will intersect Cretaceous limestones and tuffs and basalts of the Lisbon volcanic complex. In part South-East the tunnel will intersect sandy-clay soils, compact to indurated, of the series of the Miocene of Lisbon, TCB only intersects the upper layers of the Miocene. The outlets works will be embedded in the embankments of the Tagus shore. The urban context of the TMSA is very dense on the south-eastern two thirds of the route, with the crossing of three metro lines under a weak cover and the passage under old districts of great architectural value. The urban context of TCB is less dense but includes the crossing under two major railways.

Keywords: Urban tunnelling; drainage; Lisbon.

1 INTRODUCTION

Le projet général des tunnels de drainage s'inscrit dans le cadre du plan général de drainage de la ville de Lisbonne pour la période 2016-2030 (Câmara Municipal de Lisboa, 2015). Ce projet vise à la maîtrise des inondations qui se produisent en plusieurs endroits de la ville. Outre la construction de deux tunnels - le tunnel Monsanto - St. Apolónia (TMSA) d'une longueur de 4,4 km, et le tunnel Chelas - Beato (TCB) d'une longueur de 1,1km (Figure 1) le marché comprend notamment la réalisation des ouvrages de dérivation des rivières d'Alcântara et de Chelas, des chambres d'interception des réseaux d'eau pluviale, (Av. da Liberdade, R. St Marta et Av. Almirante Reis), avec les puits de chute associés, qui envoient les débits déviés dans le TMSA et les ouvrages de rejet à l'estuaire du Tage. En outre, le marché comprend la construction d'un bassin antipollution à l'entrée amont du tunnel TMSA, et d'un réservoir d'eau traitée, ainsi que la mise en œuvre du système de drainage des eaux usées de la zone basse du bassin de St. Apolónia, dans la zone entourant le rejet du TMSA.

Figure 1. Plan général de localisation des tunnels de drainage de la ville de Lisbonne.

Le système formé par les tunnels et les réseaux existants garantit ainsi le transport des débits pour des périodes de précipitations supérieures à 100 ans. Le TMSA a été dimensionné pour une capacité d'écoulement de 170m3/s et le TCB de l'ordre de 147m3/s. Dans le cas de débits dépassant la capacité des tunnels, les débits excédentaires continuent en aval (par "by-pass") et sont transportés par les infrastructures existantes. Les effluents du système de drainage, par temps sec, seront traités par les stations d'épuration existantes. Par temps de pluie, le déchargement vers les tunnels n'aura lieu qu'à partir d'un débit assurant une dilution élevée. Compte tenu de la profondeur d'implantation des tunnels, les débits interceptés dans ces chambres de dérivation sont conduits à des ouvrages de chute en vortex qui assurent une bonne dissipation d'énergie. Il est également prévu que les tunnels permettent le transport d'effluents traités pour des utilisations d'arrosage d'espaces verts et de nettoyage urbain.

2 LES OUVRAGES DE DERIVATION

2.1 Les ouvrages de dérivation amont (TM1, TC1)

Les ouvrages de dérivation du Caneiro de Alcântara (TM1), en amont du TMSA, se situent à Campolide, dans le bassin de la rivière d'Alcântara canalisée et couverte. Aujourd'hui, les eaux du collecteur de l'Alcântara coulent jusqu'au Tage. L'ouvrage de dérivation des collecteurs de la vallée de Chelas (TC1), en amont du TCB, est implanté dans le lit majeur du ruisseau de Chelas, aujourd'hui canalisé et couvert.

Les ouvrages de dérivation amont incluent fonctionnellement les principaux organes suivants:

- Un chenal d'intersection et de déviation des collecteurs existants;
- Un puits de décharge des gros éléments charriés et des fosses de tamisage/dessablage;
- Des bassins de dépollution et une station de pompage vers une station d'épuration (TM1);
- Un chenal latéral (TM1) ou une chambre (TC1) d'amené du débit de crue au tunnel;
- Divers dispositifs d'écrêtage et de contrôle du flux (seuils, vannes-écluses etc.) entre les organes.

Les débits de temps sec et les débits de pluie (jusqu'à 2 fois le débit de pointe) sont détournés en amont des ouvrages de dérivation et amenés vers une station d'épuration.

Il s'agit d'ouvrages majoritairement enterrés, avec quelques émergences (bâtiment de contrôle-commande etc.). Ainsi, les structures du TM1 sont implantés à 20m sous le terrain naturel. Elles sont constituées de piliers, de dalles massives et de murs en béton armé. Sur le TC1, la structure est enterrée à environ 15m de profondeur. Compte tenu des contraintes de site, il a été retenu des solutions de soutènement périphérique par rideaux de pieux en béton armé avec différents niveaux d'ancrages provisoires, qui seront en définitif remplacés par les dalles des niveaux enterrés.

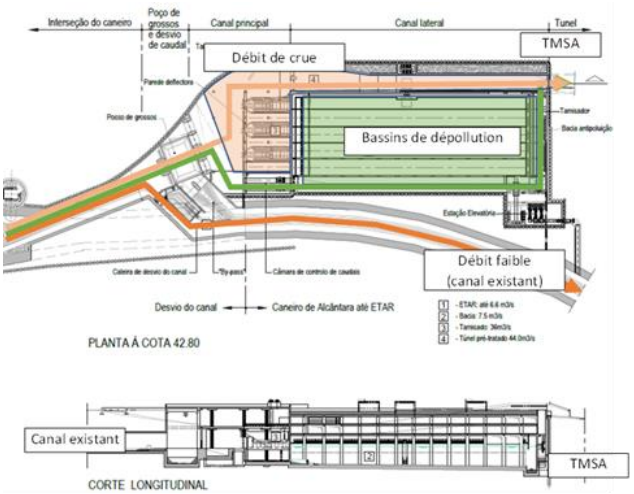

Figure 2. Ouvrage d'interception et de dérivation du collecteur d'Alcantara (TM1).

Les excavations du TM1 constituent la tranchée de départ du tunnelier pour le creusement du TMSA en pente descendante. En revanche, le tunnelier sortira de terre dans la tranchée du TC1, à la fin du creusement du TCB en attaque montante.

2.2 Les ouvrages d'interception des réseaux existants (TM2, TM3, TM4)

Ces ouvrages ne sont présents que le long du TMSA. Les ouvrages TM3 et TM4 sont implantés sur la rue St. Marta et l'Av. Almirante Reis respectivement, au droit des deux principaux thalwegs du centre

historique de Lisbonne qui se rejoignent dans la ville basse (Baixa de Lisboa) et débouchent dans le Tage au niveau de la Place du Commerce (Praça do Comercio). L'ouvrage TM2 est implanté sur l'Av. da Liberdade, sur le flanc ouest du thalweg de St. Marta.

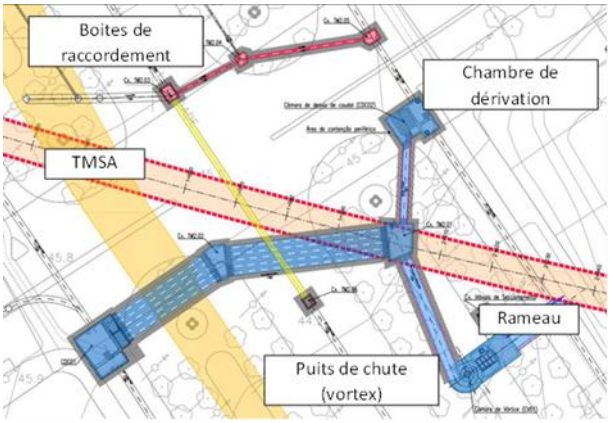

Figure 3. Ouvrage d'interception de l'Av. da Liberdade (TM2).

Les ouvrages de dérivation amont incluent fonctionnellement les principaux organes suivants:

- Des boîtes de raccordement qui interceptent les débits des collecteurs existants;
- Des chambres de dérivation qui dirige le débit de crue vers un puits de chute et les débits courants vers la station d'épuration à travers le réseau existant;
- Un puits de chute en vortex;
- Une chambre de dissipation;
- Un rameau de raccordement au TMSA.

Les puits de chute en vortex sont constitués par une rampe hélicoïdale en pente à 20% environ, à l'intérieur de l'enceinte cylindrique du puits, de 6m (puits TM2, TM3) à 8,6m de diamètre (puits TM4).

L'enceinte des puits TM3 et TM4, de 20m de profondeur environ, est constituée par des pieux en béton armé, complétée par un béton projeté armé et des anneaux de renforcement en béton armé. L'enceinte du puits TM2 est également constituée par des pieux descendus jusqu'au toit du rocher (CVL, voir § 5), et, en dessous, par un soutènement au rocher par boulonnage, béton projeté avec des anneaux de renforcement en béton armé. La base des puits et l'amorce des rameaux en section élargie (hauteur x largeur = 8m x 5m) constitue la chambre de dissipation de l'énergie de chute. Les rameaux ont une longueur de 20m environ sur TM2 et TM3 et de 75m sur TM4. Ils sont excavés en méthode conventionnelle puis revêtus en béton coffré après la réalisation de la jonction au tunnel.

3 LES TUNNELS MONSANTO-SANTA APOLONIA ET CHELAS-BEATO

3.1 Géométrie et structure

Le tunnel Monsanto-Santa Apolónia (TMSA) a une longueur de 4,4km. Il présente une pente de 0,8% sur la majeure partie de son linéaire. La couverture varie de 4m à 85m et la pression hydrostatique maximale des eaux souterraines est de 320 kPa. Il sera excavé dans le sens descendant.

Le tunnel Chelas-Beato (TCB) a une longueur de 1,1km. Il présente une pente constante de 0,5%, permettant de diriger les flux d'eaux de pluie vers l'aval. La couverture varie de 7m à 45m et la pression hydrostatique maximale des eaux souterraines est de 100 kPa. Il sera excavé dans le sens montant.

Le revêtement final est constitué d'anneaux universels composés de 6 voussoirs rhomboïdaux.

Les principaux paramètres géométriques sont listés ci-dessous:

- Diamètre intérieur: 5,50m;
- Diamètre extérieur: 6,10m;
- Epaisseur du revêtement: 0,30m;
- Longueur nominale des anneaux: 1,80m.

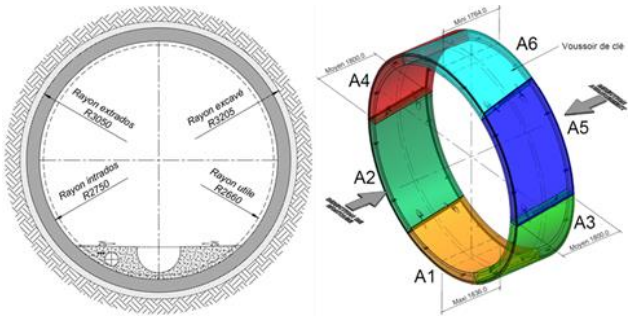

Figure 4. Géométrie du revêtement.

3.2 Contraintes de conception

Le dimensionnement du revêtement intègre des contraintes particulières:

- Le revêtement doit être en mesure de suivre une courbe de rayon 200m (courbe la plus serrée du projet). Les anneaux de voussoirs présentent donc un pincement important;
- La partie avale des tunnels peut être en contact avec l'eau de mer (zone de marnage). Cela conduit à des enrobages non courants afin d'éviter la corrosion induite par les chlorures;
- Le revêtement doit pouvoir reprendre une pression hydrostatique interne de 1 bar;
- Les tunnels sont situés en zone sismique.

4 LES OUVRAGES DE RESTITUTION

Les ouvrages de restitution dans l'estuaire du Tage (TM5 pour le TMSA, TC2 pour le TCB) sont constitués par des cadres fermés en béton armé, enterré, avec un nombre variable de cellules intérieures, et une largeur et une hauteur variables qui augmente avec le nombre de cellules, destinées à réduire les vitesses d'écoulement en sortie.

L'ouvrage TM5 à St. Apolónia, se développe sur une longueur de 180 m et l'ouvrage TC2 sur 320m à Poço do Bispo, avec une pente de l'ordre de 0,5%. Le niveau de restitution au Tage étant inférieur de quelques mètres au niveau moyen de l'estuaire, les ouvrages reçoivent le flux de la marée remontante.

L'ouvrage TM2 s'inscrit dans un site contraint, avec un passage au-dessus du tunnel de la ligne bleue du métro, avec une très faible couverture. L'ouvrage sera alors porté par des pieux descendus sous le tunnel. Le contexte géologique de ces ouvrages est caractérisé par la présence d'alluvions lâches et de remblais, d'épaisseur croissante vers l'aval.

La présence des terrains de faible compacité sous la nappe, nécessite la réalisation de rideaux de soutènements par pieux sécants, sur une grande partie du linéaire de ces ouvrages, avec la mise en place de tirants provisoires.

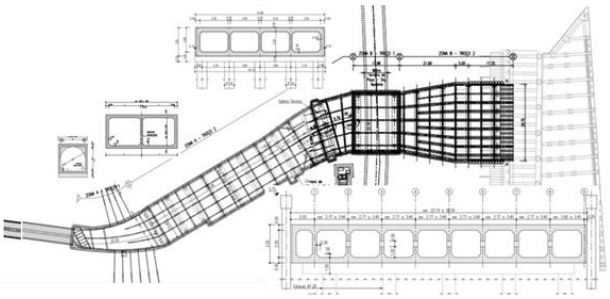

Figure 5. Ouvrage de restitution (TM5) – plan et coupes-types.

Compte tenu de la forte exposition au risque sismique de liquéfaction, ces terrains feront l'objet de traitement d'amélioration en place (colonnes ballastées etc.).

5 GEOLOGIE ET GEOTECHNIQUE

Le TMSA traverse dans sa moitié nord-ouest une structure rocheuse anticlinale, localement faillée, avec des calcaires et des calcaires marneux du Crétacé, recouverts par le complexe volcanique de Lisbonne (CVL) constitué d'une alternance de basaltes et de tufs volcaniques. Sur ce tronçon, le TMSA pourrait traverser une zone de failles avec la présence de roches altérées et fracturées, avec des passages argileux et d'éventuelles cavités karstiques.

Dans sa moitié sud-est, le tunnel interceptera une partie de la série sédimentaire miocène de Lisbonne (MI à MIVb), évoluant de l'Aquitanien au Burdigalien, constituée de terrains compacts de nature sablo-argileuse dominante avec la présence d'horizons rocheux peu nombreux et discontinus de résistance faibles de calcarènites et d'argilites.

Toutes ces assises sont légèrement basculées d'environ 5º à 10º vers le Tage.

Le contexte hydrogéologique du tronçon rocheux est déterminé par l'état de fissuration et d'altération des roches. La charge hydraulique peut atteindre quelques dizaines de mètres au-dessus du tunnel mais les flux souterrains sont généralement faibles comme le montre l'expérience sur les travaux dans ces formations, sauf potentiellement au droit des failles.

Le contexte hydrogéologique du tronçon en terrain meuble est caractérisé par la présence d'un système multicouche avec des communications latérales et verticales et des variations importantes des conditions hydrogéologiques. Les perméabilités mesurées dans les essais de perméabilité réalisés sont variables, mais généralement faibles (10^{-6} à 10^{-9} m/s).

Les calcaires du Crétacé présente une résistance moyenne, de l'ordre de 45 MPa. On observe une grande dispersion des résistances obtenues sur les roches du CVL: les basaltes sains correspondent à des roches très résistantes et très rigides et les tufs volcaniques correspondent à des roches peu résistantes et peu rigides.

Les sols de la série miocène vont des sables silteux peu plastiques aux argiles très plastiques avec des sols intermédiaires (silts ou sables silteux à très silteux peu à moyennement plastique).

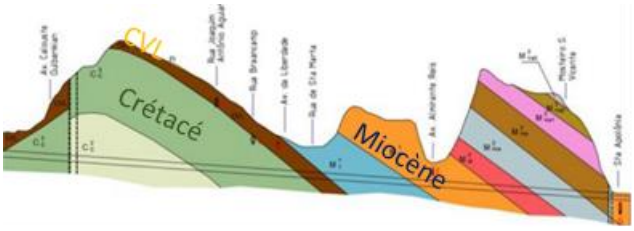

Figure 6. Profil en long géologique du TMSA.

Les terrains traversés par le TCB appartiennent à la série miocène finale, du Burdigalien Supérieur au Serravalien. Sur les deux tiers ouest, le tunnel s'inscrit dans des terrains à dominante sableuse, avec de nombreux niveaux indurés gréso-carbonatés, sous une faible charge hydraulique de quelques mètres en radier. Sur le tiers est, les terrains sont majoritairement argileux avec des niveaux marno-calcaires ou de calcarènites. La charge hydraulique peut atteindre une

dizaine de mètres sur ce tronçon. Les derniers mètres du tunnel s'inscrivent dans la formation des Grès de Grilos, affectée de phénomènes karstiques importants.

6 LES METHODES DE REALISATION DES TUNNELS

Le TMSA sera excavé par un tunnelier à confinement par pression de terre (EPB). Le TCB, initialement prévu d'être excavé en méthode conventionnelle, sera également excavé par le même tunnelier, à la suite du TMSA. La roue de coupe est de type mixte, équipée de 40 molettes 17'' et de couteaux, avec un taux d'ouverture de près de 30% Le diamètre du bouclier est de 6,4m environ, pour une longueur de 10m. La poussée totale de 38000 kN est assurée par 24 vérins au contact des voussoirs.

Le tunnelier fonctionnera selon plusieurs modes de pilotage du confinement:

- En mode « ouvert », la vis fonctionne en extraction à la pression atmosphérique;
- En mode « chambre mi-pleine » avec confinement à l'air en partie supérieure et injections de bentonite le long du bouclier éventuelles;

Le mode « ouvert » est réservé aux tronçons en terrain rocheux, hors zone de failles, prévisible sur 40% du linéaire du TMSA.

En mode « chambre pleine », avec injection de bentonite le long du bouclier.

Figure 7. Réception en atelier du tunnelier « Oli ».

Le mode « chambre mi-pleine » est prévu en terrain meuble (partie du TMSA et totalité du TCB). Le mode « chambre pleine » est réservé aux tronçons sous faible couverture (thalwegs…) sur la base d'un pilotage observationnel par les tassements en surface et une instrumentation en forage. L'injection de remplissage du vide annulaire, de type « coulis bi-composants » est également pilotée en pression-volume sur la base des observations.

La pression de consigne maximale est de 3,8 bars sur le TMSA et de 2,6 bars sur le TCB.

7 LES POINTS SENSIBLES

7.1 Les thalwegs et les passages sous le metro

Le tunnel Monsanto-Santa Apolónia passe successivement sous deux thalwegs:

- Le thalweg de l'ancienne rivière de Valverde où se trouve aujourd'hui la rue St. Marta;
- Le thalweg de l'ancienne rivière de Arroios au niveau de l'actuelle av. Almirante Reis.

Dans ces zones, la couverture est d'environ 13m (2Ø) et le contexte urbain est dense.

Sous le versant ouest du thalweg de Valverde, le tracé du TMSA croise successivement la ligne jaune du métro sous une couverture de 20m et la ligne bleue sous une couverture de 14m. Sous le thalweg de l'av. Almirante Reis, le tracé du TMSA croise la ligne verte sous une couverture réduite à 6m.

En cours de creusement, le suivi des déplacements sur ces ouvrages et le bâti environnant fera l'objet d'un monitoring renforcé, avec notamment la mise en place d'une instrumentation en forage sur le premier thalweg franchi.

7.2 Les intersections tunnel - rameaux

Au droit des intersections tunnel - rameaux, les ouvertures à réaliser dans le revêtement de voussoirs sont relativement importantes (environ 5m de largeur pour 3,5m de hauteur). Par ailleurs, les structures provisoires de reprise doivent impacter le moins possible le gabarit tunnel pendant les travaux de celui-ci. Afin de répondre à cette problématique, les structures provisoires de reprise sont constituées de deux linteaux en UPN (inférieur et supérieur) connectés par deux piédroits cintrés en HEB. Les linteaux inférieurs et supérieurs sont connectés aux anneaux par le biais de scellements et de bèches.

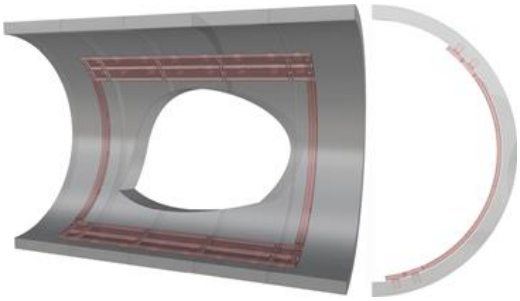

Figure 8. Structure provisoire de reprise au droit des intersections tunnel – rameaux.

7.3 La sortie du tunnelier à St. Apolónia

Le site de sortie du tunnelier à Santa Apolónia est situé au pied de la colline de l'Alfama. Le site est caractérisé par une forte pente. Les avoisinants sont constitués par un bâti très dense, de construction ancienne en

maçonnerie, de deux à quatre niveaux habitables, séparé par des ruelles étroites et des escaliers. Le bâtiment le plus proche du tympan du tunnel, avec une très faible couverture de 3m sous les fondations, est particulièrement sensible en raison de son revêtement de façade en carrelage (« Casa do Azulejo »). Le seuil de déformation admissible (« Limiting Tensile Strain, d'après Boscardin et Cording, 1989), pour un niveau de dommage "léger" est alors de 4.10^{-4}, correspondant aux paramètres de contrôle suivants:

- Tassement différentiel: $\Delta S < 25$ mm
- Angle de distorsion: $\beta < 1/350$

Compte tenu de la faible couverture, le respect de ces seuils ne permet pas d'envisager la sortie du tunnelier en mode "confinement en pression de terre".

En effet, ce mode de confinement ne permet pas une régulation suffisamment précise de la pression, notamment le long du bouclier.

Par ailleurs, le contexte géotechnique présente une forte variabilité des faciès au sein des « Sables de la Quinta do Bacalhau » et des remblais hétérogènes d'épaisseur variable, en lien avec les vestiges archéologiques de la « Muralha Fernandina ».

Figure 9. Vue de la Casa do Azulejo et élévation des cibles de suivi des déplacements.

Le principe retenu est la réalisation en méthode traditionnelle avec présoutènement par voûte parapluie, d'une galerie en demi-section supérieure, en contre-attaque à partir du tympan de la tranchée couverte du TM5 (voir § 4). La longueur de cette galerie est conditionnée par la présence d'un niveau rocheux plurimétrique de calcarénites, remontant en voûte du tunnel à 26m du tympan et constituant un toit suffisant pour abaisser en sécurité la pression de confinement du tunnelier. Une fois la section inférieure excavée par le tunnelier, le revêtement définitif de la galerie sera constitué par les voussoirs.

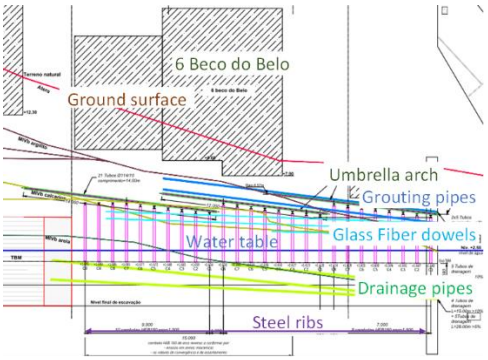

Figure 10. Profil en long de la galerie de contre-attaque.

Le vide entre l'extrados des voussoirs et l'intrados de la galerie de contre-attaque, sera comblé par des injections de mortier, à partir de conduits disposés préalablement à l'intrados de la galerie.

Une évaluation des dommages engendrés sur la « Casa do Azulejo » a été menée à l'aide d'un modèle aux éléments finis de la façade, afin de vérifier le respect du critère de déformation admissible. En cours de creusement, le suivi des déplacements sur la façade sera réalisé par un théodolite, à l'aide d'un réseau dense de cibles de mesures optiques (voir Figure 10).

8 CONCLUSION

La maitrise des inondations urbaines est un des enjeux de l'adaptation au changement climatique, auquel répond la construction des tunnels de drainage de Lisbonne. Le projet associe des ouvrages hydrauliques complexes à des tunnels de longueur et de diamètre importants, qui justifient l'utilisation d'un tunnelier. Malgré un contexte géologique relativement favorable, les contraintes en site urbain ont nécessité des études approfondies de l'impact du chantier et des solutions techniques au cas par cas, comme le recours à un tunnelier à confinement de type pression de terre, diverses solutions de traitements de terrains ou la réalisation d'une galerie de contre-attaque pour la sortie du tunnelier. Après une phase d'étude de trois ans dans le cadre du contrat de Conception-Réalisation, l'année 2023 verra le démarrage du chantier, avec un objectif de mise en service en 2026.

Department of Civil Engineering, IIT Roorkee, India

**akhilesh_cj@ce.iitr.ac.in*

ABSTRACT: This paper elaborates a real-time, full-scale, hands-on field experience of jet grouting in river borne materials (RBM). An earthen dyke of approximately 320 m length and15 m height was constructed with available river borne material (RMB) on riverbed and riverbanks. The key function of this dyke was to isolate the working front in the spillway and plunge pool area from flowing river water just downstream of a rock fill dam of a hydropower project in India. Sieve analysis of RBM showed it as gravely sand with very less fine. To check the efficacy of jet grouting the cylindrical cores are drilled and tested. Unconfined compressive strength of cylindrical cores varies from 8 to 10 MPa, which is well comparable to similar results reported worldwide. Analysis of jet grouting parameters e.g. grouting rate and pressure, properties of grout and spoil, UCS of grout and spoil, cement intake etc. is done across the length of the dyke. Jet grouting methodology, materials, test results, effectiveness, challenges faced, comparison with similar works are detailed in this paper. This experience shall reinforce the confidence of practicing engineers and academician in adopting jet grouting technology in highly variable and porous materials like RBM.

RÉSUMÉ: Cet article élabore une expérience pratique en temps réel, à grande échelle, du jet grouting dans des matériaux fluviaux (RBM). Une digue en terre d'environ 320 m de longueur et 15 m de hauteur a été construite avec des matériaux fluviaux (RMB) disponibles sur le lit et les berges de la rivière. La fonction clé de cette digue était d'isoler le front de travail dans la zone du déversoir et du bassin profond de l'eau de la rivière qui coule juste en aval d'un barrage en enrochement d'un projet hydroélectrique en Inde. L'analyse par tamisage du RBM a montré qu'il s'agissait de sable graveleux très moins fin. Pour vérifier l'efficacité du jet grouting, les noyaux cylindriques sont forés et testés. La résistance à la compression non confinée des noyaux cylindriques varie de 8 à 10 MPa, ce qui est tout à fait comparable aux résultats similaires rapportés dans le monde entier. Analyse des paramètres de jet grouting, par ex. Le taux et la pression d'injection, les propriétés du coulis et des déblais, l'UCS du coulis et des déblais, l'apport de ciment, etc. sont effectués sur toute la longueur de la digue. La méthodologie du jet grouting, les matériaux, les résultats des tests, l'efficacité, les défis rencontrés, la comparaison avec des travaux similaires sont détaillés dans cet article. Cette expérience renforcera la confiance des ingénieurs et des académiciens en exercice dans l'adoption de la technologie de jet grouting dans des matériaux très variables et poreux comme le RBM.

Keywords: Jet grouting; earthen dyke; river borne material; hydro power plant; grout and spoil properties.

1 INTRODUCTION

Jet grouting had been accepted as a well-established ground improvement technique since decades. In the present case jet grouting has been used as mainly as a seepage channel barrier to secure a dry working area. The jet grouting process involves the erosion of the in-situ soil, by a jet of fluid projected at very high velocity from a small diameter nozzle. The eroded soil is then mixed with a fluid (generally cement grout) to form a mixture, which after hardening is called soil-cement element. However, to efficiently implement this technique, it is imperative to carefully arrange the jet grouting equipment and methodically execute the process.

Apart from the technical know-how, the other bigger challenge was to execute a series of interdependent tasks of dyke construction, jet grouting, dewatering, concrete back filling etc. in very small frame and before onset of monsoon season; and to manage a huge machinery and manpower at very congested work front. Planning and monitoring of this strengthening activity without hindering the operation of hydropower generation was a rare management lesson.

2 PROJECT DESCRIPTION

Koldam Hydro Power Station (Koldam HPS) is situated on river Satjuj in district Bilaspur, Himachal Pradesh, India. The Koldam HPS is basically a run-of-the river scheme with additional storage facility for the initial 30 years. Koldam HPS envisages utilization of a head of about 140 m by constructing a 167m high (from the deepest foundation) rock/ gravel fill dam with impervious central clay core and a dam toe powerhouse with an installation of 4 units of 200 MW each. The Gross capacity at full reservior level (FRL) is 576 million cumec (MCM) and the dead storage capacity is 486 MCM. Figure 1 shows the panaromic view of Koldam HPS.

Figure 1. Panoramic View of Koldam HPS.

3 DYKE CONSTRUCTION AND JET GROUTING

An earthen dyke of approximately 320 m length and 15 m height was constructed with available river borne material (RMB). The key function of this dyke was to isolate the working front in the spillway and plunge pool area from flowing river water just downstream of a rock fill dam of a Koldam HPS in Himachal.The purpose of dyke and jet grout column is to create a impervious cut-off wall so that dewatering and further excavation & concreting works are taken up in the Plunge Pool. Dyke was made up of river bed materials by cut and fill method with the available materials nearby. Figure 2 depicts the dyke constructed along Sutlej river.

Figure 2. Dyke Constructed along Sutlej River.

4 JET GROUTING PARAMETERS

Jet grouting technique was introduced in the late 1960s in Japan and is based on the principle of injecting high-velocity fluids into the subsoil. This process requires high-velocity grout for breaking up the soil matrix, with or without water jet along with the addition of cement.

Soil improvement works using high pressure jet grouting method involves injecting a continuous selected mix of cement grout at high pressure from nozzles to cut and break into the surrounding subsoil, mixing and replacing it with cement slurry to form a hardened cemented mass. This soil improvement method modifies and improves the mechanical properties of the treated soil, most notable its shear strength, stiffness while reducing its permeability.

The high-pressure jet grouting using double tube system was implemented at site for soil improvement works presented in this paper. Jet grouting was performed with a Casagrande C7 hydraulic crawler rig and grout pump assembly with double tube system with grout pumping pressure of 400 bar with water cement ratio of 1(ordinary portland cement OPC). Depth of jet grouting was varying from 8 to 20 m based on depth of dyke and spacing of drilling holes with steel casing of 168 mm diameter for grouting was kept as 1m. Based on the jet grouting trials it was observed that the diameter of jet grouting column varies from 1.2 to 1.6 m in diameter leading to an overlap of 200 mm to 600mm. An average cement consumption of 700 to 750 kg was observed per m length of jet grout column.

5 ANALYSIS OF EXPERIMENTAL AND JET GROUTING DATA

The unconfined compressive strength (UCS) of cylindrical cores of jet grouting column is tested in site laboratory. 75 mm diameter cylindrical cores of L/D ratio about 2 were taken for different modes and ages of the jet grout column e.g. trial jet grouting column after 28 days, jet grouting column after 28 days, remains of jet grouting column parts after 7 months.

The plot of UCS shown below in fig 3 demonstrates that the UCS of jet grouting columns cores vary in the range of 4.5 MPa to 18 MPa. As expected highest UCS is observed for trail jet grouting column cores. The UCS of remains of jet grouting column after 7 months is higher than that of initial UCS values after 28 days. That is

probably due to washing of weaker zones and increase in strength with depth of column. An average UCS of 9.32 MPa is indicative of excellent quality of jet grouting works.

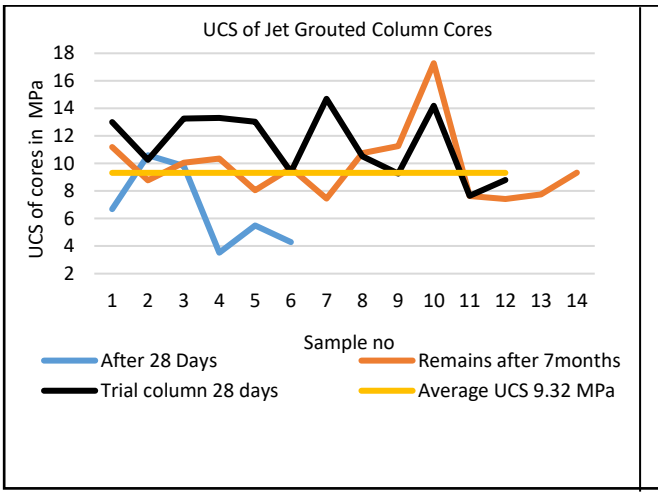

Figure 3. Variation of UCS of Jet grouted columns cores.

5.1 UCS of Grout mix

Grout mix of water cement ratio of 1:1 (ordinary portland cement OPC) was used for jet grouting of earthen Dykes. Cylindrical grout samples of diameter about 60 mm and L/D ratio 2 were tested for UCS at the age of 7 days and 28 days. The analysis of test datashown in fig 4 revealed that the 28 days strength of grout samples is about 30 to 80% higher than that of 7 days; with an average increase value of 46%. Minimum and maximum 28 days UCS values are 10.5 MPa and 20.1 MPa respectively showing a variance of about 91%.

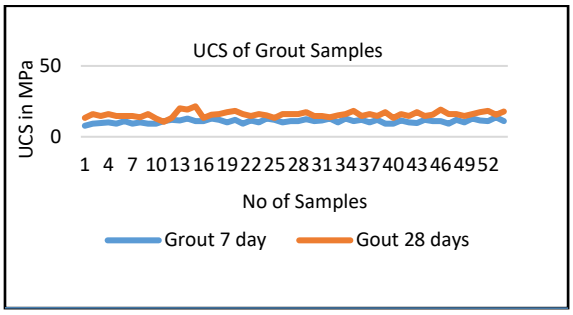

Figure 4. Variation of UCS of grout mix samples.

Comparison of UCS of grout and spoil cylindrical samples were also performed. Based on the analysis of more than 50 data sets, it can be concluded that the UCS of grout samples was always higher than UCS of spoil samples. The 28 days strength of spoil samples was quite matching to 7 days UCS value of grout sample (shown in Fig 5). Estenban Diaz et al. (2023)[2]has analyzed the 854 UCS test result data of UCS of jet grouting columns and arrived at an average UCS of 5.85 MPa. In current case study the average UCS value of 9.32 MPa is observed. In view of this extensive data base analysis also the current test results and analysis both are well validated.

The physical properties of a jet grout column are the function of the in situ properties of the soil before treatment, the properties of the grout and the operational parameters of the jetting which are injection pressure, nozzle size, monitor rotation and withdrawal rates.[3]

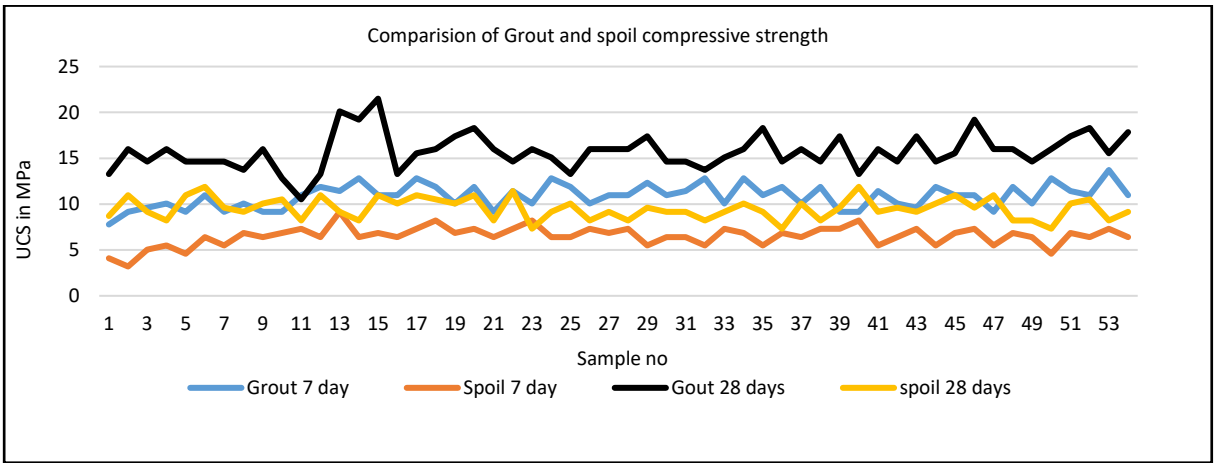

Figure 5. Comparison of UCS of Grout and Spoil Samples.

5.2 DENSITY OF GROUT AND SPOIL

The density of grout and spoil was monitored continuously. A part of data analysis shown in figure 6 shows that the density of spoil always exceeded the density of grout. At some points of time the spoil density dropped down to the level of grout density; which indicated that no grout intake was taken by underground medium in that reach. Analysis of more than 400 test data reveals that spoil density is about 4 to 19% higher than that of cement grout.

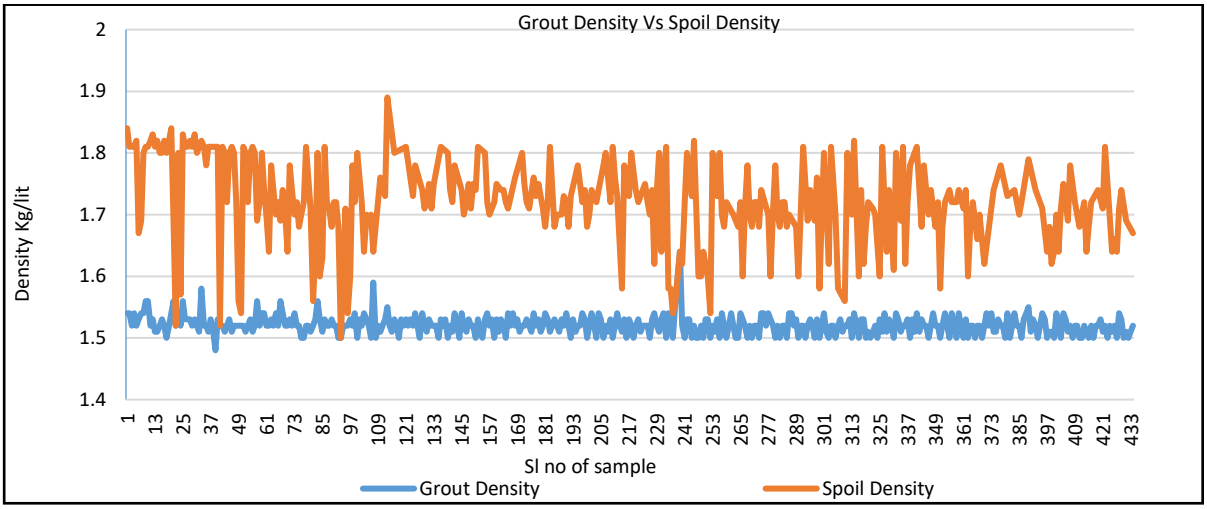

Figure 6. Variation of Grout Density and Spoil Density.

6. CONCLUSIONS

In the current case there was no direct way to establish the extent of ground improvement and seepage barrier provided by jet grouting.Efficacy of jet grouting was proven as it kept the work front practically seepage free even under the varying water depth of 3 to 12 m along the one side of dyke and river discharge of 100 to 1200 cumec in non-monsoon season.

This experience shall reinforce the confidence of practicing engineers and academician in adopting jet grouting technology in highly variable and porous materials like RBM.

It can be safely concluded that the jet grouting techniques can be deployed as effective and reliable seepage control measure and sufficient strength (up to 8 to 10 MPa) of jet grout column can also be achieved even in the variable alluvial deposited material like RBM. The grout density and viscosity were observed to be lower than spoil density and viscosity respectively.

Scope of further research includes permeability tests on the cylindrical specimen of jet grout column. Further, direct shear and triaxial tests are planned on the jet grouting column cores to have an insight of its geotechnical properties. Authors are working on detailed Analysis and comparison of similar works carried out in India and abroad.

Accelerated implicit cyclic loading with the hypoplastic sand

Chargement cyclique implicite accéléré avec le sable hypoplastique

T. Kadlíček*, D. Mašín
Faculty of Science, Charles University, Czech Republic
**tomas.kadlicek@natur.cuni.cz*

ABSTRACT: Numerical simulations of the cyclic loading can be distinguished of two types, implicit and explicit. While the implicit cyclic loading approach integrates each individual cycle in its full length separately, the explicit cyclic loading simulation is concerned only with average values of the loading cycles. Consequently, performing a robust implicit cyclic loading simulation spanning over tens or hundreds of cycles is very time consuming and therefore, the explicit cyclic loading provides a suitable alternative. Nonetheless, the explicit cyclic loading provides only accumulation of strains and related state variables. This paper introduces a new approach to the implicit cyclic loading designated as accelerated which can significantly reduce computational time. The proposed approach is applied on a simple axisymmetric numerical model first. Later a simple model of monopile subjected to the cyclic loading is performed with the fully implicit and accelerated approach and compared.

RÉSUMÉ: Les simulations numériques du chargement cyclique peuvent être distinguées en deux types, implicites et explicites. Alors que l'approche implicite du chargement cyclique intègre séparément chaque cycle individuel sur toute sa longueur, la simulation explicite du chargement cyclique ne s'intéresse qu'aux valeurs moyennes des cycles de chargement. Par conséquent, la réalisation d'une simulation de chargement cyclique implicite robuste couvrant des dizaines ou des centaines de cycles prend beaucoup de temps et le chargement cyclique explicite constitue donc une alternative appropriée. Néanmoins, le chargement cyclique explicite ne fournit qu'une accumulation de déformations et de variables d'état connexes. Cet article présente une nouvelle approche du chargement cyclique implicite désigné comme accéléré, qui peut réduire de manière significative le temps de calcul. L'approche proposée est d'abord appliquée à un modèle numérique axisymétrique simple. Ensuite, un modèle simple de monopieu soumis à une charge cyclique est réalisé avec l'approche entièrement implicite et accélérée et comparé.

Keywords: Cyclic loading; implicit; accelerated; hypoplastic sand; monopile.

1 INTRODUCTION

Numerical and experimental investigation of a cyclic loading received a significant attention due a rapid development of wind turbines installations. This process was started due to a transformation to the green energy to which the wind energy is a significant part of.

The common approach to the simulation of the cyclic loading, designated as implicit, is based on integrating each cycle in its full length. While this approach is appropriate in the case of low number o cycles, typically 1-1000 cycles, it loses its relevance once we approach tens of thousands of cycles due to its significant computational time. Furthermore, undesired consequence of the implicit approach is accumulation of the integration error when subjected to large number of cycles which can impact the results.

Alternative approach, called explicit (Niemunis, 2005), focuses on integration of average values of the cyclic loading and thus significantly decrease computational time. However, the constitutive models used for the explicit cyclic loading provides only accumulation of the strains and state variables and thus can be viewed as a type of creep-like constitutive model, where integration is performed with respect to number of cycles instead of time. Therefore, any change of stress state is related to the soil/structure interaction. This fact can hinder a proper analysis at the failure state.

In this paper we introduce a new approach to the cyclic loading simulation designated as accelerated implicit. This approach tries to remedy problems associated with both implicit and explicit modelling approaches, namely: decreasing computational time of implicit cyclic loading, and enabling stress accumulation during the cyclic loading while guaranteeing that the failure condition is satisfied. On the other hand, any shortcoming of cyclic modelling at the constitutive model level will be inherent to the accelerated implicit approach as well.

2 ACCELETERATED CYCLIC LOADING

The main idea of the accelerated cyclic loading originates in the extrapolation of the accumulated properties such as stresses, strains and other state variables. The extrapolation is performed on the local level in the integration points as well as on the global level on the finite element (FE) mesh.

The accelerated cyclic loading is performed in three steps:

1. First, the implicit cyclic loading is performed.
2. At the designated cycles, the accumulated stresses $\Delta\boldsymbol{\sigma}_{acc}$, strains $\Delta\boldsymbol{\varepsilon}_{acc}$ and other state variables are recorded in the integration points (local level) and also the displacements of the FE mesh $\Delta\mathbf{u}_{acc}$ in the nodes (global level). The accumulation can be recorded for one or multiple cycles for more precise extrapolation.
3. The displacements are extrapolated in the FE nodes for the desired number of cycles. These displacements are converted to strains in the integration points. During the acceleration, different than the constitutive model stiffness tensor $\boldsymbol{\mathcal{M}}$ has to be used since the response of the constitutive model would not match the desired extrapolation. Therefore, the acceleration stiffness tensor $\boldsymbol{\mathcal{M}}_{acc}$ must be expressed from the extrapolated strains and stresses. In general, the constitutive equation can be expressed as follows:

$$\Delta\boldsymbol{\sigma}_{acc} = \boldsymbol{\mathcal{M}}_{acc} : \Delta\boldsymbol{\varepsilon}_{acc}, \qquad (1)$$

in this case, however, the unknown is the acceleration stiffness tensor $\boldsymbol{\mathcal{M}}_{acc}$ and therefore, the $\boldsymbol{\mathcal{M}}_{acc}$ has to be derived as

$$\boldsymbol{\mathcal{M}}_{acc} = \Delta\boldsymbol{\sigma}_{acc} \otimes \Delta\boldsymbol{\varepsilon}_{acc} / (\Delta\boldsymbol{\varepsilon}_{acc} : \Delta\boldsymbol{\varepsilon}_{acc}). \qquad (2)$$

The tensor $\boldsymbol{\mathcal{M}}_{acc}$ is strain-rate direction dependent, that is, it can be applied only for the loading direction from which it was derived.

In the present study, only a linear extrapolation is used based on one implicit cycle, however, a nonlinear extrapolation can be applied too when fit through multiple recorded cycles.

Tremendous benefit of the accelerated approach is that the entire acceleration can be performed in one step without any iteration needed since all the FE nodes are loaded with prescribed displacements. It should be also noted that the numerical simulation of the cyclic loading can be performed while combining implicit, accelerated and explicit approaches in sucession.

3 CONSTITUTIVE MODELS

In this paper, two constitutive models are used. The hypoplastic sand model (Von Wolffersdorff, 1996) defines the behaviour of the soil and linear elastic model is applied to the structure of a monopile.

3.1 Hypoplastic sand model

The hypoplastic sand is a nonlinear constitutive model defined in the form of rate equation and defines these 8 parameters:

h_s – Granular hardness
n – Exponent of normal compression line
e_{i0} – Initial void ratio of the isotropic state
e_{c0} – Initial void ratio of the critical state
e_{d0} – Initial void ratio of the densest state
α – Peak state controlling exponent
β – Stiffness controlling exponent
φ_c – Critical state friction angle

The small strain enhancement (Niemunis, 1997) defines additional state variable δ designated as intergranular strain and 5 parameters:

R – Elastic strain range
m_T – Stiffness factor for 90° strain path change
m_R – Stiffness factor for 180° strain path reversal
χ – Controls stiffness degradation
β_r – Controls nonlinearity of small strain evolution

The simulations undertaken in this paper were conducted with the parameters presented in Table 1 and Table 2. Unit weight of the soil was defined as $\gamma = 20\ \mathrm{kN/m^3}$.

Table 1. Hypoplastic sand parameters.

h_s [kPa]	n [-]	e_{i0} [-]	e_{c0} [-]	e_{d0} [-]	α [-]	β [-]	φ_c [°]
3×10^6	0.2	1.2	1.0	0.6	0.3	3.0	30

Table 2. Small strains enhancement.

R[-]	m_T[-]	m_R[-]	χ[-]	β_r[-]
1×10^{-5}	2.5	5.0	5.0	1.0

3.2 Elastic model

The monopile is assigned a linear elastic constitutive model which defines two parameters, namely: Young's modulus E and Poisson's ratio ν. The parameters values are gathered in Table 3.

Table 3. Linear elastic model.

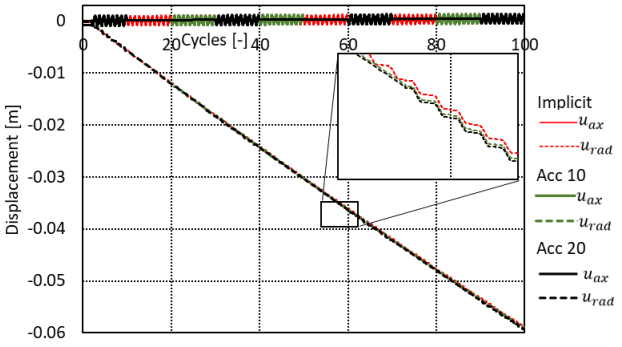
E [kPa]	ν [-]
3.10^7	0.25

4 VALIDATION

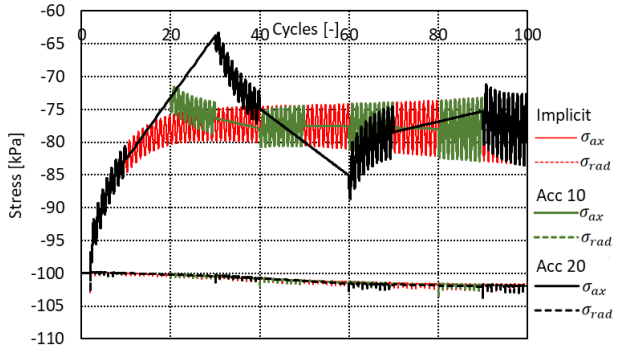
4.1 SIMPLE AXISYMMETRIC CASE

The proposed approach was first tested with the axisymmetric elements test subjected to various loading conditions in FE model discretised to 64 FE elements.

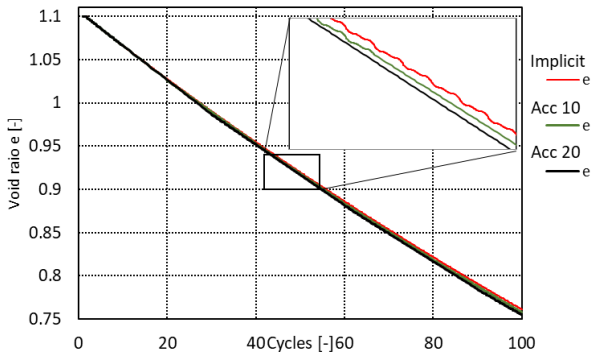
The example of drained triaxial with a strain driven loading is shown in Figure 1. Initially, the sample was isotropically consolidated to 100 kPA. The cyclic loading was performed with the vertical strain amplitude $\Delta\varepsilon_{ax}$ = 0.05%. As a benchmark, 100 implicit cycles were undertaken (red). The accelerated cyclic loading was performed with a combination of 10 implicit cycles and 10 (green) and 20 (black) accelerated cycles, respectively. The extrapolation was based on the accumulation of the last implicit cycle. While the differences in strains and void ratios between the implicit and accelerated loading are relatively small, the evolutions of the accelerated axial stresses σ_{ax} show initially significant deviations. Nonetheless, accelerated σ_{ax} asymptotically converge at 100th cycle due to a well approximated void ratios e.



a) Axial and radial displacements



b) Axial and radial stresses



c) Void ratio e

Figure 1. Element testing of the accelerated approach.

4.2 MONOPILE SIMULATION

We chose to simulate a monopile under a cyclic loading corresponds well with a current focus on wind farms and renewable energy. It is important to note that there was no contact defined on the soil/structure boundary since all constitutive models used during the acceleration must be implemented as accelerated. To remedy a problem with local tension at the soil/pile boundary, additional hypoplastic parameter p_t = 50 kPa was used, which extends admissible states to tension.

The geometry of the monopile is depicted in Figure 2 with rather coarse mesh counting 4004 tetrahedral elements. The pile is loaded on the top in the direction of the x-axis with force amplitude.

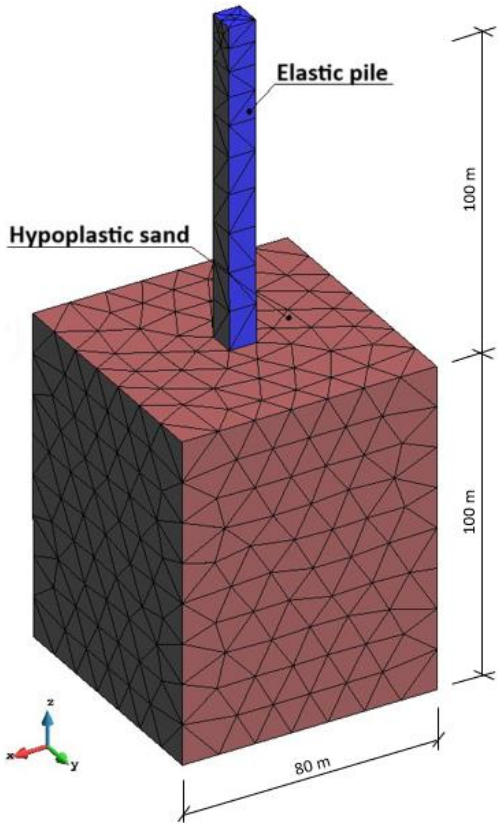


Figure 2. Geometry of the simple monopile model

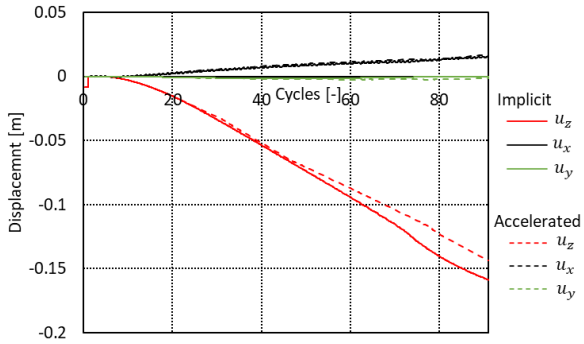
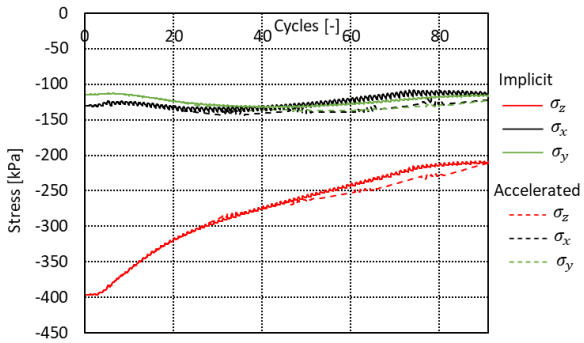
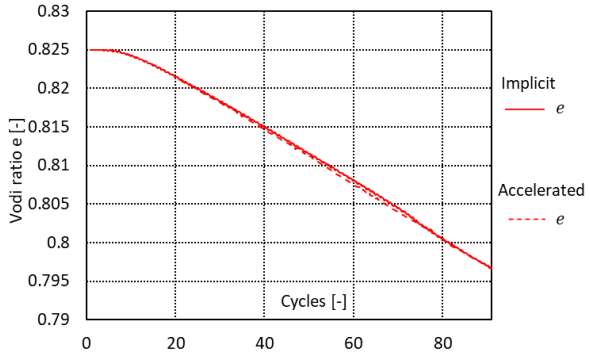
As a benchmark, a fully implicit cyclic loadings were performed. Furthermore, different combinations of the implicit and accelerated cycles were simulated. In this study, a combination of 10 accelerated and 5 implicit loading cycles is presented with the cyclic amplitude 10 kN. At the beginning, 20 cycles were performed fully implicit in order to stabilize values of state variables. Comparison of the accelerated cyclic loading and the fully implicit cyclic loading is displayed in Figure 3.



a) Horizontal and vertical displacements



b) Horizontal and vertical stresses



c) Void ratio e

Figure 3. Simple monopile model.

Simulating results are plotted for a point with coordinates P [55, 40, 80]. Similarly to the elements testing, the extrapolation is based on the accumulation over one cycle, which resulted in small deviations of the explicit loading from the implicit loading. The intergranular strain tensor δ is shown in Figure 4. For the sake of clarity only components δ_{11}, δ_{22} and δ_{33} are displayed. It was shown that after 15-20 initial cycles the intergranular strains values at the end of cycles stabilize and thus can be extrapolated with a constant value since the fully implicit and accelerated intergranular strains reach comparable values.

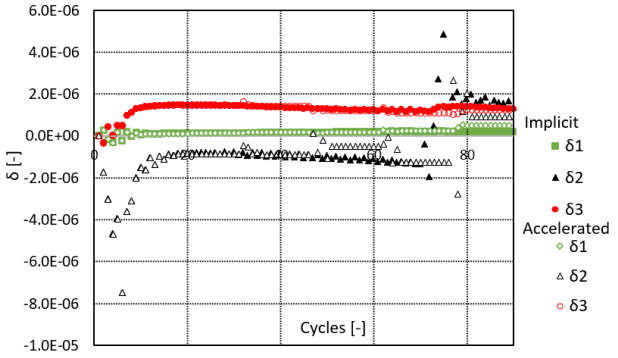


Figure 4. Small strains δ.

5 CONCLUSIONS

In this paper, a new approach to the simulation of cyclic loading was introduced which can significantly reduce computational time of the implicit cyclic loading. The approach is based in extrapolation of displacement, stresses, strains and state variables over prescribed number of cycles.

Discrete element modelling of axial load testing on piles under the influence of ageing

Modélisation par éléments discrets d'essais de charge axiale sur pieux sous l'influence du vieillissement

S.S. Kasyap*, M.B. Mohammed, D. Igoe
Trinity College Dublin, Dublin, Ireland

**sarvades@tcd.ie*

ABSTRACT: Pile ageing has shown to increase the axial shaft capacity of piles by up to 250% within 9 months of installation. Incorporating ageing effects in the design of offshore wind turbine foundations could significantly reduce pile length, and therefore material and installation costs. However, this requires a deeper understanding of the underlying mechanisms through systematic investigations. Numerous researchers have investigated the influence of ageing on the axial capacity of piles using physical models at field and laboratory scales. The time and costs of undertaking parametric studies are much higher in physical testing, and have therefore been limited to date. Discrete Element Modelling (DEM) has shed light on micro-to-macro scale mechanisms of various complex geomechanical problems. This paper is a pilot study using DEM (Particle Flow Code software) for axial pile testing, where the ageing phenomenon is simulated using bonds at the soil-pile interface. Field-scale axial loading tests on aged piles performed in Blessington, Ireland, are used as a reference in this study. This study provides an innovative DEM approach to simulate the effects of pile ageing phenomenon and explore the axial load behaviour of piles.

RÉSUMÉ: Il a été démontré que le vieillissement des pieux augmente la capacité axiale des pieux jusqu'à 250 % dans les 9 mois suivant l'installation. L'intégration des effets du vieillissement dans la conception des fondations des éoliennes offshore pourrait réduire considérablement la longueur des pieux, et donc les coûts de matériaux et d'installation. Cependant, cela nécessite une compréhension plus approfondie des mécanismes sous-jacents grâce à des enquêtes systématiques. De nombreux chercheurs ont étudié l'influence du vieillissement sur la capacité axiale des pieux à l'aide de modèles physiques à l'échelle du terrain et du laboratoire. Le temps et les coûts nécessaires pour entreprendre des études paramétriques sont beaucoup plus élevés dans les tests physiques et ont donc été limités à ce jour. La modélisation par éléments discrets (DEM) a mis en lumière les mécanismes à l'échelle micro-macro de divers problèmes géomécaniques complexes. Cet article est une étude pilote utilisant le logiciel DEM (Particle Flow Code) pour les essais de pieux axiaux, où le phénomène de vieillissement est simulé à l'aide de liaisons à l'interface sol-pieu. Des essais de chargement axial à l'échelle du terrain sur des pieux vieillis effectués à Blessington, en Irlande, sont utilisés comme référence dans cette étude. Cette étude propose une approche DEM innovante pour simuler les effets du phénomène de vieillissement des pieux et explorer le comportement des pieux en charge axiale.

Keywords: Offshore foundations; pile ageing; DEM; micro-to-macro.

1 INTRODUCTION

Axially loaded steel tubes are used as foundations for various types of offshore structures. Anchor systems for floating structures and foundations for jacket structures use large-diameter axially loaded steel tubes where the shaft resistance plays as critical role in their stability. The shaft resistance of these steel piles installed in sand increases with time following their installation due to the phenomenon known as pile ageing. The knowledge of the ageing phenomenon and its associated effects is still incoherent owing to the variability in the results obtained by various researchers (Zhang and Wang, 2014) and the understanding of the mechanism leading to the ageing phenomenon itself.

Chow (1997) suggested three different mechanisms for pile ageing: (i) Physio-chemical reaction at the pile-soil interface, (ii) Creep-induced stress redistribution, and (iii) Confined dilation of sand in the shear zone. Addressing these mechanisms, a significant amount of research has been carried out to investigate the effects of ageing in piles on their axial capacity, predominantly using field- and laboratory-scale model tests. Gavin and Igoe (2021), Lim and Lehane (2014), and Jardine et al. (2006) are a few

noteworthy works discussing the steel pile axial capacity aged in sand.

Discrete element modelling (DEM) is gaining popularity, particularly among offshore geotechnics research groups. Simulation of pile driving in finite element modelling leads to mesh distortion near the pile due to large deformation (Yang et al., 2020). A Coupled Eulerian-Lagrangian (CEL) method was developed (over the classically used Lagrangian methods) to address this issue (Qiu et al. 2011) but inaccuracies due to state variable mapping upon re-meshing were observed (Phuong et al., 2016). DEM on the other hand simulates each rigid grain's movement under the influence of surrounding forces and provides numerical stability and accuracy to the model even at large deformations. Cerfontaine et al. (2023) and Duan et al. (2018) investigated the effects of different installation methods of piles using DEM simulations. Li et al. (2021), Liu et al. (2019), and Zhang and Wang (2015) used DEM to examine plugging effect and other micromechanical aspects of the open-ended steel pile foundations.

This paper attempts to provide a background and an innovative methodology to simulate aspects of pile ageing in open-ended piles while examining the capabilities of DEM for modelling pile installation.

2 MODELLING PROCEDURE

A commercial 3D DEM software, Particle Flow Code 3D, was used in this study. The numerical model was created based on the field-scale pile testing series performed by Gavin and Igoe (2021) in Blessington, Ireland. The *Hertz contact model* (HCM) was used for defining the behaviour of grain-grain and grain-wall contacts. Also, the *Linear parallel bond model* (LPBM) was used for pile wall-grain contacts within the bonded zone (discussed in Section 4). Unlike HCM, LPBM gives a provision to define the bond strength between the contacting elements.

2.1 Calibration of DEM Microparameters

The sand from the Blessington pile testing site was simulated here. DEM triaxial test simulations were performed, and the microparameters were calibrated (trial-and-error) to match the simulation results with laboratory test results based on stress-strain responses. The calibrations were performed at two different relative densities (R_d of 30% and 60%), and this was achieved by changing the interparticle friction coefficient of the DEM sample during sample generation and consolidation. The comparison of stress-strain responses (60% R_d at 50kPa) is shown in Figure 1, and the calibrated microparameters are shown in Table 1.

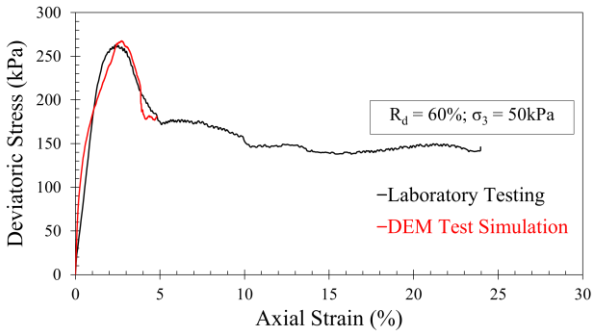

Figure 1. Comparison of stress-strain curves from DEM and physical triaxial testing.

Table 1. Microparameters of DEM model without ageing.

Parameter	Value	Units
Grain Size		
D_{50}	0.36	mm
Minimum Diameter	0.126	mm
Maximum Diameter	0.800	mm
Hertz Contact Model		
G	2e9	Pa
Poisson Ratio	0.3	-
$\mu_{grain\text{-}grain}$	0.375	-
$\mu_{grain\text{-}wall}$	0.20	-
Linear Parallel Bond Model		
E_{mod}	5e7	Pa
Stiffness ratio	1.00	-
μ	Vary with ageing period simulation.	-
Tensile strength and Cohesion		Pa

2.2 Model Preparation

The DEM model was prepared at a 100g scale compared to the field-scale tests performed by Gavin and Igoe (2021). The open-ended pile was modelled as a rigid single-walled cylinder of diameter 3.4mm and length 75mm (340mm internal diameter and 7.5m long in field-testing scale). The procedure for model preparation described here is based on the DEM work by Sharif et al. (2020). The soil domain boundary is made as a rigid wall cylinder with a diameter of 70mm and 120mm in length. The model extent to pile diameter ratio is greater than 20, so no significant boundary effects can be expected. The soil bed was prepared with particle size distribution scaling, with the scale increasing from the centre of the domain to the boundaries. The soil bed is divided into four coaxial zones with central core zone PSD as two times the Blessington sand, and the consecutive zones had a ratio of 5, 7, and 10 (Figure 2). The maximum grain diameter of the smaller fraction is kept lower than the average grain diameter of the immediate larger

fraction to ensure no overlap of zones occurs in the model. The central core zone has a diameter of pile to D_{50} ratio of more than 5, assuring that a significant number of contacts are formed around the pile, and the model instabilities are minimized. The grains are consolidated under gravity (100g), and the model is brought to equilibrium until the unbalanced force ratio becomes minimum (<1e-5).

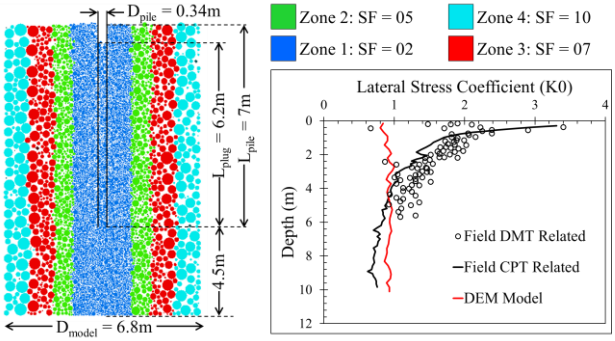

Figure 2. Cross-section of DEM model; Comparison of lateral stress coefficient values between DEM and field tests.

The variation of lateral stress coefficient, K_0, with dept, is shown in Figure 2. The K_0 trends observed from the field testing (Dilatometer Test, DMT; Cone Penetration Test, CPT) are also plotted in Figure 2 for comparison. Except for the initial 2m depth, where significantly large K_0 values were observed in-situ, the DEM model and field profiles are in a similar range. The top 2m of Blessington geotechnical testing site is considered over-consolidated in its geological history (Doherty et al., 2012).

3 PILE DRIVING AND TENSION TESTS

The field tests aimed to replicate in this numerical study used impact driving of piles. However, a simple constant velocity jacking was used here to make the pile driving simulations simple and quick. The authors acknowledge several numerical and experimental studies investigating the installation effects (Duan et al., 2018, Zarrabi and Eslami, 2016). A slow rate of jacking with 0.05m/sec was adopted in this study, with an approximate penetration of $4x10^{-5}$ mm/dt. This penetration rate resulted in a computational time of about 9.5 days (for an i9-13900K 24-core processor) for a penetration of 70mm in model scale.

The field tests showed that the piles were fully plugged over the first meter of installation and then partially plugged over the end of installation (with a final plug length of around 4.6m). In the present DEM simulations, the final plug length was higher than the field test values of around 6.2m (Figure 2). Better agreement might be possible if the similar installation mode as field tests (impact driving) was simulated in DEM, and it needs further investigation.

After installation, servo-controlled vertical translation in the upward direction was applied on the pile wall at a slow rate to stabilize the stresses generated due to pile driving. Axial tension test simulations were also performed in a displacement-controlled manner. Unlike the field tests, no holding time was exercised in these DEM simulations. As discussed in Section 2, LPBM was used to simulate bonding in the model. The HCM contacts between the pile and soil are modified to LPBM within the range of the targeted pile section, and then the model is stabilized.

3.1 No-ageing Condition

No-ageing tension test simulation was performed with no contact model changes. The force-displacement curve related to the no-ageing tension test simulation is shown in Figure 3. The peak force was observed at 440kN. The field tension test results for different ageing periods from Gavin and Igoe (2021) are also shown in Figure 3 for comparison. The DEM simulation of the no-ageing tension test is in the range of a two-day tension test from the field. The DEM simulation response is much stiffer than the field test response, owing to the rigid pile wall behaviour, unlike the steel pile's elastic behaviour in the field tests.

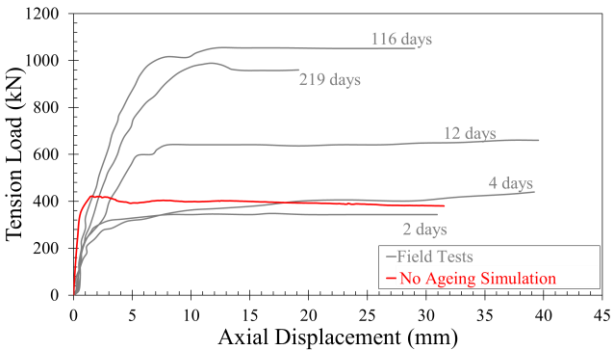

Figure 3. Comparison of DEM no ageing test DEM simulation with field tests by Gavin and Igoe (2021).

3.2 Simulation of pile ageing effects in DEM

The effects of ageing in piles were simulated in the present model by creating bonds at grain-wall contacts, i.e., soil-pile interface contacts. Hertz contact model was used initially for pile driving simulations and the no ageing tension test simulations. The contact model for a certain range of pile length was changed to the Linear Parallel Bond contact model, and tension test simulations were performed with different bond capacities. From field-scale aged pile testing by Gavin and Igoe (2021), the soil-pile interface bonding (crust

formation) was observed only in the bottom 2-3m of a 7m pile after exhuming them. Following this observation, bonding was created at the grain-wall interface for a finite part of the pile bottom (~3m) with certain bond strength (cohesion and tensile strength). In the present study, the effects of pile ageing phenomenon were simplified by applying a uniform bond strength for the pile-soil contacts in the bonded zone, which may not be the case in the actual pile ageing phenomenon. Given the lack of information on the actual bond strength characteristics of the pile-soil interface, a large range of bond strengths was simulated (50kPa to 10MPa), and the corresponding peak tension force values were examined (Figure 4). The lower bound value of 50kPa was based on the peak tension load from no ageing test simulations. The upper bound of 10MPa was based on the ultimate peak tension load capacity, where the bond capacities of 1MPa and 10MPa resulted in the same peak tension force.

Figure 4 shows the peak tension force for cohesion values in the bonded zone and for different interface friction values. Apart from the crust formation in the bottom section of the pile, the soil-pile interface friction also changes through the length of the pile over time. Starting from the calibrated interface friction coefficient of 0.1, minute increments were simulated, and the corresponding peak tension forces are plotted in Figure 4.

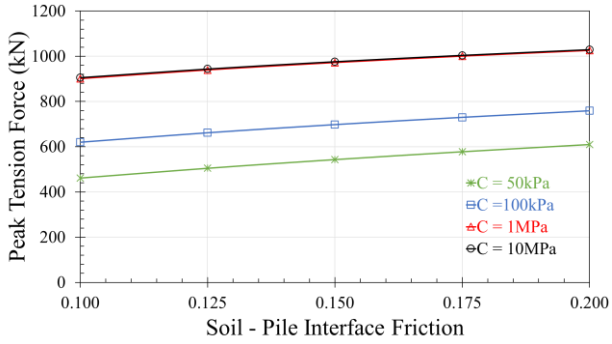

Figure 4. Variation of peak tension force for different cohesion and interface friction coefficient values of soil-pile contacts.

The authors acknowledge that the phenomenon of pile ageing is not just because of the changes in soil-pile interface properties (bonding and friction) but also changes in the stress regime around the pile due to creep effects. But as a pilot study, this simple way of generating a condition of the aged pile with increased tensile load capacity can bring new insights into the aged pile testing. Further developments would be needed to simulate the ageing conditions in DEM more accurately.

Despite certain limitations in the present DEM simulation of tension tests on aged piles, some interesting micromechanical observations were noted. One of the mechanisms leading to increased tension capacity of aged piles is the dilation of the surrounding soil. Two diametrical cross-sections of the DEM models with extreme cases of (i) no bonding and (ii) maximum bond strength are shown in Figure 5. These cross-sections show the displacements of grains in the model during the tension test (~15mm of axial displacement). The movement of grains outside the pile was minimal for the no ageing condition. On the other hand, strong bond conditions showed displacement zones with grains closer to the pile having larger displacement values, indicating enhanced dilation as the aged pile is pulled upwards. Further work is required in understanding the effects of particle and pile scaling on the dilation behaviour in DEM.

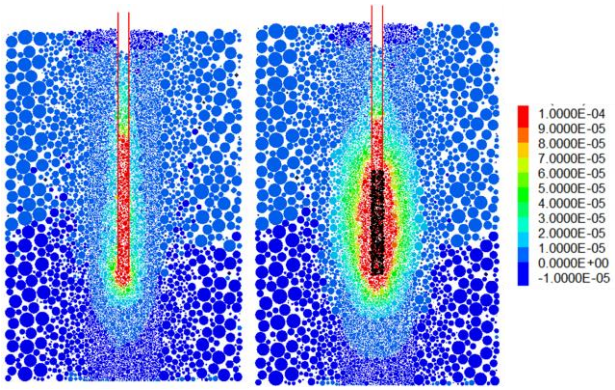

Figure 5. Cross-section of DEM model showing grain displacements during a tension test for no-ageing (left) and maximum bond strength (right) conditions.

4 CONCLUSIONS

Three-dimensional DEM simulations of pile driving and tension tests were performed in this study. Field tests on open-ended monopiles performed by Gavin and Igoe (2021) were used as basis here. For the first time, DEM was used to simulate the effects of pile ageing and the corresponding observations are reported in this paper.

- Particle size distribution scaling and 100g centrifuge scaling was employed to decrease computational costs involved with DEM.
- The K_0 variation with depth from DEM model and field tests correlations showed comparable values; except for highly over-consolidated top 2m of soil.
- Displacement-controlled jacking of pile was simulated unlike impact driving in field tests.

Hence, slightly higher plug length was observed in DEM compared to field tests.

- Tension tests were also performed in displacement-controlled manner, and no-ageing condition showed peak tension load in the vicinity of 2-day and 4-day aged pile tests in field.
- The effects of pile ageing was simulated by creating bonds at the grain-wall contacts (soil-pile contacts). Increasing bond strength and interface friction coefficient resulted in higher peak tension load.
- The range of peak loads observed from varying bond strength and friction values are within the limits of capacities observed at field tests for 2 to 219 days aged piles.
- The aspect of dilation in the bonded zone of pile-soil interface was also observed in the DEM simulations.
- Accurate calibration of interface properties of aged piles/ aged soil-pile interfaces would provide further confidence in the DEM simulation results, and prediction of the pile ageing effects in arbitrary situations. Performing various load combinations of static and cyclic loading would then be feasible, offering scope for extension of this study.

The effect of polypropylene fibre content on the mechanical properties of mass-stabilised soils

L'effet de la teneur en fibres de polypropilène sur les propriétés mécaniques des sols stabilisés en masse

**Slobodan.Mickovski@gcu.ac.uk*

ABSTRACT: Mass mixing or deep soil mixing involves cement being used as a binder within a weak or soft soil, with scope to turning it into a stable foundation. In this study, we investigate the effect polypropilene fibres have when introduced within a mass stabilised soil in order to improve the soil strength and potentially be used in production of pipework, bricks, insulation, window frames, or as a substitute to bitumen acting as a binder. In order to investigate this, polypropylene fibres were added to a soil mix originating from a site in the Scottish Central Belt. The fibres were added at different contents (0%, 0.5% and 2%) and lengths (3mm and 12mm), they were then put through a series of laboratory tests (direct shear, unconfined compressive strength and oedometer consolidation) at an accredited soil testing laboratory. The data obtained from the tests show that there is a significant strength gain if polypropilene fibres are added in large quantity. However, these strength levels are achievable at relatively high strains. The results also show that the volume compressibility of the soil reinforced with plastics increases with the polypropilene fibre content, although this may depend on the length of the fibres mixed in the soil. In conclusion, the polypropilene fibres do showcase a much more ductile failure compared to the soil only, which could possibly be used and have some limited benefits. Further testing of different plastic additions and soil mixes should be carried out to explore other effects.

RÉSUMÉ: Le stabilisation de masse ou le mélange de sol en profondeur implique l'utilisation de ciment comme liant dans un sol faible ou mou, avec la possibilité de le transformer en une fondation stable. Dans cette étude, nous étudions l'effet des fibres lorsqu'ils sont introduits dans un sol stabilisé en masse afin d'améliorer la résistance du sol et potentiellement être utilisés dans la production de tuyauterie, de briques, d'isolation, de châssis de fenêtre, ou comme substitut au bitume agissant comme liant. Afin d'étudier cela, des fibres de polypropylène ont été ajoutées à un mélange de sol provenant d'un site de la ceinture centrale écossaise. Les fibres ont été ajoutées à différentes teneurs (0%, 0,5% et 2%) et longueurs (3mm et 12mm), elles ont ensuite été soumises à une série d'essais en laboratoire (cisaillement direct, résistance à la compression libre et consolidation oedométrique) dans un sol accrédité laboratoire d'essais. Les données obtenues à partir des tests montrent qu'il y a un gain de résistance significatif si les fibres sont ajoutés en grande quantité. Cependant, ces niveaux de résistance sont réalisables à des contraintes relativement élevées. Les résultats montrent également que le taux de tassement du sol renforcé avec des fibres augmente avec la teneur en fibres, bien que cela puisse dépendre de la longueur des fibres mélangées dans le sol. En conclusion, les fibres plastiques présentent une défaillance beaucoup plus ductile par rapport au sol uniquement, ce qui pourrait éventuellement être utilisé et présenter des avantages limités. Des tests supplémentaires de différents ajouts de fibres plastiques et de mélanges de sol devraient être effectués pour explorer d'autres effets.

1 INTRODUCTION

Improving the ground stability conditions is an ongoing challenge in the construction industry worldwide. Action to improve ground stability is particularly needed in soft soils, such as peat, very soft to soft clays, or loose sands and gravels, which have very low strength and high capacity for deformation under loads which result in short and long-term settlements. These soils can be reinforced and thus made acceptable for construction through the use of in situ mass mixing method which can be costly (Topolnicki, 2004) and is limited to relatively shallow depths. The creation of soil composites through adding reinforcing, structural elements into the soil, is a well-known technique to promote ground stability and has recently been proven effective in the case of nature-based solutions (e.g. Gonzalez-Ollauri and Mickovski, 2016). However, the development of plant roots in the soil profile tends to have limitations (e.g. Tardio et al., 2016), and it is not immediate. An alternative, cost-effective soil reinforcement approach is the insertion

of biodegradable plastic fibres into the soil. Previous research has shown that different shapes and types of plastics have varying effects on the mechanical properties of the soil-plastic mix (Russell et al., 2017).

The aim of this study is to investigate the effect of adding plastics during the process of mass soil mixing on the mechanical strength properties of the treated soil. To this end, the shear strength, the unconfined compressive strength, and the consolidation capacity of soil undergoing mass mixing were investigated through standard laboratory tests. The results will allow a critical assessment of the benefits and disadvantages of adding plastics into mass soil mix processes seeking to improve ground stability in construction projects.

2 MATERIALS AND METHODS

2.1 Soil samples

The soil samples were taken from a site of proposed residential development in the Scottish Central Belt, where large bulk earthworks and ground improvement were required in order to enable construction of new roads and houses. As part of the proposed construction design, deep soil mixing was envisaged down to 4 metres below ground level (b.g.l) as foundation for the earthworks and roads, as well as for improving the bearing capacity of the soil where the residential properties were to be built. During the ground investigation works, large areas of organic clays (i.e., soil organic content, SOC > 5 %), mineral clays (i.e., SOC < 5 %), and peat were found within several areas of the proposed development and, as a result, these areas were to be treated by deep soil mixing. During the ground investigation, large bulk samples of organic clays, peat, and mineral clays from the topmost 4 m of the ground were taken in order to assess their potential for mass mixing. The samples retrieved during these investigations were used for soil laboratory testing in this study.

The bulk samples of organic clay were mixed in the laboratory using a mechanical mixer in order to create a homogenous soil sample which was then sieved through a 2 mm sieve (99% mass passed). The same process was followed for the mineral clay and peat bulk samples (97.5% mass passed). Some key mechanical properties of each soil are shown in Table 1.

Once homogenised, the three separate soil samples (i.e., organic clay, mineral clay, peat) were then subsampled for further testing. The masses of these subsamples were as follows: 5 kg organic clay, 5 kg inorganic clay, and 3.4 kg peat.

Table 1. Properties of the materials sampled from the development site.

Material	Moisture content (%)	Liquid limit (%)	Plastic limit (%)	Plasticity index (%)	Soil organic content (%)
Organic clay	35	43	22	21	5.7
	39	51	26	25	4.5
	39	48	25	23	6.8
Mineral clay	38	46	25	21	3.3
Peat	180	204	86	118	17.3

2.2 Soil mass mixing and testing

Cement binder (15% of the bulk unit weight of the soil) was added to the soil after this initial mixing/homogenisation in an attempt to replicate the process to be followed during soil improvement on site. The soils used in the mixes comprised 5 kg organic clay, 5 kg inorganic clay, 3.4 kg peat, and 5 kg sand. The latter, by bulk unit weight, replicated the worst case scenario identified on site. In total, four testing mixes were created using a combination of manual and mechanical mixing with 30 minute duration in the laboratory.

First, the cement was mixed with water (1:1.5 ratio) before incorporating them into the test mixes using a mechanical mixer. In three out of the four testing samples, plastic fibres were added after the cement-water mix and mixed until distributed throughout the sample. The three samples containing plastic comprised:

- 12mm polypropylene fibres at 0.5% of bulk unit weight of the soil sample.
- 3mm polypropylene fibres at 0.5% of bulk unit weight of the soil sample.
- 12mm polypropylene fibres at 2% bulk unit weight of the soil sample

When the samples were homogenous, they were transferred into cylindrical, cubical or ring-shaped moulds (i.e., one mould type for each mechanical test; see below) while trying to avoid/remove any air voids. The moulds were then sealed to prevent evaporation and water loss. The samples were left to cure in the laboratory at a temperature comprised between 15-18°C which, although lower than the ideal for the curing of cement, was considered acceptable as all of the samples were cured at the same temperature.

The description and classification of the soil mixes was carried out in accordance with current British Standards. The mechanical properties were investigated on the four mixes (3 mixes with plastic added and one without polypropilene fibres - i.e., control) and comprised: unconfined compressive strength (UCS) at 7 days (4 samples), 14 days (4

samples), and 28 days (8 samples), direct shear (4 samples), and consolidation (4 samples) tests in accordance with BS 1377 parts 6 and 7. The UCS tests were carried out on the samples cured in the cylindrical moulds of 200mm in height and 100mm in diameter at a displacement rate of 1mm/min. Moisture content samples were taken from every tested sample after completing each test. Direct shear tests at normal stresses of 50, 100, and 200 kPa, were carried out on 100mm x 100 mm x 20mm samples after 28 days of curing. The shearing rate was 1.5mm/min and moisture content samples were taken from every tested sample after completing each test. Consolidation tests were carried out using an oedometer at 6 loading steps on each soil mix at 28 days of curing. A small pressure was applied to the sample before starting the test. The tests were run at increasing normal pressure sequences of 12 kPa, 25 kPa, 50 kPa, 100 kPa, 200 kPa, and 400 kPa. The vertical displacement was measured during each loading stage until the primary consolidation was complete, then, the next loading step was applied. After the primary consolidation was completed at 400kPa, the unloading stage to 25kPa was initiated and the water was drained from the sample cell. After disassembling the apparatus, the final height and mass of the sample were measured before placing the sample in the oven at 105°C overnight in order to measure the final moisture content.

3 RESULTS

The liquid limit of the soil only mix was found to be 57% and the plastic limit was calculated at 35%, with a plasticity index of 22%, classifying the soil mix as a silt of high plasticity. The particle size distribution analysis showed that the sand added into the soil mix can be described as poorly graded, slightly silty sand.

The results of the UCS tests are shown in Table 2. The peak compressive strength of the 2% plastic mix sample showed a greater strength than the others, in particular the 14 day test. The 28 day tests for the 2% plastic mix were not run until failure at a peak load due to the excessive strain required to reach the peak; they were stopped at axial strains of 36% and 28%.

Table 2. Peak compressive strength (kPa).

Mix	7 days	14 days	21 days	28 days
Control	83.65	-	105.74	115.65
0.5%, 12mm	72.20	-	123.97	101.95
0.5%, 3mm	92.77	-	141.84	124.91
2%, 12mm	513.00	4924.00	-	514.57

The significant axial strain (74%) of a 2% plastic sample at peak compressive strength is shown in Table 3, the difference in peak compressive strength, with the exception of the 2% 12mm length plastic samples at 28 days of curing which were stopped before reaching their peak compressive strength.

Table 3. Peak compressive strength (kPa).

Mix	7 days	14 days	21 days	28 days
Control	2.42	-	2.76	3.37
0.5%, 12mm	4.10	-	11.61	3.58
0.5%, 3mm	4.79	-	6.13	4.71
2%, 12mm	34.41	74	-	32.63

In order to have a more relevant comparison, the compressive strength at serviceability limit was derived. Figure 1 shows that the 0.5% 3mm plastic mix generally has a higher compressive strength than the 'No plastics' sample. On the other hand, the 0.5% 12mm plastic specimen is shown to be weaker than the mix containing no fibres, this is both unexpected and unexplained. This may be down to a poor-quality mix or any deformities within the 0.5% 12mm length plastic samples. More tests would need to be carried out to explain this fully.

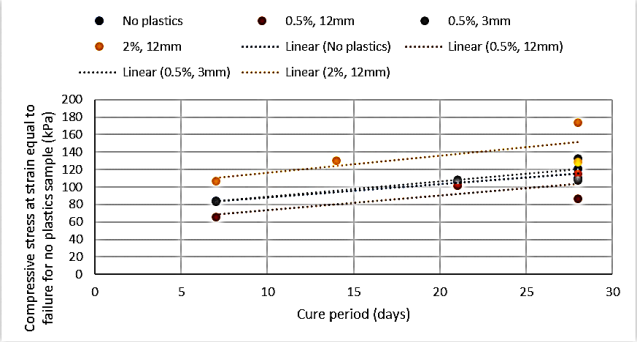

Figure 1. Compressive strength at serviceability limit.

Direct shear tests resulted in a failure of the 'No plastics' samples. Upon completion of the direct shear test on 'No plastics' samples, it was observed that it would have been beneficial to run the tests to a greater horizontal displacement. However, this was not possible due to the limitations of the standard direct shear testing apparatus. The results obtained for the 'No plastics' mix showed that the peak shear stress was either reached or was very close to be reached when the data acquisition had to stop. When carrying out the tests on the plastic mix samples, the true peak strength was not reached. This was due to the horizontal travel limit of the shear box being 15mm and, in turn, the sample was unable to be sheared beyond this limit and the peak shear strength was taken as the shear stress observed at the displacement limit. The peak stress results obtained for all of the samples can be seen in Table 4. To capture the behaviour at low

and high stresses, only the 50kPa and 200kPa normal stress tests were carried out for the plastic mix samples. The plastic mixes were shown to have higher shear strength than the 'No plastics' samples; similarly to the results of the UCS tests, this occurring at large displacements. A serviceability check was therefore carried out for analysing the shear stress for each of the tests in order to view the shear stress of the plastic mixes at the same horizontal displacement or strain as when the non-plastic samples at the same normal pressure reached their peak strength.

Table 4. Shear strength parameters of the tested samples.

Mix / normal load	50 kPa	100 kPa	200 kPa	Cohesion (kPa)	Angle of friction (°)
Control	55.7	92	136.2	33.7	27.6
0.5%, 12mm	97.0	-	186.0	67.2	30.8
0.5%, 3mm	84.3	-	208.6	42.87	42.9
2%, 12mm	112.1	-	213.3	12.60	34.0

The results of this check are shown in Table 5, where it can be seen that the plastic mixes are at least as strong as the non-plastic mix at the strain level that caused failure for the 'No plastics' sample.

Table 5. Shear strength of the tested samples at serviceability limit.

Mix	Normal stress (kPa)	
	50	200
Control	55.7	136.2
3mm 0.5%	63.6	184.5
12mm 0.5%	59.8	187.3
12mm 2%	62.2	188.2

The coefficient of volume compressibility results are shown in Table 6.

Table 6. Coefficient of volume compressibility.

Pressure (kPa)	Coefficient of volume compressibility m_v, (m^2/kN)			
	Control	0.5%, 12mm	0.5%, 3mm	2%, 12mm
12	0.171	0.412	0.246	0.392
25	0.084	0.157	0.160	0.313
50	0.065	0.115	0.097	0.165
100	0.067	0.101	0.086	0.098
200	0.094	0.111	0.109	0.055
400	0.097	0.093	0.095	0.032

4 CONCLUSIONS

Although the 2% plastic mix strength was far superior in terms of compressive strength to the others, the axial strain required to reach the strength of the sample meant that there could possibly be no practical use for this strength due to the possible serviceability issues. The behaviour of this mix resembles the one of root-permeated soil (Gonzalez-Ollauri and Mickovski, 2016). When the compressive strength was compared within the serviceability limits, it was shown that more, and shorter plastic inclusions would contribute better to the compressive strength. The shear test results showed that the cohesion and friction angle of the plastic mixes are greater than these of the 'No plastics' samples. It was observed that the 2% fibre addition has the greatest effect on the strength parameters of the soil mix. It is believed that in order to get a clearer idea of which mix would be most suitable for use, the test would need to be repeated and run to completion to understand the true peak stress of the samples containing plastic. However, due to the limitations of the standard apparatus it may not be possible to successfully test plastic mixes in the shear box. All samples tested at 50 kPa normal load had a very similar shear stress at the serviceability limit; however, for 200 kPa normal load, the samples with polypropilene fibres exhibited significantly higher shear stresses. This resulted in a steeper gradient of the best fit line for the plastic mixes. When the samples are subject to higher stresses they are all have very similar m_v values; however, when low stresses are applied, it can be seen that the 'No plastic' samples exhibit significantly lower volume compressibility than those containing polypropylene fibres. However, carbon reductions in using fibre reinforced soil may outweigh the setbacks in terms of strength and compression of such soils so more research is needed in quantifying the properties and application for soils stabilised with plastic fibres.

ABSTRACT: Offshore Wind Turbines (OWTs) located in the Belgian North Sea have been monitored for several years using different monitoring setups (accelerometers, strain gauges and Fiber Bragg Gratings). The monitoring data reveals that OWTs do not perform as expected, as they were designed using recommendations that were not adapted for large diameter and longer piles such as the API/DNV p-y methods. These design methodologies were extensively used due to their low numerical cost when compared to 3D- Finite Element (FE) simulations. Both 3D and 1D FE analyses of a laterally loaded monopile are carried in this paper. First, a 3D site-specific model of a monitored OWT is developed. The model consists of a monopile and the soil medium which is simulated using calibrated hypoplastic models. The monopile model is then subjected to representative lateral loadings then bending moments are extracted. Similar analyses are done using 1D rule-based PISA models and API/DNV models. Numerical results of a comparative study between the 3D-FE, 1D-PISA, 1D-API/DNV and the monitoring data are presented and discussed.

RÉSUMÉ: Les éoliennes offshores situées au large de la côte Belge en Mer du nord ont été monitorés depuis plusieurs années en utilisant différents appareillages (accéléromètres, gauges de déformations et Fibres). Les données issues du monitoring révèlent un comportement non-prévu des éoliennes, surement due au fait qu'elles aient été dimensionnés en utilisant des recommandations non adaptés au pieux de grand diamètre tel que les courbes p-y formulés par l'API/DNV. Ces méthodes ont été utilisés extensivement due à leurs faible cout numérique comparé aux simulations en éléments finis (EF)-3D. Des analyses EF en 3D et 1D d'un monopieu sous chargement latéral sont effectués. Tout d'abord, nous établissons un modèle de site 3D d'une éolienne soumises au monitoring. Le modèle est constitué d'un monopieu et du sol avoisinant qui est simulé en utilisant une loi de comportement hypoplastique. Le monopieu est ensuite soumis à des charges latérales représentatives des charges in situ puis les courbes de moment fléchissant son extraites. Des analyses similaires sont effectués en utilisant un modèle 1D ou les courbes de réactions sont issues de recommandations PISA et API/DNV. Une étude comparative est effectué sur les résultats numériques et les données issues du monitoring.

Keywords: Monitoring; reaction-curves; bending moment; finite element; monopile.

1 INTRODUCTION

The recently adopted consensus is to reach 120 GW and 300 GW of total power output from offshore wind in the North Sea. Offshore wind turbines can be supported by many types of support structures, for example: gravity base foundations, suction buckets and jacket foundations. However, monopiles are still the preferred type of foundations in shallow coastal waters as they represent not less than 80% of the total installed foundations for offshore wind turbines (WindEurope, 2020). Monopiles are large-diameter hollow steel piles that are designed to support the upper wind turbine structure under multiple loads such as thrust load, wind shear, waves, currents and seismic loads (in earthquake-prone regions). These loads can be induced under normal operational or extreme conditions (such as storms and earthquakes).

Monopiles are typically designed using 1D beam-column models where the soil adjacent to the pile is modelled using discrete linear or non-linear springs.

Different non-linear spring functions exist in the literature, such as the API p-y method (API, 2011) that considers a set of lateral reactions along the pile. This method has been extensively used for the design of pile foundations in the oil and gas (O&G) industry. The more recent PISA methodology (Burd et al., 2020; Byrne et al., 2020) is reputed to be more adequate for the design of laterally loaded monopiles. 3D Finite Element approaches are known to be numerically more costly than the 1D ones, however they are better at simulating the complex soil-monopile interactions, and have been used successfully in the literature for the simulation of more complex problems (Kementzetzidis et al., 2018; Kheffache et al., 2023).

Monitoring data on wind turbines can help understand and gain insight on their real in situ behaviour (Stuyts et al., 2023). The different types of monitoring data that can exist on a wind turbine are listed below:

- Supervisory Control And Data Acquisition (SCADA) data; which gives the basic wind turbine outputs such as wind speed at the hub level, wind direction and rotations per minute (rpm)
- Acceleration measurements; which can be transformed into resonance frequencies
- Strain measurements from strain gauges (SGs) /Fiber Bragg gratings (FBGs); which can be transformed into bending moments
- Pore pressures;

In this work, both 3D and 1D numerical analyses of a monitored monopile located in the Belgian North Sea are performed. The 1D analyses are done following both the API/DNV (DNV, 2014) and PISA approaches while the 3D ones are done using the ABAQUS Finite Elements (FE) software in which the soil is simulated using advanced constitutive models that are calibrated to the available laboratory test/in situ data. The approaches are compared to each other and to the monitoring data.

2 MODELING OF LATERALLY LOADED PILES

2.1 API/DNV

The first versions of API/DNV reaction curves were initially developed by Cox et al (1974) and Matlock (1970). The API sand p-y reaction curves were derived directly from the results of laterally loaded piles which had a diameter of 610mm and a penetration depth of 21m, for a corresponding L/D ratio of 33.84.

The basic input parameters of the API method for both sands and clays are listed below:

- Unit weight γ' (sand/clay)
- Pile diameter D (sand/clay)
- Undrained shear strength (clay)
- Empirical constant J (clay)
- Strain parameter ϵ_{50}(clay)
- Friction angle φ' (sand)
- Loading factor A (sand)

The mathematical formulation is not given for the sake of brevity. This method has been proven to be unreliable for the design of monopiles as they are of bigger diameter than the ones used in the API pile tests (Doherty & Gavin, 2012)

2.2 PISA method

The PISA project formulated a new design methodology for laterally loaded monopiles in clays and sands; by taking into consideration 3 new sets of reaction curves on top of the lateral p-y ones, as shown in Figure 1.

The full methodology was established through lateral pile testing on piles with an L/D ratio that is between 2 and 6 and that is comparable to the ratio of monopiles. The pile tests were simulated using a 3D-FE model from which the 1D reaction curves were then extracted, the rule-based method was then formulated in which the basic mathematical functions of every reaction curve was established. The basic input parameters of the rule-based method are listed below:

- Relative density D_R (sand)
- Small strain stiffness G_{max} (sand/clay)
- Vertical effective stress σ_v' (sand)
- Undrained shear strength S_u (clay)
- Pile diameter D (sand/clay)

By comparing the input parameters for both methods, we can see that the PISA methodology takes into account both parameters at small and large strain.

2.3 FEM

The Finite Element Method is generally not used for design but rather as a design-verification tool. It allows the soil and pile mediums to behave according to a more advanced mathematical formulation (constitutive models) when compared to 1D approaches. This method is however more computationally costly both in terms of computational time and input parameters, depending on the complexity of the constitutive models used.

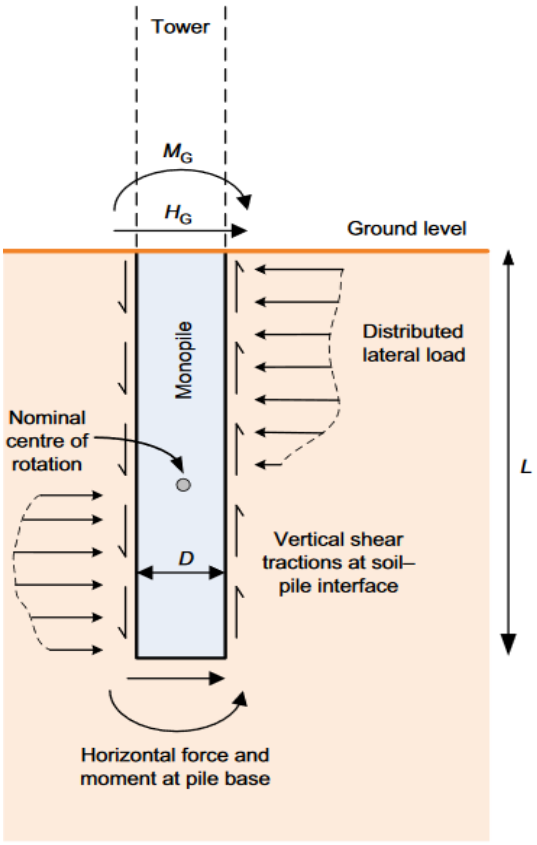

Figure 1. Different reaction curves considered in the PISA methodology (Byrne et al., 2020).

3 SITE CONDITIONS

3.1 Monopile

The studied monopile is located in the Belgian North Sea, some of the data was already presented in previous works (kheffache et al., 2022). The FBGs on the lower monopile part are shown in Figure 2

3.2 Soil conditions

The monitored wind turbine is located in the Belgian North Sea. The monopile is embedded in multilayered soil profile made of sand and clay layers. The Cone Penetration Test result and the soil layering at the wind turbine's location are shown in Figure 2.

3.3 Loads

Representative sets of loadings were extracted from the monitoring data (10-minutes strain measurements) available on the upper structure (above mudline part of the wind turbine). The derived loading consists of a point force and moment applied at the head of the monopile. A total of 23 load conditions are considered in this work. It is worth mentioning that the loads are considered to be quasi-static; the loads were exctracted

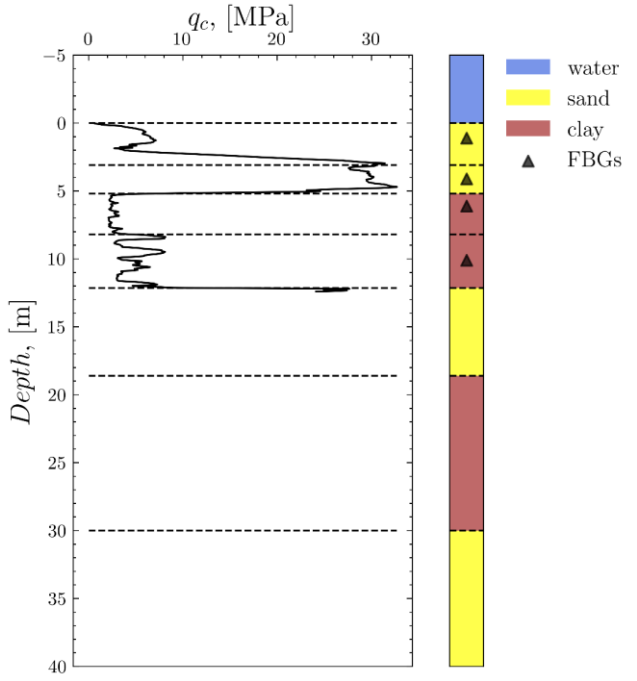

Figure 2. CPT, FBGs and soil layering at the wind turbine's location.

from episodes where the wind turbine was operating under normal conditions and where the strain measurements were seen to have relatively small variations.

4 FE MODELLING

4.1 1D models

The 1D modelling is done using an in-house beam-column model. Both API and PISA reaction curves can be assigned to the monopile. All of the PISA input parameters can be calibrated directly from in situ test results where as for the API ones; ϵ_{50} and γ' are generally calibrated from laboratory test data.

4.2 3D models

4.2.1 Soil

The sand and clay hypoplastic models are assigned to sand and clay layers respectively (Mašín, 2013; von Wolffersdorff, 1996), and are calibrated to advanced laboratory test data which consists of oedometric, triaxial, DSS, resonant column and bender element tests. The calibration methodologies discussed by Mašín, (2019) are followed. The inputs for both models have been discussed and some values have been presented in previous works (kheffache et al., 2022), the calibration is not repeated here for the sake of brevity. The calibration is further optimised using the in situ data such as Seismic Cone Penetration Tests (SCPT). The calibrated G_{max} profile is show in Figure 3.

The soil stress is initialized by considering a K_0 initial stress state, where K_0 is the earth pressure coefficient at rest and is given by the following equations:

$$K_{0,sand} = 1 - sin(\varphi_c) \quad (1)$$

$$K_{0,clay} = (1 - \sin(\varphi_c))OCR^{\sin(\varphi_c)} \quad (2)$$

where φ_c is the critical friction angle and OCR is the overconsolidation ratio interpreted from a nearby borehole. A slightly higher K_0=0.8 was assigned for the upper sand layer to take into consideration overconsolidation. The initial void ratio e_0 was derived from a nearby borehole. A drained and undrained behviour is assigned to the sand and clay layers respectively.

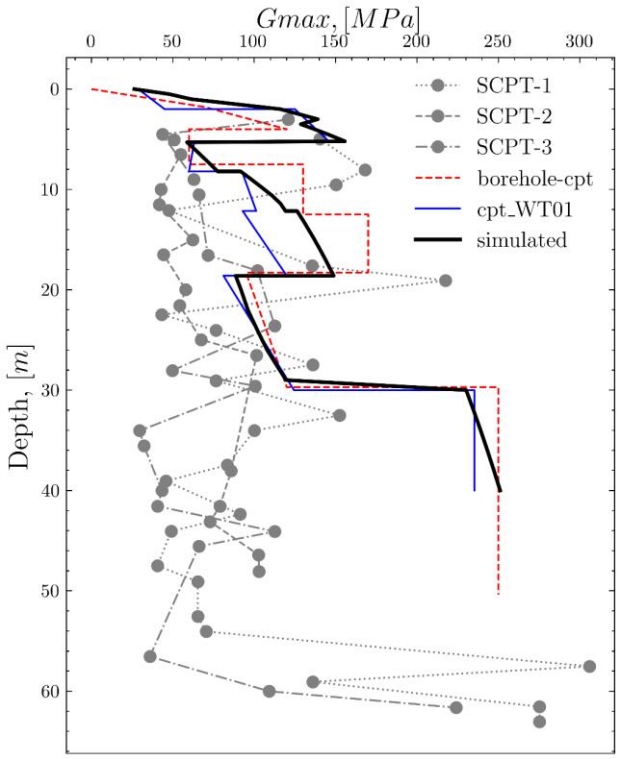

Figure 3. G_{max} profile.

4.2.2 Monopile

The monopile is modelled using C3D8I mesh elements which are incompatible 3D continuum 8 noded fully integrated linear brick elements, recommended for solid elements subject to bending (Abaqus, 2011). A comparative study was done by comparing C3D8I elements to S4R (shell) bending moments, negligeable differences were observed.

4.2.3 Boundary conditions

Only half of the model is simulated by taking into account symmetry in the y direction. The model is fixed in all direction at the bottom, while it is fixed only in the x and y directions at the edge.

4.2.4 Contact

The general contact algorithm which allows for the automatic detection of interfaces is used. The pile-soil contact is modelled by considering a Mohr-Coulomb frictional coefficient μ. A sensitivity study was conducted on the effect of the friction coefficient on the results. No significant effects were observed. A constant friction coefficient of 0.5 is assigned along the monopile-soil interface.

5 RESULTS

The results are investigated in terms of bending moments as mentioned before. 23 bending moment profiles were generated (corresponding to the 23 load cases), however only 4 profiles are shown in Figure 4 for brevity. The bending moments are normalised to the highest value, whereas the depth is normalised to the monopile's diameter. It can be seen that for the 4 load cases, the FEM-based bending moments are the closest to the monitored ones, translating a stiffer behaviour when compared to the API/PISA-based bending moments. If we compare the bending moments that result from 1D approaches, we notice that the PISA-based ones are the closest to the monitoring data (and also relatively close to the FEM ones). In all of the analyses (FEM, API and PISA), the simulated bending moments are always at the right hand side of the monitored ones (overprediction), which means that the monopile is laterally stiffer in reality compared to the simulations.

The results can also be quantified in terms of Mean Relative Error (MRE), where MRE is given by the following equation:

$$MRE_M = \frac{1}{n}\sum_{i=0}^{n-1}\frac{M_m^{z,i} - M_s^{z,i}}{M_m^{z,i}} \quad (3)$$

where n is the total number of considered load cases (23), $M_m^{z,i}$ is the monitored bending moment at the z-th sensor depth for the i-th load case, $M_s^{z,i}$ is the simulated bending moment at the same depth and for the same load case. According to the previous MRE definition, a positive value translates into an underestimation whereas a negative value translates into an overestimation of the bending moments when compared to the monitored ones.

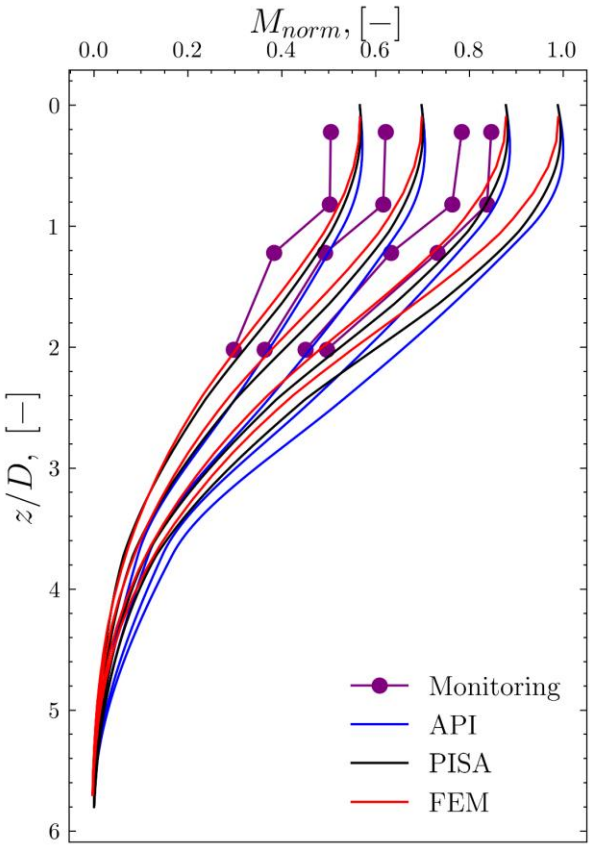

Figure 4. Bending moment versus depth.

Figure 5 represents the MRE for all the simulated cases at each sensor depth below mudline. We can see that for all the sensors depths, the MRE is always the lowest for the FEM approach, while it takes the highest values for the API one, confirming the previous observations. We can also see that the MRE difference between the approaches is larger at the lowest sensor depth when compared to the shallowest sensor depth. When comparing between the results in terms of Global MRE (GMRE, the mean of MRE for every method) given in Table 1, we see that the API method overpredicts the results by 20%, almost twice as much as the FEM approach.

Table 1.Global MRE for the different modelling approaches

Approach	API	PISA	FEM
GMRE (%)	-20.04	-14.70	-10.48

6 CONCLUSIONS

In this work, a monitored wind turbine located in the Belgian North Sea was studied. 3 different design-methodologies were used:

- API guidelines
- PISA method
- FEM.

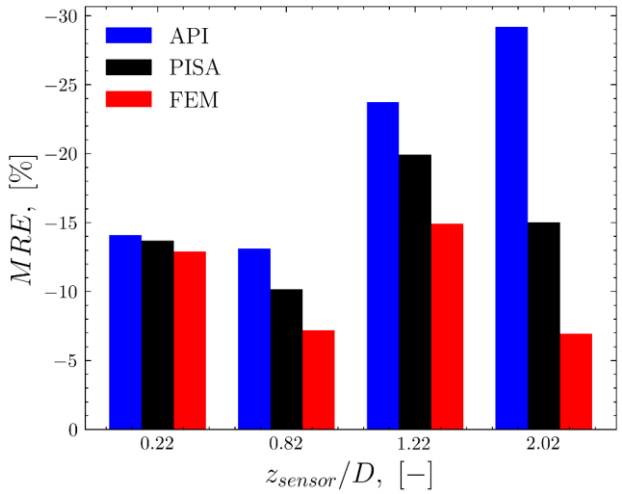

Figure 5. MRE at different sensor depths.

The monopile was subjected to representative sets of quasi-static loads extracted from the monitoring data on the wind turbine. The monitored and simulated bending moments using the different approaches were compared. All the methods were seen to overpredict the bending moment on the monopile which is due to the fact that the monopile behaves stiffer than expected, probably due to the missing contribution of the scour protection in the simulations, and the missing installation effects. The PISA rule-based method was seen to give satisfactory results, almost matching the FEM ones, while the API approach gave the least accurate ones.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the support of the Belgian Ministry of Economic Affairs through the EFT project WINDSOIL project. The Support of VLAIO through the De Blauwe Cluster SBO SOILTWIN project is also acknowledged.

ABSTRACT: Recycling waste materials for barrier system of landfills has more recently been increasingly considered in geotechnical engineering to improve sustainability. Among various geomechanical parameters, hydraulic conductivity is one of the essential factors to be evaluated when designing landfill liners. With such motive, three types of materials were studied in our ongoing research: press filter residue (PFR), cement stabilized clay (CSC) and dry crust clay (DCC). The three recycled materials were compacted in a field pilot project to investigate their applicability as landfill liners. Compacted samples from the pilot project were then cored in tube samplers and transported to the laboratory for hydraulic conductivity measurements. Permeability was measured using oedometer, flexible wall permeameter and triaxial permeability cells. Permeability measurements were made on horizontal and vertical directions to investigate potential permeability anisotropy characteristics at a wide range of consolidation stress levels (15 kPa to 650 kPa). The hydraulic conductivity measured on the samples was in the range of 2×10^{-7} m/s to 10^{-10} m/s. For most of the samples, permeability decreased to below 10^{-9} m/s with increasing stresses, where Norwegian regulations and practice recognises that it is suitable for, liners of landfills containing non-hazardous and hazardous waste. Moreover, the hydraulic conductivity of the materials was anisotropic, and the anisotropy changed with increasing consolidation stresses.

RÉSUMÉ: Le recyclage des déchets pour les systèmes de barrières d'étanchéité des décharges a plus récemment été de plus en plus pris en compte dans l'ingénierie géotechnique pour améliorer la durabilité. Parmi les différents paramètres géomécaniques, le coefficient de perméabilité est l'un des facteurs essentiels à évaluer lors de la conception des barrières d'étanchéité des décharges. C'est pour cette raison que trois types de matériaux ont été étudiés dans nos recherches en cours: les résidus de filtres presses (PFR), les argiles stabilisées au ciment (CSC) et les argiles à croûte sèche (DCC). Les trois matériaux recyclés ont été compactés dans le cadre d'un projet pilote sur le terrain pour étudier leur applicabilité en tant que barrières d'étanchéité des décharges. Les échantillons compactés du projet pilote ont ensuite été carottés dans des tubes d'échantillonnage et transportés au laboratoire pour des mesures de conductivité hydraulique. La perméabilité a été mesurée à l'aide d'un œdomètre, d'un perméamètre à paroi flexible et de cellules de perméabilité triaxiale. Des mesures de perméabilité ont été effectuées dans les directions horizontale et verticale pour étudier les caractéristiques potentielles d'anisotropie de perméabilité dans une large gamme de niveaux de contrainte de consolidation (15 kPa à 650 kPa). Le coefficient de perméabilité mesuré sur les échantillons était compris entre 2×10^{-7} m/s et 10^{-10} m/s. Pour la plupart des échantillons, la perméabilité a diminué jusqu'à moins de 10^{-9} m/s avec des contraintes croissantes, là où la réglementation et la pratique norvégiennes reconnaissent qu'elle convient aux barrières d'étanchéité des décharges contenant des déchets non-dangereux et dangereux. De plus, la conductivité hydraulique des matériaux était anisotrope, et l'anisotropie changeait avec l'augmentation des contraintes de consolidation.

1 INTRODUCTION

A research project called earthresQue on reusing waste soils from various origins was laid out by the Norwegian centre for research-based innovation (SFI). The main purpose of earthresQue is to improve the sustainability of treating waste and surplus earth materials from the building and construction industry. One work package investigates recycled earth materials as alternative, more sustainable materials for

landfill liners. As part of this, there has been constructed a final cover pilot test at a landfill site in southern Norway, using two such materials: PFR (Press Filter Residue) and CSC (Cement Stabilized Clay). These are compared to a DCC (Dry Crust Clay), a type of raw material that is a common surplus mass from construction projects in parts of Norway and has been used as barrier materials. This paper presents results from permeability tests conducted on undisturbed, compacted samples of these materials. Initial results from the pilot test itself is presented in the other paper of this conference (Ånes et al., 2024).

Norwegian regulations require barrier materials for bottom liners in hazardous and non-hazardous waste landfills to have hydraulic conductivity lower than 10^{-9} m/s(Ministry of Climate and Environment, 2004), which is classified as impermeable according to Casagrande and Fadum (1940). Typically, the environmental authorities also set the same permeability requirement to final cover for these landfills. The materials that match the criteria are usually rich in clay minerals (and clay-sized particles) and have homogenous internal structure.

The work presented in this paper aims to evaluate the suitability of the three materials as landfill liners and to characterize their hydraulic conductivity.

2 EXPERIMENTAL PROGRAMME

2.1 Materials

The press filter residual (PFR) is the clay and silt fractions of excavated, lightly contaminated soils that have been washed and sorted at a soil washing plant. The cement stabilized clay (CSC) is a marine clay that was stabilized with cement and cement-kiln dust before excavation at a construction site in Oslo. The dry crust clay (DCC), being the upper, weathered part of a clay deposit, was excavated from another construction site in Oslo. The soil properties of the tested materials are listed in Table 1. For further description of PFR and CSC, refer to (Ritter et al., 2023). Based on the index properties of the soils, hydraulic conductivity lower than 10^{-9} m/s is expected to be achievable (Benson et al., 1994).

The three materials were compacted in the field at the final cover pilot site. The samples were then cored using a 72 mm diameter Shelby tube sampler. Cored samples were sealed and sent to the laboratory at the Norwegian Geotechnical Institute (NGI) for permeability tests.

Table 1. Soil composition and index properties of three recycled materials.

Sample	Soil fraction (%)			Atterberg limit (%)			Particle density (Mg/m^3)
	Sand	Silt	Clay	Plastic limit, w_p	Liquid limit, w_l	Plasticity index, I_p	
PFR	4.2	67.3	28.5	28	53	25	2.74
CSC	1.2	63.7	35.1	23	41	18	2.76
DCC	2.5	49.3	48.2	23	43	22	2.80

2.2 Permeability measurements

Three different testing types were used for hydraulic conductivity measurements: oedometer cell, flexible wall permeameter and triaxial cell. Both vertical (normal to the bedding plane) and horizontal (parallel to the bedding plane) permeability measurements were investigated. The specimens for vertical permeability were trimmed as per normal triaxial specimens, while the specimens for horizontal permeability were sub-sampled horizontally of the vertical cores using a horizontal extruder and cradle built in-house.

Constant head method was adopted for all three types of tests (NS-ISO, 2019). Three measurements were made with different hydraulic gradients for each stage of the permeability test. The permeability was measured when the flow rate became linear assuming it reached a steady state. The three values were then averaged to obtain hydraulic conductivity at each stage.

2.2.1 Oedometer

One-dimensional incremental loading oedometer cells were used for the permeability measurements. A nominal initial specimen height of 20 mm and diameter of 67 mm was used. Vertical stress was increased step by step and permeability was measured at designated vertical stresses. Back pressure was not applied for the oedometer test.

For the permeability measurement, a VPC (Volume Pressure Controller) was connected at the bottom reservoir whilst the top reservoir was opened to the atmosphere. A small constant head difference was applied between the bottom and the top of the specimen.

To simulate a range of relevant overburdens (road embankment, final cover to bottom liner), the vertical stress range at which permeability was measured was between 20 kPa and 650 kPa.

2.2.2 Flexible wall permeameter

Flexible wall permeameter was used for measuring the horizontal permeability. Unlike the typical triaxial samples, a height to diameter (H/D) ratio of 1.0 (H = D = 50 mm) was used.

The stress conditions were always isotropic as a deviator load was not applied or measured. The mean effective stress range at which the permeability was measured was between 15 kPa and 650 kPa and the deformation was traced monitoring the pore volume and a Linear Variable Differential Transformer (LVDT) mounted externally on the piston. For the permeability test, two VPCs were connected to the top and bottom reservoirs allowing the control over the pore pressure. The permeability was measured by applying differential pressures at bottom and top reservoirs.

2.2.3 Triaxial cell

Permeability was measured as a part of triaxial testing. Initial triaxial specimens had a H/D ratio of about 2 (either H = 140 mm and D = 72 mm or H = 108 mm and, D = 54 mm). The stress conditions were isotropic, and the deformation was measured using the pore volume change and the LVDT measurements. The stress range at which permeability tests were carried out was between 20 kPa and 640 kPa. The permeability measurements were done the same way as in the flexible wall permeability test.
